HEMATOLOGY
Basic Principles and Practice

3rd Edition

Ronald Hoffman MD
Eileen Heidrick Professor of Oncology
Chief, Section of HematologyOncology
Department of Medicine
University of Illinois
College of Medicine
Chicago, Illinois

Edward J. Benz Jr. MD
Sir William Osler Professor of Medicine
Director, Department of Medicine
The Johns Hopkins University
School of Medicine
Baltimore, Maryland

Sanford J. Shattil MD
Professor, Departments of Vascular Biology and Molecular and Experimental Medicine
The Scripps Research Institute
La Jolla, California
Adjunct Professor of Medicine
University of California at San Diego
San Diego, California

Bruce Furie MD
Director, Beth Israel Deaconess Cancer Center
Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Harvey J. Cohen MD, PhD
Professor and Chairman
Department of Pediatrics
Stanford University Medical Center
Stanford, California

Leslie E. Silberstein MD
Professor, Department of Pathology and Laboratory Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Philip McGlave MD
Cecil J. Watson Professor of Medicine
Director, Division of Hematology, Oncology, and Transplantation
Department of Medicine
University of Minnesota
Minneapolis, Minnesota

Churchill Livingstone
A Division of Harcourt Brace & Company

New York Edinburgh London Philadelphia San Francisco

CHURCHILL LIVINGSTONE
A Division of Harcourt Brace & Company
The Curtis Center
Independence Square West

Philadelphia, Pennsylvania 19106

Last digit is the print number: 9 8 7 6 5 4 3 2 1

To my wife Nan, my daughter Judith, and my son Michael, for their encouragement and patience during this project. To my parents Sarah and Morris, who made great sacrifices in order for me to pursue my education. To my colleagues at the University of Illinois at Chicago who have participated in this project and supported my efforts. To Esmail D. Zanjani, Ralph Zalusky, Bernard G. Forget, and Lawrence Frohman who have each at different points in my career encouraged my commitment to academic medicine. To Ed Benz, Sandy Shattil, Bruce Furie, Harvey Cohen, Les Silberstein, and Phil McGlave who have been great colleagues and friends during the preparation of this third edition.

Ronald Hoffman, MD

To my wife Peggy, for your friendship, counsel, and patience, and for understanding why this book is important to me. To my children Tim and Jen. To my parents and my mentors, whose example and caring nurtured my interest in academic hematology: Bernard G. Forget, MD, David G. Nathan, MD, Arthur W. Nienhuis, MD, and Arthur B. Pardee, PhD. To my secretary Carol Dankelman, for her help during the preparation of the textbook.

Edward J. Benz, Jr., MD

To my wife Gloria, my son Jason, my mother Helen, my sister Sherry, and my late father, Arthur. I would like to thank my mentors at the Harvard Medical Unit of the Boston City HospitalDrs. Richard Cooper, Neil Abramson, James H. Jandl, and the late William B. Castlewho instilled in me a profound respect for the importance of basic research in blood diseases and a deep appreciation for the privilege of contributing to this endeavor.

Sanford J. Shattil, MD

To William J. Williams and the late Adrian J. Gottlieb, for introducing me to hematology and, specifically, the field of blood coagulation. To Alan N. Schechter and the late Christian B. Anfinsen, for their guidance into serious scientific research. To Robert S. Schwartz and Jane F. Desforges, for their nurturance and guidance. To my loving wife Barbara, my children Eric and Gregg, my mother Bernice, and in loving memory of my late father, J. Leon Furie.

Bruce Furie, MD

To my wife Ilene, who continues to sustain me, my children Philip, Jonathan, Nicole, and Renee, and my grandchildren Sara and Ethan, who always remind me of the importance and joy of being a father and a grandfather; and to my special friends who make my life so full and rewarding.

Harvey J. Cohen, MD, PhD

To my friends and family, for their love and support. To my mentors Eugene M. Berkman and Robert S. Schwartz, who continue to serve as my mentors. To my colleagues at the University of Pennsylvania Medical Center, for helping me to develop an academic transfusion medicine program.

Leslie E. Silberstein, MD

To my wife Anne, and my children Alice, Pavel, and Claire, for their love and support. To my colleagues past and present at the University of Minnesota, for their help, guidance and, most of all, friendship.

Philip McGlave, MD

Contributors

Camille N. Abboud MD, FACP

Professor of Medicine, HematologyOncology and Bone Marrow Transplant Unit, University of Rochester Medical School; Attending Physician, Department of Medicine, Director, Stem Cell Laboratory, Strong Memorial Hospital, Rochester, New York

Janis Abkowitz MD

Professor of Medicine and Hematology, Hematology Division, Department of Medicine, University of Washington School of Medicine; Director, Hematology Clinic, University of Washington Medical Center, Seattle, Washington

Janet L. Abrahm MD

Associate Professor of Medicine, HematologyOncology Division, University of Pennsylvania School of Medicine; Attending Physician, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Steven J. Ackerman PhD

Professor of Medicine, Biochemistry, and Molecular Biology, University of Illinois College of Medicine, Chicago, Illinois

Junius G. Adams III PhD

Former Member of Sickle Cell Branch, Division of Blood Diseases and Resources, National Heart, Blood, and Lung Institute, National Institutes of Health, Bethesda, Maryland

Saundra N. Aker RD, CD, BS

Clinical Instructor, Department of Behavioral Nursing and Health Systems, Clinical Affiliate, Interdisciplinary Graduate Degree Program in Nutritional Sciences, University of Washington; Director, Clinical Nutrition Department, Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, Washington

Jane Bradley Alavi MD

Associate Professor, Department of Medicine, University of Pennsylvania Medical School; Attending Physician, HematologyOncology Division, Department of Medicine, Hospital of the University of Pennylvania, Philadelphia, Pennsylvania

Kenneth C. Anderson MD

Associate Professor of Medicine, Harvard Medical School; Medical Director, Kraft Family Blood Donor Center, Dana-Farber Cancer Institute, Boston, Massachusetts

Stylianos E. Antonarakis MD, DSc

Professor of Medical Genetics, Department of Medical Genetics, University of Geneva Medical School; Director, Division of Medical Genetics, University Hospital of Geneva, Geneva, Switzerland

Aok C. Antony MD

Professor of Medicine, Division of HematologyOncology, Department of Medicine, Indiana University School of Medicine; Attending Physician and Consultant Indiana University Hospitals; Chief, HematologyOncology Section, Roudebush Veterans Affairs Medical Center, Indianapolis, Indiana

Robert L. Baehner MD

Professor, Department of Pediatrics, University of Southern California School of Medicine; Director of Pediatric Hematology, Los Angeles CountyUniversity of Southern California Medical Center, Los Angeles, California

Grover C. Bagby Jr. MD

Professor of Medicine, Director, Oregon Cancer Center, Oregon Health Sciences University; Head, Section of HematologyOncology, Veterans Affairs Medical Center, Portland, Oregon

Jack Ballantyne PhD, MSc

Associate Professor, Department of Chemistry, University of Central Florida, Orlando, Florida

Kenneth A. Bauer MD

Associate Professor of Medicine, Harvard Medical School, Boston, Massachusetts; Chief, HematologyOncology Section, BrocktonWest Roxbury Veterans Affairs Medical Center, West Roxbury, Massachusetts

Vittorio Bellotti MD

Assistant Professor of Biochemistry, Faculty of Pharmacy, University of Pavia, Pavia, Italy

Richard J. Benjamin MBChB, PhD

Assistant Professor of Pathology, Harvard Medical School; Associate Medical Director, Blood Bank, Brigham and Womens Hospital, Boston, Massachusetts

Joel S. Bennett MD

Professor of Medicine and Pharmacology, University of Pennsylvania School of Medicine; Attending Physician, HematologyOncology Division, Department of Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Edward J. Benz Jr. MD, FACP

Sir William Osler Professor of Medicine, Director, Department of Medicine, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Stacey L. Berg MD

Assistant Professor of Pediatrics, HematologyOncology Section, Department of Pediatrics, Baylor College of

Medicine; Associate, Texas Childrens Hospital; Active, Harris County Hospital District, Houston, Texas

Eugene M. Berkman MD

Professor of Medicine, Tufts University School of Medicine; Medical Director, Blood Bank, New England Medical Center, Boston, Massachusetts

Nancy Berliner MD

Associate Professor, Internal Medicine and Genetics, Yale University School of Medicine; Attending in Medicine, YaleNew Haven Hospital, New Haven, Connecticut

Kapil N. Bhalla MD

Professor of Medicine, Associate Director for Clinical and Translational Research, University of Miami School of Medicine and Sylvester Comprehensive Cancer Center; Professor of Medicine, Division of Hematology/Oncology, Jackson Memorial Hospital, Miami, Florida

David H. Bing PhD

Scientific Director, DNA Repository, Genomics Collaborative, Inc., Cambridge, Massachusetts

Morey A. Blinder MD

Associate Professor, Divisions of Hematology and Laboratory Medicine, Departments of Medicine and Pathology, Washington University Medical School, St. Louis, Missouri

Lawrence F. Brass MD, PhD

Professor of Medicine and Pharmacology, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

Gary M. Brittenham MD

Professor of Medicine and Pediatrics, Columbia University College of Physicians and Surgeons; Staff Physician, New York Presbyterian Hospital, New York, New York

Silvana Z. Bucur MD

Assistant Professor, Department of Pathology and Laboratory Medicine, Instructor in Medicine, Division of Hematology and Oncology, Emory University; Assistant Director, Blood Bank, Emory University Hospital, Atlanta, Georgia

Samuel A. Burstein MD

Professor of Medicine, HematologyOncology Division, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

James Bussel MD

Associate Professor of Pediatrics, Cornell University College of Medicine; Attending in Pediatrics, Lenox Hill and Memorial Sloan Kettering Hospitals, New York, New York

Joseph H. Butterfield MD

Associate Professor of Medicine, Mayo Graduate School of Medicine, Division of Allergy and Outpatient Infectious Disease, Mayo Clinic and Mayo Foundation, Rochester, Minnesota

Fernando Cabanillas MD

Ashbel Smith Professor of Medicine, Chairman, Department of Lymphoma/Myeloma, University of Texas, MD Anderson Cancer Center, Houston, Texas

David C. Calverley MD

Assistant Professor, Department of Medicine, University of Southern California, Los Angeles, California

Michael O. Carleton PhD

Post-doctoral Fellow, Fox Chase Cancer Center, Philadelphia, Pennsylvania

Douglas Cines MD

Professor, Departments of Medicine and Pathology and Laboratory Medicine, University of Pennsylvania; Director, Hematology and Coagulation Laboratories, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

David B. Clark BS, MS, PhD

Manager, Technology Transfer, American Red Cross, Washington, DC

Carol Clayberger PhD

Associate Professor of Immunology, Departments of Cardiothoracic Surgery and Pediatrics, Stanford University, Stanford, California

Thomas D. Coates MD

Associate Professor of Pediatrics and Pathology, University of Southern California School of Medicine; Section Head, Hematology, Division of Pediatric HematologyOncology, Childrens Hospital, Los Angeles, California

Harvey J. Cohen MD, PhD

Professor and Chairman, Department of Pediatrics, Stanford University Medical Center, Stanford, California

Désiré Collen MD, PhD

Professor, Department of Medicine, Center for Thrombosis and Vascular Research, University of Leuven Faculty of Medicine, Leuven, Belgium

Barry S. Coller MD

Murray M. Rosenberg Professor and Chairman, Samuel Bronfman Department of Medicine, Mount Sinai School of Medicine; Director and Chief of Medicine, Mount Sinai Hospital, Mount SinaiNYU Medical Center and Health System, New York, New York

Dennis L. Confer MD

Clinical Professor of Medicine, University of Minnesota Medical School; Chief Medical Officer, National Marrow Donor Program, Minneapolis, Minnesota

Edward A. Copelan MD

Associate Professor of Internal Medicine, College of Medicine, The Ohio State University; Director, Bone Marrow Transplantation Program, The Arthur G. James Cancer Hospital and Richard J. Solove Research Institute, Attending Physician, The Ohio State University Hospital, Columbus, Ohio

Mark A. Crowther MD, MSc, FRCPC

Research Fellow, McMaster University; Staff Hematologist, St. Josephs Hospital, Hamilton, Ontario, Canada

John T. Curnutte MD, PhD

Clinical Professor of Pediatrics, Stanford University School of Medicine, Stanford California; Senior Director of Immunology, Genentech, Inc., South San Francisco, California

Nicholas Dainiak MD

Clinical Professor of Medicine, Yale University School of Medicine, New Haven, Connecticut; Adjunct Professor of Medicine, McGill University, Montreal, Quebec, Canada; Chairman, Department of Medicine, Bridgeport Hospital, Bridgeport, Connecticut

---

Riccardo Dalla-Favera MD

Joanne and Percy Uris Professor, Departments of Pathology and Genetics & Development, College of Physicians and Surgeons, Director, Institute of Cancer Genetics, Columbia University, New York, New York

Alan D. DAndrea MD

Associate Professor of Pediatrics, Harvard Medical School; Associate Professor, Dana-Farber Cancer Institute, Boston, Massachusetts

Chi V. Dang MD, PhD

Professor of Medicine, Oncology, Pathology, and Molecular Biology and Genetics, Director, Division of Hematology, Department of Medicine, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Philip R. Daoust BS, MD

Associate Clinical Professor of Pathology, Tufts University School of Medicine; Senior Pathologist, Director, Clinical Laboratory, New England Medical Center, Boston, Massachusetts

H. Joachim Deeg MD

Professor of Medicine, University of Washington Medical School; Member, Fred Hutchinson Cancer Research Center, Seattle, Washington

Emmanuel N. Dessypris MD

Professor of Medicine, Medical College of Virginia, Virginia Commonwealth University; Chief, HematologyOncology Section, H. H. McGuire Department of Veterans Affairs Medical Center, Richmond, Virginia

Madhav V. Dhodapkar MD

Assistant Professor/Clinical Scholar, Laboratory of Immunology and Cellular Physiology, Rockefeller University, New York, New York

Kenneth Dorshkind PhD

Professor, Department of Pathology and Laboratory Medicine, Member, Jansson Comprehensive Cancer Center, University of California at Los Angeles School of Medicine, Los Angeles, California

William N. Drohan PhD

Professor, Graduate Program in Genetics, George Washington University, Washington, DC; Adjunct Professor, Department of Chemistry and Biochemical Engineering, University of Maryland, Baltimore, Maryland; Senior Director, Plasma Development, American Red Cross, Rockville, Maryland

Thomas P. Duffy MD

Professor of Medicine, Yale University School of Medicine; Attending Physician, YaleNew Haven Hospital, New Haven, Connecticut

Walter H. Dzik MD

Assistant Professor, Internal Medicine, Harvard Medical School; Co-director, Blood Transfusion Service, Massachusetts General Hospital, Boston, Massachusetts

Charles S. Eby MD

Assistant Professor of Pathology and Medicine, St. Louis University School of Medicine; Associate Director, Hemostasis Laboratory, St. Louis University Health Sciences Center, St. Louis, Missouri

Stephen H. Embury MD

Professor, Department of Medicine, University of California, San Francisco, School of Medicine; Chief, Hematology Division of Medical Service, San Francisco General Hospital; Director, Adult Patient Services, Northern California Comprehensive Sickle Cell Center, San Francisco, California

Helen Enright MD,FRCPI, FRCPath

Lecturer in Hematology, Trinity College; Consultant, Adelaide and Meath Hospitals Incorporating the National Childrens Hospital,Dublin, Ireland

Charles T. Esmon PhD

Adjunct Professor of Biochemistry, University of Oklahoma Health Sciences Center; Member and Head, Cardiovascular Biology Research Program, Lloyd Noble Chair in Cardiovascular Research, Oklahoma Medical Research Foundation; Investigator, Howard Hughes Medical Institute, Oklahoma City, Oklahoma

Elihu H. Estey MD

Professor of Medicine, Chief, Section of Acute Leukemias and Myelodysplastic Syndromes, Internist, University of Texas, MD Anderson Cancer Center, Houston, Texas

Douglas V. Faller MD, PhD

Professor of Medicine, Biochemistry, Pediatrics, Microbiology, and Pathology and Laboratory Medicine, Boston University School of Medicine; Director, Cancer Research Center, Boston University Medical Center, Boston, Massachusetts

Donald I. Feinstein MD

Professor of Medicine, University of Southern California School of Medicine; Chief of Medicine, Emeritus, USCNorris Comprehensive Cancer Center and USCUniversity Hospital, Los Angeles, California

James L.M. Ferrara MD

Professor of Medicine and Pediatrics, University of Michigan Medical School; Director, Combined Adult and Pediatric Bone Marrow Transplant Program, University of Michigan Cancer Center, Ann Arbor, Michigan

Robert Flaumenhaft MD, PhD

Instructor, Harvard Medical School; Howard Hughes Medical Institute, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Bernard G. Forget MD

Professor of Internal Medicine and Genetics, Chief, Section of Hematology, Department of Medicine, Yale University School of Medicine; Attending Physician, YaleNew Haven Hospital, New Haven, Connecticut

Stephen J. Forman MD

Director, Department of Hematology and Bone Marrow Transplantation, City of Hope National Medical Center, Duarte, California

Charles W. Francis MD

Professor of Medicine and Pathology and Laboratory Medicine, University of Rochester School of Medicine and Dentistry; Chief, Vascular Medical Unit, University of Rochester Medical Center, Rochester, New York

Melvin H. Freedman MD, FRCPC, FAAP

Professor, Department of Pediatrics, University of Toronto Faculty of Medicine; Senior Associate Scientist, Research Institute, Hospital for Sick Children, Toronto, Ontario, Canada

---

Alison G. Freifeld MD

Chief, Clinical Infectious Diseases Service, National Cancer Institute, Bethesda, Maryland

Barbara C. Furie PhD

Professor of Medicine, Harvard Medical School; Director, Center for Hemostasis and Thrombosis Research, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Bruce Furie MD

Director, Beth Israel Deaconess Medical Cancer Center; Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Gianluca Gaidano MD, PhD

Assistant Professor of Internal Medicine, Division of Internal Medicine, Department of Medical Sciences, Amedeo Avogadro University of Eastern Piedmont, Novara, Italy

Patrick G. Gallagher MD

Assistant Professor, Department of Pediatrics, Yale University School of Medicine; Attending Physician, YaleNew Haven Hospital, New Haven, Connecticut

Lawrence B. Gardner MD

Senior Clinical Fellow, Division of Hematology, Department of Medicine, The Johns Hopkins Oncology Center, The Johns Hopkins Hospital, Baltimore, Maryland

H.S.P. Garritsen MD, PhD

Staff, Department of Transfusion Medicine, Head of Tissue Typing, University Hospital, Westfälische Wilhelms University, Münster, Germany

Sharon M. Geaghan MD

Professor, Department of Pediatrics, Department of Pathology, Stanford University School of Medicine; Director Clinical Laboratories, Chief, Pathology, Lucile Salter Packard Childrens Hospital at UCSFStanford, Palo Alto, California

Adrian P. Gee PhD

Professor of Medicine and Pediatrics, Center for Cell &Gene Therapy, Baylor College of Medicine; Director, Clinical Applications Laboratory, Houston, Texas

James N. George MD

Professor of Medicine, Chairman, HematologyOncology Section, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

Stanton L. Gerson MD

Chief, Division of HematologyOncology, Shiverick Professor of Hematologic Oncology, Case Western Reserve University, University Hospitals of Cleveland, Cleveland, Ohio

Joan Cox Gill MD

Professor, Department of Pediatrics, Medical College of Wisconsin; Investigator, Blood Research Institute, Blood Center of Southeastern Wisconsin; Medical Director, Great Lakes Hemophilia Foundation, Milwaukee, Wisconsin

Jeffrey S. Ginsberg MD,FRCPC

Professor of Medicine, Department of Medicine, McMaster University; Director, Thromboembolism Unit, Chedoke and McMaster Sites, Deputy Chief of Medicine, Hamilton Health Sciences Corporation, Hamilton, Ontario, Canada

Mark H. Ginsberg MD

Professor, The Scripps Research Institute, La Jolla, California; Adjunct Professor of Medicine, University of California at San Diego, San Diego, California

David Ginsburg MD

Professor of Internal Medicine and Human Genetics, Chief, Division of Molecular Medicine and Genetics, Department of Internal Medicine, Investigator, Howard Hughes Medical Institute, University of Michigan Medical Center, Ann Arbor, Michigan

John Glick MD

Professor of Medicine, Leonard and Madlyn Abramson Professor of Clinical Oncology, University of Pennsylvania School of Medicine; Director, University of Pennsylvania Cancer Center; Director, The Leonard and Madlyn Abramson Family Cancer Research Institute, Philadelphia, Pennsylvania

Michael S. Gordon MD

Associate Professor of Medicine, HematologyOncology Division, Department of Medicine, Indiana University School of Medicine; Director, Clinical Hematology and Cytokine Program, Indiana University Medical Center, Indianapolis, Indiana

Gregory A. Grabowski MD

Professor in Pediatrics, Director, Division and Program in Human Genetics, Childrens Hospital Medical Center, Cincinnati, Ohio

Steven Grant MD

Professor of Medicine, Pharmacology, and Microbiology, Virginia Commonwealth University, Medical College of Virginia, Richmond, Virginia

Peter L. Greenberg MD

Professor of Medicine, Division of Hematology, Stanford University School of Medicine, Stanford, California; Head, Hematology Service, Palo Alto Veterans Affairs

Health Care System, Palo Alto, California

Xylina T. Gregg MD

Adjunct Assistant Professor, Division of HematologyOncology, University of Alabama at Birmingham, Birmingham, Alabama

Timothy C. Greiner MS, MD

Associate Professor, Director, Immunoperoxidase Laboratory, Department of Pathology, University of Nebraska Medical Center, Omaha, Nebraska

Thomas G. Gross MD, PhD

Associate Professor of Pediatrics, University of Cincinnati; Director, Stem Cell Transplant Program, Division of HematologyOncology, Childrens Hospital Medical Center of Cincinnati, Cincinnati, Ohio

Joan Guitart MD

Assistant Professor of Dermatology, Northwestern University Medical School, Chicago, Illinois

David Hakiman MD

Consultant, Northwestern University Medical School, Chicago, Illinois; Attending Physician, Lutheran General Hospital, Park Ridge, Illinois

John M. Harlan MD

Professor and Head, Division of Hematology, University of Washington School of Medicine, Seattle, Washington

Michael C. Heinrich BS, MD

Associate Professor of Medicine, Oregon Health Sciences University; Staff Physician, Veterans Affairs Medical Center, Portland, Oregon

Christopher D. Hillyer MD

Associate Professor, Department of Pathology and Laboratory Medicine, Assistant Professor of Medicine, Division of Hematology and Oncology, Director, Emory University Transfusion Medicine Program, Emory University, Atlanta, Georgia

Jack Hirsh MD

Professor Emeritus, McMaster University School of Medicine; Director, Hamilton Civic Hospitals Research Centre, Hamilton, Ontario, Canada

Dieter Hoelzer MD

Professor of Internal Medicine, Chief, Department of Hematology, Zentrum Der Inneren Medizin, Medizinische Klinik III, Johan Wolfgang Goethe University, Frankfurt, Germany

Maureane Hoffman MD, PhD

Associate Professor, Duke University; Director, Hematology Laboratory Service, Durham Veterans Affairs Medical Center, Durham, North Carolina; Adjunct Assistant Professor, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Ronald Hoffman MD

Eileen Heidrick Professor of Oncology, Chief, Section of HematologyOncology, Department of Medicine, University of Illinois College of Medicine, Chicago, Illinois

Mary M. Horowitz MS, MD

Professor, Department of Medicine, Medical College of Wisconsin; Scientific Director, International Bone Marrow Transplant Registry, Milwaukee, Wisconsin

James A. Hoxie MD

Professor of Medicine, HematologyOncology Division, University of Pennsylvania School of Medicine; Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Richard A. Insel MD

Professor of Pediatrics, Microbiology and Immunology, and Oncology, Department of Pediatrics, University of Rochester, Rochester, New York

Petr Jarolim MD, PhD

Assistant Professor, Department of Pathology, Harvard Medical School; Associate Medical Director, Blood Bank, Brigham and Womens Hospital, Boston, Massachusetts

Marshall E. Kadin MD

Associate Professor, Department of Pathology, Harvard Medical School; Senior Pathologist and Director of Hematopathology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Hagop Kantarjian MD

Professor of Medicine, Chairman (Ad Interim), Department of Leukemia, Internist, University of Texas, MD Anderson Cancer Center, Houston, Texas

Karen L. Kaplan MD, PhD

Professor of Medicine, University of Rochester School of Medicine and Dentistry; Clinical Director, Vascular Medicine Unit, University of Rochester Medical Center,

Rochester, New York

Aly Karsan MD

Assistant Professor, Department of Pathology and Laboratory Medicine, University of British Columbia and St. Pauls Hospital, Vancouver, British Columbia, Canada

Randal J. Kaufman PhD

Professor of Biological Chemistry, Department of Biochemistry, Howard Hughes Medical Institute, University of Michigan Medical School, Ann Arbor, Michigan

Michael J. Keating BS, MB, MD

Professor of Medicine, Associate Head for Clinical Research, McCredie ChairLeukemia Research, Internist, University of Texas, MD Anderson Cancer Center, Houston, Texas

Frank G. Keller MD

Associate Professor of Pediatrics, West Virginia University School of Medicine; Chief, Pediatric HematologyOncology, Robert C. Byrd Health Sciences Center of West Virginia University, Morgantown, West Virginia

John G. Kelton MD, FRCPC

Professor of Medicine and Pathology, Chairman, Department of Medicine, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada

Nancy A. Kernan MD

Associate Professor of Pediatrics, Cornell University Medical College; Associate Member, Memorial Sloan-Kettering Cancer Center, New York, New York

Craig M. Kessler MD

Professor of Medicine and Pathology, Division of HematologyOncology, Director, Hemophilia Comprehensive Treatment Center, Director, Division of Coagulation, Department of Clinical Pathology, Lombardi Cancer Center, Georgetown University Medical Center,Washington, DC

Thomas S. Kickler MD

Professor of Pathology, Medicine, and Oncology, Johns Hopkins University School of Medicine; Director, Hematology and Coagulation Laboratory, Johns Hopkins Hospital, Baltimore, Maryland

Leslie B. King PhD

Post-doctoral Researcher, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Harvey G. Klein MD

Chief, Department of Transfusion Medicine, Warren G. Magnusson Clinical Center, National Institutes of Health, Bethesda, Maryland

Kim Kramer MD

Instructor, Pediatric HematologyOncology Division, Memorial Sloan-Kettering Cancer Center, New York, New York

Alan M. Krensky MD

Shelagh Galligan Professor of Pediatrics, Chief, Division of Immunology and Transplantation Biology, Department of Pediatrics, Stanford University, Stanford, California

Theodore G. Krontiris MD, PhD

Professor of Molecular Medicine, Chairman, Division of Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, California

Margot S. Kruskall MD

Associate Professor of Pathology and Medicine, Harvard Medical School; Director, Division of Laboratory and Transfusion Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Thomas J. Kunicki PhD

Associate Professor, Departments of Molecular and Experimental Medicine and Vascular Biology, The Scripps Research Institute, La Jolla, California

Joanne Kurtzberg MD

Professor of Pediatrics, Director, Pediatric Bone Marrow Transplant Program, Duke University Medical Center; Duke University Hospital, Durham, North Carolina

Timothy M. Kuzel MD

Associate Professor of Medicine, Division of HematologyOncology, Department of Medicine, Northwestern University Medical School, Chicago, Illinois

Parviz Lalezari MD

Professor of Medicine and Pathology, Albert Einstein College of Medicine, New York, New York; President and Medical Director, Bergen Community Regional Blood Center, Paramus, New Jersey

Richard A. Larson MD

Professor, HematologyOncology Section, Department of Medicine, University of Chicago, Division of Biological Sciences, Pritzker School of Medicine; Director, Acute

Leukemia Program, HematologyOncology Section, Department of Medicine, Uniersity of Chicago Medical Center, Chicago, Illinois

Ellen F. Lazarus MD

Senior Staff Fellow, Department of Transfusion Medicine, Warren G. Magnusson Clinical Center, National Institutes of Health, Bethesda, Maryland

Michelle M. Le Beau PhD

Professor, HematologyOncology Section, Department of Medicine, University of Chicago, Division of Biological Sciences, Pritzker School of Medicine, Chicago, Illinois

John P. Leddy MD

Professor of Medicine, Emeritus, University of Rochester School of Medicine and Dentistry; Attending Physician, Strong Memorial Hospital, Rochester, New York

William M.F. Lee MD,PhD

Associate Professor, HematologyOncology Division, Department of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Polly Lenssen MS, RD, FADA

Assistant Director, Clinical Nutrition, Fred Hutchinson Cancer Research Center, Seattle, Washington

Nancy Leslie MD

Assistant Professor, Department of Pediatrics, Division and Program in Human Genetics, Childrens Hospital Medical Center, Cincinnati, Ohio

Howard A. Liebman MD

Associate Professor, Departments of Medicine and Pathology, University of Southern California at Los Angeles, Los Angeles, California

Jane L. Liesveld MD

Associate Professor of Medicine, HematologyOncology and Bone Marrow Transplant Unit, University of Rochester Medical School; Attending Physician, Department of Medicine, Director, Bone Marrow Transplantation Program, Strong Memorial Hospital, Rochester, New York

H. Roger Lijnen PhD

Professor, Adjunct Director, Center for Molecular and Vascular Biology, University of Leuven, Leuven, Belgium

Jeffrey M. Lipton MD, PhD

Associate Professor of Pediatrics, Mount Sinai School of Medicine; Chief, Pediatric HematologyOncology, Mount Sinai Medical Center, New York, New York

Johnson M. Liu MD

Senior Investigator, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Michael W. Long PhD

Professor, Department of Pediatrics and Communicable Diseases, University of Michigan School of Medicine, Ann Arbor, Michigan

A. Thomas Look MD

Vice-Chair for Research, Department of Pediatric Oncology, Dana-Farber Cancer Institute; Professor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts

Jay Nelson Lozier MD, PhD

Clinical Investigator, National Human Genome Research Institute, Clinical Gene Therapy Branch, Gene Transfer Technology Section, National Institutes of Health, Bethesda, Maryland

Jaroslaw P. Maciejewski MD, PhD

Staff Physician, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Marilyn J. Manco-Johnson MD

Professor of Pediatrics, Department of Pediatrics, University of Colorado Health Sciences Center, Denver, Colorado; Director, Mountain States Regional Hemophilia &Thrombosis Center, Aurora, Colorado

Robert Mandle PhD

Investigator, Center for Blood Research, Boston, Massachusetts

Victor J. Marder MD

Director, Department of Vascular Medicine, Hemophilia Center, Orthopaedic Hospital, Los Angeles, California

José Martinez MD

Professor of Medicine, Biochemistry, and Molecular Pharmacology, Associate Director, Cardeza Foundation for Hematologic Research, Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania

J. Adelia McBride MD

Assistant Professor, Section of Hematopathology, University of Texas, MD Anderson Cancer Center, Houston, Texas

Ruth McCorkle PhD

Professor and Director of Doctoral Studies, Director, Center for Excellence in Chronic Illness Management, Yale University School of Nursing, New Haven, Connecticut

Keith R. McCrae MD

Associate Professor of Medicine, HematologyOncology Section, Case Western Reserve University School of Medicine; University Hospitals of Cleveland, Cleveland, Ohio

Rodger P. McEver MD

George Lynn Cross Research Professor of Medicine and Biochemistry, University of Oklahoma Health Sciences Center; Member, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma

Philip McGlave MD

Cecil J. Watson Professor of Medicine, Director, Division of Hematology, Oncology, and Transplantation, Department of Medicine, University of Minnesota, Minneapolis, Minnesota

Jay E. Menitove MD

Clinical Professor of Internal Medicine, University of Kansas School of Medicine, Kansas City, Kansas; University of MissouriKansas City School of Medicine; Executive Director and Medical Director, Community Blood Center of Greater Kansas City, Kansas City, Missouri

Steven J. Mentzer MD

Associate Professor of Surgery, Harvard Medical School; Department of Surgery, Brigham and Womens Hospital, Boston, Massachusetts

Giampaolo Merlini MD

Associate Professor of Clinical Biochemistry, School of Medicine, University of Pavia; Director, Biotechnology Research Laboratories, University Hospital, IRCCS Policlinico San Matteo, Pavia, Italy

Dean D. Metcalfe MD

Director, Allergy and Immunology Training Program, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Kenneth B. Miller MD

Associate Professor of Medicine, Director of Bone Marrow Transplantation, Director of Leukemia Service, TuftsNew England Medical Center, Boston, Massachusetts

Narla Mohandas DSc

Professor of Medicine, University of California at San Francisco, San Francisco, California; Senior Scientist, Lawrence Berkeley National Laboratory, Berkeley, California

John G. Monroe PhD

Professor, Pathology and Laboratory Medicine, Chair, Immunology Graduate Program, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Robert R. Montgomery MD

Professor and Vice Chair, Department of Pediatrics, Medical College of Wisconsin; Senior Attending and Director of Research, Childrens Hospital of Wisconsin, Milwaukee, Wisconsin

Michael R. Moore BSc, DSc

Professor, Department of Medicine, University of Queensland; Director, National Research Centre for Environmental Toxicology, Brisbane, Queensland, Australia

Jon S. Morrow MD, PhD

Professor and Chair, Department of Pathology, Yale University School of Medicine; Chief of Pathology, YaleNew Haven Hospital, New Haven, Connecticut

Auayporn P. Nademanee MD

Associate Clinical Director, Department of Hematology and Bone Marrow Transplantation, City of Hope National Medical Center, Duarte, California

Robert S. Negrin MD

Associate Professor of Medicine, Bone Marrow Transplant Section, Stanford University, Stanford Hospital, Stanford, California

Paul M. Ness MD

Professor of Pathology and Medicine, Johns Hopkins University School of Medicine; Director, Transfusion Medicine, Johns Hopkins Hospital; Chief Executive Officer, American Red Cross Blood Services, Greater Chesapeake and Potomac Region, Baltimore, Maryland

Arthur W. Nienhuis MD

St. Jude Professor of Pediatrics and Medicine, University of Tennessee Medical School; Director, St. Jude Childrens Research Hospital, Memphis, Tennessee

Yago Nieto MD

Instructor, Bone Marrow Transplant Program, University of Colorado, Denver, Colorado

Thalia Papayannopoulou MD, DMSc

Professor of Medicine/Hematology, University of Washington School of Medicine; Attending Physician, University Hospital, Seattle, Washington

Robert I. Parker MD

Associate Professor and Vice Chairman for Academic Affairs, Department of Pediatrics, Director, Pediatric HematologyOncology, State University of New York at Stony Brook School of Medicine, Stony Brook, New York

Jeannie V. Pasacreta PhD, RN

Associate Professor, Director, PsychiatricMental Health Nursing Specialty, Yale University School of Nursing, New Haven, Connecticut

Dilip V. Patel MB, BS

Assistant Professor of Medicine, Albert Einstein College of Medicine, Bronx, New York; Fellowship Program Director, Division of HematologyOncology, Long Island Jewish Medical Center, New Hyde Park, New York

Sam L. Penza MD

Assistant Professor of Clinical Medicine, Faculty, College of Medicine, The Ohio State University; Attending Physician, Arthur G. James Cancer Hospital and Richard J. Solove Research Institute, The Ohio State University Hospital, Columbus, Ohio

LoAnn C. Peterson MD

Professor of Pathology, Northwestern University Medical School; Director of Hematopathology, Northwestern Memorial Hospital, Chicago, Illinois

Philip A. Pizzo MD

Thomas Morgan Rotch Professor and Chair, Department of Pediatrics, Harvard Medical School; Physician-in-Chief,

Chair, Department of Medicine, Childrens Hospital, Boston, Massachusetts

Edward F. Plow PhD

Chairman, Department of Molecular Cardiology, Head of Research, Joseph J. Jacobs Center for Thrombosis and Vascular Biology, Cleveland Clinic Foundation, Cleveland, Ohio

David G. Poplack MD

Professor of Pediatrics, Head, HematologyOncology Section, Department of Pediatrics, Baylor College of Medicine; Director, Texas Childrens Cancer Center, Texas Childrens Hospital, Houston, Texas

Carol S. Portlock MD

Associate Professor of Clinical Medicine, Cornell University Medical College; Attending, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, New York

Josef T. Prchal MD

Preface to the Third Edition

Over four years have elapsed since the second edition of this book was published. During this period, an enormous amount of new scientific information has been generated in the area of hematology. This knowledge has been the result of both laboratory-based research and clinical trials. Exciting new data have been reported in virtually all areas of preclinical and clinical hematology research. This new edition serves as a resource for students, residents, fellows, scientists, and practicing physicians who are eager to learn about the science and practice of hematology. This third edition of *Hematology: Basic Principles and Practice* should be viewed as a work in progress; since the appearance of the first edition of this textbook in 1991, the book has evolved as it relates to content, focus, and size. This evolution reflects, in large part, the new directions and growth of hematology as an academic and clinical discipline. In order to retain the quality and vitality displayed in the first two editions, over thirty new primary authors have been added to this book. This changing of the guard is healthy for a text in order to ensure its timeliness and freshness. A significant number of new chapters appear in this volume. These new chapters represent a commitment by the editorial group to constructive change in order to create an excellent book. The authors have continued to update their chapters several times during the 24 months it has taken to complete this volume. The editors would like to thank the authors for these additional efforts, which assure that the text is up to date and comprehensive.

The editors have recognized the increasing importance of transplantation to hematologists; the section on Stem Cell Transplantation in this volume has been expanded in size, almost threefold since the second edition. As many as 14 chapters in this edition are devoted to stem cell transplantation. This emphasis reflects the growth and importance of this area to the discipline of hematology. Phil McGlave from the University of Minnesota was added to our editorial board for the purposes of enhancing our expertise in transplantation. He has selected a wonderful group of authors who have made important contributions to the text. The area of stem cell transplantation has blossomed over the last decade. The indications for high-dose chemo-radiotherapy and stem cell transplantation have been extended and the management of transplant recipients markedly improved. The use of alternative donor grafts and the engineering of allogeneic and autologous grafts have been areas of particular focus. This information is summarized in this edition and is important to all practicing hematologists.

The editors have remained responsive to the readership. Before embarking on this edition, we analyzed reviews of the book that appeared in a variety of journals, as well as solicited and unsolicited criticisms, and corrected any deficiencies or weaknesses. This edition represents the culmination of such efforts and results in a more readable and informative text. In addition, areas of overlap have been eliminated. Many of the readers of the text have appreciated the inclusion of personal strategies provided by many authors for the diagnosis and treatment of hematologic disorders. The number of personal strategy boxes has been expanded to provide a text that is useful not only to academic scientists but also to practicing physicians.

Some mention should be made of the debt that the editors owe to the contributing authors. As we all realize, the world of academic medicine has changed over the last decade. Physician accountability has become the new buzz word in many institutions. Contributions to textbooks are not valued by some institutions since such efforts fail to contribute to an institutional balance sheet in a positive fashion. The contributors to this book continue, however, to adhere to the traditional values of academic scholarship. In the sometimes frenetic world of institutional mergers and institutional mission statements this return to core values is refreshing and greatly appreciated. Only with the aid of such altruistic contributors can *Hematology: Basic Principles and Practice* remain the creative, dynamic, scholarly book that our readership has come to expect. We as a group remain committed to these ideals and standards. We are hopeful that our readership enjoys this text and continues to provide us with the constructive criticism needed to generate the creative energy required for future editions.

Preface to the Second Edition

The first edition of *Hematology: Basic Principles and Practice* appeared in 1991. This work was intended to be a comprehensive and up-to-date textbook developed to serve a diverse group of individuals ranging from practicing general hematologists, students of the field, basic scientists involved in hematologic research, as well as practicing internists and pediatricians. During the past four years, the science and practice of hematology have continued to evolve. The rapid advancement of this field has necessitated the creation of a second edition, in order that the book remain current and useful to our readers as the field of hematology progresses.

We retained the features of the first edition that were regarded by our audience as most effective, but altered the second edition as required to further enhance the quality of the book. In response to the constructive criticisms offered in numerous positive reviews of the first edition, we have added an entirely new section titled *Immunology.* It is organized in a manner resembling the section titled *Molecular and Cellular Basis of Hematology,* which provides an overview of the basic science needed to gain insight into the field. Some chapters have been eliminated in the interest of reducing redundancy and balancing the content. The editors met twice for extended work sessions during the inception of this edition in order to organize the information to be included. These meetings led to the development of close relationships between the editors and staff which has, we believe, led to the generation of a more cohesive and comprehensive text.

The growing importance of transfusion medicine has been recognized by the appointment of Leslie E. Silberstein, MD to the editorial group. The second edition has 16 chapters that deal exclusively with transfusion medicine. This section provides a concise review of an increasingly significant and complex area. An understanding of transfusion medicine is required of all practicing hematologists. We hope this primer will serve as a framework by which students of hematology can gain mastery of this rapidly evolving area.

In the first edition we asked authors to contribute their personal strategies for managing difficult clinical problems in sections set apart from the main text. These boxed paragraphs were highlighted by a shaded tint so the reader could easily identify these clinical points. Such contributions now appear in an expanded form in most of the chapters dealing with clinical hematology.

The remarkably rapid progress of both experimental and clinical hematology, coupled with the accelerated entry of molecular and cellular concepts and techniques into clinical practice, has resulted in an entirely new set of terminologies relevant to the clinical hematologist. Oncogenes, chromosomal translocations, cell-surface antigens, growth factors, and specialized cellular receptors comprise but a few examples of entities that were identified only by the arcane jargon of research laboratories a few years ago, but are now important for the classification, diagnosis, and treatment of hematologic diseases. The translation of knowledge from research laboratory to the bedside has been so rapid that the names of these substances and phenomena have often remained in the shorthand of the basic research community. A formidable challenge facing the editors and publisher of this volume has been the development of a coherent approach to the terms used to identify these materials. In some cases, loose rules of usage have been developed. For example, the abbreviations used to designate human and mouse proto-oncogenes, their oncogene derivatives, and the proteins resulting from their expression are distinguished by differential use of lower case and upper case letters, italics, and so forth. However, these rules are not universally honored in either the primary research literature, or in reviews or textbooks. We have tried to conform to recommended usage in every situation in which a recommended terminology has been developed. However, we have deferred to the best judgment and preference of the authors of individual chapters whenever they thought the conventional terminology was inappropriate for the subjects they discuss. We have attempted to alert the reader to the use of alternative terminologies, and to define potentially confusing terms.

The contributors to this edition have done an outstanding job, and the editors are indebted to them for their diligence, perseverance, and scholarly presentations.

Preface to the First Edition

The past several decades have seen an exponential increase in new medical knowledge related to hematology. New disease entities, new diagnostic methods, and novel therapeutic modalities have been introduced into the discipline. These clinical advances have largely been based on insights into the pathophysiology of hematologic disorders and have been gained by applying the tools of cell biology, biochemistry, immunology, and molecular genetics to this discipline. Inevitably, this explosion of knowledge has also led to further subspecialization within hematology, with the appearance of experts in transfusion medicine, red cell disorders, platelet and coagulation disorders, neoplastic diseases, and immunohematology.

The practicing general hematologists, whether operating at a university or in private practice, faces the challenge of caring for patients who have a variety of hematologic disorders. It has become increasingly difficult for one individual to remain current in all aspects of this expanding discipline, yet clinical care requires intimate familiarity with the enlarging knowledge base. In addition, basic scientists without clinical training have been attracted to hematology research. To put their work in a clinical context, these scientists require a broad background in the fundamentals of hematology and comprehension of clinical presentations, diagnostics, and therapy of specific diseases. Furthermore, students of the field, including medical residents, hematology fellows, and internists with special needs for understanding hematologic diseases have a requirement for an up-to-date source of information. *Hematology: Basic Principles and Practice* is a comprehensive textbook developed to serve these diverse groups.

The structure of the book reflects the diversity of its readership. *Hematology: Basic Principles and Practice* was designed during a meeting of the editors with Bob Hurley and Beth Barry of Churchill Livingstone in Woods Hole, Massachusetts, during the summer of 1988. As our starting point, all of the Editors stressed the importance of emphasizing the scientific underpinnings of modern hematology. Part I, *Molecular and Cellular Basis of Hematology,* is the foundation of the book and provides the overview of basic science needed to gain insight into the practice of hematology during the 1990s and into the next century. The next six parts are devoted to the major subspecialty areas, *Hematopoiesis, Red Blood Cells, White Blood Cells, Hematologic Malignancies, Hemostasis and Thrombosis,* and *Transfusion Medicine.* Each part contains an up-to-date review of the scientific fundamentals, followed by the description of specific hematologic diseases and their diagnosis and treatment. To further extend the books clinical usefulness, Part VIII deals with *Consultative Hematology.* With nine chapters covering general medicine and surgery, we hope this section will be especially valuable to the clinician performing consultations on patients who do not have a primary hematologic disorder but whose primary disorder results in hematologic abnormalities. The book closes with a section on *Special Tests and Procedures* that are integral to the practice of hematology.

To strike a balance between the scientific and clinical, we believe the text should be academic and scholarly, yet still offer a practical approach to diagnosis and patient management. To reconcile these objectives and provide a forum for sharing clinical approaches, we asked authors to contribute their personal strategies for managing difficult problems in nonreferenced editorial sections set off from the main text. The boxed paragraphs are highlighted by a shaded tint so the reader can easily identify these clinical pearls.

We also asked the contributors to seek out and create helpful illustrations to make difficult concepts easier to understand. We have redrawn much of the artwork to render primary visual material in a uniform style throughout the book, and have added color and tints to emphasize the more important points in the illustrations. We hope this makes our overall presentation more comprehensible and greatly enhances the heuristic value of these illustrations.

Ultimately, the quality of this project is closely related to the quality of the contributions received from the many participants in this multi-authored textbook. The preparation of each chapter has taken considerable effort and time, and we are grateful that the experts in the field agreed to participate in this undertaking. The contributors have done an outstanding job in writing comprehensive and timely treatises on specialized subjects, and we have responded by minimizing the delay between the preparation of each chapter and publication. We want to especially thank Les Silberstein at the University of Pennsylvania School of Medicine and Ed Snyder at the Yale University School of Medicine, who organized the section on blood banking. Their knowledge and guidance have been indispensable in editing this major section of the book.

Each of the editors brings to the book different interests and perspectives. We all worked together as equal partners to create a shared vision of a hematology text for a new generation of scientists and clinicians. We hope that we have accomplished this lofty goal, and that this will be the initial edition of a book that will continue to serve its varied readership for many editions to come.

Color Plates

Plate 4-1 Arrangement of integral and peripheral membrane proteins in the red cell. Note the asymmetric distribution of lipid, the anastomosing lattice formed by spectrin-spectrin and spectrin-actin junctions.

Plate 7-1 (A) Lymph node. Several lymphatic follicles with well-developed germinal centers are visible. (H&E × 200). **(B)** Lymph node. Lymphatic follicle with prominent germinal center pushing away the follicular mantle. (H&E × 350.) **(C)** Lymph node. B cells are stained (brown color) with a peroxidase-labeled monoclonal antibody against CD20, a pan-B-cell marker. (× 250.) **(D)** Lymph node. B cells are stained (brown color) with a peroxidase-labeled monoclonal antibody against light chains. (× 300.) **(E)** Lymph node. Stain for lysozyme. Macrophages containing the enzyme are scattered throughout the germinal center and mantle zone. (× 300.) **(F)** Lymph node. T cells stained (brown color) by a peroxidase-labeled monoclonal antibody (UCHL-1) against the pan-T-cell antigen CD45RO. (× 300.) **(G)** Thymus. Thymic lobule with densely packed cellular cortex and less cellular medulla in which large, pale Hassals corpuscles are visible. (H&E × 250.)

Plate 12-1 Colony-forming unit-mixed erythroid, myeloid, megakaryocyte (CFU-Mix). (See also Fig. 123.)

Plate 12-2 Proerythroblast (upper left corner), promyelocyte (middle) and myelocyte (below, right), and metamyelocyte (lower right).

Plate 12-3 Erythrocyte maturation. Basophilic (four in middle, middle right), polychromatic (three middle right), and orthochromatic erythroblast (upper left).

Plate 12-4 Erythrocyte maturation. Basophilic (four in middle, middle right), polychromatic (three middle right), and orthochromatic erythroblast (upper left).

Plate 19-1 Bone marrow morphology in severe aplastic anemia. **(A)** Bone marrow biopsy specimen showing severe hypocellularity. **(B)** Aspirate smear showing residual stromal and lymphoid elements.

Plate 19-2 Clinical presentations of aplastic anemia. **(A)** Ecchymosis in pancytopenic women. **(B)** Submucosal hematomas. **(C)** Petechial eruptions in a thrombocytopenic patient.

Plate 19-3 Peculiar morphologic features occasionally observed in aplastic anemia. **(A)** Marrow necrosis with eosinophilic ground substance (arrowhead) on biopsy. **(B)** Scanty marrow aspirate in severe disease showing only blood elements. **(C)** Megaloblastoid erythroid dysplasia in a patient with moderate aplastic anemia. **(D)** Hemophagocytosis (small arrows) in a young man with posthepatitis aplasia. **(E&F)** Megaloblastoid erythropoiesis in the marrow aspirates of two young women recovering from aplastic anemia.

Plate 19-4 Morphology of other diseases that may present with pancytopenia. **(A)** Biopsy in myelofibrosis. **(B)** Touch preparation of biopsy specimen showing syncytium of malignant cells in metastatic breast cancer. **(C)** Biopsy specimen and **(D)** aspirate smear of lymphoma in bone marrow. A monoclonal population of B lymphocytes was determined by flow cytometry.

Plate 19-5 Cutaneous eruptions due to serum sickness.

Plate 35-1 Fragmentation hemolysis. Note the irregular, distorted forms and small fragments.

Plate 35-2 Peripheral smear from a patient with -thalassemia intermedia shows the extensive tailed forms that largely disappear following splenectomy. Similar observations have been made on tailed RBCs in patients with agnogenic myeloid metaplasia and myelofibrosis.

Plate 35-3 Peripheral smear from a patient with severe alcoholic liver disease. Note the acanthocytes, spur cells, and transitional forms. Macrocytes are also present.

Plate 35-4 Bite cells from a patient with oxidative hemolysis. Note the thin veil of membrane across a clear zone, giving the appearance of a blister.

Plate 36-1 -Carbon backbone and overall surface shape of the intact Dob IgG structure. The antigen combining sites are located at the ends of the two horizontal Fab arms formed by the association of the light chains (-carbon backbone as red lines and surface as light blue dots) and heavy chains (-carbon backbone as yellow lines and surface as blue dots). On the basis of amino acid sequence studies, Dob has a substantial deletion in the hinge region, and this probably limits its segmental flexibility. The molecular surface represents the area accessible to a probe sphere the size of a water molecule (1.4-A radius). In this representation the surface of the IgG is composed of convex regions, formed by the solvent-accessible van der Waals surface of individual atoms and concave regions. Small gaps and crevices inaccessible to the probe sphere are smoothed over. *(From Getzoff et al.,[5] with permission.)*

Plate 40-1 Peripheral blood smear stained with Wrights stain, containing a single eosinophil (right) and neutrophil (left). Note the characteristic bilobed nucleus and eosin staining of the cytoplasmic specific (secondary) granules filling the eosinophils cytoplasm.

Plate 47-1 (A) High power (× 156) Giemsa stain of a mast cell lesion in a plastic embedded bone marrow. **(B)** High power (× 250) toluidine blue stain of a mast cell lesion in a plastic embedded bone marrow. Note that on Giemsa stains, mast cell granules stain dark blue, whereas eosinophils stain bright orange. *(From Parker RI: Hematologic aspects of mastocytosis. 1. Bone marrow pathology in adult and pediatric systemic mast cell disease. J Invest Dermatol 96:47S, 1991, with permission.)***(C)** Giemsa plastic embedded bone marrow biopsy demonstrating metachromatic granules in mast cells. (× 1,000.) *(From Travis WD, Li C-Y, Bergstralh EJ et al: Systemic mast cell disease: analysis of 58 cases and literature review. Medicine 67:345, 1988, with permission.)*

Plate 53-1 Leukemia cutis in a patient with monoblastic leukemia.

Plate 53-2 Sweet syndrome in a patient with AML. Tender, pseudovesicular, erythematous plaques of Sweet syndrome. *(From Cohen,[159] with permission.)*

Plate 53-3 Gingival infiltration in a patient with myelomonocytic leukemia.

Plate 53-4 M0: Acute myeloid leukemia.

Plate 53-5 M1: Acute myeloid leukemia. Cells demonstrate no evidence of maturation or differentiation. The blasts often have large irregular nuclei with varying amounts of eccentrically placed cytoplasm. There is no definite granulation, and Auer rods are absent.

Plate 53-6 M2: Myeloblastic leukemia with differentiation. The leukemic cells demonstrate maturation through the promyelocytic stage. Azurophilic granules are seen with occasional Auer rods. *(Courtesy of Guido J.K. Tricot, MD, PhD.)*

Plate 53-7 M3: Acute promyelocytic leukemia. The leukemic cells contain multiple abnormal, coarse azurophilic granules, and Auer rods are prominent. *(Courtesy of Guido J.K. Tricot, MD, PhD.)*

Plate 53-8 M3v.

Plate 53-9 M4: Acute myelomonocytic leukemia. Both myeloid and monocytic elements are found, and myeloblasts differentiate through the promyelocyte stage. Monocytes and monoblasts make up >20% of the total number of nucleated cells. Monoblasts demonstrate a pale cytoplasm, with occasional vacuoles and granules with folded or rounded nuclei.

Plate 53-10 M4Eo: Acute myelomonocytic leukemia with eosinophils. Similar to the M4 variant but with increased eosinophils; eosinophils are atypical in appearance, with prominent basophilic granules.

Plate 53-11 M5a: Acute monocytic leukemia, undifferentiated. The predominant cell is an undifferentiated monoblast. The cytoplasm is pale, with occasional vacuoles. The nuclei are round and lack

the usual folded monocytoid appearance.

Plate 53-12 M5b: Acute monocytic leukemia, differentiated. Most of the cells are mature-looking monocytes with centrally placed folded nuclei. Rare monoblasts are found. *(Courtesy of Dr. Lorrie F. Odom.)*

Plate 53-13 M6: Erythroleukemia. Abnormal erythroid precursors with megaloblastic features are prominent. All stages of the erythroid series are found, typically with many bizarre and dysplastic features. Typical myeloblasts are also noted. *(Courtesy of the Blood and Bone Marrow Cell Recognition and Interpretation audio-visual seminars. American Society of Clinical Pathologists, Chicago, 1987.)*

Plate 53-14 M7: Acute megakaryocytic leukemia. Increased marrow fibrosis is frequent. Note the cytoplasmic budding, which is typical of megakaryocytic leukemias.

Plate 55-1 (A) Monoblastic leukemia cutis at diagnosis; lesion on forehead preceded disseminated rash by 68 weeks. **(B)** Gingival infiltration with M5a leukemia in a 21-month-old girl. **(C)** Retinal infiltration at presentation of M4 disease in a 5-year-old boy.

Plate 55-2 Cerebrospinal fluid double concentrate cytocentrifuge preparation of M5a leukemia cells.

Plate 57-1 French-American-British Cooperative Working Group classification of acute lymphocytic leukemia. **(A)** L1 lymphoblasts are small, with scanty cytoplasm and inconspicuous nucleoli. *(Courtesy of Guido J.K. Tricot, MD, PhD.)* **(B)** L2 lymphoblasts are generally larger and demonstrate considerably more variation in size and have prominent nucleoli and abundant cytoplasm. **(C)** L3 lymphoblasts are characterized by cytoplasmic basophilia and prominent cytoplasmic vacuolation. (Plates B and C courtesy of the Blood and Bone Marrow Cell Recognition and Interpretation audiovisual seminars, American Society of Clinical Pathologists, Chicago, 1987.)

Plate 67-1 Nodular sclerosis: Reed-Sternberg cell (left) and lacunar variants.

Plate 67-2 Nodular sclerosis: cohesive tumor cells in syncytial variant.

Plate 67-3 Lymphocyte predominance, diffuse: rare diagnostic Reed-Sternberg cell with mirror-image nuclei in center of field.

Plate 67-4 Lymphocyte predominance, nodular: L&H or popcorn variants of Reed-Sternberg cells.

Plate 67-5 Lymphocyte predominance, nodular: progressively transformed germinal centers.

Plate 67-6 Lymphocyte depletion: two mitoses (left), classic Reed-Sternberg cell (right), and numerous Reed-Sternberg pleomorphic variants.

Plate 67-7 Mixed cellularity: multinucleated Reed-Sternberg cell and numerous inflammatory cells.

Plate 67-8 Diagnostic Reed-Sternberg cell: note huge nucleoli and peripheral condensation of nuclear chromatin creating halo around nucleoli.

Plate 67-9 Spleen: expanded periarterial sheath with evidence of early Hodgkin disease.

Plate 67-10 Bone marrow biopsy: two focal nodules of Hodgkin disease.

Part I - Molecular and Cellular Basis of Hematology

Chapter 1 - Anatomy and Physiology of the Gene

Nancy Berliner
Edward J. Benz Jr.

Normal blood cells have limited life spans; they must be replenished in precise numbers by a continuously renewing population of progenitor cells. Homeostasis of the blood requires that proliferation of these cells be efficient, yet strictly constrained. Many distinctive types of mature blood cells must arise from these progenitors by a controlled process of commitment to, and execution of, complex programs of differentiation. Thus, developing red cells must produce large quantities of hemoglobin, but not the myeloperoxidase characteristic of granulocytes, the immunoglobulins characteristic of lymphocytes, or the fibrinogen receptors characteristic of platelets. Similarly, the maintenance of normal amounts of coagulant and anticoagulant proteins in the circulation requires exquisitely regulated production, destruction, and interaction of the components. Understanding the basic biologic principles underlying cell growth, differentiation, and protein biosynthesis requires a thorough knowledge of the structure and regulated expression of genes, because the gene is now known to be the fundamental unit by which biologic information is stored, transmitted, and expressed in a regulated fashion.

Genes were originally characterized as mathematical units of inheritance. They are now known to consist of molecules of deoxyribonucleic acid (DNA). By virtue of their ability to store information in the form of nucleotide sequences, to transmit it by means of semiconservative replication to daughter cells during mitosis and meiosis, and to express it by directing the incorporation of amino acids into proteins, DNA molecules are the chemical transducers of genetic information flow. Efforts to understand the biochemical means by which this transduction is accomplished have given rise to the discipline of molecular genetics.

Our ability to study the molecular genetics of hematologic problems has been greatly advanced by the development of recombinant DNA technology, which permits us to isolate, characterize, synthesize, and manipulate individual genes controlling known proteins or biologic phenomena. A brief overview of the basic methods and terminology of recombinant DNA technology is included in this chapter.

THE GENETIC VIEW OF THE BIOSPHERE THE CENTRAL DOGMA OF MOLECULAR BIOLOGY

The fundamental premise of the molecular biologist is that the magnificent diversity encountered in nature is ultimately governed by genes. The capacity of genes to exert this control is in turn determined by relatively simple stereochemical rules, first appreciated by Watson and Crick in the 1950s. These rules constrain the types of interactions that can occur between two molecules of DNA or ribonucleic acid (RNA).

DNA and RNA are linear polymers consisting of four types of nucleotide subunits. Proteins are linear unbranched polymers consisting of 21 types of amino acid subunits. Each amino acid is distinguished from the others by the chemical nature of its side chain, the moiety not involved in forming the peptide bond links of the chain. The properties of cells, tissues, and organisms depend largely on the aggregate structures and properties of their proteins. The central dogma of molecular biology states that genes control these properties by controlling the structures of proteins, the timing and amount of their production, and the coordination of their synthesis with that of other proteins. The information needed to achieve these ends is transmitted by a class of nucleic acid molecules called RNA. Genetic information is stored in the form of DNA nucleic acid sequences and expressed in the form of protein synthesis through the mediation of RNA. Genetic information thus flows in the direction DNA RNA protein. This central dogma provides, in principle, a universal approach for investigating the biologic properties and behavior of any given cell, tissue, or organism by study of the controlling genes. Methods permitting direct manipulation of DNA sequences should then be universally applicable to the study of all living entities. Indeed, the power of the molecular genetic approach lies in the universality of its utility.

One exception to the central dogma of molecular biology that is especially relevant to hematologists is the storage of genetic information in RNA molecules in certain viruses, notably the retroviruses associated with T-cell leukemia/lymphoma and the human immunodeficiency virus. When retroviruses enter the cell, the RNA genome is copied into a DNA replica by an enzyme called reverse transcriptase. This DNA representation of the viral genome is then expressed according to the rules of the central dogma. Retroviruses thus represent a variation on the theme, rather than a true exception to or violation of the rules.

ANATOMY AND PHYSIOLOGY OF GENES

DNA Structure

DNA molecules are extremely long, unbranched polymers of nucleotide subunits. Each nucleotide contains a sugar moiety called deoxyribose, a phosphate group attached to the 5 carbon position, and a purine or pyrimidine base attached to the 1 position (Fig. 1-1). The linkages in the chain are formed by phosphodiester bonds between the 5 position of each sugar residue and the 3 position of the adjacent residue in the chain (Fig. 1-1). The sugar phosphate links form the backbone of the polymer, from which the purine or pyrimidine bases project perpendicularly.

The haploid human genome consists of 23 long, double-stranded DNA molecules tightly complexed with histones and other nuclear proteins to form compact linear structures called chromosomes. The genome contains 3 billion nucleotides; each chromosome is thus 50 to 200 million bases in length. The individual genes are aligned along each chromosome. Blood cells, like most somatic cells, are diploid. Each chromosome is present in two copies, so that there are 46 chromosomes consisting of approximately 6 billion base pairs (bp) of DNA. The length of a DNA molecule is often described in terms of the length of the number of nucleotide bases it contains. Because each nucleotide contains one such base, it is equivalent to say a DNA molecule is 1,000 bases (1 kilobase [kb]) or 1,000 nucleotides in length. As noted later, DNA usually exists as a double-stranded structure, held together by hydrogen bonds between the bases at equivalent positions of each strand (base pairing); the length of these double-stranded molecules is described in base pairs (e.g., 1,000 bp = 1 kilobase pair [1 kbp]).

The four nucleotide bases in DNA are the purines (adenosine and guanosine) and the pyrimidines (thymine and cytosine). The basic chemical configuration of the other nucleic acid found in cells, RNA, is quite similar, except that the sugar is ribose (having a hydroxyl group attached to the 2 carbon, rather than

Figure 1-1 Structure, base pairing, polarity, and template properties of DNA. **(A)** Structures of the four nitrogenous bases projecting from sugar phosphate backbones. The hydrogen bonds between them form base pairs holding complementary strands of DNA together. Note that A-T and T-A base pairs have only two hydrogen bonds, whereas C-G and G-C pairs have three. **(B)** The double helical structure of DNA results from base pairing of strands to form a double-stranded molecule with the backbones on the outside and the hydrogen-bonded bases stacked in the middle. Also shown schematically is the separation (unwinding) of a region of the helix by mRNA polymerase, which is shown using one of the strands as a template for the synthesis of an mRNA precursor molecule. Note that new bases added to the growing RNA strand obey the rules of Watson-Crick base pairing (see text). Uracil (U) in RNA replaces T in DNA and, like T, forms base pairs with A. **(C)** Diagram of the antiparallel nature of the strands, based on the stereochemical 3 5 polarity of the strands. The chemical differences between reading along the backbone in the 5 to 3 and 3 to 5 directions can be appreciated by reference to part **(A)**.

the hydrogen found in deoxyribose) and the pyrimidine base uracil is used in place of thymine. The bases are commonly referred to by a short-hand notation: the letters A, C, T, G, and U are used to refer to adenosine, cytosine, thymine, guanosine, and uracil, respectively.

The ends of DNA and RNA strands are chemically distinct, because of the 3 5 phosphodiester bond linkage that ties adjacent bases together (Fig. 1-1). One end of the strand (the 3 end) has an unlinked (free at the 3 carbon) sugar position, and the other (the 5 end) a free 5 position. There is thus a polarity to the sequence of bases in a DNA strand: the same sequence of bases read in a 3 5 direction carries a different meaning than if read in a 5 3 direction. Cellular enzymes can thus distinguish one end of a nucleic acid from the other; most enzymes that read the DNA sequence tend to do so only in one direction (3 5 or 5 3, but not both). Most nucleic acid-synthesizing enzymes, for instance, add new bases to the strand in a 5 3 direction.

The ability of DNA molecules to store information resides in the *sequence* of nucleotide bases arrayed along the polymer chain. Under the physiologic conditions in living cells, DNA is thermodynamically most stable when two strands coil around each other to form a double-stranded helix. The strands are aligned in an antiparallel direction, having opposite 3 5 polarity (Fig. 1-1). The sugar phosphate backbones are arrayed on the outside of the helix with the nucleotide bases stacked in the center (Fig. 1-1).

The DNA strands are held together by hydrogen bonds between the bases on one strand and the bases on the opposite (complementary) strand. The stereochemistry of these interactions allows bonds to form between the two strands only when adenine on one strand pairs with thymine at the same position of the opposite strand, or guanine with cytosine. These are the Watson-Crick rules of base pairing: only A-T and G-C base pairs can form. Two strands joined together in compliance with these rules are said to have complementary base sequences.

These thermodynamic rules imply that the sequence of bases along one DNA strand immediately dictates the sequence of bases that must be present along the complementary strand in the double helix. For example, whenever an A occurs along one strand, a T must be present at that exact position on the opposite strand; a G must always be paired with a C, a T with an A, and a C with a G. In RNA-RNA or RNA-DNA double-stranded molecules, U-A base pairs replace T-A pairs.

Storage and Transmission of Genetic Information

The rules of Watson-Crick base pairing apply to DNA-RNA, RNA-RNA, and DNA-DNA double-stranded molecules. Enzymes that replicate or polymerize DNA and RNA molecules obey the base pairing rules. By using an existing strand of DNA or RNA as the template, a new (daughter) strand is copied (transcribed) by reading processively along the base sequence of the template strand, adding to the growing strand at each position only that base that is complementary to the corresponding base in the template according to the Watson-Crick rules. Thus, a DNA strand having the base sequence 5-GCTATG-3 could be copied by DNA polymerase only into a daughter strand having the sequence 3-CGATAC-5. Note that the sequence of the template strand provides all the information needed to predict the nucleotide sequence of the complementary daughter strand. Genetic information is thus stored in the form of base-paired nucleotide sequences.

If a double-stranded DNA molecule is separated into its two component strands, and each strand is then used as a template to synthesize a new daughter strand, the product will be two double-stranded daughter DNA molecules, each identical to the original parent molecule. This semiconservative replication process is exactly what occurs during mitosis and meiosis as cell division proceeds (Fig. 1-2). The rules of Watson-Crick base pairing thus provide for the faithful transmission of exact copies of the cellular genome to subsequent generations.

Expression of Genetic Information Through the Genetic Code and Protein Synthesis

The information stored in the DNA base sequence achieves its impact on the structure, function, and behavior of organisms by governing the structures and amounts of protein synthesized in the cells. The primary structure (i.e., the amino acid sequence) of each protein determines its three-dimensional conformation and therefore properties (e.g., shape, enzymatic activity, ability to interact with other molecules, stability). In the aggregate, these proteins control cell structure and metabolism. Genes determine the structures of proteins that are synthesized, the timing of their production during development or differentiation, and the amounts produced in different cells or tissues. The process by which DNA achieves its control of cells through protein synthesis is called gene expression.

An outline of the basic pathway of gene expression in eukaryotic cells is shown in Figure 1-3 . The DNA base sequence

Figure 1-2 Semiconservative replication of DNA. **(A)** The process by which the DNA molecule on the left is replicated into two daughter molecules, as occurs during cell division. Replication occurs by separation of the parent molecule into the single-stranded form at one end, reading of each of the daughter strands in the 3 5 direction by DNA polymerase, and addition of new bases to growing daughter strands in the 5 3 direction. **(B)** The replicated portions of the daughter molecules are identical to each other (red). Each carries one of the two strands of the parent molecule, accounting for the term *semiconservative replication.* Note the presence of the replication fork, the point at which the parent DNA is being unwound. **(C)** The antiparallel nature of the DNA strands demands that replication proceed toward the fork in one direction and away from the fork in the other (red). This means that replication is actually accomplished by reading of short stretches of DNA, followed by ligation of the short daughter strand regions to form an intact daughter strand.

Figure 1-3 Synthesis of mRNA and proteinthe pathway of gene expression. The diagram of the DNA gene shows the alternating array of exons (red) and introns (shaded color) typical of most eukaryotic genes. Transcription of the mRNA precursor, addition of the 5-CAP and 3-poly (A) tail, splicing and excision of introns, transport to the cytoplasm through the nuclear pores, translation into the amino acid sequence of the apoprotein, and post-translational processing of the protein are described in the text. Translation proceeds from the initiator methionine codon near the 5 end of the mRNA, with incorporation of the amino terminal end of the protein. As the mRNA is read in a 5 3 direction, the nascent polypeptide is assembled in an amino carboxyl terminal direction.

is first copied into an RNA molecule, called premessenger RNA, by messenger RNA (mRNA) polymerase. Pre-mRNA has a base sequence identical to the DNA coding strand. Genes in eukaryotic species consist of tandem arrays of sequences encoding mRNA (exons); these sequences alternate with sequences (introns) present in the initial mRNA transcript (pre-mRNA) but absent from the mature mRNA. The entire gene is transcribed into the large precursor, which is then further processed (spliced) in the nucleus. The introns are excised from the final mature mRNA molecule, which is then exported to the cytoplasm to be decoded (translated) into the amino acid sequence of the protein, by association with a biochemically complex group of ribonucleoprotein structures called ribosomes. Ribosomes contain two subunits; the 60S subunit contains a single, large (28S) ribosomal RNA molecule complexed with multiple proteins, whereas the RNA component of the 40S subunit is a smaller (18S) rRNA molecule.

Ribosomes read mRNA sequence in a ticker tape fashion *three bases at a time*, inserting the appropriate amino acid encoded by each three-base code word or codon into the appropriate position of the growing protein chain. This process is called mRNA translation. The glossary used by cells to know which amino acids are encoded by each DNA codon is called the genetic code (Table 1-1). Each amino acid is encoded by a sequence of three successive bases. Because there are four code letters (A, C, G, and U), and because sequences read in the 5 3 direction have a different biologic meaning than sequences read in the 3 5 direction, there are 4^3 , or 64, possible codons consisting of three bases.

There are 21 naturally occurring amino acids found in proteins. Thus, more codons are available than amino acids to be encoded. As noted in Table 1-1 , a consequence of this redundancy is that some amino acids are encoded by more than one codon. For example, six distinct codons can specify incorporation of arginine into a growing amino acid chain, four codons can specify valine, two can specify glutamic acid, and only one each, methionine or tryptophan. In no case does a single codon encode more than one amino acid. Codons thus predict unambiguously the amino acid sequence they encode. However, one cannot easily read backward from the amino acid sequence to decipher the *exact* encoding DNA sequence. These facts are summarized by saying that the code is degenerate but not ambiguous.

Some specialized codons serve as punctuation points during translation. The methionine codon (AUG), when surrounded by a consensus sequence (the Kozak box) near the beginning (5 end) of the mRNA, serves as the initiator codon signaling the first amino acid to be incorporated. All proteins thus begin with a methionine residue, but this is often removed later in the translational process. Three codons, UAG, UAA, and UGA, serve as translation terminators, signaling the end of translation.

The adaptor molecules mediating individual decoding events during mRNA translation are small (40 bases long) RNA molecules called transfer RNAs (tRNAs). When bound into a ribosome, each tRNA exposes a three-base segment within its sequence called the anticodon. These three bases attempt to pair with the three-base codon exposed on the mRNA. If the anticodon is complementary in sequence to the codon, a stable interaction among the mRNA, the ribosome, and the tRNA molecule results. Each tRNA also contains a separate region that is adapted for covalent binding to an amino acid. The enzymes that catalyze the binding of each amino acid are constrained in

[a] Note that most of the degeneracy in the code is in the third base position (e.g., lysine = AA [G or C], asparagine = AAC/U, valine = GUN [where N is any base]).
[c]Hydroxyproline, the 21st amino acid, is generated by post-translational modification of proline. It is almost exclusively confined to collagen subunits.
[b]AUG is also used as the chain initiation codon when surrounded by the Kozak consensus sequence.
[d] The codons that signal the end of translation, also called nonsense or termination codons, are described by their nicknames *amber* (UAG), *ochre* (UAA), and *opal* (UGA).

such a way that each tRNA species can bind only to a single amino acid. For example, tRNA molecules containing the anticodon 3-AAA-5, which is complementary to a 5-UUU-3 (phenylalanine) codon in mRNA, can only be bound to or charged with phenylalanine; tRNA containing the anticodon 3-UAG-5 can only be charged with isoleucine, and so forth.

Transfer RNAs and their amino acyl tRNA synthetases provide for the coupling of nucleic acid information to protein information needed to convert the genetic code to an amino acid sequence. Ribosomes provide the structural matrix on which tRNA anticodons and mRNA codons become properly exposed and aligned in an orderly, linear, and sequential fashion. As each new codon is exposed, the appropriate charged tRNA species is bound. A peptide bond is then formed between the amino acid carried by this tRNA and the C-terminal residue on the existing nascent protein chain. The growing chain is transferred to the new tRNA in the process, so that it is held in place as the next tRNA is brought in. This cycle is repeated until completion of translation. The completed polypeptide chain is then transferred to other organelles for further processing (e.g., to the endoplasmic reticulum and the Golgi apparatus) or released into cytosol for association of the newly completed chain with other subunits to form complex multimeric proteins (e.g., hemoglobin), and so forth, as discussed in Chapter 2 .

mRNA Metabolism

Eukaryotic and prokaryotic cells differ in the way that the initial mRNA transcript is structurally related to the mature mRNA species that is ultimately translated on ribosomes. In prokaryotes, the initial transcript and the translated transcript are essentially the same. In eukaryotes, the situation is far more complex.

In eukaryotic cells, mRNA is initially synthesized in the nucleus (Figs. 1-3 and 1-4). Before the initial transcript becomes suitable for translation in the cytoplasm, several complex events, mRNA processing and transport, must occur: excision of the portions of the mRNA corresponding to the introns of the gene (mRNA splicing), modification of the 5 and 3 ends of the mRNA to render them more stable and translatable, and transport to the cytoplasm. Moreover, the amount of any particular mRNA moiety in both prokaryotic and eukaryotic cells is governed not only by the composite rate of mRNA synthesis (transcription, processing, and transport), but by its degradation by cytoplasmic ribonucleases (RNA degradation). Many mRNA species of special importance in hematology (e.g., mRNAs for growth factors and their receptors, proto-oncogene mRNAs, acute-phase reactants) are exquisitely regulated by control of their stability (half-life) in the cytoplasm.

Post-transcriptional mRNA metabolism is complex. Only a few relevant details are considered in this section.

mRNA Splicing

The initial transcript of eukaryotic genes contains several subregions (Fig. 1-4). Most striking is the tandem alignment of exons and introns. Precise excision of intron sequences and ligation of exons is critical for production of mature mRNA. This process is called mRNA splicing, and it occurs on complexes of small nuclear RNAs and proteins called snRNPs; the term *spliceosome* is also used to describe the intranuclear organelle that mediates mRNA splicing reactions. The biochemical mechanism for splicing is complex. A consensus sequence, which includes the dinucleotide GU, is recognized as the donor site at the 5 end of the intron (5 end refers to the polarity of the mRNA strand coding for protein); a second consensus sequence ending in the dinucleotide AG is recognized as the acceptor site, which marks the distal end of the intron (Figs. 1-4 and 1-5). The spliceosome recognizes the donor and acceptor and forms an intermediate lariat structure that provides for both excision of the intron and proper alignment of the cut ends of the two exons for ligation in precise register.

Messenger RNA splicing has proved to be an important mechanism for greatly increasing the versatility and diversity of expression of a single gene. For example, some genes contain an array of more exons than are actually found in any mature mRNA species encoded by the gene. Several different mRNA protein products can arise from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA products. This phenomenon is called alternative mRNA splicing. It permits a single gene to code for multiple mRNA and protein products with related, but distinct structures and functions. The mechanisms by which individual exons are selected

Figure 1-4 Anatomy of the products of the structural gene (mRNA precursor and mRNA). This schematic shows the configuration of the critical anatomic elements of an mRNA precursor, which represents the primary copy of the structural portion of the gene. The sequences GU and AG indicate, respectively, the invariant dinucleotides present in the donor and acceptor sites at which introns are spliced out of the precursor. Not shown are the less stringently conserved consensus sequences that must precede and succeed each of these sites for a short distance.

Figure 1-5 Regulatory elements flanking the structural gene.

or rejected remain totally obscure. For present purposes, it is sufficient to note that important physiologic changes in cells can be regulated by altering the patterns of mRNA splicing products arising from single genes.

Many inherited hematologic diseases arise from mutations, which derange mRNA splicing. For example, some of the most common forms of the thalassemia syndromes and hemophilia arise by mutations that alter normal splicing signals or create splicing signals where they normally do not exist (activation of cryptic splice sites).

Modification of the Ends of the mRNA Molecule

Most eukaryotic mRNA species are polyadenylated at their 3 ends. mRNA precursors are initially synthesized as large molecules that extend further downstream from the 3 end of the mature mRNA molecule. Polyadenylation results in the addition of stretches of 100150 A residues at the 3 end. Such an addition is often called the poly-A tail, and is of variable length. Polyadenylation facilitates rapid early cleavage of the unwanted 3 sequences from the transcript and is also important for stability or transport of the mRNA out of the nucleus. Signals near the 3 extremity of the mature mRNA mark positions at which polyadenylation occurs. The consensus signal is AUAAA (Fig. 1-4). Mutations in the poly-A signal sequence have been shown to cause thalassemia.

At the 5 end of the mRNA, a complex oligonucleotide having unusual phosphodiester bonds is added. This structure contains the nucleotide 7-methyl-guanosine, and is called CAP (Fig. 1-4). The 5-CAP enhances both mRNA stability and the ability of the mRNA to interact with protein translation factors and ribosomes.

5 and 3 Untranslated Sequences

The 5 and 3 extremities of mRNA extend beyond the initiator and terminator codons that mark the beginning and the end of the sequences actually translated into proteins (Figs. 1-4 and 1-5). The functions of these so-called 5 and 3 untranslated regions (5 UTR, 3 UTR) remain poorly understood. It appears that UTRs are involved in determining mRNA stability and, possibly, the efficiency with which mRNA species can be translated. For example, if the 3 UTR of a very stable mRNA (e.g., globin mRNA) is swapped with the 3 UTR of a highly unstable mRNA (e.g., the c-*myc* proto-oncogene), the c-*myc* mRNA becomes more stable. Conversely, attachment of the 3 UTR of c-*myc* to a globin molecule renders it unstable. Instability is often associated with repeated sequences rich in A and U in the 3 UTR (Fig. 1-4).

Transport of mRNA from Nucleus to Cytoplasm: mRNP Particles

An additional potential step for regulation or disruption of mRNA metabolism occurs during the transport from nucleus to cytoplasm. mRNA transport is an active, energy-consuming process. Moreover, at least some mRNAs appear to enter the cytoplasm in the form of complexes bound to proteins (mRNPs). mRNPs may regulate stability of the mRNAs and their access to translational apparatus. There is some evidence that certain mRNPs are present in the cytoplasm but are not translated (masked message) until proper physiologic signals are received.

GENE REGULATION

Virtually all cells of an organism receive a complete copy of the DNA genome inherited at the time of conception. The panoply of distinct cell types and tissues found in any complex organism is possible only because different portions of the genome are selectively expressed or repressed in each cell type. Each cell must know which genes to express, how actively to express them, and when to express them. This biologic necessity has come to be known as gene regulation or regulated gene expression. Understanding gene regulation provides insight into how pluripotent stem cells determine that they will express the proper sets of genes in daughter progenitor cells that differentiate along each lineage. Major hematologic disorders (such as the leukemias and lymphomas), immunodeficiency states, and myeloproliferative syndromes result from derangements in the system of gene regulation. An understanding of the ways that genes are selected for expression thus remains one of the major frontiers of biology and medicine.

Active and Inactive Configurations of Genomic DNA in Chromatin

Most of the DNA in living cells is inactivated by formation of a nucleoprotein complex called chromatin. The histone and

nonhistone proteins in chromatin effectively sequester genes from enzymes needed for expression. The most tightly compacted chromatin regions are called euchromatin. Heterochromatin, less tightly packed, contains actively transcribed genes. Activation of a gene for expression (i.e., transcription) requires that it become less compacted and more accessible to the transcription apparatus. Little is known about these processes, but it is clear that both *cis*-acting and *trans*-acting factors are involved. *Cis*-acting elements are regulatory DNA sequences, within or flanking the genes. They are recognized by *trans*-acting factors, which are nuclear DNA binding proteins needed for transcriptional regulation.

DNA sequence regions flanking genes are called *cis*-acting because they influence expression of nearby genes only on the same chromosome. These sequences do not usually encode mRNA or protein molecules. They alter the conformation of the gene within chromatin in such a way as to facilitate or inhibit access to the factors that facilitate transcription. These interactions may twist or kink the DNA in such a way as to increase exposure to other molecules. When exogenous nucleases are added in small amounts to nuclei, these exposed sequence regions are especially sensitive to the DNA cutting action of the nucleases. Thus, nuclease-hypersensitive sites in DNA have come to be appreciated as markers for regions in or near genes that are interacting with regulatory nuclear proteins.

Methylation is another structural feature that can be used to recognize differences between actively transcribed and inactive genes. Most eukaryotic DNA is heavily methylated, that is, the DNA is modified by the addition of a methyl group to the 5 position of cytosines (5-methyl-C). In general, heavily methylated genes are inactive, whereas active genes are relatively hypomethylated, especially in the 5 flanking regions containing the promoter and other regulatory elements (see later). These flanking regions frequently include DNA sequences with a high content of Gs and Cs (G-C-rich islands). Hypomethylated G-C-rich islands (detectable by methylation-sensitive restriction endonucleases) serve as markers of actively transcribed genes. For example, a search for undermethylated G-C-rich islands on chromosome 7 facilitated the search for the gene for cystic fibrosis.

Several other structural configurations of DNA and their interaction with chromatin have been implicated as important for gene regulation. These include the B or Z conformation of the DNA helix, the degree of supercoiling or torsion of DNA superstructures, acetylation, phosphorylation, or ribosylation of nuclear proteins, and so forth. However, none of these mechanisms is understood in sufficient detail to merit further discussion.

Enhancers, Promoters, and Silencers

Several types of *cis*-active DNA sequence elements have been defined according to the presumed consequences of their interaction with nuclear proteins (Fig. 1-5). *Promoters* are found just upstream (to the 5 side) of the start of mRNA transcription (the CAP). mRNA polymerases appear to bind first to the promoter region and thereby gain access to the structural gene sequences downstream. Promoters thus serve a dual function of being binding sites for mRNA polymerase and marking for the polymerase the downstream point at which transcription should start. *Enhancers* are more complicated and less well understood DNA sequence elements. Enhancers can lie on either side of a gene, or even within the gene in introns. Enhancers appear to bind transcription factors and thereby stimulate expression of genes nearby. The domain of influence of enhancers (i.e., the number of genes to either side whose expression is stimulated) varies. Some enhancers influence only the adjacent gene; others seem to mark the boundaries of large multigene clusters (gene domains) whose coordinated expression is appropriate to a particular tissue type or a particular time. For example, the very high levels of globin gene expression in erythroid cells depend on the function of an enhancer that seems to activate the entire gene cluster and is thus called a locus-activating region (LAR; Fig. 1-5). The nuclear factors interacting with enhancers are probably induced into synthesis or activation as part of the process of differentiation.

Silencer sequences serve a function that is the obverse of enhancers. When bound by the appropriate nuclear proteins, silencer sequences cause repression of gene expression. There is some evidence that the same sequence elements can act as enhancers or silencers under different conditions, presumably by being bound by different sets of proteins having opposite effects on transcription.

Transcription Factors

Assays for detecting nuclear proteins that exhibit gene-specific DNA binding are now achieving widespread utility. Considerable information is now available about these nuclear proteins and their biochemical properties, but their physiologic behavior is incompletely understood. Proteins involved in the regulation of several gene systems have been isolated and their genes cloned. Common structural features have become apparent. Most transcription factors have DNA-binding domains sharing homologous structural motifs (cytosine-rich regions called zinc fingers, leucine-rich regions called leucine zippers, and so forth), but other regions appear to be unique. Many factors implicated in the regulation of growth, differentiation, and development (e.g., homeobox genes, proto-oncogenes, antioncogenes) appear to be DNA-binding proteins and may be involved in the steps needed for activation of a gene within chromatin. Others seem to bind to, or modify, DNA-binding proteins. These factors are discussed in more detail in Chapter 6 .

Regulation of mRNA Splicing, Stability, and Translation (Post-transcriptional Regulation)

It has become increasingly apparent that *post-transcriptional* and *translational* mechanisms are important strategies used by cells to govern the amounts of mRNA and protein accumulating when a particular gene is expressed. The major modes of *post-transcriptional* regulation are regulated alternative mRNA splicing, control of

mRNA *stability*, and control of *translational* efficiency.

A cell can regulate the relative amounts of different protein isoforms arising from a given gene by altering the relative amounts of an mRNA precursor that are spliced along one pathway or another (alternative mRNA splicing). Several striking examples of this type of regulation are described, including the ability of B lymphocytes to make both IgM and IgD at the same developmental stage, changes in the particular isoforms of cytoskeletal proteins produced during red cell differentiation, and a switch from one isoform of the *c-myb* proto-oncogene product to another during red cell differentiation. The effect of controlling the pathway of mRNA processing used in a cell is to include or exclude portions of the mRNA sequence. These portions encode peptide sequences that influence the ultimate physiologic behavior of the protein, or the RNA sequences that alter stability or translatability.

The importance of the control of mRNA stability for gene regulation is being increasingly appreciated. The steady-state level of any given mRNA species ultimately depends on the balance between the rate of its production (transcription and mRNA processing) and its destruction. One means by which stability is regulated is the inherent structure of the mRNA sequence, especially the 3 and 5 UTRs. As already noted, these

sequences appear to affect mRNA secondary structure or recognition by nucleases, or both. Different mRNAs thus have inherently longer or shorter half-lives, almost regardless of the cell type in which they are expressed. Some mRNAs tend to be highly unstable. In response to appropriate physiologic needs, they can thus be produced quickly and removed from the cell quickly when a need for them no longer exists. Globin mRNA, on the other hand, is inherently quite stable, with a half-life measured in the range of 50 hours. This is appropriate for the need of reticulocytes to continue to synthesize globin for 2448 hours after the ability to synthesize new mRNA has been eliminated from the terminally mature erythroblasts.

Messenger RNA stability can also be altered in response to changes in the intracellular milieu. This phenomenon usually involves nucleases capable of destroying one or more broad classes of mRNA defined on the basis of their 3 or 5 UTR sequences. Thus, for example, histone mRNAs are destabilized after the S phase of the cell cycle is complete. Presumably this occurs because histone synthesis is no longer needed. Induction of cell activation, mitogenesis, or terminal differentiation events often results in the induction of nucleases that destabilize specific subsets of mRNAs. Selective stabilization of mRNAs probably also occurs, but specific examples are less well documented.

The amount of a given protein accumulating in a cell depends on the amount of the mRNA present, the rate at which it is translated into the protein, and the stability of the protein. Translational efficiency depends on a number of variables, including polyadenylation and presence of the 5 CAP. The amounts and state of activation of protein factors needed for translation are also crucial. The secondary structure of the mRNA, particularly in the 5 UTR, greatly influences the intrinsic translatability of an mRNA molecule by constraining the access of translation factors and ribosomes to the translation initiation signal in the mRNA. Secondary structure along the coding sequence of the mRNA may also have some impact on the rate of elongation of the peptide.

Changes in capping, polyadenylation, and translation factor efficiency affect the overall rate of protein synthesis within each cell. These effects tend to be global, rather than specific to a particular gene product. However, these effects influence the relative amounts of different proteins made. mRNAs whose structures inherently lend themselves to more efficient translation tend to compete better for rate-limiting components of the translational apparatus, whereas those mRNAs that are inherently less translatable tend to be translated less efficiently in the face of limited access to other translational components. For example, the translation factor eIF-4 tends to be produced in higher amounts when cells encounter transforming or mitogenic events. This causes an increase in overall rates of protein synthesis, but also leads to a selective increase in the synthesis of some proteins that were underproduced before mitogenesis.

Translational regulation of individual mRNA species is critical for some events important to blood cell homeostasis. For example, as discussed in Chapter 26 , the amount of iron entering a cell is an exquisite regulator of the rate of ferritin mRNA translation. An mRNA sequence called the iron response element is recognized by a specific mRNA-binding protein, but only when the protein lacks iron. mRNA bound to the protein is translationally inactive. As iron accumulates in the cell, the protein becomes iron bound and loses its affinity for the mRNA, resulting in production of apoferritin molecules available to bind the iron.

Tubulin synthesis involves coordinated regulation of translation and mRNA stability. Tubulin regulates the stability of its own mRNA by a feedback loop. As tubulin concentrations rise in the cell, it interacts with its own mRNA through the intermediary of an mRNA-binding protein. This results in the formation of an mRNAprotein complex and nucleolytic cleavage of the mRNA. The mRNA is destroyed, and further tubulin production is halted.

These examples of post-transcriptional regulation emphasize that cells tend to use every step in the complex pathway of gene expression as points at which exquisite control over the amounts of a particular protein can be regulated. In other chapters, additional levels of regulation are described (e.g., regulation of the stability, activity, localization, and access to other cellular components of the proteins that are present in a cell).

Additional Structural Features of Genomic DNA

Most DNA does not code for RNA or protein molecules. The vast majority of nucleotides present in the human genome reside outside structural genes. Structural genes are separated from one another by as few as 15 kb, or as many as several thousand kilobases of DNA. Almost nothing is known about the reason for the erratic clustering and spacing of genes along chromosomes. It is clear that *intergenic* DNA contains a variegated landscape of structural features that provide useful tools to localize genes, identify individual human beings as unique from every other human being (DNA fingerprinting), and diagnose human diseases by linkage. A more detailed discussion of these techniques is included in Chapter 160 . Only a brief introduction is provided here.

The rate of mutation in DNA under normal circumstances is approximately $1/10^6$. In other words, 1 of 1 million bases of DNA will be mutated during each round of DNA replication. A set of enzymes called DNA proofreading enzymes connect many of these mutations. When these enzymes are altered by mutation, the rate of mutation (and, therefore, the odds of neoplastic transformation) increase considerably. If these mutations occur in bases critical to the structure or function of a protein or gene, altered function, disease, or a lethal condition often results. Most pathologic mutations tend not to be preserved throughout many generations because of their unfavorable phenotypes. Exceptions, such as the hemoglobinopathies, occur when the heterozygous state for these mutations confers selective advantage in the face of unusual environmental conditions, such as malaria epidemics. These adaptive mutations drive the dynamic change in the genome with time (evolution).

Most of the mutations that accumulate in the DNA of *Homo sapiens* occur in either intergenic DNA or the silent bases of DNA, such as the degenerate third bases of codons. They do not pathologically alter the function of the gene or its products. These clinically harmless mutations are called DNA polymorphisms. DNA polymorphisms can be regarded in exactly the same way as other types of polymorphisms that have been widely recognized for years (e.g., eye and hair color, blood groups). They are variations in the population that occur without apparent clinical impact. Each of us differs from other humans in the precise number and type of DNA polymorphisms that we possess.

Like other types of polymorphisms, DNA polymorphisms breed true. In other words, if an individual's DNA contains a G 1,200 bases upstream from the -globin gene, instead of the C most commonly found in the population, that G will be transmitted to that individual's offspring. Note that if one had a means for distinguishing the G at that position from a C, one would have a linked marker for that individual's -globin gene.

Occasionally, a DNA polymorphism falls within a restriction endonuclease site. (Restriction enzymes cut DNA molecules into smaller pieces, but only at limited sites, defined by short base sequences recognized by each enzyme.) The change could abolish the site or create a site where one did not exist before. These polymorphisms change the array of fragments generated when the genome is digested by that restriction endonuclease. This permits detection of the polymorphism by use of the appropriate

restriction enzyme. This specific class of polymorphisms is thus called restriction fragment length polymorphisms (RFLPs).

Restriction fragment length polymorphisms are useful because the length of a restriction endonuclease fragment on which a gene of interest resides provides a linked

marker for that gene. The exploitation of this fact for diagnosis of genetic diseases and detection of specific genes is discussed in Chapter 160 ; Figure 1-6 shows a simple example.

Restriction fragment length polymorphisms have proved to be extraordinarily useful for the diagnosis of genetic diseases, especially when the precise mutation is not known. Recall that DNA polymorphisms breed true in the population. For example, as discussed in Chapter 110 , a mutation that causes hemophilia will, when it occurs on the X chromosome, be transmitted to subsequent generations attached to the pattern (often called a framework or haplotype) of RFLPs that was present on that same X chromosome. If the pattern of RFLPs in the parents is known, the presence of the abnormal chromosome can be detected in the offspring.

An important feature of the DNA landscape is the high degree of repeated DNA sequence. A DNA sequence is said to be repeated if it or a sequence very similar (homologous) to it occurs more than once in a genome. Some multicopy genes, such as the histone genes and the ribosomal RNA genes, are repeated DNA sequences. Most repeated DNA occurs outside genes, or within introns. Indeed, 3045% of the human genome appears to consist of repeated DNA sequences.

The function of repeated sequences remains unknown, but their presence has inspired useful strategies for detecting and characterizing individual genomes. For example, a pattern of short repeated DNA sequences, characterized by the presence of flanking sites recognized by the restriction endonuclease Alu-1 (called Alu-repeats), occurs approximately 300,000 times in a human genome. These sequences are not present in the mouse genome. If one wishes to infect mouse cells with human DNA and then identify the human DNA sequences in the infected mouse cells, one simply probes for the presence of Alu-repeats. The Alu-repeat thus serves as a signature of human DNA.

Classes of highly repeated DNA sequences (tandem repeats) have proved to be useful for distinguishing genomes of each human individual. These short DNA sequences, usually less than a few hundred bases long, tend to occur in clusters, with the number of repeats varying between individuals (Fig. 1-6). Alleles of a given gene can therefore be associated with a variable number of tandem repeats (VNTR) in different individuals or populations. For example, there is a VNTR near the insulin gene. In some individuals or populations, it is present in only a few tandem copies, whereas in others it is present in many more. When the population as a whole is examined, there is a wide degree of variability from individual to individual as to the number of these repeats residing near the insulin gene. It can readily be imagined that, if probes were available to detect a dozen or so distinct VNTR regions, each human individual would differ from virtually all others with respect to the aggregate pattern of these VNTRs. Indeed, it can be shown mathematically that the probability of any two human beings sharing exactly the same pattern of VNTRs is exceedingly small if approximately 1012 different VNTR elements are mapped for each person. A technique called DNA fingerprinting that is based on VNTR analysis has become widely publicized because of its forensic applications.

Variable-number tandem repeats can be regarded as normal sequence variations in DNA that are similar to, but far more useful than, singlebase-change RFLP polymorphisms. Note that the odds of a single base change altering a convenient

Figure 1-6 Two useful forms of sequence variation among the genomes of normal individuals. **(A)** Presence of a DNA sequence polymorphism that falls within a restriction endonuclease site, thus altering the pattern of restriction endonuclease digests obtained from this region of DNA on Southern blot analysis. (Readers not familiar with Southern blot analysis should return to examine this figure after reading later sections of this chapter.) **(B)** A variable-number tandem repeat (VNTR) region (defined and discussed in the text). Note that individuals can vary from one to another in many ways according to how many repeated units of the VNTR are located on their genomes, whereas restriction fragment length polymorphism differences are in effect all-or-none differences, allowing for only two variables (restriction site presence or absence).

restriction endonuclease site are relatively small, so that RFLPs occur relatively infrequently in a useful region of the genome. Moreover, there is only one state or variable that can be examinedthat is, the presence or absence of the restriction site. By contrast, many VNTRs are scattered throughout the human genome. Most of these can be distinguished from one another quite readily by standard blotting and hybridization technology (see Chap. 160). Most important, the amount of variability from individual to individual at each site of a VNTR is considerably greater than for RFLPs. Rather than the mere presence or absence of a site, there is a whole array of banding patterns possible, depending on how many individual repeats are present at that site (Fig. 1-6). This reasoning can readily be extended to appreciate that those VNTRs occurring near genes of hematologic interest can provide highly useful markers for localizing that gene, or for distinguishing the normal allele from an allele carrying a pathologic mutation.

There are many other classes of repeated sequences in human DNA. For example, human DNA has been invaded many times in its history by retroviruses. Retroviruses tend to integrate into human DNA and then jump out of the genome when they are reactivated, to complete their life cycle. The proviral genomes often carry with them nearby bits of the genomic DNA in which they sat. If the retrovirus infects DNA of another individual at another site, it will insert this genomic bit. Through many cycles of infection, the virus will act as a transposon, scattering its attached sequence throughout the genome. These types of sequences are called long interspersed elements. They represent footprints of ancient viral infections.

BASIC TENETS OF RECOMBINANT DNA TECHNOLOGY

The informational content of DNA molecules resides in the nucleotide sequence rather than in the sugarphosphate backbone. Unfortunately, traditional methods of biochemical fractionation do not provide straightforward means for distinguishing nucleic acid molecules from one another on the basis of their nucleotide sequences. Even if such methods were available, the quantity of bulk genomic DNA necessary to isolate a gene of typical size (a few thousand or tens of thousands of nucleotides long) from a complex genome such as the human (3 billion bp long) renders these methods impractical. In addition, genes do not exist in cells as discrete DNA molecules; rather, genes are linked together in tandem with very long stretches of intergenic DNA to form chromosomes. For example, in the human genome, each chromosome is approximately 100 million bp long. These facts render DNA an unworkable substance for direct physical purification of genes.

Recombinant DNA technology circumvents the biochemical problems inherent in the properties of DNA by combining enzymologic, microbiologic, and genetic approaches.

Restriction Endonucleases

Restriction endonucleases recognize short DNA base sequences and cleave DNA within or near these recognition sequences (Table 12). For example, *Eco*RI, a restriction endonuclease isolated from *Escherichia coli*, cuts DNA at the sequence 5-GAATTC-3, but nowhere else. Thus, each DNA sample will be reduced reproducibly to an array of smaller-sized fragments whose size ranges depend on the distribution with which 5-GAATTC-3 is encountered in that particular genome. However, the DNA will not be degraded in any other way by the enzyme. Restriction endonucleases differ from other nucleases by the specificity and limited manner with which they degrade DNA.

Restriction enzymes are usually named after the bacteria from which they were isolated. Thus, the first restriction endonuclease activity purified from *Serratia marcescens* is called *Sma*I, the second from *Hemophilus parainfluenzae* is called *Hpa*II, and so forth. Each of the nearly 500 restriction endonucleases that have been described recognizes a unique oligonucleotide sequence and cleaves the DNA only at those points. Table 1-2 shows the names and recognition sites of some typical restriction endonucleases.

In some cases, two or more different restriction enzymes recognize exactly the same recognition sequence. Such restriction enzymes are called isoschizomers. A useful type of isoschizomer is a pair of restriction enzymes that recognize the same sequence

TABLE 1-2 -- Some Common Restriction Endonuclease Enzymes and Their Recognition Sequences

Name of Enzyme	Microorganism from Which Derived	Recognition and Cleavage Site

3---CCCGGG---3	3----CCC--5	3GGG--------5

but cut or fail to cut according to modifications of the DNA bases, notably methylation. For example, both *Hpa*II and *Msp*I recognize the sequence 5-GCCG-3. *Msp*I cuts regardless of whether the C residues are methylated, but *Hpa*II will cut only if the C residues are not methylated. These paired enzymes are useful for identifying positions in mammalian genomes that are methylated.

Even though their physiologic function remains unknown, restriction enzymes have proved to be extraordinarily useful in the laboratory. They reduce the sizes of DNA fragments in a controlled and reproducible manner from several hundred million base pairs long to fragment arrays ranging from a few dozen to a few tens of thousands of bases long. These ranges are far more manageable experimentally. Moreover, by digesting a DNA sample with combinations of restriction enzymes, maps or fingerprints of the restriction endonuclease sites in a genome can be constructed. Restriction endonuclease digestion is as useful an approach for

characterizing the fine structure of genomes as partial proteolytic digestion (peptide fingerprinting) has been for protein chemists.

Many restriction endonucleases cut the DNA so as to leave short, single-stranded overhanging regions or sticky ends at the 5 or 3 end of the cutting site, whereas other enzymes leave blunt or flush double-stranded ends. Because many restriction endonuclease sites are palindromes (reading exactly the same on each strand, provided one reads in the same direction (e.g., 5 3) on each strand, these overhanging ends are particularly useful. For example, if DNA from two different sources (such as a bacteriophage preparation and human genomic preparation) is digested with *Eco*RI, the sticky ends will be complementary by Watson-Crick base pairing and can thus be annealed at the single-stranded overhangs (Table 1-2). This is the most popular method for generating recombinant DNA molecules.

Enzymes Useful for Modifying and Synthesizing DNA

Several other nucleic acid-modifying enzymes have been critical to the development of recombinant DNA technology. Notable among these are reverse transcriptase (RNA-dependent DNA polymerase) and DNA ligase. Reverse transcriptase is the enzyme packaged inside retroviruses that have an RNA genome. For retroviruses to reproduce themselves within their cellular hosts, their RNA genomes must be transcribed into DNA molecules (RNA DNA) that can then be replicated (DNA DNA) and expressed by host cell machinery (DNA RNA).

Reverse transcriptase has a very useful property. If provided with an appropriate primer DNA sequence complementary to a small region of an mRNA molecule, it can read the mRNA strand in a 3 5 direction and transcribe a single-stranded DNA copy (copy DNA, complementary DNA [cDNA]) of the RNA molecule. Using an oligonucleotide consisting of 1218 dT residues (oligo dT) (recall that nearly all mRNAs in eukaryotes have a 3 poly[A] tail, complementary to the oligo dT), mRNA isolated from a cell or tissue of interest can be incubated with reverse transcriptase, generating a population of single-stranded DNA molecules representing the entire array of mRNAs expressed in that cell or tissue. For example, using additional enzymes that have been characterized and purified, a DNA-dependent DNA polymerase can synthesize a complementary second strand of DNA from the single-stranded cDNA template. This creates double-stranded DNA molecules containing the sequence information originally expressed in the form of the mRNAs in the specimen. These DNA molecules can then be manipulated in the same ways that native genomic DNA molecules can, by restriction endonuclease digestion, radioactive labeling, or insertion into microbial host vectors for cloning.

DNA ligase is an enzyme that can join the ends of two DNA molecules together to form a single DNA molecule. For example, double-stranded cDNA molecules can be joined with bacteriophage DNA molecules by incubating DNA from both sources together in the presence of DNA ligase. This ability to generate artificially recombined, or recombinant, DNA molecules has given rise to the term *recombinant DNA technology*.

Many other important enzymes have also been useful for the development of recombinant DNA technology. These include a variety of polymerases, kinases, endonucleases, and exonucleases that are used to introduce radioactive residues into DNA molecules, to phosphorylate or dephosphorylate their termini, to synthesize new strands, to elongate the ends of DNA molecules by adding single-stranded overhanging sequences, to truncate or trim single-stranded overhangs in order to generate blunt-ended molecules, and so forth. A vast array of elegant methods have been developed to exploit these enzymes to synthesize, modify, and combine DNA molecules with exquisite precision, thus re-engineering DNA.

Microbial Hosts and Infectious DNA Molecules

The development of methods to fragment DNA in a controlled fashion, polymerize it, modify it, or ligate two DNA molecules from dissimilar sources represents an impressive advance. However, these tools would have been of limited value except for the discovery of certain small DNA molecules that possess remarkable biologic properties. Microbial geneticists found that many bacteria harbored DNA molecules that were not part of the single major bacterial chromosome. These novel DNA molecules are small (a few thousand to approximately 100 thousand bases long), have circular structures, can replicate independently in host cells, and, most remarkably, are infectious in the form of naked DNA. These DNA molecules can be thought of as elemental commensal organisms, residing in the cell and capable of infecting other host bacteria. They have come to be called extrachromosomal elements or episomes.

The most relevant episome types are plasmids and bacteriophages. Plasmids (Fig. 1-7) useful in recombinant DNA technology usually carry one or more antibiotic resistance genes, an origin of DNA replication, and a limited but useful array of restriction endonuclease sites. Many useful plasmid vectors have been engineered for customized applications. Such vectors are 3,00010,000 bases long, carry one or two genes for antibiotic resistance, and include a short DNA sequence (polylinker) containing several tightly clustered restriction endonuclease sites. The polylinker sequence is in a noncritical region of the plasmid genome, so a restriction site in the linker can be cut without damaging the plasmid's genes. Cells infected with these plasmids can be detected and purified by their ability to grow in media containing the relevant antibiotic.

The most useful plasmids for recombinant DNA work are those in which the plasmid or its polylinker include several restriction endonuclease sites that occur only once in the plasmid genome. A single cut in the circle causes opening or linearization, while leaving all the biologically critical sequences intact. A DNA molecule can then be inserted into the opening and the loop resealed with DNA ligase, thereby generating a recombinant DNA molecule that retains all the useful biologic activities of the original plasmid.

Bacteriophages are viruses infective in certain species of bacteria. Their genomes are somewhat larger than plasmids (5,000100,000 bp), and the DNA is covered during the extracellular part of the viral life span by a protein coat. However, bacterial genomes relevant to this discussion can also exist in the cell as

Figure 1-7 Plasmidsstructure and properties. The upper portions of the diagram outline the basic structure of bacterial plasmids in terms of two hypothetical examples (Plasmid 1 and Plasmid 2). The three major functional attributes of plasmids are shown at the top of the figure: origin of DNA (O), one or more phenotypic marker genes such as tetracycline resistance (Tet^R [shown in red]) or ampicillin resistance (Amp^R), and restriction endonuclease sites suitable in their location and number for a particular application, such as the *Eco*RI sites shown for Plasmids 1 and 2. The remainder of the figure outlines a rudimentary recombinant DNA experiment, which results in formation of a novel plasmid carrying the gene for tetracycline resistance in addition to the ampicillin resistance gene. Note how digestion with *Eco*RI linearizes Plasmid 2 because it has only a single site, leaving the basic structure of the plasmid intact; in contrast, the two *Eco*RI sites in Plasmid 1 result in fragmentation into two pieces, one of which carries the Tet^R gene. Ligation of the two digestion mixtures results in several possible ligation products, including those formed by self-ligation of the individual plasmids or plasmid fragments by means of their own sticky ends as well as all possible combinations formed by one fragment annealing to another. However, out of this complex mixture the desired recombinant can be clearly selected, because only it will possess both ampicillin and tetracycline resistance. Thus, microbial genetics can be used to identify and purify a DNA fragment that was created chemically or enzymatically. This illustrates the fundamental strategy of recombinant DNA technology, whereby genetic selection of biologically active macromolecules can be used to identify, isolate, purify, and amplify particular products of enzymatic reactions.

episomes. The most useful phages for molecular genetics have been bacteriophage-, which can be used as a gene cloning vehicle, and the single-stranded bacteriophage M13, which is useful for DNA sequencing. Many bacteriophage genomes have been engineered to provide useful vectors.

The essential aspect of episomes important for this discussion is that they are biologically active even when they exist as naked DNA molecules. By combining the ability to attach episomal DNA to DNA from mammalian sources (using restriction enzymes and ligase) with the capacity of the episomes for infection and phenotypic alteration of host cells, these molecules can be used to introduce foreign DNA into host bacteria. Then all the useful properties of the vast array of microbial strains available become accessible for the study of genes from other species. An individual strain of bacteria can be readily isolated as a single-cell clone, inexpensively grown in large quantities, and used as factories for the production of the foreign DNA sequence contained within it, as well as any protein product encoded by the foreign DNA. Moreover, the recombinant episomal DNA can be readily isolated free of the host bacterial chromosome; this provides a simple way to retrieve large quantities of the mammalian DNA that rides as a passenger in the episomal DNA.

Advances in Nucleic Acid Chemistry

The development of automated anhydrous methods for the synthesis of DNA molecules in vitro has provided a means of synthesizing short DNA molecules without benefit of a template or DNA polymerase. For example, the polylinker sequences used to introduce restriction endonuclease sites into plasmids can be readily synthesized by automated instrumentation and ligated into a plasmid to alter its restriction endonuclease map. Synthetic oligonucleotides can also be radiolabeled and used as customized molecular hybridization probes, or used as primers for synthesis of DNA strands complementary to any desired region of a DNA template.

The tendency of DNA and RNA molecules to form double-stranded hybrids in physiologic solution has been exploited by nucleic acid chemists for the development of molecular hybridization assays. If DNA or RNA molecules are heated or exposed to certain denaturants, such as formamide, the hydrogen bonds

holding two strands together are disrupted, and the molecule is denatured into the single-stranded form. Temperature, salt, and denaturing conditions that favor reannealing into the double-stranded form can then be restored. This reannealing process is called *molecular hybridization:* reannealing rates under a given set of conditions of temperature, salinity, and denaturant are a function of the time of incubation and the initial concentration of the annealing strands.

Denatured DNA or RNA strands reanneal only with strands having a complementary sequence by the rules of Watson-Crick base pairing. This specificity forms the basis for the use of molecular hybridization as a means for detecting or quantifying (or both) specific DNA or RNA moieties in a complex mixture. A specimen of denatured DNA or RNA (e.g., mRNA from human bone marrow) can be incubated with a radioactively labeled, defined DNA or RNA sequence (e.g., a cloned human myeloperoxidase gene). The labeled denatured DNA probe will hybridize only to those mRNA molecules that are complementary by Watson-Crick base pairing (i.e., myeloperoxidase mRNA molecules). Any one of several available techniques can then be used to detect the fraction of radioactively labeled DNA probe molecules that have been bound into a double-stranded form. (For example, the enzyme S_1 nuclease degrades single-stranded DNA molecules, leaving only the double-stranded hybridized molecules intact.) The result is a highly sensitive and specific assay for identifying (in our example) myeloperoxidase mRNA in the complex mix of mRNA species present in the bone marrow mRNA. By extension of this reasoning, molecular hybridization strategies can be used to detect, quantitate, and map specific DNA or RNA sequences, provided that a complementary defined DNA probe is available.

Many hybridization assays have been devised. The range of applications, theoretic rationale, and utility of many of these assays can be appreciated by their analogy to the use of antigenantibody reactions in immunochemistry. The DNA probe is used by the molecular geneticist in much the same way as a defined antibody probe is used by the immunologist. The principles underlying the various molecular hybridization techniques are similar to those of immunochemical assays.

Polymerase Chain Reaction

The development of the polymerase chain reaction (PCR) was a major breakthrough that has revolutionized the utility of a DNA-based strategy for diagnosis and treatment. It permits the laboratorian to detect, synthesize, and isolate specific genes and to distinguish among alleles of a gene differing by as little as one base. It does not require sophisticated equipment or unusual technical skills. A clinical specimen consisting of only minute amounts of tissue will suffice; in most circumstances, no special preparation of the tissue is necessary. PCR thus makes recombinant DNA techniques accessible to clinical laboratories. This single advance has produced a quantum increase in the use of direct gene analysis for diagnosis of human diseases.

Polymerase chain reaction is based on the prerequisites for copying an existing DNA strand by DNA polymerase: an existing denatured strand of DNA to be used as the template, and a primer. Primers are short oligonucleotides, 12100 bases in length, having a base sequence complementary to the desired region of the existing DNA strand. The enzyme requires the primer in order to know where to begin copying. If the base sequence of the DNA of the gene under study is known, two synthetic oligonucleotides complementary to sequences flanking the region of interest can be prepared (see Chap. 160). If these are the only oligonucleotides present in the reaction mixture, then the DNA polymerase can only copy daughter strands of DNA downstream from those oligonucleotides. Recall that DNA is double stranded, that the strands are held together by the rules of Watson-Crick base pairing, and that they are aligned in antiparallel fashion. This implies that the effect of incorporation of both oligonucleotides into the reaction mix will be to synthesize two daughter strands of DNA, one originating upstream of the gene and the other originating downstream. The net effect is synthesis of only the DNA between the two primers, thus doubling only the DNA containing the region of interest. If the DNA is now heat denatured, allowing hybridization of the daughter strands to the primers, and the polymerization is repeated, then the region of DNA through the gene of interest is doubled again. Thus, two cycles of denaturation, annealing, and elongation result in a selective quadrupling of the gene of interest.

The cycle can be repeated 3050 times, resulting in a selective and geometric amplification of the sequence of interest to the order of 2^{30} 2^{50} times. The result is a millionfold or higher selective amplification of the gene of interest, yielding microgram quantities of that DNA sequence.

The PCR reaction achieved practical utility when DNA polymerases from thermophilic bacteria were discovered, when synthetic oligonucleotides of any desired sequence could be produced efficiently, reproducibly, and cheaply by automated instrumentation, and when DNA thermocycling machines were developed. Thermophilic bacteria live in hot springs and other exceedingly warm environments. Thermophilic DNA polymerases can tolerate 100°C incubations without substantial loss of activity. Their advantage is that they retain activity in a reaction mix that is repeatedly heated to the high temperature needed to denature the DNA strands into the single-stranded form. Microprocessor-driven DNA thermocycler machines can be programmed to increase temperatures to 95100°C (denaturation), to cool the mix to 50°C rapidly (a temperature that favors oligonucleotide annealing), and then to raise the temperature to 7075°C (the temperature for optimal activity of the thermophilic DNA polymerases). The rapidity of these changes (3060 seconds for each phase of the cycle) allows the laboratorian to include the test specimen, the thermophilic polymerase, the primers, and the chemical components (e.g., nucleotide subunits) of the reaction mix in a single tube, place it in the thermocycler, and conduct many cycles of denaturation, annealing, and polymerization in a completely automated fashion. The gene of interest can thus be amplified over one millionfold in a matter of a few hours. The DNA product is readily identified and isolated by routine agarose gel electrophoresis. The DNA can then be analyzed by restriction endonuclease, digestion, hybridization to specific probes, sequencing, further amplification by cloning, and so forth.

Producing and Isolating Recombinant DNA Molecules

Most recombinant DNA methods require defined, purified DNA molecules encompassing all or part of the gene of interest. One basic algorithm for isolating genes by molecular cloning is presented (Fig. 1-8). Genomic DNA is isolated from nuclei and digested with restriction endonucleases to generate overhanging sticky ends. (Alternatively, a restricted subset of DNA sequences that represents the genes expressed in a given cell can be created by first isolating messenger RNA, converting it into cDNA by incubation with reverse transcriptase, and then converting it to double-stranded cDNA using other enzymes.) The plasmid or bacteriophage DNA molecule to be used as a vector to carry the DNA into microbes is cut with the same restriction enzyme. The DNA molecules from the two sources thus have complementary sticky ends. They are annealed together by means of their sticky ends under conditions of a slight excess of the microbial DNA vector. This procedure ensures that most of the vector molecules ligate to only one molecule from the mammalian source. The recombinant plasmids are then sealed with DNA ligase. Each recombinant molecule is thus an

Figure 1-8 Isolation of a genomic gene copy by molecular cloning. Illustrated here is a prototypical experiment whereby the chromosomal or genomic copy of the -globin gene (shown in red) can be isolated by molecular cloning, using globin cDNA as a molecular hybridization probe. A suitable bacteriophage- cloning vector is digested with *Hind* III, which in the example cuts the phage only once, leaving two arms with sticky ends. Genomic DNA is similarly digested. A vast array of fragments (only a few of which are shown) results, their sizes depending on the location of the *Hind* III recognition sites. Ligation of the two digests to each other results in an array of bacteriophage DNA molecules, each containing a single fragment from the human genomic digest. The genomes are packaged into bacteriophage coats so that they become infectious viruses. These infect a culture of bacterial cells; each bacteriophage yields a plaque on a Petri plate as the result of subsequent rounds of reinfection and lysis of host cells on the plate. A replica of the plate is made by laying a filter over the plate, allowing it to absorb the colonies in situ, and hybridizing the filter to the radioactive globin cDNA probe. Only phage carrying the globin gene in the inserted genomic fragment will yield a positive autoradiography signal. This plaque is then isolated and used as starting material for isolation of the phage and the phage DNA. The globin gene can then readily be isolated by routine methods of DNA chemistry. The result is a highly purified representation of the gene and its surrounding sequences as it was configured in the original human genome.

infectious DNA species carrying a single DNA fragment from the mammalian source as a passenger.

The plasmids are then used to infect an excess of host bacteria; the excess cell number ensures that each bacterium, on the average, acquires only a single recombinant DNA molecule. The host bacteria chosen lack some phenotypic property conferred by the infecting molecule, such as antibiotic resistance. The infected cells are then plated onto antibiotic-containing Petri plates at a density allowing detection of individual colonies or bacteriophage plaques. Each colony or phage plaque represents the progeny of a single cell or bacteriophage and is thus a clone of a single cell or phage carrying a single DNA fragment from the mammalian source. Therefore, that DNA fragment, or gene, has been physically and genetically isolated in the colony or plaque, separated from all other mammalian DNA

fragments by the cloning process.

What remains is the need to identify the DNA fragment representing the specific gene targeted for purification. Those cells or phages carrying the DNA sequence of interest must be identified within the array of plaques or colonies (called a recombinant DNA library). Numerous stratagems have been devised for screening these libraries for the presence of the occasional clone bearing the gene of interest. The approaches that are suitable depend on what information is available about the particular gene or its protein product. In some cases, it is possible to use molecular hybridization to a DNA probe synthesized to contain a sequence encoding a known partial amino acid sequence (determined by sequencing a peptide or protein fragment of interest). In other cases, the microbial vector has the capacity to express part or all of the protein encoded by the DNA clone. The library can then be screened with antibodies raised against the protein of interest by conventional means.

Once the colony or bacteriophage plaque containing the recombinant molecule of interest has been identified, that colony or plaque can be purified free of the remainder of the library and amplified by growth in bacterial culture. In this manner, substantial quantities of recombinant DNA molecules can be produced from the cloned host cell. With respect to other DNA molecules derived from the original tissue source, the cloned gene will be pure. The purified gene can then be used as a hybridization probe, as the substrate for obtaining its DNA sequence, or as a template for controlled expression and production of its mRNA and protein products.

DNA and RNA Blotting

There are many ways that a cloned DNA sequence can be exploited to characterize the behavior of normal or pathologic genes relevant to hematology. Blotting methods deserve special mention because of their widespread use in clinical and experimental hematology. A cloned DNA fragment can be easily purified and tagged with a radioactive or nonradioactive label. The fragment provides a pure and highly specific molecular hybridization probe for the detection of complementary DNA or RNA

Figure 1-9 Southern gene blotting. Detection of a genomic gene (red) that resides on a 14-kb Bam HI fragment. To identify the presence of a gene in the genome and the size of the restriction fragment on which it resides, genomic DNA is digested with a restriction enzyme, and the fragments are separated by agarose gel electrophoresis. Human genomes contain from several hundred thousand to 1 million sites for any particular restriction enzyme, which results in a vast array of fragments and creates a blur or streak on the gel; one fragment cannot be distinguished from another readily. If the DNA in the gel is transferred to nitrocellulose by capillary blotting, however, it can be further analyzed by molecular hybridization to a radioactive cDNA probe for the gene. Only the band containing the gene yields a positive autoradiography signal, as shown. If a disease state were to result in loss of the gene, alteration of its structure, or mutation (altering recognition sites for one or more restriction enzymes), the banding pattern would be changed.

molecules in any specimen of DNA or RNA. One set of assays that has proved particularly useful involves Southern gene blotting, named after Dr. E. Southern, who invented the method. Southern blotting allows detection of a specific gene, or region in or near a gene, in a DNA preparation (Fig. 1-9). The DNA is isolated and digested with one or more restriction endonucleases, and the resulting fragments are separated according to their molecular size by electrophoresis on agarose gels. Under conditions routinely used, the largest fragments migrate most slowly and the smallest fragments most rapidly. Unfortunately, the size of the fragment containing the gene of interest often is not known. Moreover, a human genomic DNA preparation digested with most restriction enzymes yields many hundreds or thousands of fragments, producing a blur or streak on the gel. A final impediment to detection of the individual gene in this massive array of fragments is the unsuitability of agarose and acrylamide for molecular hybridization conditions.

Gene blotting circumvents these problems. The agarose gel is placed on top of a pad or sponge saturated in a high-salt buffer. A sheet of nitrocellulose, nylon, or a similar permeable membrane is laid on top of the gel. Large numbers of dry towels are laid on top of the filter, and a weight is placed on top of the entire stack to ensure air- and watertight contact among all layers. By capillary action, fluid is drawn from the saturated sponge or pad through the porous gel and the nitrocellulose membrane and into the dry pad of towels. The DNA is also drawn out of the gel, but, if care is taken to denature the DNA to the single-stranded form before initiating the blotting, it will not pass through the semipermeable membrane. Single-stranded DNA and RNA molecules stick noncovalently but tightly to the membrane. In this fashion, the membrane becomes a replica or blot of the gel. These membranes are much more amenable to subsequent manipulation and can be used in molecular hybridization assays.

After the blotting procedure is complete, the membrane is incubated in a hybridization buffer containing the radioactively labeled probe. The probe hybridizes only to the gene of interest and renders radioactive only one or a few bands containing complementary sequences. After appropriate washing and drying, the bands can be seen by autoradiography.

Digestion of a DNA preparation with several different restriction enzymes allows a restriction endonuclease map of a gene in the human genome to be constructed. Southern blotting has thus become a standard way of characterizing the configuration of genes in the genome.

Northern blotting represents an analogous blotting procedure used to detect RNA. RNA cannot be digested with restriction enzymes (they cut only DNA); rather, the RNA molecules can be run intact (mRNAs are 0.512 kb in length) through the gel, blotted onto membranes, and probed with a DNA probe. In this fashion, the laboratorian can detect the presence, absence, molecular size, number of individual species, and so forth of a particular mRNA species. Western blotting is an analogous procedure used to detect proteins with antibody probes.

USE OF TRANSGENIC AND KNOCKOUT MICE TO DEFINE GENE FUNCTION

Recombinant DNA technology has resulted in the identification of many disease-related genes. To advance the understanding of the disease related to a previously unknown gene, the function of the protein encoded by that gene must be verified or identified, and the way changes in the gene's expression influence the disease phenotype must be characterized. Analysis of the role of these genes and their encoded proteins has been made possible by the development of recombinant DNA technology that allows the production of mice that are genetically altered at the cloned locus. Mice can be produced that express an exogenous gene and thereby provide an in vivo model of its function. Linearized DNA is injected into a fertilized mouse oocyte pronucleus and reimplanted in a pseudopregnant mouse. The resultant *transgenic mice* can then be analyzed for the phenotype induced by the injected transgene. Placing the gene under the control of

a strong promoter that stimulates expression of the exogenous gene in all tissues allows the assessment of the effect of widespread overexpression of the gene. Alternatively, placing the gene under the control of a promoter that can function only in certain tissues (a tissue-specific promoter) elucidates the function of that gene in a particular tissue or cell type. A third approach is to study control elements of the gene by testing their capacity to drive expression of a marker gene that can be detected by chemical, immunologic, or functional means. For example, the promoter region of a gene of interest can be joined to the cDNA encoding green jellyfish protein, and activity of the gene assessed in various tissues of the resultant transgenic mouse by fluorescence microscopy. Use of such a reporter gene demonstrates the normal distribution and timing of expression of the gene from which the promoter elements are derived.

Transgenic mice contain exogenous genes that insert randomly into the genome of the recipient. Expression can thus depend as much on the location of the insertion as it does on the properties of the injected DNA. In contrast, any defined genetic locus can be specifically altered by targeted recombination between the locus and a plasmid carrying an altered version of that gene. If a plasmid contains that altered gene with enough flanking DNA identical to that of the normal gene locus, homologous recombination can occur, and the altered gene in the plasmid will replace the gene in the recipient cell. Using a mutation that inactivates the gene allows the production of a null mutation, in which the function of that gene is completely lost. To induce such a mutation, the plasmid is introduced into an embryonic stem cell, and the rare cells that undergo homologous recombination selected. The knockout embryonic stem cell is then introduced into the blastocyst of a developing embryo. The resultant animals are chimeric; only a fraction of the cells in the animal contain the targeted gene. If the new gene is introduced into some of the germline cells of the chimeric mouse, then some of the offspring of that mouse will carry the mutation as a gene in all of their cells. These heterozygous mice can be further bred to produce mice homozygous for the null allele. Such knockout mice reveal the function of the targeted gene by the phenotype induced by its absence. Genetically altered mice have been essential for discerning the biologic and pathologic roles of large numbers of genes implicated in the pathogenesis of human disease.

DNA-BASED THERAPIES

Gene Therapy

The application of gene therapy to genetic hematologic disorders is an appealing idea. In most cases, this would involve isolating hematopoietic stem cells from patients with diseases with defined genetic lesions, inserting normal genes into those cells, and reintroducing the genetically engineered stem cells back into the patient. Candidate diseases for such therapy include sickle cell disease, thalassemia, hemophilia, and adenosine deaminase (ADA)-deficient severe combined immunodeficiency. The technology for separating hematopoietic stem cells and for performing gene transfer into those cells has advanced rapidly, and clinical trials have begun to test the applicability of these techniques. However, despite the fact that gene therapy has progressed to the enrollment of patients in clinical protocols, major technical problems still need to be solved, and there are no proven therapeutic successes from gene therapy. However, progress in this field continues rapidly. The scientific basis for gene therapy and the clinical issues surrounding this approach are discussed in Chapter 95 .

Antisense Therapy

The recognition that abnormal expression of oncogenes plays a role in malignancy has stimulated attempts to suppress oncogene expression to reverse the neoplastic phenotype. One way of blocking mRNA expression is with antisense oligonucleotides. These are single-stranded DNA sequences, 1720 bases long, having a sequence complementary to the transcription or translation start of the mRNA. These relatively small molecules freely enter the cell and complex to the mRNA by their complementary DNA sequence. This often results in a decrease in gene expression. The binding of the oligonucleotide may directly block translation, and clearly enhances the rate of mRNA degradation. This technique has been shown to be promising in suppressing expression of *bcr-abl* and to suppress cell growth in chronic myelogenous leukemia. The technique is being tried as a therapeutic modality for the purging of tumor cells before autologous transplantation in patients with chronic myelogenous leukemia.

SUMMARY

The elegance of recombinant DNA technology resides in the capacity it confers on investigators to examine each gene as a discrete physical entity that can be purified, reduced to its basic building blocks for decoding of its primary structure, analyzed for its patterns of expression, and perturbed by alterations in sequence or molecular environment so that the effects of changes in each region of the gene can be assessed. Purified genes can be deliberately modified or mutated to create novel genes not available in nature. These provide the potential to generate useful new biologic entities, such as modified live virus or purified peptide vaccines, modified proteins customized for specific therapeutic purposes, and altered combinations of regulatory and structural genes that allow for the assumption of new functions by specific gene systems.

Purified genes facilitate the study of gene regulation in many ways. First, a cloned gene provides characterized DNA probes for molecular hybridization assays. Second, cloned genes provide the homogenous DNA moieties needed to determine the exact nucleotide sequence. Sequencing techniques have become so reliable and efficient that it is often easier to clone the gene encoding a protein of interest and determine its DNA sequence than it is to purify the protein and determine its amino acid sequence. The DNA sequence predicts exactly the amino acid sequence of its protein product. By comparing normal sequences with the sequences of alleles cloned from patients known to be abnormal, such as the globin genes in the thalassemia or sickle cell syndromes, the normal and pathologic anatomy of genes critical to major hematologic diseases can be established. In this manner, it has been possible to identify many mutations responsible for various forms of thalassemia, hemophilia, thrombasthenia, red cell enzymopathies, porphyrias, and so forth. Similarly, single base changes have been shown to be the difference between normally functioning proto-oncogenes and their cancer-promoting oncogene derivatives.

Third, cloned genes can be manipulated for studies of gene expression. Many vectors allowing efficient transfer of genes into eukaryotic cells have been perfected. Gene transfer technologies allow the gene to be placed into the desired cellular environment and the expression of that gene or the behavior of its products to be analyzed. These surrogate or reverse genetics systems allow analysis of the normal physiology of expression of a particular gene, as well as the pathophysiology of abnormal gene expression resulting from mutations.

Fourth, cloned genes enhance study of their protein products. By expressing fragments of the gene in microorganisms or eukaryotic cells, customized regions of a protein can be produced for use as an immunogen, thereby allowing preparation of a variety of useful and powerful antibody probes. Alternatively, synthetic peptides deduced from the DNA sequence can be prepared as the immunogen. Controlled production of large

amounts of the protein also allows direct analysis of specific functions attributable to regions in that protein.

Finally, all of the aforementioned techniques can be extended by mutating the gene and examining the effects of those mutations on the expression of or the properties of the encoded mRNAs and proteins. By combining portions of one gene with another (chimeric genes), or abutting structural regions of one gene with regulatory sequences of another, the researcher can investigate in previously inconceivable ways the complexities of gene regulation. These activist approaches to modifying gene structure or expression create the opportunity to generate new RNA and protein products whose applications are limited only by the collective imagination of the investigators.

The most important impact of the genetic approach to the analysis of biologic phenomena is the most indirect. Diligent and repeated application of the methods outlined in this chapter to the study of many genes from diverse groups of organisms is beginning to reveal the basic strategies used by nature for the regulation of cell and tissue behavior. As our knowledge of these rules of regulation grows, our ability to understand, detect, and correct pathologic phenomena will increase substantially.

Chapter 2 - Protein Synthesis and Intracellular Sorting

David L. Wiest
Michael O. Carleton

INTRODUCTION

The previous chapter dealt with early events in gene expression, including transcription of messenger RNA (mRNA) molecules and their translation into polypeptides. This chapter considers what happens to polypeptides after synthesis, detailing their folding, their assembly into oligomeric complexes, and their delivery to the appropriate intracellular destination. The accuracy of the delivery process is essential, especially in eukaryotic cells, which are subdivided into many membrane-bound compartments termed organelles. Each organelle serves a particular purpose. For example, oxidative phosphorylation, the process responsible for generating the majority of cellular energy (adenosine triphosphate [ATP]), occurs on mitochondrial inner membranes. The capacity of any organelle to fulfill its role in cellular physiology depends in turn on that organelle possessing a characteristic set of protein components. An elaborate targeting process ensures that the requisite set of protein components is incorporated into each organelle. Understanding the machinations that underlie protein folding, assembly, and targeting is important to the study of hematology as it provides the necessary foundation for understanding how malfunctions in these processes cause blood disorders.

Background

Proteins are polymers created by the templated joining of amino acid monomers (see Table 2-1 for single-letter designations), each of which has unique properties. The overall character of a protein is influenced both by its amino acid content and by the order in which those amino acids were incorporated. Both are dictated by the mRNA template. The mRNA is read by tRNA molecules, which link particular amino acids to the corresponding triplet of nucleotides found in the mRNA. The whole process is orchestrated by a ribonucleoprotein complex called a ribosome that contains over 80 distinct proteins and four different RNA molecules. These proteins and RNAs are

TRANSLATIONAL REGULATION

Because of structural peculiarities, not all mRNA molecules are translated with equal efficiency. Moreover, the efficiency of translation can be modulated by cellular factors that bind mRNA at specific sites. A well-characterized example of this mode of regulation is the control of iron metabolism. When cytosolic iron levels are low, the regulatory protein aconitase binds to mRNA molecules encoding ferritin (cytosolic iron storage protein) and represses ferritin synthesis. Also, under low iron conditions, aconitase binds to the mRNA of transferrin receptor (Tf-R; surface receptor responsible for iron uptake) and stabilizes it, thus increasing Tf-R synthesis. When cytosolic iron levels are increased, iron complexes with aconitase and prevents its binding to both of the mRNA species, which promotes cytosolic iron storage by allowing ferritin synthesis and decreasing Tf-R mRNA levels. (See Chapter 26.)

incorporated into two macromolecular complexes, one of 60S (S refers to the sedimentation rate in an ultracentrifuge and is a measure of size) and the other of 40S. Translation begins when the 40S ribosomal subunit binds to the 5 cap (methyl guanine) of the mRNA molecule and then scans toward the 3 end until the translation start site is encountered (usually the first AUG). At that time the 60S subunit assembles with the 40S subunit to produce an 80S ribosome. Transcription RNA molecules ferry amino acids to the ribosome, upon which they are sewn together in sequence as the ribosome moves toward the 3 end of the mRNA template. Translation is terminated when a stop codon (UAA, UAG, or UGA) is encountered, which releases the nascent polypeptide from the ribosome.

Although the synthesis of all cellular proteins begins on free ribosomes in the cytosol, the transport of nascent polypeptides to their eventual destination requires navigation through several sorting branch points (Fig. 2-1). These sorting events are governed by short linear sequences of particular amino acids (sorting motifs) and their cognate receptors. The first sorting decision encountered occurs after 30 amino acids of the nascent polypeptide have been extruded from the ribosome. If

the nascent polypeptide lacks a signal sequence, most often found near the protein's amino (N)-terminus (Table 2-1),

Figure 2-1 Flow diagram describing intracellular protein transport. Synthesis of all cellular proteins begins in the cytosol, from which they can be diverted into the indicated compartments. The sorting events responsible for directing the nascent protein to its intracellular location are governed by amino acid sequence motifs recognized by cognate receptors.

then translation of the polypeptide is completed in the cytosol. After synthesis is complete, the protein can either stay in the cytosol or be post-translationally incorporated into one of the indicated organelles (Fig. 2-1). Alternatively, if the protein does contain an N-terminal signal sequence, the polyribosome complex is docked on the membrane of the endoplasmic reticulum (ER) and the emerging polypeptide is extruded co-translationally (during synthesis) into the ER lumen. The ER is a tubular network of membranes from which all of the more distal membrane structures of the secretory apparatus (ER, Golgi complex, endosomes, lysosomes, and plasma membrane) are derived. Protein components synthesized in the ER are delivered to those compartments in transport vesicles.

PROTEIN FOLDING IN THE CYTOSOL

In general, proteins are not functional in the extended linear conformation in which they emerge from the ribosome. Rather, the polypeptide strand must be folded back on itself into a conformation that is dictated by the primary amino acid sequence. Although this process can occur spontaneously in a test tube at very low protein concentrations, it occurs very inefficiently and requires an extended time period. In the very densely packed cytosol of eukaryotic cells (protein concentrations of over 100 mg/mL) emerging polypeptides require assistance to fold, and that assistance comes in the form of a specialized set of proteins called molecular chaperones. The population of chaperones that assists folding in the cytosol is distinct from the population operating within the ER or mitochondria. Most molecular chaperones are members of the heat shock protein (Hsp) family, so called because their expression is induced by briefly heating cells to 42°C. Chaperones attach to nascent polypeptide strands and start the folding process even before translation is completed. Indeed, as the nascent polypeptide is being extruded from the ribosome, it is bound by chaperones that recognize short sequence motifs containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), these chaperones help the nascent polypeptide find its native conformation, one aspect of which is the tucking away of hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol. Some properly folded protein monomers are assembled with other proteins to form multisubunit complexes. This is also facilitated by chaperones. Proteins can contain mutations that prevent them from folding properly. Such proteins are marked for destruction by modification with a small (8,000 daltons) polypeptide appendage called ubiquitin. Ubiquitin serves as an identification marker for a cylindric multisubunit proteolysis machine called the proteasome. Ubiquitin-tagged molecules are fed into the lumen of the proteasome cylinder, where they are degraded. The end products, i.e., amino acid monomers, are then reused in the translation of new proteins.

SORTING FROM THE CYTOSOL INTO OTHER COMPARTMENTS

Some proteins synthesized on free polyribosomes remain in the cytosol. These include enzymes involved in glycolysis, signal transduction (soluble kinases and phosphatases, etc.), and components of the cytoskeleton. However, other proteins are post-translationally (after synthesis) translocated out of the cytosol and into organelles that are not part of the secretory apparatus. These organelles include the nucleus, mitochondria, and peroxisomes (Fig. 2-2).

Nuclear Proteins

The nucleus contains the cellular genome and is bounded by two concentric membranes that form the nuclear envelope (Fig. 2-2).

Figure 2-2 Intracellular protein trafficking. From the cytosol, proteins can be imported post-translationally into mitochondria, peroxisomes, or the nucleus. Alternatively, proteins can be imported co-translationally into the ER, from which selective packaging into transport vesicles can result in their delivery to any of the other membrane-bound compartments of the secretory apparatus.

The outer membrane of the nuclear envelope is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. The inner membrane contains binding sites for a two-dimensional protein lattice, termed the nuclear lamina, that serves both as a scaffold that provides shape to the nucleus and as a link between the DNA and the nuclear envelope. The nuclear envelope is perforated with nuclear pore complexes, the number of which is a general indicator of the overall level of transcriptional activity in the nucleus. Nuclear pore complexes (NPCs) are approximately 30 times larger than a ribosome and comprise more than 100 different proteins, which are arranged into an envelope-piercing channel with fibrils extending from the cytoplasmic face and a cagelike structure extending beneath the inner membrane of the nuclear envelope. NPCs are selective gates that allow passive bidirectional movement of molecules less massive than 60,000 daltons and active bidirectional passage of selected molecules as large as several million daltons (e.g., nuclei must export newly assembled ribosomal subunits). Candidate proteins for nuclear import, such as transcription factors, DNA repair enzymes, etc., most often bear a nuclear localization signal (NLS) consisting of one or more short clusters of positively charged amino acids (lysine and arginine; Table 2-1). A protein containing an NLS is bound by a heterodimeric receptor complex (/-importins) that attaches to the cytosolic fibrils of the NPC and then is translocated into the nucleus through the pore complex. Upon arrival in the intranuclear space, the /-importins release the NLS-containing proteins in response to guanosine triphosphate (GTP) hydrolysis. The importins are then shuttled back to the cytosol, where they can facilitate another round of transport. Many aspects of the regulation of nuclear import are currently unclear, but the key to its control is thought to be a GTP-binding protein, Ran. Unlike import into mitochondria or the ER, proteins to be imported into the nucleus are not unfolded prior to entry, nor is the NLS proteolytically cleaved from the imported protein. Presumably, NLS are not proteolytically removed following nuclear import because nuclear proteins must exit the nucleus and then re-enter it each time the nucleus is dismantled and reassembled during mitosis.

Mitochondrial Proteins

Although mitochondria do contain DNA and have the capability to make protein, most mitochondrial proteins are taken up after they are synthesized in the cytosol. Like nuclei, mitochondria have two membranes: an outer one that contacts the cytosol and an inner one in which the respiratory chain resides. The space enclosed by the inner mitochondrial membrane is called the matrix. Cytosolic proteins are targeted to mitochondria by a sorting motif referred to as a matrix targeting signal (MTS) or presequence that is generally between 20 and 60 residues in length and is rich in amino acids that are positively charged or

CONDITIONAL NUCLEAR LOCALIZATION

Modulation of nuclear import is an important means of regulating the activity of nuclear proteins that are relevant to the study of hematology. In particular, nuclear factor B (NF-B) is a transcription factor that is important in alterations in gene expression induced by signaling through the antigen receptors of B and T lymphocytes, the interleukin-1 receptor on macrophages, as well as the cytokine/growth factor receptors on other cell types. NF-B has a nuclear localization signal (NLS) but remains in the cytosol because its NLS is masked by association with the inhibitor of NF-B (IB). Upon exogenous stimulation through one of the receptors mentioned above, IB is phosphorylated, resulting in release of NF-B, exposure of its NLS, and import into the nucleus. Thus, the activity of NF-B is regulated by conditionally granting it access to the nucleus, and consequently the genes whose transcription it regulates.

hydroxylated (Table 2-1). After synthesis, MTS-containing proteins (also called preproteins) are kept in an unfolded state by interacting with cytoplasmic chaperones of the heat shock family and are thought to be guided to the mitochondria by a targeting factor called mitochondrial import stimulation factor (MSF). Mitochondrial import of preproteins occurs at contact sitessites where the outer and inner membranes appear to join. Both the outer and inner membranes contain complexes of proteins that act as translocators. The translocator on the outer membrane is referred to as Tom, while that on the inner membrane is termed Tim. These translocator complexes appear to have outward-facing proteins that bind the MTS as well as membrane-buried proteins (or domains) that form a transmembrane (TM) channel. Transfer of the preprotein from cytosolic chaperones to MTS-binding components of the Tom complex is facilitated by ATP hydrolysis. After transfer, the presequence binds sequentially to sites of increasing affinity, and this moves the elongated preprotein toward the Tim complex on the inner membrane. Opening and closing of the (Tim) translocation channel is regulated by MTS binding as well as by the proton gradient that exists across the inner membrane. As the preprotein emerges on the matrix side of the inner membrane channel it is met by a mitochondrially encoded Hsp70 chaperone that is thought to provide the motive force for protein import by reversibly binding incoming proteins in response to both ATP hydrolysis and nucleotide exchange. After arrival in the matrix, the preprotein is folded by another

mitochondrial chaperone, Hsp60, after which the MTS of the preprotein is removed by a matrix peptidase. In addition to the soluble proteins that reside in the mitochondrial matrix, there are membrane proteins that reside in the inner and outer membranes as well as within the intermembrane space. There is no uniform route taken by such proteins, and discussion of the various options falls outside the scope of this chapter.

Peroxisomal Proteins

Peroxisomes, which are essential for human survival, are so named because they are the site of many oxidative reactions that generate H_2O_2. H_2O_2 is used (particularly in the liver) by the enzyme catalase to oxidize toxic substances such as ethanol. Peroxisomes are also the site where long chain fatty acids are catabolized by -oxidation. The protein components that make up peroxisomes are, like those of mitochondria, synthesized in the cytosol and then imported post-translationally. Although the details of how peroxisome protein import occurs are currently unclear, most imported proteins contain a short carboxy (C)-terminal peroxisomal targeting signal, or PTS (Table 2-1). Peroxisomal import is blocked by mutations in the gene *PEX5*, whose protein product is thought to be a PTS receptor. Defects in *PEX5* also underlie the disease termed Zellweger syndrome. Zellweger syndrome is characterized by the presence of empty peroxisomes. Affected individuals are born with brain, liver, and kidney abnormalities that cause death shortly after birth.

PROTEIN TRAFFICKING WITHIN THE SECRETORY APPARATUS

Nascent proteins intended for residence within the cellular transit system termed the secretory apparatus are first diverted to the on ramp of the secretory apparatus, the ER. From the ER, the proteins can be exported in vesicles to more distal organelles (Golgi complex, plasma membrane, etc.; Fig. 2-2). The vesicles undergo successive rounds of budding and fusion, and by selective incorporation of protein cargo into those vesicles (dictated by sorting motifs), cargo proteins are delivered to their intended destination. Each of the compartments of the secretory apparatus comprises a unique collection of resident proteins and lipids. A major question in cell biology today is how the unique composition of these compartments can be maintained while at the same time allowing unimpeded passage of other, nonresident proteins.

Co-translational Import and Processing of Proteins in the ER

Overview of ER Structure and Function

The ER is an extensive membrane network that serves as the cellular site for synthesis of the massive amounts of lipid and protein used to construct the membranes of most cellular organelles. The ER is divided into three different domains according to morphologic characteristics visible with the electron microscope. Those domains are the rough ER, smooth ER, and the transitional elements. The rough ER is so called because it is studded with bound ribosomes that are actively synthesizing proteins. Smooth ER lacks ribosomes and is not very abundant in most cells (except hepatocytes). Smooth ER is thought to be the domain where lipid biosynthesis occurs and where cytochrome P-450 family proteins detoxify compounds such as phenobarbital. Finally, transitional elements are a tubulovesicular network of smooth membranes also called the intermediate compartment (IC) because it lies between the ER and Golgi complex. Protein mixtures leaving the ER are sorted in the IC, ensuring that escaped ER proteins are retrieved while allowing continued forward progress of other proteins.

Co-translational Import into the ER

Incorporation of proteins into the ER occurs co-translationally, and this distinguishes import into the ER from that into any other organelle (Fig. 2-3). Nascent secretory proteins are earmarked for import early during their synthesis on cytosolic polyribosomes by the presence of an N-terminal signal sequence (Table 2-1). Immediately after its extrusion from the ribosome, the signal sequence is bound by a ribonucleoprotein complex termed the signal recognition particle, or SRP. The bound SRP particle targets the polysome (synthesizing the secretory protein) to the ER membrane by interacting with a specific SRP receptor (SRP-R) or docking protein. Both the SRP and its receptor can bind GTP, which is a critical regulator of SRP-SRP-R interaction. When the SRP polysome complex contacts the SRP-R on the ER membrane, GTP hydrolysis is thought to

Figure 2-3 Co-translational translocation into the ER. During synthesis of nascent secretory proteins in the cytosol, an N-terminal signal sequence is extruded from the ribosome. The signal sequence is bound by the signal recognition particle (SRP), which delivers the polysome complex to the translocation machinery in the ER membrane. Ongoing translation then allows the protein to enter the ER through an aqueous channel, where it is met and folded by molecular chaperones such as the immunoglobulin heavy chain binding protein, BiP.

induce a conformational change that causes release of SRP into the cytosol, where it can participate in subsequent rounds of targeting. The timing of GTP hydrolysis is such that it occurs only after the ribosome has been productively engaged with the translocation apparatus. The translocation apparatus comprises multiple proteins, of which Sec61p (so named for the yeast mutant from which it was cloned) is a major component. Once the ribosome is firmly attached to the translocation complex, ongoing protein synthesis is thought to provide some of the motive force involved in translocating the nascent secretory protein (in an unfolded state) into the ER lumen. The growing polypeptide chain passes into the ER lumen at an approximate rate of 45 amino acids per second through a dynamic aqueous channel, which is open during passage of the unfolded protein and then closes when synthesis is completed. During passage of the nascent protein through the pore, the signal sequence is cleaved off by a signal peptidase associated with the luminal side of the translocator. After removal of the signal sequence, soluble proteins are simply released into the ER lumen; however, establishing the correct orientation (topology) of integral membrane ER proteins is somewhat more complicated and involves motifs called stop transfer sequences. Stop transfer sequences contain a hydrophobic core followed by positively charged amino acids that are thought to cause the protein to be discharged from the translocator, thus embedding it in the ER membrane.

Co-translational Addition of N-Linked Glycans

During translocation of nascent proteins into the ER, proteins that bear the motif N-X-S/T (where X is any amino acid except P) have appended to them carbohydrate moieties termed N-linked glycans. N-linked oligosaccharides are so called because they are linked to the asparagine (N) residue of the motif. These large hydrophilic sugar complexes are thought to be important in maintaining protein solubility by preventing formation of nonproductive aggregates. The N-linked glycan is constructed as a lipid-linked precursor containing mannose, glucose, and N-acetylglucosamine molecules (Fig. 2-4), and is then transferred to nascent polypeptides as a preformed oligosaccharide. The transfer is facilitated by an oligosaccharide transferase complex consisting of ribophorins I and II, and ost48. After addition, the N-linked glycans begin to be processed in the ER, and this continues during their movement through subsequent compartments (Fig. 2-4 ; discussed in detail following). The processing of N-linked glycans serves many physiologically relevant purposes. Indeed, the trimming of terminal glucose residues in the ER can modulate interaction between nascent glycoproteins and chaperones.

Folding in the ER Lumen

Even as nascent polypeptides are arriving in the lumen of the ER, their folding is initiated by chaperones like the Hsp70 family member, immunoglobulin-binding protein (BiP), which is associated with the luminal face of the translocation apparatus. Along with BiP, many other chaperones are active in folding incoming polypeptides, including a set of calcium-binding animal lectins, calnexin and calreticulin. These different classes of chaperones are thought to act in sequence in chaperone relays to achieve complete protein folding and assembly. Some aspects of protein folding occur only in the unique environment of the ER lumen. Indeed, the ER lumen is an oxidizing environment (the cytosol is reducing) in which the sulfur-containing amino acid cysteine can be linked through a disulfide bond to another cysteine residue. These bonds can form either within a given protein or between protein subunits of a receptor complex. This reaction is facilitated by the enzyme protein disulfide isomerase and is a critical reaction for proper folding of proteins of the immunoglobulin (Ig) domain superfamily. For example, each fully folded and assembled IgM monomer requires the formation of at least 16 disulfide bonds. Folding of nascent proteins does not always go to completion, particularly for proteins bearing mutations, such as the mutant forms of the cystic fibrosis TM conductance regulator found in cystic fibrosis patients. Consequently, the ER must have a disposal system to eliminate such proteins. For many years it was thought that such proteins were proteolytically degraded in the ER lumen. However, it has

been determined that mutant proteins are not degraded in the ER but instead are dislocated back into the cytosol, where they are destroyed via a ubiquitin-dependent degradation pathway. Because the ER contains both mutant proteins that cannot fold properly and normal proteins that are in the process of folding, there must be some means whereby the two are distinguished; however, it is unclear how this is accomplished. Interestingly, the ER seems able to monitor the number of unfolded proteins it contains and, when that number exceeds a certain threshold, to trigger a transcriptional increase in chaperone expression. This unfolded protein signal is transduced across the ER membrane to the nucleus by an ER membrane-bound kinase called Ire1p. This unfolded protein response presumably exists to match the magnitude of the ER's chaperone activity with its workload.

Figure 2-4 Processing of N-linked glycans during trafficking. During import of nascent proteins into the lumen of the ER, their asparagine (N) residues are modified by the addition of oligosaccharides. These N-linked oligosaccharides are then processed as indicated during passage of the protein through the secretory apparatus. Prior to exit from the ER, the triplet of terminal glucose residues is removed and mannose trimming begins. Mannose trimming continues during movement through the cis and medial cisternae of the Golgi apparatus. In addition, N-acetylglucosamine residues are added that confer resistance to cleavage by endoglycosidase H (endo H), an enzyme used as a diagnostic tool to determine if a nascent glycoprotein has traversed the medial Golgi compartment. Subsequently, galactose and terminal sialic acid residues are added in the trans-Golgi/TGN. Sensitivity to neuraminidase digestion (which removes sialic acid) can also be used as a diagnostic tool to indicate that a glycoprotein has arrived in the trans-Golgi/TGN.

Achieving Transport Competence

Many of the proteins that are translocated into the ER lumen or inserted into its membrane are only temporary residents intended for a more distal compartment in the secretory pathway. How does the ER know when the temporary residents are ready to leave, and how are these proteins distinguished from those intended to remain in the ER? For many years it was thought that to exit the ER, proteins had to have motifs directing them to do so; currently, however, the consensus is that there is no absolute requirement for such exit signals; rather, proteins must achieve transport competence. Transport competence means simply that the protein must be fully folded before exit can occur. Although the molecular definition of transport competence is currently unclear, in many cases it correlates with the absence

of persistent chaperone association. Generally, chaperone association is transient with normal proteins, but that association persists with mutant polypeptides. This is presumably because the amino acid sequence of the mutant polypeptide cannot assume a conformation that allows its hydrophobic chaperone-binding sites to be hidden within the protein. Conversely, when a normal protein has folded, its chaperone recognition sequences are tucked inside the protein in question, causing release from the chaperone and allowing the protein to exit the ER. Exit from the ER occurs from tubulovesicular transitional elements, where secretory proteins are packaged into either tubules or vesicles (hereafter referred to as vesicles), which shuttle them to the Golgi complex. The packaging of proteins into vesicles is likely to involve factors in addition to release from chaperone association, as cargo proteins appear to be markedly concentrated in vesicles relative to their overall abundance within the ER. The encapsulation of cargo proteins into transport vesicles as well as the mechanics of their budding and movement will be described below. Interestingly, transport competence sometimes requires assembly of two independently folded subunits. For example, the IgM heavy chain, Ig, cannot exit the ER until it has paired with the Ig or light chain, thus ensuring that only functional IgM molecules reach the circulation. Moreover, transport competence can be conditionally defined. Before they are activated, B lymphocytes produce a secreted form of Ig (s) and a form that is membrane bound ($_m$). Although both of these assemble with Ig light chain, only $_m$ is competent to exit the ER. After stimulation by its cognate antigen, the B lymphocyte becomes activated and still produces both $_m$ and $_s$, but now only $_s$ is competent to exit the ER.

ER Retention

Given that resident ER proteins are also completely folded, why are they compartmentalized in the ER and not exported to the plasma membrane along with the secretory proteins? ER proteins localize in the ER because they possess retention signals. There are currently two consensus ER retention motifs at the C-termini of ER proteins: KDEL, for soluble ER proteins, and KKXX, for membrane-bound proteins. Curiously, however, when these ER retention motifs are grafted onto test proteins, those test proteins still acquire modifications conferred by resident Golgi enzymes. This suggests that the test proteins were permitted to exit the ER and reach the Golgi apparatus. Indeed, there is good evidence that the above ER retention signals are really retrieval signals. That is, proteins bearing retrieval signals can transiently escape from the ER into the IC/cis-Golgi, from which they are returned to the ER via the retrograde (reverse) transport pathway (Fig. 2-5). Although escaped proteins are probably most often retrieved before they move past the cis-Golgi, modification of these proteins by trans-Golgi enzymes has been observed. For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified. However, for the KKXX motif it remains unclear whether there is a specific receptor or, alternatively, whether the retrieval motif interacts directly with the retrograde transport machinery. In support of

Figure 2-5 Retrieval of escaped ER proteins from the IC/cis-Golgi. Occasionally, a resident ER protein is packaged along with secretory proteins in anterograde vesicles leaving the ER. Upon arrival in the IC/cis-Golgi stack, protein sorting occurs. The secretory proteins are allowed to continue on to the plasma membrane, while the escaped ER proteins are bound by a retention receptor and returned to the ER.

IMPACT OF RETENTION SIGNALS ON RECEPTOR FUNCTION

In addition to their role in maintaining organelle integrity, retention/retrieval signals can facilitate assembly of multisubunit complexes. In particular, the T-cell antigen receptor (TCR) complex must be capable of both recognizing a specific antigen and transducing a signal to the cytoplasm, which can only occur if the TCR possesses all of its six subunits. The surface expression of only complete TCR complexes is facilitated by the presence of ER retention motifs on several TCR subunits. These subunits exit the ER only after assembly into a full complex because assembly serves to bury the ER retention motifs of the individual subunits, preventing their binding by putative retention receptors. In this way, partial receptor complexes that are only marginally functional are prevented from reaching the cell surface, where they might interfere with the function of complete TCR complexes.

the latter possibility, recent reports demonstrate that KKXX-containing proteins can interact with the coatomer complex, which coats certain transport vesicles. Retrograde transport, along with its role in the specific retrieval of escaped ER proteins, serves to replenish the vesicle components lost due to anterograde (forward) transport. The need for balance between the anterograde and retrograde pathways is clearly exhibited when cells are treated with the fungal metabolite Brefeldin A (BFA). BFA treatment of cells selectively blocks the anterograde pathway, causing all but the most distal cisternae of the Golgi complex to collapse into the ER (Fig. 2-5). Interestingly, most endogenous ER proteins are not modified by Golgi enzymes, which suggests that they do not escape the ER even transiently. The means whereby these proteins are sequestered in the ER is unclear, but may result from formation of oligomeric complexes.

Protein Transport Within the Golgi Complex

Subdivision of the Golgi Complex

The Golgi complex comprises a stack of flattened, membrane-bound cisternae that is highly dependent on microtubules for structural integrity. The stack of cisternae can be subdivided into three parts, referred to as *cis*, *medial*, and *trans.* Both the cis and trans faces of the Golgi complex are associated with tubulovesicular bundles of membranes. The bundle on the cis side of the Golgi stack is termed the transitional elements/IC (see above) and is the site where incoming proteins from the ER dock and are sortedthat is, where escaped ER proteins marked for retrieval by the retrograde transport pathway are separated from proteins bound for more distal compartments. Protein cargo is moved vectorially across the Golgi stack from the cis to the trans side, where a second tubulovesicular bundle is encountered. The bundle at the trans face of the Golgi stack is called the trans-Golgi network (TGN) and, like the IC, is a major site of sorting where proteins can be diverted into lysosomes or secretory granules or, alternatively, continue by default to the plasma membrane. During vectorial movement across the Golgi stack, the N-linked glycans on cargo proteins are modified by resident Golgi enzymes (Fig. 2-4). The processing events are ordered in time and separated in space because the processing enzymes have a characteristic distribution across the Golgi stack. Following entry and during movement into the medial Golgi stack, the N-linked glycans of incoming glycoproteins are trimmed by mannosidases I and II and then have N-acetylglucosamine (GlcNAc) appended to them by GlcNAc transferase. Addition of GlcNAc confers resistance to the enzyme endoglycosidase H, a widely used diagnostic test for passage of proteins through the medial Golgi. During movement from the medial to the trans-Golgi stack and TGN, the N-linked glycans are appended first with galactose by galactosyltransferase and then with sialic acid by sialyltransferase. Sialic acid is a negatively charged carbohydrate that, when expressed on the surface, helps to protect cells from mechanical damage. In addition, the loss of sialic acid from secreted glycoproteins is a means of marking aged proteins for removal from the circulation and degradation by hepatocytes.

Retention of Resident Golgi Proteins

The ordered processing of glycoproteins during their movement across the Golgi stack reflects the distinctive protein composition of each Golgi subdomain. For example, mannosidases I and II are found in the cis/medial cisternae, whereas sialyltransferase is found in the trans-Golgi stack and TGN. Consequently, there must be a subdomain-specific means of retaining resident Golgi proteins while at the same time allowing the passage of itinerant proteins. However, extensive mutational analysis of resident Golgi enzymes has failed to reveal a consensus retention motif. Sequences important for retention have been found in all domains of Golgi complex proteins (luminal, TM, and cytoplasmic). Furthermore, overexpression of certain Golgi proteins does not result in their release to the plasma membrane, which suggests that retention is not mediated by a saturable retention receptor. Based on these analyses, two hypotheses to explain the retention of Golgi proteins have been put forth. They are the bilayer thickness and the kin-recognition/oligomerization models. The bilayer thickness model proposes that Golgi complex proteins are not packaged into anterograde transport vesicles exiting the Golgi complex because their TM domains are too short to be stable within the thicker membrane bilayer found at the plasma membrane. Evidence supporting this model is as follows: (1) TM domains of Golgi proteins are on average about 5 amino acids shorter than those of plasma membrane proteins; (2) there is an increasing cholesterol gradient in the lipid bilayers from the ER to the plasma membrane, and cholesterol has been reported to increase bilayer thickness; and (3) lengthening the TM domains of certain Golgi enzymes results in their escape to the cell surface. The kin-recognition/oligomerization model proposes that proteins of a given subdomain can form large detergent-insoluble oligomers that prevent their entry into the vesicles and thus their traffic to more distal cisternae. Mechanistically, the graded distribution of oligomers across the Golgi stack would result from the selective triggering of oligomerization by the different lipid compositions in different cisternae. Evidence in support of the oligomerization model is as follows: (1) the TM domains of many of the Golgi glycosyltransferases have been implicated in retention; and (2) ER retention of one medial Golgi enzyme, GlcNAc-transferase, causes the ER retention of another medial Golgi enzyme, mannosidase II. Possibly a combination of both retention mechanisms is active in maintaining the protein composition of the Golgi complex.

Anterograde Movement of Proteins

Transport competent proteins exit the ER and enter the IC in vesicles covered with a protein coat called COPII (detailed later). COPII-coated vesicles then fuse with the membranes of the IC, releasing their cargo proteins. However, the means whereby cargo proteins move from the IC to the trans-Golgi stack remains controversial. Two explanations have been proposed. The first proposal is that anterograde transport through the Golgi apparatus occurs in transport vesicles covered with a second kind of protein coat, COPI or coatomer (described later).

COPI-coated vesicles are thought to shuttle proteins around the outer rims of Golgi cisternae. Although COPI-coated vesicles are found swarming around the rims of Golgi cisternae, they do not appear to contain anterograde cargo. The second proposal, the directed maturation or fractional distillation model, states that anterograde movement occurs because nascent Golgi cisternae, which are formed by vesicular fusion in the IC, drift forward (anterograde) like icebergs while resident Golgi proteins are selectively pinched off in vesicles and trafficked back to the cis side of the Golgi stack. The farther away from the cis side the cisternae have drifted, the more their contents have been refined by the extraction of proteins in retrograde transport vesicles. Although it is currently unclear which of these models is correct, the bulk of the experimental evidence supports the fractional distillation model.

Sorting Events at the TGN

The TGN is an extremely important site of intracellular sorting where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive transport pathway leading to the plasma membrane. The constitutive or default pathway is so called because it was previously thought that transport to the plasma membrane occurred by default (i.e., no specific structural features were required) unless the protein was actively diverted into a different compartment. Although we still lack a thorough understanding of the molecular criteria for entry of cargo proteins into constitutive secretory vesicles, the concentration of cargo proteins within those vesicles suggests that active recruitment of cargo proteins is required. Proteins not entering the default pathway can be diverted into either lysosomes or, alternatively, regulated secretory granules. In polarized epithelial cells, structures called tight junctions subdivide the plasma membrane into two domains: an apical domain, which faces the lumen or sinus, and a basolateral domain, which faces adjoining cells and underlying connective tissue. In such polarized cells, proteins in the TGN have an additional sorting option: to go to the apical or basolateral domain of the plasma membrane.

Sorting into Lysosomes

Lysosomes are membrane-bound organelles with an acidic lumen (pH 5.05.5) containing numerous hydrolytic enzymes designed to destroy proteins, carbohydrates, and lipids. The lysosomal membrane has a unique composition that includes a proton pump that maintains the low pH of this organelle and numerous heavily glycosylated proteins, which presumably protect the membrane from hydrolysis. Soluble hydrolases are marked for sorting into lysosomes by a post-translational modification acquired during transport from the ER to the cis-Golgi. Indeed, the hydrolases bear a three-dimensional signal patch that induces phosphorylation of their N-linked sugars, creating the mannose-6-phosphate (M6P) sorting signal. Upon arrival at the TGN, the modified hydrolase is bound by an M6P receptor (M6P-R), which delivers it to lysosomes. It is thought that delivery to lysosomes is not direct but instead involves passage through a late endosomal compartment (Fig. 2-2 and following) where the low pH releases the hydrolase from the M6P-R. Subsequently the hydrolase is delivered to the lysosome and the M6P-R returns to the TGN to capture another hydrolase molecule.

M6P marks hydrolases for delivery to lysosomes, but what targets the M6P-R itself? The motif that enables M6P-R to deliver cargo to lysosomes is YSKV, found in its cytosolic domain. YSKV is recognized by the machinery responsible for formation of clathrin-coated vesicles (see later), which in turn underlies proper routing of the M6PR. In addition to the soluble hydrolases that reside in the lumen of lysosomes, there is also a

LYSOSOMAL STORAGE DISEASES

Failure to accurately target lysosomal hydrolases underlies two well-known human diseases, Hurler's syndrome and I-cell disease. Hurler's syndrome is caused by a mutation in a hydrolase responsible for breakdown of glycosaminoglycans that prevents the hydrolase from acquiring the M6P modification, consequently preventing targeting to lysosomes. Similarly, in I-cell disease, undigested material accumulates in lysosomes because a mutation in the enzymes that create the M6P modification causes missorting of lysosomal hydrolases.

wide array of proteins residing in the lysosomal membrane. The targeting signals for many of these integral membrane proteins have been identified and comprise either of two consensus motifs: (1) GYXXZ, where X is any amino acid and Z can be I, F, V, L, or M (the Z position may determine the efficiency of sorting); and (2) a leucine-based motif (LL or LI). Although the motifs are well established, the exact route taken by lysosomal membrane proteins after leaving the TGN is a matter of debate. The clathrin-coated vesicles containing these hydrolases may be transported to late endosomes, as is thought to occur for the M6P-R, or, alternatively, may be transported first to the plasma membrane from which they are retrieved to lysosomes.

Sorting into Regulated Secretory Granules

Regulated secretion differs from constitutive secretion in that proteins are condensed into stored secretory granules that are released to the plasma membrane only after the cell has received an appropriate stimulus (Fig. 2-2). For example, the cross-linking of Fc-epsilon receptors on mast cells by IgE-antigen complexes induces the release of preformed histamine-containing secretory granules. The biogenesis of secretory granules is not well understood but is thought to occur in two phases. The first involves sorting proteins into immature secretory granules that bud from the TGN, and the second involves the maturation of the granules after budding has occurred. Clues to the basic mechanism(s) have been gathered by analysis of the granule proteins themselves. In general, the luminal components of granules tend to self-associate and appear to exist in both soluble and membrane-associated forms. Based on these observations, a model has been proposed. It suggests that in the TGN a fraction of the granule protein molecules associate with the inner leaflet of the TGN membrane, possibly through a receptor protein. The remainder of the granule protein population attaches to the membrane-bound form through self-association, resulting in packaging of the whole population into a vesicle. After budding, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents into clathrin-coated vesicles. At some point during budding or maturation, the granule proteins, which are often packaged as proforms, are proteolytically cleaved to generate the mature form(s). Mature granules are then thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis, e.g., when the TCR complex of a cytotoxic T lymphocyte encounters its antigen on the surface of a target cell. Upon conjugation with its target, the cytotoxic cell's microtubules and their associated granules are reoriented to face the target cell, after which the motor protein kinesin conveys the granules along microtubules until they fuse with the plasma membrane, releasing their hydrolytic contents on the target cell. It is unclear why the granule contents damage only the target cell, but it may be because the cytotoxic cell is protected by the granule inner membrane. After release of the granule

contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

Sorting to Plasma Membrane Domains in Polarized Cells

The apical and basolateral plasma membrane domains of polarized cells (epithelium) have distinct protein compositions generated by sorting events occurring in the TGN. This routing is of obvious importance, as a violation of cellular polarity would have disastrous consequences. (Consider the effect of gut epithelium secreting digestive enzymes at the basolateral surface instead of into the gut cavity at the apical surface.) Currently, there are two models for establishing the distinct protein compositions of the apical and basolateral surfaces: the direct and indirect pathways. The direct transport model proposes that basolateral and apical proteins are packaged into distinct vesicles at the TGN and transported directly to the basolateral and apical domains, respectively. The indirect transport model proposes that all proteins go first to the basolateral surface, from which apical proteins are selectively retrieved. It is currently unclear which model is correct, and it is likely that the answer will depend on the protein in question. Sorting motifs underlying basolateral targeting are similar to those of lysosomal membrane proteins (Y or LL motifs) and are usually associated with a protein structure called a type I turn. The apical surfaces of cells are enriched for glycolipids (sphingomyelins) and proteins bearing a glycophosphatidylinositol (GPI; added in the ER) anchor. In fact, the lipid component of these molecules may underlie their targeting to apical surfaces. The glycolipids and lipoproteins are thought to self-associate to form subdomains or rafts that exclude dissimilar proteins, thereby achieving segregation from basolaterally targeted proteins; however, it is completely unclear how such rafts would be packaged into transport vesicles and trafficked to the apical surface. After the polarity of an epithelial cell is established, it can be exploited to move cargo from one side of the cell (basolateral) to the other (apical) by a process termed transcytosis. A pertinent example of transcytosis is important in the maintenance of mucosal immunity. The polymeric Ig receptor (pIgR) acquires dimeric IgA molecules at the basolateral surface of gut epithelium, which induces trafficking of the Ig molecules to the apical surface where a proteolytic cleavage event destroys the pIgR and releases its cargo into the gut. The means whereby Ig binding triggers transcytosis of the pIgR is unclear but appears to involve phosphorylation of an S residue in the pIgR cytoplasmic tail.

Endocytic Traffic

The previous sections described delivery of endogenous proteins from the intracellular site of synthesis to their intended destination. This section considers the means whereby substances are imported from the extracellular milieu by a process termed endocytosis. Endocytosis also serves to recover protein and lipid placed on the plasma membrane by ongoing secretory activity. There are two types of endocytosis: phagocytosis (cell eating) and pinocytosis (cell drinking). Defects in endocytosis can underlie human disease. In particular, the receptor for low-density lipoprotein (LDL) regulates serum cholesterol by endocytically removing LDL from the circulation and delivering it to lysosomes, where the cholesterol is catabolically released for reuse in the biosynthesis of cellular membranes. Individuals with familial hypercholesterolemia have elevated serum cholesterol levels because mutations in the LDL receptor prevent removal of LDL from the circulation.

Phagocytosis

Phagocytosis refers to the ingestion of large particles (>0.5 M) and is primarily executed by specialized cells such as macrophages and neutrophils. Phagocytosis serves not only to engulf and destroy invading bacteria, but also to clear cellular debris at wound sites and to dispose of aged erythrocytes. Estimates are that human macrophages destroy 10^{11} aged erythrocytes each day. Phagocytosis is triggered when specific receptors on the phagocytic cell contact structural triggers on the particle. These structural triggers include bound antibodies and complement components (opsins) as well as certain oligosaccharide structures. When a particle binds a cellular triggering receptor, the polymerization of actin (a cytoskeletal component) is stimulated, driving the extension of pseudopods, which surround the particle and engulf it in a vacuole. The engulfed material is destroyed when the vacuole fuses with a lysosome, exposing the contents to hydrolytic enzymes. In addition to being a means of destroying invading pathogens, phagocytosis is a means of presenting the pathogen's components to lymphocytes, thus eliciting an immune response to protect against future exposure.

Pinocytosis

Pinocytosis refers to the constitutive ingestion of fluid in small vesicles (<0.2 M), which in some cells can result in turnover of the entire plasma membrane in less than 1 hour. After invagination and budding, the vesicle is part of the endocytic compartment, a complex network of interrelated membranous vesicles and tubules that are in intimate contact with one another and in flux. The four types of endocytic vesicles are early endosomes (EE), late endosomes (LE), recycling vesicles, and lysosomes. Each will be described in the order in which it is encountered during endocytic trafficking (see Fig. 2-2).

The invagination of endocytic vesicles occurs in regions of the plasma membrane containing a coat on the cytoplasmic side called clathrin. Cargo molecules can be captured in these clathrin-coated pits either stochastically in the fluid phase or in association with a specific surface receptor. Receptor-mediated capture (endocytosis) is much more efficient, enriching cargo up to 1,000-fold in the resulting endocytic vesicle relative to its normal concentration in the extracellular fluid.

The enrichment of cargo is so extensive because the formation of clathrin-coated pits is linked by adaptors to the receptors themselves (detailed later). Receptors are recognized by the adaptor molecules via sequence motifs very similar to those involved in trafficking membrane proteins to lysosomes: (1) a YXXZ motif (Z, an amino acid with a large hydrophobic side chain) that will adopt a tight-turn configuration; and (2) a dileucine motif.

Clathrin-coated pits invaginate into coated vesicles, after which the clathrin coat is removed by a cytoplasmic ATPase of the Hsp70 family. Removal of the clathrin coat facilitates vesicle fusion with EE, a dynamic network of tubules and vesicles that is occupied by endocytic tracers after 1 to 5 minutes of incubation with the cell. The primary function of EE is sorting, distinguishing receptors that will rapidly recycle back to the plasma membrane (transferrin receptor) from those that will continue on to lysosomes and be destroyed (Ig-antigen complexes). EE are also the compartment where receptor and ligand are uncoupled. For example, the slightly acidic pH (6.36.8) of EE causes uncoupling of transferrin receptor (Tf-R) from its cargo. The vacant Tf-R molecules are moved into the tubular extensions of EE, from which they are recycled back to the plasma membrane by recycling vesicles; meanwhile, the dissociated cargo molecules accumulate in the large central cavity. Recycling vesicles appear to have a biochemical composition distinct from that of EE, which validates the idea that membrane components are specifically sorted into these vesicles; however, the basis for this discrimination is unclear.

The cargo contained in EE is then delivered into late endosomes (LE) in a microtubule-dependent manner. It is unclear whether EE mature into LE through acquisition of nascent protein

INFLUENCE OF MHC-I AND MHC-II BIOSYNTHESIS ON THE TYPE OF ANTIGEN PRESENTED

Peptide antigens are presented to T lymphocytes in association with either class I or class II major histocompatibility complex (MHC) molecules. Peptides presented by class I are derived largely from endogenously synthesized proteins (or viruses) whereas those presented by class II are derived from proteins found in the extracellular milieu. The mechanistic basis for the differences in antigens presented results from differences in the intracellular trafficking of class I and class II MHC molecules. Class I MHC molecules are held in the ER in association with molecular chaperones until they acquire cytosolic peptide that has been fed into the ER by a transmembrane transporter. After acquiring peptide, class I molecules dissociate from chaperones and transit directly to the cell surface, where they display their peptide to T lymphocytes. Like class I molecules, class II molecules are also assembled in the ER; however, they are prevented from acquiring peptide there by an associated protein called invariant chain, which plugs the peptide-binding pocket of the class molecule. In addition, invariant chain possesses sorting signals that divert class II molecules into the endosome/lysosome pathway, where proteolytic removal of invariant chain allows acquisition of peptides that were derived from degradation of endocytosed material. Thus, the respective roles of class I and class II molecules in presenting antigens to the immune system are dramatically influenced by their biosynthesis.

components or if the EE and LE are distinct compartments between which cargo is moved by vesicular intermediates. LE are defined as endocytic vesicles that label after 5 to 15 minutes of incubation with an endocytic tracer and are usually located near the Golgi apparatus or nucleus. LE have abundant internal membranes, contain lysosomal hydrolases, and are likely to be the site where degradation of endocytosed material begins. LE, sometimes called prelysosomes, are distinct from lysosomes in that they are less dense, contain M6P-R, and are not the end point where endocytosed material accumulates. Endocytosed material accumulates in the lysosome, which it probably receives by fusion with LE.

MECHANICS AND SPECIFICITY OF VESICULAR TARGETING

The movement of protein cargo from one compartment of the secretory apparatus to another generally involves the selective packaging of cargo proteins into transport vesicles, which are themselves targeted to a particular intracellular destination. The previous sections described the motifs known to be involved in selective incorporation of cargo into vesicles. This section considers the mechanics of vesicle budding and the means whereby vesicles find and fuse with the correct target membrane.

Linking Cargo Acquisition with Vesiculation

Cargo proteins are concentrated in transport vesicles, which markedly increases the efficiency of vesicular transport. The concentration occurs because cargo selection is linked to vesicle formation. The key to this linkage is the complex of coat proteins that surrounds the vesicle exterior. The coat proteins bind to transmembrane cargo molecules, either directly or through intermediate adaptor proteins. Coat binding also provides some of the force that causes the membrane to deform into a bud, thereby linking cargo acquisition with vesiculation. There are three kinds of coats: (1) clathrin, (2) COPI or coatomer, and (3) COPII. Clathrin-coated vesicles mediate endocytosis and the diversion of proteins from the TGN to endosomes and lysosomes. COPI-coated vesicles mediate retrograde transport from the Golgi complex to the ER. COPII-coated vesicles mediate anterograde transport from the ER to the Golgi complex. At steady state, COPII is located on ER membranes, COPI on the Golgi complex and IC membranes, and clathrin on the TGN and plasma membrane.

Clathrin-Mediated Vesiculation

Clathrin molecules do not recognize cargo receptors directly, but instead do so through intermediate molecules called clathrin adaptor proteins (APs) (Fig. 2-6). APs are soluble cytoplasmic heterotetrameric complexes that bind both sorting motifs in the cytoplasmic tails of cargo receptors (the tyrosine-based and dileucine motifs described previously) and clathrin. Through the specificity of the AP (particularly the subunit), a unique set of cargo receptors is incorporated into the coated transport vesicle. Indeed, the APs that mediate coated vesicle formation at the plasma membrane (AP-2; comprising , , 2, and 2 subunits) are different from those that mediate budding of vesicles at the TGN (AP-1; comprising , , 1, and 1 subunits). How AP recruitment to the membrane is regulated is not clear; however, phosphorylation may play a role. Indeed, it is clear that phosphorylation of the Y residue in the tyrosine-based sorting motif can abrogate AP binding. Furthermore, recruitment of AP-1 proteins to the TGN requires the function of the cytosolic GTPase, ADP-ribosylating factor (ARF). After attachment of the AP complex to the membrane, the clathrin coat is recruited to the AP complex. The clathrin coat comprises a heavy chain (180,000 daltons) and three light chains (3035,000 daltons) that are arranged in a functional unit called a triskelion. Clathrin triskelions are able to self-assemble into a lattice comprising 36 triskelions in vitro in the absence of ATP. Consequently, lattice formation may provide some of the energy required for vesiculation. The final stages of vesiculation are dependent on the GTPase dynamin, which is proposed to be a pinchase. Dynamin is recruited to the clathrin lattice, forming rings around the constricted neck of the budding vesicle. GTP hydrolysis is then thought to induce a conformational change in dynamin that severs the neck, releasing the vesicle from the membrane. Soon after release of the clathrin-coated vesicle, its clathrin coat is removed by a cytosolic protein of the Hsp70 family.

COPI-Mediated Vesiculation

Unlike clathrin, the coatomer or COPI complex (which comprises -, -, -, -, -, epsilon-, and -COP) recognizes at least some cargo proteins directly. Indeed, COPI subunits are able to bind in vitro to KKXX retention motifs on ER proteins, which suggests that direct binding of the retention motifs of escaped ER proteins underlies their retrieval in COPI-coated vesicles. The regulation of COPI recruitment is not completely understood but requires the function of the GTPase ARF. ARF is a monomeric GTPase with a fatty acid tail that is found abundantly in the cytosol in a GDP-bound form. The donor membranes from which COPI vesicles bud contain guanine nucleotide exchange factors that activate ARF (by binding GTP), exposing its fatty acid tail, and inducing membrane association (Fig. 2-7). Membrane-bound ARF in turn recruits coatomer subunits that form the vesicle coat and induce budding. The COPI coat is maintained on the transport vesicle until arrival at the correct recipient membrane, at which time a GTPase in the recipient membrane triggers hydrolysis of ARF's bound GTP molecule,

Figure 2-6 Linking the packaging of cargo with vesicle budding. Surface receptors acquire ligands from the extracellular milieu; the ligands are delivered to the cell interior by endocytosis. The receptors have motifs in their cytoplasmic tails that are bound by adaptor molecules (AP). Adaptor proteins in turn are bound by clathrin coat proteins, which deform the membrane and start the process of vesiculation. After budding, the clathrin coat is removed by a cytoplasmic uncoating ATPase of the Hsp70 family. Uncoating promotes fusion of the endocytic vesicle with early endosomes.

Figure 2-7 Vesicle targeting. Donor membranes contain targeting receptors called SNAREs that are packaged into transport vesicles along with cargo proteins. As with clathrin, coatomer complexes also initiate vesicle budding; however, before coatomer can bind, the GTP-binding protein ARF must be activated and must bind to the membrane. Along with the coatomer, another GTP-binding protein, Rab, is recruited to the transport vesicle. Rab aids in the targeting reaction, possibly by improving the interaction between the SNARE on the vesicle (v-SNARE) and the SNARE on the target membrane (t-SNARE). If the v-SNARE and t-SNARE are compatible, the vesicle fuses with the target membrane, thereby delivering its cargo.

triggering ARF dislocation from the vesicle membrane and removal of the COPI coat.

COPII-Mediated Vesiculation

The structural features on cargo proteins that are required for packaging in COPII-coated vesicles have not been identified, but the process appears to require the function of a new class of adaptor proteins that are similar to the yeast protein Emp24p. Recruitment of the COPII coat complex (which comprises four proteins: Sec31p, Sec13p, Sec23p, and Sec24p) to the ER membrane requires the function of a GTPase, Sar1p. Much like ARF, in its GTP-bound form Sar1p becomes

membrane associated, providing binding sites for the COPII components.

Vesicular Targeting

Vesicular traffic proceeds from a specific donor membrane to a specific target membrane and does not go astray, suggesting that each vesicle must have an accurate targeting mechanism. Although we presently lack a detailed mechanistic explanation for the accuracy of vesicular trafficking, the SNARE hypothesis fits well with the available data. The SNARE hypothesis proposes that receptors called SNAREs on vesicles (v-SNAREs) fit precisely with a corresponding set of SNAREs on the target membranes (t-SNAREs), forming a lock-and-key interaction that is required to permit vesicle fusion (Fig. 2-7). Consequently, every fusion step in vesicular transport is controlled by compartment-specific SNAREs. Analysis of the subcellular locations of known members of the SNARE family supports this contention. Interestingly, the neurotoxic proteases in snake venom that block neurotransmission do so by cleaving SNARE proteins, which blocks synaptic vesicle fusion. It is thought that the SNAREs in donor membranes (v-SNAREs) are maintained in an inactive state. Recent evidence suggests that SNARE activity may be controlled by association with a repressor protein, which can be selectively dissociated after vesicle budding and prior to v-SNARE/t-SNARE interaction.

Prime candidates for controlling the association between SNAREs and their putative repressor proteins are the Rabs. Rabs are a family of small GTP-binding proteins (40 in mammalian cells), each of which is able to associate with a characteristic membrane when in the GTP-bound state, consequently controlling the activity of a particular subset of SNAREs. Upon arrival of a vesicle at the target membrane, the vesicle-associated Rab protein is thought to deprotect the t-SNARE by dissociating its repressor. The Rab-induced deprotection is thought to be transient because GTPase-activating proteins in the target membrane return Rab to the GDP-bound state, causing it to dissociate from the vesicle. If the SNAREs are compatible, fusion can proceed. If not, the vesicle dissociates and moves to a new target membrane to try again. Additional proteins that are required for membrane fusion are NSF (NEM-sensitive factor, a trimeric ATPase) and SNAP (soluble NSF attachment protein), which are thought to act in dissociating the SNARE complexes so they can be recycled for future targeting events. Although these proteins are necessary to prime vesicles for fusion, they do not appear to play a role in the specificity of targeting.

SUMMARY

Substantial progress has been made in understanding the mechanistic basis for the fidelity of intracellular vesicular trafficking. Protein motifs and their cognate receptors have been identified for almost all intracellular transport steps imaginable. The challenge now is to find ways of exploiting that knowledge to intervene in the numerous disease processes resulting from errors in protein targeting.

Chapter 3 - Protein Architecture: Relationship of Form and Function

Barbara C. Furie

INTRODUCTION

The previous chapters have described how the information stored in the gene is transcribed into mRNA, how the mRNA template is translated to synthesize proteins, and how newly synthesized proteins are transported to their appropriate site of function. It is the selective expression of a constellation of proteins from the genomic firmament that provides different cell types with their distinct characters. Proteins are linear polymers made up of amino acids linked together by peptide bonds. Twenty different amino acids are incorporated into these polymers when protein is synthesized from mRNA. The features distinguishing one protein from another are determined not by the polypeptide backbone but by the different side chains of the amino acids incorporated into the protein and the sequence in which they occur. These long arrays of amino acids fold to form compact structures with a specific three-dimensional architecture. The three-dimensional structure of a protein is determined by its unique amino acid sequence. Folded proteins have the capacity to accomplish many different tasks: formation of larger structures (as in the assembly of fibrin monomers into polymers), transport of ligands (as in the binding of oxygen by hemoglobin), catalysis of chemical reactions (as in proteolytic zymogen activation during the propagation of blood coagulation), or the modulation of biologic processes (as in regulation of DNA function by DNA-binding proteins).

A mutation within the coding region of a gene can have varied consequences for synthesis of the gene product. Some mutations are silent, that is, the alteration in the gene product, usually the replacement of one single amino acid by another, has no effect on the ability of the protein to assume its normal three-dimensional structure or to perform its normal function. On the other hand, a single amino acid replacement, if it occurs at a critical position in a protein, can have profound consequences for function. The abnormal factor VIII or factor IX molecules that result in hemophilia A or B frequently arise as the result of a single point mutation (see Chaps. 107 and 108). Similarly, a single point mutation at residue 6 in the -chain of hemoglobin, a change from glutamic acid to valine, results in sickle cell disease (see Chap. 30). Introduction of a stop codon into the translated portion of a gene, insertion or deletion of codons, or addition or deletion of bases leading to a shift in reading frame can all result in production of nonfunctional proteins. The altered proteins may fail to function either because a critical functional residue has been lost or because alterations in amino acid sequence prevent the protein from achieving its proper three-dimensional structure. Proteins that are improperly folded or that are drastically altered in sequence may never escape from the site of synthesis to their proper location within the cell or into the secretory pathway.

AMINO ACIDS: THE BUILDING BLOCKS OF PROTEINS

The structure of an amino acid is illustrated in Figure 3-1 . The central or -carbon atom bears four substituents: an amino group, a carboxyl group, a group of varying chemical structure (R, usually referred to as the side chain), and a hydrogen atom. Since, with the exception of glycine, which bears two hydrogen atoms, each of the substituents carried by the -carbon is chemically different, amino acids are chiral molecules that may exist in two different forms, the L form or the D form. These chiral forms differ from one another in the same sense as your left hand differs from your right. Proteins contain only L amino acids.

The side chains of the amino acids provide each one with its distinct chemical character. The amino acids can be divided into three general classes based on the properties of their side chains, as illustrated in Figure 3-2 . In one group are amino acids whose side chains are hydrophobic (i.e., they are most at home in a nonaqueous environment). Amino acids in this category include alanine, valine, leucine, isoleucine, proline, tryptophan, phenylalanine, and methionine. The side chains in a second group of amino acidsaspartic acid, glutamic acid, lysine, and argininеare charged at physiologic pH and thus are at home in an aqueous environment. The side chains of the third group of amino acidsserine, threonine, tyrosine, histidine, cysteine, asparagine, and glutamineare considered polar. The side chains of this group of amino acids may participate in hydrogen

Figure 3-1 Schematic representation of an amino acid, including an amino group, a carboxyl group, a side chain (R), and a hydrogen atom all linked to the -carbon (C). Each of the substituents on the -carbon is different, rendering the amino acid chiral. The enantiomeric forms of the amino acid, the D and L forms, are shown.

Figure 3-2 The 20 different amino acids that are incorporated into proteins are shown, with the side chain groups highlighted. The amino acids are grouped according to the chemical nature of the side chains. **(A)** Hydrophobic amino acids, those that prefer a nonaqueous environment. **(B)** Amino acids that bear side chains charged at physiologic pH. **(C)** Amino acids with polar side chains that can form hydrogen bonds. As described in Chapter 2 , amino acids other than these 20 can appear in proteins. These additional amino acids arise by post-translational chemical modification of 1 of the 20 amino acids incorporated into a growing polypeptide chain during translation of messenger RNA. Each amino acid has a three-letter abbreviation and is also referred to by a single-letter code.

Figure 3-3 In a hydrogen bond two electronegative atoms share a single proton. The proton is located at the normal covalent distance from the atom to which it is formally bound and at a somewhat shorter distance than the normal van der Waals contact from the other. Hydrogen bonds form in proteins between electronegative atoms in two polar side chains (shown between serine and glutamine side chains), between water and a polar amino acid side chain (shown between water and the glutamine side chain), between carbonyl oxygen atoms and amide nitrogen atoms of the protein backbone (shown between the carbonyl oxygen of a methionine residue and the amide nitrogen of a phenylalanine residue), and between polar side chains and the polypeptide backbone (not shown). Amino acid side chains are shaded.

bond formation. Hydrogen bonds may be formed between these polar side chains and water molecules, making them adaptable to the aqueous milieu. Hydrogen bonds may also form between two polar side chains (Fig. 3-3). Glycine, which

Figure 3-4 Formation of a peptide bond occurs when the carboxyl (C) group of one amino acid condenses with the amino (N) group of the next amino acid, with concomitant loss of a water molecule.

has as its side chain a second hydrogen atom, is sometimes considered to be the single member of a fourth class of amino acids and is sometimes included, as here, in the first class.

It is interesting to note that histidine is unique in that it is the only amino acid whose side chain may be protonated or unprotonated, and therefore charged or uncharged, at physiologic pH. This property of the histidine side chain is functionally significant. For example, the catalytic mechanism of serine proteases, such as the enzymes in the blood coagulation cascade or the complement pathways, is dependent on the ability of a histidine residue in the active site of the enzyme to act as a general base, accepting and then releasing a proton in sequential steps of the enzymatic reaction.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

NATURE OF THE PEPTIDE BOND

The amino acid building blocks become incorporated into proteins in a pattern determined by the encoding genes and are held together in this array by peptide bonds. A peptide bond is formed when the carboxyl group of one amino acid condenses with the amino group of a second, eliminating water and establishing the covalent link between the two amino acids (Fig. 3-4). The peptide bond is formed between the carbonyl carbon of one amino acid and the nitrogen of the next amino acid in the protein sequence. This process is repeated as the polypeptide chain elongates. The result is a structure in which the amino group of the first amino acid in the chain and the carboxyl group of the last are not modified: a protein's polypeptide chain, the main chain or backbone, is described as running from its N terminus to its C terminus. The peptide backbone is comprised of the repeating unit

. (The carbonyl carbon of the protein backbone is referred to as C for ease of identification.)

The fundamental properties of the peptide bond dictate the conformation of the main chain of a protein. The chemical nature of the peptide bond (partial double-bond) requires that each segment of the polypeptide chain between one C and the

Figure 3-5 In a peptide bond, the amide nitrogen shares its lone pair of electrons with the carbonyl oxygen, lending a considerable double-bond character to the CN bond. As a consequence, the main chain of a protein is planar from one C to the next C . Each planar unit has 2 degrees of freedom; it can rotate about the NC bond and about the C C bond. The peptide bonds of the polypeptide depicted are in the trans configuration; adjacent C carbons and the side chains they bear are on opposite sides of the planar CN bond. This is the preferred configuration for most amino acids, as it minimizes steric hindrance. For proline the trans configuration is not favored as much as for other amino acids, and the cis configuration occurs with significant frequency. The planar units of the polypeptide backbone are enclosed in gray boxes. The amino acid side chains are highlighted.

next one in the main chain be planar (Fig. 3-5). The conformation of the polypeptide backbone is thus dictated by the angles between these planar segments. The angles of rotation about the NC bond and the angles of rotation about the C C bond are restricted because some angles of rotation would result in steric interference between the main chain and amino acid side chains. The only exception to these restrictions is the angles of rotation permissible for glycine residues. Since the side chain of glycine is a single hydrogen atom, a much wider range of conformations is available about the glycine C . Conversely, the bulky side chain of a tryptophan residue would be most restrictive of these angles of rotation.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DISULFIDE BRIDGES

In addition to the peptide bond, there is one other covalent bond between amino acid residues that frequently occurs in proteins. The sulfhydryl groups on proximal cysteine residues can be oxidized to form cystine, which contains a disulfide bond (Fig. 3-6). This reaction requires an oxidizing environment. Since the intracellular space is a reducing environment, disulfide bonds are not usually found in intracellular proteins. Disulfide bonds are frequently found in extracellular soluble and integral membrane proteins: they are formed in the lumen of the endoplasmic reticulum, the initial compartment of the secretory pathway. Disulfide bonds may be formed from cysteines that are members of the same polypeptide chain, in which case they are thought to stabilize an already folded polypeptide backbone. Alternatively, a disulfide bond may serve to join covalently two different polypeptide chains, for example, the heavy and light chains of immunoglobulins.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ELEMENTS OF SECONDARY STRUCTURE

The amino acid sequence of a protein is termed its primary structure. This structure is coded in the gene. When a number of consecutive amino acid residues have similar angles of rotation about NC and C C, the main chain of the protein will assume a regular structure. The rotational constraints imposed on these bonds dictate that these regular structures are almost always one of two forms, -helices and -sheets. These structural elements of proteins are termed secondary structures.

Formation of these secondary structures resolves a dilemma posed by the folding of a polypeptide chain by permitting formation of hydrogen bonds between the NH groups and the C=O groups of the protein main chain. The major driving

Figure 3-6 Disulfide bonds are formed between neighboring cysteine residues in an oxidizing environment. The side chains of cysteine and cystine are shaded.

force for folding of proteins in the aqueous environment is to remove nonpolar amino acid side chains from water by sequestering them in the hydrophobic core of the protein. This is akin to the coalescence of oil droplets when oil is dropped into water. The formation of larger globules minimizes contact of hydrophobic moieties of the oil with water. The main chain of a protein with its NH and C=O groups is highly polar. To bring the nonpolar side chains into the hydrophobic interior of the protein the main chain must follow. The hydrophilic nature of the main chain is neutralized in regions of secondary structure by the formation of hydrogen bonds between its polar elements, as illustrated in Figure 3-3 .

-HELIX

-Helices ranging from four or five residues to 40 residues are found in compact globular proteins such as hemoglobin, while long rodlike proteins like the tail of the cytoskeletal protein myosin are made up of long helices twisted around each other to form coiled coils. The membrane-spanning regions of integral membrane proteins, for example, those of the red cell membrane protein glycophorin and the platelet $_2$ -adrenergic (epinephrine) receptor, are frequently -helical regions of about 20 amino acids. An -helix is formed from a continuous sequence of amino acid residues in a protein. One turn of an -helix contains 3.6 amino acid residues, with hydrogen bonds forming between the carbonyl oxygen of residue n and the amide hydrogen of residue n + 4 (Fig. 3-7A). The distance between one turn of an -helix and the next, its pitch, is 5.4 A. With 3.6 residues per turn, the rise per residue along the vertical axis of the helix is 1.5 A. Theoretically, an -helix can be either right-handed or left-handed with regard to direction of screw. In proteins, left-handed helices are rarely seen as the side chains of L amino acids approach the C=O group too closely.

With the exception of proline, there are no strong predictors of whether a particular amino acid side chain is likely or not to be incorporated into an -helix. The last atom of the proline side chain is bonded to the main chain nitrogen atom, preventing the nitrogen atom from participating in hydrogen bond formation

Figure 3-7 The -helix is formed from a continuous sequence of amino acids. **(A)** A right-handed -helix is illustrated. The hydrogen bonds between residue n and residue n + 4, which stabilize the helix, are illustrated by the dotted lines. **(B)** Amino acids in the propeptide of factor IX are plotted on a helical wheel. The asymmetric distribution of hydrophilic amino acid side chains (color) and hydrophobic amino acid side chains (gray) about the helix is easy to visualize with this representation.

(Fig. 3-2A). In addition, the proline side chain sterically hinders the -helical conformation, producing a bend in the helix if it appears after the first turn. Therefore, proline is not found within -helices.

The distribution of residues on the surface of a helix can be visualized using a helical wheel. Residues are plotted every 100 degrees (360°/3.6) around a circle or spiral (Fig. 3-7B). The plot shows the projection of the position of side chains on a plane perpendicular to the helix axis with side chains on one side of the helix appearing on one side of the wheel. Given the periodicity of the residues in an -helix, charged and polar residues may be arrayed on one face of the helix, while hydrophobic residues appear on the opposite face. A region of the propeptide of factor IX is an amphipathic helix, having a hydrophilic face and a hydrophobic face (Fig. 3-7B).

-SHEETS

The second important element of secondary structure is the -sheet. In contrast to the -helix, the -sheet is formed from several different regions of a polypeptide chain. The stretches of polypeptide, usually 510 residues long, that form the -sheet are called -strands. The -strands are aligned to form hydrogen bonds between the carbonyl oxygen atoms on one strand and the amide hydrogen atom on the opposite strand. If in successive -strands the amino acids are running in the same direction, N terminal to C terminal, then the -sheet is termed parallel (Fig. 3-8A); if successive strands alternate directions, the sheet is termed antiparallel (Fig. 3-8B). Mixed -sheets in which some of the -strands are parallel and some antiparallel are uncommon. The hydrogen-bonding pattern is distinct in the two forms of -sheet. In either case, however, the sheet appears pleated; alternate C groups appear above and below the plane of the -sheet. Likewise, the amino acid side chains on a

Figure 3-8 -Sheets are formed from several regions of a polypeptide chain. The strands of polypeptide assembled in a -sheet may be parallel, that is, aligned in the same direction from N to C terminus, or the strands may be antiparallel, that is, aligned in alternating direction from N to C terminus. **(A)** Schematic drawing of a parallel -sheet. **(B)** Schematic drawing of an antiparallel -sheet. The hydrogen bonds that stabilize these structures are highlighted.

-strand are alternately above and below the plane of the -sheet.

PROTEIN TERTIARY STRUCTURE: ASSEMBLY OF SECONDARY STRUCTURES AND DOMAINS

Most proteins are made up of combinations of -helices and -sheets connected by regions of less regular structure usually termed *loops.* The -helices and -sheets pack together to form the hydrophobic core of a protein, while the loop regions tend to appear on the surface of the protein. Loops can be of three general types: (1) tight turns, in which the carbonyl oxygen of the first residue and the amide hydrogen of the fourth residue share a hydrogen bond; (2) loops that are stabilized primarily by side chain-to-main chain hydrogen bonds; and (3) extended structures that do not contain hydrogen bonds. Comparison of homologous proteins among species suggests greater mutability of loop regions than of regions of regular secondary structure. The structures of the folded cores of the proteins are preserved during evolution, while insertions or deletions of several amino acids occur primarily in loop regions.

The arrangement of secondary structures within a polypeptide defines its tertiary structure. The packing of secondary structural elements into a compact folded form brings distant parts of the polypeptide chain into close proximity. Proteins may be assigned to one of four classes, depending on the content and arrangement of secondary structure within the core of the protein. Proteins of the -class are made up primarily of -helices with connecting loop structures. Similarly, -proteins are made up of -sheets connected by loop regions. In -proteins the two elements of secondary structure alternate, again connected by loops. A fourth class of proteins, + , incorporates both -helices and -sheets, but these elements are not arranged in an easily identifiable pattern. Most proteins studied to date are of the -, -, or -classes. Figure 3-9 shows examples of -, -, and -proteins.

Figure 3-9 Models illustrating the three-dimensional structures of several protein domains. **(AC)** Ribbon diagrams, making it easy to discern the elements of secondary structure that make up a protein domain. **(A)** -Subunit of hemoglobin, composed almost entirely of -helices. **(B)** H-*ras* oncogene protein p21, composed of both -helices and -sheets. **(C)** Variable domain of an immunoglobulin heavy chain, composed almost entirely of -sheets. Although the ribbon diagrams, which omit amino acid side chains and trace the protein backbone, are useful for observing the secondary structures within a protein, they give the misleading impression that there is a large amount of empty space within the molecule. This is not the case. In fact, the core of globular proteins is densely packed with atoms. **(D)** -Subunit of hemoglobin in a space-filling model in which the atoms are represented by spheres with radii proportional to their van der Waals radii. It is clear from this representation that very little empty space is present within the protein core.

Figure 3-10 Structure of ovine prostaglandin H_2 synthase-1 is used to illustrate the hierarchical nature of protein folding. The organization of the secondary structures within a domain defines its tertiary structure; the orientation of protein domains and protein modules within a protein subunit defines its tertiary structure. When a protein is made up of more than one subunit, the spatial relationship of the subunits in the assembled protein defines the protein's quaternary structure. *(The coordinates for this structure were kindly provided by Dr. Michael Garavito, Department of Biochemistry and Molecular Biology, University of Chicago; the structure is described in Picot et al.)*

Many proteins are made up of multiple domains. A protein domain, frequently encoded in a single exon, is a region of a polypeptide chain that can fold autonomously into a stable tertiary structure. The spatial relationship of these independent domains within a protein is part of the description of its tertiary structure. The relationship of secondary structure, protein domains, tertiary structure, and quaternary structure is illustrated in Figure 3-10 .

During evolution a limited number of protein domains have been used repeatedly: related domains from different proteins share enough sequence homology to preserve the polypeptide fold but may have markedly different amino acid sequences

and functions. Such domains, which appear to be associated with exon shuffling and duplication, have been termed modules. Examples of proteins whose tertiary structures are built from such conserved modules abound in plasma and as components of cells within the vasculature. A demonstration of the assembly of discrete proteins from such modules is given in Chapter 103 for the proteins involved in hemostasis and fibrinolysis. These proteins incorporate epidermal growth factor-like domains, kringle domains, and type I and type II fibronectin domains, all of which are widely distributed in mammalian proteins. The DNA-binding zinc finger domain is an example of the importance of these conserved domains to intracellular proteins as well. It is hypothesized that the modules within a given class share a stable core structure with discrete functions determined by the nonconserved amino acids expressed on the module's surface.

QUATERNARY STRUCTURE: ASSEMBLY OF POLYPEPTIDE CHAINS

For some proteins the functional unit is made up of more than one independently synthesized polypeptide chain. The orientation of the polypeptide chains to one another within the functional unit is termed the quaternary structure of a multimeric protein. A multimeric protein may be made up of identical subunits or polypeptide chains, as in glucosephosphate isomerase, a dimer of two identical polypeptide chains, or different subunits, as in hemoglobin, in which the functional protein contains two - and two -subunits. The interaction between the subunits of a multimeric protein may be stabilized by disulfide bonds between the polypeptide chains. The interaction of the light and heavy chains of immunoglobulin molecules and the A-chains, B-chains, and -chains of fibrinogen are examples of such proteins. The subunits of a multimeric protein may influence one another, as in the binding of oxygen to hemoglobin, in which the occupancy of one heme group with oxygen influences the affinity of the heme groups of the remaining three subunits for oxygen. Alternatively, the subunits of the assembled multimeric protein may provide a unique function, as in the formation of the antigen-binding site of an immunoglobulin, the complementarity-determining site being formed by the variable regions of both the heavy and light chains of the immunoglobulin molecule. Finally, there are multi-subunit proteins in which each subunit has a distinct function: RNA polymerase is an example of such a protein.

Chapter 4 - Plasma Membrane Dynamics and Organization

Narla Mohandas
Jon S. Morrow

INTRODUCTION

The plasma membrane is so fundamental to the cellular basis of life that the concept of the membrane as a semipermeable fluid lipid bilayer is taught in elementary biology courses. However, the common depiction of the membrane as a soap bubble or as a fluid mosaic ignores the complexity of real cells and the diverse mechanisms by which cell membranes are stabilized and organized. Of particular interest is how different membrane components are assembled to provide unique material properties and form specialized receptor domains to achieve vectorial exchange of nutrients and information with other cells and their milieu. As a result of this complexity and the fundamental importance of the plasma membrane, it is difficult to conceive of a disease process that at the cellular level does not involve altered membrane function, often as the primary event.

The plasma membrane consists of a complex, ordered array of lipids and protein stretched over the outer surface of the cell in the form of a lipid bilayer punctuated by penetrating or attached proteins. The membrane thus forms the interface between each cell and its environment. Biologic membranes display numerous properties that may seem paradoxical. These features issue from the general properties of the lipids and proteins that compose the plasma membrane and from specialized interactions between specific membrane proteins or lipids, or both. Three features stand out: (1) Plasma membranes are noncovalent assemblies of billions of molecules, yet they tend to be self-assemblying, self-sealing, and stable. A typical cell plasma membrane contains a billion molecules of lipid and 10 million protein molecules. All these molecules remain indefinitely associated as an extraordinarily thin (610 nm), continuous sheetlike membrane enveloping the cell. (2) Plasma membranes are fluid structures, yet they are highly ordered with respect to the distribution of molecules both across the bilayer as well as within the plane of the bilayer. Thus, the distribution of both membrane lipids and proteins is highly asymmetric. Many factors,

both intrinsic and extrinsic, act to order the membrane. (3) Plasma membranes function as a barrier, yet they readily pass ions, nutrients, and information (signals) between the cytoplasm and the extracellular environment. They are more than simply a semipermeable membrane, since they can transport some molecules against a concentration gradient. In addition, transmembrane signaling (information transfer) often occurs without transmembrane molecular passage.

In this chapter the biochemical basis of the general properties of biologic membranes is discussed, emphasizing the common principles that underlie their assembly and function. The red cell membrane is chosen as the central focus of this discussion because it is the best characterized plasma membrane and because understanding the structural basis for its function has direct relevance to understanding a number of hematologic disorders. Factors that establish and maintain order within the membrane are outlined, because it is the extent of organization of the plasma membrane that distinguishes it from simple lipid bilayers.

While the red cell membrane serves as the best-defined model for understanding the organization and interactions that maintain cell shape and the integrity of the structures inside and outside the cell, the role of the membrane as a communications surface is universal among many cell types. Thus, a brief introduction to signal transduction is also included.

STRUCTURAL REQUIREMENTS FOR RED CELL FUNCTION

The human red cell leaves the bone marrow in the form of the reticulocyte; thereafter, the mature erythrocyte spends its circulatory lifetime of approximately 120 days performing its function of oxygen delivery. To carry out this function optimally, it must possess a remarkable ability to undergo cellular deformation. The diameter of the human red cell (8 m) far exceeds that of the capillaries (23 m) through which it must pass in the process of delivering oxygen to the tissues. The ability of normal red blood cells (RBCs) to undergo marked deformation during passage through capillaries was originally documented in 1675 by Leeuwenhoek, who noted that the globules underwent deformation into an ellipsoidal shape during passage through the microvasculature but resumed their original shape when they returned to large vessels. After observing his own blood, Leeuwenhoek noticed, with remarkable prescience, that when he was greatly disordered, globules of his blood appeared hard and rigid, but grew softer and more pliable as his health returned to normal. Since these insightful original observations, a substantial body of evidence has been gathered that suggests the ability of the red cell to undergo extensive deformation is essential not only for its function, but also for its survival. [1] [2] [3] [4] [5]

The ability of the red cell to undergo the deformation necessary to negotiate splenic channels and capillaries (Fig. 41) while withstanding continuous circulatory stresses is programmed into its geometry, the viscosity of the intracellular milieu, and the material properties of its membrane. [6] [7] The biochemical composition and anatomic organization of various components of the red cell membrane determine these cellular characteristics. The red cell is unique among eukaryotic cells in that its principal physical structure is its membrane, which encloses a concentrated hemoglobin solution. In contrast to other cells, the RBC has no cytoplasmic structures or organelles and lacks a nucleus. Thus, all the structural elements of the red cell are in one way or other linked to the cell membrane. The mechanisms by which different membrane components and their interactions contribute to the unique features of the human red cell are summarized.

RED CELL MEMBRANE STRUCTURAL ORGANIZATION

The red cell membrane is composed of a lipid bilayer to which is anchored a filamentous network of proteins that underlies the cytoplasmic surface of the membrane. This network, also referred to as the membrane skeleton, is important for maintaining red cell shape and regulating membrane properties of deformability and mechanical stability.[6] [7] The red cell membrane has been well characterized biochemically. The structural organization of the various lipid and protein components has been well delineated.[8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] About 52% of the membrane mass is protein, 40% is lipid, and 8% is carbohydrate. The major lipid components are unesterified cholesterol and phospholipids, present in nearly equimolar quantities. Free fatty acid and glycolipids are present in small amounts. [8] The phospholipid composition of the membrane is phosphatidylcholine (PC), 30%; sphingomyelin (SM), 25%; phosphatidylethanolamine (PE), 28%; and phosphatidylserine (PS), 14%. Phospholipids such as phosphatidic acid, phosphatidylinositol-4-phosphate, and phosphatidylinositol-4,5-diphosphate make up about 23% of the total. These phospholipids are asymmetrically distributed in the membrane, with more than 75% of the choline-containing uncharged phospholipids PC and SM found in the outer monolayer of the lipid bilayer, while 80% of PE and all PS, the charged phospholipids, reside in the inner monolayer. [9]

The maintenance of asymmetric phospholipid distribution in the normal red cell membrane appears to be the result of (1) a slow and symmetric rate of passive diffusion of choline-containing phospholipids (PC and SM) across the two lipid monolayers (half-times on the order of hours), (2) a direct interaction

of the charged phospholipids and membrane skeletal proteins, and (3) active transport of the aminophospholipids (PS and PE) by an ATP-dependent aminophospholipid translocase or flippase from the outer to the inner monolayer. [10] In contrast to phospholipids, cholesterol diffuses across the membrane on a physiologic time scale (a half-time of seconds or less). [20] The mature red cell is unable to synthesize lipids de novo, but a number of lipid renewal pathways produce considerable turnover of the various phospholipids with no net change in lipid composition. In addition, the cholesterol content of the membrane is regulated by the exchange that takes place between plasma cholesterol and membrane cholesterol. The function of the phospholipid bilayer is to provide physical continuity to the membrane. This membrane continuity, in turn, is responsible for solute impermeability. The lipid bilayer also serves as the matrix in which transmembrane proteins reside. The fluidity of this matrix is regulated by lipid composition.

Analysis of proteins of the red cell membrane by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS/PAGE) in one dimension indicates the presence of about a dozen distinct species, most of which have been well characterized. By contrast, two-dimensional separation employing isoelectric focusing and SDS/PAGE shows the membrane to be composed of more than 100 different proteins, many of which have yet to be characterized. The proteins of the membrane are divided into two general groups, integral and peripheral proteins. The integral proteins are tightly bound to the membrane through hydrophobic interactions with the lipids in the bilayer. Band 3, aquaporin, and glycophorins belong to this class; these proteins span the membrane and have distinct structural and functional domains, both within the bilayer and on either side of the membrane (Fig. 42). The peripheral proteins are located on the cytoplasmic surface of the lipid bilayer and can be readily released from the membrane by manipulation of the ionic strength of the milieu or other protein perturbants. The peripheral proteins, which include spectrin, actin, ankyrin, adducin, tropomyosin, tropomodulin, and protein 4.1, constitute the membrane skeleton (Fig. 42).

The most abundant and best-studied integral proteins of the red cell membrane are band 3, aquaporin, and a family of sialoglycoproteins called glycophorins. Band 3, the anion exchanger, is the major integral protein, constituting about 25% of total membrane protein. Recent cloning studies have demonstrated that this protein is the product of a gene residing on chromosome 17 that encodes a 911-amino acid protein (101,791 Mr). [21] Each red cell contains approximately 1×10^6 copies of band 3. This protein is composed of three dissimilar and functionally distinct domains. The hydrophilic cytoplasmic domain (residues 1403) interacts with a variety of peripheral membrane and cytoplasmic proteins, including ankyrin, protein 4.1, protein 4.2, hemoglobin, and a variety of glycolytic enzymes. The hydrophobic transmembrane domain (residues 404882) contains multiple membrane-spanning domains and forms the anion transporter. The acidic C-terminal domain (residues 883911) has no known function, although recent evidence suggests that this domain can bind carbonic anhydrase. Band 3 contains a single N-glycosidically linked oligosaccharide that possesses the blood group antigen activities I and i. The two clearly established functions of band 3 in the membrane are (1) anion transport, resulting in one-for-one exchange of HCO_3 or Cl across the membrane; and (2) physical linkage of the lipid bilayer to the underlying membrane skeleton, primarily through its interaction with ankyrin and secondarily through binding to protein 4.1 or protein 4.2.

Four sialic acidrich glycoproteins (glycophorins A, B, C, and D) compose a class of integral proteins termed glycophorins, constituting approximately 2% of the total red cell membrane proteins.[22] Glycophorins A, B, and C are distinctly different polypeptides containing 131, 72, and 128 residues, respectively. Recent cloning and sequencing studies have shown that these proteins are the product of distinct genes. The genes coding for glycophorins A and B reside on chromosome 4, and glycophorin C is encoded by a gene residing on chromosome 2. Glycophorins consist of three domains: a cytoplasmic domain, containing a cluster of basic residues positioned near the plasma membrane; a hydrophobic domain, which forms a single -helix spanning the bilayer; and an extracellular domain, which is heavily glycosylated. The glycophorin A molecule carries the MN blood group specificity, glycophorin B the Ss specificity, and glycophorin C the Gerbich blood group specificity. The presence of carbohydrates imparts a strong net negative charge to the cell surface; this is functionally important in reducing the interaction of red cells with one another as well as with other cells, including vascular endothelium. Glycophorin C appears to interact with p55 and protein 4.1, and through this association it regulates the membrane content of p55 and protein 4.1.

A number of other integral proteins are present in the red cell membrane. Aquaporin-1, present in the red cell membrane, belongs to a family of membrane channel proteins that serve as selective pores for water transport.[23] Colton blood group antigens represent a polymorphism on the aquaporin-1 protein. Of the different human red cell surface antigens, the Rh blood group system is unique in that its antigens are carried by a family of nonglycosylated but palmitoylated membrane proteins consisting of Rh30 (RhD and RhCE) polypeptides and the Rh50 glycoprotein. [24] The function of this protein complex remains undefined. Other blood group-specific determinants on the red cell membrane include Duffy, Kell, Kidd, Lutheran, and Lewis. Although the function of these proteins remains to be defined, it is likely that some of these integral proteins possess transport

Figure 4-2 Schematic diagram of the red cell membrane organization based on our current understanding of various membrane components. The key protein interactions identified to be important in regulating red cell membrane mechanical properties include spectrin dimer-dimer interaction, spectrin-ankyrin-band 3 interaction, and spectrin-actin-protein 4.1 interaction.

functions while others are involved either in mediating adhesive interactions or in linking the bilayer to the membrane skeleton.

The filamentous network of peripheral proteins is anchored to the bilayer by interaction with several integral proteins. The network, generally referred to as the membrane skeleton, is composed of seven principal components: spectrin, actin, ankyrin, adducin, tropomyosin, tropomodulin, and protein 4.1 (Fig. 42 ; Plate 41). Spectrin is a flexible, rodlike molecule present in red cells at approximately 200,000 copies per cell. It is composed of two nonidentical subunits of 260,000 daltons (spectrin -subunit) and 246,000 daltons (spectrin -subunit) intertwined side to side, forming a heterodimer with a contour length of approximately 100 nm. The gene that codes for -spectrin resides on chromosome 1 and that for -spectrin on chromosome 14. Each polypeptide is organized into a number of independently folded domains, each containing 106 residues. The subunits are linked, like beads on a string, by flexible joining regions. Spectrin heterodimers associate head to head to form $()_2$ tetramers, which have a contour length of approximately 200 nm. Tetrameric species of spectrin appear to predominate in the membrane skeleton. Oligomers larger than the tetramers are also observed; they appear to be formed by spectrin dimers joined by head-to-head linkages into a central ring. [25] The tail ends of spectrin tetramers are associated with short oligomers of actin composed of 12 monomers. Red cell actin is unusual in being organized into short, highly uniform filaments of approximately 35 nm in length. The strict control of actin filament length may be modulated by the proteins tropomyosin and tropomodulin. [26] On average, six spectrin ends complex with each actin oligomer, creating an irregular network with an approximately hexagonal lattice. Each spectrin-actin junction is stabilized by the formation of a ternary complex with protein 4.1. The gene coding for protein 4.1 has been sequenced and localized to chromosome 1. The protein is composed of 622 amino acids; approximately 200,000 copies of this molecule are present in each red cell. Spectrin-actin interactions that are independently weak are greatly stabilized by protein 4.1. [26] This stabilization occurs through the direct interaction of protein 4.1 with both spectrin and actin. Adducin is yet another skeletal protein that stabilizes the interaction of spectrin with actin. However, in contrast to protein 4.1, adducin is much less abundant in the red cell, with only 30,000 molecules present in each cell. An interesting feature of adducin is that it is a target for the calcium-dependent regulating protein, calmodulin; as such, its ability to promote spectrin-actin interactions is regulated by intracellular calcium concentrations. The red cell membrane skeleton can be envisioned as an irregular network in which the basic unit is composed of a hexagonal lattice with six spectrin molecules. The structural model for organization of the membrane skeleton has been confirmed by high-resolution electron microscopy of isolated membranes. [27] The micrographs show a highly repeated and remarkably regular organization of the spectrin-actin-protein 4.1 complexes in which each complex is linked to adjacent complexes by multiple spectrin tetramers.

One physical linkage of the membrane skeleton to the lipid bilayer is accomplished by ankyrin (band 2.1), which simultaneously interacts with spectrin in the skeleton and band 3, localized in the bilayer. [14] [16] The gene coding for ankyrin has been sequenced and localized to chromosome 8. Ankyrin is 1,879 amino acids long. It contains distinct binding sites for both -spectrin and band 3 and is present in the red cell at 100,000 copies per cell. The ankyrin-binding site on -spectrin is located approximately 20 nm from the C-terminus. The second linkage between the skeleton and the bilayer is through the interaction of the integral protein glycophorin C with the skeletal component, protein 4.1. Other direct linkages also exist, but the nature of these in the red cell is less well understood. [26] [27] Through these linkages, the lipid bilayer is mechanically coupled to the membrane skeleton; this composite structure is responsible for the unique properties of the red cell membrane. [28] [29]

The discussion thus far may seem to imply that various protein-protein associations are fixed in space and time, but this is a simplistic view. During its time in circulation, the red cell constantly undergoes cycles of deformation and relaxation, requiring the membrane to accommodate extensive and dynamic changes in cell shape. In all likelihood this is accomplished by dynamic regulation of the protein interactions. Potential mechanisms for regulation of skeletal protein associations and skeletal protein-integral protein interactions include phosphorylation, variations in intracellular magnesium and 2,3-diphosphoglycerate (2,3-DPG) during the oxygenation-deoxygenation cycle, and calmodulin effects due to elevated intracellular calcium. [14] [28] Only limited information is available regarding these regulatory pathways, but most available evidence suggests that phosphorylation tends to lower the affinity of protein-protein interactions. For example, phosphorylation of protein 4.1 results in a fivefold decrease in its affinity for spectrin and in its ability to promote spectrin-actin association. Phosphorylation of -spectrin reduces membrane mechanical stability. Similarly, increased levels of intracellular 2,3-DPG and elevated cytoplasmic concentrations of calcium, in association with calmodulin, decrease membrane mechanical stability by destabilizing spectrin-actin-protein 4.1 and spectrin-actin-adducin interactions, respectively. Thus, the red cell membrane is a dynamic structure in which multiple protein-protein associations are subjected to regulation. The most important function of these protein assemblies is to provide the cell with a flexible yet mechanically resilient and stable membrane.

RED CELL MEMBRANE MECHANICS AND SKELETAL PROTEINS

During its 120-day life span, the erythrocyte must undergo extensive passive deformation and resist fragmentation. These two essential qualities require a highly deformable yet remarkably stable membrane. The property of membrane deformability determines the extent of membrane deformation that can be induced by a defined level of applied force. The more deformable the membrane, the less applied force is necessary to allow the cell to pass through the capillaries. By contrast, membrane stability is defined as the maximum extent of deformation that a membrane can undergo, beyond which it cannot completely recover its initial shape, that is, the point at which it fails. Normal membrane stability allows red cells to circulate without fragmenting, while decreased stability leads to cell fragmentation under normal circulating stresses.

A model designed to conceptualize how these membrane properties are regulated by the membrane components is presented in Figure 43 . [28] This model takes into account the known structure, associations, and stoichiometry of the skeletal proteins. In the nondeformed state, spectrin molecules exist in a folded confirmation. Reversible deformation of the red cell membrane occurs with a change in geometric shape, but at constant surface area. During reversible deformation, a rearrangement of the skeletal network occurs in which some spectrin molecules become uncoiled and extended, while others become more compressed and folded. Direct evidence for such reversible structural changes in the spectrin network has recently been documented. [29] With increased deformation, the membrane becomes increasingly extended; some of the spectrin molecules attain their maximal linear extension. This point is the limit of reversible deformability. A continued application of force would necessitate an increase in surface area and the breaking of junctional complexes. When the red cells are exposed to fluid forces great enough to require an increase in surface area, the membrane fails. This failure will occur at the weakest of the lateral protein-protein associations (spectrin-spectrin

Figure 4-3 Conceptual depiction of rearrangements in membrane skeleton during reversible deformation of red cells. Reversible deformation occurs with a change in geometric shape, but at a constant surface area. **(A)** Organization of membrane skeleton in the nondeformed membrane. **(B & C)** With increased deformation, the membrane becomes increasingly extended. Further extension beyond stage C would result in an increase in surface area and the breaking of junction points. This is the stage at which membrane fragmentation occurs. (
) protein 4.1-actin-spectrin junction; () spectrin-spectrin junction. Linear coils are spectrin dimer.

junction or spectrin-actin-protein 4.1 junction), leading to membrane fragmentation. Another form of membrane failure involves the separation of the lipid bilayer from the underlying membrane skeleton as a result of decreased cohesion between the bilayer and the membrane skeleton. A decrease in spectrin density beneath the membrane skeleton, or decreased numbers of linkages between the bilayer and the membrane skeleton, as a result of deficiencies in band 3, protein 4.2, or ankyrin leads to this form of membrane failure. By contrast, for the membrane to deform normally, the skeletal network must be able to undergo rearrangement and the spectrin molecules must be able to fold and unfold. Thus, an increase in intermolecular or intramolecular associations of the skeletal proteins or an increased association of integral membrane proteins such as band 3 with the skeletal network will markedly decrease membrane deformability. [7] Deformability and mechanical stability measurements of pathologic red cells with different mutant forms of membrane proteins, as well as of biochemically perturbed normal red cells, strongly support this model and point unequivocally to a crucial role for membrane proteins and their associations in regulating these two membrane properties. [6] [7]

ROLE OF THE MEMBRANE IN DETERMINING THE SHAPE AND DEFORMABILITY OF THE RED CELL

Cellular deformability is the term generally used to characterize the ability of the red cell to undergo deformation during flow. This property is influenced by three distinct cellular components: cell shape or cell geometry, which determines the ratio of cell surface area to cell volume; cytoplasmic viscosity, which is regulated by intracellular hemoglobin concentration; and membrane deformability. [6] [7] Membrane deformability, in and of itself, is regulated by multiple membrane properties, which include elastic shear modulus, bending modulus, and yield stress. Directly or indirectly, membrane components and their organization play an important role in regulating each factor that influences cellular deformability.

Cell Shape

The biconcave disk shape of the normal red cell creates an advantageous surface area-volume relationship, allowing the red cell to undergo marked deformation while maintaining a constant surface area. The normal human adult red cell has a volume of 90 fl and a surface area of 140 m^2 . If the red cell were a sphere of identical volume, it would have a surface area of only 98 m^2 . Therefore, the discoid shape provides half again as much surface area as would a sphere of equivalent volume, and it is this excess surface area of approximately 40 m^2 that allows the red cell to undergo extensive deformation. Most deformations occurring in vivo and in vitro involve no increase in surface area. The normal red cell can undergo large linear extensions of up to 230% of its original dimension, but an increase of even 34% in surface area results in cell lysis. Because the acquisition and maintenance of a favorable surface area-volume relationship is crucial to red cell function, it is useful to understand how the cell acquires a discoid shape during its development from a nucleated erythroid precursor cell. The immediate

Figure 4-4 Morphology of cells during reticulocyte maturation. Left column, phase-contrast microscopy; middle column, scanning electron microscopy; right column, transmission electron microscopy. The nuclear extrusion process is illustrated in the top row. The least mature reticulocytes, which are motile and multilobular, are shown in the second row. The more mature reticulocytes, which are cup-shaped and nonmotile, are depicted in the third row. Mature red cells are illustrated in the bottom row.

precursor of the mature discocytic red cell is the nonnucleated reticulocyte, produced when the normoblast extrudes its nucleus (Fig. 44). In contrast to red cells, these immature reticulocytes are multilobular and motile, contain mitochondria and ribosomes, and synthesize hemoglobin and certain membrane components, including protein 4.1 and glycophorin C. Reticulocytes exhibit much less cellular deformability and mechanical stability than are displayed by mature red cells. Both deformability and mechanical stability improve during maturation. [30] In 23 days, motile reticulocytes evolve further in the bone marrow, first to become deep cup-shaped nonmotile cells that still contain ribosomes, and finally to mature, fully hemoglobinized discocytic RBCs lacking organelles. Major reorganizations of membrane phospholipids, skeletal proteins, and integral proteins accompany the acquisition of discoid shape and enhanced deformability. These reorganizations include loss of membrane lipids, loss of integral proteins such as transferrin receptors, insulin receptors, and fibronectin receptors, and a major reorganization of the skeletal protein network.

Having acquired the discoid shape with its favorable geometric parameters during reticulocyte maturation, the red cell must maintain this favorable surface area-volume relationship during its circulating life span. Either membrane loss, leading to reduction in surface area, or an increase in cell water content, leading to an increase in cell volume, will create a more spherical shape with less redundant surface area. This loss of surface area redundancy leads to decreased cellular deformability, compromised red cell function, and reduced survival. Skeletal protein defects involving spectrin, ankyrin, band 3, or protein 4.1 lead to a mechanically unstable membrane, resulting in cell fragmentation and generation of cells with reduced surface area in congenital hemolytic anemias, such as hereditary spherocytosis and hereditary elliptocytosis. [31] [32] [33] Similarly, partial phagocytosis of the red cell by macrophages leads to reduced surface area and generation of spherocytes in certain immune hemolytic anemias. By contrast, in some forms of hereditary stomatocytosis, increased cell volume due to deranged volume regulation as a result of a membrane defect generates red cells with reduced redundant surface area. Increased osmotic fragility is a characteristic feature of all these red cell populations with less than normal surface redundancy. A different type of red cell abnormality is manifested in liver disease. In this instance, elevated membrane cholesterol content causes increased cell surface area; in the setting of normal cell volume, this results in higher than normal redundant surface area. This excess surface area, in turn, is manifested morphologically by the presence of target cells and functionally by increased osmotic resistance. Conversely, decreased cell volume in the setting of a normal membrane surface area (e.g., in thalassemic red cells as well as in hemoglobin CC- and hemoglobin EE-containing red cells) generates the same abnormality. Abnormal red cell shape and altered cell geometry in various red cell disorders are thus characterized by the inability of these cells to maintain their surface area and control their cell volume appropriately as a result of membrane defects involving lipids, integral and skeletal proteins, or abnormal interactions of mutant hemoglobins with the red cell membrane.

Cytoplasmic Viscosity

Cytoplasmic viscosity is regulated by cellular hemoglobin concentration, and consequently by cell water content. Viscosity is another regulatory component of cellular deformability.[6] As the hemoglobin concentration increases from 27 to 35 g/dl, the viscosity of the hemoglobin solution increases from 5 to 15 centipoise (cP) (the viscosity of water is 1 cP). The distribution of red cell hemoglobin concentrations in whole blood from normal persons is 2735 g/dl. In this range of hemoglobin concentrations, the contribution of cytoplasmic viscosity to cellular deformability is negligible. Concentrations of greater than 37 gdl, however, increase viscosity exponentially, reaching 45 cP at 40 g/dl, 170 cP at 45 g/dl, and 650 cP at 50 g/dl. At these levels, the contribution of cytoplasmic viscosity to cellular deformability begins to dominate. Thus, the failure of normal-volume homeostasis mechanisms, which results in cellular dehydration, can limit cellular deformability owing to increased cytoplasmic viscosity. Mutations in proteins involved in transport processes, alterations induced in these proteins as a result of membrane oxidation, or other changes due to mutant hemoglobin interacting with the membrane can lead to marked cellular dehydration. Reduced cellular deformability in hereditary xerocytosis, sickle red cells, and hemoglobin CC red cells is primarily due to increased cytoplasmic viscosity as a consequence of cellular dehydration. [4] [6] The lipid components and the integral proteins of the red cell membrane involved in transport function play a crucial role in volume homeostasis of the red cell in order to maintain the cellular hemoglobin concentration at levels that do not unduly influence the ability of the cell to deform.

Membrane Material Properties

The mechanical behavior of the red cell membrane is complex. Its responses depend on the duration and magnitude of applied stresses. [6] [7] [34] [35] At small values of applied force for short duration, the red cell membrane behaves as a viscoelastic solid; that is, it is capable of undergoing large elastic extensions and completely recovers its initial shape. A reversible unfolding and refolding

of spectrin networks is crucial for the elastic behavior of the membrane. By contrast, when small forces are applied over a long period, or when large forces are applied for a short period, the membrane yields and is unable to recover its initial shape. Under these circumstances, the membrane exhibits permanent plastic deformation owing to inability of the skeletal network to recover its prestressed configuration. Whereas normal red cells completely recover their shape following repeated cycles of deformation in the circulation, pathologic red cells with weakened junctions between skeletal proteins fail to recover their initial shape and undergo plastic deformation. This explains in part the generation of elliptocytic shapes in congenital hemolytic anemias with defective spectrin oligomerization and decreased spectrin-actin-protein 4.1 association. The generation of irreversibly sickled cells in sickle cell anemia is also the result of plastic deformation of the membrane due to skeletal protein reorganization during repeated cycles of sickling and unsickling in the circulation.

In addition to contributing significantly to the regulation of the elastic behavior of the membrane, the membrane skeleton has a crucial role in regulating membrane mechanical stability. The junctional complexes in the skeletal network are the key regulators of mechanical stability. Decreased membrane mechanical stability is a hallmark of hereditary elliptocytosis due to either weakened spectrin-spectrin association as a result of mutations in either - or -spectrin or a weakened spectrin-actin-protein 4.1 junction due to mutations in protein 4.1. [6] [7] A decrease in the number of linkages between the bilayer and the membrane skeleton also results in membrane surface area loss such as that seen in hereditary spherocytosis. By contrast, an increased number of linkages between the bilayer and the membrane skeleton results in decreased membrane deformability.[6] [7] Although substantial changes in lipid composition of the membrane have little effect on membrane mechanical properties, small changes in individual protein components can profoundly alter membrane behavior. The integral proteins in association with the skeletal protein network determine the complex mechanical behavior of the red cell membrane.

The complex and regulated assembly of lipids and proteins in the membrane lends the unique shape and deformability characteristics to the red cell, enabling it to survive its tortuous and at times turbulent journey through the vasculature. Derangement in the structural organization as a result of changes in any of the individual components of the membrane, either lipid or protein moieties, leads to altered cell shape or deformability characteristics, or both, the hallmarks of many red cell disorders.

Membranes of other cell types appear to be organized in a manner analogous to the red cell membrane. Clearly, however, these membranes need not exhibit the same adaptations to the mechanical, chemical, and osmotic forces of the circulation. Rather, membrane cytoskeletal interactions analogous to those just described seem to maintain the distinctive shape and organization of the cell surfaces that are crucial to the organization of tissues. Examples include the polarity of ion transport molecules in epithelial cells, the localization of tight junctions in epithelial cells and endothelial linings, and the dynamic reorganization (capping or clustering) of receptors or antigens that occurs during ligand or antibody binding. Unfortunately, the biochemical basis for the membrane interactions is insufficiently understood to be discussed in this chapter. For our purposes, it is sufficient to note that similar lipids, integral proteins and peripheral proteins, seem to participate, and that analogous interactions seem to mediate the nonrandom organization of distinct membrane domains on different regions of the cell surface. In other words, the membrane cytoskeleton appears not only to strengthen the membrane but also to limit its diffusional degrees of freedom, thereby promoting topological organization.

SIGNAL TRANSDUCTION: RELIANCE ON ALTERED MEMBRANE ORDER

Many signals are propagated across the plasma membrane by the passage of effector molecules, such as steroid hormones, Ca^{2+} ions, Na^{+} or K^{+} ions, lipophilic drugs, and so forth. Usually such events involve specific membrane proteins that function as pores or transport molecules. Alternative pathways of signal transduction do not involve the passage of molecules across the membrane but instead rely on changes in the organization of the membrane to transmit information. Four such signal transduction mechanisms are depicted in Figure 45 . All involve rearrangements of either integral or peripheral membrane proteins, or of certain membrane lipids, as an essential step in the transduction process. None requires the net passage of molecules across the bilayer. Two involve the generation of second messengers (cAMP and IP_3) at the cytoplasmic face of the membrane.

One of the first signal transduction pathways to be clearly elucidated was that involving the -adrenergic receptor. Subsequently it was recognized that this receptor is just one of many hormone receptors coupled to their effector proteins by the intermediary of a guanyl nucleotide-binding protein (G protein). (Fig. 45A).[36] [37] Other receptors acting via heterotrimeric G proteins include the $_2$ -adrenergic receptor (a cyclase inhibitory receptor), the M_2 -muscarinic receptor, and all of the rhodopsins. These receptors are all integral membrane proteins with an approximately globular structure composed of seven transmembrane -helices (similar to bacteriorhodopsin). The nature of the G protein varies between tissues, as does the nature of the effector protein. For example, stimulation of the -adrenergic receptor releases a G protein that subsequently activates adenylate cyclase to produce cAMP, whereas stimulation of rhodopsin (by light) energizes a different G protein (called transducin), which then activates phosphodiesterase and leads to the conversion of cGMP to 5 GMP. The product of the *ras* oncogene (p21ras) is also a G protein of sorts, except that it appears to function as a monomer. In yeast (*Saccharomyces cerevisiae*), this protein stimulates adenylate cyclase. Its function in mammalian cells remains uncertain. However, regardless of the variability in the specific molecules participating in different G-protein receptor systems, all are activated by an allosteric rearrangement within an integral transmembrane protein, followed by a redistribution of specific peripheral membrane proteins (the G-protein complex).

A similar rearrangement of peripheral proteins may also accompany activation of the PIP_2 -IP_3 signal pathway. In this pathway, there is a rearrangement of membrane lipid as well, due to the hydrolysis of PIP_2 to DAG (Fig. 45B). As with the -adrenergic receptor, recent evidence[36] [38] suggests that rearrangement of a G protein is involved in the activation of phospholipase C. The activation of this enzyme has two consequences: (1) the release of IP_3 as a soluble second messenger and (2) the conversion of PIP_2 to DAG in the membrane. DAG enhances the activity of protein kinase C and its association with the cytoplasmic face of the membrane. [39] Thus, signaling via the PIP_2 pathway involves a transmembrane allosteric signal, followed by the rearrangement of phospholipid and peripheral membrane.

Another family of receptors includes those that recognize polypeptide growth factors and those that possess tyrosine kinase activity. [40] [41] Such receptors include epidermal growth factor receptor (EGF-R), platelet-derived growth factor, and colony-stimulating factor-1 receptors. They all share a tripartite domain structure similar to that of glycophorins, with a single -helix spanning the membrane. On binding of ligand to their extracellular domain, tyrosine kinase activity is elicited in the cytoplasmic domain. This remarkable effect is propagated across the membrane (using a single stretch of -helix) by the

Figure 4-5 Signal transduction pathways that require changes in membrane order. **(A)** Cascades utilizing cyclic nucleotides as second messengers rely on a redistribution of the peripheral G-protein unit (a heterotrimer composed of -, -, and -subunits) from the transmembrane receptor to adenylate cyclase (or other catalytic unit, such as transducin). The same event occurs with a different G-unit for inhibitory cascades. **(B)** Pathways based on the hydrolysis of PIP_2 probably require the redistribution of a G-protein-like unit from the transmembrane receptor to phospholipase C. The hydrolysis of PIP_2 leads to a redistribution of these lipids in the membrane, with DAG stimulating the binding of C-kinase to the membrane and the release of protein 4.1 from the membrane. **(C)** The binding of ligands to receptors of the epidermal growth factor type (EGF-R) promotes the self-association of the receptor. Self-association appears to be a necessary and probably sufficient signal to activate the latent tyr-kinase activity resident in the cytoplasmic domain of EGF-R. **(D)** Receptor clustering is induced by the binding of an external polyvalent ligand. In the case of B lymphocytes, if the cluster achieves a sufficient size (an immunon), cell activation will occur. [44] Note that in all of the pathways depicted here, no molecules pass across the membrane.

ligand-induced dimerization of the receptor in the plane of the membrane. Once two receptors are brought together, their cytoplasmic domains interact in a way that evokes their latent tyrosine kinase activity. It is uncertain whether ligand-induced allosteric changes in the external domain play a role in this process or whether the growth factor peptide itself may cross-link two receptors. Given that the transmembrane domain of glycophorin A may control its dimerization, it is even possible that ligand-induced changes in the transmembrane domain of the growth factor receptors may activate their self-association. In any event, it appears that the actual propagation of the signal across the membrane, as measured by the activation of tyrosine kinase activity, requires only a change in the organization of the receptors in the plane of the membrane.

Many other receptors also appear to transmit their message to the cell interior via rearrangements in the distribution of integral and peripheral membrane proteins (Fig. 45D). Examples include integrin-mediated signaling[42] or the homotypic binding of adhesion proteins such as those of the cadherin family. [43] Clustering of receptors with weak affinity for cytoplasmic proteins might activate events in the cell that result in a strong binding site for cytoplasmic proteins. A similar mechanism has been proposed for the T-cell-independent activation of B lymphocytes by polyvalent antigens. [44] The activation of B lymphocytes by such antigens appears to be a threshold phenomenon, since it was found that only certain polyvalent ligands (polyacrylamides with more than 20 DNP haptens per polymer unit) were capable of activating the lymphocytes. Presumably, the threshold effect arises from the need to form confluent patches of surface receptors of some minimal size, since occupancy of the same number of receptor sites by ligands of lesser valency does not activate the cells. The receptor clusters created by such activation-competent ligands were called immunons.[44] Very recent work with T cells also indicates that a similar process involving the ligand-specific oligomerization of T-cell receptor molecules (TCR + MHC) sends a biochemical signal to the cell. In these cells, the size of the oligomers involving two to six ternary complexes was sufficient to send a graded signal to the cell. [45]

Finally, the clustering of membrane proteins into functional signaling complexes need not be driven only by protein-protein interactions. Recent evidence indicates that the dynamic clustering of sphingolipids and cholesterol in the plane of the membrane, so as to form rafts of laterally separated lipid microdomains, is yet another mechanism by which order in the membrane is achieved. Such rafts form relatively stable microdomains in which certain membrane- and GPI-linked proteins are stably associated. It is believed that the concerted movement of such lipid islands through the secretory pathway (with their entrapped proteins) is one mechanism by which selective targeting of proteins to the apical pole of epithelial cells is achieved. [46] The clustering of such protein-laden lipid rafts, via direct lipid interactions (that

are cholesterol dependent), is another way that the various components of membrane-based signaling systems can be brought into proximity.

Chapter 5 - Cell Adhesion

Rodger P. McEver

INTRODUCTION

Cell adhesion is essential for the development and maintenance of multicellular organisms. Cell-cell and cell-matrix contacts facilitate intercellular communication and define the architecture of organs. The regulated nature of cell adhesion is particularly evident in the hematopoietic system, where cells routinely make transitions between nonadherent and adherent phenotypes during differentiation and in response to stimuli in the circulation or extravascular tissues.

In the bone marrow, proliferation and differentiation of hematopoietic stem cells is controlled not only by soluble growth factors, but also by adhesion to stromal cells and matrix molecules. Weakening of these adhesive bonds is required for mature blood cells to enter the circulation. Circulating erythrocytes normally remain nonadhesive until they are finally cleared by the reticuloendothelial system. Other circulating cells often participate in regulated adhesive events during their life span. For example, prothymocytes adhere to components of the thymus, where they undergo further maturation before reentering the circulation. Lymphocytes regularly stick to the specialized high endothelial venules of lymphoid tissues, migrate into these tissues for sampling of processed antigens, and then exit via the lymphatics. During inflammation, specific classes of leukocytes roll on the endothelium, then adhere more tightly, and finally emigrate between endothelial cells into the tissues. There, neutrophils and monocytes phagocytose invading pathogens, whereas lymphocytes adhere to antigen-presenting macrophages. During hemorrhage, platelets stick to exposed subendothelial matrix components, spread, and recruit additional platelets into large aggregates that serve as an efficient surface for thrombin and fibrin generation. Leukocytes also adhere to activated platelets, a mechanism for linking hemostatic and inflammatory responses. The endothelial cells express molecules that affect the adhesiveness of platelets or leukocytes. Tight contacts between adjacent endothelial cells also limit access of blood cells to the underlying tissues.

ADHESION MOLECULES

Cells adhere through noncovalent bond formation between macromolecules on cell surfaces with macromolecules on other cell surfaces or in extracellular matrix. These interactions involve either protein-protein or protein-carbohydrate recognition. Although some adhesion molecules are expressed only by blood or endothelial cells, most are also synthesized by other cells. Many adhesion molecules can be grouped into families according to related structural and functional features.

Extracellular Matrix Proteins

The principal constituents of the extracellular matrix are adhesive proteins and proteoglycans. The major proteins are von Willebrand factor (vWF), thrombospondin, collagen, fibronectin, laminin, and vitronectin. These proteins are large, often highly extended, and consist of multiple domains with different binding functions. In some proteins such as fibronectin, alternative splicing can increase diversity by producing molecules with variable numbers of domains. The many binding domains allow adhesive proteins to interact with each other as well as with cell-surface receptors, resulting in multipoint contacts that stabilize matrix structure. One large adhesive protein, fibrinogen, is found predominantly in plasma but may also be deposited in exposed subendothelial matrix following vascular injury. Fibronectin, vitronectin, thrombospondin, and vWF are located predominantly in the extracellular matrix, but are also found in plasma. Several adhesive proteins are also stored in -granules of platelets, where they are secreted following platelet activation at sites of hemorrhage.

Proteoglycans contain protein cores to which are covalently attached many glycosoaminoglycans, long linear polymers of repeating disaccharides. Most proteoglycans are in the extracellular matrix, but some are anchored on cell surfaces through a core protein that contains a membrane-spanning domain. Hyaluronan is a unique glycosoaminoglycan that forms polymers with molecular masses up to several million that are not covalently attached to a protein. Hyaluronan forms noncovalent interactions with globular domains on the protein core of proteoglycans and with a small molecule called link protein. The resultant hyaluronan-proteoglycan complexes can become very large, contributing to the structural stability of matrix. Hyaluronan can also bind to cell-surface receptors (see following).

Integrins

Integrins are a broadly distributed group of cell-surface adhesion receptors that consist of noncovalently associated - and -subunits (Fig. 51 and Table 51). There are more than 15 - and 8 -chains that pair in many, but not all, of the possible combinations. All blood cells have several different integrins. The four $_{2}$ integrins, each paired with a unique -subunit, are expressed only by leukocytes, and the $_{IIb\ 3}$ integrin (also known as glycoprotein IIb/IIIa or GPIIb/IIIa) is expressed only by megakaryocytes and platelets. Multidomain adhesive proteins of the extracellular matrix are ligands for many integrins. Some integrins bind to specific domains of several different proteins, and some adhesive proteins bind to several different integrins. These interactions generally mediate cell-matrix adhesion. Cell-cell interactions result from integrin recognition of cell-surface members of the immunoglobulin superfamily. Binding of fibrinogen to $_{IIb\ 3}$ integrins on adjacent platelets serves as a molecular bridge that promotes platelet aggregation. Furthermore, fibrinogen simultaneously binds to the $_{M\ 2}$ integrin on leukocytes and to an immunoglobulin-like receptor on endothelial cells, promoting leukocyte adhesion to the endothelium.

Immunoglobulin-like Receptors

Immunoglobulin superfamily members contain a variable number of disulfide-stabilized -barrel motifs (also found in antibodies) that are linked to transmembrane and cytoplasmic domains (Fig. 51 and Table 52). The immunoglobulin-like motif provides a framework to which specific recognition structures for other proteins can be added. Some of these motifs also

Figure 5-1 Schematic diagrams of several types of cell-surface adhesion receptors. Integrins consist of noncovalently linked - and -subunits, both of which contribute to ligand binding. The platelet $_{IIb\ 3}$ integrin is illustrated. Immunoglobulin-like receptors contain a variable number of immunoglobulin homology domains, some of which bind ligands, while others extend the ligand-binding domains from the membrane. Shown is VCAM-1, which contains seven immunoglobulin domains. The platelet GPIb/IX/V complex consists of several leucine-rich protein subunits. CD44 contains an N-terminal domain that binds to hyaluronan. Each of the selectins contains an N-terminal carbohydrate-recognition domain that binds sialylated and fucosylated oligosaccharides on specific cell-surface glycoprotein ligands. Illustrated is P-selectin, the largest of the three selectins.

TABLE 5-1 -- Integrins on Blood Cells

Integrin Designation	Other Names	Expressed By	Ligand	Function
$_{1\ 1}$	VLA-1	Leukocytes, other cells	Collagens, LM	Adhesion to ECM
$_{2\ 1}$	VLA-2 GPIa/IIa	Leukocytes, platelets, other cells	Collagens, LM	Adhesion to ECM
$_{3\ 1}$	VLA-3	Leukocytes, other cells	Collagens, LM, FN	Adhesion to ECM

TABLE 5-2 -- Immunoglobulin-like Receptors

Name	Other Names	Expressed By	Ligand	Function
ICAM-1		Macrophages, EC, other cells	M 2 , L 2 , FIB	T-cell responses, leukocyte adhesion to EC
ICAM-2		EC	L 2	Leukocyte adhesion to EC
ICAM-3		Leukocytes	L 2 , D 2	T-cell responses, leukocyte aggregation
PECAM-1	CD31	Leukocytes, platelets, EC	PECAM-1, V 3 ?	EC junctions, leukocyte transmigration, platelet signaling?
VCAM-1	INCAM-110	Activated EC, smooth muscle cells	4 1 , 4 7	Mononuclear cell adhesion to EC
MAdCAM-1		EC of Peyers patches	4 7	Lymphocyte homing
CD2		T cells	LFA-3[a]	T-cell responses
CD4		T cells	Class II MHC[a]	T-cell responses
CD8		T cells	Class I MHC[a]	T-cell responses
CD3	T-cell receptor	T cells	Antigen on MHC[a]	T-cell responses
CD22		B cells	Sialylated glycoproteins	B-cell adhesion and signaling
Sialoadhesin		Macrophages in bone marrow and lymphoid tissue	Sialylated glycoproteins	Hematopoiesis?

Abbreviations: ICAM-1, -2, -3, intercellular adhesion molecules; PECAM-1, platelet and endothelial cell adhesion molecule-1. For EC, FIB, LFA, MAdCAM-1, and VCAM-1, see Table 51 footnote.

[a]LFA-3 and classes I and II MHC molecules are also immunoglobulin-like receptors.

recognize glycoconjugates (see following). The immunoglobulin-like molecules intercellular adhesion molecule (ICAM)-1, ICAM-2, and vascular cell adhesion molecule (VCAM)-1, expressed on endothelial cells, as well as ICAM-3, expressed on leukocytes, mediate cell-cell contact through recognition of specific integrins on leukocytes. Interactions between immunoglobulin-like molecules help to mediate adhesion between T cells and antigen-presenting cells. Thus, the immunoglobulin-like molecules CD8 and CD4 on T cells bind to the conserved membrane-proximal domains of class I and class II MHC proteins, respectively, whereas the T-cell receptor (CD3) binds to the polymorphic antigen-presenting domain. In addition, the immunoglobulin-like protein CD2 on T cells binds to the immunoglobulin-like protein leukocyte functionassociated antigen-3 (LFA-3) on antigen-presenting cells. In many tissues, the immunoglobulin-like neural cell adhesion molecule (NCAM) mediates cell-cell contact through homotypic interactions, that is, binding of an NCAM molecule on one cell to an NCAM molecule on another cell. Similarly, the immunoglobulin-like receptor platelet and endothelial cell adhesion molecule-1 (PECAM-1) (CD31) may use homotypic interactions to promote contacts between adjacent endothelial cells and mediate adhesion of leukocytes to platelets and endothelium.

Other Adhesion Receptors That Mediate Protein-Protein Interactions

Cadherins are cytoskeletally linked membrane proteins that mediate cell-cell contact in many organs through homotypic binding to cadherins on adjacent cells (Table 53). Cadherins have not been described on blood cells, but are found on endothelial cells, where, like PECAM-1, they help form cell junctions.

The GPIb/IX/V complex on platelets consists of leucine-rich protein subunits (Fig. 51). Under conditions of high shear like those found in the arterial circulation, this complex promotes the initial platelet adhesion to injured vessels by binding avidly to vWF exposed in the subendothelium. The GPIb complex is also expressed by endothelial cells exposed to inflammatory cytokines such as tumor necrosis factor-, but its function on the endothelium is less well understood.

TABLE 5-3 -- Other Adhesion Receptors

Name	Other Names	Expressed By	Ligand	Function
Cadherins		EC, many other cells	Homotypic binding	Formation of EC junctions
GPIb/IX/V		Platelets, activated endothelial cells	vWF	Platelet adhesion to ECM under shear
CD36	GPIV	Platelets, many other cells	Collagens, TSP	Platelet adhesion to ECM
CD44		Leukocytes, other cells	Hyaluronan, serglycin	Lymphopoiesis, lymphocyte activation?
Natural killer cell receptors		Natural killer cells	Carbohydrate?, MHC molecules	Recognition of virus-infected or other foreign cells

For abbreviations, see Table 51 footnote.

CD36 is a receptor with at least two membrane-spanning domains that is expressed on many cell types. On platelets, it has been implicated as a receptor for collagen and perhaps for thrombospondin; both interactions could facilitate adhesion to subendothelial matrix at sites of hemorrhage.

Lectin Adhesion Receptors

CD44 is an unusual transmembrane glycoprotein expressed to variable degrees on many subsets of leukocytes (Fig. 51). It has a membrane-distal domain that is structurally related to link protein of extracellular matrix and, like link protein, can bind to hyaluronan. CD44 also binds to serglycin, a proteoglycan secreted by hematopoietic cells. The hyaluronan-binding function of CD44 may modulate a number of leukocyte responses. The most clearly demonstrated function is in lymphopoiesis, where maturation of lymphocyte precursors requires contacts with bone marrow stromal cells bearing surface hyaluronan. CD44-hyaluronate interactions may also promote lymphocyte entry to and transit through organized lymphoid tissues. The membrane-proximal regions of CD44 are structurally diverse

because of the insertion of variable numbers of domains through alternative splicing. These insertions may regulate the ability of CD44 to bind hyaluronan and may mediate postbinding events that affect cell signaling.

The selectins are a group of three asymmetric receptors that terminate in a membrane-distal carbohydrate-recognition domain related to those in Ca^{2+} -dependent (C-type) animal lectins such as the hepatic asialoglycoprotein receptor (Fig. 51). L-selectin is expressed on leukocytes, E-selectin on cytokine-activated endothelium, and P-selectin on platelets and endothelial cells exposed to secretagogues such as thrombin (Table 54). The selectins mediate leukocyte adhesion to platelets, endothelium, or other leukocytes through Ca^{2+} -dependent interactions of the carbohydrate-recognition domains with cell-surface carbohydrates on apposing cells. High-affinity binding appears to require specific carbohydrate structures that are displayed on a limited number of membrane glycoproteins. The best characterized glycoprotein ligands for selectins are mucins that have large numbers of clustered, sialylated O-linked oligosaccharides. Site-specific construction of O-glycans with specific sialylated, fucosylated, and in some cases sulfated moieties is required for these mucins to bind optimally to selectins. In the case of one mucin, P-selectin glycoprotein ligand-1 (PSGL-1), sulfation of tyrosine residues near a specific O-glycan is required for binding to P- and L-selectin.

Natural killer cells express a group of membrane proteins that are distinct from the selectins but also have membrane-distal C-type carbohydrate-recognition domains. Although these receptors are important for interactions of natural killer cells with target cells, their carbohydrate-recognition functions have not been established.

I-type lectins are a subgroup of membrane proteins of the immunoglobulin superfamily that bind to carbohydrates instead of proteins (Table 52). The first two N-terminal domains appear to be necessary and sufficient for carbohydrate recognition. The N-terminal domain is a V-type structure that includes an unusual disulfide bond that is not found in the more common C-type immunoglobulin domains. I-type lectins bind well to sialylated glycans on some but not all glycoproteins. Depending on the lectin, recognition requires that the sialic acid be either 2,6- or 2,3-linked to an underlying galactose residue. The functions of I-type lectins have not been fully defined. CD22, expressed on B cells, may promote adhesion to other leukocytes. Sialoadhesin, expressed on bone marrow macrophages, may regulate hematopoietic cell differentiation.

LIGAND BINDING VERSUS CELL ADHESION

Like all macromolecular interactions, adhesion molecules bind to each other with equilibrium affinities that are defined by their on and off rates. However, the efficiency of cell adhesion is not simply a function of the solution-phase equilibrium affinities of adhesion molecules for one another. Adhesion molecules in cell membranes and matrix are primarily limited to two dimensions, and even low-affinity molecular interactions may allow time for additional bonds to form along the plane of cell contact, stabilizing adhesion. The efficiency of cell attachment, and the ensuing strength of adhesion, may reflect multiple factors that dictate the probability of bonds forming between adhesion molecules on cell or matrix surfaces. The requirements for cell attachment are particularly stringent in the circulation, where

TABLE 5-4 -- **Selectins**

Name	Other Names	Expressed By	Ligand[a]	Ligands Expressed By	Function
P-selectin	CD62P, GMP-140, PADGEM	Thrombin-activated platelets and EC, cytokine-activated EC	PSGL-1	Leukocytes	Leukocyte adhesion to activated EC and platelets
E-selectin	CD62E, ELAM-1	Cytokine-activated EC	ESL-1, others	Leukocytes	Leukocyte adhesion to activated EC

Abbreviations: EC, endothelial cells; ELAM-1, endothelial leukocyte adhesion molecule-1; ESL-1, E-selectin ligand-1; GlyCAM-1, glycosylation-dependent cell adhesion molecule-1; GMP-140, granule membrane protein-140; LAM-1, leukocyte adhesion molecule-1; LECAM-1, leukocyte endothelial cell adhesion molecule-1; PADGEM, platelet activationdependent granule external membrane protein; PSGL-1, P-selectin glycoprotein ligand-1.

[a] The selectins bind to sialylated, fucosylated, and (in some cases) sulfated oligosaccharides on specific glycoproteins, of which only some have been identified.

platelets and leukocytes must rapidly adhere to the blood vessel wall under shear conditions. Factors that affect bond formation include the number of adhesion molecules on a cell or matrix surface, the distance the binding domain of an adhesion receptor protrudes from the cell membrane, the lateral mobility of receptors, and the clustering of receptors on microvilli or other membrane domains. Cell adhesion can be further stabilized by events that occur after bond formation between adhesion molecules. For example, the cytoplasmic domains of the integrins, cadherins, CD44, L-selectin, and some immunoglobulin-like molecules interact with cytoskeletal components, allowing clustering of receptors into surface patches that strengthen adhesion and promote cell spreading or migration.

REGULATION OF ADHESION RECEPTORS

To prevent inappropriate interactions of cells with each other or with extracellular matrix, the expression and function of adhesion receptors must be tightly controlled. Three primary control mechanisms are used: (1) the rate of synthesis of the receptor, (2) the time the receptor is displayed on the cell surface, and (3) the binding affinity/avidity of the receptor for ligands (Table 55). All these mechanisms are used to control interactions of blood and vascular cells, examples of which are given following.

Regulation of Synthesis

The synthesis of many adhesion receptors is regulated. Erythroid precursors synthesize integrins that mediate their interactions with stromal cells and with extracellular matrix in the bone marrow. As the precursors mature, synthesis ceases, resulting in loss of expression of cell-surface integrins by the time a mature erythrocyte enters the circulation. Lymphocyte precursors synthesize CD44 during differentiation in the bone marrow, stop synthesis prior to release, and resume synthesis during maturation in the thymus. On exposure to antigens, immunologically naive lymphocytes synthesize increased amounts of several adhesion receptors during their conversion to the memory phenotype; this process presumably allows these cells to become more adhesive in response to a subsequent antigenic challenge. When exposed to inflammatory cytokines such as tumor necrosis factor- and interleukin-1, endothelial cells transiently increase synthesis of E- and P-selectin, ICAM-1, and VCAM-1, resulting in an adhesive surface for leukocytes.

Regulation of Surface Expression

The surface expression of some adhesion receptors is tightly controlled. L-selectin is present on the plasma membrane of leukocytes, where it is available to bind to inducible ligands on the endothelial cell surface. Stimulation of the leukocyte causes L-selectin to be shed into the plasma by proteolytic cleavage, a mechanism for down-regulating adhesion. P-selectin is constitutively synthesized by megakaryocytes (where it is incorporated into platelets) and by endothelial cells. Rather than being directly delivered to the plasma membrane, however, it is sorted into secretory storage granules: the -granules of platelets and the Weibel-Palade bodies of endothelial cells. On stimulation of these cells by agonists such as thrombin or histamine, P-selectin is rapidly transported to the cell surface during fusion of granule membranes with the plasma membrane. Once on the surface of the endothelium, both E- and P-selectin are internalized and delivered to lysosomes for degradation. The cytoplasmic domain of P-selectin contains signals that direct sorting into secretory granules, internalization through coated pits of the plasma membrane, and movement from endosomes to lysosomes; the latter two signals are probably also present in the cytoplasmic domain of E-selectin. The net result of these events is to control the duration that E- and P-selectin are exposed on the endothelium, where they can mediate adhesion of leukocytes. Activation of leukocytes also mobilizes a pool of $_{2}$ integrins from storage compartments to the plasma membrane, although some of these molecules are also constitutively expressed on the cell surface. Finally, platelet activation redistributes a portion of the GPIb/IX/V complexes from ligand-accessible positions on the plasma membrane to sequestered, invaginated membrane domains known as the surface-connected canalicular system. This process, which requires interactions of the cytoplasmic domain of GPIb/IX/V with the cytoskeleton, may serve to down-regulate GPIb-mediated adhesion of platelets to immobilized vWF.

Regulation of Binding Affinity

Regulation of binding affinity is an important control mechanism for other adhesion receptors. Many integrins are constitutively present on the cell surface but interact poorly with their ligands. Cell activation by a number of agonists induces conformational changes in integrins so that they effectively recognize their ligands. An example is the $_{IIb\ 3}$ integrin, which requires platelet stimulation to bind fibrinogen. If this binding affinity were not regulated, circulating platelets would indiscriminately aggregate in the fibrinogen-rich plasma milieu. The mechanisms for activation-induced affinity increases in integrins are still being defined. The cytoplasmic domains of integrins can exert both positive and negative influences on binding affinity. Binding of specific cytoplasmic proteins to these domains may propagate structural changes to the extracellular ligand-binding regions of the integrins. Low-affinity ligand binding may stabilize the active conformation of integrins, which may explain why integrins on unactivated cells will sometimes bind to immobilized, multivalent adhesive proteins but not to the same proteins in solution. Cellular activation may also regulate the

TABLE 5-5 -- Regulation of Adhesion Receptors

Mechanism	Example

CELL SIGNALING THROUGH ADHESION MOLECULES

In addition to their roles in cell-cell and cell-matrix contacts, adhesion molecules may affect cell signaling through indirect or direct mechanisms. Proteoglycans in the extracellular matrix can sequester growth factors that can be released to bind to surface receptors on nearby cells. Some chemoattractants bind to proteoglycan-like molecules on the surface of endothelial cells, where they can activate adherent leukocytes. Binding of adhesive ligands to cell-surface integrins, GPIb/IX/V, CD44, cadherins, CD36, PECAM-1, selectins, and perhaps other receptors can directly trigger intracellular events. The consequences of these signals include increases in affinity/avidity of other adhesion receptors for their ligands, shape change, secretion, proliferation, synthesis of cytokines and other molecules, and migration. In some cases, binding of a monovalent adhesive ligand to a receptor may induce a signal. More commonly, signaling requires cross-linking of several receptors through interactions with multivalent ligands in matrix or on apposing cells.

Many of the recent studies on adhesion receptor signaling have focused on integrins. Binding of the same ligand to different integrins can mediate different responses in the same cell. Furthermore, ligand binding to the same integrin expressed in different cells can result in different signals. These data suggest that very specific interactions occur between ligand-occupied integrins and intracellular components. The cytoplasmic domains of integrins are probably essential for initiating signaling. Phosphorylation of such domains, while an attractive candidate for regulation, has not been shown to have important effects on cellular responses in the integrins that have been studied. However, tyrosine kinases have been localized at the interaction zones between integrins and the cytoskeleton, and tyrosine phosphorylation of a number of proteins accompanies integrin-mediated cell signaling. The localization of tyrosine kinases near the cytoplasmic domains of integrins is analogous to the *lck*-encoded tyrosine kinase associated with the cytoplasmic domains of CD4 and CD8, which appears to function in T-cell signaling. Tyrosine phosphorylation can initiate a cascade of signaling events, including the activation of serine-threonine kinases that cause a variety of cellular responses. Ligand binding to integrins also results in generation of lipid second messengers, alkalinization of the cytoplasm, and influxes of Ca^{2+}. The latter event may be due to Ca^{2+} transport through an integrin-associated protein that has several membrane-spanning domains.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COOPERATIVE INTERACTIONS BETWEEN SIGNALING AND ADHESION MOLECULES

Signaling and adhesion molecules frequently function cooperatively in sequential cascades to enhance the specificity of cell adhesion. Three examples of how these cooperative interactions facilitate blood cell responses are illustrated.

Platelet Adhesion and Aggregation.

At sites of hemorrhage in the arterial circuit, platelets rapidly adhere to the damaged vessel through interactions of GPIb/IX/V receptors with immobilized vWF exposed in the subendothelial matrix (Fig. 52). This interaction is actually facilitated by high shear rates, perhaps because of shear-induced conformational effects on GPIb or vWF, or both. An important feature of this initial adhesive event is that prior activation of the platelets is not required. After adhesion, however, the interaction of immobilized vWF with GPIb receptors triggers intracellular signals that lead to platelet activation. These signals may be synergistic with those produced by small amounts of locally produced thrombin to enhance platelet activation. Platelet activation, in turn, increases the affinity of platelet integrins for other matrix adhesive proteins such as collagen and fibronectin, which stabilize adhesion. Binding of these ligands transduces signals that propagate further activation responses such as spreading, secretion of granule contents, and recruitment of additional platelets through cell-cell contact mediated by binding of fibrinogen to activated $_{IIb\ 3}$ integrins. This adhesion cascade allows unstimulated platelets to home to the site of vascular injury and subsequently be activated by locally generated mediators.

Neutrophil Rolling, Spreading, and Migration.

Near sites of extravascular bacterial infections, neutrophils first tether to and roll on the endothelial surface of venules through the interactions of selectins with cell-surface carbohydrate ligands (Fig. 53). Neutrophil rolling on the endothelium must occur under shear forces, just as platelets must adhere to subendothelial matrix under shear forces, although the shear rates in postcapillary venules are lower than those in arteries. The selectins are capable of forming rapid, yet reversible, bonds with their ligands under these conditions. Just as the initial adhesion to vWF does not require prior activation of platelets, selectin-mediated rolling does not require prior activation of neutrophils. Instead, locally

Figure 5-2 Platelet adhesion and aggregation. In response to arterial injury under high shear forces, platelets rapidly adhere to the subendothelial matrix. The initial contacts are made between GPIb/IX/V on platelets and vWF in the matrix. These molecular interactions help activate platelets, thereby increasing the affinity of several platelet integrins for other adhesive matrix proteins such as fibronectin, laminin, and collagen. CD36 also interacts with both collagen and thrombospondin. Fibrinogen cross-links activated platelets into aggregates by binding to $_{IIb\ 3}$ integrins. The platelet plug then serves as an efficient surface for generation of thrombin and fibrin.

Figure 5-3 Neutrophil rolling, spreading, and emigration. At sites of tissue injury or infection, neutrophils first roll on the endothelial cells in postcapillary venules. These transient adhesive interactions are mediated by activation-induced expression of E- or P-selectin, or a ligand for L-selectin, on the endothelial cell surface. E- and P-selectin bind to carbohydrate ligands on the neutrophil, whereas L-selectin on the neutrophil binds to a carbohydrate on the endothelial cell. These molecular bonds can form under the shear forces in the venular circulation. The rolling neutrophils are then activated by locally generated inflammatory mediators that increase the affinity of $_{2}$ integrins for immunoglobulin-like receptors such as ICAM-1 on the endothelium. These bonds strengthen adhesion. Neutrophil migration between endothelial cells into tissues at the site of infection requires disengagement of old adhesive bonds and formation of new bonds between integrins, PECAM-1, and their respective ligands.

generated inflammatory mediators induce expression of E- or P-selectin, and probably a ligand(s) for L-selectin, on the endothelial cell surface. The requirement for activation of endothelial cells rather than leukocytes allows the latter to adhere to vessels only at the site of microbial invasion. Once situated on the vessel wall through selectin-mediated contacts, however, the neutrophils become exposed to activators such as platelet-activating factor, a phospholipid signaling molecule, and interleukin-8, a potent chemoattractant, both of which are presented on the surface of activated endothelial cells. Neutrophil activation increases the affinity of $_{2}$ integrins for immunoglobulin counter-receptors on the endothelial cell surface such as ICAM-1 and ICAM-2. Although these bonds will not form under shear conditions, they do form once neutrophils are transiently arrested on the endothelium by the selectins. The integrin-ICAM interactions strengthen adhesion, promote spreading, and ultimately favor migration, presumably because of disengagement of integrin-ICAM bonds and redistribution of integrins to the leading edge of the cell, where new bonds form. Subsequent interactions of leukocytes with PECAM-1 in interendothelial cell junctions facilitates transendothelial migration of the neutrophils into the underlying tissues. Adhesion of leukocytes to the endothelium disrupts cytoskeletal tethers to the endothelial cadherins; this leads to dissociation of homotypic cadherin interactions that normally prevent passage of leukocytes. Both the integrin- and PECAM-1-mediated adhesive events may signal cytoskeletal redistributions in leukocytes that enhance migration toward chemotactic molecules released in the vicinity of the infection. Once in the tissues, integrin recognition of extracellular matrix protein ligands may trigger secretion of proteolytic enzymes and production of superoxide anions, both required for optimal bactericidal function.

Adhesion of T Lymphocytes to Antigen-Presenting Cells.

The initial interaction of T lymphocytes with antigen-presenting cells requires that the T-cell receptor (CD3) recognize antigen

Figure 5-4 Adhesion between T lymphocytes and antigen-presenting cells. The initial contact is mediated by the T-cell receptor (CD3), which binds with low affinity but high specificity to a specific antigen presented by an MHC molecule. Additional contacts, also of low affinity, are between CD4 (on helper cells) or CD8 (on cytotoxic cells) and MHC, and between CD2 and LFA-3. These interactions signal the T cell to increase transiently the affinity of the $_{2}$ integrin, LFA-1, for the immunoglobulin-like molecules ICAM-1, -2, and -3 on the antigen-presenting cell. These bonds strengthen adhesion and transduce further signals to the T cell that cause proliferation and cytokine secretion. Additional signals result from binding of $_{1}$ integrins on the T cell to adhesive proteins in the extracellular matrix.

presented by the polymorphic domain of MHC molecules (Fig. 54). Subsequent interactions include the binding of CD8 or CD4 to MHC class I or II molecules, respectively, plus the binding of CD2 to LFA-3. These molecular contacts are all of low affinity but are highly specific because they first require specific antigen presentation to the appropriate T cell. The combination of these binding events triggers signals that increase the affinity of LFA-1 ($_{L\ 2}$), a $_{2}$ integrin on T cells, for its ligand, ICAM-1 on antigen-presenting cells, strengthening adhesion. After ICAM-1 binds to LFA-1, the T cell is further activated, resulting in cytokine secretion and proliferation. Additional signaling is mediated through binding of other integrins on T cells to protein ligands in the extracellular matrix.

Principles of Cooperative Interactions

The first key principle of the three responses just described is that the initial adhesive event, while relatively limited, is highly specific. Thus, platelets bind only to exposed subendothelial matrix, neutrophils bind only to endothelium near the site of infection, and T cells bind only to cells presenting specific antigen. The second key principle is that subsequent activation events strengthen cell adhesion and lead to further responses such as secretion, fibrin formation, migration, proliferation, or release of cytotoxic mediators. Activation often results from cooperative signaling by soluble agonists and by binding of ligands to adhesion receptors. Co-stimulation by multiple signals can amplify, and provide specificity to, cellular responses by mechanisms not always feasible for individual mediators. Thus, adhesion and cell signaling are highly interrelated processes.

The process of reversing cell adhesion, while less well understood, is equally important for the control of cell behavior. Some molecules such as the selectins can be proteolytically cleaved or internalized. The activation-induced increases in affinity of integrins and CD44 for their ligands are generally transient, but the mechanisms for return to the inactive conformation are obscure.

ALTERED EXPRESSION OF ADHESION MOLECULES

The highly regulated nature of adhesive events by hematopoietic cells suggests that defects in, or excessive expression of, adhesion

TABLE 5-6 -- Genetic Deficiencies in Adhesion Molecules

Molecule	Disease	Laboratory Findings	Clinical Findings
IIb 3	Glanzmann thrombasthenia	Impaired platelet aggregation	Mucocutaneous bleeding
GPIb/IX/V	Bernard-Soulier syndrome	Impaired platelet adhesion to vWF	Mucocutaneous bleeding
2 integrins	Leukocyte adhesion deficiency-1	Impaired adhesion of activated leukocytes to EC	Frequent infections
Selectin ligands	Leukocyte adhesion deficiency-2	Impaired fucose metabolism resulting in defective carbohydrate ligands for selectins, impaired rolling of leukocytes on venules	Frequent infections

For abbreviations, see Table 51 footnote.

molecules could contribute to the pathogenesis of disease. A variety of clinical observations support this hypothesis.

Genetic Deficiencies in Adhesion Molecules

Genetic deficiencies in platelet adhesion receptors such as the GPIb complex (Bernard-Soulier syndrome) and the $_{IIb\ 3}$ integrin (Glanzmann thrombasthenia) result in hemorrhagic symptoms similar to those seen in patients with thrombocytopenia. Genetic deficiencies in the leukocyte $_{2}$ integrins (leukocyte adhesion deficiency-1) are associated with frequent severe bacterial infections and a failure of neutrophils to enter the infected tissues. Similar symptoms are seen in patients with a congenital defect in fucose metabolism that prevents synthesis of the carbohydrate ligands for selectins (leukocyte adhesion deficiency-2) (Table 56).

Dysregulated Expression of Adhesion Molecules

Inappropriate expression of adhesion molecules has been implicated in thrombotic and inflammatory disorders and in tumor metastasis. For example, erythrocytes from patients with sickle cell anemia adhere to each other and to the endothelium, contributing to vaso-occlusive crises. These adhesive events may reflect, in part, the expression of integrins and other adhesion molecules not normally found on mature erythrocytes. Inappropriate adhesion and activation of platelets on exposed atherosclerotic plaques may contribute to thrombosis. Dysregulated expression of selectins on the endothelium of ischemic blood vessels during myocardial infarction or shock may contribute to neutrophil-mediated tissue necrosis following reperfusion of the vessel. Mediators released while the neutrophils are adherent in the reperfused vessels may activate integrin function, strengthening adhesion and generating further signals that release destructive oxygen radicals and proteases within the vasculature. Finally, malignant cells appear to utilize molecules normally used for adhesion of blood cells to promote metastatic spread through interactions with platelets, endothelial cells, and extravascular matrix.

These examples underscore the importance of proper regulation of adhesion molecule expression in the physiology of blood cells. Further studies of the structure and function of these molecules may lead to effective treatments for disorders in which their expression becomes dysregulated.

Chapter 6 - Control of Cell Growth and Differentiation

William M. F. Lee
Chi V. Dang

INTRODUCTION

Somatic cells undergo one of three general fates: They (1) proliferate by mitotic cell division, (2) differentiate and acquire specialized functions, or (3) die and are eliminated from the body. Cell proliferation is necessary for growth of the organism and ensures repletion of cells lost to terminal differentiation, cell death, or cell loss; in the case of lymphocytes, it serves the additional function of amplifying immune responses to specific antigens. Differentiation provides the organism with a supply of cells to execute specific and specialized functions. In some cell types, such as muscle and nerve cells, differentiation and proliferation are mutually exclusive fates, and cells undergo terminal differentiation. In other cell types, such as those of the hematopoietic lineage, proliferation may continue after cells acquire differentiated characteristics. For example, erythroblasts, myeloblasts, and megakaryoblasts committed to particular differentiation pathways and possessing lineage-specific markers continue to proliferate, and T and B lymphocytes expressing antigen-specific receptors and immunoglobulins actively proliferate when appropriately stimulated. Cell death is an active process, initiated by the cell itself (apoptosis), and is physiologically as important as cell proliferation and differentiation. It allows tissue renewal and changes in cellular composition without undesirable cell accumulation. When the regulation of any of these three cellular processes goes awry and their balance becomes abnormal, the consequences to the organism are usually dire and result in either functional insufficiency or neoplasia. The relevance of these events to normal tissue function and neoplasia has led to investigations of their mechanisms and regulation at a molecular level.

SIGNAL TRANSDUCTION AND CELL PROLIFERATION

Cells normally proliferate, differentiate, and die in response to signals from their environment. Of these, mitogenic signals and signaling mechanisms are the best studied and provide a paradigm for how cells respond to environmental signals in general. Cell proliferation is normally stimulated by extracellular growth factors interacting with specific receptors located at the cell surface, and signal transduction is the process by which information about growth factors at the cell surface is transmitted to the nucleus where ultimate control of most cellular events resides. Signal transduction pathways leading to differentiation and apoptosis are being unravelled and operate on similar principles. An overview of some of the biochemical events involved in mitogenic signal transduction is provided as an introduction to the discussion of cell cycle regulation. [1] [2] Chapter 5 provides a more detailed discussion of signal transduction.

Much of what is known about signal transduction is based on studies of the cellular biochemical response to platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). When these ligands bind to their cognate cell surface receptors (PDGF-R and EGF-R, respectively), the receptors dimerize, activate their intrinsic tyrosine kinase activity, and catalyze the transfer of phosphate groups from adenosine triphosphate (ATP) to tyrosine residues of specific cellular proteins, including the receptors themselves (Fig. 61). [3] Some other types of receptors, such as the T-cell antigen receptor, are not tyrosine kinases, and the tyrosine phosphorylation that they induce upon ligand binding is mediated by associated nonreceptor tyrosine kinases. The presence of phosphotyrosines in target proteins enables them to form noncovalent complexes with proteins containing SH2 domains (src-homology region 2; defined by homology to a region in the src retroviral oncoprotein), which are peptide domains that bind phosphotyrosine-containing peptides. [4] Thus, phosphorylation of the EGF-R and PDGF-R enables them to interact with SH2-containing proteins near or at the plasma membrane, which initiates downstream signaling events. Certain enzymes with SH2 domains, such as the 1 isoform of phospholipase C (PLC1), directly associate with phosphorylated EGF-R and PDGF-R and become tyrosine phosphorylated by them, which, in the case of PLC1, results in enhancement of enzymatic activity. Activation of PLC1 catalyzes the hydrolysis of phosphotidylinositol (PIP_3) into diacylglycerol (DAG) and inositol (1,4,5)-trisphosphate (IP_3), both of which act as second messengers that launch additional actions inside cells: DAG activates protein kinase C (PKC, a kinase that phosphorylates serine/threonine residues in substrate proteins) and IP_3 induces Ca^{2+} release from intracellular stores, which in turn activates Ca^{2+} /calmodulin-dependent serine/threonine protein kinases and other Ca^{2+} -dependent events.[5]

Another signaling molecule that is activated when receptors bind their ligand and become phosphorylated is Ras. This proto-oncoprotein is a member of the class of low-molecular-weight GTP-binding proteins that are inactive in their GDP-bound form and active in their GTP-bound form. The intrinsic GTPase activity of Ras, enhanced by the presence of a GTPase-activating protein (GAP), hydrolyzes bound GTP to GDP and maintains Ras in its inactive state. [6] [7] Following EGF binding by EGF-R, two cytoplasmic proteins, Grb2 and SOS, that exist as heterodimers in unstimulated cells physically link EGF-R with Ras in a quaternary complex through binding of phosphorylated EGF-R with the SH2 domain of Grb2 and the binding of SOS to Ras. Formation of this complex activates the function of SOS as a guanine nucleotide exchange factor (GEF), resulting in the conversion of Ras-GDP to Ras-GTP and Ras activation. Activation of Ras initiates a cascade of serine/threonine kinase activation, which may begin with the association of GTP-Ras with Raf-1, leading to activation of the latters serine/threonine kinase function. Raf-1 phosphorylates and activates the kinase (MAPK kinase, or MEK) that phosphorylates and activates MAP kinase (MAPK, or mitogen-activated protein kinase). The host of serine/threonine kinases activated following mitogen exposure phosphorylate diverse cellular proteins and modulate their activities. [8] [9] Prominent among these targets are transcription factors.[10] Phosphorylation may directly alter the ability of transcription factors to bind DNA or activate transcription. Alternatively, phosphorylation may indirectly activate a transcription factor by inactivating an antagonist. Mitogen stimulation may result in activation of protein phosphatases that dephosphorylate specific phosphorylated residues in certain transcription factors to alter function. [11] The end result is a rapid change in the transcriptional program of the cell independent of any new mRNA or protein synthesis. These initial post-translational

Figure 6-1 Mitogenic signal transduction. Shown are signal transduction pathways activated by the binding of mitogenic ligands (L), such as PDGF or EGF, to their cognate receptors (R) at the cell surface. Binding results in dimerization and autophosphorylation (P) of the receptors on tyrosine residues (Y). This enables them to associate with and activate specific SH2 domain-containing downstream components of the signaling pathway. In the case of phospholipase C1 (PLC1), association leads to tyrosine phosphorylation by the receptor kinase and an enhanced ability to hydrolyze phosphoinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3); in turn, DAG activates protein kinase C (PKC) and IP_3 mobilizes Ca^{2+} from intracellular stores. In the case of Grb2-SOS, association with phosphorylated receptors stimulates its ability to facilitate Ras GTP-GDP exchange; GTP-Ras activates the MAP kinase (MAPK) cascade, which eventually induces serine (S)/threonine (T) phosphorylation of nuclear proteins that modulate gene transcription. Note that MAPK is activated by serine/threonine and tyrosine phosphorylation and that both result from the activity of a single dual-function kinase, MAPK kinase.

changes lead to rapid transcriptional induction of certain genes (so-called immediate early response genes, e.g., c- *fos* and c-*myc*), which adds to the transcriptional reprogramming of the cell that eventually enables cells to undergo DNA synthesis and cell cycling. Not surprisingly, some of the transcription factors at the end of the mitogenic signaling pathway, such as c-Myc, c-Fos, and c-Jun, have oncogenic potential when inappropriately activated.

Ligands other than EGF and PDGF may use different schemes for signal transduction. Neuroactive and vasoactive peptides (e.g., epinephrine and thrombin) activate responsive cells through specific receptors that have seven membrane-spanning domains. These receptors are typically coupled to heterotrimeric G-proteins that resemble Ras in being regulated by GTP and GDP.[6] [12] These receptor-coupled G-proteins are linked to effector enzymes (e.g., adenylyl cyclases) that generate molecular signaling intermediates (e.g., cyclic AMP) upon ligand binding. Steroid and thyroid hormones and retinoids can enter cells by virtue of their lipophilic nature. Their receptors are intracellularly located and able to bind sequence-specific DNA and directly modulate the transcription of responsive genes. Thus, the receptors are transcription factors whose activities are influenced by binding of the cognate hormone. [13] Interferon signaling uses a different signal transduction paradigm. Tyrosine kinases of the Janus kinase (JAK) family associate with interferon receptor subunits. Upon ligand binding, association of the receptor subunits allows these JAKs to phosphorylate and activate each other and to phosphorylate the associated receptors. Specific members of the STAT (signal transducers and activators of transcription) family of latent cytoplasmic transcription factors, which have SH2 domains, dock to the receptor phosphotyrosines and become phosphorylated by JAK. Tyrosine phosphorylation allows STATs to dimerize and translocate to the nucleus, where they bind sequence-specific DNA and modulate transcription of interferon-responsive genes.[14] Signal transduction using JAK-STAT protein is used by many peptide ligands and cytokines of hematologic interest (e.g., erythropoietin, IL-2, IL-3, IL-4, IL-6, IL-12).

The signal transduction shemes outlined permit a single event, ligand-receptor interaction, to have several downstream consequences. Its multiplex, frequently cascading nature allows signal amplification and diversification but also permits their modulation and fine regulation. Signaling pathways can intersect and interact at different levels, which allows one ligand to modify the signals generated by another ligand. For example, STATs can be phosphorylated by receptor tyrosine kinases, such as PDGF-R and EGF-R, as well as by JAK and can undergo serine/threonine phosphorylation, which modulates their transcriptional activity. [14] This allows PDGF and EGF to initiate some events usually initiated by cytokines and interferons, and the phenotypic changes brought about by cytokines and interferons may be altered in the presence of PDGF and EGF.

Transcription factors are final participants in afferent signal transduction pathways and initiators of cellular responses to these signals. [10] In general, they are sequence-specific DNA-binding proteins that modulate the expression of genes to which they bind. When these factors bind their cognate DNA sequence, they interact with the basal transcription machinery either directly or via intermediary proteins (co-activators and co-repressors) to initiate, enhance, or inhibit transcription. Transcription factors have peptide domains with characteristic secondary structures that are responsible for their ability to bind DNA. Many bind DNA only as dimers, making the peptide domain responsible for dimerization essential for DNA binding. Transcription factors use one of a number of peptide motifs to dimerize and bind DNA, among them zinc finger, basic region-leucine zipper (bZip), basic region-helix-loop-helix (bHLH), or helix-turn-helix motifs. [15] Factors that activate gene transcription generally do so because they have a distinct transcriptional activation domain that is frequently acidic in nature, glutamine rich or proline rich. Transcriptional gene regulation is highly complex, not only because of the multitude of transcription factors present in cells but also because of the ability of many factors to heterodimerize and form combinatorial pairs that have DNA-binding, transactivation, and/or regulatory properties that differ from those of the parental homodimers. A striking example is provided by heterodimers containing the Id protein, which is an HLH protein that can dimerize with selected bHLH proteins, such as the myogenic transcription factor MyoD, but that does not possess a DNA-binding basic region (see following). Id-containing heterodimers are incapable of binding DNA, making Id a negative transcriptional regulator that inhibits the function of positive factors. Negative gene regulation also occurs by active repression of transcription, and certain transcriptional repressors have been shown to recruit factors that bind histone deacetylases. Histones are a family of nuclear proteins that interact with DNA and organize it into higher-order structures consisting of DNA wrapped around a histone core (nucleosomes). Acetylation of histones masks their basic residues, destabilizes their interaction with DNA, loosens nucleosome DNA, and facilitates transcription. Deacetylation of histones, in contrast, stabilizes their interaction with DNA, which tightens nucleosome DNA and inhibits transcription. Reversible, regional histone acetylation, through recruitment of co-activators with acetyltransferase activity or recruitment of co-repressors with deacetylase activity, may be a general mechanism by which transcription factors facilitate or repress expression of specific genes. [16]

THE CELL CYCLE

A cell stimulated to divide passes through a cyclic series of states, defined by biochemical and morphologic criteria, collectively termed the cell cycle (Fig. 62). Passage through the cell cycle provides an ordered sequence to the complex series of events necessary for the production of two identical progeny cells. The normal cell cycle is divided into discrete and sequential phases, S, G_2 , M, and G_1 .

S Phase.

S phase is the period of wholesale DNA synthesis during which the cell replicates its genetic content; a normal diploid somatic cell with a 2N complement of DNA at the beginning of S phase acquires a 4N complement of DNA at its end. The duration of S phase may vary from only a few minutes in rapidly dividing, early embryo cells to a few hours in most somatic cells. Early embryo cells generally live off the accumulated stores of maternal RNA and proteins present in the egg and are transcriptionally silent, whereas cells in later development and mature organisms must actively transcribe subsets of their genes to survive and maintain specialized functions. The longer time required for the latter to complete S phase may be adaptive, allowing the cell to coordinate DNA replication with

Figure 6-2 The cell cycle. The somatic cell cycle is divided into phases of DNA replication (S), mitosis (M), and the gaps in between (G_1 between M and S; G_2 between S and M). G_0 is not shown for the sake of simplicity but would be a side loop exiting and entering G_1 . The point in late G_1 at which cells become committed to DNA replication is called the restriction point (R). The inner circle shows the pattern of Rb phosphorylation through the cell cycle, with the density of stippling indicating the degree of Rb phosphorylation. Places in the cell cycle where individual cyclins (A, B, D1, D2, E) appear are shown by the outer arcs.

transcription and to preserve higher-order structural information, influencing gene expression for transmission to progeny cells.

M Phase.

M phase or mitosis is the period of actual nuclear and cell division during which the duplicated chromosomes are divided equally between the two progeny cells. It is obvious microscopically as the period of chromosome condensation, nuclear envelope breakdown, chromosome segregation to opposite poles, reformation of nuclear envelopes (which completes nuclear division, or karyokinesis), and physical separation of the two daughter cells (which completes cell division, or cytokinesis). A cell entering M phase has a 4N DNA content and finishes as two cells, each with an identical 2N complement of DNA.

G_1 and G_2 Phases.

$G_1$and G_2phases were originally conceived of as gaps between the distinctive M and S phases of the cell cycle. G_2 is the period between S and M when cells have finished replicating their DNA, are preparing to divide, and have a 4N DNA content. For most cells entering S phase, passage through G_2 is automatic, and the duration of G_2 is fixed except under unusual circumstances. G_2 duration can be extremely short and is essentially undetectable in rapidly proliferating, early embryonic cells. G_1 , which occupies the period between M and S, is the interval between the completion of one round of cell division and initiation of the next. Its duration is the most variable, can be prolonged (depending on the cell type), and is subject to regulation by environmental factors such as the availability of growth factors and nutrients. It is the period of cell growth, and a certain increase in mass is usually required before the cell initiates the next S phase. As a first approximation, the amount of time a cell spends in G_1 is inversely related to its rate of proliferation. When conditions are unsuitable for proliferation, cells arrest in G_1 , and those that are already in S, G_2 , or M usually complete the round to which they

have been committed and arrest only when they reach G_1 again. On the other hand, when rapid cell proliferation is mandated, as in embryos shortly after fertilization, G_1 is virtually undetectable, and there is no cell enlargement. This results in the original mass of egg cytoplasm being partitioned among thousands of cells within a few hours without a noticeable increase in size. G_1 has been subdivided into segments and regulatory points largely based on the study of the proliferative response of cells to sequential application of different growth factors, nutrients, and metabolic inhibitors. From the standpoint of cell cycle regulation, a particularly important point in G_1 is the restriction point or R, which occurs near the G_1 -S boundary. This is the point at which cells become committed to entering S phase regardless of growth factor stimulation or the availability of essential amino acids, and is analogous to the commitment point in the yeast cell cycle called Start.

G_0 Phase.

Viable cells may remain for prolonged periods in a nonproliferative G_0 state. Such cells have a 2N DNA content and may be difficult to distinguish from cells in prolonged G_1 . The distinction, if not obvious morphologically, may be made biochemically since they have differences in their protein and RNA metabolism. Terminally differentiated cells, such as neutrophilic granulocytes, have irreversibly exited the cell cycle during the process of differentiation and are examples of cells in G_0 . However, other cells reversibly enter G_0 and may be induced to return to G_1 and begin cycling with appropriate stimuli. For example, hepatocytes are usually in G_0 unless partial hepatectomy induces them to proliferate to reconstitute the functional mass of the liver; resting, antigen-specific lymphocytes are in G_0 until antigen and cytokine stimulation induces them to proliferate.

The enforced sequence, G_1 -S-G_2 -M, during normal progression through the cell cycle means that a cell must duplicate its DNA before dividing and that it must divide before duplicating its DNA again. This sequence ensures euploidy, and its enforcement maintains genetic stability. The dependence of later events in the cell cycle on normal completion of earlier events is ensured by checkpoint control mechanisms that prevent a cell that has not successfully completed one phase of the cycle from entering the next.[17] [18] The existence and importance of checkpoints are illustrated by yeast mutants defective in the *RAD9* gene. Normally, yeast cannot enter M phase until their DNA is fully replicated. Yeast defective in the *RAD9* gene enter M phase even if they are prevented from completing DNA replication. They also die more rapidly, presumably because the progeny inherit incomplete or damaged genetic material. In mammalian cells, the activity of checkpoints is seen after exposure to DNA-damaging agents, such as ionizing radiation, that delay cell entry into S and M by inducing temporary G_1 or G_2 arrest. This delay allows cells time either to repair the damaged DNA or to execute a program of self-destruction or apoptosis if the damage is irreparable. Caffeine antagonizes the G_2 /M checkpoint mechanism, and cells that are exposed to caffeine fail to arrest in G_2 and are less viable after irradiation. The p53 tumor suppressor protein participates in the G_1 /S checkpoint

mechanism, and its loss predisposes to cancer (see following).

CELL CYCLE REGULATION

The progression of cells through the cell cycle is driven by serine/threonine kinases of the Cdk (cyclin-dependent kinase) family. As their name implies, the catalytic activities of these kinases are under the stringent control of associated regulatory proteins called cyclins. The latter were so named because levels of the first to be described, cyclins A and B, were seen to fluctuate periodically with the cell cycle. Numerous Cdks and cyclins exist in the cell and form various combinatorial pairs with distinct activities. Control of cyclin/Cdk activity exists at many levels and occurs by the appearance and disappearance of the cyclins at specific phases of the cell cycle, by post-translational modification of Cdks, and by association with Cdk inhibitors. In turn, cyclin/Cdks regulate cell cycling by modulating the activity of critical transcription factors.

Cyclins and Cyclin-Dependent Kinases

Entry into M

The molecular mechanisms regulating cell entry into M [19] were first revealed by studies of a conditional cell cycle mutant of *Schizosaccharomyces pombe* (fission yeasts) called *cdc2* (cell division cycle 2). Grown under nonpermissive conditions, these mutants arrest in G_1 or G_2 and do not enter S or M. Cloning of the *cdc2* gene revealed that it encodes a 34-kd serine/threonine kinase. Human cells have a structurally and functionally similar protein, which underscores the evolutionary conservation and importance of this regulatory mechanism. p34 *cdc2* is the prototypic Cdk (Cdk1), and subsequently discovered members of this kinase family have been designated Cdk2, Cdk3, and so forth. An independent line of study examining the effect of cytoplasmic extracts from mature *Xenopus* frog eggs microinjected into immature frog oocytes showed that these extracts contain a material that induces oocytes to mature and undergo typical M-phase changes such as nuclear membrane breakdown. After purification, the maturation-promoting factor (MPF) in these extracts was found to contain two proteins: one is p34 *cdc2*, and the other is a B-type cyclin. Cyclin B has no known enzymatic function and plays a regulatory role in the MPF complex, evidenced by the fact that p34 *cdc2* exhibits kinase/MPF activity only in association with cyclin B.

Cyclin B levels increase during S and G_2 (Fig. 62), and levels of the cyclin B/p34 *cdc2* complex sufficient for the G_2 -M transition are reached well before the onset of M. Mitosis is not prematurely triggered because the complex accumulates in an inactive form (Fig. 63). During S and G_2 , the p34*cdc2* complexed with cyclin B accumulates as a multiply phosphorylated protein. In human p34 *cdc2*, phosphorylation of threonine (Thr) 161 stabilizes its association with cyclin B and is essential for activity. The kinase responsible for Thr 161 phosphorylation, CAK (Cdk-activating kinase), is itself a Cdk (designated Cdk7) that associates with a novel cyclin, cyclin H. On the other hand, phosphorylation of Thr 14 and tyrosine (Tyr) 15 in p34 *cdc2* suppresses its kinase activity and keeps the cyclin B/p34 *cdc2* complex inactive. Activation of p34*cdc2* just prior to entry into M requires dephosphorylation of both Thr 14 and Tyr 15, which is accomplished by a dual-specificity phosphatase, Cdc25. The kinase and phosphatase that regulate p34 *cdc2* activity and time cell entry into M are themselves regulated by phosphorylation. This inhibits the kinase responsible for Tyr 15 phosphorylation (homolog of the product of the *S. pombe wee1* gene) and enhances the phosphatase function of Cdc25. Once activated, cyclin B/p34 *cdc2* can phosphorylate Cdc25 and create a self-amplifying feedback loop that generates more oocyte MPF activity from a small initial amount of active MPF and the large preexisting stock of inactive MPF. What starts this sequence of events by initially phosphorylating Cdc25 is unclear, although cyclin A/Cdks are candidates because they are active prior to cyclin B/p34 *cdc2* activation, have MPF activity, and inhibition of cyclin A during S prevents entry into M.

Activated p34*cdc2*/cyclin B complex can phosphorylate serine/threonine residues in many cellular proteins. Discerning its physiologic substrates is difficult, however, because many other cyclin/Cdk complexes are also active. Candidates include the lamins and vimentin, which are respectively nuclear and cytoplasmic proteins important for the structural organization of their compartments. These proteins undergo M-phase phosphorylation and are substrates for p34 *cdc2*/cyclin B kinase activity in vitro. Phosphorylation of lamins is important for nuclear

Figure 6-3 Regulation of cell entry into M by p34 *cdc2*/cyclin B (maturation promoting factor [MPF]). p34 *cdc2* kinase activity controls cell entry into M and is regulated during the cell cycle. Association with cyclin B, which first appears during S phase, is necessary for its kinase activity, and formation of the p34 *cdc2*/cyclin B complex (MPF) is stabilized by phosphorylation of Thr (T) 161. Accumulating MPF is maintained in an inactive state by phosphorylation of Thr 14 and Tyr (Y) 15, which is catalyzed by the homolog of the *S. pombe wee1* gene product and another kinase. At the G_2 /M transition, MPF is activated by dephosphorylation of Thr 14 and Tyr 15 by the homolog of the *S. pombe cdc25* gene product. This may be a self-amplifying reaction because activated MPF can phosphorylate and activate more Cdc25. Activated MPF phosphorylates cellular substrates and brings about the biochemical changes needed for M phase. During progression through M, degradation of cyclin B generates inactive p34*cdc2* and permits cell exit from M.

lamina disassembly and envelope breakdown, and phosphorylation of vimentin may cause depolymerization of vimentin intermediate filaments. If these are physiologic substrates, p34 *cdc2*/cyclin B kinase activity may initiate the structural reorganization that is essential for mitosis. As M phase progresses, p34 *cdc2*/cyclin B is inactivated by degradation of the cyclin B component via the ubiquitin pathway. Inactivation is important for cells to exit M, because recombinant cyclin B that is resistant to proteolysis induces cell arrest in M.

Entry into S

The rate of cell proliferation in somatic cells is generally determined by events in G_1 , with the irreversible decision to undergo DNA replication made at R. The importance of the decisions made in G_1 and their relevance to neoplastic cell behavior have made the identification of regulatory factors involved in G_1 and the G_1 -S transition a prime objective. [20] In *S. pombe*, p34*cdc2* is responsible for both the G_1 -S and G_2 -M transitions. In higher organisms, p34*cdc2* has a clear role in G_2 and M, but appears unnecessary for G_1 - and S-phase events, which are conducted by other Cdks. The specific function of several Cdks has yet to be defined, but some, like Cdk2 and Cdk4, are known to be important in G_1 and S. Their activities are regulated by the cyclins with which they pair, and the permitted partnerships determine where and how in the cell cycle the individual cyclin/Cdk complexes function. The disappearance of cyclins A and B during M and their reappearance only in S (Fig. 62) preclude a role for them in G_1 . Other cyclins, therefore, must be important in G_1 and the G_1 -S transition, and human cyclins potentially fulfilling these roles (C, D, and E) have been identified by functional complementation of *S. cerevisiae* (budding yeast) mutants deficient in three G_1 cyclin genes (*CLN13*). D-type cyclin genes were independently identified during the search for an oncogene involved in parathyroid adenomas and for genes induced during mitogenic stimulation of macrophages. Studies indicate that the D cyclins (of which there are threeD1, D2, and D3) associate with Cdk2, 4, and 6 and that Cdk4 and 6 associate only with D cyclins. Cdk2, in contrast, associates with cyclins A and E as well, and cyclin A associates with p34 *cdc2* as well as Cdk2.

D-type cyclins are clearly important regulators of G_1 events. Cyclin D/Cdk4, 6 complexes phosphorylate Rb, the protein product of the retinoblastoma susceptibility (*Rb*) gene and an inhibitor of S-phase entry in its hypophosphorylated state (see following). Rb substrate specificity is conferred in part by the D cyclins, which bind Rb via a peptide motif that is shared with Rb-binding viral oncoproteins, SV40 T antigen and adenovirus E1A. With the observations that inhibition of cyclin D1 expression

prevents cell entry into S and that cyclins D1 and D2 can reverse Rb-induced G_1 growth arrest, these data suggest that D-type cyclins function as regulators of G_1 progression and entry into S phase. Cyclin E is thought to play an important role in the G_1-S transition. In mitogen-stimulated cells, it appears later in G_1, peaks near the G_1/S boundary, and declines in S (Fig. 62). Cyclin E associates primarily with Cdk2, and in cells in G_1 is found in a quaternary complex with Rb-related p107 protein, transcription factor E2F, and Cdk2. This complex disappears as cells enter S, just as a similar complex containing cyclin A instead of E makes its appearance. Cyclin E induces Rb phosphorylation and counters G_1 growth arrest induced by hypophosphorylated Rb. Cyclin A first appears at the beginning of S and declines in G_2 and M and has an expression pattern that parallels but precedes that of cyclin B (Fig. 62). It may associate with either $p32^{cdc2}$ or Cdk2 and, in S phase, is found in a quaternary complex with Cdk2, E2F, and p107. These data and the results of cyclin A inhibition and addition experiments have led to the view that cyclin A plays a major role in driving S-phase events. Cyclin A in complex with $p32^{cdc2}$ may trigger the G_2-M transition by phosphorylating Cdc25 and initiating activation of cyclin B/$p32^{cdc2}$.

Inhibitors of Cyclin-Dependent Kinases

More recently, another layer of cell cycle regulation complexity has been discovered with the identification of inhibitors of Cdk and cyclin/Cdk complexes. [21] The first inhibitor to be identified and cloned in mammalian cells was p21 (Waf1, Cip1, Sdi1), which binds several different cyclin/Cdk complexes and has been classified as a universal inhibitor. While addition of p21 inhibits the activity of many cyclin/Cdk complexes, p21 is also found in complexes with kinase activity, indicating that the stoichiometry of p21 association with cyclin/Cdk probably determines inhibition. p21 also binds PCNA (proliferating cell nuclear antigen, a processivity factor during DNA synthesis) and inhibits its ability to facilitate the function of DNA polymerase-, the polymerase responsible for DNA replication. While these properties of p21 readily account for its ability to induce cell cycle arrest, the regulation of p21 expression sheds even more light on its potential function. Expression is transcriptionally induced by p53, the tumor suppressor protein activated by DNA damage (see following), suggesting that p21 is responsible for halting cell proliferation after DNA damage to allow time for damage assessment and repair. However, p21 can also be abundantly expressed in cells lacking functional p53, indicating that p53-independent pathways of expression exist. These other pathways may account for increased p21 expression in other cellular circumstances, such as in senescent cells that have reduced proliferative capacity and in cells induced to terminally differentiate. Other Cdk inhibitors with structural and functional similarities to p21 exist. These include p27 (Kip1) and the more recently described p57 (Kip2), which, like p21, bind multiple cyclin/Cdk complexes. Up-regulation of p27 is thought to mediate the growth arrest of TGF--treated or contact-inhibited cells. Regulation of p27 expression differs from that of p21 and seems to occur post-transcriptionally, with levels of the protein increasing while mRNA levels remain constant. Studies to date have not revealed a significant role for defects in universal Cdk inhibitors in carcinogenesis.

p16 (INK4a, MTS1, Cdk4I) and p15 (INK4b, MTS2) are Cdk inhibitors that differ structurally from the universal inhibitors and have restricted Cdk-binding specificity. Both p16 and p15 bind Cdk4 and Cdk6 exclusively, and binding inhibits Cdk4 and Cdk6 association with cyclin D and kinase activity. Rb is believed to be a critical target of cyclin D/Cdk4,6 kinase activity, and Rb phosphorylation prevents it from arresting cells in G_1 (see following). Thus, p15 and p16 may inhibit cell proliferation by preventing Rb phosphorylation. This view is supported by the observation that p16 overexpression inhibits proliferation of cells expressing Rb but not of cells devoid of Rb. p16 is probably important for preventing neoplastic cell proliferation in vivo. Its importance was initially suggested by the finding that the *p16* and *p15* genes were, in the region of chromosome 9, mutated in the germline of patients with familial melanoma and in the genome of many human tumor cell lines. Questions arose when *p16* was found to be much less frequently mutated in freshly isolated human tumors. However, with the discovery that p16 knockout mice are cancer prone and that many human tumors carry *p16* that is unmutated but transcriptionally silent due to aberrant methylation of upstream regulatory CpG islands, there is no doubt of its importance in carcinogenesis.

TRANSCRIPTIONAL REGULATION AND THE CELL CYCLE

Cell proliferation requires coordinate expression of the genes needed for the complex biochemical processes involved, and proliferating cells must orchestrate the timely expression of these genes beginning with their transcription. Since the necessary genes are many (those encoding cyclins, DNA polymerases, accessory factors for DNA replication, purine/pyrimidine biosynthetic enzymes, just to name the obvious), a mechanism for orchestration must exist. Studies of the Rb protein have provided insights into how this occurs.[22] Rb is the product of the retinoblastoma susceptibility gene, *Rb*, which predisposes individuals to retinoblastomas and other tumors when only one functional copy is present in the germline. *Rb* is a tumor suppressor gene, and certain somatic cells (e.g., retinoblasts) become transformed when both copies are functionally inactivated. *Rb* is ubiquitously expressed, and Rb is normally present throughout the cell cycle. The known antiproliferative effect of Rb is explained by the cyclic regulation of its activity by phosphorylation (Fig. 64). Rb is hypophosphorylated in early G_1 . As cells progress through G_1 and approach the G_1 -S transition, Rb is phosphorylated on serine and threonine residues, probably by cyclin D/Cdk4 or 6 complexes, and becomes hyperphosphorylated. This persists until M, at which time Rb is dephosphorylated and returned to its hypophosphorylated, early G_1 state. Hypophosphorylated Rb inhibits cell cycling, and inhibition can be relieved either by phosphorylation or by Rb binding to certain viral oncoproteins that enforce cell cycling, such as adenovirus E1A, SV40 large T antigen, or human papillomavirus (HPV) E7. Two other cellular proteins, p107 and p130, are related to Rb (p105) structurally and functionally and have similar but not identical properties.

The link between Rb proteins and transcription of genes needed for cell cycling is established by members of the E2F family of transcription factors. Originally described as a cellular factor necessary for adenovirus E2 gene transcription, E2F proteins heterodimerize with members of the DP family of proteins to activate transcription. E2F proteins complex with hypophosphorylated Rb, which renders them transcriptionally inactive. E2F is released and its transcriptional activity restored by Rb phosphorylation or Rb binding to E1A, large T, or E7 protein (Fig. 64). In normal cells, cyclic Rb phosphorylation results in cyclic E2F activation and expression of E2F-responsive genes, a process that links specific cell cycle events near the end of G_1 (accumulation of cyclin D/Cdk4 complexes) to specific gene activation and production of proteins necessary for DNA synthesis (e.g., dihydrofolate reductase, thymidine kinase). In cells where Rb is absent or inactive due to homozygous deletion or mutation (e.g., in retinoblastoma and many other types of tumor cells) and in virally transformed cells where hypophosphorylated Rb is inactivated by viral oncoproteins, loss of normal regulation of E2F transcriptional activity leads to deregulated expression of cell cycleregulated genes and cell proliferation.

Figure 6-4 Regulation of the retinoblastoma susceptibility gene product (Rb) through the cell cycle. Rb is regulated by serine/threonine phosphorylation (P) through the cell cycle. Non- or hypophosphorylated Rb present in early and mid-G_1 can bind transcription factor E2F and thereby alter or sequester its activity. In late G_1 , Rb becomes hyperphosphorylated (perhaps due to Cdk/cyclin D kinase activity), releasing E2F for transcriptional duties or formation of other complexes. Removal of phosphate groups in M restores Rb to its hypophosphorylated form. In cells transformed by adenovirus E1A, SV40 large T, or HPV E7, these oncoproteins can bind hypophosphorylated RB and displace E2F (dashed lines). The Rb-like p107 protein also binds E2F and is found in quaternary complexes with Cdk2-cyclin E in G_1 or with Cdk2-cyclin A in S phase.

The regulatory model outlined is consistent with Rb being an integral and necessary part of the cell cycle mechanism, helping to drive cells to enter S through phosphorylation-regulated interactions with E2F. Alternatively, Rb may be a regulatory element of the cycling mechanism, such that Rb phosphorylation is permissive for cell cycling, but maintaining Rb in a hypophosphorylated state is how differentiation and growth-inhibitory signals stop cells from cycling. The latter view is supported by the phenotype of *Rb* knockout mice. *Rb*$^{-/-}$ embryos arise in expected numbers up to day 13 of gestation but fail to develop much beyond that, with evidence of abnormal central nervous system (CNS) development and defective erythropoiesis. Their development more than halfway through gestation and grossly normal appearance indicate that Rb is not essential for cell proliferation, while the failure of CNS and erythroid development argues for a role for Rb in enforcing terminal differentiation in these tissues. Neither are the p107 and p130 members of the Rb family obligatory components of the cell cycle: knockout of *p107* and *p130* individually permits normal mouse development, and knockout of both in combination results in abnormal chondrocyte development and neonatal lethality. Although the developmental abnormalities in *Rb*$^{-/-}$ embryos suggest a tissue-restricted role for Rb in normal development, Rb is part of a more global regulatory pathway for controlling cell growth, evidenced by the fact that the p16-cyclin D/Cdk4-Rb pathway is corrupted in many types of cancers. Depending on the particular cancer, one or another element of this pathway is frequently found to be altered: growth-inhibitory Rb and p16 are inactivated by mutation or epigenetic silencing, while growth-promoting cyclin D or Cdk4 are activated by deregulation or overexpression.

p53 AND DNA DAMAGE CHECKPOINTS

In multicellular organisms, host welfare after exposure to DNA-damaging agents demands that cells either repair their damaged DNA or eliminate themselves if the damage is severe. The *p53* tumor suppressor gene plays a central role in this protective mechanism, and its derangement predisposes to cancer. [23] Originally described as a 53-kd cellular protein that is overexpressed in a wide variety of transformed cells, p53 was believed to be an oncoprotein, because *p53* genes cloned from nontumorigenic cell lines could immortalize and help transform primary rodent cells. Subsequently, mutations were found in these *p53* genes, and normal *p53* was found to suppress rather than promote cell transformation. The results of many studies have contributed to the current view that normal *p53* is a tumor suppressor gene with a negative effect on cell proliferation, generally stopping cells at the G_1-S transition. Some mutant *p53* genes exert a dominant negative effect and transform cells by inhibiting the activities of the normal gene. The facts that *p53* is the most frequently deleted or mutated gene in human tumors and that certain kindreds prone to developing cancer (Li-Fraumeni syndrome) are heterozygous for mutated *p53* in their germline attest

---

to its importance in preventing malignant transformation. At the biochemical level, p53 is a homotetrameric, sequence-specific DNA-binding protein with transcriptional activation properties. Mutant p53 from tumor cells loses this ability to bind DNA and fails to activate transcription. p53 associates with a variety of other cellular (TBP [TATA-binding protein], c-Abl, Mdm2, etc.) and viral (SV40 large T antigen, adenovirus E1B, and HPV E6) proteins, and these associations have functional significance. For example, the Mdm2 oncoprotein complexes with p53 and inhibits its ability to transactivate a responsive promoter, while the viral oncoproteins that complex with p53 either inactivate its function or accelerate its decay.

A gene that plays so prominent a role in oncogenesis might be expected to perform crucial cellular functions and be indispensible for normal development. It was surprising, therefore, to find that mice with homozygous deletions of *p53* developed normally and were abnormal only in being prone to developing spontaneous tumors. How *p53* prevents tumorigenesis but is not essential for normal growth and development is best explained by a conditional requirement for its activity. Cells without p53 function fail to arrest in G_1 after DNA damage, and the absence of this checkpoint mechanism predisposes to genomic instability and failure to eliminate genetically damaged cells by apoptosis. Under conditions that engender DNA damage (e.g., exposure to -irradiation and chemotherapy agents), p53 levels increase by post-transcriptional mechanisms, and the protein becomes functionally activated. p53 transcriptionally activates expression of several cellular genes, some of which, such as *p21* and *GADD45* (growth arrest and DNA damage-inducible gene), inhibit cell cycling and DNA replication and are responsible for p53s DNA damage G_1 checkpoint function. The ensuing pause presumably allows the cell time for repairs before the damaged DNA is replicated and transmitted to progeny cells and becomes an ongoing source of genetic misinformation. Other genes transcriptionally activated by p53, such as *Bax*, engender apoptosis rather than cell cycle arrest and presumably lead to elimination of cells that are genetically damaged beyond repair. The cell cycle arrest and apoptosis-inducing functions of p53 that protect genetic integrity following genotoxic insults must not be needed for developmental programs, given the normal development of *p53*$^{/}$ mice. However, the absence of p53 protective mechanisms in *p53*$^{/}$ mice and somatic loss of these mechanisms in Li-Fraumeni kindreds must allow DNA damage to accumulate, culminating in cell transformation. Although both the cell cycle arrest and apoptosis function of p53 would seem to help maintain genomic integrity, the latter may be more important for tumor suppression. That p21-mediated cell cycle arrest may not be essential for p53 tumor suppression is suggested by the observation that *p21*$^{/}$ mice develop normally and are not predisposed to developing malignancies. In contrast, p53-induced tumor cell apoptosis has been shown to retard tumorigenesis induced by SV40 large T antigen transgenes and to influence the survival of cells transformed by other oncogenes. With evidence suggesting that p53 may also influence tumor cell responses to therapy, p53-dependent apoptotic mechanisms may have impact beyond tumor development.

DIFFERENTIATION

Cell proliferation stocks an organism with the necessary number of cells to allow growth and to compensate for cell loss, but differentiation is the process by which these cells become endowed with the specialized functions needed. Each year an average adult man or woman produces about three to four body weight equivalents (200300 kg) of blood cells to maintain the steady-state numbers of cells in the circulation. Such a high cellular turnover suggests that control of hematopoietic cell proliferation and differentiation must be tightly regulated; otherwise a slight increase in proliferation rate could result in leukemia or hyperviscosity. By contrast, a tip of the balance in the opposite direction could lead to severe cytopenias.

The lineage-specific pathways of hematopoiesis have provided a paradigm for the study of cell differentiation. However, the molecular switches that determine lineage-specific cell differentiation remain incompletely understood. Nevertheless, limited insights into the molecular basis of cell differentiation have been gained through the study of various lower eukaryotic genetic systems as well as model cell culture systems. For example, conceptual paradigms of the transcriptional regulation of cell differentiation have been generated from the study of myogenesis and gene regulatory sequences in *Drosophila*.

Organization of Genomic Regulatory Systems

The regulation of cell differentiation and development is encoded in DNA in the form of arrays of transcription factorbinding sites (cis-regulatory elements). Decoding the cis-regulatory elements requires multiple transcription factors. These bind together to form higher-order protein complexes that provide machineries with vast combinatorial possibilities capable of activating specific gene transcription. The hard-wiring of transcription factors to each other and to the cis-elements enables them to process genomic information in the differentiation gene regulatory networks consisting of cis-elements of all relevant genes (Fig. 65). To fully understand cell differentiation, the organization of genomic regulatory networks must be comprehended.

Some general patterns of genomic regulatory systems have emerged.[24] When a gene is expressed in a number of different circumstances in a differentiating cell, separate groups of cis-elements, termed modules, may carry out the overall regulatory function (Fig. 65). Many modular cis-regulatory organizations are now well studied, particularly in *Drosophila*, which is highly amenable to genetic and biochemical analyses. From comparing and studying the complexity of cis-regulatory modules, it appears that modules usually consist of four to eight different factors. That is, the number of transcription factors bound per module averages five. Cell-specific cis-acting modules may be defined by specific combinations of transcription factors, which together are able to tether to the cis-regulatory DNA sequences and regulate transcription of specific differentiation-related genes.

The tethering of transcription factors to their cognate sites is restricted by nucleosomes. [25] Regions of genomic DNA that are transcriptionally active are marked by DNase I hypersensitivity sites that lack a nucleosome. Studies of the chicken erythroid-specific (A)/epsilon-globin gene enhancer, consisting of both tissue-specific and ubiquitous transcription factorbinding sites, suggest that hypersensitivity is determined primarily by erythroid factors and that their binding additively increased accessibility. Accessibility of DNase I to hypersensitive sites is an all-or-none phenomenon, such that binding of erythroid factors additively increases the probability of switching a particular cis-acting module into a hypersensitive state free of a canonical nucleosome. [26] These and other observations contribute to the emerging concept (Fig. 65) that transcriptional regulation is stochastic and that binding of transcription factors to their target sites in cis-regulatory modules enhances the probability of switching a transcription unit into an active state. [27] The all-or-none phenomenon of transcription provides a basis for the stochastic nature of hematopoietic differentiation.

The Myogenic Differentiation Model

The cell culture myogenesis model has provided astounding insights into some molecular mechanisms of lineage-specific cell differentiation induction. [28] [29] Early studies of myogenesis

Figure 6-5 Wiring of extracellular stimuli to transcription of genes during differentiation. The upper diagram depicts growth factor- or extracellular matrix/integrin-mediated signal transduction to activate transcription factors shown as a square, circle, or triangle. Activation of a subset of transcription factors is shown to regulate a specific category of genes (X and Y). The lower diagram illustrates the stochastic nature of transcription. Each gene may be regarded as an all-or-none transcription unit. Transcription factors bound to their target DNA sites increase the probability of a unit being switched on. For example, the square transcription factor may impart a 0.1 probability, which on a population basis would cause 10% of cells expressing the square factor to express a specific gene. The transcription factors are shown to increase the probability of transcription additively.

generated the idea that a single master gene may control muscle cell differentiation. Brief treatment of C3H 10T 1/2 fibroblastic cells with 5-azacytidine induced the formation of many myogenic colonies and fewer numbers of chondrogenic and adipogenic colonies. Transfection experiments showed that genomic DNA from 5-azacytidine-induced myoblasts, but not DNA from parental cells, conferred the muscle phenotype to C3H 10T 1/2 cells. A cDNA for the gene termed *myo*D was cloned by subtractive hybridization to identify mRNAs that were specifically expressed in myoblasts but not in parental C3H 10T 1/2 cells. Transfection of *myo*D cDNA alone was sufficient for myogenic conversion of C3H 10T 1/2 cells. MyoD is a transcription factor that was subsequently shown to activate muscle-specific genes. As with the adipocyte differentiation model, overexpression of c-*myc* also inhibited myogenic differentiation, suggesting that signals for cell proliferation could override cues for differentiation.

MyoD, a member of the helix-loop-helix family of transcription factors, binds to consensus DNA sites that include a CATG sequence present in most muscle-specific enhancers. MyoD is also a member of a family of myogenic transcription regulators, such as myogenin, myf-5, and myf-6-mrf-4-herculin, that can confer muscle phenotype to C3H 10T 1/2 cells. The MyoD protein is comprised of a basic-helix-loop-helix (bHLH) DNA-binding domain and an N-terminal transcriptional activation domain. MyoD binds its target sites as homodimers but more tightly so as heterodimers with ubiquitous bHLH E2A transcription factors. The association of MyoD with E2A is regulated by a third factor that was sought because MyoD protein is present in proliferating undifferentiated myoblasts. Indeed, the *Id* (inhibitor of differentiation) gene was cloned as a cDNA whose protein product was homologous to helix 2 of MyoD. Id contains an HLH motif but lacks the DNA-binding basic region. It can form heterodimers with MyoD or E2A proteins, but these dimers are unable to bind DNA. Transfection experiments have demonstrated that Id could inhibit the ability of MyoD to trans-activate a muscle-specific gene and retard myogenic differentiation. The myogenic differentiation model led to the discoveries of MyoD and Id, both of which participate in a network of protein-protein interactions that alters muscle-specific gene expression. It will become apparent in the subsequent discussions that these general paradigms hold true for myeloid maturation as well.

Hematopoietic Differentiation

Hematopoiesis is a fascinating system in which pluripotent hematopoietic stem cells (PHSCs) differentiate into many highly specialized circulating blood cells. [30] [31] [32] The long-term repopulating PHSCs are capable of self-renewal as well as limited differentiation toward the common lymphoid stem cell or myeloid multipotent stem cell (Fig. 66). Most PHSCs are believed to be dormant and stochastically awakened to enter the cell cycle. The common lymphoid stem cell differentiates into either mature T cells or B cells. The myeloid multipotent stem cell differentiates into a variety of circulating blood cells, including basophils, eosinophils, neutrophils, monocytes, erythrocytes, and megakaryocytes (platelets). The developmental program for each type of mature circulating cell consists of networks of cellextracellular matrix, cellcell, and cellgrowth factor/lymphokine interactions.

It has been established experimentally that PHSCs can differentiate toward either a lymphoid or a common myeloid progenitor. Retroviral labeling of the genome to analyze the clonality of differentiated cells revealed that myeloid and lymphoid cells arise from pluripotent stem cells. The mechanisms determining the commitment of PHSCs to differentiate toward either lymphoid or myeloid progenitors remain incompletely understood; however, the process by which cells differentiate along specific lineages of defined phenotypes is now known to be a result of coordinated lineage specific gene expression. It has been proposed that commitment to differentiate is a stochastic process based on paired daughter cell analysis. In these studies, daughter cells derived from a single parent progenitor cell frequently displayed varied combinations of cell lineages. Such observations have been construed to suggest that random activation of a group of differentiation genes might be required for single-lineage expression. This suggestion has precedence in the known random shuffling of immunoglobulin gene fragments through V(D)J rearrangements to generate antibody diversity. Clones of B cells are then expanded by specific antigens that select for specific antibody variable region structures arising from random V(D)J rearrangements. A stochastic model for hematopoietic cell differentiation has been proposed based on notions similar to those for generation of antibody diversity.

The stochastic model for commitment suggests that dormant PHSCs are recruited into the cell cycle by many lymphokines, including combinations of IL-1, IL-3, IL-4, IL-6, IL-11, IL-12, G-CSF, GM-CSF, FLT, and stem cell factor. Although the molecular basis for synergisms between these factors remains unknown, certain functional and structural homologies among them are notable. For example, IL-6, IL-11, and leukemia inhibitory

Figure 6-6 Stochastic switches and transcription factors in hematopoiesis. The diagram depicts hematopoietic differentiation as a combinatorial switching of key signaling pathways or factors (squares) in hematopoietic cells. Homologous recombination allowing for the inactivation of specific transcription factor genes has revealed the level of participation of different factors in hematopoiesis. The points at which knockout of each factor results in developmental abnormalities are shown. For example, knockout of GATA-1 deranges erythroid development of FC3, osteoclast development, and so forth. *(Adapted from Shivdasani and Orkin,[33] with permission.)*

factor (LIF) require cooperation with a signal-transducing protein GP130 for function. Likewise, receptors for IL-3, IL-5, and GM-CSF share a common -subunit that associates with unique factor-specific chains. Once recruited into the cycling fraction of cells, PHSCs must divide, survive, and differentiate into a certain lineage of cells. It is hypothesized that the stochastic establishment of specific differentiation programs (perhaps by random expression of groups of differentiation genes) in PHSCs provides a population of partially committed cells that are poised to receive additional instructions. Intermediate stage-acting, lineage-nonspecific factors such as IL-3, GM-CSF, and IL-4 support the proliferation of the multipotential progenitors after they have been awakened from their dormant state.

Lineage-specific factors support the survival, proliferation, and maturation of progenitors that are committed through hypothetical stochastic expression of specific groups of differentiation genes. [33] [34] For example, M-CSF promotes the proliferation and differentiation of macrophage/monocytes. Erythropoietin promotes the survival, proliferation, and differentiation of erythrocytes. IL-5 and G-CSF are thought to be specific for eosinophils and granulocytes, respectively. A late-acting lineage-specific factor for megakaryocytopoiesis, termed MGDF or thrombopoietin, has been cloned and extensively studied in recent years. [35] These late-acting lineage-specific factors could be viewed as factors that induce specific transcription factors such as PU.1, GATA-1, and a variety of HOX proteins (Fig. 66). Activation of cis-regulatory modules by these transcription factors selects out and promotes the proliferation of subsets of committed cells whose differentiation programs have been randomly selected. The activation of groups of differentiation genes that are not supported by lineage-specific factors will hypothetically result in cell death.

Lymphoid Differentiation

The commitment of PHSCs to lymphohematopoietic progenitors is thought to be mediated in part by the lineage-nonspecific factors mentioned previously. The mechanisms of early lymphoid development remain poorly understood. B-cell differentiation occurs in the bone marrow of adults, where expression of the immunoglobulin (Ig) heavy chain precedes that of the light chain. Completed Ig chains expressed on the surface lead to the surface-Ig-positive B lymphocytes that migrate to the peripheral lymphoid organs such as the spleen. [36] [37]

Several molecular events that are critical for maturation of lymphoid cells have been identified. Study of Bruton X-linked agammaglobulinemia, which is a disorder of B-cell development, has localized the defect to a B-cell-specific cytoplasmic tyrosine kinase gene locus. This tyrosine kinase, termed BPK, has classic tyrosine kinase, SH2, and SH3 domains. Pre-B or B-cell lines from X-linked agammaglobulinemia patients displayed reduced or absent *BPK* mRNA. Study of genetically engineered (knockout) mice in which the recombination-mediating protein RAG1 or RAG2 (necessary for V[D]J recombination)

is absent revealed that RAG1 and RAG2 are required for the normal maturation of lymphocytes. The V(D)J reaction appears restricted to particular antigen receptor loci in a lineage-specific and stage-specific fashion. [38] Cis-regulatory elements, which regulate the transcription of the germline (unrearranged) antigen receptor loci, are involved in the specificity of the V(D)J reaction. In the T-cell lineage, the first gene rearranged is TCR-. In B cells, the IgH locus is rearranged first. The products of the rearranged antigen receptor genes themselves appear to generate signals that regulate the develpment of T and B lineages. For example, deletion of the transmembrane domain for IgM causes a block of differentiation from the pro-B to the pre-B stage. In addition to these internal cues for differentiation, a number of cytokines such as IL-2, IL-4, IL-7, IL-9 and IL-15 provide other signals that are required for lymphocytic differentiation and maturation.

Myelomonocytic Differentiation

The study of myeloid differentiation underscores our lack of understanding of early events in the commitment of PHSCs to the multipotent myeloid progenitor CFU-GEMM (colony-forming unit-granulocytes, erythrocytes, monocytes, and megakaryocytes). Colony-forming units specific for granulocytes (CFU-G) are thought to arise from a precursor common to granulocytes and monocytes (CFU-GM). The committed myeloid precursors (CFU-G) are presumably selected for and amplified by a myeloid-specific factor, G-CSF. The monocyte-macrophage lineage is selected by M-CSF (CSF-1), which stimulates growth and differentiation through the CSF-1 receptor (CSF-1R) encoded by the proto-oncogene c-*fms*.

CSF-1 exerts its effects by binding to a class of high-affinity receptor that is expressed predominantly on monocytes and macrophages. [39] The receptor CSF-1R is a member of growth factor receptors that display ligand-induced tyrosine-specific protein kinase activity. Activation of CSF-1R triggers a cascade of events, many of which are described for the activation of EGF-R and PDGF-R, that convey signals from the plasma membrane to the cell nucleus. Dissection of CSF-1R by mutagenesis has led to the paradigm that a single plasma membrane receptor can give rise to separate nuclear transcription programs. Specifically, a point mutation in CSF-1R has been identified that results in the activation of the *fos* and *jun* proto-oncogenes, but not *myc*, by CSF-1.[40] This mutant receptor cannot trigger mitogenesis in transfected cultured cells unless complemented by a constitutively expressing *myc* allele. In separate studies of cell lines with the potential for differentiation into neutrophils or macrophages, the zinc finger transcription factor Egr-1 has been shown to be essential for differentiation along the macrophage lineage. Egr-1 appears to restrict differentiation of HL-60 (promyelocytic leukemia) cells into macrophages. Farther downstream events leading to the monocyte-macrophage phenotype remain unestablished.

With the availability of recombinant G-CSF, several cell culture models for granulocytopoiesis have been studied at the molecular level. [41] [42] For example,

differentiation of the myelomonoblastic murine cell line 32D C13 induced by G-CSF is accompanied by differential expression of the C/EBP family of proteins. In contrast to fat cell differentiation, in which C/EBP- protein increases with differentiation, myeloid differentiation of the 32D C13 cells is accompanied by a marked decrease in C/EBP- protein levels. The role of C/EBP- in myeloid differentiation has been further substantiated by the observation that genetically engineered C/EBP- null mice lack mature neutrophils. Myeloid differentiation is also associated with the expression of the *myb*-responsive myeloid-specific *mim*-1 gene, which encodes a protein with an as yet unknown function. Full activation of *mim*-1 requires both myb and C/EBP- binding to their cognate sites in the *mim*-1 promoter. In fact, this combination of activators is sufficient to activate *mim*-1 in heterologous cells such as fibroblasts or erythroid cells. [43] These observations support the hypothesis that tissue-specific gene expression could arise from combinations of transcription factors that are not tissue specific.

Azurophilic cytoplasmic granules are formed with the differentiation of myeloblasts to promyelocytes. [44] Myeloperoxidase is a major protein of the azurophilic granules, and hence its gene is an ideal target to study cis-regulatory modules. Recent studies on the myeloperoxidase gene promoter suggest that myeloid-specific expression of myeloperoxidase might in part be dictated by a cell-type-restricted transcription factor MyNF1 (myeloid nuclear factor 1), which is not yet cloned. Other transcription factors that may form the neutrophil-specific cis-regulatory module include myb, PEBP2/CBF/AML1, and ETS. [42] Identification of relevant cis elements and trans-acting factors required for myeloid-specific gene expression will provide novel avenues to connect extracellular signals from G-CSF to nuclear events that lead to the expression of the myeloid phenotype.

Erythroid Differentiation

Cells committed to differentiate stochastically into the erythroid lineage are amplified by the erythroid-specific factor erythropoietin. Erythropoietin is thought not to determine lineage commitment but to function as a growth factor as well as a survival factor in cell culture studies of erythroid cell lines and normal bone marrow erythroid precursors. Thus, according to the stochastic lineage commitment model, erythropoietin serves to rescue those cells (CFU-E or BFU-E) that express the erythropoietin receptor. [45] When bound to its receptor, erythropoietin initiates a signal transduction pathway that involves the serine/threonine protein kinase raf, protein kinase C, STAT5, and a genetic program that activates the expression of the c- *myc* proto-oncogene. Expression of Bcl-X_L , a Bcl-2 family member, is highly elevated in late erythroid differentiation induced by erythropoietin. Without erythropoietin, the caspase CPP32/apopain is activated and committed erythroid cells undergo programmed cell death with the characteristic laddering of DNA due to nuclease-mediated fragmentation. In these models, hemoglobin synthesis and other manifestations of the erythroid phenotype follow; however, the molecular events responsible for the initiation of these events remain unknown.

Insights into the regulation of the globin gene have emerged with the identification of cis and trans factors that regulate erythroid-specific genes. Erythroid-specific cis-acting elements have been identified in several erythroid genes. The sequence (A/T)GATA(A/G) is found in the globin gene enhancer in several species and in the promoter of the erythropoietin receptor (EpR) gene. [33] This consensus sequence is recognized by a cell-restricted transcription factor, GATA-1, found in megakaryocytes, erythroid, and mast cells. GATA-1 is one of four related members of the GATA family of transcription factors. High expression of globin also requires a regulatory region, located about 20 kb upstream of the epsilon-globin gene, termed the locus-activating region (LAR), which also contains a GATA sequence. Genetic knockout of GATA-1 in mice results in a block in normal erythropoiesis, attesting to the importance of GATA-1 in erythroid differentiation. The block in maturation occurs at the proerythroblast stage. Myeloid cells, however, do arise from hematopoietic cells lacking GATA-1, indicating that GATA-1 acts at a later stage than PHSCs or their immediate descendants. Homozygous deletion of the Kruppel-like factor EKLF gene results in absent -globin gene transcription but persistent epsilon- and -globin gene expression. This observation suggests the EKLF may be important for the interaction between the LAR and the -globin gene. The accumulation of knowledge about these factors will contribute to a fuller understanding of erythroid differentiation.

Megakaryocytic Differentiation

Megakaryocytic differentiation is an intriguing biological phenomenon in which a cell undergoes several rounds of DNA replication without cytokinesis. The resultant mature polyploid megakaryocyte then sheds small, membrane-bound, metabolically active cytoplasmic fragments that become circulating platelets. The platelet cell participates in thrombosis through several signal transduction pathways, including activation of the thrombin receptor and fibrinogen receptor (GPIIb/IIIa). The activated platelet lets the cellular glue plug up small anatomic defects in the vasculature. It is clinically apparent that thrombocytopenia due to peripheral destruction is accompanied by recruitment of mature megakaryocytes from precursor cells. The factor involved in this feedback loop has been purified, cloned, and termed thrombopoietin, or MDGF. [35]

Some of the later megakaryocytic differentiation events are beginning to emerge from studies of megakaryotic cell lines and megakaryocyte-specific genes. Several cell lines can be induced to differentiate and express various megakaryocytic phenotypes, including the platelet-specific fibrinogen receptor GPIIb/IIIa. These cells also display repeated rounds of DNA replication that result in polyploidism. The molecular mechanisms that control polyploidism are likely to involve certain molecules that determine cell fate, such as the cyclins, molecules that control the mitotic checkpoint, [18] as well as genes that regulate the initiation of DNA replication such as *CDC6*. Future studies of these genes in megakaryocytic differentiation will shed more light on this fascinating phenomenon.

As the promoters of several platelet-specific genes are cloned and thrombopoietin is available as a specific megakaryoctyic differentiation and growth factor, the mechanism of regulation of platelet-specific genes is beginning to emerge. [46] Inspection of the promoters for platelet genes GPIb, GPIIb, and GPIIIa indicates that there is a common putative DNA-binding site, termed putative meg-specific element (PMS-E), that may be megakaryocyte specific. It is also apparent that unique combinations of many ubiquitous transcription factors, such as SP1, are likely to dictate tissue specificity. Indeed, various DNA-binding sites have been identified in promoters of megakaryocyte-specific genes. Among these sites is the GATA sequence that was previously thought to be erythroid specific. In fact, enforced expression of GATA-1, a GATA-binding protein, in a myeloid cell line induced the megakaryocyte phenotype. Conversely, selective loss of megakaryocyte GATA-1 expression resulted in mutant mice with markedly reduced platelet numbers, deregulated megakaryocyte proliferation, and impaired cytoplasmic maturation. Intriguingly, when mice lacking the p45 subunit of the heteromeric erythroid transcription factor NF-E2 were generated, the NF-E2 $^{/}$ mice lacked circulating platelets and died of hemorrhage. [33] Their megakaryocytes showed no cytoplasmic platelet formation and yet proliferated in vivo in response to thrombopoietin. Loss of NF-E2 affected the erythroid lineage only mildly. With the availability of thrombopoietin, it is expected that the thrombopoietin-responsive cis elements in megakaryocyte-specific genes, such as those encoding GPIIb and platelet factor 4, are likely to be rapidly identified. In the next few years, the challenge remains to link events triggered by thrombopoietin through its receptor, c-Mpl, to the activation of cis-regulatory modules found in megakaryocyte-restricted genes.

PROGRAMMED CELL DEATH (APOPTOSIS) AND HEMATOPOIESIS

Apoptosis and Programmed Cell Death

Apoptosis is a morphologically unique process of cell death that is distinct from necrosis. [47] [48] [49] Necrosis denotes accidental cell death resulting from severe and sudden thermal, physical, or

Figure 6-7 Apoptosis is a morphologically and biochemically defined phenomenon in which cells die. The apoptotic cell undergoes blebbing of the plasma membrane and condensation of nuclear material with nuclease digestion, resulting in nicked DNA ends that are detectable by fluorescent (FL) polyuridyl (UUU) labeling using terminal deoxynucleotidyl transferase (TUNEL assay). Release of nucleosomal DNA is detected as a ladder of DNA fragments.

chemical trauma. Morphologically, there is early mitochondrial and cellular swelling with ensuing cytoskeletal disruption and ruptured plasma membrane and organelles. During necrosis, the nuclear structure remains intact. In contrast, apoptosis is a sequential process that starts with condensation of the chromatin and shrinkage of cell volume (Fig. 67). The plasma membrane becomes ruffled and blebbed. The nucleus and cytoplasm then become partitioned into membrane-bound apoptotic bodies that are shed from the dying cells. The term apoptosis was proposed by Kerr, Wyllie, and Currie to describe these cellular alterations and used in Greek () to describe the falling off of petals from flowers or leaves from trees. [50] Most cells in the last stages of apoptosis display DNA strand breaks, which are detectable by terminal deoxynucleotidyl transferase labeling, and a characteristic degradation of nuclear DNA into multimers of 180 base pairs (DNA laddering; see Fig. 67). Throughout apoptosis, the mitochondria remain morphologically normal. Apoptosis participates in many physiologic processes, including morphogenesis, death of short-lived neutrophils, elimination of self-reactive T cells, and perhaps death of B cells with nonproductive V(D)J gene rearrangements.

Genetic Basis of Programmed Cell Death

Although apoptosis is commonly equated with programmed cell death in vertebrate systems, a genetic program for cell death

has been unequivocally established for the death of individual cells in *Caenorhabtditis elegans* (a small worm) and *Drosophila*. [49] [51] In *C. elegans*, 131 out of 1,090 somatic cells are programmed to die during development. Studies of mutant *C. elegans* have revealed at least 14 genes (complementation groups) that are involved in cell death. Of these, *nuc-1* is a gene that encodes an endonuclease. Mutants of *ced-3* or *ced-4* genes that are required for cell death have extra somatic cells. Mutation of the locus *ced-9*, which antagonizes *ced-3* and *ced-4*, results in developmental arrest. The product of *ced-9* blocks apoptosis, and hence its loss presumably results in untimely cell death. The biochemical properties of *ced-3, ced-4,* and *ced-9* are now better understood and their mammalian homologs have all been identified.[52] The emerging picture of this highly conserved suicide program is that the *ced-3* and *ced-4* proteins directly bind each other (Fig. 68). Ced-3 is a member of an ever-expanding family of proteases, termed caspases, that cleave critical cellular substrates after (to the C-terminal side) aspartate residues leading to irreversible cell damage and hence death. [53] [54] Ced-4 was found to bind directly with Ced-3 or Ced-9, which is homologous to Bcl-2 and is able to block cell death.

An understanding of the genetic regulation of programmed cell death in vertebrates is only beginning to emerge. An intriguing clue to the genetics of vertebrate apoptosis came from the study of *bcl-2*, a gene that is characteristically translocated [t(14:18)] in most follicular lymphomas. [55] [56] The protein Bcl-2 has significant sequence homology to the product of the *C. elegans ced-9* gene.[52] Expression of the Bcl-2 protein is restricted to tissues characterized by apoptotic death. For example, Bcl-2 is found in the thymic medulla, where surviving T cells are located, but Bcl-2 is not found in cortical thymocytes destined to die. In transgenic mice experiments, targeted *bcl-2* expression in B cells resulted in memory cells with an extended lifetime. Targeted *bcl-2* expression in T cells resulted in immature thymocytes that were resistant to apoptosis induced by glucocorticoids, irradiation, or anti-CD3 antibody. Thus, follicular lymphomas, which are characterized by a low growth fraction and deregulated expression of *bcl-2*, proliferate predominantly by a decrease in the rate of cell death. The function of Bcl-2 at the molecular level still eludes complete characterization; however, the Bcl-2 protein is known to exist in mitochondrial, endoplasmic reticular, and perinuclear membranes. Recent studies suggest that Bcl-2 may form channels for small electrolytes in lipid bilayers. Other studies suggest that its antiapoptotic effect is mediated through the retention of cytochrome c, which is released from mitochondria to activate caspases and initiate the final apoptotic pathway.

Figure 6-8 Studies in the nematode *C. elegans* reveal genetically determined pathways that regulate cell death. The death genes (ced) are shown with their corresponding mammalian analogs in parentheses. The CED3/CED4 complex is shown to culminate in programmed cell death (PCD).

Insights into signal transduction and activation of caspases have come from the study of the membrane protein termed Fas/APO-1 (Fig. 69), which induces apoptosis when cross-linked by anti-Fas/APO-1 antibody. [57] [58] The Fas protein is homologous to receptors for tumor necrosis factor and nerve growth factor. A lymphoproliferative condition is found in mice bearing the *lpr* mutation that is responsible for a defect in Fas or the *gld* mouse which is defective in the Fas ligand (FasL). The interaction of Fas with its ligand is now known to be central for clonal deletion of lymphocytes. The signals transduced by Fas are rapidly emerging as a complex yet tangible system. Conversion of sphingomyelin to ceramide by sphingomyelinase may play an important role in this signal transduction pathway, although the role of ceramide as a second messenger of death is controversial and therefore requires additional studies. [59] The apoptotic signaling by Fas or a related tumor necrosis factor receptor (TNF-R1) requires a cytoplasmic death domain (DD). [60] Adaptor proteins, such as FADD or RAIDD, tether to these receptors through their own DD domains. A death effector domain (DED) of the adaptor FADD is required for the propagation of the death signal. In the case of FADD, the DED binds to the prodomain of caspase 8 (MACH/FLICE) and activates its proteolytic activity. Some of the targets of the caspases include poly(ADP-ribose) polymerase, DNA-dependent protein kinase, and actin. Presumably the cleavage of these and other proteins contributes to the demise and morphologic changes of apoptotic cells.

The tumor suppressor protein p53 has been shown to participate in the regulation of cell cycle G_1-S transition.[23] [61] It is thought to be involved in the monitoring of DNA breaks induced by various physical and chemical agents such as ionizing radiation. Through an unknown mechanism involving the ataxia-telangiectasia protein ATM, DNA breaks are detected and p53 protein levels are subsequently increased (by post-transcriptional events), resulting in cellular arrest in G_1. Overexpression of wild-type p53 protein in tissue culture cells has been associated with an increase in the rate of apoptosis. On the other hand, homologous genetic knockout of the *p53* gene resulted in thymocytes that did not undergo apoptosis on exposure to ionizing radiation but continued to die on exposure to glucocorticoid. These observations suggest that several pathways leading to apoptosis in thymocytes exist and that at least one of these pathways is p53 dependent.

The participation of c-Myc in cell proliferation and neoplastic transformation has been established by a variety of studies. [61] [62] A new twist on the function of the c-Myc

protein in cell fate, however, was unveiled when cells overexpressing Myc were deprived of nutrients and growth factors through serum deprivation. In contrast to parental fibroblastic cell lines that undergo growth arrest and withdraw into the G_0 phase with serum deprivation, the Myc-overexpressing cells undergo apoptosis. The apoptotic phenotype is dependent on domains of the c-Myc protein required for transcriptional activation and cellular transformation, suggesting that Myc actively participates in apoptosis. Hypothetically, the Myc-overexpressing cells appear to contend with conflicting signals for cell proliferation (Myc) and for growth arrest (serum withdrawal) by executing the cell death program. Although serum deprivation provides a convenient experimental maneuver, its physiologic significance is obscure unless one considers the growth of a tumor mass. In a mass that is sufficiently large, access to nutrients becomes diffusion limited toward the center of the mass as tumor size increases. Thus, cells at the center of the mass may undergo apoptosis unless additional genetic alterations are sustained. Such additional genetic alteration might be the expression of Bcl-2 that can block the apoptotic effects of Myc.

Eosinophils, monocytes, and neutrophils all participate in the initiation and control of inflammatory responses. [63] Their elimination from circulation may in part be mediated by

Figure 6-9 The Fas and related TNF-R pathway are depicted with the intermediate adaptor molecules (TRADD, FADD). The adaptors interact with and activate FLICE, which belongs to the family of caspase proteases. The caspases cleave cellular protein substrates to mediate the final pathway of cellular death.

apoptosis. Isolated eosinophils undergo apoptosis after about 80 hours in culture. IL-5 appears to extend eosinophil lifetime by delaying apoptosis. Mature neutrophils have also been shown to undergo apoptosis. Likewise, monocytes undergo programmed cell death that can be averted by exposure to IL-1b, TNF-, GM-CSF, and interferon-.

Programmed cell death appears to be an integral component of the stochastic hematopoietic cell lineage commitment and differentiation model. Apoptosis also appears to participate in the physiology of the more mature hematopoietic cells. For example, thymocytes undergo a stringent selection process that uses apoptosis to eliminate cells that recognize self antigen. In addition to the roles of apoptosis in normal hematopoiesis, its role in the pathophysiology of hematopoietic disorders is rapidly and extensively becoming recognized.

Chapter 7 - Overview of the Immune System (Including Compartmentalization of the Immune Response)

Ellen Puré

The immune system must detect and respond to a broad range of antigenic challenges from foreign substances. Although the immune system has evolved to protect the host against pathogenic microorganisms, similar types of immune responses are elicited by noninfectious foreign antigens as well. Furthermore, many of the nonspecific mechanisms that are engaged as the result of antigenic stimulation are used in the inflammatory response and in the repair of tissue damaged as the result of noninfectious injury such as wounding, burns, and trauma.

To succeed in its protective function, the immune response must react to particular antigens quickly and efficiently, especially those pathogens that it encounters repeatedly. The two host defense systems that provide immunity against infectious agents are the innate, or natural immune system, and the acquired (adaptive) or specific immune system (Table 71). The innate immune system is the first to respond and, as a result, limits or cures infection before an adaptive immune response is generated. The innate immune response involves mainly nonlymphocytic cells, including macrophages and polymorphonuclear leukocytes, as well as complement and acute-phase proteins. The cells that mount the innate immune response are also important effectors in acquired or adaptive immunity. Innate immunity is present in all individuals all the time and does not change with repeated exposure to antigen. If the innate immune response cures rather than limits an infection, it can prevent development of adaptive immunity, in which case no long-lasting immunity is established.

In comparison, the central players in the adaptive, inducible response are antigen-specific lymphocytes. The main challenge of the adaptive immune system is the requirement to respond to the myriad of foreign antigens introduced at any site with only a very small number of lymphocytes specific for any one antigen. Several features of the cells and tissues of the immune system allow this challenge to be met successfully. One key feature is the anatomic organization of the immune system. The primary lymphoid organs (i.e., the thymus and bone marrow) produce, under antigen-independent conditions, millions of lymphocytes displaying a vast diversity of antigen-specific receptors that form the basis of the broad immune response. The lymphocytes generated in the primary lymphoid organs are exported to the peripheral blood, where they form a naive pool of circulating lymphocytes capable of recognizing most antigens (Fig. 71). Importantly, recirculating lymphocytes migrate and are exchanged between the circulation and the peripheral or secondary lymphoid organs (i.e., the spleen and lymph

TABLE 7-1 -- Innate and Adaptive Immunity

Innate	Adaptive
Early: First 45 days	Late: 5 days
Constitutive	Inducible by antigen
No memory	Memory/immunity
Nonlymphocytic/not clonal	Lymphocytic/clonal

Figure 7-1 Leukocyte circulation. Leukocytes are bone marrow derived. Most leukocytes differentiate in the bone marrow and migrate from the marrow directly to the peripheral circulation. However, T-cell precursors migrate from the marrow to the thymus where they undergo maturation before they are exported to the periphery. Naive lymphocytes migrate and are exchanged between the circulation (blood and lymph) and the peripheral lymphoid organs where antigen-dependent immune responses are initiated. Antigen-stimulated effector cells home to sites of antigen exposure or inflammation.

nodes), where antigen-dependent immune responses are initiated. The specialized architecture of the secondary lymphoid organs makes them optimal sites for acquiring and concentrating antigens and for antigen-induced lymphocyte growth and differentiation to effector cells. On antigenic stimulation, the relevant lymphocytes become activated, proliferate, differentiate to effector cells, home to sites of antigen exposure, and are retained at these sites and eventually dispense with the antigen. A second peripheral lymphocyte compartment is formed when some of the antigen-stimulated lymphocytes become diverted to a memory pool, composed of cells that respond to antigen more immediately than those in the naive pool. The memory cells differ from the naive cells in their surface phenotype, homing properties, signaling requirements, and cytokine secretion pattern. The establishment of memory cells ensures that recurrent exposure to the same antigen results in a more rapid response, and changes the quality and maximal level of the response. Interactions between antigen-specific lymphocytes and other cells that are involved in the cognitive and effector phases of immune responses serve to optimize these responses. Multiple amplification loops magnify the effects of stimulating the few antigen-specific lymphocytes for one antigen.

There are two branches of adaptive immunity; humoral adaptive immunity and cellular adaptive immunity (Fig. 72). An essential difference between the B lymphocytes, which are responsible for humoral immunity, and T lymphocytes, which are responsible for cellular immunity, is the form of antigens that they recognize. Each clone of B and T cells expresses distinct antigen receptors. However, B lymphocytes recognize conformations

Figure 7-2 The two branches of adaptive immunity: humoral adaptive immunity and cellular adaptive immunity. The main function of B lymphocytes is to produce the antibodies that mediate humoral immunity. Antibodies neutralize pathogens or toxic products, opsonize pathogens for phagocytosis, and activate complement to enhance phagocytosis and destroy pathogens. T cells are required for cellular immunity. T cells act to eliminate antigen directly by differentiating into cytolytic cells. T cells also mediate cellular immunity indirectly by activating macrophages. T cells are also typically required to stimulate B cells to produce antibodies.

of native antigen, whereas the receptors expressed by T lymphocytes recognize peptides derived from processed antigen that are bound to cell surface protein products of the major histocompatibility complex (MHC). The main function of B lymphocytes is to produce the antibodies that mediate humoral immunity by neutralizing pathogens or toxic products, opsonizing pathogens for phagocytosis, or activating complement to enhance phagocytosis and destroy pathogens. B cells can also serve as antigen-presenting cells (APCs) for T cells. T cells generate cell-mediated immunity directly by differentiating into cytolytic cells that are able to kill, for example, virus-infected cells. T cells also mediate cellular immunity indirectly by activating macrophages against intracellular pathogens like *Mycoplasma tuberculosis*. In addition, T cells are typically required to stimulate B cells to produce antibody.

The multiple components of the immune system, including innate immunity and humoral and cellular adaptive immunity, all must work as an integrated host defense mechanism to effectively eliminate any infectious agent and provide long-lasting protective immunity. In this chapter, we briefly review the various components of the innate and adaptive immune systems with an emphasis on the links between innate and adaptive immunity and on how and where antigens and lymphoid cells meet and cooperate at various stages of infection to effectively eliminate invading pathogens.

CELLS OF THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

The nonlymphocytic leukocytes that mediate innate immunity and also serve as effector cells of adaptive cellular immunity are all bone marrow derived and develop from multipotential hematopoietic stem cells. Lineage commitment and differentiation of the various cell types depend on stromal cell contact and cytokines.

Dendritic cells are bone marrow derived, professional APCs that possess characteristic processes that accommodate contact with T cells. Dendritic cells can develop from CD34+ peripheral blood monocytic precursors, in the presence of granulocytemacrophage colony-stimulating factor and interleukin (IL)-4 or IL-13, into immature dendritic cells that effectively take up and process antigens. Activation by stimuli such as tumor necrosis factor (TNF), lipopolysaccharides, or IL-1 induces further differentiation to mature dendritic cells that effectively stimulate antigen-specific T cells. Dendritic cells are found in the interstitium of most organs and mainly in the T-cell areas of peripheral lymphoid organs. As is characteristic of APCs, dendritic cells express both MHC class I and class II molecules.

A second population of unrelated cells that are mainly localized to the follicular, B-cell areas of peripheral lymphoid organs are referred to as follicular dendritic cells. Follicular dendritic cells are *not* bone marrow derived and are not related to interdigitating dendritic cells. Follicular dendritic cells display antigens for recognition by B cells in the form of immune complexes that are retained long-term on the cell surface.

There are two major classes of phagocytic cells, polymorphonuclear leukocytes (PMNs) and macrophages. Granulocytes are inflammatory cells with abundant cytoplasmic granules that are essential for the elimination of microbes and dead tissue. Eosinophils are leukocytes that contain eosinophilic granules. They express Fc (crystalline fragment) receptors for IgE, which is prevalent in the response to parasitic infections and mediates activation of eosinophil killing mechanisms. Eosinophils also play a role in immediate hypersensitivity to allergens and cause tissue injury and inflammation. Eosinophils are recruited and activated by IL-5 made by T cells. Basophils in the circulation and mast cells in tissues also express Fc receptors for IgE, and IgE immune complexes induce their granular exocytosis, resulting in the release of the chemical mediators of immediate hypersensitivity.

Neutrophils are the major class of phagocytic granulocytes. They contain multilobed nuclei and neutrophilic granules. Neutrophils respond rapidly to chemotactic stimuli and phagocytose and destroy foreign particles. Neutrophils are activated by macrophage- and endothelial-derived cytokines and are the major population of cells involved in acute inflammatory responses. Neutrophils express Fc receptors for IgG and complement receptors and thus bind and phagocytose opsonized antigens, providing an important link between innate immunity and humoral immunity. Neutrophils are the major cellular component of the acute inflammatory response and are the primary effector cells in immune responses to pyogenic organisms such as extracellular bacteria.

By contrast, macrophages are the major cellular component in most chronic immunologic responses and act as key regulators of the specific acquired response. A well established dichotomy within the immune system is that between an acute and a delayed inflammatory cellular response. PMNs and macrophages are both professional phagocytes whose major effector function is killing microorganisms. However, PMNs respond within minutes to hours, appearing in large numbers in the tissue and being largely responsible for the acute phase of inflammation. Macrophages are fewer in number, with peak response in hours to days, and participate in both acute and chronic inflammation.

Polymorphonuclear cells can regulate the activation and recruitment of macrophages primarily by the release of a wide variety of cytokines. In addition, macrophages are the principal scavengers of PMNs undergoing apoptosis in the secondary phase of an acute inflammatory response. The most important microbial killing mechanisms in phagocytes are the activation of the respiratory burst and the production of cytotoxic reactive oxygen intermediates, and, through a different mechanism, the generation of reactive nitrogen intermediates such as nitrous oxide.

Tissue macrophages are the second major class of phagocytic cells. They provide innate cellular immunity in tissues and initiate host defense responses. A second function of macrophages is the release of inflammatory cytokines. Macrophages also play a key role in many other phases of host defense, including acting as APCs, and provide important links between innate immunity and adaptive humoral and cellular immunity.

Large granular lymphocytes or natural killer (NK) cells are important cellular effectors of innate immune responses and

TABLE 7-2 -- Modes of Antigen Recognition

B Cells	T Cells	Other
Membrane immunoglobin	T-cell receptor	Fc receptor; complement receptor
Direct	Presented by antigen-presenting cell	Indirect
Native antigen	Peptide/major histocompatibility	Immune complexes

as such are often regarded as a first line of defense. NK cells target virus-infected cells or tumor cells for killing. NK cells can also participate in antigen-specific immune responses by virtue of their expression of receptors for IgG that mediate their antibody-dependent cell cytotoxicity function.

An essential difference between the cells of the innate immune system and the lymphocytes that mediate adaptive immunity is the means by which they recognize microorganisms (Table 72). Cells of the innate immune system recognize microorganisms directly through receptors for components of microorganisms or their products. These receptors usually recognize carbohydrate structures. For example, macrophages express a mannose receptor with a broad carbohydrate specificity. Macrophages also express a receptor for lipopolysaccharides, which are a major component of the surface of gram-negative bacteria. Cells of the innate system also detect microorganisms indirectly through receptors for opsonins such as antibody and complement and receptors for products of the acute-phase reaction.

In contrast, B and T lymphocytes, which mediate the adaptive immune response, recognize antigen specifically and directly. Lymphopoiesis is governed by the tenets of clonal selection. Each clone of lymphocytes expresses antigen receptors with a single specificity. B and T lymphocytes somatically rearrange the V, D, and J elements of the immunoglobulin and T-cell receptor genes, respectively, to generate as many as 10^{11} different clones of B and T lymphocytes that express distinct antigen receptors. The basis of antigen recognition by B and T lymphocytes is, however, quite distinct. B lymphocytes recognize native antigens, whereas T lymphocytes recognize processed antigens in the context of macromolecular complexes with products of the major histocompatibility locus. In either case, antigen

binding to the receptor leads to lymphocyte activation and clonal expansion. The progeny and resulting effector cells or products of a lymphocyte clone all have the same specificity as the parental cell. Furthermore, self-reactive clones are deleted or inactivated.

Antigen-independent maturation of lymphocytes occurs in the primary lymphoid organs, the thymus and bone marrow, whereas antigen-dependent differentiation occurs in secondary lymphoid organs. B and T lymphocytes are indistinguishable morphologically but are phenotypically and functionally distinct. B cells generate antibody responses, whereas T cells mediate cellular immunity but are also required for the generation of the vast majority of antibody responses. B and T lymphocytes reside predominantly in architecturally distinct areas of peripheral lymphoid organs.

B lymphocytes are formed along with other white blood cells in several tissues, including the yolk sac and the fetal liver and spleen during development. The bone marrow is the major source of B cells postnatally and in the adult. There are two subsets of B cells recognized. B1 B cells develop earlier in the bone marrow, but in adults are renewed from peritoneal cells rather than bone marrow cells. They are a self-renewing population and long lived. B1 B cells in general produce antibodies to common bacterial polysaccharides. Conventional B cells, B2 cells, are bone marrow derived throughout life. The main function of B cells is to produce antibodies that neutralize pathogens or toxic products, opsonize pathogens for phagocytosis, or activate complement to enhance phagocytosis and destroy pathogens. They also serve as APCs for T cells. The activation of B cells and their differentiation into antibody-producing lymphoblasts and plasma cells usually depend on T-cell help. Plasma cells are end-stage cells that produce large quantities of antibody. They are found initially in the medullary cords of lymph nodes but then in large part home to bone marrow or sites of inflammation. Memory B cells are generated in the germinal centers of the secondary lymphoid organs, where somatic mutation and isotype switching to downstream immunoglobulin heavy chain genes occur. Memory cells respond rapidly on reexposure to an antigen. They are long lived cells and can reside in the bone marrow or recirculate. Memory cells exhibit decreased activation thresholds/requirements and produce antibodies of higher affinity for the eliciting antigen.

T cells generate cell-mediated immunity directly by differentiating into cytotoxic T cells that kill, for example, virus-infected cells. T cells also mediate cellular immunity indirectly by activating macrophages, such as in the case of infection with intracellular pathogens like *M. tuberculosis*. T lymphocytes are also intimately involved in humoral immunity by providing essential help for B lymphocytes.

T cells develop from bone marrow progenitors that migrate to the thymus, where they undergo a careful selection process to eliminate or inactivate self-reactive clones and promote the survival of cells expressing receptors that recognize self-MHC. There are two lineages of T cells that are defined by their utilization of distinct T-cell receptor genes, / and /. The latter represent a small proportion of the total T-cell population and exhibit somewhat more limited diversity and a distinct tissue distribution; they are enriched in underlying mucosal epithelium.

The two major subsets of / T cells, CD4 and CD8 T cells, are defined by the restriction of their clonal recognition of antigenic peptides in the context of MHC class II and class I molecules, respectively. Also, in general, CD4 T cells function mainly as helper cells that stimulate the immune response and inflammation, whereas CD8 cells mainly function as cytotoxic cells that recognize infected targets and lyse them. Activated mature T cells can differentiate further into functionally distinct type 1 and type 2 populations that are characterized by the profile of cytokines they produce. Type 1 T cells secrete IL-2 and interferon-, whereas IL-4, 5, and 10 are typically produced by type 2 cells.

OVERALL ANATOMIC AND FUNCTIONAL ORGANIZATION OF THE IMMUNE SYSTEM

The anatomic organization of the cells of the immune system and their ability to circulate are critical for the generation of the immune response. They are present as circulating cells in blood and lymph, defined collections in lymphoid organs, and scattered cells in virtually all tissues (Table 73).

The central or primary lymphoid organs, the thymus and bone marrow, are the sites of hematopoiesis and lymphopoiesis. The secondary organs include the spleen, lymph nodes, and Peyer's patches. The secondary lymphoid organs are architecturally ordered collections of lymphoid cells that are intricately connected to the vascular and lymphatic systems to provide optimal

TABLE 7-3 -- Organization of the Immune System

Lymphoid Organ System	Primary Function	Sites
Primary	Lymphopoiesis	Bone marrow Thymus

Tertiary	Effector responses	
Circulation	Surveillance Dissemination	Lymphatics

sites for the concentration of free or cell-associated antigens and recirculating lymphocytes. Furthermore, the cells in secondary lymphoid organs are compartmentalized to optimize the generation of immune responses. Immune effector responses usually are manifested at tertiary sites of extralymphoid tissues that, under normal circumstances, contain few lymphoid components but that have the capability to rapidly import appropriate lymphoid and accessory populations after inflammatory provocation.

The peripheral or secondary lymphoid organs are the sites of initiation or the sensitization phase of immune responses and their anatomy is specialized for acquiring antigen and mediating cell-cell interactions. Lymph nodes are nodular aggregates of lymphoid tissue situated along lymphatic channels, epithelium, and the mucosa of the gastrointestinal and respiratory tracts. Compartmentalization of lymphoid organs optimizes the immune response by facilitating exposure of antigen-specific cells to free antigen or antigens in the context of professional APCs, and facilitates cell-cell interactions required for initiation and amplification of the immune response. Secondary lymphoid organs are in general compartmentalized into B- and T-cell areas, but the various cell types can access the different compartments at critical stages to interact with other appropriate cells.

Lymphocytes enter the peripheral lymph nodes through postcapillary venules that are lined by a specialized endothelium (referred to as high endothelial venules [HEV]) that facilitates the extravasation of circulating cells into the organ (Fig. 73). Afferent lymphatics drain from each tissue into the draining nodes, allowing for collection of free or cell-associated antigens in the lymph nodes where the circulating lymphocytes can sample them. APCs, such as tissue dendritic cells, can carry antigen from tissue to the draining nodes, or free antigen can access the draining node through the lymphatics, where it can then be taken up by APCs as it percolates through the cortex and medulla (Fig. 73). Antigen is then presented in the context of the MHC molecules expressed on the APC to T cells in close proximity. T cells that come into contact with APCs displaying their cognate antigen in the context of the appropriate MHC restricting element are activated and temporarily detained in the lymph node, where they interact with antigen-activated B cells and differentiate into effector cells.

B lymphocytes preside mainly in the primary follicles. B cells migrate through the T-cell area on their way to primary follicles (Fig. 73). B-cell blasts that result from early activation events move into follicles to expand in an oligoclonal fashion to give rise to secondary follicles containing germinal centers. Using multiparameter flow cytometry, it is possible to separate five B-cell populations of the germinal center (BMI-5) (Fig. 74 ; Plate 7-1). Germinal centers contain follicular dendritic cells, which display on their surfaces antigen in the form of immune complexes, and proliferating B cells. Proliferating B cells in germinal centers undergo somatic mutation of their antigen receptors, and selection of clones expressing new antigen receptors leads to affinity maturation of the humoral immune response. In addition, B cells in the germinal centers undergo isotype switching, leading to the production of isotypes of immunoglobulin such as IgG, IgA, and IgE that use various downstream heavy chain genes, and thus determine the nature of the humoral immune response. Plasma cells are found in the medullary cords, then circulate to other tissues, especially bone marrow. Newly generated memory cells reenter the circulation.

In spleen, where the immune response to blood-borne antigens is initiated, antigen is delivered into the marginal sinus. T lymphocytes are activated in the periarterial lymphatic sheaths and then move to the marginal zone, where they interact with B cells. Activated B lymphocytes then form germinal centers and plasma cells enter the red pulp.

The mucosal lymphoid system services the gastrointestinal, pulmonary, and genitourinary tracts. The structure of mucosal

Figure 7-3 Morphology of a lymph node. The peripheral or secondary lymphoid organs are the sites of initiation or the sensitization phase of the immune response. The architecture of these organs is specialized for acquiring antigen and mediating the cell-cell interactions involved in initiation of an immune response. Secondary lymphoid organs are compartmentalized into B-cellrich areas (follicles) and T-cellrich areas (parafollicular regions). Lymphocytes enter lymph nodes through postcapillary venules. Afferent lymphatics carry antigen from all tissues to the draining lymph nodes, where it can be recognized by circulating lymphocytes.

Figure 7-4 Activated B cells enter lymphoid follicles and generate germinal centers. Activated B cells in follicles undergoing rapid proliferation are referred to as centroblasts and collectively form the dark zone. B cells in the dark zone give rise to the centrocytes that localize to the light zone where they interact with the network of follicular dendritic cells. The mantle zone contains naive B cells that reside in the follicles that are not participating in the ongoing immune response.

lymphoid organs varies somewhat from site to site, but overall is similar and comparable to that of the lymph nodes. A major difference is how they are exposed to antigen. In mucosal secondary lymphoid tissues, antigen influx occurs across a mucosal epithelium, rather than through afferent lymph. They are usually situated within the lamina propria, the highly vascularized connective tissue immediately subjacent to the mucosal epithelium. The mucosal lymphoid tissues contain clear B- and T-cell areas. The overlying epithelium is specially modified for the uptake and transport of luminal antigens across the epithelium by cells designated M cells. Lymphatic capillaries surround the mucosal secondary lymphoid tissues and serve to transport lymphocytes and accessory cells, as well as antigen, to draining lymph nodes and ultimately to the thoracic duct.

Finally, the cutaneous immune system is associated with the epithelium and underlying vascularized connective tissue (dermis) of the skin.

The tertiary lymphoid tissues are sites of the effector phase of the immune response including in nonlymphoid tissue. Tertiary sites contain two compartments; the first is a vascularized connective tissue with fibroblasts, macrophages, mast cells, and blood and lymphatic vascular channels embedded in an extracellular matrix that provide the route of lymphocyte recruitment into the tissues and egress by lymphatics. This compartment is adjacent to a second compartment consisting of differentiated parenchymal cells that make up a given organ or tissue.

INTEGRATED HOST RESPONSE TO INFECTION

Only occasionally do the microorganisms encountered daily in the life of a normal, healthy individual cause perceptible disease. Most organisms are detected and destroyed within hours by host defense mechanisms that are not antigen specific and do not require a prolonged period of induction; these are the mechanisms of innate (natural) immunity. Only if an infectious organism survives this early line of defense will an adaptive (acquired) immune response ensue. The adaptive response leads to the generation of antigen-specific effector cells that specifically target the pathogen, and the generation of memory cells that prevent subsequent infection with the same microorganisms.

Infection occurs in several stages, each of which can be blocked by different host defense mechanisms. In general, the first phase involves adherence of the pathogen to epithelium. The epithelial surfaces of the body serve as an efficient barrier to most microorganisms. Epithelium represents a mechanical, chemical, microbiologic, and immunologic barrier to infection. Inhibition of attachment or binding by organisms to the host, for example by neutralizing antibodies present in the secretions at epithelial surfaces, can prevent infection. Next, local infection is established as the pathogen penetrates the epithelium and infects the local tissue. The major host defense mechanisms at this stage include intraepithelial (/) T cells, wound-healing processes, the release of antibacterial peptides (e.g., defensins), and phagocytes. Antibodies against invasins also can inhibit at this stage. Most of the pathologic process associated with an infection occurs as the result of the third phase of infection, in which the organism spreads. Extracellular pathogens spread by direct extension of the infected foci through the lymphatics and, usually only if the lymphatic system is overwhelmed by the infection, through the bloodstream. Intracellular pathogens spread from cell to cell either by direct transfer from one cell to the next or by release into the extracellular fluid and reinfection of adjacent and distant cells. Protective mechanisms at this stage include activation of the alternative complement pathway, phagocytes, cytokines, and NK cells. Assuming that the infection persists in spite of the early innate immune response and other host defense mechanisms, the host then mounts an adaptive immune response. In addition to clearing the infectious agent, an effective adaptive immune response prevents reinfection. Mechanisms include specific antibody, T-cell dependent macrophage activation, and cytotoxic T cells.

Two key features make the immune system effective against infection by diverse pathogens. The first is the variety of mechanisms of host defense, which includes innate immunity, humoral adaptive immunity, and cellular adaptive immunity. The second is the diversity of antigen-specific receptors and the polymorphism of MHC molecules required for the recognition of foreign antigens by T cells. Immunity to intracellular pathogens that reside in the host cell cytoplasm requires the generation of cytotoxic T cells (cellular immunity) and possibly antibody-dependent cell-mediated cytotoxicity (humoral and cellular immunity). Immunity to intracellular pathogens that reside in vesicular compartments requires T-celldependent macrophage activation (cellular immunity). Extracellular pathogens in interstitial spaces, blood, and lymph require antibodies, complement activation, phagocytosis, or neutralization, whereas the major defense at epithelial surfaces consists of antibodies (mainly IgA).

The alternative pathway of complement activation provides a nonadaptive first line of defense against many microorganisms. The alternative complement pathway can proceed on some microbial surfaces in the absence of specific antibody and lead to lysis or opsonization (by C3b) of the organism.

Phagocytosis is the principal mechanism for destruction of extracellular bacterial pathogens as well as several viral and fungal organisms. The importance of phagocytosis is indicated by the increased susceptibility to infection of patients with disorders of phagocytic function (e.g., chronic granulomatous disease; Chediak-Higashi syndrome; glucose-6-phosphate dehydrogenase deficiency; and secondary disorders like side effects of immune suppression and C and Ig deficiencies. Phagocytic cells enter the site of infection in response to products of coagulation,

fibrinolytic, and kinin pathways (especially for PMNs); bacterial production of N-formylmethionine (PMNs and macrophages); products of the activation of the classic and alternative complement pathways (C5a, C3a, C3b); and cellular products (i.e., chemokines, histamine). Most pathogenic bacteria resist direct phagocyte attachment, but the host produces opsonins that make them susceptible to phagocytosis through receptors for immunoglobulins (Fc receptors) and complement receptors (C3b).

Once a microorganism has been ingested into phagocytic vacuoles, phagocytes kill the pathogen either by aerobic (oxygen-dependent) or anaerobic (oxygen-independent) mechanisms. Infection is associated with increased oxygen consumption. Activation of nicotinamide-adenine dinucleotide phosphate hydrogenase (NADPH) oxidase catalyzes the reduction of O_2 to superoxide (O_2). Superoxide dismutase catalyzes the production of hydrogen peroxide (H_2O_2) that results in microbial killing by myeloperoxidase-catalyzed oxidation of halide ions to halide radicals. H_2O_2 can also kill directly and can interact with superoxide to form toxic hydroxyl radicals. Anaerobic mechanisms include degradation of ingested material by the activity of multiple lysosomal enzymes, including lysozyme, phospholipase A_2 , serine esterases, lipases, and acid phosphatases, and basic proteins, the defensins.

Pathogens and their products also induce cytokine production by phagocytes, including IL-1, IL-6, IL-8, IL-12, and TNF, which induce subsequent host defense mechanisms. TNF initiates a local inflammatory response and induces the expression of adhesion molecules on local blood vessels that mediate leukocyte adhesion, infiltration, retention, and activation. The small vessels later clot, preventing spread of infection to the blood. However, once an infection spreads to the bloodstream, these same effects of TNF at a systemic level can lead to septic shock. Chemokines such as IL-8 produced locally by macrophages, endothelial cells, and connective tissue cells promote the migration of monocytes, neutrophils, and lymphocytes into the inflammatory lesion. Cytokines (IL-1 and IL-6) released by macrophages also activate the acute-phase response that leads to the production of molecules that bind to bacteria: C-reactive protein is an opsonin and activates complement; mannose-binding protein is an opsonin for monocytes. Macrophage-derived cytokines induce a leukocytosis (increase in circulating PMNs).

Adaptive immunity is triggered when an infection eludes the innate defense mechanisms and generates a threshold dose of antigen. It does not become effective until several days after infection. The lag represents the proliferation and differentiation processes required to generate effector cells from the 1 per 10^6 resting lymphocytes that can recognize the antigen.

B-cell responses develop in lymphoid tissues. The production of antibodies by B cells to most antigens depends on helper (CD4) T cells. Activated B cells proliferate, forming germinal centers where they undergo isotype switching and somatic hypermutation. The antibodies secreted initially provide protection but may also trap antigen in the form of antigenantibody (immune) complexes on the surface of follicular dendritic cells for a long time, thus contributing to B-cell selection in the germinal center. The antibody-secreting plasma cells generated in the lymphoid tissue remain in the medullary cords of lymph nodes and in the red pulp of the spleen. However, other B cells leave the germinal center and migrate to the bone marrow, where they complete their differentiation into plasma cells, and approximately 90% of all antibody is produced by these bone marrow plasma cells. Antibodies are the key defense against extracellular bacteria. Antibodies interact directly with the bacteria or bacterial products.

T cells are the central mediators of protection against intracellular bacterial infections. The T cells do not interact with the microbes directly, but instead interact with

the infected host cells. T-cell activation is initiated when recirculating T cells encounter specific antigen in draining lymphoid tissues. Antigens in tissues are trapped by APCs in draining lymph nodes, whereas blood-borne antigens are taken up by APCs in the spleen. The trapping of antigen by APCs in the lymphoid tissues and the continuous recirculation of T cells through the lymphoid tissues ensure that rare, antigen-specific T cells will encounter that antigen on a professional APC (e.g., dendritic cells). Activation of T cells results in increased expression and function of cell adhesion molecules, which bind to their ligands that are upregulated at sites of inflammation and thereby promote the migration of effector cells to sites of infection.

Activated CD4 T cells can differentiate into functionally distinct effector cells that are distinguished based on the cytokines they produce. TH_1 (inflammatory) cells selectively produce IL-1, TNF, and interferon- and promote macrophage activation. TH_2 (helper) cells selectively produce IL-4 and IL-5 and preferentially promote antibody production. Infections with intracellular pathogens are accompanied by delayed-type hypersensitivity. Thus, in an individual immune to an intracellular bacterium, a skin reaction develops at the site of local administration of soluble antigens from this agent. This reaction is mediated in large part by T cells and is characterized by monocyte infiltration 2472 hours post-exposure.

One of the most important consequences of an adaptive immune response to natural infection or vaccination is the establishment of a state of immunologic memory. Immunologic memory is defined as the ability of the immune system to respond more rapidly and effectively to pathogens that have been encountered previously because of increased numbers of antigen-specific cells (as the result of antigen-induced clonal expansion). Secondary and subsequent responses differ qualitatively from primary responses; for example, the affinity as well as the amount of antibody increase with repeated immunization, and memory T cells are increased in frequency and have distinct activation requirements and cell surface phenotypes.

In summary, a variety of innate and adaptive defense mechanisms act in a concerted fashion to protect the host against a myriad of antigenic challenges. Phagocytes, neutralizing antibodies, and antibody-dependent complement-mediated and cellular cytotoxicity are the major protective mechanisms involved in defense against extracellular pathogens. Extracellular pathogens typically cause acute disease, which develops soon after entry of the organism into the host and is terminated once the immune response has developed. Defense against intracellular pathogens results in attack against the infected cells (lymphocyte-mediated cytotoxicity) or provides a potentially lethal cellular environment (activated macrophages). In general, intracellular pathogens coexist with their cellular habitat for longer periods of time and result in chronic disease. Tissue reactions against intracellular pathogens are granulomatous. Granuloma formation is responsible for the protection of the host, but also causes the pathologic processes associated with these lesions.

Chapter 8 - B-Cell Development

Kenneth Dorshkind

B cells are the subset of lymphocytes specialized to synthesize and secrete immunoglobulin (Ig); their name derives from the fact that they were first characterized in the *B*ursa of Fabricius in birds. However, B lymphopoiesis in adult mammals occurs in the bone marrow. Production in that site, which is antigen-independent, is referred to as primary B-cell development.

B-cell production is a dynamic process in which immature hematopoietic precursors progress through a series of developmental stages that culminate in the generation of newly produced B lymphocytes that express Ig on their cell surface. However, transforming events can occur in B lineage cells at particular developmental stages and may result in various forms of B-cell leukemia. Additional abnormalities of primary B lymphopoiesis can result in failure of surface Ig-expressing cells to develop, thereby resulting in deficiencies of humoral immunity.

This chapter describes the cellular and molecular events that occur during normal, primary B-cell development, in order to provide a basis for understanding abnormalities of that process. Although human B lymphopoiesis is emphasized, murine studies have contributed to much of what is known about B-cell development and will be discussed in parallel. A detailed list of primary references on each topic cannot be cited due to space limitations. Therefore, key reviews on particular subjects will be noted and may be consulted for additional information.

STAGES OF B-CELL DEVELOPMENT

B lymphocytes, like all blood cells, are the progeny of pluripotential hematopoietic stem cells (PHSC). [1] [2] [3] [4] PHSC in humans are CD34+ cells that lack expression of additional lineage-specific determinants (lin cells) present on the surface of cells committed to development of the myeloid, erythroid, and lymphoid lineages. PHSC in mice are also lin and express the Thy-1 antigen at low levels (Thy-1 ^{lo}) and stem cell antigen-1 (Sca-1).

As shown in Figure 81 , progeny of the PHSC ultimately become committed to the development of myeloid or lymphoid cells. The existence of a multipotential myeloid-restricted precursor that generates progenitor cells committed to the erythroid, granulocytic, monocytic, or megakaryocytic lineages is well established. Figure 81 depicts a lymphoid-committed precursor and there is recent evidence supporting its existence. Nevertheless, developmental relationships during early lymphocyte production are unresolved, and reports of precursors that can generate both B cells and macrophages, but not cells of other hematopoietic lineages, [5] indicate that lineage diagrams such as those shown in Figure 81 will continue to evolve.

There is less ambiguity in defining precursorprogeny relationships within the B-cell developmental pathway itself. Although a uniform terminology for naming stages of B-cell differentiation has not been formulated, in both humans and mice the earliest committed B-cell precursors are referred to as pro-B cells. Their immediate progeny, referred to as pre-B cells, express immunoglobulin heavy chain protein of the class in their cytoplasm. Subsequently, as light chain protein is expressed, it combines with heavy chain protein, and the newly assembled IgM molecule is expressed on the surface of immature B lymphocytes. Immature B cells generally do not proliferate or differentiate in response to antigen, and their encounter with self-antigens may lead to their tolerization or elimination. As these cells mature, they acquire IgD. Surface IgD expression is indicative of the mature B-cell stage of development. These newly produced B cells leave the bone marrow to seed secondary lymphoid tissues such as spleen and lymph nodes, and during this period they undergo further maturation. If antigen is not encountered, these B cells die within a few days, but upon antigen binding IgM+/IgD+ B cells proliferate and differentiate into short-lived immunoglobulin-secreting plasma cells and long-lived memory B cells. Figure 81 shows a scheme of human and murine B-cell differentiation from the pro-B cell to the surface IgM/IgD stage of development.

As described previously, the expression of immunoglobulin has traditionally been used to delineate different stages of B lymphopoiesis. However, the development of antibodies that recognize additional cell surface antigens on B lineage cells and the use of flow cytometry have permitted stages of B-cell development to be defined more precisely. These molecules are described below, followed by a detailed discussion of the steps involved in the rearrangement and expression of the immunoglobulin heavy and light chain genes.

Cell Surface Antigens Expressed on Developing Human B Lineage Cells

Figure 81 shows a scheme of B lymphopoiesis in which several cellular determinants used to stage developing human B lineage cells are depicted. [1] [6] [7] [8] As shown in the figure, CD34, the human PHSC marker, is also expressed on pro-B cells. However, pro-B cells express additional determinants that distinguish them from the lin PHSC population.

Several of these determinants, which include CD10, CD19, and CD45, are expressed on the earliest B lineage-committed pro-B cells and continue to be expressed at most subsequent stages of primary differentiation. CD10, also known as common acute lymphocytic leukemia antigen, or CALLA, is a 100,000 molecular weight (MW) member of a family of peptidases expressed on lymphoid precursors, myeloid cells, and most acute lymphocytic leukemias. CD10 expression is down-regulated by the time IgD appears. CD19 is a 95,000 MW Ig superfamily protein that associates with other cellular determinants to generate a signal transduction complex on B lineage cells. Cross-linking of CD19 results in calcium mobilization and activation of phospholipase C and protein tyrosine and serine kinases. There is a gradual increase in expression of CD19 with maturation in the B-cell lineage. CD45 encodes a family of protein tyrosine phosphatases involved in the regulation of signal transduction in leukocytes.

Other cell surface determinants have a somewhat more restricted pattern of expression. For example, CD20 is expressed at the pro-B to pre-B cell transition and is lost upon differentiation into plasma cells. It may be involved in B-cell activation and proliferation. CD21 is the receptor for the C3d component of complement and the Epstein-Barr virus. It is expressed by

Figure 8-1 The hematopoietic hierarchy with an emphasis on B-cell development. Stages of human and murine B-cell development, and the cell surface, cytoplasmic, and nuclear determinants expressed on those cells are indicated. When comparing this scheme to others, it is important to understand that a uniform terminology for stages of development has not been adopted. Placement of lineage markers and their intensity of expression at various stages of development, indicated by the thickness of lines, is an approximation. Letters next to cells refer to the Hardy stages of murine B-cell development.

most IgD^{+} B cells and is lost upon B-cell activation. CD21 and cell surface IgM can form an activation complex with CD19 and CD81 (not shown in Fig. 81), a 26 kd integral membrane protein expressed on various cell types. This complex amplifies signaling through the B-cell receptor. CD22 is first detected in the cytoplasm of pro-B and pre-B cells and is expressed on the surface of a subset of B cells. CD22 is an adhesion receptor that may be involved in B-cell activation. CD24 is a GPI-linked sialoglycoprotein expressed at low levels from the late pro-B cell stage until plasma cell differentiation. CD38 is a type II membrane glycoprotein expressed on pro-B cells. CD38 expression is then extinguished before its reappearance in activated B cells. It may function as an adhesion receptor. Finally, expression of CD40 initiates at the pro-B cell stage of development. It is involved in B-cell proliferation, somatic hypermutation, and isotype switching in germinal centers. Defects in the CD40 gene result in X-linked hyper-IgM syndrome.

Cell Surface Antigens Expressed on Developing Murine B Lineage Cells

Hardy and colleagues have developed a scheme of murine B lymphopoiesis based on expression of various cell surface determinants. [9] The most immature pro-B cells (Fraction A) express the CD45R tyrosine phosphatase and CD43, a molecule of unknown function that may be involved in activation of B lineage cells. As they mature into Fraction B cells, they continue to express CD45R, CD43 and acquire CD24, the Heat Stable Antigen (HSA). Fraction B cells have initiated Ig heavy chain gene rearrangements. As cells mature to the Fraction C stage, they continue to express CD45R and HSA and acquire BP-1, a cell surface metallopeptidase. Cells in Fraction D, which are CD43, CD45R+, and HSA+, have undergone a functional heavy chain gene rearrangement and express heavy chain in their cytoplasm. Finally, as light chain protein is expressed, the Ig molecule is assembled and IgM appears on the surface of immature B cells. These newly produced B cells are distinguished based on the differential expression of IgM (Fraction E) or IgD (Fraction F). Finer resolution of the above fractions can be achieved based on the level at which

particular determinants are expressed and through the introduction of additional markers. [10]

Cells at most of the previous stages also express CD19, a cell surface antigen that is also a reliable indicator of commitment to the B-cell lineage. Pro-B cells express CD19 at relatively high levels and there is a 2.5-fold increase in CD19 expression as cells mature. B-1 B cells, described below, express CD19 at levels 50% higher than conventional B lymphocytes.

Expression of the Surrogate Light Chain Proteins

Analysis of various pre-B-cell lines revealed that heavy chain protein could be detected on the cell surface in association with two noncovalently linked proteins referred to as Vpre-B and lambda()5. These proteins were termed surrogate light chains

because of their homology with conventional light chains and are encoded by the Vpre-B and 5 genes which are located on chromosome 16 in mice and chromosome 22 in humans.[2] [11] Their detection on the surface of murine pre-B cell lines led investigators to hypothesize that expression of a cell surface /surrogate light chain complex occurred during normal development and that its ligand was expressed on cells of the hematopoietic microenvironment.

In an attempt to define the stage at which surrogate light chains are expressed during normal B-cell differentiation, analysis of primary bone marrow B lineage cells with monoclonal antibodies to surrogate light chain proteins has been made. The results are not always consistent between laboratories, possibly due in part to the use of different antibodies for detection of surrogate light chains. Thus, this area of research is an evolving one.

One model that has resulted from these studies is that murine pro-B and early pre-B cells express surrogate light chain on their surface as a pro-B-cell receptor. These cells do not express heavy chain protein, and the surrogate light chains may form a complex with another as yet uncharacterized 130 kDa glycoprotein. At later stages of development, a subpopulation of early pre-B cells may express a cell surface surrogate light chain//Ig/Ig receptor (Ig and Ig are defined in a subsequent section). However, surrogate light chain expression is down-regulated as differentiation proceeds, and most pre-B cells that express heavy chain protein no longer express surrogate light chain. In humans, there have been suggestions that, analogous to mice, some pro-/pre-B cells may express cell surface surrogate light chains in the absence of protein. However, there is general agreement that a /surrogate light chain/Ig/Ig complex is expressed on the surface of normal human pre-B cells. [12]

Pre-B cell and B-cell numbers are drastically reduced in 5 knockout mice, [2] [11] indicating that surrogate light chains must play a crucial role during B-cell development. However, although /surrogate light chain complexes can transduce signals resulting in mobilization of intracellular Ca_2^+ and tyrosine phosphorylation of intracellular proteins, their ligand has not been identified and their precise role during primary B lymphopoiesis remains undetermined.

REARRANGEMENT AND EXPRESSION OF IMMUNOGLOBULIN GENES

The Ig molecule consists of two heavy chains and two light chains (Fig. 82). The amino acid sequences at the antigen binding amino terminal ends of the molecule are highly variable, thus this area is referred to as the variable region. Highly divergent regions within the variable portion of the heavy and light chains are referred to as hypervariable or complementary-determining regions. The remaining part of the heavy and light chains is more conserved and is referred to as the constant region.

The expression of Ig is unique to B lineage cells and is dependent on the successful rearrangement of genes that encode the heavy and light chain proteins. [13] [14] [15] [16] [17] In general (and as described following), heavy chain gene rearrangement and expression precedes light chain recombination. However, there may be exceptions to this sequence of events during normal B lymphopoiesis, and light chain gene rearrangements with heavy chain genes in the germ-line configuration have been detected in some leukemias and lymphomas.

Heavy Chain Gene Rearrangements

The genes that encode the heavy chain protein are located on chromosome 14 in humans and chromosome 12 in mice. Both the human and murine heavy chain gene include variable (V), diversity (D), and joining (J) regions that encode the variable portion of the immunoglobulin molecule located at its amino terminus (Figs. 82 and 83). V region genes, which number around 100 in humans and up to 1,000 in mice, are located at the 5 end of the heavy chain locus. Each V region exon is approximately 300 base pairs in length and is separated from other V region genes by short intronic sequences. V genes are organized into families based on sequence homology with other members; seven humanV_H gene families have been described. 5 of each V gene is an exon that encodes a translation initiation signal and leader peptide involved in intracellular trafficking of the heavy chain protein. Sequences encoded by this exon are not part of the mature heavy chain protein. There are about 30 human and 12 murine D region genes located 3 to the V region. These may also be grouped into families; at least 10 families have been described in humans. There are 6 human J region genes and 4 murine ones and multiple C region genes arranged in tandem with a species-specific order. [18] Each C region gene includes multiple exons.

As noted above, the first Ig rearrangements in developing B-cell precursors most commonly occur in the heavy chain genes. The recombination process in humans, depicted in Figure 83 , is similar to that in mice. The initial event during heavy chain gene rearrangement in a pro-B cell juxtaposes one D region segment to a J_H segment. Although in theory any one D locus can join with equal frequency to any one J_H region gene, there may be preferential use of selected D and J_H region genes at various stages of development. Murine studies also indicate that rearrangement of a particular D region gene to a J heavy chain gene segment can result in recombination at any one of three possible reading frames. A strong bias for reading frame I is seen in conventional B cells, and there is counterselection against reading frame III; approximately 70% of such D rearrangements have a stop codon. Pre-B cells in which reading frame II is used may produce a DJC protein. The precise role played by such a molecule is not understood, but it is hypothesized that its expression may somehow signal a cessation of further development. Following successful D-J_H recombination, a V_H region gene rearranges to the D-J_H complex during the pro-B to pre-B-cell transition. There are indications that biased use of J_H proximal V_H genes occurs in the newly generated repertoire of neonatal mice and humans. [18]

The heavy chain constant (C) region remains separated from the rearranged $V_H DJ_H$ complex by an intron, and this entire sequence is transcribed. Subsequent RNA processing leads to deletion of the intron between the $V_H DJ_H$ complex and the most proximal C region genes. Following translation, heavy chain protein is expressed in the cytoplasm of pre-B cells (Fig. 81). The heavy chain is retained there by a heavy chain binding protein (Bip) until it binds to light chain proteins.

Each B-cell precursor has two sets of immunoglobulin heavy chain genes, and if initial rearrangements are successful and protein is produced, further heavy chain rearrangements at the second locus are inhibited. [19] This process is known as allelic exclusion and results in expression of only one Ig heavy chain allele in any given cell. However, if rearrangements are unsuccessful at one heavy chain locus during B-cell development, recombination will initiate at the second one.

Light Chain Gene Rearrangements

The Ig light chain protein can be encoded by the kappa () or lambda () genes (Fig. 84). Over 90% of murine B cells and 60% of human B cells express light chain protein, which is encoded by a gene located on human chromosome 2 and murine chromosome 6. The human locus consists of approximately 76 V region genes, clustered into 6 families; 5 functional J region genes; and 1 constant region C gene. The murine light chain gene consists of approximately 160 V exons, organized into 19

Figure 8-2 The immunoglobulin molecule and the B-cell antigen receptor complex. The Ig molecule consists of two heavy and two light chain proteins. Two additional transmembrane proteins, Ig- and Ig-, are noncovalently associated with the heavy chain, and linked to these molecules are various protein kinases. Following binding of antigen to the Ig molecule, signaling cascades are activated, resulting in events that can include cell proliferation, synthesis of additional Ig classes, and Ig secretion.

families; 5 J region genes; and a single C region gene. There may be skewed use of particular V genes during fetal and adult B-cell development. Alternatively, B cells can express light chain protein, encoded by a gene located on human chromosome 22 and murine chromosome 16. Approximately 52 human V genes, grouped into ten families, have been described. There are seven human C genes, three of which are pseudogenes. Each C gene is located 3 of a respective J gene. [18] D region segments are not present in light chain genes.

Light chain gene rearrangements initiate following expression of cytoplasmic heavy chain protein in most B lineage cells. Rearrangements occur first at the locus, where the initial event is the joining of a V segment to a J segment. The V -J complex remains separated from the light chain C region by an intron, this entire complex is transcribed, and further splicing of the intron between the J and C segment results in formation of a mature V -J -C transcript. If rearrangements at the first allele are unsuccessful, attempts are made to rearrange the second gene. If this fails, the locus is used. Lambda-producing murine B cells may have deletions of both loci or exhibit rearrangements to a recombination signal sequence that is 1020 kB 3 of the C exon. Light chain gene rearrangements may only be productive in approximately one-third of pre-B cells, because up to 60% of nondividing pre-B cells never progress to the surface IgM+ stage.

Ig Gene Recombination

Immunoglobulin gene recombination is dependent on an enzymatic machinery that deletes intronic sequences and joins coding segments of DNA. [13] [16] [17] The

enzymes that mediate these functions act through recognition of recombination signal sequences that are located 3' of each heavy and light chain V-region exon, 5 of each heavy and light chain J segment, and 5 and 3 of each heavy chain D region gene. Figure 83 shows the association of these recognition sequences with the various

Figure 8-3 Rearrangement and expression of the human Ig heavy chain gene. The figure shows the Ig heavy chain gene and the signal sequences 3 of each V region locus, 5 and 3 of each D region locus, and 5 of each J region locus. These consist of a heptamer and nonamer sequences separated by either 12 or 23 base pairs. During Ig recombination a signal sequence of 12 base pairs can only join to another of 23 base pairs (the so-called 12-23 rule). As shown in the figure, initial heavy chain gene rearrangements form coding joints between D and J regions as well as signal joints that are ultimately degraded. Subsequently, joining of the V region gene to the DJ complex occurs. Following a successful rearrangement, the VDJ complex, the intron, and portions of the constant regions are transcribed. RNA processing and differential splicing results in formation of an mRNA molecule that is then translated. In the example shown, the rearranged VDJ complex and the constant region, with the and C region genes, is transcribed. Following RNA processing and translation, a particular B cell could then express and/or protein.

Figure 8-4 Structure of the human Ig light chain genes and their chromosomal locations.

heavy chain exons. Each recombination signal sequence consists of conserved heptamer and nonamer sequences, separated by nonconserved DNA segments of 12 or 23 base pairs. During immunoglobulin gene recombination, these recognition sequences form loops of DNA which in turn bring the coding exons in apposition to one another. These noncoding loops are subsequently deleted and degraded.

The expression of two proteins, referred to as Recombinase Activating protein (RAG)-1 and RAG-2, is required for heavy and light chain gene recombination in developing B lineage cells. Results from cell free systems that measure V(D)J recombination indicate that RAG proteins are involved in cleavage of DNA at recombination signal sequences, thereby producing a blunt DNA end on each signal sequence and a hairpin end on adjacent coding gene segments. The RAG proteins, in addition to various molecules that ligate the free DNA ends, are also needed for subsequent efficient joining of coding sequences to one another. [20]

Immunoglobulin Gene Transcription

Following productive heavy and light chain gene rearrangements, transcription of the rearranged loci occurs. Transcription of Ig genes is dependent on the interaction of various DNA binding proteins with specific promoter sequences located 5 of each heavy and light chain V region and one or more heavy and light chain enhancer regions.[13] [14] [15] [16] Enhancer sequences have been identified in both human and murine heavy and and light chain genes. Heavy chain enhancers are located in the intron and downstream of the C_H region genes and light chain enhancers are located in the intron and downstream of the C gene (Figs. 83 and 84).

A number of transcription factors that bind to motifs in these enhancers and potentiate transcription have been identified. For example, the E12 and E47 transcription factors, which are basic helix-loop-helix (HLH) proteins encoded by the E2A gene, bind to specific sequences in the heavy chain enhancer. E2A proteins are expressed in pro-B cells, but they may be complexed to another HLH protein known as Id that can form heterodimeric complexes with these proteins and prevent their binding to DNA. It is thought that upon cessation of Id expression, E12 and E47 molecules are free to bind their enhancer and pro-B cell maturation can occur. Studies of two transgenic mouse strains provide support for this sequence of events. Mice expressing an Id transgene have a complete block in B-cell differentiation, and B-cell development is blocked at Fraction A in knockout mice in which the E2A gene has been inactivated.

DNA binding proteins such as NF-B are also involved in regulating light chain gene expression. Analogous to the situation in which the actions of E2A proteins are inhibited by Id, NF-B is complexed to an inhibitory molecule, I-B, in the cytoplasm of pre-B cells. During pre-B-cell differentiation I-B dissociates from NF-B and the latter molecule translocates to the nucleus where it can then bind DNA.

Studies of mice in which the genes encoding these transcription factors have been disrupted have demonstrated that many

TABLE 8-1 -- Selected Transcription Factors That Regulate B-Cell Development

Transcription Factor	Function/Targets	Effect of Loss of Expression
PU.1/Ets proteins	Ig H and L chain genes, RAG-1, Ig, Ig, Vpre-B, 5, bcl-2, TdT, CD19, J chain	B-cell development blocked. Few CD45R+ cells; no Ig gene rearrangements
Ikaros	Lymphoid-specific genes in early lymphoid precursors	Block in all lymphocyte development
BSAP/Pax-5	Lymphoid-specific genes in early lymphoid precursors	Block at pro-B-cell stage
E2A/Basic helix loop helix proteins	Heavy chain enhancer	Block at pro-B-cell stage
Id	Binds to and inhibits E2A binding to DNA	Block at pro-B-cell stage when overexpressed
Bmi-1	Hox genes	Reduction of CD45R+ cell number
Early B-cell factor (EBF)	Ig promoter	Block at pro-B-cell stage; no D-J_H rearrangements
NF-B	Kappa light chain enhancer	Modest effects on primary B-cell development

of these molecules play an obligate role during B-cell development. Selected examples of transcription factors which have been demonstrated to play a key role in B-cell development are given in Table 81 , and in-depth reviews on this topic can be consulted for additional details. [21]

Sterile Transcripts

It is clear that transcription of Ig genes occurs subsequent to the formation of productive heavy and light chain gene rearrangements, but transcription of unrearranged heavy chain genes also takes place. This results in the production of developmentally regulated transcripts of unrearranged Ig genes, referred to as germ line or sterile transcripts. Multiple species of heavy and light chain gene germ line transcripts have been described, and some could conceivably encode proteins. It has been hypothesized that there is a mechanistic link between transcription and Ig gene rearrangement. For example, transcription might make unrearranged Ig genes somehow accessible to both RNA polymerase and V(D)J recombinase; the germline transcripts could function in the rearrangement reaction; or transcription could alter structural characteristics of DNA, making the recombination signal sequences better targets for recombination. [13] [14] [15]

Class Switching

At the terminal stage of primary B-cell development, B cells can express both IgM and IgD. This occurs through alternative processing of a primary RNA transcript. As noted above, the rearranged V_H -D-J_H heavy chain, part of the constant region, and the intron separating these exons are transcribed following productive rearrangements in a cell. If the intron is spliced, resulting in association of the C region with the VDJ complex, the B cell expresses IgM. Alternatively, if the C exon is

spliced out along with the heavy chain intron, the VDJ complex and the C exon become contiguous and the B cell expresses IgD. The differential processing of heavy chain transcripts within a single cell explains why some newly produced B cells coexpress both IgM and IgD (Fig. 83).

Class switching resulting in expression of additional heavy chain constant regions other than IgM and IgD can also occur. Deletion of germ line DNA resulting in religation of the VDJ complex with a particular downstream heavy chain constant gene appears to be the mechanism by which this takes place. In this case, for example, deletions of and result in juxtaposition of the VDJ complex to the next downstream 3 CH segment. These DNA deletions are believed to occur at or near nucleotide sequences called switch regions, which are located in the intron 5 to each C_H exon. Class switching that results in expression of , , and epsilon is a highly regulated, secondary differentiation event potentiated by helper T cells and their products. [22] [23]

GENERATION OF THE IMMUNOGLOBULIN REPERTOIRE

The murine B-cell repertoire has the potential to include up to 10^9 antigen-binding specificities. There are several means by which this repertoire diversity is generated during Ig gene recombination. First, heavy and light chain proteins are encoded by multiple germline V, J, and, in the case of heavy chain, D region genes; the combinatorial diversity among them is enormous. Second, DNA joints that form during recombination are often imprecise and can occur at any of several nucleotides in the germline. This junctional diversity has the potential to generate different amino acid sequences resulting in added diversity of the Ig repertoire. However, as noted previously, out-of-frame joints that cannot be transcribed may also result. Finally, nucleotides not encoded in the germline can be added to D-J_H and V_H -DJ_H junctions during postnatal (but not prenatal) life by a nuclear enzyme known as terminal deoxynucleotidyl transferase (TdT). It is reasonable to assume that similar processes are operative in humans.

Not all B lineage cells successfully rearrange their heavy and light chain genes. Heavy chain gene rearrangements are productive in approximately one-third of pre-B cells, and of these cells, only about one-third progress to make functional light chain gene rearrangements. Those cells with nonproductive rearrangements are eliminated from the marrow, possibly by a macrophage-mediated mechanism.[3] [24] In view of this, it is obvious that a considerable degree of cell loss must occur during B lymphopoiesis, and, as a result, the number of B-cell precursors exceeds the number of mature B cells produced. In this regard, murine bone marrow has been estimated to contain up to 10^8 B lineage cells, but only about 3×10^6 mature B cells are produced each day. Thus, the generation of millions of mature B lymphocytes, each of which expresses an Ig molecule with a unique antigen-binding specificity, is dependent upon a high daily rate of bone marrow B lymphopoiesis.

As noted, those mature B cells that are produced in the bone marrow emigrate to secondary lymphoid tissues, such as spleen and lymph nodes. If the newly produced B cell does not encounter antigen, it is a short-lived cell that soon dies. Thus, that particular Ig antigen-binding specificity is lost and must be regenerated de novo during primary B lymphopoiesis in the bone marrow. However, if the mature B cell binds antigen, it clonally expands and subsequently reverts to small resting memory cells

that are retained by the organism. Thus, that Ig antigen-binding specificity is retained and if the same antigen is encountered again, a rapid secondary immune response is generated. Within secondary lymphoid tissues, such as spleen and lymph nodes, somatic mutation of V region genes can occur during the immune response. These latter events involve point mutations in V region genes that can often result in an increase in the affinity of an antibody for antigen.

B-CELL TOLERANCE

It is obviously critical that the mature B cells that exit the bone marrow not be autoreactive, but because the process of Ig recombination is random, it is possible for B cells that recognize self-antigens to be generated. Several mechanisms have been proposed to account for the fate of such autoreactive B cells. In some cases the presence of self-antigen may not activate the self-reactive B cells. This scenario may result if binding of autoantigen to the B cell is weak, if the B-cell affinity for the antigen is weak, or if the autoantigens are present at an extremely low concentration. In other instances interaction of antigen with the autoreactive B cell may result in an anergic state. The level of membrane Ig on such anergic B cells may be reduced up to twentyfold, the cell's ability to proliferate may be impaired, and differentiation into immunoglobulin secreting cells may be blocked. Finally, self-reactive B cells may be clonally deleted. Clonal deletion may result from cytolysis by other cells, such as bone marrow macrophages, or autoreactive B cells may undergo a physiologic change resulting in cell death following receptor engagement. The intracellular mechanisms that underlie these processes remain to be defined, but further understanding of signaling mechanisms in B lineage cells should reveal differences between activated and anergized populations. [25] [26]

Recognition of self-antigen by a B cell may not necessarily result in anergy or apoptosis, however, because receptor editing is thought to occur in some self-reactive B lymphocytes. In this process, rearranged chain alleles can be replaced by secondary rearrangements of upstream V genes to downstream, unrearranged J segments. These secondary rearrangements, which may delete the primary V J complex or separate it from C by inversion, are possible because of the continual presence of unrearranged V regions upstream of the joined V J coding segments. The detection of RAG-1 and RAG-2 in B lymphocytes suggests that the recombinatorial machinery necessary for further Ig gene recombination is present in mature cells. Although most data in support of receptor editing are derived from murine studies, it has been suggested that this process may also occur in human B cells. [27]

B-CELL ANTIGEN RECEPTOR COMPLEX

The interaction of antigen with the B cell results in cross-linking of membrane Ig and the transduction of intracellular signals. However, although Ig is a transmembrane protein, its cytoplasmic carboxy tail is relatively short. For example, the carboxy terminus of IgM and IgD consists of only three amino acids, and signal transduction after antigen binding to B cells is dependent upon the noncovalent association of Ig with two additional transmembrane proteins termed Ig and Ig. The Ig Ig proteins, which are encoded by the mb-1 and B29 genes, respectively, are expressed at early stages of B-cell development before the production of heavy chain protein and link membrane Ig to cytoplasmic tyrosine kinases (Fig. 82). Following binding of antigen to the Ig molecule, Ig and Ig proteins are phosphorylated by these associated protein kinases, and multiple signaling cascades are generated within the B cell. The end result of these activation events is cell proliferation and Ig secretion. Details of B-cell signaling events following antigen binding can be found in several recent reviews. [28] [29] [30]

As noted previously, the Ig and Ig molecules may be part of the pre-B-cell receptor that also includes surrogate light chain proteins and heavy chain. Thus, it is not surprising that Ig, Ig, and other components of the B-cell antigen receptor and the associated signaling machinery also play a key role in B-cell development. [31] Pro-B-cell differentiation in mice lacking Ig is blocked and failure to express Ig results in a marked reduction in the number of peripheral B cells. Many of the protein kinases expressed in B lineage cells have also been demonstrated to transduce signals required for normal differentiation. For example, patients with X-linked agammaglobulinemia, a condition in which B-cell numbers are reduced by over 95%, resulting in a severe deficiency of circulating Ig, have a mutation in the gene encoding Bruton's tyrosine kinase (Btk). Btk is a member of a family of nonreceptor tyrosine kinases. Mutations in this gene also account for the X-linked immunodeficiency of xid mice. Other kinases that appear to play key developmental roles during B lymphopoiesis include JAK, Syk, and Lyn. JAK knockout mice have a severe lymphocyte deficiency, Syk knockout mice have a block in the development of CD43 cells from CD43+ precursors, and production of B-1 cells (see following) is defective in Lyn knockout mice. [31]

FETAL B-CELL DEVELOPMENT AND B-1 (CD5) B CELLS

The yolk sac is a major site of erythropoiesis, and murine studies have demonstrated that precursors with lymphoid developmental potential are present in that site. It has traditionally been considered to be the site at which hematopoiesis initiates during embryogenesis. However, recent evidence that B-cell progenitors can be detected in murine embryos at the same time or just before their appearance in the yolk sac has challenged this view and suggested that hematopoietic stem cells originate in an intraembryonic site. [32] This issue aside, it is clear that during embryogenesis, hematopoiesis, and B-cell development in particular, occurs in several intraembryonic sites in both humans and mice.[1]

The human fetal liver is seeded by hematopoietic precursors at week five to six of gestation, and pre-B cells that express cytoplasmic are detectable in it at seven weeks of gestation. Surface Ig-expressing B cells are present in the liver two to four weeks thereafter. Liver hematopoiesis ceases at birth. The spleen is also a site of human embryonic hematopoiesis by week five of development, and blood cell production continues in that organ until late fetal life. Surface Ig+ cells can be detected in the human embryonic spleen by 12 weeks of gestation. After birth the spleen is a secondary lymphoid tissue in which mature B and T cells are present. Hematopoiesis in the bone marrow is evident by three months of gestation, and by the time of birth bone marrow hematopoiesis predominates. [33]

A similar scenario is observed in mice. By day 13 of murine development, fetal liver B-cell progenitors that express cytoplasmic heavy chain protein are easily detectable, and by day 17 surface IgM-expressing cells are present. B lineage cells in murine fetal liver express the AA4 antigen, which has been useful for their isolation from that tissue. Fetal spleen is also a site of lymphopoiesis. However, shortly after birth the spleen becomes a secondary lymphoid organ and the bone marrow, which has been seeded with bloodborne hematopoietic precursors during embryogenesis, becomes the definitive site of primary B-cell development.

In addition to the above organs, other embryonic tissues, including the omentum, placenta, and blood have been reported to contain B-cell progenitors.

It is thought that B cells that develop during fetal life, referred to as B-1 or CD5 B cells, are distinct from those, termed B-2 cells, that are produced after birth in the bone marrow. These B-1 (CD5) B cells are distinguished from conventional B-2

cells by their high levels of surface IgM, low levels of membrane IgD, expression of CD5, their localization in the peritoneal and pleural cavities, the preferential use of certain immunoglobulin heavy chain variable region family members, and their predominant secretion of IgM and IgA antibodies, which are thought to provide defense against environmental flora. B cells from patients with chronic lymphocytic leukemia commonly express CD5, as do many autoreactive B lymphocytes. [34]

Although the existence of B cells with these different phenotypic and functional properties is accepted, whether or not they represent distinct B-cell lineages has been the subject of considerable debate among some investigators. Evidence that B-1 (CD5) B cells are a distinct B-cell lineage derived from a fetal stem cell is supported by experimental evidence demonstrating that repopulation of CD5-expressing B-1 cells occurs following reconstitution of mice with fetal liver cells but not with adult bone marrow. In addition to the phenotypic characteristics noted above, adult bone marrow pre-B cells in the mouse express a novel myosin light chain that is not detected in fetal liver pre-B cells. Others argue that B-1 cells are conventional B cells whose characteristics result from selective pressures following antigen exposure.

REGULATION OF B LYMPHOPOIESIS BY STROMAL CELLS AND THEIR PRODUCTS

Hematopoiesis takes place in the intersinusoidal spaces of the medullary cavity in association with a fixed population of stromal cells. The latter cells are nondividing and form a three-dimensional framework with which developing blood cells associate. The stroma is a source of signals that regulate the growth and differentiation of B lineage cells through direct interactions with B-cell progenitors and through the secretion of soluble mediators. [7] [35] [36] [37]

CellCell Interactions

Direct contact between developing B lineage and stromal cells can be observed upon analysis of intact bone marrow or of B lymphopoiesis in long-term cultures, and the molecular bases for these associations are being defined in both humans and mice. For example, both murine and human pre-B cells express the VLA-4 integrin that interacts with a stromal cell ligand identified as vascular cell adhesion molecule-1 (VCAM-1). VLA-4 also promotes binding to fibronectin, an extracellular matrix protein. CD44 on developing B lineage cells has also been implicated in mediating stromal celllymphocyte interactions in the mouse through binding to stromal cell derived hyaluronate. These intercellular interactions would presumably allow B cells to receive proliferative and/or developmental signals from stromal cells. It is important to understand that the stromal cells may not be passive populations that constitutively provide these signals. Instead, the binding of the B lineage cell may stimulate the stromal cell to produce such differentiation or growth-potentiating activities.

Stromal Cell Derived Cytokines

Another means by which stromal cells regulate B-cell development is through the secretion of soluble mediators. [38] A selective list of factors that have been implicated in the growth and/or differentiation of B lineage cells is presented in Table 82 . Although a clear definition of all the factors that may affect B lymphopoiesis is still evolving, studies of knockout mice have demonstrated that many of the cytokines described in the table and below play an obligate role during B-cell development. Some of the cytokines involved in normal B-cell development include the following.

IL-7

Although there is recent evidence that Interleukin-7 (IL-7) acts as a differentiation factor that potentiates Ig heavy chain gene rearrangements, [39] it has generally been considered to be a B-cell growth factor. [40] In mice, generation of normal numbers of murine B lineage cells is dependent upon stromal cell-derived IL-7, and cells that have initiated Ig heavy chain D-J_H rearrangements are particularly IL-7 responsive. By the time cells have matured to the late pre-B cell stage of development responsiveness to IL-7 is lost, presumably as a result of failure of cells to express the IL-7 receptor. Studies in which mice are treated with antibodies to IL-7 or its receptor, and studies of IL-7- and IL-7-receptor knockout mice indicate that IL-7 is an obligate B lymphopoietic factor, because the number of B lineage cells is dramatically reduced in these animals. However, these findings may be species-specific, because the proliferative response of human B lineage cells to IL-7 is not as vigorous as in mice. That IL-7 may not be a critical human B lymphopoietic factor is supported by the finding that B cells are generated in humans whose hematopoietic cells lack IL-7-receptor expression.

IL-7 Cofactors

A number of stromal cell-derived proliferation cofactors have been described that synergize with IL-7, but when used alone these cofactors have little or no demonstrable effect on the growth of B lineage cells. These include c-kit ligand (KL), flk2/flt3 ligand, insulin-like growth factor-I (IGF-I), pre-B-cell colony enhancing factor, and pre-B-cell growth stimulatory factor/stromal cell derived factor-I (PBSF/SDF-1). However, PBSF/SDF-1 may play an additional role during B lymphopoiesis. Mice lacking PBSF/SDF-1, a member of the CxC group of chemokines, die perinatally as a result of targeted gene inactivation and exhibit a number of abnormalities that include a significant reduction of CD43+CD45R+ pro-B cells and pre-B cells in fetal liver. The precise role of PBSF/SDF-1 in B-cell development remains unclear.

Differentiation Factors

One of the first transitions that must occur during B lymphopoiesis is the maturation of pro-B cells into pre-B cells, and stromal cell derived cytokines that include insulin-like growth factor-I (IGF-I) and fltk2/flt3 ligand may be involved in this process. Upon culture of murine CD45R negative populations with either of these cytokines, maturation of cells into CD45R+, cytoplasmic expressing pre-B cells occurs. The combination of c-kit ligand (KL) and IL-11 has also been reported to support the B-cell potential of lymphomyeloid progenitors and potentiate their maturation. Studies of mice in which the IGF-I gene has been inactivated have failed to indicate an obligate role for that factor during B-cell development. On the other hand, the frequency of pro-B cells in fractions A-C of flk2/flt3 receptor knockout mice is significantly reduced, indicating a requirement for flk2/flt3 ligand during the early stages of primary B-cell development.

Little information is available about mediators that act at later stages of development, although it has been suggested that stromal cells secrete an IL-4 like molecule that potentiates the pre-B to B-cell transition.

TABLE 8-2 -- Selected Cytokines and Hormones That Regulate Primary B Lymphopoiesis

Cytokine/Hormone	Source	Reported Effects
Positive Regulators		
IL-7	Stromal cells	Proliferation of DJ_H rearranged B-cell progenitors; rearrangement of Ig heavy chain genes
c-kit ligand (KL)	Stromal cells	Synergizes with IL-7 to stimulate proliferation of B-cell progenitors
Pre-B cell stromal cell derived factor/stromal cell derived lymphopoietin (PBSF/SDF-1)	Stromal cells	Synergizes with IL-7 to stimulate proliferation of B-cell progenitors. CD43+CD45R+ cell numbers reduced perinatally in mice lacking PBSF/SDF-1
Insulin-like growth factor-I (IGF-I)	Stromal cells	Synergizes with IL-7 to stimulate proliferation of B-cell progenitors; differentiation of CD45R cells to CD45R+ and cytoplasmic +

Pre-B-cell enhancing factor (PBEF)	Activated peripheral blood lymphocytes	Stimulates pre-B-cell growth in the presence of IL-7 + KL
Flk2/flt3 ligand	Stromal cells	Differentiation of CD45R cells to CD45R+
Thyroid hormone	Thyroid gland	Required for normal B-cell production in murine bone marrow
IL-11 + KL	Stromal cells	Supports B-cell potential of lymphomyeloid progenitors; potentiates maturation of immature B-cell precursors
IL-4-like molecule	Stromal cells	Potentiates pre-B to B-cell transition
Thymic stromal cell derived lymphopoietin (TSLP)	Stromal cells	Stimulates growth of B lineage cells
Negative Regulators		
IL-1	Macrophages	Indirectly inhibits B-cell production through stimulation of CSF production by stromal cells; may also directly inhibit proliferation of B-cell progenitors
IL-4	Stromal cells	Inhibits pro-B to pre-B-cell transition
Transforming growth factor beta (TGF-)	Stromal cells; ubiquitous	Inhibits pre-B to B-cell transition; inhibition of proliferation/differentiation of earlier stages?
Interferon- (IGN-)	T cells	May directly inhibit proliferation of B-cell progenitors and may indirectly affect the ability of stromal cells to support B lymphopoiesis
Estrogens	Ovaries	Inhibition of B-cell development in vivo; may function through direct effects on B-cell progenitors and indirect effects on stroma
Colony stimulating factors	Stromal cells; T cells	Augments myelopoiesis and inhibits B-cell development in vivo and in vitro; may indirectly inhibit B-cell production due to myeloid overgrowth

Negative Regulators

Although the preceding discussion has focused on positive regulation of B-cell development, some agents may inhibit growth and/or differentiation of B lineage cells at various stages of development.[41] IL-1 and TNF- have been shown to inhibit the proliferation of human pro-B cells, and these cytokines, as well as transforming growth factor-, -interferon, and various colony stimulating factors, have also been shown to inhibit murine B-cell development in vitro or in vivo. Some of these cytokines may directly bind to B lineage cells and inhibit their growth and/or differentiation, whereas others may act indirectly. For example, IL-1 may function by stimulating stromal cells to secrete factors that in turn inhibit B-cell production. The study of negative regulators is further complicated by the fact that even within the B-cell lineage, the same factor may stimulate some stages of development while inhibiting others. In this regard, IL-4 has been proposed to potentiate the pre-B to B-cell transition while inhibiting pro-B-cell growth.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

REGULATION OF B-CELL DEVELOPMENT BY SYSTEMIC FACTORS

In addition to regulatory signals produced in the medullary cavity, increasing evidence indicates that mediators of systemic origin also influence B-cell production. In particular, many classical endocrine hormones can affect B-cell development. For example, B-cell development in mice appears to be dependent upon the integrity of the pituitary/thyroid axis. A growing literature also suggests that steroid hormones may act as negative regulators of B lymphopoiesis. Increased levels of estrogens occurring during pregnancy inhibit B-cell development. [42] As with stromal cell-derived factors, hormones could act directly on B

lineage cells or mediate their effects indirectly through actions on the stroma.

Chapter 9 - T-Cell Immunity

Carol Clayberger
Alan M. Krensky

ANTIGEN RECOGNITION AND T-CELL DEVELOPMENT

Lymphocytes recognize and respond to antigenic challenge. They are divided into B lymphocytes, which produce antibodies, and T lymphocytes, which regulate cell-mediated immunity. T lymphocytes, so called because they are thymus derived, are further subdivided into helper and cytotoxic T lymphocytes. Antigen receptors of T cells are structurally related to antibodies but, instead of recognizing soluble proteins, recognize foreign antigens as protein fragments (peptides) bound to major histocompatibility complex (MHC) molecules and presented on the surface of antigen-presenting cells. During development, T-cell receptors rearrange, much as antibodies do, and also undergo both positive and negative selection so that mature T cells recognize a broad spectrum of foreign but not self antigens.

T-Cell Antigen Receptor

The antigen receptor on the majority of T cells is a heterodimer consisting of two polypeptides, and , that are covalently linked by disulfide bonds (Fig. 9-1).[1] A minority of T cells express

Figure 9-1 Schematic of the T-cell receptor. C and V are Ig-like constant and variable domains. The transmembrane regions of the two chains are indicated as helices interrupting the plasma membrane phospholipid bilayer. S-S, disulfide bonds; indicates the approximate location of carbohydrate moieties.

a related receptor composed of and chains.[2] The chain is a 4050-kd acidic glycoprotein and the chain is a 4045-kd uncharged or basic glycoprotein. There are a number of structural similarities between the T-cell receptor (TCR) and immunoglobulin (Ig). All TCR chains contain variable (V) and constant (C) regions (Fig. 9-2). The junction between the V and C regions is encoded by a joining (J) segment, and, for the and chains, one or two diversity (D) segments. In addition, there are three highly diverse regions in the TCR chains that correspond to the complementarity-determining regions (CDR) of Ig. These regions form the contact points between the TCR and peptide/MHC.

The TCR recognizes a complex of processed peptide, generated from proteolysis of foreign proteins, bound to self MHC. Although the TCR confers specificity for the particular antigen/MHC complex, it depends on associated proteins called the CD3 complex for signal transduction (Fig. 9-3).[3] The CD3 complex consists of five separate integral membrane proteins (, , epsilon, , and) that are noncovalently associated with each other and with the TCR. The CD3 , , and epsilon chains exist as monomers in the TCR/CD3 complex. In mice, the chain is a homodimer in 90% of T cells and a heterodimer with the chain in the remaining 10% of T cells. However, the chain has not been identified in humans. Antibodies specific for CD3 react with 100% of peripheral T cells.

The synthesis, assembly, and expression of the TCR/CD3 complex are tightly regulated and coordinated in the thymus during T-cell differentiation (see below). [4] The CD3 , , and epsilon genes are expressed in very immature thymocytes, before the and TCR genes. In mature T cells, the TCR- heterodimer associates with the CD3-epsilon complex in the endoplasmic reticulum

Figure 9-2 Linear representation of the polypeptide chains of the , , , and TCR. The relation of the variable (V), diversity (D), and joining (J) segments of the TCR chains is shown. The C (constant), H (hinge), T (transmembrane), and CY (cytoplasmic) regions are also shown. S-S, disulfide bonds; indicates the approximate location of carbohydrate moieties. The approximate positions of the hypervariable regions CDR1, CDR2, and CDR3 are depicted by *, , and , respectively. *(Modified from Davis and Bjorkman,[1] with permission. Figure 9-3 The TCR associates with the multimeric CD3 complex. The CD3 complex, composed of a epsilon heterodimer, a epsilon heterodimer, and a homodimer, noncovalently associates with the TCR in the plasma membrane. S-S, disulfide bonds.

(ER), and the complex is then transported to the Golgi complex for glycosylation of N-linked oligosaccharides. The CD3 chain homodimers must associate with the TCRepsilon CD3 complex prior to transport of the entire assembly to the cell surface.

Recently the three-dimensional structure of two different TCRs bound to their specific peptide/MHC complex was solved by x-ray crystallography. [5] [6] The most surprising finding of this work is that the TCR is diagonally oriented, with the CDR loops aligning over the strands that form the base of the peptide-binding groove (Fig. 9-4). This arrangement may lock the TCR and MHC structures, with the TCR- chain covering the amino-terminal half of the bound peptide and the TCR- chain covering the carboxy-terminal half. Thus, the antigenic peptide is completely buried at the TCR/MHC interface.

As noted above, approximately 10% of human peripheral T cells express an alternative TCR designated . [2] The and chains are glycoproteins ranging from 35 to 60 kd, depending on the size of the polypeptide backbone and the degree of glycosylation. Although the TCR also associates with the CD3 complex, cells expressing this alternative receptor do not appear to recognize peptide fragments bound to MHC molecules (see below).

Rearrangement and Expression of T-Cell Receptor Genes

During T-cell maturation, TCR genes undergo rearrangement analogous to that for immunoglobulin genes (Fig. 9-5). In the earliest precursors, TCR genes are in a nonfunctional germline configuration consisting of variable (V), joining (J), and constant (C) gene segments separated by intervening sequences of DNA. The chain also contains diversity (D) gene segments. In humans, the -chain locus is on chromosome 7 and the -chain locus is on chromosome 14. The -chain locus consists of two very similar C genes, associated with a cluster of J segments and one D segment. During development, somatic rearrangement occurs, allowing these gene segments to come together.

Somatic rearrangement of the TCR V, D, and J genes is directed by recombinases that recognize specific heptamer and nonamer sequences of nucleotides adjacent to each rearranging segment. The chain rearranges before the chain (see following), and diversity is generated in the joining process from the possible arrangement of VDJ, VJ, and VDDJ joins. D segments are used in all three reading frames, adding to the potential -chain diversity. The -chain diversity comes from the joining of V and J segments. Other mechanisms, such as N nucleotide insertion at the V/D/J joining sites, also increase diversity. Interestingly, the -chain V and J genes are encoded on chromosome 14 between the -chain V and J genes. Therefore, rearrangement of the chain inactivates the chain. The locus is similar to the -chain locus and is also located on chromosome 7. There are many fewer V gene segments for the and loci than for the and loci (Table 9-1), but increased junctional variability of the chain may compensate for this reduced number of possible variable regions. The TCR shares many features with the TCR but also resembles Ig in a number of ways. The CDR3 region shares more homology with Ig than with the TCR. Structural analysis of the CDR3 suggests that it accommodates many different types of antigenic ligands and may bind to antigen directly in the absence of antigen-presenting cells, similar to Ig.

Although somatic mutation is an important mechanism for generating diversity in immunoglobulin molecules, it does not occur in TCR genes. [7] This may prevent the development of autoreactive TCR once T cells exit the thymus. It has been estimated that approximately 4.5×10^{13} different forms of V and 6.5×10^{12} forms of V are possible.[8] If only 1% of the sequences coded for viable proteins, 3×10^{24} receptors are still possible. If 99% of these are deleted because of self-reactivity, low affinity, or structural defects, 3×10^{22} murine TCRs are possible. That fewer than 10^{9} thymocytes exit the thymus during a mouses lifetime raises the question as to how random the generation of TCR is.

Each immature T cell contains two genes for each chain of the TCR. However, only one of the two inherited genes for the chain and one of the two inherited genes for the chain are

Figure 9-4 (A) Complex of TCR (top) and HLA-A2/peptide (bottom) shown as an -carbon trace. The TCR C domain is not shown. *(From Garboczi et al.,[5] with permission. The regions of interaction of the TCR and chains are shown in dark lines, with the rough positions of the CDR loops shown in numerals. This view is perpendicular to that shown in **A.** *(From Parham P: Pictures of MHC restriction. Nature 384:109, 1996,with permission. Copyright 1996 Macmillan Magazines, Ltd.)*

functionally rearranged and expressed in a single T cell. [9] This phenomenon, called allelic exclusion, occurs because the productive rearrangement of the TCR locus on one chromosome prevents the rearrangement of the corresponding allelic gene on the other chromosome. If the rearrangement on the first chromosome is not functional, i.e., if it cannot be transcribed or its transcript cannot be translated, the corresponding locus on the other chromosome will rearrange. Therefore, nonfunctional TCR transcripts are often found in T cells. The -chain genes rearrange first, so if both rearrangements are unproductive, no -chain gene rearrangements occur and the T cell dies.

T-Cell Development

Blood cells are derived from multipotent hematopoietic stem cells (HSC) produced in the liver in fetal life and then in the bone marrow in adults. [10] These HSC must receive signals provided by thymic stromal cells in order to develop into mature T cells. [10] [11] That the thymus is critical for T-cell development was shown in the early 1960s in a series of experiments by Miller[12] and others. Researchers found that mice thymectomized within a few days of birth had a marked deficiency of lymphocytes, did not reject foreign skin grafts, and were susceptible to infections. HSC reach the thymus via the blood and migrate through the vessel walls to enter the stroma, where the earliest differentiation steps begin in the cortex.

Current understanding of T-cell differentiation is largely derived from studies in mice in which combinations of antibodies recognizing specific cell-surface markers were used to select subpopulations of thymocytes.[13] These cells were then reintroduced into lethally irradiated animals to determine their ability to differentiate into mature T cells. Four major developmental stages can be identified in the thymus prior to expression of a mature TCR/CD3 complex and the lineage-specific antigens CD4 and CD8 (Fig. 9-6).[14]

Thymic Lymphoid Progenitors

The precursor cells that have newly entered the thymus express high levels of CD44, a homing receptor that may be responsible for targeting these cells to the thymus. They also express CD117 (stem cell factor receptor) and the interleukin-7 (IL-7) receptor, which promote thymocyte growth and survival. Thymic lymphoid progenitors are not, however, committed to the T-cell lineage; intravenous injection of these cells can also give rise to B lymphocytes and dendritic cells.

Pro-T Cells

Within a day of thymic entry, thymic lymphoid progenitors up-regulate expression of CD25 (IL-2 receptor) and are now defined as pro-T cells. These cells begin to proliferate rapidly, although the TCR- and TCR- in pro-T cells remain in germline configuration and are not expressed. This suggests that the pro-T-cell stage involves a TCR-independent activation event, for activation of mature T cells requires stimulation through their

Figure 9-5 Schematic representation of TCR and TCR chain rearrangement. The leader (L), variable (V), diversity (D), joining (J), and constant (C) genes are shown. Each C gene consists of multiple exons that are not shown. (See Table 9-1 for the number of V, D, J, and C exons in each locus.) In this example, recombination of the TCR- locus uses the V_{1} exon with the J_{7} exon; following recombination, intervening V and J exons are deleted.

TABLE 9-1 -- Human T-Cell Receptor Gene Segments

Variable (V)	7080	52	12	4[a]
Diversity (D)	0	2	0	3
Joining (J)	61	13	5	3
Constant (C)	1	2	2	1

[a] The TCR locus is located within the TCR locus. The V genes are interspersed with the V genes, but there are at least four TCR V genes.

TCRs. Finally, commitment to a T-cell lineage occurs during the transition from thymic lymphoid precursors to pro-T cells and is dependent on cytokines produced by the thymic stroma. In particular, IL-1 and tumor necrosis factor- (TNF-) play pivotal roles in the expression of CD25 on pro-T cells.

Early Pre-T Cells

Early pre-T cells down-regulate expression of CD44 and CD117, continue to express high levels of CD25, and also up-regulate expression of Thy-1, heat-stable antigen (HSA), and Sca-1/2. Early pre-T cells constitute the majority (60%) of triple-negative (CD3/CD4/CD8) thymocytes, but nearly three quarters of them fail to progress to the late pre-T-cell stage. During the transition from pro-T to early pre-T cell, the rate of proliferation slows and TCR- rearrangement begins. TCR- rearrangement precedes that of TCR- and is required for further differentiation. Mice with severe combined immune deficiency (SCID) or recombinase-activating gene deficiency cannot carry out V(D)J recombination, and thymocyte maturation arrests at the early pre-T-cell stage. Reconstitution of SCID mice with a productively rearranged TCR- transgene is sufficient to initiate the differentiation of early pre-T cells into double-positive (CD4+/CD8+) thymocytes. In mice that have been genetically altered such that they cannot express TCR- protein (TCR- knockout mice), thymocyte differentiation is arrested at the early pre-T-cell stage, although TCR- rearrangement proceeds normally. These findings underscore the important regulatory role served by TCR- and indicate that TCR- partners with a molecule other than TCR- at the early pre-T-cell stage. That molecule was identified by von Boehmer and co-workers in 1993 and designated pre-T. [15]

Pre-T is a type I transmembrane protein and a member of the Ig superfamily (Fig. 9-7).[16] It contains a single extracellular Ig-like domain that exhibits little homology with any other antigen receptor molecule and does not contain a J-like sequence. Pre-T and rearranged TCR- form a disulfide-linked heterodimer called pre-TCR. The cytoplasmic tail of pre-T is about 30 amino acids long, but it is not necessary for signal transduction. The asymmetric structure of pre-TCR suggests that other, as yet unidentified small proteins may be part of this receptor, and some evidence for this exists. In addition, results from biochemical and gene targeting studies indicate that CD3-, CD3-epsilon, and CD3- are complexed with pre-TCR and are responsible for signal transduction following engagement of pre-TCR with ligand. This allows cells that have successfully rearranged their TCR- to escape from programmed cell death and to undergo TCR- rearrangement that is terminated only when the TCR binds to intrathymic ligands. Thus, a key function of pre-TCR is to select TCR-+ cells for expansion and further differentiation, thereby permitting a large number of rearranged TCR- chains to combine with a single TCR- chain.

Late Pre-T Cells

Late pre-T cells lose CD25 expression and once again begin to proliferate rapidly. TCR- rearrangement occurs at this stage, and the newly synthesized TCR chains displace the pre-T, forming a mature TCR complex. At this point, pre-T expression is turned off, and early, large CD4+/CD8+ thymocytes evolve into small resting CD4+/CD8+ thymocytes.

Figure 9-6 Maturation of hematopoietic stem cells (HSC) in the thymus.

Figure 9-7 Schematic of the pre-T/TCR- heterodimer. The transmembrane regions of the two chains are indicated as helices interrupting the plasma membrane phospholipid bilayer. S-S, disulfide bonds; indicates the approximate location of carbohydrate moieties.

CD4/CD8 Lineage Commitment

The interaction of TCR with peptide/MHC prompts the CD4+/CD8+ T cell to make a commitment to either the CD4 or CD8 lineage. CD4 and CD8 are called co-receptors because during TCR interaction with peptide/MHC, CD4 and CD8 simultaneously bind to invariant parts of the MHC molecule. CD4 binds to constant regions of MHC class II, while CD8 binds to constant regions of MHC class I. Selection of CD4 or CD8 lineage occurs by two distinct processes. [17] [18] In the instructional model, cells whose TCR binds to MHC class II molecules lose expression of CD8, while those cells whose TCR interacts with MHC class I molecules lose expression of CD4. In the stochastic model, CD4+/CD8+ thymocytes randomly lose expression of either CD4 or CD8. Cells whose co-receptor expression correlates with the MHC specificity of the TCR continue to develop, while the majority of cells whose TCR MHC specificity does not match co-receptor expression (e.g., TCR specificity for MHC class II on a CD8+ cell) are deleted. Evidence exists for both the instructional and stochastic mechanisms of lineage selection in thymocyte development.

Positive and Negative Selection of T Cells

The vast majority of thymocytes undergo apoptosis in the thymus, never reaching the periphery. To exit the thymus, T cells must pass two tests, called positive and negative selection.[19] [20] In positive selection, T cells are selected for binding to self MHC. [21] Presumably, interaction between the TCR and self MHC molecules on thymic stromal cells sends a positive signal to the immature T cell that blocks apoptosis and activates further developmental steps. Surprisingly, the particular peptide bound to thymic MHC molecules does not play a critical role in positive selection. [22] [23] [24] TCR transgenic mice, expressing a single TCR on all their T cells, develop normally in the thymus even in the absence of the peptide to which the mature transgenic T cells respond. In addition, most T cells selected by a single peptide/MHC complex will respond to that MHC molecule bound to a spectrum of peptides. Thus, it appears that there is some flexibility in the requirement for peptide/TCR interaction such that a single peptide/MHC complex can select a large variety of TCR. In contrast, if the affinity of the TCR interaction with the selecting peptide/MHC complex is too high, the T cell will undergo apoptosis. [25] This process, called negative selection, prevents autoreactive T cells from reaching the periphery. Therefore, T cells that emerge from the thymus are both self-tolerant and self-MHC restricted.

CELLULAR BASIS OF THE IMMUNE RESPONSE

Antigen Presentation

T cells are both effectors and regulators of the immune response. To mediate these activities, T cells must first recognize specific antigenic peptide/MHC complexes. These complexes are formed by two distinct pathways (Fig. 9-8).[26] [27] Intracellular antigens, such as viral proteins, are synthesized in the cytoplasm of infected cells. A fraction of these newly synthesized proteins are broken down into peptides in specialized cytoplasmic structures called proteosomes. These peptides are then transported into the ER by the transporter of antigenic peptides (TAP). In the ER they associate with newly synthesized MHC class I molecules. In contrast, extracellular antigens, such as extracellular microbes and secreted molecules, are taken up into specialized antigen-presenting cells (dendritic cells and macrophages) by endocytosis. The proteins are broken down into peptides in lysosomes and associate with newly synthesized or recycled MHC class II molecules in postlysosomal vesicles before transport to the plasma membrane. Thus, class I and class II MHC molecules present largely nonoverlapping antigenic peptides, with class I molecules generally presenting endogenous (intracellular) antigens and class II molecules generally presenting exogenous (extracellular) antigens.

Accessory Molecules

Although T-cell specificity is dependent on interaction of the TCR with antigenic peptide/MHC, activation of T cells requires the binding of additional, or accessory, molecules on the T cell to their ligands on the antigen-presenting cells (macrophages, dendritic cells, and B cells). This may reflect both the low affinity (estimated at about 10^5 M) of the TCR for peptide/MHC and that only a very small fraction of MHC molecules on an antigen-presenting cell are bound with the specific peptide recognized by an individual TCR. [28] [29] Accessory molecules can increase the strength of the interaction between the T cell and can provide additional signals for T-cell activation.

T-Cell Subsets and Their Functions

CD4+ Helper T Cells

CD4+ T cells initiate specific immunity by recognizing antigenic peptides bound to MHC class II molecules on B cells or other antigen-presenting cells such as dendritic cells and macrophages. Upon activation, these cells secrete soluble proteins such as IL-2, IL-4, and IFN- that are collectively referred to as cytokines (Table 9-2). Cytokines provide the necessary help for the activation and differentiation of other lymphoid cells; hence the designation of CD4+ T cells as helper T cells.

Figure 9-8 MHC class I and MHC class II molecules acquire antigenic peptides from different compartments. MHC class II molecules bind exogenous antigen. Peptide-free MHC class II molecules are synthesized in the rough endoplasmic reticulum (rER), mature through the Golgi complex, and fuse with endosomes that contain peptides derived from antigens brought into the cell by endocytosis. MHC class I molecules bind endogenous antigens. Soon after completion of synthesis of MHC class I molecules in the rER, they bind antigenic peptides derived from intracellular antigens such as viruses. Viral proteins are broken down into peptides in the proteosome and moved into the rER by the transporter of antigenic peptides (TAP).

TABLE 9-2 -- Functions of T-Cell-Derived Cytokines

IL-2	Stimulates T-cell proliferation and differentiation
	Induces antibody production by B cells
	Increases lytic activity of NK and LAK cells
IL-3	Stimulates production and differentiation of macrophages, neutrophils, eosinophils, basophils, mast cells, megakaryocytic cells, and erythroid cells
	Supports proliferation of HSC
IL-4	Induces differentiation of Th2 cells
	Induces proliferation and differentiation of B cells
IL-5	Stimulates growth and differentiation of eosinophils
IL-6	Induces growth and differentiation of T cells, B cells, hepatocytes, keratinocytes, and nerve cells
	Stimulates production of acute phase proteins
IL-8	Chemotactic for neutrophils, T cells, and basophils
	Causes adhesion of neutrophils to endothelial cells
IL-9	Synergizes with erythropoietin to support development of erythroid burst-forming units by bone marrow cells
	Promotes in vitro T-cell growth and survival
IL-10	Suppresses macrophage function
	Induces B-cell proliferation and Ig secretion
IL-12	Induces differentiation of Th1 cells
	Stimulates growth and function of NK and T cells
IL-13	Induces B-cell growth and differentiation
	Inhibits inflammatory cytokine production by macrophages
IL-14	Induces proliferation of activated B cells
IL-15	Stimulates growth of T cells and NK cells

IL-17	Induces fibroblast and endothelial cell cytokine production
G-CSF	Stimulates production of granulocytes and neutrophils
	Activates neutrophils
GM-CSF	Promotes differentiation and growth of HSC
IFN-	Antiviral activity
	Enhances expression of MHC molecules
	Activates macrophage activity
MIP-1	Chemoattracts T cells, monocytes, and eosinophils
MIP-1	Chemoattracts monocytes and T cells
RANTES	Chemoattracts monocytes, T cells, and eosinophils

In 1989 Mossman and Coffman reported that murine CD4+ helper T-cell clones could be divided into two mutually exclusive subsets. [30] We now know that these subsets can be distinguished not only by the cytokines they produce, but also by the lymphocytes they affect and the types of pathogen to which they respond (Table 9-3). [31] [32] The Th1 subset produces cytokines such as IL-2, IFN-, and tumor necrosis factor-/, while the Th2 subset produces IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 cells promote secretion of IgG_2 antibody, whereas Th2 cells induce IgG_1 and IgE. Th1 cells mediate delayed-type hypersensitivity and cytotoxicity, and have limited effects on B cells; Th2 cells mediate B-cell help and also activate eosinophils and mast cells. Th1 cells are beneficial in immune response to leishmaniasis, leprosy, viruses, and allergy, while Th2 cells are beneficial in arthritis, autoimmunity, helminth infection, and pregnancy. In humans, a Th0 subset has also been described. These cells can produce various combinations of both Th1 and Th2 cytokines.

There is now overwhelming evidence that Th1 and Th2 cells are derived from a common precursor. The major factor that determines Th1 versus Th2 lineage is the predominance of a particular cytokine in the microenvironment of the developing cell. Cells that differentiate in the presence of IL-4 largely become Th2 cells, whereas those that differentiate in the presence of IL-12 and IFN develop into Th1 cells. The source of these cytokines is still under investigation, but in some cases, T cells and natural killer (NK) cells can provide IL-4 early in an immune response while phagocytes can produce IL-12 in response to certain pathogens.

CD4+ T cells also regulate immune responses by a mechanism that involves direct cell-cell contact rather than secreted factors. Activated T cells and some other cells express a cell surface molecule called Fas (CD95), a member of the TNF receptor family. [33] Engagement of Fas by another cell-surface molecule called Fas ligand triggers apoptosis in the Fas-expressing cell. Homeostasis of the immune system is in part maintained by activated CD4+ cells expressing Fas ligand on their surface. Once the number of activated lymphoid cells in a particular site exceeds a critical number, Fas ligandbearing cells induce apoptosis of Fas+ cells. Without such a regulatory mechanism,

TABLE 9-3 -- Characteristics of Th1 and Th2 Cells

	Th1	Th2
Cytokines	IL-2	IL-4
	IFN-	IL-5
	TNF-/	IL-6
		IL-10
		IL-13
Functions	DTH	B-cell help
	Cytotoxicity	Eosinophil activation
	Macrophage activation	Mast cell activation
Help for pre-dominant antibody isotype	IgG_2	IgG_1
		IgE
Beneficial in	Leishmaniasis	Arthritis
	Leprosy	Autoimmunity
	Viral infection	Helminths
	Allergy	Pregnancy
		Organ transplantation
Detrimental in	Arthritis	Allergy
	Autoimmunity	Viral infection
	Helminths	Leprosy
	Organ transplantation	

the immune compartment would continue to expand enormously and eventually overwhelm the animal. In fact, this idea is confirmed by *lpr* and *gld* mice, two mutant strains that lack functional Fas and Fas ligand, respectively. These animals exhibit severe lymphoproliferative disorders, and eventually die with lupus-like symptoms.

Other cells have adopted expression of Fas ligand as a way to protect against immune cells. [34] Tissues such as cornea and testis are said to enjoy immune privilege in that they are not infiltrated by lymphocytes. Recent studies have shown that these tissues consitutively express Fas ligand, so that infiltrating Fas+ lymphocytes undergo apoptosis. Unfortunately, some tumors also express Fas ligand, thereby allowing escape from immune surveillance by activated tumor-specific T cells.

CD8+ Cytotoxic T Cells

CD8+ T cells recognize antigenic peptides presented by MHC class I molecules. The majority of CD8+ T cells kill target cells that bear the peptide/MHC complex for which the CD8 T-cell receptor is specific. These cells, therefore, are designated cytotoxic T lymphocytes (CTL). CD8+ T cells that emerge from the thymus are not yet capable of lysing targets, but upon stimulation with antigen/MHC and cytokines such as IL-2 and IFN- produced by CD4+ helper cells, they differentiate from precursor CTL into mature effector CTL.[35] Acquisition of effector CTL function also involves the synthesis of lytic molecules and their sequestration into membrane-bound granules. The granules contain a number of different components, including perforin, a pore-forming protein with structural similarities to complement proteins, and granzymes, a family of serine esterases. Effector CTL also acquire the capability to produce and secrete cytokines and, as for CD4+ cells, can be divided into type 1 and type 2, depending on the pattern of cytokines produced. [32]

Lysis of targets by CTL is well studied (Fig. 9-9). Upon conjugation of the target and CTL, the CTL cell becomes activated and the cytoplasmic granules are polarized toward the target cell. A fraction of these granules are exocytosed into the junction between the two cells, and the granules deliver their lethal contents to

the target cell. At this point, the CTL can detach, and target lysis proceeds in the absence of the CTL. Video microscopy has shown that conjugation and delivery of the lethal hit takes less than 20 minutes and that a single CTL is capable of lysing many targets in a short period.

Target cell death is mediated by the synergistic activity of the granzymes and perforin (Fig. 9-10). Perforin polymerizes in the target cell membrane to form pores that allow water and ions to move into the cytosol, leading to osmotic swelling and lysis. Granzymes activate a cascade of enzymes called caspases that culminate in the degradation of DNA, similar to the apoptosis induced by engagement of Fas. Although CTL can express Fas ligand, the greater part of CTL-mediated lysis results from granule exocytosis and not engagement of Fas. Interestingly, most CTL are resistant to CTL-mediated lysis. This may result from directed release of lytic granules toward the target cell and/or intrinsic resistance of the CTL to perforin and granule-mediated lysis.

Much of our understanding of the mechanism of CTL comes from studies using CTL recognizing non-self MHC molecules, as is the case in organ allograft rejection. However, the primary function of CTL is to eradicate viral infection. This is accomplished by two mechanisms: (1) CTL lysis of host cells that are the source of replicating virus, and (2) secretion of the antiviral cytokine, IFN-.

T Cells

A minority of peripheral blood T cells (<10%) express the TCR. Although our understanding of the rules governing TCR recognition of antigen lags far behind that of the TCR, some features have recently been identified. [36] Although the TCR is associated with the CD3 complex, many of these cells do not express either CD4 or CD8 (double negative). This is consistent with the observation that, with a few exceptions, antigen recognition by T cells is not MHC restricted. Some T cells recognize intact proteins while others recognize nonpeptidic antigens from bacteria or other pathogens. [37] T cells also recognize heat shock proteins or phosphorylated alkyl, carbohydrate, or nucleotide residues. Thus, T cells appear to recognize an overall structure in the absence of antigen processing

Figure 9-9 Schematic of target recognition and lysis by CTL.

Figure 9-10 Apoptosis can be caused by either granule exocytosis or Fas/Fas ligand pathways. Following the interaction of the TCR with MHC class I/peptide, granules containing perforin/granzymes localize toward the target cells and are released. Perforin inserts into the plasma membrane, and granzymes move into the target cell. Perforin and granzyme act synergistically to activate the caspase cascade, resulting in apoptosis. Binding of Fas ligand (FasL) to Fas also activates the caspase cascade, resulting in apoptosis.

and MHC presentation, in contrast to the fine specificity for antigenic peptide and MHC restriction observed for T cells.

The response of T cells to antigen is often more rapid than that of T cells, perhaps because T-cell antigens can be presented earlier than T-cell antigens. T cells secrete a variety of cytokines, and many mediate antigen-unrestricted cytotoxicity. Finally, an increasing body of evidence supports the proposition that T cells play a unique protective role in microbial infections, such as tuberculosis. This has stimulated research into whether vaccines or other therapies directed toward T cells may be important therapeutics.

Delayed-Type Hypersensitivity Responses

Delayed-type hypersensitivity is a cell-mediated immune response in which the ultimate effector cell is an activated mononuclear phagocyte (macrophage). DTH is the primary immune defense against intracellular bacteria such as *Listeria monocytogenes* and mycobacteria. It can also be induced by sensitization to chemicals or environmental antigens or by intradermal injection of microbial antigens, e.g., purified protein derivative (PPD) from *Mycobacterium tuberculosis* in presensitized or vaccinated individuals. The response begins when CD4+ or CD8+ T cells respond to the presence of MHC-associated antigenic peptide and produce inflammatory cytokines such as IL-2, TNF, and IL-8. Within a few hours, neutrophils accumulate at postcapillary venules at the injection site, and by 12 hours, neutrophils are replaced by T cells and macrophages. The T cells produce additional inflammatory cytokines, including IFN-, which activate the macrophages. The endothelial cells lining the postcapillary venules swell and fibrinogen leaks from the blood vessels into the surrounding tissue, where it is cleaved to fibrin. This deposition of fibrin, as well as the infiltrating T cells and macrophages, causes the tissue to become swollen and hard. Induration is obvious by about 18 hours after injection with antigen and peaks by 2448 hours. The activated macrophages eliminate the antigen, leading to resolution of the response.

T-Cell Memory

In most cases, the immune responses to infectious agents have distinct short- and long-term phases. Immediately after the primary antigenic challenge there is a rapid expansion of specific effector T cells that destroy the pathogen. Most effector cells are relatively short-lived and are eliminated at the end of the primary immune response. However, some of these cells are spared, and a state of long-lived memory develops. Subsequent challenge with the same pathogen leads to a more rapid and effective response, reflecting both an increase in the precursor frequency of antigen-specific T cells and an increased sensitivity

to antigen. [38] Memory T cells are small resting cells that may be sequestered in areas such as lymph nodes, where they can be periodically stimulated by low levels of residual antigen. Although memory T cells do not express activation antigens such as CD25 (IL-2 receptor), they typically express a low-molecular-weight isoform of CD45 (CD45R0).

SUMMARY

Although B cells use cell surface Ig to recognize foreign antigens in soluble form, T cells have evolved to discriminate self from nonself based on TCR recognition of foreign antigenic peptides bound to self MHC molecules. TCR resemble Ig in many ways and may use similar molecular mechanisms to generate the receptor diversity needed to recognize the variety of pathogens that confront the immune system. T cells produce soluble mediators called cytokines and can also directly damage infected cells by both secretory and nonsecretory pathways. In these ways, T lymphocytes both regulate and orchestrate the antigen-specific immune response.

Chapter 10 - Regulation of Activation of B and T Lymphocytes

John G. Monroe
Leslie B. King

OVERVIEW

As discussed in previous chapters in this section, the immune system is compartmentalized into different cell types that perform defined effector functions and have evolved to respond to specific types of pathogens. Lymphocytes comprise the effector cells of the adaptive antigen-specific immune response. They are the cells responsible for the characteristics that we often associate with the immune system, namely memory, specificity, and tolerance to self-antigens. Lymphocytes can be subdivided into two general subpopulations, B lymphocytes and T lymphocytes. The former is responsible for antibody production and derives its name from its hematopoietic origin, the bursa of Fabricius in birds and the bone marrow in mammals. T lymphocytes, although derived from hematopoietic precursors in the bone marrow, become committed to the T-cell lineage and undergo most of their maturation in the mammalian thymus, from whence they derive their name. T lymphocytes are the

mediators of cellular immunity: cytotoxic T-cell responses, delayed-type hypersensitivity, graft-versus-host reactions, and so forth.

Postulated as long ago as 1900 by Ehrlich [1] and confirmed by numerous studies since then, lymphocytes express on their surface clonally distributed receptors that confer specificity for antigen and serve as signaling molecules to initiate the activation of these cells. On an individual lymphocyte, all of the expressed receptors for antigen exhibit identical specificity. As discussed later and in Chapter 8 , the specificity of the B- and T-cell antigen receptors is determined at the DNA level. Because the antigen specificity of the lymphocyte is determined at the genetic level, the progeny and effector cells derived from a B or T lymphocyte after antigen activation maintain the identical antigen specificity of the original responding cell. This process maintains the clonality of the immune response. A specific exception to this rule is the induced somatic hypermutation of the B-cell antigen receptor that occurs during germinal center reactions. [2] [3]

B lymphocytes recognize and bind to antigen by a surface form of immunoglobulin. Likewise, the T-cell antigen receptor is a complex of antigen recognition and signal transducer proteins. Most T cells use a molecule composed of two disulfide-linked proteins called the and chains as their receptor for antigen recognition. Notably, some T cells use a different receptor for antigen recognition. In this case, these lymphocytes express / T-cell receptors (TCRs). In all cases, B and T cells generate their receptor structures by a complex genetic mechanism. The variable regions, which are the regions that bind to antigen, are assembled by combining multiple genetic segments that serve to generate enormous diversity in the antigen-combining regions of these receptors. As a consequence, the potential variability and therefore the limits on the theoretic number of antigenic epitopes that can be recognized has been calculated to exceed 10^{11} .

Besides recognizing and binding antigen, the B- and T-cell antigen receptors also generate signals necessary for initiation of an antigen-specific response. However, neither the surface immunoglobulin molecule nor the TCR / or / proteins possess intrinsic signaling capabilities. Moreover, each of these proteins has negligible cytoplasmic domains and therefore is likely incapable of direct interaction with intracellular signal transduction molecules. For each of these receptors, coupling to cytoplasmic signaling pathways is accomplished by other transmembrane proteins that interact noncovalently with the antigen recognition proteins. As such, the antigen receptors of B and T cells are in fact complexes of proteins, some serving as antigen binding proteins and others functioning to generate signals for the lymphocyte response. More detail on the structure and function of the various components of these signaling complexes is presented later.

Although theoretically sufficient for antigen binding and signal initiation, the B- and T-cell antigen receptors are aided by other surface proteins called co-receptors. These co-receptor molecules play a role in the types of antigens that are bound to the receptors and influence the strength of the signal that is generated as a consequence of antigen binding. CD4 and CD8 influence the ability of the TCR to interact productively with antigen-presenting cells expressing peptide in the context of major histocompatibility complex (MHC) class II or class I, respectively. On the other hand, B-cell receptor (BCR) recognition and binding is not influenced by the MHC because these receptors can bind native antigen. Nonetheless, CD22 and CD19/CD21 serve as co-receptor-like molecules on B cells. As is discussed in more detail later, these co-receptors probably play specific roles in modulating receptor sensitivity under defined conditions in the case of CD22 or to specific forms of antigen in the case of CD19/CD21.

Finally, although signals generated as a consequence of antigen binding through the BCRs or TCRs is important in initiating activation responses by these cells, they are by no means sufficient to generate complete functional responses. Both types of lymphocytes require signals generated through secondary receptors called co-stimulatory molecules to achieve a complete activation response. In the case of T cells, signaling through the CD28 co-receptor is required for growth factor interleukin (IL)-2 production and clonal expansion. Similarly, B cells require CD40 co-receptor signaling for optimal clonal expansion and antibody production. Finally, for both types of lymphocytes, soluble cytokines play specific roles in amplifying and modifying the activation response and altering the effector functions of these cells.

In this chapter, we discuss the current understanding of how antigen-induced lymphocyte responses are initiated and regulated. Our focus will be on (1) the mechanism and role of the antigen receptor-induced activation signals; (2) to what degree these signals are necessary for lymphocyte-mediated immune responses; and, (3) how they can be modified to adapt the response to different pathogens.

B LYMPHOCYTES

B lymphocytes are the primary effector cells of the antibody-mediated immune response and are antigen-presenting cells for activated, and in some circumstances, resting T cells. Antigen recognition and triggering is accomplished by the BCR, expressed on the surface of mature, immunocompetent B cells. On binding antigen, the BCRantigen complex is endocytosed, and protein antigens processed and re-presented as peptides on the B-cell surface in association with class II MHC antigens. These peptideMHC class II complexes are recognized by antigen-specific T cells. This interaction serves not only to facilitate activation of the T cell (see section on T-Cell Activation), but the activated T cell in turn delivers activation and differentiation signals to the B cell. In this context, the antigen-specific B and T cells can be viewed as communicating with each other, each in turn providing cues to the other to increase levels of activation and effector cell commitment. This stepwise process provides multiple levels of regulation, providing the immune system with critical checkpoints to ensure the appropriate magnitude and effector function is achieved. In addition to its role as a recognition structure and as a mechanism for antigen capture, the BCR serves also as a signaling molecule. In this regard, it is responsible for generation of the initial antigen-induced activation signals for the B cell.

B-Lymphocyte Antigen Receptor

The antigen recognition structure of the BCR is a surface form of immunoglobulin (sIg). The basic monomeric structure of sIg is identical to that of the secreted form of this molecule. Each molecule possesses two light chains disulfide-coupled to two disulfide-linked heavy chain molecules. The surface or membrane form of immunoglobulin differs from the secreted form with respect to the carboxy end of the molecule. Surface immunoglobulin includes additional amino acid residues comprising a spacer, transmembrane, and cytoplasmic region. The carboxy-terminal end of the membrane form is encoded by two additional exons, which differ for each immunoglobulin isotype. For sIgM and sIgD, the cytoplasmic region is only three amino acids long, whereas IgG and IgA are slightly more extensive, 28 and 14 amino acids, respectively. Antigen binding is mediated by the amino-terminal end of the molecule. There is enormous variability in this region between individual B cells. The primary sequence of the variable region of these receptors determines the antigen specificity of a particular B cell clone, and the

diversity of the variable region sequences expressed determine the repertoire of the individual.

All of the immunoglobulin isotypes function as antigen receptors on B cells. For the most part, only one is expressed on an individual cell at any given time. The exceptions are IgM and IgD, which are co-expressed on the majority of resting mature B cells. Co-expression of other isotypes has been reported, but they likely represent cells in transition during isotype switching. For isotypes other than IgM and IgD (i.e., IgG, IgA, and IgE), genetic mechanisms similar to those involved in variable region gene rearrangement (see later) make it genetically impossible to co-express these other isotypes.

The amino acid sequence of the variable region is determined by a genetic process involving the rearrangement of the exons that encode heavy and light chain variable regions. Through a process involving stochastic selection of variable region segments, random nucleotide additions, and junctional diversity, receptor genes are generated that have only a 1 in 10^9 10^{12} chance of being identical to any other BCR. Because this genetic process occurs without antigen selection, the intrinsic antigen specificity of the B cells produced is random and highly varied, enhancing the likelihood of clones responsive to new foreign antigens. Although this potential diversity can never be realized in the immune system of a single individual, it provides a tremendous advantage to the species because it ensures that the potential exists in a group of individuals to recognize and mount a response to a nearly infinite spectrum of antigens. However, this survival advantage must be balanced against the likelihood that many of the BCRs produced will be reactive to self-antigens. Although it is not discussed here, the immune system has evolved mechanisms to identify and remove self-reactive B and T lymphocytes from the repertoire based in part on signals generated through their BCRs (the reader is directed to reviews by Klinman, Monroe, and Goodnow et al. [4] [5] [6]).

The BCR exists as a protein complex in the plasma membrane of the B cell. IgM and IgD are the isotypes expressed on resting B cells with no prior history of antigen-induced activation (naive or virgin B cells). However, the brief cytoplasmic domain of cell surface IgM or IgD is unable on its own to generate a signal in response to sIg cross-linking by antigen or to couple to intracellular signal transducers. To initiate signals for B-lymphocyte activation, sIg exists noncovalently associated with at least two other proteins, Ig (CD79a) and Ig (CD79b). [7] [8] These proteins are products of the *mb-1* and *B29* genes, respectively, and constitute the signaling components of the BCR. [9] [10] Furthermore, expression of Ig and Ig are necessary for surface expression of membrane immunoglobulin.

The structures of CD79a and CD79b are superficially very similar. Each is a transmembrane protein with a single immunoglobulin superfamily domain in the extracellular sequence. Importantly, each has extensive cytoplasmic domains. As first noted by Reth, [11] within each of these cytoplasmic domains are regions of high homology with other immunological signaling molecules such as the , , and chains of the CD3 complex (see later), CD5, and the high-affinity IgE receptor and chains. These regions exist as motifs containing two tyrosines in a pattern of Y X X L/I (X 6-8) Y X X L/I, where X represents any amino acid. In chains of the TCR (see later), it was shown that these tyrosine-containing motifs are necessary and sufficient for signal transduction. [12] This motif is referred to as an ITAM, for *i*mmunoreceptor *t*yrosine-based *a*ctivation *m*otif. These motifs serve to couple the receptor to cytoplasmic proteins. The tyrosines (Y) associated with this motif are significant because they represent substrates for tyrosine phosphorylation by specific kinases and subsequent docking sites for intracellular signaling molecules, which is discussed later.

The earliest detected BCR-induced event is the activation and phosphorylation of tyrosine-specific kinases, [13] [14] particularly those belonging to the src family of protein tyrosine kinases. [15] [16] The tyrosine phosphorylation of CD79a and CD79b after BCR cross-linking provided the first clue that these proteins were involved in transmembrane signaling. Phosphorylation of these proteins is believed to be accomplished by specific protein tyrosine kinases that exist in noncovalent association with the BCR in an inactive form in resting B cells. [17] Clustering of the BCR signaling complex as would occur after binding to multivalent antigen or antigen aggregates results in the activation of these receptor-associated tyrosine kinases. The initial tyrosine phosphorylation of CD79a and CD79b is restricted to the ITAM-associated tyrosines and facilitates recruitment of secondary intracellular signal transducers. [10] Figure 10-1 illustrates the basic composition of the BCR of resting B cells, including the known receptor-associated tyrosine kinases. The stoichiometry is inferred by theoretic considerations based on the transmembrane region sequences of the CD79a (Ig), CD79b (Ig), and Ig heavy chain proteins. [18]

B-cell receptorassociated protein tyrosine kinases so far identified are Lyn, Blk, Fyn, and Lck. [15] [16] All are members of the src family, containing a conserved arrangement of proteinprotein interaction domains, as well as a kinase domain and sites for autoregulation by phosphorylation. [19] Kinases of the src family each have a myristylation sequence at the N-terminal, which facilitates an association of the kinases with the plasma membrane. Adjacent to the myristylation sequence is a stretch of unique sequence, which differs for each member of the src family kinases. This region is thought responsible for interactions with the unphosphorylated Ig/Ig complex in resting B cells. [17] At the C-terminal of the unique region is a single SH3 domain, which is known to mediate proteinprotein interactions by recognition of sequences rich in proline residues. C-terminal to the SH3 domain in the kinase is the SH2 domain. SH2 domains are known to interact with phosphotyrosine residues. An emerging common theme for molecules intimately involved in signal transduction is their modular construction associating different discrete proteinprotein interaction domains with domains mediating effector function. These interaction domains not only facilitate recruitment of enzyme substrates, as in the case of

kinases, but facilitate the localization of these signal transducers with membrane receptors and cytoplasmic signaling molecules that lack intrinsic enzymatic activity. For the src family kinases, the enzymatically active kinase domain is at the C-terminal of the protein. Each of these family members also shares common regulatory mechanisms. One tyrosine residue, at the C-terminal of the protein, provides negative regulation. If this site is phosphorylated, the kinase is inactivated, thereby providing a mechanism to turn off the response. Conversely, initiation of the response requires dephosphorylation at this site. [19] Dephosphorylation is believed to be mediated by co-clustering of CD45 (see later) with the aggregated BCR complex. The mechanism by which phosphorylation and dephosphorylation are believed to regulate kinase activity for the src family protein tyrosine kinases is illustrated in Figure 10-2 .

Subsequent to the initial wave of protein tyrosine kinase activation mediated by the BCR-associated kinases discussed previously, there follows a second wave of protein tyrosine kinase activity. Two of the kinases thought to play unique and critical roles in B-cell activation are Brutons tyrosine kinase (Btk) and Syk. As the name implies, Btk activity is associated with Brutons immunodeficiency. Accordingly, mutations in the Btk kinase have been shown to be responsible for X-chromosomelinked B-cell immune defects in both mouse and man.[20] [21] [22]

The Syk kinase bears homology to the ZAP-70 (*z*eta-*a*ssociated *p*rotein with an Mr of *70*,000) tyrosine kinase found associated with the chain of the TCR complex [12] (see later). Both ZAP-70 and Syk contain tandem SH2 domains at the N-terminal end of the protein, and contain a kinase domain in the C-terminal region. [23] [24] Syk kinase is also activated and

Figure 10-1 Composition of the B-lymphocyte antigen receptor complex (BCR) on resting B cells. Shown are heterodimers of Ig and Ig in noncovalent association with the membrane form of IgM. Also illustrated are BCR-associated src family tyrosine kinases because they are believed to associate with the complex in the resting state. These kinases are tethered to the cytoplasmic side of the plasma membrane by a short myristylated sequence and in noncovalent association with Ig and Ig by the N-terminal portion of the kinase. The specific association of each kinase with either Ig or Ig is not known and is illustrated here only for convenience.

Figure 10-2 Regulation of the activity of the src family protein tyrosine kinases. Illustrated is the model accounting for decreased activity as a consequence of Csk-mediated phosphorylation of the C-terminal tyrosine, which then interacts with the SH2 domain (shaded) of the kinase, resulting in an inaccessible kinase domain (cross-hatched). Cross-linking of the B-cell or T-cell receptor is believed to cluster CD45 and the receptor-associated src family tyrosine kinases. CD45-associated phosphatase-catalyzed dephosphorylation of the C-terminal tyrosine results in an open configuration in which the kinase domain-associated tyrosine is phosphorylated by adjacent tyrosine kinase molecules. This phosphorylated tyrosine serves as a docking site to position substrate proteins near the catalytic domain of the kinase. P, phosphate group; Y, tyrosine.

tyrosine phosphorylated on BCR cross-linking, although with slower kinetics than the src family kinases and Btk. [25]

Although not considered a principal component of the signaling machinery leading to B-cell activation, another kinase expressed by B cells is the Csk tyrosine kinase. This kinase is structurally related to the src family kinases, containing single SH2 and SH3 domains near the N-terminal of the molecule. Csk is functionally unique, however, in its substrate specificity. The main function of Csk kinase is to phosphorylate src family kinases, at their C-terminal negative regulatory site. [26] As such, the principal function of Csk is to maintain the BCR in the inactive state in the absence of antigen and possibly to modulate signaling once antigen is no longer present.

B-Lymphocyte Intracellular Signaling

The previous discussion has centered on the initiation and transmembrane transduction of BCR signals. Now we focus on how these signals are amplified, propagated, and translated by the B cell into appropriate responses. Many of the issues are common to T cells as well. The linkage of antigen receptor-initiated signals to changes in gene expression necessary to alter the activation state and effector capabilities of the lymphocyte occurs through the generation of cytoplasmic second messengers. These second messenger molecules are produced as a consequence of initiation of second messenger pathways. For all defined second messenger pathways linked to the BCRs and TCRs, there is a requirement for tyrosine kinase activation as an initiating event. Interestingly, as will become evident, the initial and secondary waves of tyrosine kinase activity are followed by activation of either serine/threonine-directed protein kinases or phosphatases. The activity of these proteins appears generally directed at the activation of transcription factors that

preexist in the resting lymphocyte but in an inactive state (reviewed in Birkeland and Monroe [27]).

Thus far, three major second messenger pathways have been implicated in BCR-mediated signaling. These include the inositol phospholipid (PI) hydrolysis pathway, which is initiated by the activation of phospholipase C (PLC). In B cells, PLC is a substrate for the Syk protein tyrosine kinase. [28] Syk-mediated phosphorylation of PLC is necessary for initiation of this signaling pathway. The preferred substrate of PLC is a relatively rare plasma membrane phospholipid, phosphatidyl 4,5-bisphosphate (PIP2). PLC-mediated cleavage of PIP2 generates diacylglycerol and inositol 1,4,5-trisphosphate, which trigger two second messenger molecules, a serine/threonine protein kinase called protein kinase C (PKC) and cytoplasmic free Ca^{2+} . The rise in intracellular free Ca^{2+} probably triggers a number of changes in lymphocyte physiology; however, minimally it results in the activation of calcineurin. Calcineurin is a cytoplasmic serine/threonine phosphatase whose activity is required for the activation response of B and T lymphocytes through its ability to activate the transcription factor NFAT. [29] The immunosuppressive effects of cyclosporine A and FK506 are due to the ability of these molecules to inhibit calcineurin. The precise role of PKC in B-cell activation is not known, although there is some evidence that its activation may be required for BCR-induced proliferation [30] and responses to thymus-independent antigens. [31]

A second pathway linked to BCR signaling is the phosphatidyl inositol-3-kinase (PI3-K) pathway. This pathway is initiated by kinase-mediated tyrosine phosphorylation of the regulatory subunit of PI3-K. [32] [33] Activated PI3-K in turn catalyzes the phosphorylation of inositol phospholipids, in one case converting PIP2 to PIP3. Although activation of PI3-K has been shown to be important in growth factor-mediated signaling, its role in B-lymphocyte signaling is not completely clear, although it is known to be activated by BCR-mediated signaling. [34] [35] One recently described consequence of PI3-K activity is the ability of the PIP3 product to activate a unique isoform of protein kinase C, PKC .[36] PI3-K may also be important for the activation of another kinase, S6K, which has been shown to be important for the progression of stimulated cells through the cell cycle. [37] [38] [39] PI3-K in this case exhibits a different enzymatic activity and is able to trigger serine and threonine phosphorylation of S6K.[40] The role of PKC and S6K in BCR signaling is still unclear.

Another network of regulatory proteins activated by BCR signaling are the proteins of the *ras* pathway.[41] [42] This signaling pathway represents the third pathway demonstrated to be involved in BCR signal transduction. In its active state, $p21^{ras}$ binds the guanine nucleotide guanosine triphosphate (GTP), and can activate raf-1, a serine/threonine kinase. Activated raf-1 is able to phosphorylate and activate MAP kinase/ERK kinase (MEK), a tyrosine and serine/threonine protein kinase that can then activate mitogen activated protein kinase (MAPK). MAPKs can in turn phosphorylate and activate transcription factors, thereby causing their localization to the nucleus, ultimately leading to specific gene activation. The activity of *ras* is controlled by a number of modulator proteins, which can either negatively regulate *ras* by promoting GTP hydrolysis to guanosine diphosphate (GDP), or positively regulate *ras* by promoting the exchange of bound GDP for GTP, thereby activating *ras*. Proteins that promote *ras* activity (guanine nucleotide exchange factors, or GNEF) include Vav and SOS. Localization of these components of the *ras* pathway is achieved by a number of SH2 and SH3 domain-containing proteins. [43] One such protein, Grb-2, binds to SOS via its SH3 domain. [44] Grb-2 itself consists of two SH3 domains that flank a single SH2 domain. It has been shown in other systems that the Grb-2 SH2 domain binds phosphorylated tyrosines of activated receptors. [45] The Grb-2 SH2 domain can also bind to phosphorylated Shc, a protein that is phosphorylated after antigen receptor cross-linking in B cells. [42] [46] [47] Nagai et al.[46] showed that both src family kinases and the Syk kinase were important for Shc phosphorylation. The Vav protein is expressed only in cells of hematopoietic origin. Vav is phosphorylated on tyrosines, [48] and a GNEF activity is stimulated[49] on BCR cross-linking. Deficiencies of Vav in B cells are associated with reduction in the number of peripheral B cells and inability to proliferate in response to BCR signaling. [50] [51]

BCR Co-receptor Molecules

Although the BCR is capable of initiating those signaling pathways described previously, its ability to do so is influenced by the selective recruitment of co-receptor molecules by antigen. One of these co-receptors is the CD19 complex. CD19 is a protein expressed on all cells of the B-cell lineage. CD19 is a B-cellspecific, single

transmembrane cell surface glycoprotein. The protein has a large (238242-amino-acid) intracellular domain, which contains 9 tyrosine residues. On mature-stage B cells, co-ligation of CD19 with the BCR dramatically shifts the dose response of B cells to antigen, enhancing the signaling generated through the BCR when CD19 is co-ligated.[52] [53] The cytoplasmic tail of CD19 interacts with the PI3-K p85 regulatory subunit and the Fyn tyrosine kinase. [54] Other studies have suggested that the CD19 cytoplasmic domain can bind to the Lyn tyrosine kinase. [55] These interactions suggest that the CD19 cytoplasmic domain will be important for signaling. In this regard, its nine cytoplasmic region tyrosines are rapidly phosphorylated after BCR cross-linking. [54]

On mature B cells, CD19 exists on the surface of the cell as a ternary complex consisting of the complement receptor CD21 as well as Leu-13 and target of an antiproliferative antibody (TAPA-1) (CD81). [56] [57] [58] [59] To this complex each protein seems to bring a unique function: CD19, with its extensive intracellular domain, is a substrate for tyrosine kinases and can associate with a variety of intracellular proteins to facilitate transmembrane signal transduction. CD21 is able to link this complex with the BCR because it can bind antigens that are associated with components of the complement cascade. In so doing, CD21 drags CD19 and its cytoplasmic associated signaling molecules into the BCR complex. Thus, this co-receptor functions to enhance the signal generated through the BCR when antigencomplement complexes are bound by the B cell. The roles of TAPA-1 (CD81) and Leu-13 are less clear. Both of these proteins have been shown to mediate homotypic cell adhesion, so it may be that their role is to facilitate cellcell interaction during the immune response. Figure 10-3 is a diagram of the BCR/CD19/CD21 co-receptor interaction, illustrating its enhanced signaling capabilities when co-ligated by an antigencomplement bridge.

Another molecule that exhibits activities consistent with a BCR co-receptor is CD45. CD45 is an abundant, highly glycosylated, leukocyte-specific cell surface protein. It is estimated to comprise 10% of the total cell surface glycoprotein. [60] [61] CD45 proteins appear in various sizes on different lymphocyte cell types, and on the same cell type during development and differentiation. This variation in the size of CD45 is achieved by alternate splicing of three or four exons that encode the N-terminal of the protein. Differential exon usage is found on different lymphocyte types, but the highest-molecularweight isoform of the molecule, containing all of the alternately spliced exons, is found on the B-cell surface. The cytoplasmic domain of the CD45 protein contains an active phosphatase domain that appears to play an important function in BCR signaling. B-cell lines lacking CD45 show defects in early BCR-mediated signal transduction. [62]

B cells from mice lacking CD45 cannot proliferate in response to BCR cross-linking, although they are able to proliferate in response to the mitogen lipopolysaccharide (LPS).[63] Further characterization of the phenotype and responses of B cells from CD45-deficient mice showed that these cells had severe

Figure 10-3 Model for antigen-complement C3b,d-mediated co-aggregation of the B-cell receptor (BCR) and the CD19CD21 co-receptor complex. Co-clustering mediated by simultaneous binding of BCR and CD21 serves to recruit the CD19-associated signaling proteins to the BCR signaling complex. As discussed, this is believed to enhance the signal that is generated by BCR aggregation.

functional defects.[64] The population of high-density, IgM^{low} IgD^{high} B cells was greatly diminished in the knockout mice. The cells from these CD45-deficient mice were also defective in their ability to flux calcium from the extracellular space, although they could release calcium from intracellular stores in response to BCR cross-linking.

It can be concluded from these studies that CD45 expression is necessary for optimal antigen receptor signaling. Whether CD45 is a part of the actual signaling complex and therefore functions as a legitimate co-receptor is still unclear. Because of the abundance of this protein, it might be expected that its associated phosphatase activity would be in close physical proximity to any cell surface protein in need of dephosphorylation, obviating a need for co-ligation with the BCR for effects on BCR signaling. One argument for proximity being sufficient for CD45 action is that CD45-deficient cells were shown to have antigen receptor signaling restored when the cells were transfected with only the cytoplasmic domain of CD45. [65] [66]

Another B-cell surface molecule, CD22, may also play a co-receptor role in early BCR signal transduction. It has been observed that CD22 can be co-immunoprecipitated with sIg from B-cell lysates made in mild detergent, and it has also been shown that cross-linking the BCR with anti-Ig leads to phosphorylation of the CD22 cytoplasmic domain.[67] [68] [69] CD22 is a single transmembrane-spanning glycoprotein that contains seven immunoglobulin superfamily domains in its extracellular region.[70] A ligand for CD22 has not been definitively identified, although the CD22 extracellular domain is able to bind sialic acid residues on a variety of proteins.[71] The intracellular domain of CD22 contains six tyrosine residues, which can be substrates for tyrosine kinases. These two observations led to the inclusion of CD22 into some models of the BCR complex. It seems more likely, given that not all sIg has CD22 associated with it,[67] that CD22 can instead transiently associate with the BCR during an immune reaction, and can use its phosphorylated tail to bring phosphotyrosine binding proteins into the antigenreceptor complex, where they can then modify other receptor components. In this regard, it has been shown that the CD22 cytoplasmic domain is able to associate with a tyrosine-specific phosphatase, protein tyrosine phosphatase 1C SH2-containing tyrosine phosphatase (PTP1C[SHP-1]). [72] [73] PTP1C(SHP-1) is found physically associated with the BCR in resting B cells, where it probably functions to dephosphorylate tyrosine residues within the ITAM motifs of Ig and Ig. One paradigm explaining CD22 enhancement of BCR signaling is that in secondary lymphoid organs, sequestration of CD22 is accomplished by B-cell association with sialic acid-modified proteins on the surface of T cells or stroma. In antigen-stimulated B cells where CD22 is tyrosine phosphorylated, its putative co-receptor function would be to sequester PTP1C(SHP-1) away from the BCR, thereby enhancing the tyrosine phosphorylation of the Ig/Ig ITAMs. This process is diagrammed in Figure 10-4 .

Negative Modulators of BCR Signal Transduction

B-cell receptormediated signaling is also subject to negative modulation by potential co-receptor proteins. It was observed

Figure 10-4 One hypothetical model to account for the ability of CD22 clustering to enhance B-cell receptor (BCR) signal transduction. In the resting B cell, the cytoplasmic phosphatase SHP-1 is in proximity to the complex, where it functions to maintain dephosphorylation of the Ig- and Ig-associated immunoreceptor tyrosine-based activation motifs (ITAMs), thereby decreasing the ability of the receptor to generate signals. Simple cross-linking of the BCR by antigen activates src family kinases, leading to ITAM phosphorylation as well as tyrosine phosphorylation of the cytoplasmic domain of CD22. Phosphorylated CD22 recruits SHP-1. However, in this instance it is still in the vicinity of the BCR, so SHP-1 can still down-modulate BCR signal transduction through ITAM dephosphorylation. In contrast, in environments where T cells or stromal cells expressing sialylated proteins are present, CD22 and its associated SHP-1 is sequestered away from the BCR. As a consequence, antigen-induced signals through the BCR would be expected to be stronger when antigen is encountered in appropriate anatomic niches or in the presence of T-helper cells.

many years ago that treatment of B cells with anti-Ig antibodies that lack the crystalline fragment (Fc) portion of the molecule led to B-cell proliferation whereas anti-Ig antibodies with the Fc region intact did not. [74] Furthermore, intact anti-Ig antibodies fail to trigger the signaling pathways leading to PI hydrolysis that is observed when BCR is cross-linked with F(ab)2 anti-Ig that does not contain the Fc portion. [75] This effect was presumed to be due to the cocross-linking of the sIg receptor complex with Fc receptors (FcR) on B cells. This would provide a mechanism for down-modulating a B-cell response late in an immune reaction, if B cells encounter an antigen that has been coated with secreted antibody. As illustrated in Figure 10-5 , simultaneous stimulation of FcRs and the BCR would send a signal to the B cell to shut down production of specific antibody.

The FcR expressed by B cells is the FcRIIB1. The cytoplasmic domain sequences important for FcR negative signaling in B cells have been defined, and a 13amino-acid motif has been identified that is both necessary and sufficient for FcR-mediated inhibition of the intact anti-Ig response. A single tyrosine residue contained in this motif was shown to be critical for inhibition of BCR-induced Ca^{2+} flux. [76] The proteins that interact with this 13amino-acid motif were subsequently defined and the motif referred to as the ITIM, for *i*mmunoreceptor *t*yrosine-based *i*nhibition *m*otif.[77] This sequence has been established only in FcRII receptors thus far, although other molecules such as CD22 may have similar motifs. However, in these cases the function of these putative ITIMs has not been established. The FcR ITIM motif is responsible for the interaction of this protein with the SHP-1 and SHIP-1 cytoplasmic phosphatases. The tyrosine residue contained within the putative ITIM motif is inducibly phosphorylated, and can thereby interact with these phosphatases through the tandem SH2 domains of the latter. Recruitment of these enzymes into the BCR complex presumably allows dephosphorylation of key tyrosine residues present in the cytoplasmic domains of Ig and Ig, or in other signaling molecules that interact with them, and thus can inhibit antigen receptor signaling.

These examples of co-receptors, all of which are able to modulate signaling through the antigen receptor, indicate that BCR-mediated signaling is a tightly regulated process. More interestingly, it again points out similarities to antigen receptor signaling in T cells, in which the participation of co-receptors (e.g., CD4, CD8, CD2) for

optimal responses is well established. Definition of the roles of these co-receptors suggests that optimal BCR signaling is not mediated by cross-linking sIg molecules

Figure 10-5 Model illustrating modulation of B-cell receptor (BCR) signal transduction by Fc RII B1. Antigen (black)antibody complexes co-cluster the BCR and the FcR. The latter positions the cytoplasmic phosphatases SHP-1 and SHIP-1 in proximity of the Ig and Ig ITAMs thereby dephosphorylating them (note faded P) and down-regulating their ability to recruit SH2-containing signal transduction proteins.

alone, but can involve an accumulation of signaling receptors into a large complex, each element of which brings along associated proteins. When the minimum threshold for a response is reached, by accumulation of a critical concentration of enzymes and modulators at the cytoplasmic face in association with the BCR and its co-receptors, B-cell activation can ensue. However, when sIg is extensively cross-linked (i.e., by anti-Ig antibody, or by multivalent antigens), a requirement for co-receptor engagement may not be evident. Although ligands for some of the putative co-receptors are known (i.e., complement components and the Fc portion of Ig), specific ligands for others, such as CD22, CD45, or CD19, remain to be defined. Definition of ligands for these proteins will clarify the roles that they play, and the circumstances that require their presence in BCR-mediated signaling.

Secondary, Co-stimulatory Signals for B-Lymphocyte Activation

The preceding discussion focused on the process by which antigen initiates activation signals in mature, immunocompetent B cells. However, by themselves these signals are usually insufficient to cause clonal expansion and antibody secretion. For these processes, secondary signals provided by CD4+ antigen-specific T cells are necessary. In this way, a B-cell immune response requires the integration of T- as well as B-cell activation.

Secondary signals for B-cell activation come in two forms: (1) those requiring direct physical contact between B and T cells, and (2) those mediated by soluble cytokines secreted by antigen-activated T cells. CD40 on the surface of resting and stimulated B cells is the primary receptor for cell contact-mediated secondary signals. CD40 is a 48-kd transmembrane protein belonging to the tumor necrosis factor receptor family. [78] Gp39 (CD40 ligand) on the surface of antigen-activated CD4+ T cells binds to CD40 and generates signals that promote B-cell survival and maintain or facilitate B-cell proliferative responses. [78] [79] Agents that block gp39CD40 interactions greatly impair the ability of activated T cells to interact with and drive B-cell proliferation. In humans, lack of gp39 is the molecular defect causing X-linked hyper-IgM syndrome. These patients can make IgM responses to T-cellindependent antigens, but fail to generate any B-cell responses to T-celldependent protein antigens. Even to T-cellindependent antigens, switching to other Ig isotypes is absent. [80] [81] [82] [83] Thus, although BCR signals may initiate B-cell activation, co-stimulation through CD40 is necessary for effector-level B-cell responses.

It is generally held that BCR signaling in the absence of T-cellmediated co-stimulatory signals results in an abortive activation response that is followed by B-cell death and elimination from the immune cell repertoire. [6] [84] This may then provide a mechanism for deletion of self-reactive mature B cells because they would be expected to encounter antigen but the necessary co-stimulatory signals by antigen-specific T cells would be absent.

Resting B cells express CD40, and there is evidence that CD40 signals together with cytokine signaling can activate the B cell in the absence of BCR signaling. This might be expected to be problematic in an immune response because it would allow activation of B cells with antibody specificities irrelevant to the pathogen or, worse, autoreactive. However, in vivo it is likely that CD40 stimulation does not occur without prior BCR engagement on resting B cells. The ability of the B cell to interact productively with the T cell (see next section) depends on molecules such as class II and B7, each of which is up-regulated on BCR-stimulated B cells.

In addition to CD40gp39 interactions, other surface ligandreceptor pairs mediate physical interactions between the B and T cell. These are diagrammed in Figure 10-6 . Some of these, as

Figure 10-6 Receptorligand pairs contributing to association-dependent secondary signals for B- and T-cell activation. These interactions illustrate the tremendous level of communication between the B and T cells during a lymphocyte-mediated immune response. Expression of some of these proteins is enhanced or their signaling capabilities activated as the B- and T-cell activation response proceeds. In this way, there is continued reinforcement and checkpoints to ensure that the immune response continues to be appropriate.

has been and will be discussed later, function as signaling molecules; others, such as intercellular adhesion molecule-1 and lymphocyte function associated-1, are adhesion molecules that increase the strength of the B-cellT-cell interaction. Even these adhesion molecules may possess some signaling capabilities as well.

Besides co-stimulatory signals generated through direct B-cellT-cell contact, various T-cellderived cytokines facilitate and regulate the activation response of the B cell after BCR initiation of the activation response. Although their precise role in B-cell activation responses and effector function have not been as well defined as for CD40, they clearly play a role in response of B cells in certain instances. [86] For example, IL-4 facilitates isotype switching to IgG1 and IgE, whereas transforming growth factor- results in switching to IgA. In addition, IL-4 can augment the early stages of BCR-induced activation, whereas IL-5 has been suggested to play a role in maintaining clonal expansion. Because they do not require cellcell contact for their function, cytokine-mediated effects on B-cell activation are likely limited to previously antigenand CD40-activated clones. In this manner, they probably function to enhance and modify the response to specific pathogens.

T LYMPHOCYTES

As mentioned previously, T cells are responsible for mediating the cellular arm of the immune response. Effector T cells are basically of two types, helper T cells (Th), which produce cytokines important for the regulation of both cellular and humoral responses, and cytotoxic T cells (CTL), which serve to eliminate virally infected, and in some cases, transformed cells. As with B cells, T lymphocytes recognize specific antigen by virtue of a structurally unique cell surface antigen receptor (TCR). However, unlike B cells which have evolved to protect us from extracellular pathogens and which are capable of recognizing foreign antigens in their native conformation, T cells have evolved to protect us from intracellular pathogens and typically recognize a peptide determinant (epitope) bound to a molecule encoded in the MHC, and presented on the surface of an antigen-presenting cell such as a dendritic cell or B cell. Although there are certainly exceptions, most Th cells express the CD4 co-receptor and recognize antigenic peptide displayed on MHC class II molecules, whereas CTLs express the CD8 co-receptor and recognize peptide bound to MHC class I molecules.

T-Lymphocyte Antigen Receptor

The TCR is a multisubunit complex composed of at least eight chains. The antigen-specific, ligand-binding capacity is provided by only two chains, the TCR and chain on most T cells and the TCR and chains on the remaining cells (the so-called / T cells). The ligand-binding TCR chains are members of the immunoglobulin gene superfamily,[86] and are therefore related to a large number of proteins of immunologic interest, including immunoglobulin, CD4, CD8, and MHC class I and class II molecules. The extracellular portion of each ligand-binding chain contains the NH_2 -terminal polymorphic region involved in antigen recognition. [87] Analysis of the TCR crystal structure shows considerable similarity to that of the immunoglobulin antigen-combining site in this region. [88] The heterodimeric, ligand-binding subunits are identical for each TCR on a given T cell and its progeny (a T-cell clone), but each independent T-cell clone expresses a unique TCR with a distinct primary amino acid sequence (clonal variation).

As with B cells, the ligand-binding chains of the TCR are assembled from individual gene segments, variable (V), diversity (D), joining (J), and constant (C). Clonally diverse TCRs are generated following unique patterns of rearrangement of distinct members of these gene families in individual maturing T cells, with each ligand-binding chain containing just one representative family member from each gene segment (V, J, and C for TCR- and - and V, D, J, and C for TCR- and -). Thus, the germline diversity contributed by the unique nucleotide sequence of multiple, germline-encoded V, D, and J family members, coupled with the combinatorial diversity achieved during independent, random rearrangement of V, D, and J segments, provides the ability to generate an enormous number of genes that encode proteins with different primary amino acid sequences. Additionally, junctional diversity provided by nucleotides that are not present in the original DNA gene sequence (so-called N-regions) can occur in all four of the polymorphic TCR chains, [89] further adding to the diversity of antigen recognition elements that can be generated. Finally, because both chains of the TCR ligand-binding complex contribute to antigen specificity, diversity is increased by the heterodimeric structure of the TCR ligand-binding chains. In contrast to the BCR, TCR ligand-binding chains are not thought to undergo somatic hypermutation in peripheral lymphoid organs, except in rare cases.[90]

As with the BCR, the COOH-terminal intracytoplasmic portions of the polymorphic chains are quite small, ranging from 5 to 11 amino acids, a strong indication that they have no intrinsic signaling capacity. [91] [92] The remaining polypeptides in the TCR complex are nonpolymorphic (invariant in their sequence) and appear to be critical for the proper assembly and cell surface expression of the TCR as well as for the transduction of activation signals (see later). The nonpolymorphic components include three 2026-kd structurally related polypeptides, CD3-, -, and -epsilon [93] [94] (not to be confused with the polymorphic, ligand-binding chains TCR- and -), the structurally distinct chain, [95] and, in the mouse, . However, the functional significance of the murine subunit is in question because of the lack of an obvious human analog, the poor conservation across species, and a failure to demonstrate a unique function for . [95] [96] Finally, stoichiometric analyses reveal that the TCR complex is actually an octamer composed of four dimers, a disulfide-bonded ligand-binding heterodimer (TCR- or -), noncovalently coupled CD3-epsilon and CD3-epsilon heterodimers, and a disulfide-linked homodimer (Fig. 10-7).

TCR Signal Transduction

T-cell receptormediated cellular activation is initiated after interaction with membrane-bound ligand. Interaction with antigenic

Figure 10-7 Composition of the T-lymphocyte antigen receptor (TCR) complex. Shown are the nonpolymorphic members (CD3-, -, -epsilon, and chains) in association with the ligand-binding polymorphic TCR- and - chains. Also illustrated are the immunoreceptor tyrosine-based activation motifs (ITAMs; unfilled ovals in the cytoplasmic domains of the CD3 complex and the chain) that are tyrosine phosphorylated upon receptor cross-linking and are responsible for the recruitment of other signaling molecules to the TCR complex.

peptides on the surface of antigen-presenting cells results in the aggregation of TCR complexes, a process that appears to be critical for signaling through the TCR. TCR cross-linking then induces a complex series of biochemical cascades that result in T-cell activation and initiation of effector functions (e.g., cytokine production, proliferation, cytotoxicity). Recognition of several MHCpeptide complexes by multiple TCRs on a given T cell also increases the apparent strength of the interaction because the actual affinity of individual TCRs for appropriate antigenMHC complexes appear to be quite low (Kd 10^{-5} 10^{-6} LM). In addition, co-receptors such as CD4 and CD8 increase the affinity of the antigenantigen receptor interaction as well as increasing the sensitivity of the TCR by recruiting other important signaling molecules into the activation complex (see later).

Cross-linking of the TCR results in the rapid phosphorylation of many proteins on tyrosine residues as well as on serine/threonine residues. For the main part, tyrosine kinases and serine/threonine kinases are nonoverlapping subsets of protein kinases. Activation of tyrosine kinases occurs rapidly on TCR cross-linking, resulting in tyrosine phosphorylation of a subset of molecules [97] [98] as well as the other CD3 components.[99] Tyrosine phosphorylation of and the CD3 components occurs on a common motif, the ITAM, which is also present in subunits of the BCR and the Fcepsilon receptor [11] (see earlier). Each of the three CD3 components has one ITAM motif, while each monomer contains three. Although the kinase(s) responsible for phosphorylation in mature T cells has not been identified with certainty, the most likely candidates include the src-like kinases $p56^{lck}$ (Lck) and $p59^{fyn}$ (Fyn), because co-transfection studies in non-T cells demonstrate that Fyn or Lck can phosphorylate the ITAMs of ,[100] [101] and Lck appears mainly responsible for phosphorylating in thymocytes. [102] Furthermore, the localization of Lck and Fyn to the plasma membrane by a myristylation signal and the association of Lck with CD4 and CD8 (see later) and Fyn with TCR components [103] may contribute to their ability to phosphorylate in response to TCR aggregation or co-engagement of antigenMHC complexes by the TCR and the CD4 or CD8 co-receptors. The importance of both Lck and Fyn in normal T-cell activation has been revealed in Lck-deficient mice, which have very few peripheral, mature T cells, all of which are deficient in their ability to transduce TCR-induced signals, [104] and in mice deficient in both Lck and Fyn, in which mature T-cell development is totally abrogated. [105]

After phosphorylation of by src kinase family members, a member of the Syk family of tyrosine kinases, ZAP-70, associates with phospho-. This interaction is thought to be mediated by the N-terminal tandem SH2 domains in ZAP-70 interacting with the phosphotyrosines in the ITAM motif of [106] (see earlier; Fig. 10-8). During transduction of an activation signal through the TCR, binding of ZAP-70 to phospho- appears to lead to an increase in its kinase activity, resulting in an increase in intracellular phosphorylation levels. [107] However, in cases where a full activation signal is not transduced through the TCR, inactive ZAP-70 may be found bound to phospho-,[108] a phenomenon that may be related to the induction of tolerance in these cells. [109] [110]

The ITAM motifs in the invariant subunits of the TCR are thought to be critical for TCR signaling. Chimeric molecules containing intracellular ITAM motifs and the transmembrane and extracellular domains of unrelated proteins can, on cross-linking, transduce signals that mimic both early and late signal transduction events characteristic of the intact TCR. [111] As described previously, phosphorylated ITAMs of the invariant subunits of the TCR appear to act as a scaffolding for recruiting other signaling molecules by virtue of phosphotyrosineSH2 domain interactions. When compared with the other CD3 components, the prominent role of in TCR-induced signaling could be due to its higher concentration of ITAM (three ITAMs per monomer) relative to those observed in the CD3 complex (one ITAM per monomer). In support of this, chimeric molecules containing multimers of a single ITAM from the chain transduce signals more efficiently than do chimeric proteins containing a single ITAM motif. [101] However, it is also possible that the individual TCR subunits may have unique roles in signal transduction. The latter possibility is supported by the

Figure 10-8 The T-cell receptor (TCR) complex and co-receptor molecules in both resting and antigen-activated T cells. In the resting T cell, the TCR complex, the CD4 co-receptor, and CD45 are not associated in the membrane. The tyrosine kinase Lck is found associated with CD4 and low levels of the Fyn kinase are thought to associate with the TCR complex. However, neither enzyme is active because of phosphorylation at a negative regulatory site. Upon receptor ligation, CD45 and CD4 are drawn into the receptor complex. CD45 is thought to be responsible for dephosphorylating the negative regulatory tyrosines on Lck and Fyn (notice the light-colored P). Activation of Lck or Fyn is thought to lead to phosphorylation of the CD3 complex and the chain, allowing for the association of ZAP-70 by its tandem SH2 domains and its subsequent activation.

observation that stimulation of cells through or CD3-epsilon chimeras results in different patterns of tyrosine phosphorylated substrates. [112]

There have been several reported cases of inherited immunodeficiencies associated with abnormalities in the expression of invariant TCR components; [113] for a more complete description, see Chapter 42 . In these patients, mature T cells are often found in peripheral lymphoid organs, but T-cell function is impaired. A severe combined immunodeficiency syndrome that is marked by an absence of CD8+ peripheral T cells and a deficiency in TCR signal transduction in peripheral CD4+ T cells was found to be associated with mutations in ZAP-70. [114] Interestingly, although peripheral CD4+ T cells from a ZAP-70deficient patient were not able to transduce signals through the TCR, thymocytes from this patient were TCRsignal-transductioncompetent. [115] It appears that in ZAP-deficient thymocytes, but not mature T cells, Syk kinase can compensate for ZAP-70 in TCR-induced signal transduction. The maturation of CD4+, but not CD8+ T cells in these patients, suggests that the stronger association of Lck with CD4 (see later) may be required to activate Syk in the absence of ZAP-70.

Intracellular Signaling

Amplification, propagation, and translation of early TCR-induced signal transduction events in T cells utilize many of the same pathways already described for B cells (see previous discussion), including: (1) increased intracellular calcium levels and activation of PKC as a consequence of PLC activation, (2) activation of PI3-K, and (3) activation of the *ras* pathway (Fig. 10-9). As in B cells, most of the secondarily induced signaling cascades depend initially on the activation of tyrosine kinases. Increased intracellular Ca^{2+} levels and PKC activation after the tyrosine phosphorylation of PLC has been causally linked to TCR-induced cellular responses such as the transcriptional activation of the IL-2 gene. [111] [116] The molecular consequences of increased intracellular Ca^{2+} levels have been revealed using the immunosuppressive drugs cyclosporine A and FK506. Cyclosporine A and FK506 bind to distinct

Figure 10-9 Second messenger pathways activated by activation through both the T-cell receptor (TCR) and co-stimulatory molecule, CD28. Upon TCR cross-linking, tyrosine phosphorylation of the chain is thought to lead to the association of several important signaling molecules such as the tyrosine kinase, ZAP-70 (*z*eta-*a*ssociated *p*rotein with an Mr of *70*,000), and adaptor molecules such as Shc, p36, and Crk that are involved in linking tyrosine-phosphorylated receptor chains to guanine nucleotide exchange factors important for activating small guanosine triphosphates (GTPases) such as Ras, Rac1, and Rap-1. Activation of these small GTPases activates a cascade of serine/threonine kinases (the MAPK pathway) that leads to the activation of Erk-1 and Erk-2 as well as Jun N-terminal kinase (JNK), kinases that are critical for up-regulating the activity of various transcription factors such as AP-1 and NFAT. ZAP-70 activation leads to the phosphorylation and activation of phospholipase C (PLC) and the breakdown of the inositol phospholipid PIP2 into IP3 and DAG. IP3 generation leads to a release of calcium from intracellular stores, resulting in the activation of calcium-dependent enzymes such as the phosphatase calcineurin. Calcineurin dephosphorylates a subunit of the NFAT transcription factor, which promotes its translocation to the nucleus. Upon binding of its ligand, CD80 or CD86, co-stimulatory signals transduced through CD28, activate PI-3K, which serves to up-regulate JNK fully and also activate another transcription factor, NF-B. AP-1, activating protein-1; NFAT, nuclear factor of activated T cells; IP3, inositol triphosphate; DAG, diacylglycerol; NF-B, nuclear factor-B.

molecules, collectively referred to as immunophilins, which form complexes to inhibit a calcium/calmodulin-dependent serine phosphatase, calcineurin. [117] Because cyclosporine A is an effective inhibitor of IL-2 transcription, it has been inferred that at least one critical Ca^{2+} -regulated pathway in T cells involves activation of calcineurin. Subsequent experiments showed that calcineurins role in TCR-initiated signal transduction is to dephosphorylate and promote nuclear localization of a subunit of the transcription factor, NFAT, which is involved in IL-2 transcription. [118] The exact role of PKC in TCR-induced activation events is not yet clear, in part because phorbol esters, pharmacological activators of PKC, also lead to *ras* activation in T cells,[119] so that many downstream effects originally ascribed to PKC activation may actually be mediated by the *ras* pathway.

Although PI3-K is thought to be activated after TCR engagement, the stimulatory effect is actually quite weak. In T cells, PI3-K is thought to be optimally stimulated after engagement of the co-stimulatory molecule, CD28[120] (see later). It is not yet clear what role PI3-K may have during TCR-mediated signal transduction or after engagement of CD28. It is possible that PI3-K is indirectly involved in the activation of the transcription factor nuclear factor (NF)-B through the regulation of PKC-. [121] In addition, the serine/threonine kinase Akt is thought to be activated by the phosphorylated product of PI3-K, phosphatidylinositol-3,4-bisphosphate. [122] Finally, as described later, activation of PI3-K after CD28 signaling may up-regulate the activity of Jun N-terminal kinase (JNK), a stress-activated protein kinase involved in the regulation of transcription factors such as activating protein (AP)-1 and NFAT that are required for the transcriptional activation of IL-2.

As in BCR signal transduction, TCR cross-linking is also linked to the activation of the *ras* pathway,[120] resulting in the downstream activation of the MAPK pathway (see earlier). Activation of *ras* in T cells is thought to occur, at least in part, by the activation of the nucleotide exchange factor, SOS (described previously). Although somewhat controversial, it appears that SOS is linked to the TCR by the adaptor protein Grb2 interacting with other adaptor proteins, such as p36 or perhaps Shc. [123] Activation of *ras* leads to the induction of a series of serine/threonine kinases, which culminates in the activation of two MAPKs, Erk-1 and Erk-2. These kinases are critical for the phosphorylation of transcription factors that up-regulate the expression and activity of AP-1, a transcription factor complex required for IL-2 gene expression.

To make matters more complicated, in addition to *ras* gene products, there are several other small GTP-binding proteins expressed in T cells that may contribute to TCR-induced signal transduction. For instance, the adaptor Crk is linked to the nucleotide exchange factor, C3G, which serves to activate the small GTPase, Rap-1. In addition, members of the Rho family (Rac and Cdc42) of GTPases may serve to regulate the activation of JNK in T cells. [123] It is likely that all of these pathways contribute to the functional responses induced by TCR signal transduction.

CD4 and CD8 Co-receptors

The CD4 and CD8 co-receptors act to enhance TCR signal transduction by (1) increasing the affinity of the TCR complex for its MHCpeptide ligand, and (2) by recruiting signaling molecules such as Lck to the signal complex (see Fig. 10-8). CD4 and CD8 increase the affinity of the TCR for MHCantigenic peptide complexes both by physically associating with the TCR and by binding MHC molecules, ligands that are also bound by the TCR. [124] Although the expression of CD4 and CD8 was originally thought to define specific functional T-cell subsets (Th cells being CD4+ and CTLs being CD8+), it has become increasingly clear that the expression of these molecules on a particular T cell closely correlates with the type of MHC molecule that is recognized by its TCR: CD4+ T cells recognize antigen in the context of class II molecules, CD8+ T cells recognize antigen presented by class I molecules.

CD4 and CD8 are quite distinct structurally; CD4 is a single-chain, type I transmembrane glycoprotein containing four immunoglobulin-like domains, whereas CD8 is composed of two disulfide-linked type I membrane-spanning glycoproteins, each with a single immunoglobulin-like extracellular domain. [125] Despite the structural dissimilarity, CD4 and CD8 serve analogous co-receptor functions by virtue of their ability to bind MHC class II and I molecules, respectively. The extracellular portion of CD4 binds to a monomorphic element on the 2 domain of MHC class II molecules, [126] a site that is structurally analogous to the CD8 binding domain on the MHC class I 3 membrane proximal domain. [127] [128] Importantly, co-receptor binding to monomorphic regions of the MHC molecule does not sterically inhibit TCR binding to the polymorphic, peptide-binding groove. Indeed, the ability of the co-receptor and TCR to co-engage the same MHCpeptide complex has been shown to be critical for the enhancement of TCR-mediated signal transduction. [129]

CD4 and CD8 enhance the signaling efficiency of the TCR complex by drawing the src family kinase, Lck, into the TCR complex. CD4 is in general considered a stronger co-receptor because it binds more Lck than does CD8. In addition, CD4 cross-linking results in a clear increase in the enzymatic activity of Lck, whereas similar increases are not observed after CD8 cross-linking. [130] CD4 and CD8 interact with a Cys-X-X-Cys motif in the NH_2 -terminal region of Lck through a Cys-X-Cys motif found in their cytoplasmic tails. [130] During antigen recognition by the TCR, co-engagement of the TCR and co-receptor molecules helps draw the co-receptor molecules into the TCR complex, thus bringing the associated Lck into the signaling complex and enhancing tyrosine phosphorylation of intracellular substrates. Once substrates such as the CD3 components are phosphorylated, the SH2 domain of Lck may interact with the phosphorylated ITAMs, anchoring the co-receptor to the activated TCR complex and further promoting co-receptor function. [131]

CD45

As described for B cells, CD45 is a highly abundant transmembrane glycoprotein that contains an active phosphatase domain in its cytoplasmic tail. Like in B cells, expression of CD45 appears to be required for efficient TCR signaling; T-cell lines deficient in CD45 expression are impaired in TCR signal transduction. [132] In CD45-deficient mice, T-cell development is impaired such that few mature T cells are found in peripheral lymphoid organs, and those that are produced have a diminished ability to proliferate in response to TCR cross-linking. [63] As described previously, CD45 is thought to mediate some of its effects on TCR signaling by dephosphorylating the C-terminal phosphotyrosine of Lck and Fyn; when phosphorylated, this residue down-regulates the kinase activity of these src family kinases. Consistent with this hypothesis, TCR-induced stimulation of CD45-deficient T-cell lines does not result in enhanced tyrosine kinase activation [133] (although these cells exhibit constitutive hyperphosphorylation, presumably because of the absence of CD45 phosphatase activity).

Although CD45 is known to bind to CD22 on B cells, [134] the lack of an obvious ligand on other types of antigen-presenting cells that would promote aggregation into the TCR complex precludes CD45 from being considered a legitimate TCR co-receptor. However, CD45 has been shown constitutively to associate with the TCR, [135] suggesting that CD45 may have an intrinsic ability to interact with the TCR, either by a specific interaction or by mass action due to its shear abundance in the membrane. Moreover, as mentioned previously, expression of the cytoplasmic domain alone in CD45-deficient cells is sufficient

to reconstitute efficient TCR signaling, suggesting that ligand binding by CD45 is not required for augmentation of TCR signaling, [136] [137] and there is some evidence to suggest that dimerization may actually have a negative effect on CD45 function. [138]

Secondary Signals for T-Cell Activation

Co-stimulatory Signals

Although ligation of the TCR results in the induction of many signal transduction pathways, TCR signaling alone is not sufficient to drive proliferation of naive T cells (T cells that have never been exposed to antigen). For naive T cells to proliferate, they need to receive a signal through both the TCR and the co-stimulatory molecule, CD28. In fact, in the absence of co-stimulatory signals, TCR stimulation of at least some naive T cells results in long-term functional inactivation or anergy. [139] Co-stimulation through CD28 is thought to lower the threshold of activation as well as increase the longevity of the TCR-induced response by stabilizing important transcripts such as those for IL-2 and IL-4. [140] Finally, although in some cases early stages of T-cell proliferation can be induced in the absence of obvious co-stimulation, such cells eventually undergo apoptotic death. [141] The increase in apoptotic cell death in the absence of CD28 co-stimulatory signals appears to be due to the inability to up-regulate an antiapoptotic molecule, Bcl-X_L . [142]

CD28 is a member of the immunoglobulin superfamily that is constitutively expressed on the T-cell surface as either a disulfide-linked homodimer or as a monomer. [141] For CD28 to transduce a signal, it must engage a ligand (CD80 or CD86) on the surface of an antigen-presenting cell. CD80 and CD86 are also members of the immunoglobulin supergene family and, although they share relatively little homology with each other, both are capable of binding CD28. In addition, both CD80 and CD86 bind CTLA-4, a molecule that is structurally analogous to CD28, with an affinity that is even higher than their affinity for CD28. Interestingly, whereas CD28 is thought to transduce a positive signal during TCR ligation, CTLA-4 is apparently involved in negative regulation of this response [140] (see following).

Although much is known about the functional requirements for CD28 during T-cell activation, less is known about the signaling events responsible for the co-stimulatory effect. After ligation, tyrosine phosphorylation of the CD28 cytoplasmic tail allows for the association of downstream effector molecules such as Grb-2, the tyrosine kinase Itk, and perhaps most important, PI3-K. [140] Although stimulation through the TCR has been found to result in an association of PI3-K with the TCR complex, the association of PI3-K with CD28 is far greater and presumably leads to a much stronger activation signal. The importance of PI3-K activation during co-stimulation appears to be due, at least in part, to the activation of JNK through an as-yet-unidentified mechanism that may involve the small GTPase, Rac1. [143] The co-stimulatory effects of CD28 appear to be tightly linked to the activation of JNK, which leads to the phosphorylation of cJun and the activation of AP-1containing transcription factors [144] (see Fig. 10-9).

The requirement for CD28 in T-cell activation has been supported by the diminished T-cell proliferative responses and IL-2 production observed in mice deficient in CD28 expression. [145] [146] Because interruption of this pathway leads to an inhibition of T-cell activation, novel immunosuppressive agents that target this pathway have been developed in an attempt to tolerize antigen-specific T cells. For example, based on the differential affinity of CTLA-4 and CD28 for ligand binding, a soluble chimeric molecule, CTLA-4Ig, which contains the secretory domains of immunoglobulin and the extracellular domains of CTLA-4, has been successfully used specifically to compete for binding of CD80 and CD86 by CD28. Administration of soluble CTLA-4Ig leads to the prolongation of graft survival and the diminution of autoimmune disease. [141]

In contrast to the positive co-stimulatory role played by CD28, CTLA-4 appears to play an important negative immunoregulatory role. Mice deficient in CTLA-4 expression are hyperresponsive to antigenic stimulation, and the proliferation of T cells (perhaps to self-antigens) leads to massive lymphadenopathy and autoimmune disease. [147] [148] Coupled with the ability of activated, but not resting, T cells to express CTLA-4, these data suggest that CTLA-4 plays an important role in the negative regulation of immune responses, either by directly inducing apoptosis of activated T cells [149] or by competing with CD28 for its ligands and preventing the up-regulation of Bcl-X_L . [141]

Cytokines

After TCR activation, Th lymphocytes are stimulated to secrete a wide variety of cytokines, including interleukins, interferons, and chemokines. These cytokines are critical for promoting lymphocyte proliferation and effector function and may act in either an autocrine (on the same cell that secretes it) or paracrine (on other cells) fashion. For instance, the proliferation of naive T cells in response to TCR cross-linking depends on the presence of IL-2. [150] IL-4 and -10 support the expansion of a subset of Th, Th_2 , which help regulate humoral immune responses, while at the same time impeding the development of cells that mediate cellular immune

responses, Th_1 cells.[151] Conversely, interferon- and IL-12 promote the expansion of Th_1 cells at the expense of Th_2 cells.[152] By regulating the extent of lymphocyte proliferation and differentiation into specific effector populations, cytokines provide a potent, late-acting mechanism for regulating T-cell activation and modifying effector function in a manner appropriate to a particular immune system insult.

Chapter 11 - Tolerance and Autoimmunity

Mark J. Shlomchik

INTRODUCTION

The immune system must balance the capacity to respond to foreign antigens and the need not to respond to self-antigens. A complex and multilayered approach has evolved to successfully handle this problem. However, autoimmune diseases, in which this balance is upset, are remarkably common in the population. The diversity and variable severity of such diseases most likely reflects the various approaches the immune system takes to regulate antiself responses, and thereby, the various points at which this multilayered system can break down. The normal functions that may prevent autoimmune disease are collectively known as self-tolerance mechanisms.

Autoimmune diseases are relevant to hematology at several levels. Autoimmune hemolytic anemia (AIHA) and idiopathic thrombocytopenic purpura are syndromes in which spontaneous autoimmunity to formed blood components may require transfusion support that is rendered difficult due to the presence of autoantibodies. Some cases of aplastic anemia may also fall into this category. Autoantibodies to red blood cells, whether pathogenic or not, are often problematic in terms of typing and screening. Another class of diseases are those induced by transfusion, but which are nonetheless autoimmune in nature: these include post-transfusion purpura (PTP)[1] [2] [3] and possibly AIHA associated with transfused thallasemia.[4] [5] [6] Finally, graft-versus-host disease, a common complication of allogeneic stem cell transplantation, although not a classical autoimmune disease, shares many features of autoimmune syndromes.[7] [8]

An important principle in understanding the etiology of autoimmune diseases is that no special mechanisms, cells, antibody types, or reactions are specific to autoimmune diseases. Rather, the pathogenesis involves the inappropriate or dysregulated triggering of the normal mechanisms of immunity. Therefore, an understanding of autoimmune disease induction and pathogenesis requires a grounding in the basic immune cell functions and interactions, which can be found in the preceding chapters.

SELF-REACTIVE LYMPHOCYTES: ORIGIN AND CONTROL

Origins

Inevitably, autoreactive lymphocytes are generated as a consequence of the fact that immunoglobulin (Ig) and T-cell receptor (TCR) genes are encoded in pieces that rearrange in the DNA of precursor lymphocytes to ultimately form a complete gene. This process allows for many possible gene segment combinations (e.g., 4,000 different ones for the human Ig heavy chain alone), and in addition, small deletions and random additions at the sites where the pieces are joined together create additional diversity. There are two implications of this process for self-tolerance. First, it is impossible to prevent the assembly of a self-reactive receptor by filtering these out of the germline gene repertoire. Second, a developing lymphocyte cannot be considered autoreactive until the assembly process is complete and the Ig or TCR is expressed. Thus, autoreactive lymphocytes are produced every day, and it is at this key developmental stagewhen Ig or TCR is first expressed by the cellthat the immune system can first eliminate these potentially harmful cells. In particular for B cells, this occurs in the bone marrow, the primary central lymphoid organ (Fig. 11-1). The process is thus termed central tolerance.

Regulation: Central Tolerance

Clonal Deletion

The classical experiments of Pike and Nossal were the first to demonstrate that developing autoreactive B cells can be eliminated in the bone marrow. [9] [10] [11] The details of this process remained murky until the Goodnow and Nemazee groups each developed an Ig transgenic mouse system for the study of self-tolerance. [12] [13] [14] These mice have been genetically altered to carry the preformed Ig variable (V) genes that encode a specific autoantibody. Mice that have undergone this genetic transfer are termed transgenic and the gene that is transferred is termed the transgene (Fig. 11-2). The presence of this preformed transgene short circuits and prevents the normal rearrangement process at the natural Ig gene loci. Thus each B cell in the animal expresses only the transgene and has the same specificity. By choosing a target antigen that is carried by only some strains of mice (such as the polymorphic major histocompatibility complex class I genes used by Nemazee), it is possible to render the transgenic B cells autoreactive when crossed onto one strain (Fig. 11-3) but not autoreactive in a different strain. The results of such systems were dramatic. A complete loss or deletion of the B cells was demonstrated in the strain of mice that had the autoantigen, but perfectly good expression of the B cells was observed when the autoantigen was absent. This provided clear proof of B-cell clonal deletion. Further, it was shown that this deletion occurred at the immature B-cell stage, just when the cells first express their Ig receptor. [15] [16] [17] The exact fate of deleted B cells is still controversial. [15] [17] [18] [19] It has been recognized, under some circumstances, that B cells which have completed H- and L-chain rearrangement and then recognize self-antigen while still immature in the bone marrow may actually undergo a second round of V gene rearrangement. This most likely occurs at the L-chain loci, which are particularly suited to secondary V to J rearrangements. This process has been termed receptor editing. As expected, the editing process is accompanied by reexpression of the key lymphoid-specific genes that are required to catalyze the V gene rearrangements, *rag*-1 and *rag*-2. These genes had been preciously down-regulated when the cell first succeeded in making productive or expressible H- and L-chain rearrangements. Evidently, a cell has a certain period of time in which to produce a second L-chain rearrangement that will inactivate the cells self-reactivity. If this does not occur, the cell fails to mature and is eventually eliminated. The physiologic role of the editing process is still unclear, but it could represent a way to maximize the efficiency of B-cell generation while still maintaining an effective filter against strongly self-reactive B cells.

Figure 11-1 Stages at which self-tolerance can block B-cell development. Arrows indicate the normal pathway of development. X indicates where these differentiation steps can be interrupted for self-reactive B cells as a consequence of encountering self-antigen. Each X is labeled with the type of self-tolerance it represents. The clonal disability steps are somewhat more hypothetical than the earlier steps. See text for details.

Clonal Anergy

Another type of self-tolerance mechanism was also revealed by these experiments. This form, clonal anergy, involves inactivation of the self-reactive cell, but not its elimination.[10] [14] Such B cells seem to remain in the peripheral lymphoid circulation, albeit with a shorter life span than normal B cells. In addition, these cells have a lower amount of surface Ig and, moreover, seem much less capable of sensing the presence of antigen when the sIg receptor is triggered. This second form of B-cell tolerance, demonstrated dramatically through the use of Ig transgenic mice, was also anticipated in the experiments of Pike and Nossal. [10] The physiologic advantage of maintaining these anergic cells is unclear. They can be activated by strong stimulation under certain conditions; thus it has been suggested that they are maintained as a secondary repertoire to maintain greater B-cell diversity and thus better protect against a broader spectrum of pathogens. However, the presence of these cells also raises a danger that they may be activated by self-antigens as well, which could represent a source of autoantibodies. Indeed, it has been suggested that autoantibody-secreting B cells can arise by the activation of anergic B cells.

Clonal deletion and clonal anergy are often referred to as central self-tolerance because they can occur in the central lymphopoietic organs and act on immature lymphocytes that have just expressed their antigen receptors. Central tolerance is probably most important in purging or controlling very high affinity antiself lymphocytes.

Tolerance of Memory B Cells

Figure 11-1 indicates that there are yet other stages of B-cell development at which one could imagine that self-tolerance should occur. The most important of these is development of memory B cells, the long-lasting cells that harbor the ability of the immune system to respond better and faster to antigens that have already been encountered once. An important and unique process occurs during memory cell developmentthe genes that encode the antibody receptor molecule undergo a process of random mutation.[20] [21] [22] This process is thought to provide mutants with an increased affinity for the immunizing antigen, and in fact, the secondary immune response is known to be of higher affinity. However, a side effect of any random process, just as in the receptor rearrangement itself, is the potential to create novel antiself specificities. [23] [24] Thus, many have postulated that there should be a screening of cells for self-reactivity during memory B-cell development. [25] [26] [27] In fact, some evidence suggests this process exists, but it is much more elusive than clonal deletion or clonal anergy.

T Cells

In many respects, self-tolerance for T cells is similar to that for B cells; both deletion and anergy exist. [28] [29] [30] [31] [32] The principle differences reflect the basic differences in B and T development. Deletion for T cells occurs in the thymus (where TCR gene rearrangement occurs), not in the bone marrow. In addition, the

self-antigens for T cells consist of self-peptides, just as the foreign antigens for T cells are foreign peptides. Recent data have shown that T cells also undergo somatic mutation in germinal centers, but whether there is any mechanism to eliminate self-reactive T cells at this stage is unknown. [33]

Limitations of Central Tolerance

Although these mechanisms to eliminate or inactivate self-reactive B cells as they first emerge are clearly critical for the viability of an animal, they only account for part of the overall system that protects against autoimmunity. There are many reasons to believe that central tolerance cannot and should not be perfectly efficient. One is that the ability to tolerate self must

Figure 11-2 Clonal diversity in a normal versus transgenic mouse. The great diversity of B-cell specificities found in a normal mouse is indicated by the different patterns in each type of B cell. In contrast, in a transgenic mouse, each B cell expresses the same specificity because each carries the genes for a preformed heavy and light chain Ig gene (the transgenes). This is indicated by the same pattern in each B cell. The one B cell with a different pattern signifies that occasional cells will express a unique specificity even in a transgenic because the system is imperfect.

be balanced against the ability to efficiently respond to a wide variety of foreign antigens. Each cell that is eliminated in the interests of self-tolerance is one that cannot respond to a potential foreign antigen. This concept is illustrated metaphorically in Figure 11-4 . Thus one must suppose that it might be advantageous to allow some (weakly) antiself cells to escape these purging mechanisms. This is indeed the case. A second way to view this same problem is that even if it were desirable to have complete elimination of antiself lymphocytes, it would be impossible. It is unlikely that during development each cell will be exposed to a sufficient quantity of each and every self-antigen in the body to be functionally tested for self-reactivity. Furthermore, some antigens are tissue specific, such as thyroglobulin, and are unlikely to be found in the circulation at appreciable quantities.

Persistence of Self-reactive Lymphocytes

Despite central tolerance, self-reactive cells nonetheless exist in peripheral lymphoid organs of normal animals. It has been observed for some time that many immune responses are accompanied by transient antiself antibody responses. [34] [35] [36] [37] [38] For example, rheumatoid factors with specificity for self-IgG often accompany strong secondary immune responses to foreign proteins

Figure 11-3 Mating strategy to generate transgenic mice with and without a polymorphic autoantigen. Two mice are crossed, each of which is heterozygous: one for the transgene and the other for a polymorphic autoantigen (much as people can be heterozygous for blood group antigens). Shown are the possible resulting progeny of such a cross, each of which would occur at 1/4 frequency. TG indicates transgenic and Ag indicates presence of the autoantigen. The first two types of mice, one with TG and Ag and the other control with TG and not the Ag are compared in experiments to determine how autoantigen affects the development of the autoreactive B cells.

or viruses. [34] [35] [36] The simplest explanation for such phenomena is that the B cells that make these autoantibodies already exist in the peripheral lymphoid compartment, but are quiescent until they receive the proper stimulus. (How such cells get activated and why in normal animals this does not pose a threat are discussed following.)

Transgenic mouse models similar to those described above have provided the most convincing evidence of the existence of such B cells. One of particular relevance to hematology was generated by Honjo and colleagues. [39] These workers isolated the V genes that came from an actual anti-red blood cell autoantibody originally obtained from an NZB mouse with AIHA. Much like Goodnow and Nemazee, they used the transgenic approach to express the anti-red blood cell antibody in a normal nonautoimmune mouse. Although central deletion was seen in most of the transgenic mice studied, many also had some residual autoreactive B cells in spleen and lymph nodes, and some otherwise normal mice even developed frank AIHA. These results were interpreted as follows: central tolerance is not completely efficient even in a nonautoimmune mouse and some autoreactive B cells can be stimulated to cause disease. Shlomchik and colleagues, also using a transgenic approach, demonstrated that a rheumatoid factor autoantibody that was isolated from a diseased mouse was not subject to self-tolerance when expressed in a normal BALB/c mouse. [40] These B cells generally remained quiescent in a normal animal suggesting that those B cells that are not usually regulated by self-tolerance (perhaps because they recognize the self-antigen only weakly) may be the precursors of pathogenic autoantibodies in disease.

Control of Self-reactive Lymphocytes: Preventing Activation

The recognition that potentially self-reactive lymphocytes exist in the peripheral lymphoid repertoire of normal individuals, [41] despite central tolerance, raises the question of why they do not usually cause disease. One reason is the second layer of immune tolerance that prevents activation of self-reactive lymphocytes that exist in the periphery. This layer consists of several facets, which are described in the following sections.

Figure 11-4 How elimination of autoreactive cells affects the repertoire of lymphocytes capable of responding to foreign antigens. A hypothetical population of diverse B cells representing the entire repertoire available to respond to foreign antigen is depicted. The population is arrayed according to increasing self-reactivity (left panel). Tolerizing only the high affinity antiself B cells (right panel) leaves most of the potential repertoire intact. However, as the affinity cutoff for self-reactivity increases, fewer B cells will be included. It can be readily seen (bottom panel) that a low threshold for inactivation or deletion of self-reactive cells will lead to a small number of competent residual cells available for responses to foreign antigens. Thus, a stringent tolerization of low affinity antiself cells will compromise the ability to respond to nonself.

Absence of Self-antigen

The simplest explanation for why a self-specific lymphocyte is not spontaneously activated in the peripheral lymphoid compartment is the absence of self-antigen. This may be the reason why it was not eliminated in the first place. This situation has been termed clonal ignorance. It is related to the scenario described for rheumatoid factor B cells above in that the cell does not seem to care about the concentration of its autoantigen. In the case of rheumatoid factor, though, this is because the cell has relatively low affinity for self-IgG; in the case of thyroglobulin, for example, this is because the antigen concentration is vanishingly small. However, a change in antigen concentration, such as after thyroid damage from a viral infection, might then precipitate activation of these heretofore ignorant cells, leading to autoimmunity.

This antigen sequestration concept only applies to a limited set of autoantigens. A more general reason that self-specific lymphocytes remain quiescent, despite the ubiquity of self-antigens, is that T cells and B cells are dependent on each other for activation [42] [43] [44] [45] (Chap. 10). It is evident that for this to occur, B cells and T cells specific for the same self-antigen must be in the same place at the same time. If such cells are rare, then the requisite coexistence of two such cells will happen very infrequently, minimizing the chance of starting an autoimmune reaction. A second consequence of T-B interdependence is that specific inefficiencies of central tolerance in one limb can be compensated for in the other. For example, T cells are probably very efficiently purged of cells that react with thymus-specific antigens, whereas B cells are probably not. However, antithymus B-cell responses are unlikely even though many thymus-specific B cells probably circulate; the cognate T cell with specificity for the same self-antigen simply does not exist.

Co-stimulation

Even when a B cell and a T cell that do recognize the same self-antigen encounter each other, the result may still not be activation. This is because a positive response by a lymphocyte to antigen encounter also requires a second signal, aside from the stimulus of antigen recognition itself. These signals are transmitted through a series of ligand-receptor molecular pairs known as co-stimulatory molecules (Chap. 10). The most important of these are: B7.1 and B7.2 [46] [47] [48] [49] [50] [51] (expressed on B cells, macrophages, and dendritic cells) and CD28 [50] [51] (expressed on T cells). Another important pair is CD40 [52] [53] (expressed on B cells,

macrophages, and dendritic cells) and CD40 ligand [54] [55] [56] [57] [58] [59] (CD40L, expressed on T cells and missing in patients with X-linked immunodeficiency/hyper-IgM syndrome[60] [61] [62] [63]). CD40 stimulation is especially important for B cells, as it is for other antigen-presenting cells as well. Also in this category are lymphokine signals. For B cells, interleukin-4 (IL-4) signaling is important, but other cytokines such as interleukins-5, -6, and -2 (IL-5, IL-6, IL-2) also play roles in growth and differentiation. As shown in Figure 11-5 , some of these molecules are constitutively expressed, whereas others are induced in activated cells. This pattern of expression and induction leads to a cascade of events that occur during immune activation.

Figure 11-5 Timing of expression of costimulatory molecules. The schematic shows the regulated expression of the CD40-CD40L family (light red) and the B7-CD28/CTLA4 family (dark red) of molecules. From left to right is depicted increasing cellular activation as time elapses after initial encounter with antigen. The expression level of each molecule over time is indicated by a polygonal shape. The vertical width of the shape at any time reflects the degree of expression at that time. For example, CTLA4 is expressed little at the start and the expression increases continuously over time. The shapes depicting expression of molecules that are thought to deliver signals are outlined in bold, whereas those of molecules thought to receive signals are in fine line. The top three molecules are chiefly expressed on B cells and the lower three on T cells.

In general, for proper transmission of this second signal, one or the other of the lymphocytes must have been previously activated. This concept generates a paradox in that if one lymphocyte must already be activated, how is it possible to start an immune response at all? This is resolved in several ways. First, it is indeed difficult to start immune responses, and this is one of the mechanisms by which nonresponsiveness to self is maintained. However, a strong first signal to a T or B cell may be sufficient for it to induce its co-stimulatory molecules. [46] [64] Second, inflammation of any type is a powerful nonspecific inducer of these same co-stimulatory molecules.[65] [66] [67] Thus, in the presence of ongoing inflammation, such as would occur with infection or trauma, immune responses are much easier to start. Third, certain professional antigen-presenting cells, such as dendritic cells, may constitutively express these co-stimulatory molecules at moderate levels and can start the cascade, for example, by activating T cells, which is then amplified by T-B interactions. [67] In summary, there are two main functions of co-stimulatory requirements: they focus the interactions between two antigen-specific T and B cells and limit nonspecific interactions; and they restrict immune responses in the absence of inflammation. Both of these features of co-stimulation tend to prevent the activation of self-reactive lymphocytes that exist in peripheral lymphoid organs. For B cells this means that tolerance in the T-cell compartment alone will prevent many self-reactive B cells from being activated.

Even with antigen sequestration and co-stimulatory regulation, mechanisms that prevent the activation of self-reactive lymphocytes are incomplete at best. For example, it seems likely during infection or trauma that antiself responses could initiate because co-stimulatory molecules will be nonspecifically induced. Indeed, this is the case. Further, during infection and tissue damage, self-proteins that ordinarily are sequestered can be released. This leads to activation of the ignorant cells circulating in the body. [68] [69] [70] [71] [72] [73] In fact, (usually) self-limited autoimmune responses after infection are well known, such as poststreptococcal glomerulonephritis or postmycoplasmal cold agglutinins. Although these syndromes can cause serious clinical problems, they are self-limited, unlike autoimmune diseases such as systemic lupus erythematosus (SLE).

Control of Self-reactive Lymphocytes: Down-regulation

The difference between transient autoimmune responses and chronic severe autoimmunity may lie in the third layer of protection against autoimmunity: down-regulation of ongoing responses. Again, this layer is a normal part of the immune system, functioning to regulate both normal and autoimmune responses. Initially, in a normal response to a viral pathogen, there is great proliferation of lymphocytes specific for viral antigens. This process leads ultimately to the elimination of the pathogen, which was traditionally thought of as the signal to stop an immune response. However, when the pathogen is eliminated, in the absence of any other regulatory mechanism, there would be many residual cells that had been responding to the pathogen. Although a few such cells could be retained to provide immunologic memory, most of these are no longer useful in the short term. In addition to unnecessarily filling the lymphoid compartment, these cells may be a risk for causing autoimmunity. This is because of the possibility of the generation of newly autoreactive B cells by virtue of random somatic mutation. [24] B cells responding to foreign antigens begin to mutate their antibody V region genes. Mutation is a random process, and thus a mutation could occur that converts a nonautoimmune B cell into a self-reactive B cell. [24] No clear mechanism exists by which the body can discriminate and specifically eliminate these newly self-reactive mutant B cells. However, at a minimum, elimination of most of the reactive B cells regardless of specificity would mitigate this problem.

Over the last several years, several pathways for the elimination of such postexpansion cells have been elucidated. One seems to be an inborn program that causes cells to apoptose after undergoing a certain amount of proliferation. [74] [75] [76] Certain signals that probably include CD40 signaling in concert with BCR and IL-4 signaling may rescue a few of these cells from this self-destructive fate, and it is believed that these cells become long-lived memory cells. [77] [78] [79] [80] There are also active mechanisms that signal cells to apoptose. One receptor-ligand pair called Fas and FasL is central in this process. Generally, when Fas is ligated by FasL, the cell expressing Fas is triggered to die by apoptosis. [81] [82] [83] [84] Fas and FasL are not expressed at high levels on unstimulated resting lymphocytes. On activation, T cells express both Fas and FasL, whereas B cells express Fas. [84] [85] Sensitivity to the Fas signal may also be regulated in the Fas-expressing cell as well. Thus, after a certain degree of activation and proliferation, a T cell (expressing FasL) encountering an activated B cell (expressing Fas) may actually kill that B cell. There are likely other ligand pairs, particularly those in the tumor necrosis factor family that may serve similar functions, both for B and T cells.

A particularly interesting and instructive receptor ligand pair that down-regulates ongoing responses has been elucidated. The receptor, CTLA4, is expressed on activated T cells, and when ligated, causes inactivation or death of the receptive T cell; it is said to therefore transduce a negative signal. [86] [87] [88] [89] The other ligand in this pair is none other than B7, the same ligand that gives a positive signal to naive T cells by ligating CD28. The same molecule can promote activation early on in the immune response while, through a change in the receptive T cell, it can inhibit activation at a later time. This underscores the careful means by which the immune system regulates and dampens activation presumably to prevent autoimmunity.

How does regulation of ongoing immune responses prevent autoimmunity? In the first place, these normal forms of down-regulation undoubtedly prevent common transient autoimmune responses from becoming chronic. More subtlely, elimination of cells after immune responses will prevent the accumulation of a large number of self-specific memory cells. As long as such cells are rare, it is unlikely for autoreactive T cells and B cells, each specific for the same self-antigen, to wind up in the same place at the same time. Thus, down-regulation and elimination of responding cells prevents a critical mass of self-reactive cells from ever forming.

Control of Self-reactive Lymphocytes: Channeling the Type of Effector Response

A final layer of protection against self-inflicted immune damage involves channeling of responses so they are not harmful. Depending on the context, only certain effector functions will effectively eliminate certain pathogens. For example, antibodies will not be effective against intracellular pathogens. By analogy, only certain effector functions may cause autoimmune disease, depending on the circumstances. It is clear that there are two major types of T-helper cell responses, Th1 and Th2, that in turn lead to very different effector functions. [90] [91] [92] The propensity to make these various types of responses depends on a number of ill-understood factors, but these include genetics, route of antigen exposure, and dose of antigen. [93] [94] Intriguingly, in certain murine models of autoimmunity such as the NOD diabetes model, experimental manipulations that shift responses away from Th1 and toward Th2 are highly protective against disease. [95] [96] [97] This is also relevant to B-cell autoimmunity per se because, through the use of different isotypes of Ig, different effector functions can occur. The cytokines secreted by Th1 and Th2 cells have profound effects on the isotypes of Igs that are

produced during a response. Thus, not only is the T-cell component of the response channeled in this way, but the humoral response is also influenced.

BREAKDOWN OF SELF-TOLERANCE IN AUTOIMMUNE DISEASES

Presumably, for autoimmune diseases and autoantibody production to occur, one or more of the multilayered mechanisms to prevent autoimmunity must fail. Surprisingly, the precise nature of these failures is not well understood. The mechanism of failure will differ for different autoimmune diseases and perhaps even for different patients with similar syndromes. Moreover, it seems likely both from phenomenologic and genetic studies that failures at several levels are required to generate clinically significant autoimmunity. In the following section, examples of the current state of knowledge are given.

This chapter is not meant to review the nature of autoimmune diseases; however, before considering the likely points at which self-tolerance mechanisms break down it is useful to review some basic concepts about these diseases. Grossly, autoimmune diseases have often been divided into organ-specific and systemic autoimmune syndromes. This classification is useful, but as these diseases are becoming better understood, the dividing lines are blurring; pathogeneses of all these diseases are likely to have much in common. In particular, systemic autoimmune diseases are actually much more specific in their antigenic targets than is commonly realized. Table 11-1 shows the types of autoantibodies commonly found in several systemic autoimmune diseases. Certain autoantibodies are diagnostic for specific autoimmune diseases, such as anti-Sm in SLE. Thus Sm is a specific target in SLE, but other autoimmune patients, such as those with rheumatoid arthritis, do not respond to this autoantigen. In fact, only 30% of all patients with SLE make anti-Sm, meaning that the other 70% are tolerant of their own Sm, despite having a systemic autoimmune disease.[98] Another salient feature of most human autoimmune diseases is adult onset. Both the selective nature of disease and its late onset argue against gross defects in the basic central tolerance mechanisms as being the cause.

Instead, these considerations suggest that most clinical autoimmune diseases are likely to arise from defects in the later stages of self-tolerance, such as preventing the activation of autoreactive cells or down-regulating them once they are activated. Because in no case is the primary cause of an autoimmune disease known, it cannot be excluded that subtle defects in the earlier stages, including central tolerance, may also play a role. However, it does seem clear that a gross defect in central tolerance would lead to a severe syndrome of congenital autoimmunity.

Genetic and Environmental Factors

Genetic Factors

Both genetic and environmental factors play a role in the occurrence of autoimmunity in some individuals and not others. The most well-known genetic factor is the major histocompatibility complex, known as HLA in the human. Many different autoimmune diseases are more or less associated with specific genotypes at this polymorphic locus. Among these are ankylosing spondylitis (HLA-B27), insulin-dependent diabetes mellitus (HLA-DR3/4), rheumatoid arthritis (HLA-DR4), and to some degree SLE (HLA-DR2/3).[99] It should be emphasized that although individuals with these genotypes are relatively more prone, most will not develop the autoimmune disease. How certain HLA genes predispose to autoimmunity is not very clear. These genes could be involved in the efficiency or specificity of central tolerance in the thymus, but could also be involved in the activation of autoreactive T cells in the periphery.

Inheritance patterns of all systemic autoimmune diseases suggest that multiple genes, in addition to the HLA locus, contribute to susceptibility. Such genes are beginning to be identified in animal models. Recent work in murine SLE has used genomic scanning with polymerase chain reaction-based polymorphic short simple repeat sequences to identify and map genes that are associated with autoimmune phenotypes. In this type of analysis, an autoimmune strain is crossed with a non-autoimmune strain and then the progeny are back-crossed to the autoimmune strain. Genetic loci segregate in this cross, and for each individual mouse, with the help of the murine genome map, the origin of 100200 genetic locations all along the chromosomes are identified as either from the autoimmune parent or the nonautoimmune parent. Simultaneously, the autoimmune phenotype of each mouse is determined in a variety of assays, most commonly including autoantibody production and glomerulonephritis. By typing a few hundred mice in this way, correlations can be made that link certain genetic loci with certain phenotypic traits. Several genes have been mapped with this approach, and their phenotypes investigated in greater detail. [100] [101] [102] [103] Interestingly, most of them seem to have direct effects on B cell function or activity. In the next several years, some of these genes may be identified and cloned and the exact nature of the defects defined. This will in turn permit screening for defects in the homologous genes in human autoimmune disease patients.

TABLE 11-1 -- Patterns of Autoantibody Expression in Systemic Autoimmune Diseases

Autoantigen	Autoimmune Diseases (% of patients *with* autoantibody)			
	Systemic Lupus Erythematosus	Rheumatoid Arthritis	Scleroderma	Sjögren Syndrome
dsDNA	40			
ssDNA	70			
Histones	70			
Sm	30			
nRNP	30			
Ro (SS-A)	35			60
La (SS-B)	15			40
IgG (RF)	5	90		1020
Scl-70 (Topo I)			70	
Centromere			70	

Abbreviations: dsDNA, double-stranded DNA; ssDNA, single-stranded DNA; Sm, Smith ribonucleoprotein; nRNP, native ribonucleoprotein; Scl-70, scleroderma 70-kD antigen (topoisomerase I). Blank space indicates rarely or never detected.

Information derived from Tan.[98]

TABLE 11-2 -- Genes Involved in Regulation of Autoimmune Responses

Category	Types of Genes[a]	Known Examples[b]
Central and peripheral deletion and anergy	Receptor signaling, MHC genes, receptor V genes	CD45,[119] PTP-1C, [120] [121] [122] HLA (certain types),[99] CD3,[123] CD4, CD8, CD28/B7[32]
Initiation of response	Receptor signaling, co-stimulatory molecules, adhesion molecules	CD45, PTP-1C, FcRII[121]
Down-regulation of response	Apoptosis genes, interleukins, negative co-stimulatory molecules	Fas, [107] [105] TNF,[124] [125] CTLA4,[87] CD40, CD3,[126] CD28/B7[50] [127]
Channeling of response	Interleukins, interleukin receptors	IL-4, IL-10, IL-12, IFN-[96] [97]

Abbreviations: PTP-1C, phosphotyrosine phosphatase; IL, interleukin; FcRII, receptor for IgG-type II; Fas, see text; TNF, tumor necrosis factor, CTLA4, see text; IFN-, interferon gamma; MHC, major histocompatibility complex.

[a]Indicates some of the categories of genes that may be involved in regulating autoimmunity at the indicated step.
[b]Some genes in the Types of Genes category which have been shown to play a role in the process indicated in the left column. Some have also been directly shown to play a role in autoimmunity.

Although animal models suggest multigenic inheritance, there are certain instructive cases in which single gene defects play a major role. Table 11-2 is a list of categories of genes that are likely involved in genetic predisposition to autoimmune disease. Note that these include genes involved in the processes of antigen sequestration, T-B collaboration, and immune response down-regulation that were discussed above as key features of the self-tolerance mechanisms that normally prevent autoimmune disease.

The best studied example of mutations in these genes is the *lpr/lpr* mouse, a natural variant originally discovered at the Jackson Laboratories, which carries an inactivated murine Fas.[81] [104] [105] The *gld* mutation (another natural variant discovered at Jackson), which inactivates murine Fas ligand (FasL) [84] has a very similar phenotype to the *lpr.* Both of these mutations lead to an age-dependent autoimmune syndrome with auto antibody profiles that remarkably resemble human SLE. [105] These mice die prematurely of renal failure. They also have an accumulation of lymphocytes that leads to marked lymphadenopathy. [106] Presumably, this is the result of failure to eliminate postactivation T and B cells by the Fas-based mechanism. [107] [108] [109] Exactly how defects in the apoptotic Fas pathway lead to autoimmunity has yet to be elucidated. Interestingly, a rare syndrome in humans with incomplete penetrance, called autoimmune lymphoproliferation syndrome, has recently been traced to mutations in human Fas.[110] Often these patients are misdiagnosed with leukemia or lymphoma and some have even been treated for (and survived) these neoplasms. Clonality and chromosomal studies in autoimmune lymphoproliferation syndrome reveal polyclonal B and T cell proliferations with normal karyotypes, in distinction with true lymphoma or leukemia.

The phenotypes of these mutants in the Fas pathway, though more fulminant than most human autoimmune syndromes, illustrate two important points. They demonstrate the critical nature of the late down-regulatory controls in preventing autoimmune disease. They also point out pathways in which less severe mutations might be discovered that account for human disease.

Environmental Factors

Environment plays a role that is at least as important as genetics. This is illustrated by the fact that concordance rates among identical twins, even raised in the same household, are surprisingly low. Only 20% of twins of patients with rheumatoid arthritis also get rheumatoid arthritis. [99] There are many examples of environmental factors causing either chronic or transient autoimmune diseases. There are postinfectious syndromes such as postmycoplasmal cold agglutinin disease. The pattern of incidence of multiple sclerosis suggests a viral etiology, though no causative virus has ever been convincingly demonstrated. Another category of infectious associations includes postviral myocarditis, which follows certain coxsackievirus infections. [72] It is sometimes conceptually difficult to draw a line between viral damage and consequent immune system damage; however, if sensitization to self-antigens occurs as a consequence of viral infection, and these later are pathogenic targets independent of viral antigens, it seems reasonable to consider the syndrome as autoimmune.

Infections are not the only source of environmental stimuli for autoimmunity. Toxins, such as mercury, cause autoimmunity in animal models. [111] [112] Another form more familiar to those in hematology is drug-induced autoimmunity, as in AIHA. Drugs that cause lupus-like syndromes, such as procainamide, are particularly prominent examples.[113] [114] Despite these specific examples, the environmental factors that play a role in promoting common autoimmune diseases such as rheumatoid arthritis or SLE are unknown.

Immunodeficiency and Autoimmunity

Paradoxically, immunodeficiency is often accompanied by B-cell autoimmunity. A clear example that is particularly relevant to hematologic practice is advanced human immunodeficiency virus (HIV) infection. Autoantibodies, along with clinically significant idiopathic thrombocytopenic purpura and/or AIHA are not uncommon. Serum protein electrophoresis often reveals oligoclonal IgG bands. Indeed, the extent to which features of acquired immunodeficiency syndrome (AIDS) are related to B-cell autoimmunity is not completely defined. The mechanism for this paradoxical autoimmunity is not proven, but it almost certainly relates to the lack of regulation of T cells by B cells. T cells not only promote B-cell activation, but also can negatively regulate and even kill B cells. The Fas-FasL ligand pair is instrumental in this. The tumor necrosis factor-family cytokines also likely play this role, and transforming growth factor-, another T-cell-derived cytokine, may have a negative regulatory effect. Because B cells that have already been activated by T cells may not require much in the way of additional positive signals, the growth of such clones may actually be promoted by a lack of T cells that on balance would provide more negative than positive signaling. Indeed, the B-cell lymphoproliferations associated with T cell immunodeficiency, such as HIV and iatrogenic immunosuppression, may also have their route in this mechanism.

Examples in Hematology: Epitope Spreading in PTP

One potential way to break self-tolerance may be particularly relevant to syndromes found in hematology and is worthy of

elaboration. This is a form of environmental stimulation, albeit iatrogenic. In PTP, transfusion with allogeneic platelets that contain a platelet-specific antigen (such as HPA-1^a) lacking in the (HPA-1^b) recipient leads to rapid destruction of the transfused platelets and antibody formation to the foreign platelet antigen. [3] [115] However, several days later, the recipient becomes severely thrombocytopenic due to increased destruction of the recipients own platelets. Although how such destruction of self-platelets occurs secondary to destruction of allogeneic platelets may still be controversial, [3] [115] [116] the best explanation is an autoimmune response. [1] [2] [3] How does this response get stimulated? The probable pathway bears significant parallels to one demonstrated in mice several years ago by Mamula, Janeway, and colleagues.[117] [118] These workers immunized normal mice with human cytochrome c, which differed slightly from endogenous murine cytochrome c. The mice made both an antibody response and a T-cell response to the human cytochrome c; however, since the human and mouse cytochromes are so similar, the antibody response (but not the T-cell response) cross-reacted with murine cytochrome c. Presumably, this reflected activation of ignorant B cells with specificity for self-cytochrome c (and also human). However, several weeks later, if the mice were given a dose of self-cytochrome c, now both a vigorous B-cell and T-cell antiself response ensued. These authors suggested that priming with the cross-reactive antigen first induced self-reactive B cells, which in turn could then break tolerance in anergic or ignorant self-reactive T cells.

How does this relate to PTP? Figure 11-6 illustrates the authors hypothetical adaptation of this mechanism to the platelet transfusion situation. The foreign platelets actually share many common antigens with the host, as well as differ at the HPA-1^a locus. The foreign antigenic difference allows ignorant self-specific B cells (as well as HPA-1^a -specific B cells) to interact with helper T cells that are specific for the foreign HPA-1^a antigen and become activated. Moreover, these activated B cells can then present self-platelet antigens along with co-stimulatory signals to self-reactive T cells. When this happens, the immune

Figure 11-6 Epitope spreading as a possible autoimmune mechanism for PTP. Events are depicted as progressing from left to right. An HPA-1 ^{b} person is transfused with an HPA-1$^{a/b}$ platelet product. An alloantibody response ensues as an HPA-1^{a} -specific B cell recognizes the platelet, becomes activated to secrete antibody, and presents the HPA-1 ^{a} antigen to an anti-HPA-1^{a} T cell (step 1). In addition, the activated B cell may now activate a previously ignorant anti-HPA-1 ^{b} -specific T cell to initiate an autoimmune response (step 2). The activated B cell acquired the self-HPA-1 ^{b} antigen as a passenger on the HPA-1$^{a/b}$ allogeneic platelet. This autoreactive T cell can then activate an ignorant anti-HPA-1 ^{b} B cell to make an autoantibody response (step 3) in response to autologous platelets. Note that the sensitization involved in steps 1 and 2 may take place in a primary response during the first transfusion or exposure and that step 3 may take place in a clinically noticeable way only after a secondary exposure to homologous platelets. [, Ag Receptor; =, MHC Class II.

response can perpetuate even in the absence of the foreign platelets. This is exactly what is seen in PTP, where a delayed response continues to eliminate self-platelets for many days after the disappearance of the transfused platelets. Thus, a foreign platelet is analogous to foreign cytochrome c in having a few different antigens along with many shared antigens. In the same way as shown experimentally with cytochrome c, it is hypothesized that the few foreign antigens existing on the same particle (in the case of cytochrome c it is the same molecule) allow spreading of autoimmunity from a foreign antigen to self-antigens. The key events are the activation of ignorant B cells that cross-react with both self and foreign molecules, and then the activation by these B cells of T cells that are specific for self.

It is reasonable to question how such antiself responses are ever stopped once started. PTP, for example, is a self-limited syndrome. In fact, the answer is not known; however, both down-regulation of antigen as the platelet count falls to near zero as well as the natural mechanisms that cause apoptosis of responding lymphocytes probably play a role. In the absence of an autoimmune prone host who has mutations affecting the down-regulation of immune responses, these autoimmune reactions will remain transient. It is speculated that when similar events occur in people who do have genetically based problems in down-regulating such responses that a chronic autoimmune syndrome can be induced.

IMPLICATIONS AND THERAPY

The significance of this issue to hematology ranges from syndromes such as AIHA and idiopathic thrombocytopenic purpura to iatrogenically induced autoimmunity as in PTP. In the latter case, a phenomenon known as epitope spreading, which is documented in murine models, but little discussed in terms of PTP, is speculated to be a relevant pathogenetic mechanism. A basic understanding of the mechanisms of self-tolerance and their breakdown in autoimmune disease raises the possibility of many types of specific therapeutic interventions. One of the clearest would be to identify initiating factors, such as infections, and to prevent or treat them. A second approach would be to reset tolerance. Some of the previous examples, such as in PTP, illustrate how an initiating event can be amplified leading to broken tolerance. If the system can be set back to the state before that event, the disease could be cured. At present, it is unclear how to do this; however, an autologous or even allogeneic hematopoietic stem cell transplant may have the desired effect. In fact, this sort of radical therapy has been tried in selected cases of severe SLE and seems to have some efficacy. Another promising area is in channeling the immune response, particularly as the steering mechanisms are becoming better understood at the molecular level. Work in this area is currently active. A third area is to design more specific modulators of inflammation, including interfering with co-stimulatory signals. These latter approaches have seemed promising in various animal models and may be ready for clinical trials soon.

Current therapy is much more crude, and typically involves general nonspecific immunosuppression either with steroids or cytotoxic drugs. Although these therapies can be effective, they have numerous undesirable side effects, not the least of which is increased susceptibility to infection due to immunosuppression. Therapies should ultimately be directed toward either prevention or else specific down-regulation of ongoing responses. Future work in this area will include continuing to define how self-tolerance is imposed and how it is broken in disease, what the critical triggers and autoantigens are, and how to use immunomodulation to treat autoimmune diseases based on a better understanding of the pathogenesis.

Chapter 12 - Stem Cell Model of Hematopoiesis

David A. Williams

INTRODUCTION

Healthy individuals require adequate production of enormous numbers of differentiated blood cells daily. Mature blood cells are derived from undifferentiated stem and progenitor cells in a complex series of maturational and divisional steps not yet completely understood. The complexity of this system is enormous, since as many as 15×10^9 erythrocytes and 15×10^9 white blood cells are produced each hour each day during the lifetime of the individual. Additional complexities include the need for rapid responses to acute stress (blood loss or infection) and the need to maintain a pool of undifferentiated cells from which mature cells are derived. Finally, mature blood cells must function in anatomic locations widely separated from the bone marrow, where most cells arise. These general concepts are important for the understanding of blood formation. Clearly any perturbations, even small ones, in the enormous production of hematopoietic cells will cause large abnormalities in blood production. Abnormalities of this process are manifested by sometimes life-threatening diseases such as aplastic anemia, cytopenias, leukemias, and other myeloproliferative disorders.

Understanding of the complex relationships involved in blood cell production has increased through basic science research by experimental hematologists, radiobiologists, and immunologists. During hematopoietic cell production, hematopoietic stem and progenitor cells give rise to morphologically distinguishable daughter cells, called precursors. Careful staining and microscopic observation of bone marrow cells by pathologists and hematopathologists have led to a clear understanding of the maturational steps involved in precursor cell differentiation. In 1961 Till and McCullough [1] developed an in vivo colony assay that identified a murine multipotent stem cell, the colony-forming unit-spleen (CFU-S); this assay allowed initial characterization of a transplantable primitive bone marrow cell. Pluznik and Sachs[2] and Bradley and Metcalf[3] later described in vitro colony assays for hematopoietic progenitor cells, which led to new understanding of the role of growth-stimulatory proteins in hematopoietic cell survival and differentiation. The molecular cloning of a number of growth factors, including several now in clinical use, is in part due to these early accomplishments (see Chap. 51). The influence of the bone marrow environment on hematopoiesis was initially suggested by Wolf and Trentin.[4] Again, progress in our understanding of the role of environmental signals in hematopoiesis was brought about by the description by Dexter et al. [5] of an in vitro culture system that mimicked the medullary environment and allowed continued production of myeloid hematopoietic cells for months in culture flasks.

HEMATOPOIETIC CELL HIERARCHY

The experimental systems described previously, as well as many other experimental approaches and observations, have led to some general concepts concerning hematopoiesis. Blood cell formation occurs as a result of a series of maturational cell divisions. The hematopoietic system, which gives rise to all circulating blood cells, can be envisioned as a series of overlapping functional compartments (Fig. 12-1). The stem cell compartment is made up of rare primitive cells that are multipotential (maintain the capacity to give rise to all lineages of blood cells) and have a high self-renewal capacity (give rise to identical daughter stem cells). [6] A characteristic of the stem cell compartment is that most stem cells are mitotically quiescent.

A process termed commitment involves the transition from pluripotent, self-renewing cells in the stem cell compartment to the progenitor cell compartment. This process is not completely understood, but is characterized by restriction in the stem cell

Figure 12-1 Schematic view of hematopoiesis. Primitive stem cells reside in close association with cells making up the hematopoietic microenvironment, represented in vitro by CFU-F/RF. Several in vitro and in vivo assays are represented below. Since the relationship of these cells and the reconstituting hematopoietic stem cell is unclear, these compartments are shown overlapping. Primitive cells are represented as long-term and short-term repopulating cells, LTC-IC and CAFC. Cells in the progenitor compartments are defined by in vitro colony assays, such as CFU-C, CFU-Mix and HPP-CFC. Precursor cells are morphologically recognizable cells in the bone marrow environment. See text for full details.

differentiative and proliferative capacity. Progenitor cell compartments are comprised mainly of cells with the capacity to differentiate along one lineage (unipotential progenitors), with lower frequencies of bipotential and multipotential primitive cells. Therefore, commitment involves the acquisition of some specific growth factor receptors and loss of others. Progenitor cells are generally defined functionally, that is, by the capacity of the cells to form colonies in in vitro assays; they demonstrate little self-renewal capacity. Mitotically active cells are far more frequent in progenitor compartments compared with stem cell compartments.

Most cells in the bone marrow make up the precursor compartment. These cells exhibit easily recognized nuclear and cytoplasmic morphologic characteristics that can be used to classify the lineage of commitment of the precursor cell. For example, a myeloblast has distinguishing morphologic characteristics that allow classification into the lineage of cells destined to become granulocytes. Little self-renewal capacity exists in this compartment, but because of the large number of precursor cells and the high mitotic activity of these less primitive cells, considerable amplification in absolute cell numbers occurs within these compartments. Therefore, early cells have the capacity to give rise to large numbers of progeny cells through cloning during the transition from stem cell to differentiated and functional cell.

PURIFICATION AND FUNCTIONAL CHARACTERISTICS OF HEMATOPOIETIC STEM AND PROGENITOR CELLS

Stem cells have been defined functionally by the ability to reconstitute both lymphoid and myeloid hematopoiesis when transplanted into a recipient. Initial studies used radioprotection as an assay for this rare cell, [7] whereas Till and McCulloch[1] developed the first quantitative assay for stem cells based on reinfusion of cells into an irradiated recipient (Fig. 12-2). Detailed understanding of the biology of the hematopoietic stem cell has been hindered by the low frequency of this cell in the bone marrow nucleated cell population, the lack of reagents to distinguish the stem cell from other immature cell types, and the lack of practical and quantitative assays for human hematopoietic stem cells. Recent advances have been made in all of these problematic areas. Hematopoietic stem cells have been reported to be purified to a high degree using density gradient centrifugation, labeling with antibodies, lectins, or dyes, and separation using fluorescence-activated cell sorters. Additional separation methods include immunomagnetic bead selection or the use of immunopanning. [8] Immunologic characteristics of murine hematopoietic cells include lack of antigens present on more lineage-restricted progenitors (termed Lin), expression of the antigens Sca-1 (Ly6), [9] Qa-m7, [10] and Thy-1.[9] In addition, several investigators have used the intensity of staining with rhodamine 123, which is effluxed by the multidrug-resistance gene product or P-glycoprotein. [11] Similarly, putative human hematopoietic stem cells have been purified using expression of the CD34 antigen, [12] [13] lack of HLA-DR expression,[14] and lack of antigens expressed on more lineage-restricted progenitors. [15] Recent studies have provided evidence that a population of primitive CD34-negative cells exists in multiple species with culture characteristics similar to stem cells. [16] These cells, isolated by flow cytometric analysis based on staining with the DNA-binding dye Hoechst 33342, have been shown to be lineage marker-negative and capable of initiating long-term hematopoiesis in mice in vivo. A complicating feature of the analysis of human stem cells is the inability to test purified populations routinely in in vivo reconstitution assays. New approaches include the use of xenografts for reconstitution of human cell populations after transplantation. [17] [18] These models include the classical C.B-17 scid/scid severe combined immunodeficiency (SCID) mouse, [19] the beige athymic nude X-linked (bnx) immunodeficient mouse,[20] the humanized SCID (SCID-hu) mouse, in which human (fetal) hematopoietic tissues such as liver, thymus, and bone fragments, are surgically transplanted, [21] and a transgenic SCID mouse that expresses the genes for IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF) and stem cell factor (SCF). [22] Recently, a new mouse strain (NOD/TtSz-scid/scid, called NOD/SCID) was developed by crossing SCID mice with nonobese diabetic (NOD/Lt) mice.[23] In all these models, human hematopoiesis can be established, repopulating frequency can be estimated, and some degree of proliferation and differentiation takes place. For a recent review see Wermann et al. [24] Table 12-1 summarizes characteristics of murine and putative human hematopoietic stem cells. Human stem cell purification is an area of intense research and may provide new therapeutic approaches to the treatment of certain diseases, such as chronic myeloid leukemia (CML), for which

the goal of current work is to purify normal stem cells from cytogenetically abnormal CML stem cells.

Both murine and human primitive hematopoietic cells can form colonies in semisolid media and sustain hematopoiesis in specialized stromal-containing liquid cultures (Table 12-2). Several different assays have been established, but the relationship between the cells defined by these assays and a transplantable and reconstituting hematopoietic stem cell is not clear. Multipotent and unipotential progenitor cells can also be assayed by the ability to form colonies in semisolid medium in vitro (Fig. 12-3 and Plate 12-1). These colonies are stimulated by inclusion of appropriate growth regulatory proteins, termed growth factors, and are comprised of maturing granulocytes and macrophages: CFU-granulocyte/macrophage (CFU-GM), erythrocytes (burst-forming unit-erythroid [BFU-E], and CFU-erythroid [CFU-E]), megakaryocytes (BFU- and CFU-megakaryocyte [BFU-Mk and CFU-Mk]), and mixtures of all lineages (CFU-Mix or CFU-GEMM). Progenitor colonies are generally composed of 50 to 100,000 cells, most which exhibit a relatively mature phenotype. In addition, murine [5] and to a lesser extent human[25] hematopoietic stem and progenitor cells can be cultured for prolonged periods in vitro in a culture system, termed long-term marrow or Dexter culture, which allows direct contact between these hematopoietic cells and supporting cells derived from the medullary cavity. A recent modification of these long-term cultures, called the long-term culture-initiating cell (LTC-IC) assay, also allows precise measurement of the frequency of the cell responsible for sustained hematopoiesis in such cultures. [26]

Commitment

The factors that regulate hematopoietic cell proliferation and differentiation, including commitment, remain unknown. Theories of stem cell behavior include the stochastic model,[27] which considers stem cell renewal versus differentiation to be based on probability, and the hematopoietic inductive environment theory, [4] which links commitment to local environmental signals. If stem cell self-renewal capacity is unlimited and stem cells are truly immortal, they could likely function for an individual's entire lifetime. Stem cell immortality would confer stability on the clonal composition of an animal's hematopoietic system. On the other hand, stem cell self-renewal capacity could also be much more limited. Under these circumstances, only a

TABLE 12-2 -- Assays for Primitive Human Hematopoietic Cells

Xenograft models[24]

portion of the total stem cell population would be active at any given time, and new stem cells would be required to contribute to active blood cell production to replace dying cells. This constant turnover in the active stem cell populations would likely lead to changes in the clonal makeup of the different hematopoietic lineages over time. Hematopoiesis then would be maintained by a succession of short-lived clones (clonal succession model). The concept of short-lived stem cells is supported by the finding that the hematopoietic systems of irradiated, reconstituted animals undergo clonal changes with time. Equally convincing evidence, however, indicates that at least a subpopulation of stem cells are long-lived, able to function for prolonged periods, and able to expand clonally during the regeneration of a new hematopoietic system. Recent evidence suggests that stem cells derived from different stages of development function in distinct fashion, implying that factors intrinsic to the stem cell, itself, may regulate stem cell fate. In addition, these changes in stem cell function correlate with measurable changes in telomere length, suggesting that the replicative potential of some stem cells may be limited. [28] The survival and differentiation of hematopoietic stem cells can also be influenced by an ever-increasing number of glycoproteins, termed cytokines, which stimulate both cell division and survival [29] (see Chap. 14). Evidence suggests that the provision of appropriate cytokines in vitro can induce the expansion of primitive murine progenitor cells without the loss of reconstitution capacity. [30] Growth factors that appear to be important in the survival of stem cells and expansion of progenitor cells in vitro include steel factor (also called stem cell factor, kit ligand, and mast cell growth factor, and discussed later in this chapter), interleukin-1 (IL-1), [30] IL-6, and possibly IL-11,[31] granulocyte colony-stimulating factor (G-CSF), [32] leukemia inhibitory factor (LIF),[33] megakaryocyte growth and development factor (MGDF, also called thrombopoietin) [34] and FLT3 ligand.[31]

Based on in vitro data, Ogawa[35] has proposed that these factors may function by triggering cell cycle-dormant primitive cells into proliferation. Some of these factors (G-CSF, IL-3, and steel factor) may be required for the survival of primitive hematopoietic cells in G_0. Interestingly, IL-6, IL-11, and LIF appear to interact with distinct receptors, but may share common signal-transduction pathways, whereas IL-6 and G-CSF share some structural homology.

At the molecular level, little is known about the process of commitment. Although it is clear that differentiation is accompanied by increased expression of certain lineage-specific genes, the regulation of gene expression during hematopoietic cell differentiation is due to largely unknown transcriptional regulatory proteins. It has become increasingly understood that extracellular regulatory signals affect cell behavior by activation of intracellular targets, which ultimately determine lineage or cell-specific gene expression by a complex of transcriptional factors (reviewed by Shivdasani and Orkin; [36] see Chaps. 6 and 52). These regulatory proteins bind to DNA sequences that either up- or down-regulate the expression of a nearby gene. [37] The best-studied transcription regulators in hematopoietic cell differentiation are the GATA-1, PU.1, tal-1/SCL, and NFE-2. Both GATA-1 and NFE-2 proteins appear to be critical for expression of many erythroid-specific genes. DNA sequences that lie within the regulatory regions of erythroid-specific genes are recognized by these proteins. GATA-1-binding protein recognizes a specific DNA sequence [T/A(GATA)A/G] (hence the name GATA-1) that is present near the promoter, enhancer, or locus control region (LCR) of erythroid genes. [38] Protein binding to the cognate DNA stretch via domains resembling zinc fingers transactivates the neighboring promoter. [37] GATA-1 motifs appear to be required for full promoter activity of a wide variety of erythroid-specific genes, including - and -globin, erythropoietin-receptor gene, porphobilinogen deaminase, pyruvate kinase, and glycophorin. [38] Genetic disruption of

Figure 12-3 Progenitor assay. the murine GATA-1-binding protein gene is incompatible with development of erythrocytes either in vitro or in vivo. [39] Other members of the GATA family, especially GATA-2, may play an important role in hematopoietic cell differentiation. Both GATA-1 and GATA-2 are expressed not only in erythroid cells, but also in megakaryocytes and mast cell lineages.[40] [41] Several promoters of lineage-specific genes in these lineages have been demonstrated to contain GATA-1 sites.

NF-E2 binds to an activator protein-1-like site upstream of several erythroid-specific promoters and in the LCR of both - and -globin. NF-E2 has the same tissue expression profile as GATA-1. However, NF-E2 affects transcriptional activation as a heterodimer with a ubiquitous protein, p18. [41] Thus NF-E2 and GATA-1 proteins function together and largely control the tissue-specific expression of a great number of genes expressed only in red blood cells. The transcription factor PU.1 is a member of the ets family of proteins, the expression of which is restricted to hematopoietic cells. Mice deficient of PU.1 expression created by gene knock-out studies die early after birth with a deficiency of monocytes, granulocytes, and T- and B lymphocytes. [42] Tal-1/SCL is a hematopoietic basic-loop-helix factor which binds to cis elements of genes containing the sequence CANNTG (e boxes). Mice homozygous for deletion of this gene die during development from a complete absence of blood formation, even in the yolk sac.[43] [44] In addition, there are virtually no myeloid colony forming cells demonstrating that this transcription factor is essential for early hematopoietic cell proliferation or differentiation. Although multiple transcription factors affecting hematopoietic cell proliferation and differentiation have been described, it remains unclear how the interaction of growth factors with growth factor receptors and other cell-cell interactions modulate transcription factor function, and thus ultimately control blood formation under physiologic conditions or in response to commonly encountered stress situations.

C-kit Proto-oncogene and Its Ligand

Two mouse mutants have contributed significantly to our understanding of the hematopoietic stem cell biology. The murine mutants of bone marrow failure syndromes, *dominant white spotting (W)* and *steel (Sl)* have now been fully characterized at the molecular level. Because of the key role of these mutations in our understanding of the basic biology of hematopoietic stem cells, a summary of their phenotypic abnormalities and molecular biology is included here.

Phenotypically the *Sl* and the better characterized *W* mutants are black-eyed white mice with reduced fertility and macrocytic anemia[45] (Fig. 12-4). All hematopoietic lineages are affected. [45] [46] [47] The hematopoietic abnormalities associated with the *W* mutation can be corrected by bone marrow transplantation, whereas the abnormalities of *Sl* mutants are manifested in supporting cells, such as stromal cells in the bone marrow environment. In recent years, the molecular bases of both mutations have been delineated. The *W* mutations affect the c-kit proto-oncogene, a growth factor receptor and member of the tyrosine kinase receptor family, which includes the receptor or CSF-1.[48] [49] This receptor is expressed on primitive hematopoietic stem and progenitor cells. Specific c-kit mutations and the severity of the phenotypic abnormalities have been correlated with functional impairment of the c-kit-associated tyrosine kinase activity. [50] Piebald syndrome in humans appears to be associated with genetic mutations of the c-kit receptor[51] (Fig. 12-5).

The molecular and biochemical nature of *Sl* mutations has also been identified.[52] [53] [54] The gene identified in these studies encodes a protein that is the ligand for the c-kit receptor mutated in W mice. [55] [56] [57] The gene maps to chromosome 10 in mice and is deleted in alleles associated with embryonic lethal phenotypes. [56] [57] [58] The cloned Sl cDNA predicts a membrane-associated and glycosylated protein with structural homology to CSF-1. Although the physiologic role(s) of these isoforms are unknown, Kapur et al.,[59] using transgenic mice crossed into Steel mutants, have demonstrated that membrane-associated protein appears critical for erythroid cell production. Recombinant growth factor expressed from the cloned cDNA, which has been called stem cell factor, kit ligand, mast cell growth factor, and steel factor, corrects the bone marrow manifestations of the mutation when administered to mice.[56] The protein has pleiotropic effects on hematopoietic stem and progenitor cells in vitro, which has been tested in human trials in vivo. [60]

Hematopoietic Microenvironment

Hematopoiesis occurs within a complex environment in the medullary cavity of adults[61] and the fetal liver[62] and yolk sac[63] [64] of the developing fetus. Many cells making up this hematopoietic microenvironment (HM) are not derived from hematopoietic

stem cells, whereas hematopoietic cells develop in nests termed cobblestone areas (Fig. 12-6). Adventitial reticular cells reside on the adluminal surface of venous endothelial cells, which branch through the medullary cavity. [65] These cells appear to provide a reticular network that supports developing blood cells. In addition, both adventitial reticular cells and adipocytic cells play an active role in hematopoiesis by producing both soluble and membrane-associated growth factors. [66] These cells also respond to hematopoietic stress by changing volume; impaired hematopoiesis is associated with increased accumulation of fat inclusions in both cell types, and accelerated hematopoiesis is associated with loss of fat vacuoles and the provision of increased space for hematopoietic cells. [67] Adipocytes may play an additional role in blood cell production as a reservoir for lipids needed in cell metabolism during proliferation. Macrophages and osteoclasts, cells derived from hematopoietic precursor cells and osteoblasts, may also play important roles in the HM. The organization of the HM in situ is detailed in Chapter 13 .

The HM provides more than structural support for hematopoietic cells during proliferation and differentiation. Studies by Wolf and Trentin [4] show the effects of specific microenvironments on stem cell differentiation. Femoral shafts placed in the spleen pulp of mice give rise to hematopoietic colonies located at the junction of the spleen and femur tissues. Differentiation of cells derived from a single stem cell at this junction occurred in a lineage-specific manner according to the geographic distribution of the colony. Myeloid cells developed in the part of the stem cell-derived colony arising in the medullary cavity, while erythroid cells developed in the part of the colony arising in the splenic environment. These and similar observations led to the theory that the HM in which stem and progenitor cells reside influences the commitment process, termed the hematopoietic inductive microenvironment.

Dexter et al.[5] described a culture system in which the HM is replicated in tissue culture flasks. These cultures (Dexter cultures or long-term marrow cultures) allow survival and proliferation of primitive cells for extended periods in vitro. Modifications of the cultures allow support of lineages restricted to myeloid, erythroid, [68] [69] or lymphoid (termed Whitlock-Witte cultures) [70] cells. Cells produced in such cultures can be collected and used for bone marrow transplantation. There is some evidence that CML and acute myeloid leukemia (AML) stem or progenitor cells survive less well in such cultures than phenotypically normal cells. [71] [72] These observations have led to the use of long-term marrow cultures for experimental autologous transplants in CML and AML patients. Some patients treated with these protocols have re-established normal hematopoiesis, although it appears unlikely that long-term sustained remissions can be obtained using this approach.

The HM provides support for hematopoietic stem cell proliferation and differentiation both in vivo and in vitro. At least two hematopoietic growth factors have been shown to be important in vivo in the normal function of the HM. Mice deficient in steel factor (homozygous Sl/Sl mice [see discussion earlier in this chapter]) and LIF (LIF-deficient mice generated by gene targeting) [33] have hematopoietic deficiencies as a result of the lack of presentation by the HM of each protein. Sl/Sl ^{d} mice (from a viable mutant allele of Sl) have deficient CFU-S stem cells and low peripheral blood counts. [56] [73] LIF-deficient mice have normal peripheral blood counts but are deficient in CFU-S and committed progenitor cells. The bone marrow of both animals

Figure 12-6 Hematopoietic nest arising in long-term marrow (see Dexter et al. [5]) culture. Round refractile cells in the middle represent area of active hematopoiesis within the stromal hematopoietic microenvironment of the adherent layer.

is capable of reconstituting normal hematopoiesis when transferred by bone marrow transplantation into a normal HM.

Several theories concerning the physiologic roles of HM in the regulation of hematopoiesis have been proposed and are under investigation (Table 12-3). The HM provides adhesive interactions important for co-localization of stem and progenitor cells and growth regulatory proteins within the medullary cavity. Long [74] has suggested the categories of cell-cell, cell-matrix, and cell-growth factor for these interactions. Important matrix adhesive molecules include fibronectin, thrombospondin, glycosaminoglycans, and proteoglycans. Integral membrane proteins important in these interactions include haemonectin and vascular cell adhesion molecule-1. Pluripotent hematopoietic stem cells (CFU-S_{12} , reconstituting murine hematopoietic stem cells, and CD34+ human bone marrow cells) have been demonstrated to adhere to the CS-1 sequence in the alternatively spliced IIICS region of the extracellular matrix protein fibronectin. [75] [76] Other investigators have demonstrated adhesion of primitive hematopoietic cells to the matrix protein thrombospondin and the high-affinity heparin binding site in the C-terminal sequence of fibronectin.[77] [78] The receptor for the fibronectin CS-1 sequence is the integrin VLA-4, which has been shown to be expressed on primitive hematopoietic cells. The thrombospondin receptor is expressed on multilineage human progenitor cells.

Adhesion of primitive cells to the HM via lectins has also

TABLE 12-3 -- Possible Roles of Hematopoietic Microenvironment in Hematopoiesis

been demonstrated. Aizawa and Tavossoli,[79] using sugar-modified bovine serum albumin, have demonstrated inhibition of adhesion of CFU-S to stromal cells in vitro and inhibition of homing in vivo. The specificity of this interaction is via unknown core proteins, but appears to be related to galactose or mannose sugar residues (or both). CD44 expression has also been detected on early hematopoietic progenitor cells. [80]

Both myeloid and erythroid differentiation are accompanied by changes in adhesive interactions. Patel and colleagues [81] [82] have demonstrated that erythroid differentiation is accompanied by increased adhesion to the RGDS-containing central cell-binding domain of fibronectin via the VLA-5 receptor. Loss of adhesion to RGDS is temporally related to enucleation and terminal differentiation, and increased efficiency of enucleation of some erythroid cell lines has been demonstrated on fibronectin in vitro. Adhesion to the protein haemonectin by myeloid progenitor and precursor cells has been demonstrated. [83] Loss of adhesion to this protein has been postulated to be involved in maturing granulocyte egress from the marrow.

The HM may also provide binding sites for hematopoietic growth factors. Proteoglycans and glycosaminoglycans are produced by several cells in the HM. [84] Both GM-CSF and IL-3 have been shown to bind noncovalently to glycosaminoglycans in the extracellular matrix of bone marrow. [85] [86] Co-localization of hematopoietic cells with locally high concentrations of growth factors bound in this fashion may be one way in which local area networks are established throughout the medullary cavity.[87] Multiple other adhesive interactions have been studied and are important in lymphocyte homing and leukocyte trafficking in the periphery. [88] These interactions utilize receptors in the immunoglobulin superfamily, integrins, selectin/LEC-CAM, and CD44. Many hematopoietic cell/stromal cell adhesive interactions have been described with receptor/ligand pairs of unknown identity. [89]

PRECURSOR CELL DIFFERENTIATION

Most cells present in the bone marrow of a healthy individual are recognizable precursor cells of the myeloid or erythroid lineage. The ratio of myeloid/erythroid precursors (M/E) is normally

3:1, with approximately 10% of nucleated cells recognizable as lymphocytes, plasma cells, macrophages and rare morphologically indistinct blasts, progenitor cells, and stem cells. Megakaryocytes are present at a frequency of 45/1,000 nucleated bone marrow cells. Alterations in the M/E can be determined by staining bone marrow aspirates and are often useful in evaluating peripheral cytopenias. However, absolute cellularity is difficult to determine by examination of aspirate samples and is best determined by bone marrow biopsy. A relative lymphocytosis and variation in the M/E ratio are normal developmental differences seen in the bone marrow of infants and young children and make the interpretation of these bone marrow samples more difficult.

As seen on standard Wright-Giemsa staining at the light microscope level, the normal differentiation of erythrocytes occurs in well-defined stages. The first identifiable and also largest precursor of the erythroid lineage is the erythroblast (Plate 12-2). The cell diameter is 1219 m, and the nucleus is large, oval and homogeneously staining (violet) with indistinct nucleoli. The cytoplasm is darkly basophilic, with lighter staining areas (hyaloplasm) usually near the nucleus that reflect the position of the Golgi apparatus and lipid-containing mitochondria. Maturation to the basophilic normoblast is accompanied by reduction in cell size and pronounced changes in the nuclear chromatin structure (Plate 12-3). The basophilic normoblast is 1217 m in diameter, with basophilic cytoplasm, and the nuclear chromatin shows a coarsening and prominent clumping leading to descriptions of a spoked wheel or cartwheel appearance. Nucleoli are generally not seen. The polychromatic normoblast is nearly the same size as the basophilic normoblast (Plate 12-4). The accumulation of hemoglobin is now seen by the presence of less basophilic and muddy gray-colored cytoplasm. The nucleus shows further condensation and is nearly black. The last nucleated red cell precursor is the orthochromatic normoblast (Plate 12-3). The cell now approaches the diameter of a reticulocyte (812 m), and the eosinophilic staining cytoplasm contains nearly a full amount of hemoglobin. The nucleus is now fully condensed and pyknotic.

Extrusion of the nucleus results in the reticulocyte, a cell slightly larger than a fully mature erythrocyte. The reticulocyte is characterized by the presence of a fine granular or reticular network of ribosomal RNA observed with supravital stains such as cresyl violet or methylene blue. Such cells are present at low frequency in the peripheral blood of normal individuals but are increased in response to stress on the erythroid lineage, such as hemolysis or blood loss. Stress reticulocytes are prematurely released into the peripheral blood, where further maturation is completed. Characteristics of stress reticulocytes include a larger cell diameter and more basophilic cytoplasm than reticulocytes.

Additional morphologic indications of stress erythropoiesis include polychromatophilia (violet tinting seen with Wright-Giemsa staining) and basophilia (blue or black stippling diffusely distributed throughout the cell). These staining characteristics are the result of RNA remnants that stain in the cytoplasm of the erythrocyte. The premature destruction of erythroid precursors in the medullary cavity, termed ineffective erythropoiesis, is accompanied by elevation of serum lactate dehydrogenase, decreased levels of serum haptoglobin, slight elevation of the reticulocyte count (1.54%), and the occasional appearance of nucleated red blood cells in the peripheral blood. The destruction of erythrocyte precursors in the medullary cavity normally occurs in <10% of developing erythrocytes. Increased destruction of erythrocyte precursors accompanies hemoglobinopathies, iron deficiency anemia, megaloblastic anemias, and other rarer congenital anemias, such as congenital dyserythropoietic anemias.

The final stage of erythroid maturation is the erythrocyte. The cell is a biconcave, relatively flat, non-nucleated disk 78 m in diameter. Normal erythrocyte survival is 100120 days in humans.

Leukocytes that circulate in the peripheral blood are divided into those of the myeloid, monocyte/macrophage, and lymphocytic lineages. The differentiation and function of the lymphocyte lineage is discussed elsewhere (see Chaps. 7 , 8 , and 9). In myeloid and monocyte lineages, four distinct granule populations are seen that distinguish these cells morphologically during differentiation. Azurophilic granules are present in cells of both lineages, stain pink with Romanowsky dyes, and contain myeloperoxidase, acid phosphatase, basic cationic protein, and other hydrolases. Eosinophilic granules are a conspicuous reddish orange, and basophilic granules are intensely blue. Specific neutrophilic granules do not stain intensely with standard Wright-Giemsa stains.

The earliest identifiable cell of the myeloid lineage is the myeloblast (Fig. 12-7). The cell is approximately 1214 m in diameter,

Figure 12-7 Myeloblast transition to promyelocyte. Neutrophil below.

Figure 12-8 Promyelocyte in the middle. Eosinophilic myelocyte on the left.

with a round or oval nucleus and basophilic cytoplasm that lacks granules. Nuclear chromatin is fine, and one to five nucleoli are easily visible. The nucleus often stains reddish. Promyelocytes are the largest and most frequent of the primitive myeloid precursors (Fig. 12-8). Promyelocytes are variable in nuclear shape, with less prominent nucleoli, and chromatin of medium density that is coarser than that of the myeloblast. The cytoplasm is deeply basophilic and contains variable numbers of peroxidase-positive granules. These granules can overlie the nucleus and can vary in color from deep red to blue; they distinguish the promyelocyte from the myeloblast.

Myelocytes are characterized by round-to-oval nuclei with characteristic nuclear indentations, indistinct nucleoli, and unevenly stained, coarse chromatin structure (Fig. 12-9). The cytoplasm stains pale gray-brown or pink-brown, with numerous specific granules covering the nucleus and throughout the cytoplasm except in a clear area near the nuclear indentation (centrosphere), which represents the Golgi apparatus. The myelocyte is also characterized by the first appearance of specific granules and is the last cell capable of cell division during myeloid differentiation. The metamyelocyte exhibits a characteristic bean-shaped nucleus, the band neutrophil a horseshoe- or S-shaped nuclear structure without recognizable nuclear constrictions, and the segmented neutrophil is characterized by the typical

nuclear segmentations for which it is named, which divide the nucleus into two to five lobes (Fig. 12-9). These myeloid forms exhibit cytoplasmic characteristics similar to the those of the myelocyte without the centrosphere and with progressive reduction in the overall cell size. An additional nuclear lobule, termed a drumstick, is seen in 1012% of neutrophils of females.

Maturation of the eosinophil and basophil follows the same morphologic steps as the neutrophil until the appearance of

Figure 12-9 Myeloid maturation. Myelocytes, band, and segmented neutrophils.

Figure 12-10 Eosinophilic myelocyte (left) and basophil (right).

specific granules (Fig. 12-10). The eosinophil exhibits a bilobed nucleus, and the basophilic cytoplasm is filled with prominent orange-red granules (Fig. 12-11). Basophils exhibit less segmentation of the nucleus and cytoplasm that is sparsely filled with deeply staining blue-to-purple metachromatic granules (Fig. 12-10). The granules often obscure the nucleus and cytoplasm, which stains pink to reddish pink and frequently exhibits vacuoles. Frequencies in the peripheral blood of normal individuals are 04% and 00.5%, respectively, for eosinophils and basophils.

The earliest cell of the monocyte/macrophage lineage is difficult to distinguish from the myeloblast. The cell is 1218 m in diameter, with a round or oval nucleus that is frequently convoluted. The chromatin is fine, and nucleoli are sometimes present. The cytoplasm is basophilic, with a grayish cast and, although devoid of granules, may contain vacuoles. Blunt pseudopodia are sometimes present. The naphthol-AS-acetate esterase reaction is positive and is inhibited by fluoride. The promonocyte is a large cell with an indented nucleus exhibiting fine chromatin and a single nucleolus (Fig. 12-12). The cytoplasm stains light blue with azurophilic granules and a small centrosphere. The monocyte is the largest cell present in the peripheral blood and measures 1320 m in diameter (Fig. 12-13). The nucleus is large, lobulated, or bean-shaped, with coarse nuclear chromatin; it lacks nucleoli and is often eccentric in location. The cytoplasm stains a characteristic smoke-blue with azurophilic granules. The chromatin structure of the monocyte is less clumped and the cytoplasm grayer than the lymphocyte, characteristics that (along with nuclear convolutions) help to distinguish these cells from moderate-size lymphocytes in the peripheral blood. Other helpful distinguishing characteristics are blunt pseudopodia. Monocytes usually make

Figure 12-11 Mature, bilobed eosinophils (middle and right).

Figure 12-12 Promonocyte in peripheral blood.

up <510% of the peripheral leukocytes. Egress of monocytes from the blood into tissues is associated with increased cell size and larger, more lightly staining nucleus. These cells, termed macrophages or histiocytes, are phagocytic and mobile, and intracellular debris is often present.

Morphologic differentiation of platelet-forming cells is distinctly different from either erythroid or leukocyte cell lineages. Distinct morphologic maturational steps and divisions do not take place; these processes are instead replaced by the process of polyploidization. In the process, successive nuclear divisions without concomitant cytoplasmic divisions lead to megakaryocytes with 132 nuclei representing diploid to 64N nuclear content. The first identifiable cell in this lineage is the megakaryoblast, a distinctly large cell with a high nuclear/cytoplasmic ratio. The nucleus shows variable chromatin coarseness and may contain nucleoli. The nuclear shape varies, but the nucleus frequently displays convolutions or deep furrows. The cytoplasm stains basophilic, does not contain granules, and may exhibit fraying at the cytoplasmic membrane. Some megakaryoblasts may contain multiple nuclei. The promegakaryocyte exhibits a lobulated nuclear structure without nucleoli and with a coarse chromatin structure. The cytoplasm is basophilic, with azurophilic granules adjacent to the nucleus, and formed platelets are seen on the cytoplasmic cell surface.

Occasionally the presence of other cells apparently within the cytoplasm (emperipolesis) of the promegakaryocyte is noted, although the mechanism leading to this occurrence is unknown. Mature megakaryocytes are the largest hematopoietic cell in the bone marrow (Fig. 12-14). The nucleus is lobulated and exhibits coarse and clumped chromatin. Nuclear number varies from eight diploid nuclei (65% of marrow megakaryocytes) to four nuclei (10% of marrow megakaryocytes). The cytoplasm is basophilic, with numerous azurophilic granules. Platelets can be seen at the periphery of the cytoplasm

Figure 12-13 Monocyte with band neutrophil (above).

Figure 12-14 Megakaryocytes.

and are attached to the cell membrane. Megakaryocytes constitute 0.10.5% of cells in the medullary cavity of normal individuals.

SUMMARY

The formation of blood cells represents a complex interaction between stem cells, cells making up the HM, and growth regulatory proteins, which are presented in soluble and localized forms. These interactions give rise to an enormous number and diversity of cells that function in widely separated parts of the body to transport oxygen, defend against infectious agents, and provide a stimulus for clotting. Abnormalities that affect this process can lead to life-threatening illnesses such as aplastic anemia and myeloproliferative diseases. In addition to contributing to our understanding of the basic pathophysiology of these diseases, research in hematopoiesis is providing new therapeutic tools, such as growth factors, which are being used in treatment of both congenital and induced hypoplastic conditions of the bone marrow.

Chapter 13 - Anatomy and Physiology of Hematopoiesis

Catherine M. Verfaillie

INTRODUCTION

Hematopoiesis is a complex process in which hematopoietic stem cells (HSC) can self-replicate but also differentiate into myeloid and lymphoid lineage committed hematopoietic progenitor cells (HPC). The committed HPC undergo further multiplications before they terminally differentiate into mature blood elements. The process of myelopoiesis and lymphopoiesis occurs in close proximity with a permissive microenvironment. In adult life the hematopoietic microenvironment is provided in the bone marrow (BM). Earlier in ontogeny, hematopoiesis takes place in the aorta-gonadal-mesonephros (AGM) region, yolk sac, and fetal liver. The hematopoietic microenvironment contains stromal cells of mesenchymal origin, such as endothelial cells, fibroblasts, adipocytes, and osteoblasts, and cells of nonmesenchymal origin, including macrophages. These stromal cells produce and deposit a complex extracellular matrix (ECM) and produce and concentrate locally hematopoietic cytokines that can induce or inhibit progenitor proliferation and differentiation. Hematopoietic cells interact through specific cell surface receptors with either immobilized or secreted cytokines and with adhesive ligands present on stromal cells or ECM components, interactions that underlie the normal hematopoietic process. Once HPC differentiate into mature blood elements, they egress from the BM in the blood or secondary hematopoietic organs, a process that is still not well understood. This chapter focuses on the ontogeny of hematopoietic tissues and the interactions between hematopoietic elements and the adult marrow microenvironment that underlie the normal hematopoietic process. Mechanisms that underlie egress of mature as well as more primitive progenitors from the BM, known as mobilization, and the mechanisms underlying the homing and engraftment of HPC and HSC into the BM will also be discussed.

ONTOGENY OF HEMATOPOIETIC TISSUES

Until recently it was thought that hematopoiesis originated solely from the extra-embryonic mesoderm in the yolk sac (Fig. 13-1).[1] It was believed that HSC originating in the yolk sac colonize sequentially the fetal liver, thymus, and BM, providing definitive hematopoiesis in embryonic, fetal, and adult life. Data on mice indicate, however, that HSC can also be found in the AGM region and may arise from hemangioblastic cells that can differentiate into both HSC and endothelial cells.[2] [3] [4] [5] The analogous area in birds is responsible for the development of adult hematopoiesis. In the mouse, HSC can be detected around the dorsal aorta and in the urogenital ridges as early as days 9 and 10 of development, possibly before the development of HSC in the yolk. When serially transplanted in adult conditioned recipients, cells from the AGM region can restore long-term multilineage hematopoiesis. This has led to the notion that HSC arising in the AGM region are responsible for the colonization of fetal liver, thymus, and BM and should therefore be considered stem cells that give rise to definitive hematopoiesis in adult life. Some studies suggest that HSC found in the yolk sac may not contribute significantly to adult hematopoiesis. Other studies demonstrate, however, that transplantation of HSC recovered from the yolk sac on days 9 and 10 of development into newborn conditioned recipients can also reestablish hematopoiesis. [6] [7] If HSC from the AGM region colonize the yolk sac or vice versa, and are therefore derived from the same stem cell pool, is not known. Additional studies will therefore be needed to clarify the contribution of HSC found in the AGM region and the yolk sac to the establishment of embryonic, fetal, and adult hematopoiesis.

A similar population of $CD34^+$ cells has been identified in the AGM region in human embryos at 3037 days of gestation. [8] In humans, HSC colonize the fetal liver at 5 weeks of gestation.[1] Fetal liver hematopoiesis becomes active at 6 weeks and the liver remains the dominant hematopoietic organ throughout fetal life. From the fetal liver, HSC seed the BM at 8 weeks of gestation. In contrast to the fetal liver where hematopoiesis is predominantly erythroid, hematopoiesis occurring in the fetal BM is mainly myeloid in nature and contributes only minimally to the blood pool throughout fetal life. HSC colonize the spleen at 12 weeks and the thymic rudiment at 8 weeks. B-cell development first begins in the fetal liver at 7 weeks of gestation and shifts to the BM at 1214 weeks. Liver stem cells differentiate in the thymus into mature T lymphocytes which populate fetal lymph nodes, spleen, and gut by the 12th week of gestation and other peripheral lymphoid tissues by week 1415 of gestation. Finally, NK cell activity has been reported in human fetal liver cells at 812 weeks of gestation, with $CD56^+$ cells first seen in fetal liver at 6 weeks.

Figure 13-1 Ontogeny of human hemopoiesis. The hemopoietic stem cell is believed to arise within the aorto-gonadal-mesonephros region and/or extra-embryonic yolk sac. After 5 weeks of gestation, hemopoietic stem cells colonize the liver from which they migrate to the bone marrow at 8 weeks, thymus at 8 weeks, and spleen at 12 weeks. During fetal life, the liver is the chief organ responsible for production of myeloid and erythroid cells. B-lymphopoiesis initially takes place in the liver, but shifts to the bone marrow after 12 weeks of gestation. T-lymphopoiesis starts in the thymus around week 10. After birth, the main hemopoietic organ becomes the BM.

During fetal life and immediately after birth a large number of HPC and HSC can also be found in the circulation. [9] However, within 2448 hours after birth, circulating progenitors disappear from the circulation, presumably because of lodgment in the BM cavity. In the adult, hematopoiesis takes place chiefly in the BM.

The reasons for the migratory behavior or the mechanisms underlying the localization, migration, and homing in different organs of HSC throughout embryonic and fetal life are not well understood. Changes in sites of hematopoiesis may be due to differences in the adhesive behavior of HSC and HPC at different stages of ontogenic differentiation, enabling them to interact with a specific hematopoietic microenvironment. Alternatively, differences in the capacity of the different hematopoietic organs to support the development of progenitors of different ontogenic ages may underlie the sequential establishment of hematopoiesis in AGM and yolk sac, liver, and BM. In vivo and in vitro biological evidence supports both hypotheses. Transplantation of fetal liver HSC in fetal sheep results in homing to the fetal liver but not BM if the transplants are performed before day 60 of gestation when the liver is the only hematopoietic organ. [10] By contrast, when fetal liver HSC are transplanted beyond day 80 of gestation, at which stage endogenous HSC have colonized the BM, exclusive homing to the BM is observed rather than homing to the fetal liver. Interestingly, although fetal liver HSC engraft in the fetal BM, appearance of their mature progeny in the blood does not occur until the perinatal period when BM hematopoiesis becomes active. The nature of receptors expressed on stem cells at different stages of ontogeny that govern their ability to interact with, for instance, the liver but not the BM microenvironment, is still unknown. Studies done with HSC derived from 1-integrin-deficient embryonic stem cells have demonstrated that 1-deficient HSC cannot colonize the fetal liver hematopoiesis even though these cells can differentiate in vivo in erythroid, myeloid, and B-lymphoid progeny, suggesting an important role for 1-integrins in the migratory behavior of embryonic and fetal HSC. [11] Supporting the hypothesis that supportive capacity differs among various hematopoietic organs is the observation that transplantation of day 10 murine yolk sac HSC in conditioned adult recipients do not engraft, whereas the same yolk sac HSC can repopulate the hematopoietic system of newborn mice in which the liver and spleen, like the BM, function as a site for hematopoiesis.[7] In vitro studies have shown that factors secreted by adult BM stroma inhibit growth of fetal liver erythroid progenitors. [12] These studies strongly suggest that homing and development of HSC may not occur when they are transferred to an ontogenically more mature microenvironment. These observations have important implications for the use of fetal liver progenitors for transplantation into adult recipients.

COMPONENTS OF THE BONE MARROW MICROENVIRONMENT

Stromal Cells

The BM microenvironment is a complex organ in which stromal cells are responsible for providing most, if not all, factors required for the orderly development of the HSC (Fig. 13-2). Stromal cells are both mesenchymal and hematopoietic in origin, and include osteoblasts, fibroblasts, adipocytes, myocytes, endothelial cells, dendritic cells, and macrophages.[13] [14] When hematopoietic BM is examined in vivo, hematopoietic cells of different stages of differentiation and lineage commitment can be found in distinct areas throughout the bone marrow space. For instance, cells with an immature morphology can be found lining the subendosteal region in close proximity with osteoblasts.[15] [16] More differentiated progenitors and precursors of the

Figure 13-2 Bone marrow microenvironment. The BM microenvironment is composed of stromal cells (1) that are of mesenchy-mal (adipocyte, fibroblast, and endothelial cell, and osteoblast) and hemopoietic (macrophages) origin. Stromal cells produce both soluble and membrane-bound cytokines (2) as well as ECM components (3). Adhesion receptors (5) on hemopoietic stem cell and progenitor cells (4) support interaction with stromal adhesive ligands and cytokine receptors allow interaction with bound or soluble cytokines. Interactions between hemopoietic stem and progenitor cells and stromal cells, ECM components, and cytokines are responsible for the ordered production of mature blood elements.

myeloid, erythroid, and megakaryocytic lineage are located throughout the marrow. The apparent association of lineage-specific progenitors and their more differentiated precursors in islands suggests that lineage-specific differentiation may depend on specialized progenitor-stromal cell interactions. This has led to the concept of stem cell/progenitor niches.[17] [18] Such niches would consist of specialized stromal cells that produce extracellular matrix components and hematopoietic supportive cytokines that are conducive for the commitment and/or differentiation of progenitor cells at a specific stage of differentiation (Fig. 13-3).

Characterization of the role of the BM microenvironment in the hematopoietic process became possible with the development of stroma-dependent cultures, initially developed by Dexter and coworkers, also termed long-term marrow cultures (LTC).[19] [20] In LTC, human or mouse BM is cultured in serum-containing medium in plastic culture vessels. The stromal cells establish an adherent feeder layer, and HSC and HPC in the inoculum proliferate and differentiate in the stromal feeder for weeks to months in the absence of exogenous factors.[21] More primitive progenitors, termed long-term culture initiating cells (LTC-IC) or cobblestone area forming cells (CAFC)[22] [23] can be found between or under the stromal cells and have an appearance of cobblestones when evaluated by phase contrast microscopy. Because LTC-IC persist for long periods of time in culture and can re-initiate secondary LTC, they are closely related to HSC. [24] [25] More differentiated progeny, including colony-forming cells (CFC) and more mature precursors, are present in or suspended above the stromal layer. In the murine system, long-term repopulating HSC survive weeks in such stroma-dependent LTC, indicating that examination of hematopoiesis in stroma-based cultures can provide insights on the role of stromal cells in hematopoiesis.

A number of investigators have cloned murine stromal cell

Figure 13-3 Stem cell and progenitor niches. Stromal cell lines that support growth of stem cells but not more mature progenitors have been described. [26] [27] Likewise, stromal cell lines that support myelopoiesis[26] [27] or B-lymphopoiesis,[30] but not more immature progenitors have been cloned. Progenitors at different stages of differentiation can interact with certain but not all ECM components and can be induced to proliferate or differentiate by some but not all cytokines. This has led to the concept of stem cell niches and progenitor niches which would consist of specialized stromal cells and their secreted cytokine and/or ECM product that interact with progenitors at specific stages of differentiation and of a specific hemopoietic lineage. These interactions would tightly regulate progenitor differentiation and proliferation. Depicted are two putative niches: for instance, primitive CD34 $^{+}$ cells adhere through 1-integrins to fibronectin or VCAM-1. Primitive progenitors can also interact with SCF, which is expressed by fibroblasts. The combined stem cellECMcytokine interactions regulate growth of hemopoietic stem cells. Alternatively, more mature myeloid progenitors and their precursors adhere, for instance, to hemonectin. These progenitor and precursors are stimulated to proliferate and differentiate by the single lineage cytokine, G-CSF. The combined action of myeloid progenitor specific ECM components and cytokines is thought to regulate proliferation and differentiation of this cell lineage.

lines from either fetal liver or adult BM. [26] [27] [28] [29] [30] [31] [32] [33] [34] Some of these cell lines support the ex vivo maintenance and expansion of multipotent HSC populations, while they support poorly more committed HPC.[26] [27] Other cell lines support myelopoiesis or B-cell development but are incapable of supporting survival and proliferation of more immature, multilineage progenitors.[27] The nature of the factors expressed or secreted by stromal cells capable of supporting multipotent or lineage restricted progenitors is still largely unknown. However, the availability of these cell lines provides a potent tool to begin characterizing factors required for self-renewal or lineage commitment of HSC, or factors necessary for the proliferation or differentiation of lineage-committed HPC.

Fibroblasts

The best-studied BM microenvironment stromal cell is the fibroblast. Numerous murine BM or fetal liver fibroblast cell lines have been cloned. [28] [29] [30] [31] In addition, SV-40 transformed fibroblast-like cell lines have been generated from murine or human BM or fetal liver. [26] [27] In general, primitive and to a lesser extent more committed HPC adhere to the fibroblast feeders.[35] [36] Progenitor adhesion occurs either to cell surface expressed ligands, such as vascular cell adhesion molecule (VCAM),[36] cell surface expressed growth factors, such as stem cell factor (SCF), [37] [38] or to ECM components secreted by the fibroblast. [35] Although the type and concentrations of cytokines produced by the different cloned fibroblast feeders does not differ significantly, [26] [27] [28] [29] [30] [31] [32] [33] [34] [39] [40] some but not all feeders support the primitive progenitor compartment whereas others support committed myeloid or lymphoid progenitors, and still others support hematopoiesis poorly or not at all. Further, fibroblasts cloned from nonhematopoietic organs express frequently the same types of cytokines as fibroblasts derived from hematopoietic organs. [39] [40] However, fibroblasts from nonhematopoietic tissues often do not support hematopoiesis. This indicates that aside from the known cytokines, other factors produced and/or secreted by BM- or fetal liver-derived fibroblasts are important for the support of hematopoiesis. As yet unidentified growth factors may underlie the differences in hematopoietic supportive ability of different fibroblast cell lines. Alternatively, differences in presentation or local concentration of cytokines, which are regulated by the ECM, may affect the ability of fibroblast cell lines to support hematopoiesis. As adhesive interactions per se may influence the growth and differentiation of HSC and HPC, differences in adhesive ligands on the fibroblasts themselves or in the cell ECM may be important determinants of their hematopoietic supportive capacity.

Endothelial Cells

In vivo, endothelial cells line the sinusoids of the bone marrow cavity. As in other tissues, entry to and exit from the BM requires that progenitors and mature blood cells pass through the endothelial barrier of the sinusoids. Because endothelial cells are an integral part of the hematopoietic microenvironment, they may also affect the growth of HSC and HPC. Purified BM endothelial cell (BMEC) feeders have been generated. [34] [41] [42] [43] Like fibroblasts, BMEC produce a number of cytokines known to support hematopoiesis. When CD34^{+} cells are co-cultured with BMEC, primitive LTC-IC are maintained and more committed HPC proliferate and

differentiate, indicating a role for BMEC in the regulation of progenitor proliferation and differentiation. [34] [42] $CD34^+$ cells adhere to endothelial cells. [41] Furthermore, $CD34^+$ cells can migrate through BMEC barriers, a process that depends on the interaction of 2-integrins on $CD34^+$ cells and ICAM-1 expressed on BMEC.[43] Endothelial cell feeders can also be generated from tissues other than BM, such as human umbilical vein endothelial cells (HUVEC). [41] $CD34^+$ cells adhere to and migrate through BMEC significantly better than to HUVEC.[44] HUVEC also support in vitro hematopoiesis significantly less than BMEC. Endothelial cells derived from hematopoietic organs, like fibroblasts, have as yet undefined unique characteristics that make them suitable for the support of hematopoiesis.

Osteoblasts

Until recently, little attention was given to the potential role of osteoblasts as stromal cells in the BM microenvironment. However, the simple fact that adult hematopoiesis is localized almost exclusively in the bone may well be because bone cells themselves provide specific signals for either homing of stem cells or for the development of adult HSC and HPC. In addition, the most primitive progenitors can be found in close proximity with the endosteal lining of the BM cavity. [15] [16] In vitro studies have shown that human $CD34^+$ cells adhere tightly to osteoblast feeders, even though the nature of the receptorligand pairs in this interaction is not yet known.[45] Osteoblasts produce cytokines, such as G-CSF, GM-CSF, and IL-6, known to support hematopoiesis. [45] [46] When human $CD34^+$ cells are cocultured with osteoblast feeders, primitive LTC-IC can be maintained and expanded to the same or greater extent than when cocultured with mixed BM stromal feeders. [45] [46] These studies thus suggest an important

role for the osteoblast component of the BM microenvironment in hematopoiesis.

Extracellular Matrix Components

Stromal cells produce cytokines and ECM components, both of which are required for the regulation of hematopoiesis. A number of ECM components can be found in BM-derived stromal feeders. The same ECM components can be detected in situ in BM biopsies. They include several types of collagen, laminin, fibronectin, thrombospondin, proteoglycans, and hemonectin. Although the exact role of ECM components in hematopoiesis is not known, they serve to localize HPC and HSC in the BM microenvironment. In addition, adhesion of HSC and HPC to the ECM may affect proliferation and differentiation of progenitors directly or may alter the response of progenitors to cytokines. Finally, ECM components, in particular proteoglycans, may play a role by concentrating, protecting, and presenting cytokines.

Fibronectin

Fibronectin is a large 450 kDa fibril-forming glycoprotein composed of two similar subunits joined by a pair of disulfide bonds at their carboxyl termini and folded in a series of globular domains separated by regions of flexible polypeptide chains. [47] Alternative splicing of the mRNA results in a variety of fibronectin isoforms in which certain cell adhesion promoting domains can be present or absent. Fibronectin is found in almost all tissues. Various domains of the fibronectin molecule that interact with different cell surface receptors have been identified. A 75120 kDa proteolytic fragment in the center of the fibronectin molecule contains the sequence arginyl-glycyl-aspartyl-serine (RGDS). [48] The 51 integrin mediates interaction of different cell types with this RGDS-containing fragment of fibronectin. Adhesion to fibronectin can also occur in an RGDS-independent fashion via the 33/66 kDa heparin-binding fragment at the COOH-terminal end of the fibronectin molecule. Several RGDS-independent cell-adhesion promoting peptides have been identified within the 33/66 kDa COOH-terminal fragment of fibronectin. These include CS1, to which the 41 integrin binds,[49] and a number of heparin-binding peptides to which cells adhere through cell surface heparin-like molecules. [50] It has long been established that adhesion of cells to fibronectin serves to localize cells in a specific microenvironment. It has also become clear that adhesion to fibronectin can influence the growth of cells. Aside from serving a permissive role in up-regulating the sensitivity of cells to soluble cytokines, the adhesive interaction itself between cells and fibronectin may affect cell survival and proliferation. [51] [52]

Fibronectin is abundantly present in normal adult BM [53] where it is produced by endothelial cells and fibroblasts. Fibronectin may play an important role in homing of HSC and affect proliferation and differentiation of HSC and HPC. In vivo and in vitro studies have shown the importance of the CS1-binding 41-integrin in mobilization and homing of HSC/HPC, which will be discussed further in the following sections. [36] [54] [55] Further, engagement of 41- and 51-integrins affects progenitor proliferation and survival[52] [56] [57] This demonstrates that adhesion of HPC to fibronectin may play an important role in the growth regulation of these progenitors. Interaction with fibronectin is also required for the terminal differentiation of erythroid progenitors [51] [58] and for the survival and differentiation of B-lymphoid progenitors. [59] Because fibronectin is universally present, specificity and selectivity for the adhesion of different cell types or the same cells at different stages of maturation to fibronectin is provided by tissue-specific expression of various isoforms of fibronectin, [47] [60] and by differential expression of the multiple fibronectin cell surface receptors. [48] [49] [50]

Thrombospondin

Thrombospondin is a 450 kDa glycoprotein produced by platelets, endothelial cells, and fibroblasts. [61] As for fibronectin, several thrombospondin domains have been identified that bind to other ECM components, such as glycosaminoglycans, fibrinogen, or cell-surface receptors. The molecular basis of the thrombospondin-cell interaction is complex. Cell-surface proteoglycans, 41-integrins, av3-integrins, and CD36 bind to different sites in thrombospondin. [62] [63] [64] Thrombospondin is abundantly present in the BM microenvironment localized in megakaryocytes, fibroblasts, and the ECM associated with active hematopoiesis. [65] Thrombospondin serves as a ligand for committed progenitors[66] and adhesion of HPC to thrombospondin may constitute a signal that modulates the response of progenitors to cytokines. Co-culture of CFC with immobilized SCF and thrombospondin amplifies the response of CFC to soluble cytokines such as IL3 and GM-CSF. [67]

Proteoglycans and Glycosaminoglycans

Like most tissues, the BM microenvironment is rich in proteoglycans. These include heparan, dermatan, and chondroitin sulfate proteoglycans and hyaluronic acid. [68] Proteoglycans consist of a core protein to which one or more glycosaminoglycans (GAGs) are attached. GAGs are long, negatively charged, unbranched polysaccharide chains composed of repeating sulfated disaccharide units. [69] The type of sugar residues, the type of linkage between these residues, and the number and location of sulfate groups are important for the interaction of GAGs with ECM components, cells, and growth factors, and provide specificity. Heparan-sulfate GAGs secreted by hematopoietic supportive stromal cell lines play an important role in the maintenance and expansion of LTC-IC. [40] [70] Characteristics associated with the hematopoietic supportive nature of heparan-sulfate GAGs include a high degree of sulfation, localization of the sulfate groups (6-O rather than N-sulfation), and length of the GAG-chains.[71] BM-specific heparan-sulfate GAGs allow adhesion of $CD34^+$ cells.[72] The receptors on human hematopoietic progenitors responsible for their interaction with BM-derived heparan sulfate GAGs have not yet been identified. In addition, BM-specific heparan-sulfate GAGs can concentrate hematopoietic growth factors, such as IL3, GM-CSF, b-FGF, and MIP-1.[71] [73] [74] [75] The ability of BM-specific heparan-sulfate GAGs to selectively colocalize certain growth factors and HPC at a specific stage of differentiation may be crucial for the regulation of proliferation and differentiation. Heparan-sulfate GAGs can therefore be seen as the orchestrators of the putative HPC or HSC niche (Fig. 13-4).

Besides heparan-sulfate GAGs, chondroitin-sulfate GAGs are important in the hematopoietic process. When -d-xyloside, an agent that uncouples chondroitin sulfate glycosaminoglycan synthesis from proteoglycan synthesis, is added to LTC, a significant increase in chondroitin/dermatan sulfate GAGs is seen in stromal supernatants.[76] Hematopoiesis in -d-xyloside treated LTC is significantly increased, suggesting a role for chondroitin sulfate in hematopoiesis. Finally, as will be discussed later $CD34^+$ cells can adhere to hyaluronic acid in BM ECM through the CD44 receptor. [77] [78] Engagement of the CD44 receptor by hyaluronic acid may result not only in adhesion of HPC but may also affect their growth. [79]

Collagens and Laminin

Collagens are fibrous proteins found in the extracellular space. [80] The most common types are collagens type I, II, III, and IV. Collagen types IIII are assembled in collagen fibers and constitute the structural backbone of the extracellular space, seen as reticulin fibers on BM biopsies. [81] [82] Collagen type IV, in contrast,

Figure 13-4 Glycosaminoglycans are orchestrators of progenitor niches. Proteoglycans are common to all tissues. The glycosaminoglycan (GAG) side chains of proteoglycans have multiple functions: They support adhesion of cells, they bind to other ECM components, and they allow binding of cytokines. The type of sugar residues, the type of linkage between these residues, and the number and location of sulfate groups provide specificity to these interactions. Heparan-sulfate GAGs secreted by hemopoietic supportive stromal cell lines play an important role in the maintenance and expansion of LTC-IC.[40] These heparan-sulfate GAGs allow adhesion of $CD34^+$ cells.[72] In addition, BM-specific heparan-sulfate GAGs can concentrate hemopoietic growth factors such as IL-3, GM-CSF, and MIP-1 [71] [73] [74] [75] and can bind to ECM components, including thrombospondin (TSP) and fibronectin. The ability of BM-specific heparan-sulfate GAGs to selectively colocalize certain growth factors, other ECM components, and progenitors at a specific stage of differentiation may be crucial for the regulation of proliferation and differentiation of these progenitors. Heparan-sulfate GAGs can therefore be seen as the orchestrators of the putative progenitor or stem cell niche.

is not assembled in large fibrils but into a sheetlike mesh that constitutes a major part of basal membranes. [83] *Laminin* is an 850 kDa complex of three very long polypeptide chains arranged in the shape of a cross held together by disulfide bonds. Like fibronectin, it consists of a number of functional domains that can bind collagen type IV (basal membranes), proteoglycans, and cell surface receptors. [83] A specific role for collagen or laminin in the process of localization, proliferation, or differentiation of human hematopoietic progenitors in the bone marrow microenvironment has, however, not been defined. Egress of mature (and sometimes immature) hematopoietic cells from the BM microenvironment into the bloodstream requires passage of these cells through the basal membranes of endothelium. [84] 21- and 61-integrins present on granulocytes allow them to bind to and migrate through basal membranes. [85] [86] 21- and 61-integrins are not present on normal HPC and HSC. Of note, certain leukemic $CD34^+$ cells, in contrast to their normal counterparts, express 21- and 61-integrins, [85] [86] which may enable them to egress from the BM at an undifferentiated stage.

Hemonectin

Hemonectin is a 60 kDa extracellular matrix protein found exclusively in the BM microenvironment. [87] [88] It is believed that hemonectin preferentially supports binding of myeloid progenitors. Hemonectin is detected in fetal liver and fetal BM immediately before the onset of granulocytopoiesis. [89] The molecular structure of hemonectin and the cell-surface receptors responsible for the interaction of granulocytic progenitors with hemonectin have not yet been identified. The exact role of hemonectin in hematopoiesis is therefore still unknown.

Cytokines

The role of cytokines in hematopoiesis is discussed at length in Chapter 14 . However, a few concepts are discussed here in order to describe the regulation of hematopoiesis by the BM microenvironment.

First, almost all known cytokines are produced by cells present in the BM microenvironment. Low concentrations of most cytokines can be detected in supernatants of stromal feeders.[39] [40] [90] In vitro and in the absence of stromal cells, nanogram concentrations of cytokines are required to induce progenitor proliferation. How then do the picogram concentrations of cytokines found in stromal cultures (and in serum in vivo) affect progenitor growth? One possibility is that the combination of several different growth factors in small concentrations may induce progenitor proliferation and differentiation. [90] [91] In addition, growth factors can be bound and concentrated by ECM components, such as glycosaminoglycans.[71] [73] [74] [75] Therefore, the concentration of cytokines in local microenvironments may actually be significantly higher than that found in the circulation or in culture supernatants. There is also evidence that interaction with these ECM components may present cytokines in a biologically more active form to hematopoietic progenitors. [67] [74] Aside from secreted cytokines, stromal cells also produce cytokines that are presented in a membrane-bound form[38] [92] which would not be measured in stromal supernatants. Further, certain membrane-bound cytokine isoforms are significantly more active than in their soluble form. [38] Finally, adhesive interactions between HPC and stromal cells or ECM components may enhance the responsiveness of progenitors to small concentrations of cytokines. [40] [52] [67]

Second, although more than 40 cytokines have been described that promote proliferation and/or differentiation of progenitors, and other cytokines are thought to inhibit these processes, it remains unclear how the normal hematopoietic process is regulated. For instance, except for erythroid cells [93] it is unknown how HSC and HPC are instructed that increased numbers of mature blood elements of a specific lineage are required. Alternatively, it is unclear how HSC/HPC learn that sufficient mature blood elements are present and that further proliferation is not necessary (Table 13-1). One possible mechanism is contact-mediated regulation of progenitor proliferation, similar to contact inhibition seen in other biological systems. [94] In the BM, HSC and HPC are located in close proximity with progenitors at the same stage of differentiation, more mature precursors and blood cells and stromal cells. [15] [19] [20] Progenitors therefore receive signals through adhesion to neighboring hematopoietic or nonhematopoietic cells. These adhesive interactions are at least in part responsible for instructing HPC to continue or stop proliferating because of the lack or excess of maturing and terminally differentiated blood elements. As is seen in vivo, [95] HPC cultured in vitro in the presence of a stromal feeder are generally quiescent. [96] [97] Quiescence is in part mediated by growth inhibitory cytokines, such as TGF- [97] and MIP-1 [98] which are concentrated in the stromal ECM. [75] [99] There is also evidence that adhesive interactions per se signal HPC under physiological conditions to remain quiescent, [56] which will be discussed at length in the next section. A second mechanism involved in the local regulation of HPC proliferation is that HPC themselves can instruct the BM microenvironment to increase or decrease production of cytokines. For instance, osteoblast production of G-CSF is up-regulated by soluble factors produced by $CD34^+$ cells.[100] Likewise, when $CD34^+$ cells are cocultured with human primary BM stromal layers, stromal cells increase production of IL6 and GCSF. [101] When more mature $CD15^+$ precursors are present, production of G-CSF and IL6 returns to basal levels. Presence of increased cytokine concentrations induced by the $CD34^+$ cell population can override the contact-mediated inhibitory signals and induce $CD34^+$ cell proliferation and differentiation. [97] [102] [103] Once sufficient mature cells have been generated, stromal cell production of cytokines returns to baseline and increased hematopoiesis ceases. Thus, contact interactions between progenitors and stromal elements may be responsible for inhibiting excessive proliferation of these progenitors, and these growth inhibitory signals can be overridden by cytokines produced likely in response to a declining number of mature blood elements.

TABLE 13-1 -- Growth Factors Regulating Hematopoietic Cell Production

Growth Factor	Depletion of Blood/Progenitor Compartment	Producing Organ	Trigger
Erythropoietin	Anemia	Kidney	Oxygen tension
G-CSF	Leukopenia	Marrow ?	Soluble factor produced by HPC?
MGDF	Thrombocytopenia	Marrow ?	?
Flt-3 L	Aplasia	Marrow ?	?

ADHESIVE INTERACTIONS AND HEMATOPOIESIS

What are the receptors on hematopoietic cells that allow them to interact with cells and ECM in the BM microenvironment? As discussed in the previous section, HSC and HPC as well as more mature precursors express cytokine receptors that allow them to interact with cell-surface expressed cytokines or cytokines present in the ECM. In addition to cytokine receptors, HPC also express a number of adhesion receptors. [104] [105] It is well accepted that adhesion receptors serve to localize progenitors in the BM microenvironment. Adhesion receptors can also transmit signals that modulate the response of the cell to other extracellular factors or directly induce or inhibit cell proliferation and differentiation.

The role of 1-integrins on HSC, HPC, and their progeny has been most extensively studied. 1-integrins allow interaction with the ECM components, fibronectin, collagens, laminin, and thrombospondin, as well as with the cell-surface expressed vascular cell adhesion molecule (VCAM)-1. [106] [107] [108] In addition to 1-integrins, HPC also express a number of other adhesion receptors, whose function has not been as extensively studied, including 2-integrins, 3-integrins, CD44, selectins, members of the immunoglobulin family, sialomucins, and lectins (Table 13-2).

Integrins

Integrins are a family of divalent cation-dependent cell-surface glycoproteins, consisting of an - and -chain (Fig. 13-5). They are responsible for cell-ECM and cell-cell adhesion events. [106] [107] [108] Integrins have a large, heterodimeric extracellular domain, a small membrane-spanning domain, and a cytoplasmic domain. Ligand-binding specificity is dictated mostly by the extracellular domain of the -chain. The cytoplasmic domain of the subunit is responsible for mediating integrin-cytoskeletal interactions and for activating signal pathways that may affect the growth and survival of cells (outside-in signaling). The cytoplasmic tail of the subunit is also responsible for affinity modulation of the integrin in response to signals provided to the cells through cytokine or other adhesion receptors (inside-out signaling).

Presence of an integrin on the cell surface does not necessarily indicate that the receptor has functional significance. Integrins can be constitutively expressed in a nonfunctional or low affinity state. Different activation signals, including stimulation of cells through other adhesion receptors, through cytokines, with PMA, and incubation with activating antibodies can switch the integrin to a functional, high-affinity state. [109] [110] [111] The increased affinity state of the integrin following one of these stimuli, a process termed inside-out activation, enables more avid binding of the integrin to its adhesive ligands (Fig. 13-4). Integrins colocalize with -actinin, talin, vinculin, and F-actin in focal contacts or adhesions [112] (Fig. 13-6). Because integrins do not have intrinsic kinase activity, activation of signal pathways requires recruitment of nonreceptor kinases. Engagement of integrins results in recruitment and autophosphorylation of the focal adhesion kinase, Fak, [113] which can bind to the integrin itself or with talin. Phosphorylation of FAK creates a binding site for c-Src, which phosphorylates Fak further, creating binding sites for a number of SH2-containing proteins, such as paxillin, Crk, Grb-2, and the p85 subunit of PI3-kinase. Thus, much like stimulation of cytokine receptors, integrins can activate the Ras/MAPK pathway that leads to the increased expression of c-myc and c-fos, activate PI3K, which affects cell proliferation and survival, induce immediate-early inflammatory response genes and alter levels of cyclins, cyclin-dependent kinases, and cyclin-dependent kinase inhibitors (CKIs). [114] [115] [116] [117] How these observations made mainly in fibroblasts and cell lines of nonhematopoietic origin relate to the assembly of focal contacts that affect adhesion, migration, or integrin-dependent growth modulatory signaling in HPC is still unknown.

1-Integrins

41-integrins play an important role in the interaction of HPC and the BM microenvironment. Several in vivo studies demonstrate a dominant role for the 1-integrin family in the homing and retention of HSC in the BM microenvironment. Engraftment of murine HSC can be inhibited by anti-4 antibodies. [55] [118] Homing of human HSC to a xenogeneic ovine BM microenvironment can be inhibited by anti-human 4 antibodies. [119] Intravenous infusion of anti-4 antibodies in mice or baboons results in peripheralization of HPC and HSC [118] [120] (Fig. 13-7). Finally, 1-defective HSC cannot successfully compete with wild type stem cells in competitive engraftment experiments, due to their inability to migrate. [11] All these studies indicate that 41-dependent interactions are needed to localize HSC in the BM and to allow their migration and adhesion to the BM. In vitro, CFC and LTC-IC adhere to BM stroma [36] at least in part through 1-integrins. Further, LTC-IC and CFC adhere to fibronectin and VCAM. [36] [54] [85] Of interest, although more than 80% of $CD34^+$ cells express 41- and 51-integrins, only a fraction adheres to CS1 or GRGDSP, [54] [85] indicating that a proportion of these receptors is present in a nonfunctional state. As in other biological systems, the functional state of 1-integrins on HPC can be affected by cytokines that can increase or decrease their affinity. In addition, intrinsic cellular changes, such as the presence of the BCR/ABL gene rearrangement in CML, can decrease the affinity of 1-integrins. [85] [121] It is thought that the decreased ability of integrins present on malignant CML progenitors to adhere to stroma may at least in part be responsible for their premature release into the PB. [122] [123] However, one needs to keep in mind that 1-integrins are responsible for only 50% of the adhesion of CFC or LTC-IC to stroma. It is not known which receptors account for the remainder. [35] [36]

TABLE 13-2 -- Adhesion Receptors and Their Ligands

Receptor Family	Receptor	Cell	Ligand
Integrins:			
1-family	41	HSC, HPC, erythroid, myeloid, and lymphoid precursors and blood cells	Fibronectin, Thrombospondin, VCAM
	51	HSC?, HPC, erythroid, myeloid, and lymphoid precursors and blood cells	GRGDSP
	11, 31, 21, 61	Mature WBC and platelets	Collagen and laminin
2-family	CD11a/18	HSC?, HPC, myeloid, and lymphoid precursors and blood cells	ICAM-1, ICAM-2, ICAM-3
	CD11b/18	HPC, myeloid, and lymphoid precursors and blood cells	ICAM-1, fibrinogen, iC3b
	CD11c/18	Myeloid and lymphoid precursors and blood cells	Fibrinogen
3-family	av3	Megakaryocytes and platelets	Fibrinogen, thrombospondin
7-family	47	Lymphoid progenitors and cells, mature myeloid cells	MadCAM and VCAM
CD44		HSC?, HPC, erythroid, myeloid, and lymphoid precursors and blood cells	Hyaluronate, fibronectin, collagen

Lectins	L-Selectin	HSC?, HPC, erythroid, myeloid, and lymphoid precursors and blood cells	s-Lex glycoproteins
	P-Selectin	HSC?, HPC, fibroblast, endothelial cells	s-Lex glycoproteins
	E-Selectin	Endothelial cells	s-Lex glycoproteins
Sialomucins	CD34	HSC, HPC, endothelial cells	Selectins
	CD43	HSC?, HPC, myeloid, and lymphoid precursors and blood cells	?, ICAM-1
	CD164	HSC?, HPC, myeloid, and lymphoid precursors and blood cells	?
Immunoglobulin superfamily	VCAM	Fibroblasts, endothelial cells	41, 47
	ICAMs	HSC?, HPC, mature myeloid, and lymphoid cells, fibroblasts, endothelial cells	CD11a/CD18, CD11b/CD18
	NCAM	Lymphoid cells, fibroblasts	N-CAM
	PECAM	HSC?, HPC, platelets, endothelium	PECAM

Figure 13-5 Affinity modulation of integrins. Integrins are transmembrane receptors consisting of an alpha and beta chain which connect the cytoskeleton of the cell with the extracellular milieu. Presence of an integrin on the cell does not mean that the receptor has functional activity. Signals from cytokines, other adhesion receptors, or oncogenes can affect the affinity (ability of the integrin to bind to its ligand) of integrin receptors (*inside-out signaling*).

Figure 13-6 Integrin-dependent regulation of adhesion and cell growth. Following engagement of integrins by their ligand, they laterally associate and translocate to focal adhesions/contact. Engagement of an integrin leads to the recruitment and activation of signal and adaptor molecules as well as structural proteins to such focal contacts/adhesion, including F-actin, Fak, c-SRC, Tensin, Paxillin, GRB-2, CRK, CBL, and PI3-K. These are then responsible for establishing firm adhesions as well as for initiating signal cascades that can affect cell survival and proliferation.

Figure 13-7 41-integrins are responsible for localization and homing of HSC. A number of in vivo studies have demonstrated an important role of the 41-integrin in the retention of stem and progenitor cells in the BM and for the homing of these cells to the BM microenvironment. [50] [118] [119] [120] [214] Infusion of anti-4 antibodies in mice or baboons results in the mobilization of long-term repopulating stem cells in the blood. Likewise, preincubation of murine, baboon, or human HSC with anti-4 antibodies prevents their homing and eventual engraftment in the BM microenvironment.

1-integrin-mediated interactions between HPC and fibronectin or other stromal components may also directly influence their survival, proliferation, and differentiation. For instance, co-culture of $CD34^+$ cells with fibronectin or engagement of 1-integrins on $CD34^+$ cells with blocking monoclonal antibodies under physiological cytokine conditions inhibits CFC proliferation. [56] [124] In contrast, engagement of 1-integrins by its ligand in the presence of high concentrations of cytokines promotes progenitor proliferation [52] while engagement of 1-integrins of HPC maintained under serum- and cytokine-starved conditions may delay apoptotic cell death. [122] [125] Thus, aside from anchoring progenitors in the BM, 1-integrins are also responsible for transferring growth modulatory signals. As has been seen in other biological systems, the final result of integrin-mediated signals depends on other external signals to which the progenitors are subjected.

Once progenitors differentiate, the expression pattern and functional status of 51- and 41-integrins changes. For instance, CFU-E adhere significantly better to fibronectin than more differentiated proerythroblasts. [126] [127] Further differentiation into erythroblasts and normoblasts is accompanied with a complete loss of adhesion to fibronectin and a concomitant loss of expression of the 51-integrin receptor at the reticulocyte stage. In contrast to more primitive HPC, erythroid differentiation may require interaction between progenitors and fibronectin. For instance, suspensions of MEL-14 erythroleukemic cells, but not fibronectin-adherent MEL 14 cells, fail to differentiate to the reticulocyte stage after induction with DMSO. [51] [58] [127] Likewise, differentiation of CFU-E to erythroblasts and erythrocytes requires interaction with fibronectin. [58] [128]

Similar observations have been made for B-lymphocyte maturation. [129] [130] Upon differentiation, B-cell precursors and mature B cells lose their capacity to adhere to fibroblasts. This loss is due to a decreased 41- and 51-integrin expression. Generation of B cells in stroma-dependent cultures requires close interaction between the immature progenitors and the stromal layer, as survival and proliferation of B-cell precursors depends on 41/VCAM and possibly fibronectin interactions. [59] [131]

Other members of the 1-integrin family, including 11, 21, 21, and 61, known to interact with collagen and laminin, are not expressed on normal $CD34^+$ cells. [85] [86] This underlies the observation that normal HPC fail to adhere to collagen or laminin. However, aberrant expression of 1, 2, 3, or 6 on transformed, leukemic $CD34^+$ cells in patients with acute or chronic leukemia may allow leukemic blasts to interact with collagen and/or laminin. This may be implicated in the ability of leukemic blasts to prematurely circulate in the blood.

2-Integrins

$CD34^+$ cells as well as their progeny express 2-integrins, known to interact with endothelial cell surface ligands, such as the intracellular adhesion molecules (ICAMs). [132] [133] As egress from and entry into the BM requires HSC to pass through endothelial barriers, one could hypothesize that 2-integrins play a role in the egress of HSC and HPC from the BM during mobilization or for their return to the BM following transplantation. In vitro, $CD34^+$ cells adhere to tumor necrosis factor- (TNF) activated stroma through the CD11b/CD18ICAM-1 ligand-receptor pair. [133] However, a number of in vivo observations indicate that 2-integrins may not play an important role in the interaction of HSC with the BM microenvironment. Patients with the leukocyte adhesion deficiency syndrome (LAD), [134] [135] in whom 2-integrins are defective, have no obvious defects in hematopoiesis. 2-dependent interactions seem not to be required for steady-state hematopoiesis nor for egress of HSC from the BM in the PB. Likewise, IV administration of anti-CD18 antibodies to baboons does not affect the number of peripheralized HPC although it increases the number of circulating granulocytes. [120] Finally, infusion of anti-CD11a antibodies in vivo in children undergoing mismatched transplantations improves rather than prevents engraftment. [136] Thus, 2-integrins may only be minimally important for the passage of HSC through the capillary sinusoids and for the ordered development of the hematopoietic process.

Other Integrins

Members of the 3- [137] [138] and 7- [139] integrin family can be found on maturing lymphoid and megakaryocytic precursors and blood cells. The av3-integrin on megakaryocytes and platelets allows interaction with fibrinogen, vitronectin, and thrombospondin. [137] [138] There is no evidence that av3 is expressed on $CD34^+$ HPC or HSC. The 47-integrin, known to interact with the addressins MadCAM [140] and VCAM, [141] is found on B-cell and T-cell precursors and mature lymphoid cells and plays an important role in the homing and recirculation of these cells. 47 is also found on mature myeloid cells, including monocytes and eosinophils, and mediates their interaction with the same ligands. [142] There is no evidence that 7-integrins are present on more primitive HPC and HSC.

CD44

Almost all $CD34^+$ cells, precursors, and blood cells express the CD44 receptor. [78] [79] [143] [144] CD44 is an integral membrane protein with an extracellular domain homologous to the cartilage link protein to which sialic acids and glycosaminoglycan side chains are attached. [145] Specificity of interaction depends on the structural heterogeneity of CD44. Ten putative exons can be inserted either alone or in tandem in the extracellular domain. [146] Use of alternative donor or acceptor splice sites within exons may result in an even greater degree of heterogeneity. As for integrins, mere presence of CD44 does not indicate that the receptor has functional significance. Stimulation with cytokines, phorbol esters (PMA) or with specific activating antibodies can modulate the affinity of CD44 for its ligand. [78] [147] [148] [149] The ligands for CD44 include hyaluronic acid, collagen, and fibronectin. CD44 is in part responsible for the adhesion of HPC to the BM microenvironment [77] [150] [151]

Incubation of stromal layers with hyaluronase [151] or BM cells with anti-CD44 antibodies [77] inhibit HPC adhesion to stroma. $CD34^+$ progenitors adhere to immobilized

hyaluronate [78] and fibronectin [150] through CD44. CD44-mediated interactions may also be important to regulate hematopoiesis. Studies in mouse [152] and human [77] [149] [153] have demonstrated that interference with CD44-mediated progenitor-stroma interactions alters hematopoiesis in long-term stroma-dependent marrow cultures. Although some studies have examined the signaling pathways affected by triggering the CD44 receptors, [154] [155] the mechanism(s) through which CD44 regulates hematopoiesis are not as well elucidated.

Selectins

Selectins have a long extracellular domain containing an amino-terminal Ca^{++} binding domain, an epidermal growth factor domain, and a series of consensus repeats like those in complement regulatory molecules. [156] Selectins also have a short membrane spanning domain and a short cytoplasmic tail. As in most adhesion receptors, the selectin cytoplasmic tail is responsible for transferring signals from the extracellular milieu to the cell. [157] The ligands for selectins are sialylated fucosylglucoconjugates present on endothelium, termed adressins. [158] [159] L-selectin is expressed on $CD34^+$ hematopoietic progenitors [160] whereas L-selectin and P-selectin are present on more mature myeloid and lymphoid cells. [158] [159] On neutrophils, selectins serve as adhesion receptors responsible for initial, reversible attachment to the endothelium. Tethering by selectins then allows integrin-mediated firm adhesion to the endothelium. The role of L-selectin present on $CD34^+$ cells is not known. Individuals lacking the fucosyl-transferase gene, responsible for fucosylation of selectin ligands, do not appear to have abnormal hematopoietic function. [161] Thus, if selectins are important for hematopoiesis, their function can be assumed by other adhesion receptors. Expression of L-selectin is upregulated on HPC found in the PB both under steady-state conditions or after mobilization with cytokines. [162] The implications of this for mobilization from and homing to the BM are, however, still unclear.

Sialomucins

As discussed previously, selectins recognize sialylated, fucosylated carbohydrate ligands of the sialyl Lewis X (sLex) type. [163] These carbohydrate ligands are presented by a class of adhesion molecules with mucin-like structure, termed sialomucins. Sialomucins present selectin carbohydrate ligands in a clustered, tissue-specific manner, increasing the avidity of selectin-ligand interactions. A number of sialomucins have been described on HPC; their function in progenitor-microenvironment interactions is not entirely clear.

CD34

CD34 is expressed on HSC and HPC as well as endothelial cells. [164] [165] Its role in hematopoiesis is not clear. Endothelial cell expressed CD34 serves as a ligand for selectins on lymphocytes and neutrophils. [165] [166] [167] CD34 on HPC may play a role in adhesion, although conflicting data is available. [168] [169] Ectopic expression of human CD34 in murine thymic precursors does not affect their growth but significantly increases their ability to adhere to BM stromal feeders. [168] It is unclear if this is CD34-mediated or mediated through another receptor, whose function is activated by the presence of CD34. In addition, several studies have shown that crosslinking of CD34 using antibodies that recognize sialoglycoprotease sensitive epitopes (e.g., QBEND10, ICH3, BI.3C5, MY10) but not other antibodies (9F2, 8G12) induces homotypic aggregation. CD34-mediated homotypic aggregation can be blocked by antibodies against 2-integrins but not by the anti-CD34-antibodies themselves. [170] Thus, some but not all isoforms of CD34 may be involved in HPC adhesion, albeit indirectly through activation of other cell surface adhesion receptors. Most in vitro HPC adhesion studies have used cells selected with anti-CD34 antibodies. No significant differences have been documented between adhesion of CFC and LTC-IC present in unselected mononuclear cells or in $CD34^+$ enriched cell populations [35] [36] [41] [54] [56] [77] [78] [85] [171] [172] This suggests that anti-CD34 antibodies do not usually increase or decrease adhesion of HPC to stromal feeders. Whether CD34-dependent interactions affect HSC or HPC growth is also not known. $CD34^{-/-}$ mice have decreased numbers of progenitors in the marrow. [173] This may indicate that the CD34 antigen is involved in progenitor growth.

CD43

Like CD34, CD43 is a transmembrane sialomucin expressed on the majority of HPC, including myeloid and lymphoid committed and primitive progenitors. [174] [175] Its role in adhesion of HPC to stroma is not well established. However, studies have indicated that it may be important for the regulation of proliferation/survival of committed myeloid progenitors, as crosslinking of CD43 induces apoptosis of CFC [174] [175]

CD164

CD164 has been identified on human $CD34^+$ cells and more mature blood cells. [176] Like the other sialomucins, CD164 is a transmembrane receptor found on HPC and possibly HSC as well as on a number of other cells. [176] [177] Its role in hematopoiesis still needs to be defined, although CD164 may play a role in the adhesion of HPC to stromal feeders and, like CD43, may impart growth inhibitory signals on $CD34^+$ progenitors. [178]

Lectins

Lectin receptors with galactosyl and mannosyl specificity present on HSC are believed to be important for the homing of murine HSC to the BM, but not to the spleen. [179] Addition of synthetic galactosyl and mannosyl probes but not fucosyl probes to murine long-term BM cultures results in disappearance of active hematopoiesis. [180] In contrast to the adhesion receptors described previously, lectin homing receptors may be the only adhesion receptors that are exclusively expressed on HSC. The receptor has not yet been cloned but is thought to consist of a 110 kDa glycoprotein containing approximately 5% N-linked carbohydrate which binds mannosyl and galactosyl residues with low affinity. [181]

The Immunoglobulin Superfamily

Several molecules result in cell-cell interaction and are therefore termed cell-adhesion molecules or CAMs. [182] [183] Almost all of these molecules are members of the immunoglobulin superfamily. This group of molecules receives its name as a result of the presence of large 90100 amino acid repeats which are also seen in immunoglobulins. All receptors within the immunoglobulin superfamily are expressed as plasma membrane spanning molecules, enabling them to affect growth and survival of cells and to affect the activation status of other adhesion receptors.

Vascular Cell Adhesion Molecule (VCAM)

VCAM is expressed on BM endothelial cells, [34] [41] Stro-1 positive BM stromal cells, [36] and dendritic cells. [184] Both myeloid and lymphoid progenitors and more mature cells can interact with VCAM through 41- or 47-integrins. [36] [141] [142] [185] VCAM is a transmembrane receptor. Engagement of VCAM, like engagement of adhesion receptors or cytokine receptors, may signal

stromal cells. [141] Coculture of myeloid and lymphoid progenitors with stromal feeders, to which they adhere chiefly through an 41-VCAM interaction, [126] [129] [130] [131] can induce changes in stromal cytokine production. Although VCAM may be in part responsible for this signaling, other receptors are also involved. [186]

Intercellular Cell Adhesion Molecule (ICAM)

ICAMs are expressed on mesenchymal and hematopoietic cells. [182] [187] [188] Three distinct ICAMs have been cloned. They have a high degree of homology, but their constitutive and induced expression profile differs. ICAM-1 is expressed on BM fibroblasts [189] and can be induced on endothelial cells. [133] It is also present on mature myeloid and lymphoid cells. [190] [191] ICAM-2 is significantly smaller than ICAM-1 and is constitutively expressed by endothelial cells. [188] ICAM-3 is expressed chiefly on cells of hematopoietic origin. [182] Like VCAM, ICAMs are transmembrane receptors capable of activating a number of signal pathways that may affect for instance

cytokine production or the activation state of other cell surface receptors. [149] [191] Although ICAM-1 and ICAM-3 are present on $CD34^+$ cells, their function on these cells is unclear.[192]

Neural Cell Adhesion Molecule (NCAM)

NCAM is present on stromal cells that support hematopoiesis.[193] Its function on stromal cells is unclear. NCAM is also present on mature T lymphocytes and NK cells,[194] but absent from myeloid or lymphoid precursors and progenitors. Abnormal expression of NCAM has been described on myeloid precursors of some patients with chronic myelogenous leukemia[195] and malignant lymphocytes of some patients with lymphoma.[196] Changes in NCAM expression in melanoma and colon carcinoma have been implicated in altered trafficking of the transformed cells. It has not been determined whether the presence of NCAM on HPC in some malignancies correlates with differences in tumor cell phenotype or homing to novel environments.

Platelet Endothelial Cell Adhesion Molecule (PECAM)

PECAM is expressed on endothelial cells, neutrophils, and platelets. [197] [198] Like NCAM, PECAM-mediated adhesion occurs through homotypic interactions. This is responsible for the maintenance of tight contacts between endothelial cells. Its extracellular domain can also bind to glycosaminoglycans, such as heparan sulfate. [199] It is expressed not only on mature hematopoietic cells but also on hematopoietic progenitors. [199] The role of PECAM in HPCstroma interactions is unknown. As has been shown for other receptors such as L-selectin[200] and CD44,[150] there is evidence that adhesive interactions through PECAM may modulate adhesion through 1-integrins.[201] Like L-selectin, PECAM is more highly expressed on $CD34^+$ cells mobilized in the blood by cytokines and chemotherapy. [201] [202] [203] The functional implications of this are unknown.

EGRESS FROM AND HOMING TO THE BONE MARROW

Egress under Physiological Conditions

Once hematopoietic progenitors have matured, they are released from the BM in the PB. The exact mechanism(s) underlying this process is not well understood (Fig. 13-8). Upon maturation, adhesion receptor expression and/or function changes. For instance, myeloid progenitors express functional 41- and 51-integrins which are thought to retain them in the BM microenvironment attached to VCAM and fibronectin. [36] [54] [85] [130]

Figure 13-8 Egress of mature hemopoietic elements from the BM microenvironment. Little is known concerning the adhesive interactions governing the egress of mature blood cells from the BM microenvironment. Maturing myeloid, [36] [54] [85] [130] [160] erythroid, [126] [127] [128] and B-lymphoid [129] [130] precursors and blood cells express a different array of adhesion receptors than more primitive progenitors. In addition, the functional status of these receptors changes upon maturation. It is unknown whether acquisition of novel, functional adhesion receptors that allow interaction with basement proteins and endothelial cells, such as 11, 21, 31 or 61-integrins, 2 integrins and selectins, or loss of functional receptors such as the 41-integrins, thought to be important for the localization of cells in the BM microenvironment, is responsible for the egress of mature blood elements from the BM. It is also unclear whether similar mechanisms underlie the spontaneous release of the small population of stem and progenitor cells than can be found in the circulation under steady-state conditions.

Even though these progenitors also express members of the 2-integrin family, [85] [86] the role of 2-integrins in attachment of HPC to stromal cells is less clear. [133] [134] [135] [136] Mature neutrophils, in contrast, express functional 2-integrins, which allows them to interact with endothelial expressed ligands, such as members from the ICAM family. [187] [188] In addition, mature neutrophils also express 1-integrins that interact with collagen and laminin, present in basal membranes, [80] [84] and functional L-selectin. [156] [157] [158] [159] Acquisition of functional receptors on more mature progeny that can bind to endothelial barriers may be a prerequisite for egress from the BM microenvironment. Likewise, immature erythroid progenitors express functional 41- and 51-integrins, [126] [127] [128] which allows them to interact with VCAM and fibronectin and may retain them in the BM. These receptors are nonfunctional on more differentiated erythroblasts and normoblasts. Mature red cells no longer express 41- or 51-integrins.

Under steady-state physiological conditions the majority of more primitive HPC and HSC are retained in the BM microenvironment. A small population of $CD34^+$ cells, CFC, LTC-IC and long-term repopulating HSC can, however, be found circulating in the PB, [203] a phenomenon that has been exploited for transplantation. Physiological stressors such as exercise, stress, and infections can increase the number of circulating HSC and HPC. [204] [205] [206] The mechanism underlying the spontaneous mobilization of this HSC/HPC pool is not understood. Some studies

suggest that expression of the 41-integrin on these circulating $CD34^+$ cells may be lower than what is seen on $CD34^+$ cells recovered from the BM. [207] This may contribute to the spontaneous release of these progenitors from the BM. Whether and how these HPC/HSC traffic spontaneously between the PB and BM is not known.

Mobilization of HSC

The observation that HSC and HPC can be mobilized in the blood by treatment with cytokines and/or chemotherapy has led to the now widespread use of HSC from PB rather than BM for transplantation. [201] [202] [208] [209] [210] [211] A number of studies have described differences in adhesion receptor expression and other characteristics between $CD34^+$ cells present in mobilized PB and steady-state BM. For instance, $CD34^+$ present in mobilized PB express less 4 and CD11a/CD18 and more PECAM-1, CD62L, and CD44 than their counterparts from steady-state BM. [162] [202] [203] [212] [213] Furthermore, significantly fewer HPC in mobilized PB are in S-phase than among their counterparts in the BM. [212] [213] Although such differences have been documented, it is still unclear how chemotherapy/cytokines induce these differences and how these differences may be related to or responsible for the mobilization phenomenon (Fig. 13-9). These questions have been addressed in part in studies in mice and baboons in which specific HPC-stromal interactions were targeted by infusion of anti-adhesion receptor antibodies (Fig. 13-7). These studies indicate that alterations in 41-VCAM interactions, [118] [120] [214] but not 41-fibronectin, [215] 51-GRGDSP, [214] or 2-integrin-mediated interactions [120] may play an important role in mobilization of HSC.

A number of questions still remain. For instance, are changes in adhesion receptor expression directly induced by the pharmacological concentrations of cytokines or chemotherapy themselves? If so, do these differences in expression of adhesion receptors induced by the mobilization regimen have functional implications for the subsequent in vivo behavior of HSC? Is mobilization induced by chemotherapy also in part due to alterations in the BMblood barrier as a result of chemotherapy-induced damage to endothelial cells? Are the phenotypic differences observed between steady-state BM $CD34^+$ cells and $CD34^+$ cells present in the PB following mobilization reflective of intrinsic differences in the characteristics of these two cell populations? If so, how does this impact on the short-term and long-term engraftment and differentiation potential of HSC?

Homing and Engraftment

Although stem cell transplantations have successfully been done for more than 30 years, it remains somewhat of a mystery how HSC infused intravenously home to the BM microenvironment (Fig. 13-9). As outlined previously, except perhaps for lectins, [179] [180] [181] no adhesion receptor has yet been identified that is exclusively present on HSC. In addition, no adhesive ligand, except perhaps for hemonectin, [87] [88] [89] has been identified that is exclusively present in the BM microenvironment. So, what underlies the specificity of the HSCBM microenvironment interaction? When infused intravenously, HSC lodge initially in the microvasculature of the lung and liver. [216] [217] [218] [219] From there they colonize the BM. To enter the BM space and provide permanent hematopoiesis, HSC must pass through sinusoids, migrate through the

Figure 13-9 Mechanisms of mobilization and homing. Under steady-state conditions, a small population of progenitor and stem cells can be found circulating in the blood. What the differences in adhesive characteristics are between the progenitors found spontaneously in the blood or present in the BM is unknown. Under conditions of stress, following infection, or following administration of cytokines, alone or in combination with chemotherapy, a significantly larger population of progenitor and stem cells is recovered from the circulation. [201] [202] [203] [204] [205] [206] [207] [208] [209] [210] In vivo animal studies have demonstrated an important role for the 41-integrin in mobilization of murine and baboon stem and progenitor cells in the blood. It is not clear whether decreased function or expression of this integrin is responsible for the mobilization of human hemopoietic progenitor and stem cells in the blood. It is also not clear whether changes in other adhesion receptors such as L-selectin or PECAM-1 contribute to the aberrant premature circulation of progenitors. Finally, it is also not known whether changes in the microenvironment itself caused by exposure to chemotherapy and/or cytokines contribute to the mobilization of cells that under steady-state conditions are found almost exclusively in the BM. Although transplantation of stem cells has been performed for over 30 years, little is known concerning mechanisms underlying their homing to the BM microenvironment. For engraftment to occur, multiple different steps are required: cells have to

diapedese (*transmigration*) through the endothelial lining of BM sinusoids, migrate through the extracellular space of the marrow (*migration*), and adhere to niches and start proliferation (*adhesion*). It is likely that this requires multiple sequential migration and adhesion events involving more than one adhesion receptor. Animal studies have shown an important role of 41-integrins in homing and engraftment.[118] [119] [120] [214] [215] The nature of the specificity that adhesive interactions provide to the homing of hemopoietic stem and progenitor cells to the BM but not to other organs is not known. It is possible that lectins with mannosyl and galactosyl specificity serve to guide progenitors to the bone marrow microenvironment. [87] [88] [89] As for mobilization, the role of L-selectins, PECAM-1 or 2-integrin, which allow interaction with endothelial cell expressed ligands such as ICAM-1, adressins and basement membrane proteins, in the transmigration process through the endothelial barrier is unknown. It is also not known whether 1-integrins or other receptors are required for migration through the BM space. Finally, there is evidence that exposure of the BM microenvironment to chemotherapy or radiation therapy alters the microenvironment. What role this has in homing and engraftment remains to be determined.

BM extracellular space, and attach to the so-called stem cell niches. Passage through endothelial barriers requires that cells attach to the endothelium. For neutrophil diapedesis through endothelium, this requires tethering of the neutrophil through selectins [157] [158] [159] [160] to endothelial expressed addressins, [163] followed by firm integrin-mediated attachment. Subsequently, integrins will allow migration through the endothelium and the BM extracellular space. In contrast to adhesion, cell migration depends on the coordinated establishment of adhesion at the leading edge of a cell and simultaneous release at the trailing edge. [220] The rate of migration depends on dynamic changes in the strength of cellligand interactions. [112] [113] [114] [115] Several factors dictate the strength of cellligand interactions including the number and affinity state[109] [110] [111] [171] [172] of the adhesion receptors and the strength of the adhesion receptorcytoskeletal interactions. This can be influenced by cytokine-mediated signals[109] [114] [171] [172] or signals originating from other adhesion receptors. [110] [150] [200] It therefore

follows that successful engraftment will depend not only on the presence of several different adhesion receptors, but also on the functional state of these receptors to accommodate both adhesive and migratory events. Finally, alterations in the microenvironment itself due to the preparative radiation therapy and/or chemotherapy may affect engraftment.[221] [222] [223]

In vivo studies in animal models have demonstrated that 41-VCAM interactions are important for successful engraftment (Fig. 13-7). Infusion of HSC preincubated with anti-4 integrin antibodies results in increased recovery of HSC from the PB and spleen and decreased recovery of HSC in the marrow during the first 24 days after transplantation.[118] Continued presence of the anti-4 antibodies will disallow engraftment. [55] [118] [120] [214] Further, 1$^{-/-}$ HSC cannot compete successfully with 1-expressing HSC for colonization of hematopoietic organs.[11] Thus, it is believed that 1-integrins play an important role in homing/engraftment as well as in mobilization. Decreased 1-integrin-mediated interactions are thought to be responsible for mobilization [118] [120] [207] and integrin-mediated adhesion and migration required for homing.[55] [118] [119] [120] [214] This leaves us with one question that still needs answers: How then do mobilized progenitors, which by definition adhere less, result in earlier engraftment, which requires adhesion, than steady-state marrow?

Lectins with mannosyl-galactosyl specificity expressed on HSC have also been implicated in homing to the BM. [179] In humans, more rapid engraftment has been reported when CD34^{+} cells expressing high levels of L-selectin are used as grafts. [162] It is not known whether this is due to the high density of L-selectin receptors which should allow better HSCendothelial interactions, or due to associated and also not yet understood differences between L-selectin ^{high} and L-selectin^{low} cells.

CONCLUSION

In embryonic and fetal life, hematopoiesis takes place mainly outside the BM microenvironment. However, at birth, HSC relocate to the BM which becomes almost the exclusive hematopoietic organ. The reasons underlying the migration from organ to organ are unclear. In adult life, the majority of immature progenitors resides in the BM, although small numbers of HSC and HPC can be found in the PB circulation. Certain external factors or stem cell intrinsic factors can affect the localization of HSC and HPC, resulting in the premature circulation of immature cells in the circulation, also termed mobilization. Although this process is now extensively being exploited in the transplant setting, we are only starting to decipher the reasons underlying this phenomenon.

Steady-state hematopoiesis, however, is concentrated in the BM microenvironment (Fig. 13-10). The interactions occurring in the BM microenvironment necessary for the ordered progression of the hematopoietic process under normal steady-state conditions are complex. It is clear that the majority of cells present in the BM, including fibroblasts, osteoblasts, and endothelial cells, not only serve to contain the HSC and HPC in the BM, but play an active role in the regulation of their growth. Fibroblasts, endothelial cells, and osteoblasts produce a number of cytokines. The local concentrations within the BM are unknown, but likely modest. Low concentrations of multiple cytokines are thought to cooperate in the induction of HSC/HPC proliferation, differentiation, or survival. In addition, several cytokines can be presented as membrane-expressed molecules and therefore be more active. Alternatively, they may be concentrated in and protected by ECM molecules such as GAGs. These GAGs may also activate the function of bound cytokines. In addition to GAGs, the stromal cells produce a number of other ECM components. These ECM components combined with other adhesive ligands that are expressed on the surface of stromal cells serve as anchoring places for HSC and HPC. They are likely

Figure 13-10 Interactions in the BM microenvironment that govern hemopoiesis. Steady-state hemopoiesis takes place in the BM microenvironment. Interactions occurring in the BM microenvironment necessary for the ordered progression of hemopoiesis are complex. Stromal cells (A) produce a number of growth-promoting (B) and growth inhibitory (C) cytokines in low concentrations which cooperate in the induction of progenitor proliferation, differentiation, or survival. The activity of cytokines may be greater when the cytokine is present in a membrane expressed form or because it is concentrated in, protected by, or activated by ECM molecules, such as GAGs (D). Production of these cytokines may be regulated by the presence of hemopoietic cells themselves (1). Stromal cells produce ECM components (D) which combined with other adhesive ligands that are expressed on the surface of stromal cells serve as anchoring places for progenitors (2). Adhesive interactions themselves between progenitors and stromal cell- or ECM-expressed adhesive ligands can profoundly affect the growth and survival of progenitors. Every interaction, whether initiated by cytokines, by engagement of an adhesion receptor, or by interaction between progenitor cells and other hemopoietic cells (3), will affect subsequent interactions and signaling events, further increasing the complexity of the network of signals between stem cells, progenitors, mature blood elements, and stromal cells.

responsible for the as yet unexplained observation that HSC and HPC specifically home to the BM. In addition, engagement of specialized transmembrane adhesion receptors on HSC and HPC by these adhesive ligands may, like cytokine receptor engagement, profoundly affect the fate of HSC and HPC. Adhesion may alter the response of progenitors to cytokines as well as directly stimulate signal pathways that will influence progenitor proliferation, differentiation, and survival. Finally, one needs to keep in mind that every interaction, whether initiated by cytokines or an adhesive event, will affect subsequent interactions and signal events, further complicating the network of signals between HSC, HPC, mature blood elements, and the mesenchymal stromal cells. Although significant progress has been made over the last several decades in our understanding of the players in this complex set of interactions, an equally large number of questions remain to be answered.

Chapter 14 - Growth Factors, Cytokines, and the Control of Hematopoiesis

Grover C. Bagby Jr.
Michael C. Heinrich

INTRODUCTION

The bone marrow, like all mammalian organ systems, has an exquisite capacity to respond to environmental stimuli in ways that protect the host from the attendant hazards of such stimuli. The responsiveness of each lineage of the hematopoietic system results from coordinated increases in the production and functional activity of appropriate hematopoietic cell types, without expansion of irrelevant ones. A mountaineer at high altitude, for instance, will develop a specific expansion of the erythroid bone marrow and subsequent erythrocytosis, but the bone marrow will not increase production of neutrophils, monocytes, eosinophils, mast cells, T lymphocytes, or B lymphocytes. This response is highly focused on protecting the host from the particular threat: hypoxia. Not surprisingly, the hematopoietic response evolves directly from a hypoxia-induced increase in circulating levels of erythropoietin (EPO), a glycoprotein hormone that specifically stimulates the proliferation and differentiation of cells of the erythroid lineage. [1] [2] EPO is but one of about 30 well-characterized hematopoietic growth factors that regulate the production and activity of blood cells. Additional ones will likely be characterized at an increasing pace. With each new discovery it becomes increasingly clear that all lineage-specific and multilineage responses of hematopoietic cells in the steady state and under conditions of environmental stress depend almost exclusively on the availability of proteins in hematopoietic tissues that stimulate or inhibit the production, differentiation, or traffic of mature blood cells or their progenitors. It is also true that certain redundancies exist. Some of these are sufficient to induce growth and differentiation but not necessary to maintain hematopoiesis in the steady state. Others are necessary, and

their deficiency in an animal results in serious hematopoietic deficiencies of one kind or another. The anemia associated with the erythropoietin deficiency of renal failure, and its responsiveness to treatment with recombinant human EPO, [3] is a clear indication that EPO is necessary for optimal red cell production in mammals.

Fully characterized recombinant hematopoietic growth factors and the genes encoding their receptors have recently become available, enabling hundreds of laboratories to test exactly how a given change in the environment incites expression of the right genes at the right time. In vitro experiments in many laboratories using genomic and cDNA clones, in vitro transcripts, and recombinant proteins have uncovered new levels of complexity and provided new explanations of how biologic organisms work. Studies using mice carrying germline disruptions of such genes have been informative and, in some cases, even surprising. In general, however, results of studies on knockout mice, as well as results of therapeutic trials, confirm the hematopoietic responses predicted by scientists using in vitro techniques. Today, there is an excitingly clear picture of a complex and highly efficient intercellular molecular communication system. That system is the subject of this chapter.

Despite the advances of the past decade, research on hematopoietic growth factors and related cytokines is still in its infancy. Each year additional factors are identified and new activities are found for existing ones. Organizing growth factors and interleukins in chronologic order is not useful because the order of discovery doesnt appoint a factor to a functional category. Accordingly, we will present the hematopoietic growth factors by assigning them to one of three groups: those that function largely in support of a specific lineage, those with an effect on multipotential hematopoietic cells (so-called early-acting factors), and those that regulate hematopoiesis indirectly by inducing the expression of direct-acting growth factor genes in auxiliary cells.

This organizational approach also attempts to illustrate how hematopoietic growth factors actually work. There is some arbitrariness to our choice of big picture assignments. Granulocyte-macrophage colony-stimulating factor (GM-CSF), for example, is assigned to the granulopoietic lineage, not because it has no influence on the behavior of nongranulopoietic cells, but because the biologically dominant effect of the factor, when administered to humans, is on the production and activation state of phagocytic leukocytes. GM-CSF does have effects on progenitors of other lineages. M-CSF is similarly assigned because a major manifestation of M-CSF deficiency is monocytopenia. [4] Certain recurrent themes will become evident that permit a more holistic view of hematopoietic control; these themes are outlined in Table 14-1 . It will become obvious that most of the hematopoietic growth factors do more than one thing and can act on more than one cell type. Consequently, because the lineage assignments we have made are sometimes arbitrary (e.g., interleukin [IL]-5 is in the granulopoiesis section, but has clear effects on lymphoid cells too), we have listed many of the heterogeneous biologic activities of these proteins in Table 14-2 . Some factors influence the production of blood cells directly by binding to receptors on progenitor cells; others influence the process indirectly by binding to receptors on auxiliary cells, which then respond by releasing growth factors; some do both. Some factors can induce cell division; others only permit the survival of progenitors of a given lineage. Some factors, particularly lineage-specific ones, influence the replication or survival of primitive cells and also activate the function of the terminally differentiated cells of that lineage. Some factors act synergistically with other cytokines. Auxiliary cells and progenitor cells can cross-talk and exhibit signal amplification circuits. Finally, the reader will find that hematopoietic growth factors and their receptors also have a number of structural elements in common. Each of these principles will be emphasized later.

TABLE 14-1 -- Repetitive Themes in Hematopoietic Growth Factor Biology

1.Hematopoietic growth and differentiation factors (HGFs), even ones with a high degree of lineage specificity, have multiple biologic activities (reviewed in Table 14-2).
2.HGFs influencing the growth or differentiation of hematopoietic progenitor cells can do so directly or indirectly. For this reason, the role of any given factor in regulating hematopoiesis cannot be fully assessed by simply challenging progenitor cells in vitro or administering the recombinant HGF to an animal. Loss of function analyses (i.e., in HGF-deficient [knockout] mice) are also essential.
3.Cytokines that induce proliferation of hematopoietic precursor cells often have the capacity to enhance the functional activity of the terminally differentiated progeny of these precursor cells.
4.Most lineage-specific factors inhibit programmed cell death of the progenitors of the specific lineage they influence.
5.HGFs commonly act synergistically with other cytokines (examples reviewed in Table 14-3).
6.Hematopoietic regulatory cytokines are organized in a highly complex ordered network.
7.The cytokine network exhibits many signal amplification circuits.

8.HGF receptors share important structural features.

9.Structural abnormalities of HGFs or their receptors may result in clinically significant abnormalities of hematopoiesis.

10.Certain HGFs are of substantial value in clinical practice.

HEMATOPOIETIC GROWTH FACTOR RECEPTORS

The structures of hematopoietic growth factors and cytokines are quite variable. The receptors for these factors are less so. There are at least six receptor superfamilies involved in controlling the behavior of hematopoietic cells. Most receptors for hematopoietic growth factors are members of the type I cytokine receptor family.

The Hematopoietic Growth Factor Receptor Superfamily (Type I Cytokine Receptors)

The receptors for the majority of hematopoietic growth and differentiation factors are members of this family. The receptors do not possess intrinsic kinase activity but lead to phosphorylation of cellular substrates by serving as docking sites for adaptor molecules that do have kinase activity. The characterization of receptors for many of the growth factors has permitted the identification of a group that includes receptors for leukemia-inhibitory factor (LIF), IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-13, IL-18, GM-CSF, G-CSF, EPO, prolactin, growth hormone, ciliary neurotrophic factor, and c-mpl. [5] [6] As shown in Figure 14-1 , there are a number of repetitive structural and functional themes in this unique integral membrane protein superfamily, including:

1. Four cysteine residues in the extracellular domain
2. The sequence WSXWS in the ligand binding extracellular domain that may optimize the tertiary structure of the receptors [7]
3. A capacity for enhanced binding and/or signal transduction when expressed as a heterodimer or homodimer
4. Lack of a known catalytic domain in the cytoplasmic portion of the molecule
5. The presence of fibronectin type III domains [8] in the extracellular regions.

Apart from these shared homologous domains, there is minimal sequence homology among these receptors, and their cytoplasmic domains are immensely variable in size. Nonetheless, these homologies are likely of substantial functional importance and also provide clues to the evolution of this family. For

TABLE 14-2 -- Heterogeneous Biologic Activities of the Hematopoietic Growth Factors and Interleukins

Factor	Bioactivities
Erythropoietic factors	
EPO	Stimulates clonal growth of CFU-E and a subset of BFU-E
	Suppresses apoptosis in erythroid progenitor cells
	Induces release of reticulocytes from marrow
	Induces globin synthesis in erythroid precursor cells
	Stimulates murine megakaryocyte colony growth and terminal maturation in vitro but has no apparent thrombopoietic activity in vivo
	Mitogen for neonatal rat cardiac myocytes
SF	Promotes the proliferation and differentiation of pre-CFCs
	Acts synergistically with IL-3, GM-CSF, and EPO to support clonal growth of CFU-GEMM, BFU-E, and CFU-Mk
	Enhances hematopoietic colony growth in cultures of marrow cells from patients with congenital marrow failure states
	Stimulates the proliferation and differentiation of mast cell precursors
	Chemotactic for mast cells
	Independently stimulates mast cell degranulation and enhances IgE-dependent mediator release from mast cells
	Stimulates expansion of committed progenitor cell compartment in vivo
	Stimulates mast cell hyperplasia in vivo
	Supports melanocyte development and migration
	Supports gametogenesis
IGF-1 (hematopoietic effects of)	Induces erythroid colony formation at high doses in absence of EPO
	Induces DNA synthesis in erythroid progenitor cells
	Anti-apoptotic effects in erythroid progenitor cells and IL-3-dependent cells
Granulopoietic factors	

GM-CSF	Stimulates multilineage hematopoietic progenitor cells
	Stimulates BFU-E growth
	Stimulates granulocyte, macrophage, and eosinophil colony growth
	Stimulates functional activity of eosinophils, neutrophils, monocytes, and macrophages
	Induces IL-1 gene expression in neutrophils and peripheral blood mononuclear leukocytes
	Costimulates T-cell proliferation with IL-2
	Induces or co-induces TNF- gene expression with IFN- in monocytes
	Stimulates proliferation of myeloid leukemic cells
	Stimulates growth of certain nonhematopoietic cancer cells in vitro
	Induces migration and proliferation of vascular endothelial cells in vitro
G-CSF	Stimulates growth of progenitor cells committed to the neutrophil lineage
	Stimulates neutrophil maturation of certain leukemic cells
	Activates phagocytic function of mature neutrophils
	Stimulates quiescent pluripotent hematopoietic progenitor cells to enter G_1-S phase
	Stimulates mobilization of stem cells and progenitors from hematopoietic niches into peripheral blood
	Maintenance of steady-state neutrophil numbers
M-CSF	Induces monocyte/macrophage growth and differentiation
	Activates macrophage phagocytic function
	Activates macrophage secretory function
	Maintenance of steady-state monocyte levels
	Maintenance of steady-state osteoclast numbers
IL-5	Stimulates eosinophil production and activation
	Activates cytotoxic T cells
	Induces or co-induces immunoglobulin secretion
Megakaryocytopoietic factors	
TPO	Stimulates in vitro growth of CFU-Mk, megakaryocytes, and platelets
	Stimulates clonal growth of individual CD34+CD38 cells
	Synergizes with SF, IL-3, and FL
	In single CD34+CD38+ cells, TPO synergized with SF and IL-3 but not Flt3 ligand; no increase in colony growth nor colony size is seen when TPO is added to multicytokine combinations
	Increases megakaryocyte ploidy in vitro and in vivo
	Enhances the proliferation and differentiation of yolk-sac erythroid lineage precursors
	Stimulates production of PDGF, platelet factor 4, and -thromboglobulin from megakaryocytes
	Supports continuous growth of cytokine-dependent human leukemic cell lines
	Stimulates adhesion of hematopoietic progenitor cells to fibronectin by activation of VLA-4 and VLA-5
	No direct effect on platelet aggregation but primes the response to ADP, epinephrine, and thrombin; also increases platelet release of ATP and thromboxane B_2 production and platelet expression of CD62 (P-selectin)
	Stimulates proliferation of c-mpl-positive AML blasts
IL-11	Stimulates proliferation of murine plasmacytoma and hybridoma cell lines
	Stimulates CD4+ T-cell-dependent proliferation of antigen-specific plaque-forming B cells
	Shortens the duration of G_0 of primitive hematopoietic progenitor cells
	Acts synergistically with IL-3 or SF to stimulate the clonal growth of erythroid (BFU-E and CFU-E) and primitive megakaryocytic (BFU-Mk) progenitors
	Increases the ploidy of cultured megakaryocytes
	Increases peripheral platelet and neutrophil counts
	Increases the numbers and cycling activity of committed progenitor cells
	Hastens hematopoietic recovery following cytotoxic chemotherapy, ionizing radiation, and bone marrow transplantation
	Acts as an autocrine growth factor for certain megakaryoblastic cell lines
	Stimulates hepatic acute-phase reactant production
	Suppresses adipogenesis in pre-adipocytes
Lymphopoietic factors	
IL-7	Induces clonal growth of pre-B cells
	Stimulates growth of pre-T cells
	Stimulates growth of CLL, acute leukemia, and Sézary cells
	Enhances IL-3 and GM-CSF production by activated T cells
	Induces expression of IL-6, IL-1, TNF-, and IL-8 in peripheral blood monocytes
IL-2	Induces proliferation and activation of T lymphocytes
	Induces proliferation and activation of B lymphocytes
	Induces proliferation and activation of NK cells
	Induces expression of IL-1 in monocytes and macrophages
	Co-induces (with IL-1) expression of interferon- in T cells

IL-15	Induces proliferation and activation of T cells
	Synergizes with IL-12 to induce proliferation and activation of T cells
	Induces proliferation and activation of B cells
	Induces proliferation and activation of NK cells
	IL-15 (as a single factor) induces differentiation of CD3-CD56+ NK cells from CD34+ HPC
	SF synergizes with IL-15 to increase expansion without altering differentiation state of expanded NK cells
	Induces antitumor responses in animal models in which the tumor is also responsive to IL-2 treatment
	Induces angiogenesis in vivo
	Stimulates accumulation of contractile proteins in muscle fibers of differentiated myocytes
	Stimulates the expansion of PBMC anti-HIV-specific CTL
	Stimulates mast cell proliferation
IL-4	Induces proliferation of activated B cells
	Inhibits IL-2-stimulated proliferation of B cells
	Co-induces immunoglobulin secretion and isotype switching
	Induces proliferation of T cells
	Induces proliferation of fibroblasts
	Co-induces (with PMA) IL-2 receptor expression in T cells
	Inhibits induction and function of LAK cells
	Inhibits IL-1 release
	Induces expression of M-CSF and G-CSF genes in monocytes
IL-10	Inhibits monocyte/macrophage-dependent synthesis of T_H 1-derived cytokines (IL-2, IFN-, lymphotoxin) in humans and mice
	Inhibits monocyte/macrophage-dependent synthesis of T_H 2-type (IL-3, IL-4, IL-5) and NK-derived cytokines (IFN- and TNF-)
	Inhibits monocyte/macrophage-dependent T-cell proliferation
	Inhibits proliferation of and IL-2 production by purified T cells
	Acts as co-stimulator of B-cell proliferation
	Represses constitutive and IFN-induced MHC class II antigen expression on mononuclear phagocytes
	Inhibits the production of IL-1, TNF-, IL-6, IL-8, G-CSF, GM-CSF, and IL-10 by mononuclear phagocytes
	Inhibits the production of reactive oxygen species and NO by mononuclear phagocytes
IL-12	Induces the differentiation of naïve T-helper cells into T_H 1 cells
	Augments functional activity of NK cells
	Acts synergistically with TNF- to stimulate IFN- production by NK cells
	Induces LAK activity in NK cells
IL-13	Shares many biologic activities with IL-4 but is not known to influence T lymphocytes
	Enhances expression of lymphocyte antigens in B cells
	Enhances B-cell proliferation
	Promotes isotype switching to permit IgE expression
	Enhances production of IgG4 and IgM
	Inhibits IFN- production by NK cells exposed to IL-2
	Induces VCAM-1 in endothelial cells but not E-selectin or ICAM-1
IL-14	Stimulates the proliferation of anti-m or *Staphylococcus aureus* Cowan-treated B cells
	Synergizes with IL-2 to stimulate proliferation of anti-m B cells
	Stimulates proliferation of pre-B-cell ALL, hairy cell leukemia cells, prolymphocytic leukemia, and CLL cells
	Inhibits secretion of immunoglobulin by activated B cells
	Autocrine growth factor for some B-cell lymphoma cell lines
IL-16	Chemotactic for CD4+ T cells, monocytes, eosinophils at nanomolar concentrations
	Growth factor for CD4+ T cells
	Induces functional IL-2 receptors on CD4+ T cells
	Inhibits HIV-1 replication in vitro
	Inhibits proliferation in mixed lymphocyte reactions
Multipotential factors (early-acting factors)	
IL-3	Stimulates multilineage colony growth
	Stimulates growth of primitive hematopoietic cell lines with multilineage potential
	Stimulates BFU-E proliferation in vitro
	Stimulates proliferation of murine CFU-S
	Induces B-lymphocyte differentiation
	Co-stimulates T-cell proliferation with IL-2
	Induces macrophages to express M-CSF (this may explain reports that IL-3 induces clonal growth of pulmonary alveolar macrophages)
	Stimulates growth of myeloid leukemic cells in vitro
	Primes hapten-specific contact hypersensitivity responses

FL	Stimulates proliferation of some AML and ALL blasts
	Stimulates proliferation and differentiation of dendritic cells in vitro and in vivo
	Addition of FL to multicytokine combinations augments retroviral transduction of HPC
	Stimulates antitumor responses in murine models of syngeneic cancer
	Mobilizes peripheral blood stem cells weakly as a single agent but markedly synergizes with G-CSF
	Weak colony-stimulating activity as single agent but synergizes with IL-3, GM-CSF, SF, IL-11, IL-6, G-CSF, IL-7, and multicytokine combinations
IL-9	Stimulates clonal growth of BFU-E in combination with EPO
	Stimulates clonal growth of fetal CFU-Mix and CFU-GM
	Augments IL-3-induced growth of murine bone marrow-derived mast cells
	Stimulates proliferation of preactivated PBMC-derived T-cell lines
IL-6	Synergistic with IL-3 in CFU-GEMM colony growth
	Synergistic with M-CSF in macrophage colony growth and with GM-CSF in granulocyte colony growth
	Synergistic with IL-4 in inducing T-cell proliferation, immunoglobulin secretion, and hematopoietic colony formation
	Synergistic with IL-2 and IL-1 in inducing T-cell proliferation
	Co-induces differentiation of B cells
	Induces terminal differentiation of myeloid leukemic cell lines
	Induces neuronal differentiation in certain pheochromocytoma cell lines
	Co-induces cytotoxic T cells in vitro
	Stimulates plasmacytoma growth
	Induces acute-phase responses in vivo
	Induces acute-phase protein synthesis in hepatocytes
	Stimulates megakaryocytopoiesis in vitro and in vivo
Indirect acting factors	
IL-1	Induces expression of GM-CSF, G-CSF, IL-6, and IL-1 in fibroblasts, endothelial cells, keratinocytes, and thymic epithelial cells
	Induces proliferation of preactivated T cells
	Induces acute-phase protein synthesis
	Induces fever and sleep in vivo
	Stimulates release of ACTH
	Promotes transendothelial passage of neutrophils
	Synergizes with IL-3 in stimulating proliferation in primitive hematopoietic progenitor cells in vitro
	Stimulates prostaglandin E production in fibroblasts, monocytes, and neutrophils
TNF-	Modulates EGF receptor expression
	Induces expression of GM-CSF, G-CSF, IL-6, and IL-1 in fibroblasts and endothelial cells
	Enhances mitogen-induced GM-CSF expression in T cells
	Induces release of GM-CSF and M-CSF in vivo
	Inhibits virus replication synergistically with interferons
	Stimulates prostaglandin E production in fibroblasts and neutrophils
	Enhances parasite and tumor cell cytotoxicity of eosinophils and macrophages
	Inhibits proliferation of hematopoietic progenitor cells, lymphocytes, and certain leukemia cell lines in vitro
	Mediates the hemodynamic and toxic effects of endotoxin
	Induces expression of IL-6 in fibroblasts
	Induces expression of adhesion molecules in myeloid cells
	Activates phagocytic function of neutrophils
	Induces expression of IL-8
	Increases production of plasminogen-activator inhibitor in vascular endothelial cells
	Suppresses transcription of the thrombomodulin gene in endothelial cells
	Modulates EGF receptor expression
	Promotes transendothelial passage of neutrophils
	Activates NF B trans-activating protein in lymphoid cells
IL-17	Induces secretion of IL-6, IL-8, PGE_2 , and G-CSF from stromal cells
	Synergizes with TNF- and IFN- to induce stromal cell production of GM-CSF and IL-1
	Up-regulates ICAM-1 expression by fibroblasts
IL-18	Induces IFN- production from T cells, B cells, NK cells, peripheral blood mononuclear cells
	Synergizes with IL-12 to enhance production of IFN- by activated T cells
	Induces GM-CSF production from T cells
	Inhibits production of osteoclast-like multinucleated giant cells in cocultures of osteoblasts and hematopoietic cells
	Augments NK activity in human and mouse PBMC
	Inhibits IL-10 production by T cells
	Enhances *fas*-mediated cytotoxicity of murine T_H 1 but not T_H 0 or T_H 2 cells
The chemokine IL-8	

IL-8	Modulates neutrophil production in the steady state (potential feedback inhibitor of that lineage)
	Stimulates neutrophil chemotaxis, exocytosis, respiratory burst, shape change, adhesion molecule expression, and complement receptor type 1 expression
	Stimulates T-lymphocyte chemotaxis
	Stimulates basophil chemotaxis, histamine release, and leukotriene release
	Stimulates endothelial cell chemotaxis and proliferation
	Stimulates angiogenesis

Figure 14-1 Class I cytokine receptors. This family includes receptors for EPO, TPO, GM-CSF, G-CSF, LIF, prolactin, growth hormone, and interleukins 2, 3, 4, 5, 6, 7, 9, 11, 12, and 15. Shown here are the two components of the high-affinity IL-6 receptor, IL-6R and gp130. Regions of homology are found both in the extracellular and cytoplasmic regions. The conserved extracellular regions of class I receptors contain fibronectin type III regions (rectangles), which contain the ligand binding pockets, four conserved cysteine residues (double lines), and a Trp-Ser-any-Trp-Ser (WSXWS) box (black bar), each of which is essential for receptor function, although in the unique case of the erythropoietin receptor, recent saturation mutagenesis of the WSXWS box revealed no mutation that interdicted signaling. Cytoplasmic domains contain conserved residues as well in regions termed box-1 and box-2 located close to the membrane. Three members of the family, gp130, G-CSFR, and LIFR, also have a third homologous region, box-3. Binding of the ligand causes chain homodimerization or heterodimerization and tyrosine phosphorylation of cellular proteins. Because the members of this family lack their own kinase domains, they transduce signals by associating with cytoplasmic protein tyrosine kinases, often members of the Jak family. Jak molecules phosphorylate sites in the receptor complex that create docking sites for latent cytoplasmic molecules known as signal transducers and activators of transcription (STAT) molecules, which themselves become phosphorylated, dimerize, and move to the nucleus to serve as transcription factors that drive the biologic response. The JAK/STAT pathway is reviewed in Figure 14-5 . Almost all the hematopoietic growth factor receptors are type I cytokine family members. Exceptions include c- *kit* (CD117), the receptor for Steel factor, and M-CSFR, the receptor encoded by c-fms for M-CSF, both of which are receptor tyrosine kinases, and the chemokine IL-8, the receptor for which, located on chromosome 2q35, is a member of the seven transmembrane domain G protein-coupled receptor superfamily.

example, fibronectin type III domains are shared with several cell-adhesion molecules, suggesting that cytokine receptors evolved from ancestors whose products functioned largely to facilitate cellular adhesion to both substrates and other cells.

Another shared feature of many hematopoietic growth factor receptors is their ability to transduce signals that prevent programmed cell death (apoptosis), in some cases without inducing mitogenic signals. This is particularly true of the lineage-specific factors, EPO, M-CSF, IL-5, and IL-7, each of which is reviewed following. [9] [10] [11] [12] [13] Apoptosis is characterized by chromatin condensation at the edge of the nuclear envelope, followed by convolution and fragmentation of the nucleus in terminally differentiated cells or in undifferentiated cells. This process occurs after mild injury, during the aging process of terminally differentiated cells, with factor deprivation, or after exposure to mitotic inhibitors. [14] An emerging view holds that some factors largely transduce anti-apoptotic signals but that additional mitogenic factors are required for a full growth and differentiative response from progenitor cell populations. For example, Krantzs group [15] found that EPO greatly reduced apoptosis in highly purified colony-forming units-erythroid (CFU-E). They also reported that steel factor (SF) and insulin-like growth factor type 1 (IGF-1) served as mitogenic and differentiation-inducing factors, respectively. An alternative view is that the capacity of a given receptor complex to transduce a set of biologic signals depends on discrete functional domains in one or more of the receptor chains. In support of this notion is the observation that discrete sets of signaling pathways can be disrupted by mutagenesis without interdicting all functions of the receptor. [16]

The receptors for many hematopoietic growth and differentiation factors share peptide subunits with other receptors. This kind of swapping is seen in granulopoiesis and lymphopoiesis. For example, IL-5, GM-CSF, and IL-3 have unique low-affinity (-chain) receptors, but they share the same chain, [17] [18] and association of the two chains results in the formation of a specific high-affinity subunit capable of effective signal transduction (Fig. 14-2A). The role of each chain in signal transduction is now being carefully examined. For example, distinct regions within the cytoplasmic domain of the GM-CSFR chain have been identified. [19] A membrane proximal region is necessary for the chain to activate c- *myc* gene expression, while a more distal region, between residues 626 and 763, is required for activation of *ras*, raf-1, and mitogen-activated protein (MAP) kinase and induction of c- *fos* and c-*jun*. [19] Different shared subunits have also been identified for high-affinity complexes that serve as receptors for LIF, IL-6, ciliary neurotrophic factor (CNTF), IL-11, and oncostatin M [20] [21] (Fig. 14-2B). In this case, gp130 functions as a signal transducing component of the IL-6R/gp130, and CNTFR/LIFR/IL-11R:gp130 complexes. Given its capacity to function with so many chains, it isnt surprising that germline disruption of gp130 is incompatible with life. [22] The details of the stimulus-response coupling pathways are not yet known,

Figure 14-2 Receptor chain swapping. Three groups of hematopoietic growth factor receptors share some of their heteromeric receptor chains. **(A)** The heterodimeric IL-3, IL-5, and GM-CSF receptors each have unique chains, and each of them associate with a common beta chain (c) that increases the binding affinity of the complex when compared to the chains alone. **(B)** IL-6 interacts with a complex consisting of an 80 kDa binding subunit (IL-6R) and a second 130 kDa chain (gp130) that is also shared as the second partner with LIFR, OSMR, CNTFR (not shown), and the IL-11R chains. Each of the specific chains serves as a low-affinity binding subunit, the binding affinity of which increases substantially when in a complex with gp130. **(C)** Receptor complexes for many of the factors that influence lymphopoiesis are shared as well; indeed, there are six receptors that are structured this way: IL-2, IL-15, IL-4, IL-7, IL-9, and IL-13. The heterotrimeric IL-2 and IL-15 receptors share two chains.

Figure 14-3 Production of soluble growth factor receptor molecules. Differential splicing of functional (interacting of signaling) domains from high-molecular-weight RNA can result in the production of soluble receptor molecules. This is true for the ligand for c- *kit* (shown here) and the receptors for IL-4, IL-5, IL-7, G-CSF, EPO, and GM-CSF receptors. In some cases the soluble receptors can act as competitive inhibitors for ligand binding. In this figure, the soluble Steel factor molecule in reaction #1 derives from proteolysis of membrane-bound Steel factor at a major cleavage site (MCS). A slightly smaller protein derives from a transcript from which exon 6 has been spliced. This membrane protein has only an inducible cleavage site (ICS) and the released protein is slightly smaller. In the exon 6 + form, the exon6 encoded sequences are represented as a black box within the extracellular domain. The third soluble form is that which is synthesized naturally by mice with the Steel-Dickie mutation. These mutant molecules are not integrated into the membrane, and although the soluble form shows some biologic activity in vitro, these mice are anemic and have bone marrow failure.

but it has been reported that gp130 is phosphorylated on tyrosine residues on stimulation of cells with the ligand. [23] The most highly shared receptor system occurs in lymphopoiesis, in which six different cytokines, IL-2, 4, 7, 9, 13, and 15, share certain subunits and in which IL-2 and IL-15 share two common subunits (Fig. 14-2C). In many instances, soluble forms of the receptor are released, sometimes resulting from translation of differentially spliced mRNA (Fig. 14-3). Soluble forms have been described for IL-4, IL-5, IL-7, G-CSF, c- *kit*, EPO, and GM-CSF receptors.[24] [25] [26] [27] [28] Although the biologic meaning of this phenomenon is not yet fully understood, the soluble forms may act as competitive binding proteins for the ligand and, as is clearly the case for the soluble IL-4 receptor, [28] serve as natural in vivo antagonists for specific cytokines.

Receptors with Cytoplasmic Tyrosine Kinase Domains

Amino acid sequence analysis has permitted the categorization of three subclasses of a tyrosine kinase receptor family. Subclass 1 includes the neu/HER2 proto-oncogene and epidermal growth factor, subclass 2 the insulin and IGF-1 receptors, and type 3 the receptors for M-CSF, SF, Flt3/Flk2 ligand (FL), and platelet-derived growth factor (PDGF). C- *kit*, the flt3 gene, and c-*fms* are genes that encode three related hematopoietic growth factor receptors, the ligands for which are SF, FL, and M-CSF, respectively. Along with PDGF (A and B) receptors, they constitute a subclass of receptor tyrosine kinases with similar topologies. [29] All receptors with tyrosine kinase activity possess large glycosylated extracellular domains, a single transmembrane spanning region, and a cytoplasmic domain that contains one or more tyrosine kinase catalytic sites (Fig. 14-4). These three receptors will be discussed in greater detail following.

Type II Cytokine Receptors

The class II subgroup of cytokine receptors includes the interferon receptors and the receptors for tissue factor and IL-10. Each has an extracellular domain containing a region resembling the fibronectin III domain found in the type I receptors, [30] which may serve as the ligand binding site. While the signaling pathways for IL-10 are not fully elucidated, the interferon signaling pathways have been widely studied and are outlined in Figure 14-5 .

Protein Serine-Threonine Kinase Receptors

The 30 members of the transforming growth factor- (TGF-) superfamily bind to their receptors as homodimers. Although no member of this family of ligands is uniquely hematopoietic, certain of them have profound inhibitory effects on many lineages of cells and function to suppress growth and differentiation signals evolving from auxiliary cells as well. There are three TGF- receptors, a 53 kDa type I receptor (TbRI), a 75 kDa type II receptor (TbRII), and a type III receptor of 200 kDa. Binding of TGF- requires TbRII. Once binding occurs, TbRI associates with the complex and signals are transduced by activation of the serine-threonine kinase cytoplasmic domains of the receptor chains, which, in turn, phosphorylate cytoplasmic signaling molecules known as Smad molecules on serines. [31] For example, after ligation of TGF- receptors, Smad2 and Smad3 are phosphorylated and form heteromeric complexes with Smad4. Phosphorylated Ser465 and Ser467 in Smad2 seems to represent a recognition site for Smad4 binding. [32] As is the case with the signal transducer and activator of transcription (STAT) molecules, phosphorylated Smad complexes translocate to the nucleus, where they act as either inducers or repressors of transcription. The major influence of TGF- on hematopoietic cells is as a mitotic inhibitor. This cytokine governs the activity of cyclinCdk complexes by inhibiting Cdk4; inducing p27/Kip1, an inhibitor of cyclinCdk complexes; inducing p21/Cip1/Waf1, an inhibitor of cyclinECdk2 complexes; inducing p16INK4a and p15INK4b expression, inhibitors of Cdks 4 and 6; and repressing the phosphorylation of the retinoblastoma protein (Fig. 14-6). The importance of the TGF receptor family as braking factors for a variety of cells is clarified by the capacity of inactivated receptors to permit autonomous growth and the frequency

Figure 14-4 The receptor for Steel factor, c-*kit*, is a type III (PDGF-like) cytoplasmic tyrosine kinase receptor. **(A)** The extracellular domain contains no fibronectin-like modules or WSXWS motif, but has five immunoglobulin-like domains (oval-shaped). There are at least six potential sites (indicated with asterisks) for tyrosine phosphorylation in the cytoplasmic region, each of which may serve as a docking site for adaptor proteins containings SH2 domains. **(B)** When growth factors (in this case, Steel factor, SF) bind to this class of receptors, receptor chains dimer-ize. Dimerization induces autotransphosphorylation, which can enhance the catalytic activity of the tyrosine kinase domain. The phosphorylated sites can then serve as docking sites for a variety of adaptor proteins that serve as signal transducers. These adaptor proteins contain SH2 domains that specifically associate with proteins on phosphotyrosines and adjacent carboxyterminal residues. Other adaptor proteins include those with PTB domains (not shown) that differ structurally from SH2 motifs and bind to proteins on phosphotyrosines and adjacent amino terminal residues.

with which these receptors or their downstream targets are inactivated by somatic mutation in a variety of cancers. [33] [34] [35]

Chemokine Receptors

The chemokine receptor family includes receptors for a few factors relevant to blood cell production; IL-8 and mip-1a, for example, both serve, at least in part, as braking factors, slowing progenitor cell proliferation. The chemokine receptors are seven transmembrane-spanning G protein-linked receptors [36] that are divided into three families: or CXC, or CC, and or C.[37] The families are classified based on the variability in cysteine residues. The initial scientific investigation of these molecules focused to a substantial degree on their capacity to influence chemotaxis, but it has become clear that some of these factors (e.g., IL-8 and mip) may serve as feedback inhibitors of hematopoiesis. [38] [39]

Tumor Necrosis Factor Receptor (TNFR) Family

The TNFR family includes TNFR1, TNFR2, *fas*, CD40, nerve growth factor (NGF) receptor, CD27, CD30, and OX40. Each has one or more distinct biologic effects. Both TNF- and *fas* have the capacity to suppress hematopoiesis profoundly by triggering programmed cell death in progenitor cells. [40] [41] [42] [43] *Fas*-mediated apoptosis of stem cells and progenitors may represent a major pathophysiologic mechanism of bone marrow failure in idiopathic aplastic anemia [44] and certain inherited marrow

Figure 14-5 Class II subgroup of cytokine receptors. Shown here is the ligand-binding induced assembly of the IFN- receptor. Each member of this group has an extracellular domain containing a region resembling the fibronectin III domain found in the type I receptors, [30] which may serve as the ligand binding site. **(A)** Binding of the IFN molecule to the IFNR chain, with which jak-1 (Janus kinase 1) is associated, causes the association of with chains of the receptor (the chain is associated with jak-2). **(B)** The Jak-1/Jak-2 complex (dark oval with asterisk) phosphorylates tyrosines on the chain, one of which become a docking site for stat1. When stat1 docks, it too is phosphorylated on tyrosines, dissociates from the chain, and forms a homodimer, which is then transported to the nucleus to bind to activating sequences (GAS elements).

Figure 14-6 The TGF- receptor. There are three TGF- receptors, a 53 kDa type I receptor (TR-I), a 75 kDa type II receptor (TRII), and a type III receptor of 200 kDa (not shown). Binding of TGF- requires TRII. Once binding occurs, TRI associates with the complex and signals are transduced by activation of the serine-threonine kinase cytoplasmic domains (STK) of the receptor chains, which, in turn, phosphorylate cytoplasmic signaling molecules known as Smad molecules on serines. After ligation of TGF- receptors, Smad2 and Smad3 are phosphorylated and form heteromeric complexes with Smad4. Phosphorylated Ser[465] and Ser[467] in Smad2 represent a recognition site for Smad4 binding. Phosphorylated Smad complexes translocate to the nucleus, where they act as either inducers or repressors of transcription. The major influence of TGF- on hematopoietic cells is as a mitotic inhibitor.

Figure 14-7 The TNF-R family. The TNF-R family includes TNFRI, TNFR2, *fas*, CD40, NGF receptor, CD27, CD30, and OX40. Both TNF- and *fas* have the capacity to suppress hematopoiesis profoundly by triggering programmed cell death in progenitor cells. **(A)** *Fas*-mediated apoptosis in lymphoid cells involves the trimeric *fas* complex (containing a cysteine-rich region [CRR] in the extracellular domain and a death domain in the cytoplasmic region) and a set of signaling molecules, many of which are proenzymes. **(B)** After binding of the FasL, the death domains of *fas* and FADD associate, prompting the association of the DED domains of pro-caspase 8 (FLICE) and FADD. Association with FADD induces autocatalytic cleavage of procaspase 8 to produce caspase 8. Caspase 8 cleaves pro-caspase 1 to caspase 1 (IL-1 converting enzyme, ICE) which in turn cleaves pro-caspase 3 to caspase 3 (CPP32). Caspase 3 is responsible for proteolysis of a wide variety of structural cellular proteins, including lamin and poly-ADP ribose polymerase (PARP). **(C)** The TNF receptor can also cause the activation of caspase 8 and apoptosis, but because, in some cells, the death domain (DD) of TNFR1 also associates with TRADD, which activates TRAF2 (which in turn activates NF-B), TNF does not always induce apoptosis on its own (NF-B activation generally protects cells from apoptosis). **(D)** Ligation of more than one TNFR member may influence the apoptosis/survival response substantially. For example, in some cells exposed to TNF, simultaneous ligation of CD30 induces TRAF2 degradation, whic then disconnects the TNF receptor ann NF-B activation. Consequently, when cells are simultaneously stimulated through the TNFRI and CD30 molecules, the cell will undergo apoptosis.

failure states, including Fanconi anemia. [45] Unlike *fas*, TNFRs transduce complex signals via multiple pathways that in some cells induce programmed cell death and in others induce mesenchymal cells to secrete hematopoietic growth factors. The majority of these receptors contain Cys-rich repeats in the extracellular domains and have cytoplasmic portions containing 80 amino acid death domains required for transducing apoptotic signals and for NF B activation. Both TNFR1 and 2 have death domains, as does *fas*. Ligation of more than one TNFR member may influence the type of response substantially. For example, in some cells exposed to TNF, NF B is induced through the activation of TNF receptor associated factor 2 (TRAF2), and the cell survives (NF B protects some cells from TNF-induced programmed cell death[46]). However, ligation of CD30 induces TRAF2 degradation, which then disconnects the TNF receptor and NF B activation. Consequently, when cells are simultaneously stimulated through the TNFR1 and CD30 molecules, the cell will undergo apoptosis. [47] The TNF and *fas* receptors are shown in Figure 14-7 .

HEMATOPOIETIC CONTROL

Erythropoiesis

Factors involved in effective production of red cells include IL-3, [48] [49] [50] IL-9, [51] [52] IL-11, [53] SF, IGF-1,[54] thrombopoietin (TPO),[55] and GM-CSF,[49] [56] [57] which induce proliferation of primitive erythroid progenitors (Fig. 14-8). Other factors might play a role as well, including angiotensin II. [58] Few of these factors induce erythroid cellular proliferation in the absence of the lineage specific factor EPO, which is the pivotal humoral factor that functions to prevent programmed cell death of the most committed erythroid progenitor cells and their progeny.[15] However, steel factor (SF) and IGF-1 have also emerged as unique regulators of erythropoiesis. [59] These three factors will be reviewed here.

Erythropoietin

Erythropoietin (EPO), an 18 kDa protein [60] (3439 kDa when fully glycosylated [61]) encoded by a gene on the long arm of chromosome

Figure 14-8 Humoral control of erythropoiesis. A number of growth factors control multipotential progenitor cell replication and primitive erythroid progenitor cell growth (BFU-E), but the two most lineage-specific differentiation and survival factors known are erythropoietin and IGF-1. While these two factors are sufficient for erythroid differentiation, the necessary factors seem to be Steel factor and EPO, because deficiencies of either of these factor results in anemia.

7,[62] is expressed largely by cells in the liver in embryonic life, [63] [64] cells of the kidney[65] and, to a lesser extent, liver[63] in adult life, and certain hepatoma cell lines. [66] The production of EPO is induced by hypoxia, a mechanism that may involve the initial activation [66] [67] of heme proteins that stimulate EPO gene expression.[67] EPO stimulates growth, survival (in part by inducing expression of Bcl-x(L) [68]) and differentiation[61] of erythroid progenitor cells and stimulates proliferation and RNA synthesis in more well-differentiated erythroid precursors as well. [69] The EPO receptor (EPO-R) genes, located on murine chromosome 9 and human chromosome 19, encode a classic type I cytokine receptor (Fig. 14-1) that utilizes the Janus activated kinase (JAK)/STAT pathway for signal transduction. [70] Specifically, tyrosine phosphorylation of the EPO-R creates docking sites for SH2 domain(s) in signaling molecules that include STAT2, STAT5, protein tyrosine phosphatases SH-PTP1 and SH-PTP2, and phosphoinositide 3-kinase (PI3 kinase). [71] [72] Subsequent association of EPO-R with SHP-1 terminates signaling.[73] Other signaling pathways, including those involving protein kinase C family members, may also be involved, and the

linkage of these pathways with the JAK/STAT pathway is unclear. [68]

The effects of EPO on progenitor cell proliferation are optimal in the presence of SF, and its effects on terminal erythroid differentiation are optimized by IGF-1. [15] EPO has been reported to stimulate various levels of megakaryocytopoiesis in vitro and platelet production in experimental animals, [74] and high-affinity EPO receptors have been reported in rodent megakaryocytes.[75] However, the physiologic relevance of these observations is unclear because the effect is not seen in serum-free cultures[76] or in cultures of cells enriched for progenitors [77] (and relatively free, therefore, of accessory cells). Moreover, in clinical trials, recombinant human EPO has shown no consistent effects on platelet counts.

EPO was the first hematopoietic growth factor to be identified experimentally, and the use of the recombinant protein has been shown to be effective in the management of anemia associated with renal failure.[3] [78] [79] Other clinical uses of EPO have also emerged. Patients with myelodysplasia, [70] [80] those with progressive anemia in the setting of cancer therapy,[81] and patients who refuse blood transfusions[82] are candidates for erythropoietin therapy, generally given subcutaneously, three times weekly, at 100 units/kg/dose. Patients with acquired immune deficiency syndrome (AIDS) with endogenous erythropoietin levels <500 IU/L need fewer red cell transfusions, have higher hemoglobin levels, and report an improvement in quality of life when treated with EPO. [83]

EPO

Chromosome: 7q21
Gene product: 3439 kDa
Produced by: kidney in adult, liver during development, hepatoma lines
Induced by: hypoxia
Receptor: class I cytokine receptor encoded by a single gene on human chromosome 19p13.3-p13.2 utilizing JAK2 and STAT5 for signaling
Bioactivity: see Table 14-2
Deficiency: anemia in humans; homozygous deletion of EPO or EPO-R in mice is lethal, resulting in embryonic anemia and death

Steel Factor

Steel factor (SF) is a highly glycosylated 2836 kDa protein encoded by a gene on the long arm of human chromosome 12q22. [84] The widely expressed gene gives rise, via alternate splicing, to two mRNA species, one containing exon 6 (exon 6+) and a second in which exon 6 has been spliced out (exon 6). [85] [86] The ratio of exon 6+ to exon 6 transcripts is approximately 3:1.[87] SF expression has been demonstrated in fibroblasts, bone marrow stromal (fibroblast-like) cells, vascular endothelial cells, and Sertoli cells, as well as in various embryonic tissues. [87] [88] [89] No inductive cytokines for SF expression have yet been convincingly documented, [87] although TGF- represses SF expression.[90] SF is elaborated in both membrane-bound and soluble forms, the latter resulting from protease cleavage of the exon 6+ transcript-encoded protein at an exon 6-encoded consensus cleavage site. [86] The membrane-bound and soluble forms of SF display equivalent bioactivity in

clonogenic assays in vitro.[85] However, the particular relevance of the membrane-bound form to normal hematopoiesis, gametogenesis, and pigmentation is clearly illustrated by mice homozygous for the *Sl*d allele, in which a genomic deletion gives rise to a soluble protein lacking the anchoring transmembrane and cytoplasmic domains.[86] [91] Although the soluble protein retains full biologic activity in vitro, these animals are anemic, sterile, and nonpigmented. [86] [91]

Identification of SF and its receptor, the c-*kit* gene product, resulted from years of study of mice carrying mutations in the dominant white spotting (*W*) or Steel (*Sl*) loci.[92] [93] These animals display defects of varying severity in hematopoiesis (macrocytic anemia and reduced numbers of stem cells and tissue mast cells), skin pigmentation, and fertility. Reciprocal marrow transplantation studies with *W, Sl*, and normal mice clearly demonstrated that the hematopoietic defect in *W* mice resides in progenitor cells, while the defect in *Sl* animals was in the hematopoietic microenvironment.[94] [95] Subsequently, *W* mutations were localized to the c-*kit* gene, which encodes a transmembrane protein of the type III tyrosine kinase class of growth factor receptors. [96] [97] In the hematopoietic system, the 145 kDa c-*kit* protein, encoded by a gene on human chromosome 4q11-34[98] [99] and murine 5D-E, is expressed on pre-colony-forming cell (CFC) progenitor cells, [100] CFCs,[101] mast cells and their precursors,[102] interstitial cells of the gastrointestinal tract, [103] and leukemic cell lines. Heterozygous defects in the human c-*kit* gene have been associated with several cases of the piebald trait, a dominantly inherited depigmented state reminiscent of the murine *W* trait,[104] [105] and certain mutations of c-*kit* have been associated with autonomous c-*kit* expression and malignant transformation in mesenchymal tumors of the gut.[103]

SF

Also known as: stem cell factor, kit ligand, mast cell growth factor
Chromosome: 12q22-24
Gene product: approximately 40 kDa
Produced by: fibroblasts, endothelial cells, bone marrow stromal cells, Sertoli cells, hepatocytes, various embryonic tissues
Induced by: expression is constitutive
Receptor: c-kit protein (CD117), a receptor tyrosine kinase encoded by a gene on human chromosome 4q11-q13 (the piebald locus) and murine chromosome 5 (the white spotting locus), certain mutations of which are oncogenic
Bioactivity: see Table 14-2
Deficiency: anemia, mast cell deficiency, reduced stem cell numbers (mice)

SF promotes the proliferation and differentiation of the most primitive hematopoietic progenitor cells (pre-CFCs) into committed progenitor cells (multipotential colony-forming units [CFU-GEMM] erythroid burst-forming units [BFU-E], granulocyte-macrophage colony-forming units [CFU-GM], and megakaryocyte colony-forming units [CFU-Mk].[100] [106] [107] Whether SF promotes self-renewal of pre-CFCs is controversial. While SF has no independent colony-stimulating activity, it acts synergistically with IL-3, GM-CSF, and erythropoietin to promote CFU-GEMM-, BFU-E-, and CFU-Mk-derived colony growth. [108] [109] [110] [111] SF promotes the survival, proliferation, and differentiation of mast cell precursors. [102] [112] In addition, SF is chemotactic for mast cells[113] and enhances the release of mast cell mediators such as histamine.[114] [115] SF administration in vivo induces a marked expansion in the compartment of committed hematopoietic progenitor cells and striking mast cell hyperplasia.[116] [117] Outside the hematopoietic system, appropriate developmentally regulated SF expression is necessary for normal melanocyte development and migration and gametogenesis.[118] Because SF has an influence on primitive hematopoietic cells of other lineages and on multipotential cells, [119] [120] some categorize this factor as an early-acting hematopoietic growth factor. In our

view, however, persuasive evidence that SF plays an essential role in erythropoiesis derives from the anemia that attends SF deficiency in mice, the capacity of SF to enhance DNA synthesis in isolated erythroid progenitor cells, [15] and findings that EPO-R and c-*kit* are co-expressed in erythroid progenitor cells [121] and that these receptors interact in erythroid cells. [122] [123]

Insulin-like Growth Factor

Insulin-like growth factors 1 and 2 [124] (located on chromosomes 12q22-q24.1 and 11p15, respectively [125]) are small peptide (70 and 67 residues, respectively) homologs of proinsulin.[126] Because the role of IGF-2 in hematopoietic cells is unclear, we will focus only on IGF-1. The major site of IGF-1 synthesis is the liver. IGF-1 has multiple effects on a wide variety of cells, and its receptor (IGF-1R) is expressed ubiquitously. The bioactivity of IGF-1 is largely mitogenic and is known to regulate the growth of both normal and malignant cells. [127] [128] IGF-1 knockout mice exhibit extreme embryonic and postnatal growth retardation, neurologic defects, and prenatal mortality.[129] Growth failure and neurologic deficits have also been described in humans with IGF-1 deficiency, [130] but complete IGF-1 deficiency is likely lethal. IGF-1R is a receptor protein kinase encoded by a 100 kb gene on human chromosome 15q26. [131] It is synthesized as a single precursor that dimerizes and is processed into alpha and beta subunits that form a heterotetrameric receptor complex. [132] The activated receptor phosphorylates the Crk adaptor protein, which associates with the guanine releasing proteins Sos and C3G in the *ras* signaling pathway.[133]

First noted by Sawada et al.,[134] the erythropoietic activity of IGF-1 was confirmed by Axelrads group,[135] using serum-free cultures of erythroid progenitor cells from adult human peripheral blood. They discovered that erythroid progenitor cells formed erythroid colonies in the presence of IGF-1, even in the absence of EPO. Moreover, the activities of EPO and IGF-1 overlapped because combinations of these factors resulted in clonal growth that was less than the sum of colony formation with each factor alone.[135] The same group also demonstrated that progenitors from polycythemia vera patients were two orders of magnitude more sensitive to IGF-1 than were normal cells,[136] and that the effect was transduced through the IGF-1R.[137] The effects of IGF-1 are both mitogenic and anti-apoptotic in erythroid progenitor cells,[54] and in IL-3-responsive cell lines as well. [138]

Insulin-like growth factors form complexes with IGF-binding proteins (IGFBP), a group of at least eight important regulatory proteins that bind to IGF-1 and/or IGF-2 differentially and influence their mitogenic activity. [139] Interestingly, certain IGFBP molecules stimulate erythroid colony growth, and plasma IGFBP levels seems to be at least four-fold higher in polycythemia vera patients than in normal volunteers. [140] For these reasons, and notwithstanding the myriad effects of IGF-1 and IGF-2 on many types of cells, we include IGF-1 as an important erythropoietic factor that shares biologic activities with both SF and EPO.

IGF-1

Also known as: somatomedin C
Chromosomal location: human chromosomes 12q22-q24.1
Gene product: 70 amino acids
Produced by: liver
Induced by: growth hormone
Receptor: receptor protein kinase family member, synthesized as single precursor (151 kDa, encoded by a gene on human chromosome 15q25-q26[124]) and processed into (80 kDa) and (70 kDa) subunits that form heterotetramers
Bioactivity: see Table 14-2
Deficiency: embryonic and postnatal growth retardation, neurologic deficits; [129] [130] homozygous inactivating IGF-1 lesions are lethal

Granulopoiesis

Neutrophils

As shown in Figure 14-9 , the production of neutrophilic leukocytes involves a variety of different factors, including GM-CSF, IL-3, M-CSF, and G-CSF. Other factors, including IL-11, SF, and FL, stimulate or enhance neutrophil clonal growth in vitro. Studies on G-CSF knockout mice indicate that the most significant lineage-specific factor for neutrophils is G-CSF. [141]

Granulocyte-Macrophage Colony-Stimulating Factor

GM-CSF is a glycoprotein of 1435 kDa [142] [143] (the molecular weight varies with the degree of glycosylation) encoded

Figure 14-9 Humoral control of granulopoiesis. A number of growth factors control multipotential progenitor cell replication, but production of specific phagocytic lineages depends on specific factors. G-CSF is necessary for neutrophil production. M-CSF is necessary for monocyte production. IL-5 is a strong growth and survival factor for eosinophils. The production of basophils and mast cells is less well understood, but the mast cell deficiency found in Steel factor-deficient mice suggests that Steel factor is a necessary factor for this process, which is also influenced by IL-3 and TGF-.

Figure 14-10 Lineage-specific growth and survival factors influence the functional activity of terminally differentiated cells of the same lineage. GM-CSF activates the functional activity of most phagocytes, including neutrophils. In fact, in GM-CSF-deficient mice, the major morbidity results from the absence of normal phagocytic function rather than a failure to produce phagocytes. M-CSF and IL-5 activate the function of monocytes and macrophages and eosinophils, respectively.

by a gene on the long arm of chromosome 5.[144] GM-CSF stimulates clonal growth of CFU-GEMM, BFU-E, CFU-Mk, CFU-GM, and eosinophil colony-forming cells (CFU-Eo),[145] [146] [147] [148] [149] [150] although some evidence suggests that the effect of GM-CSF on neutrophil colony growth is indirect [151] [152] (e.g., GM-CSF induces auxiliary cells to release neutrophil-specific growth factors [151]). GM-CSF activates the functional activity of most phagocytes, including neutrophils, [153] macrophages,[154] [155] [156] [157] and eosinophils,[158] [159] [160] demonstrating a recurrent theme in hematopoietic control; namely, that lineage-specific growth factors frequently activate the function of the terminally differentiated progeny (Fig. 14-10). In fact, in GM-CSF-deficient mice, the major morbidity results from the absence of normal phagocytic function rather than a failure to produce phagocytes.

The GM-CSF receptor is a type I cytokine receptor with a 44 kDa (CD116) chain and a 96 kDa (CDw131) chain. The receptor is expressed by mononuclear phagocytes, neutrophils, endothelial cells, eosinophils, and fibroblasts. The chain is shared with the chains for IL-3 and IL-5 (Fig. 14-2). The association of the and chains increases the binding affinity of the chain from about 5 nM to about 100 pM. [161]

GM-CSF administered therapeutically enhances the production of neutrophils, monocytes, and eosinophils. [162] In vitro, GM-CSF induces neutrophil, macrophage, and eosinophil colony growth, but there is no strict evidence that GM-CSF alone induces neutrophil differentiation in the absence of G-CSF. [151] In fact, the degree of neutropenia in G-CSF knockout mice is comparable to that of mice nullizygous for both G-CSF and GM-CSF. [163] The observation that white blood cell production in germ-free GM-CSF knockout mice is not perturbed indicates that GM-CSF has no role in steady-state white cell production. [164] Thus, it is likely that neutrophilic leukocytosis in recipients of GM-CSF reflects the capacity of GM-CSF to induce expression of other factors, especially IL-1, [165] [166] which induces expression of G-CSF[167] [168] by a variety of cell types. We have suspected that the putative effects of GM-CSF on eosinophil colony growth might also be indirect through the induction of IL-5 gene expression in auxiliary cells; while this may be the case, it appears as though GM-CSF is capable of activating Jak2 and prolonging the survival of eosinophils.[169] GM-CSF is used in clinical practice, and the indications for its use will be discussed following.

GM-CSF

Chromosome: 5q31.1
Gene product: 1828 kDa
Produced by: mast cells, T lymphocytes, endothelial cells, fibroblasts, and thymic epithelial cells
Induced by: TNF-, IL-1, Lipopolysaccharide (LPS), phorbol esters, calcium ionophore A23187
Receptor: heterodimer composed of a GM-CSF-specific subunit (CD116 on chromosomes Xp22.32, Yp11.3 in the pseudo-autosomal regions) and a subunit (CDw131 on chromosome 22q12.2-13.1) shared with high-affinity IL-3 and IL-5 receptors
Bioactivity: see Table 14-2
Deficiency: susceptibility to infections by obligate intracellular organisms, pulmonary lesions resembling pulmonary alveolar proteinosis

Granulocyte Colony-Stimulating Factor

G-CSF, an 18 kDa protein encoded by a gene on the long arm of chromosome 17,[170] stimulates the proliferation of granulocyte progenitor cells [171] [172] [173] [174] [175] and activates neutrophil function.[176] [177] [178] G-CSF is produced by a wide variety of mesenchymal cells under the influence of inductive factors such as IL-1, [168] endotoxin, [179] and TNF.[180] The 115 kDa G-CSF receptor is a member of the type I cytokine receptor family with one N-terminal immunoglobulin domain, [181] four fibronectin domains in the extracellular region, and a WSXWS motif necessary for signal transduction. [27] [181] [182] There are four forms of the receptor, which result from alternative splicing.[27] Ligand binding results in activation of Jak1, Tyk2, and Jak2 and phosphorylation of stat1, stat3, and stat5. [183] Jak1 is critical for stat activation and Jak2 and Tyk2 are dispensable.[184] Although some have argued that G-CSF has a proliferative influence on pluripotent stem cells, [185] [186] G-CSF-deficient mice show selective chronic neutropenia and have neutrophil counts only 20% those of control animals. [163] G-CSF receptor mutations may cause certain severe congenital neutropenic syndromes,[187] dogs that develop neutralizing antibodies to G-CSF develop neutropenia, [188] and the use of G-CSF in clinical situations has one dominant effect: the induction of neutrophil production and release. Consequently, this gene encodes the clearest neutrophilic granulopoietin yet discovered. Recombinant human G-CSF is widely used in clinical practice, and the indications for its use will be reviewed following.

G-CSF
Chromosome: 17q11.2-q12 *Gene product:* 18 kDa *Produced by:* monocytes, macrophages, endothelial cells, fibroblasts *Induced by:* IL-1, TNF-, endotoxin *Receptor:* G-CSFR (CD114 on chromosome 1p35-34.3), 89.5 kDa polypeptides, four forms each differing only at the C-terminus, probably generated by alternative splicing *Bioactivity:* see Table 14-2 *Deficiency:* neutropenia and failure to develop a neutrophilic leukocytosis response to infections

Granulopoietic Factors in Clinical Practice

G-CSF is one of the most widely utilized hematopoietic growth factors in practice today. G-CSF is approved for mobilizing stem cell traffic in the peripheral blood to support peripheral blood progenitor cell transplantation; the proof of this principle is the successful transduction of pluripotent stem cells obtained using

G-CSF mobilization by retroviral vectors.[189] When peripheral blood is compared with marrow as a source of stem cells for autologous transplantation, it has been shown to result in fewer red cell transfusions, earlier platelet recovery, earlier neutrophil recovery, and earlier discharge from the hospital. [190] G-CSF also reduces the duration of neutropenia after allogeneic and autologous transplantation [191] and is approved for use in patients with severe chronic neutropenia to prevent infectious complications. However, it is most commonly used today to reduce the morbidity of myelosuppressive chemotherapy.

The principal goal of granulopoietin therapies (either G-CSF or GM-CSF) in patients with bone marrow failure is to increase the leukocyte counts to reduce the risk of infection. Most clinical studies using either of these factors after administration of cytoreductive chemotherapy or radiation clearly demonstrate that while the neutrophil counts do decline on time, they recover faster. [192] In addition, neutrophil recovery is also faster (2 vs. 4 days) in patients treated for neutropenic fever with G-CSF.[193] While one would expect, intuitively, that this would reduce the number of patients at risk for infectious complications, studies from the Mayo Clinic, [193] Indiana University,[194] and St. Jude Childrens Research Hospital[195] did not demonstrate this. In other words, such therapy did not reduce the rate of hospitalization for febrile episodes, prolong survival, reduce the number of culture-positive infections, or reduce the costs of supportive care, whether given preemptively [194] [195] or to treat neutropenic fever. The role of either G-CSF or GM-CSF in the management of these common clinical conditions is still uncertain. It is very important to assess the potential for granulopoietin therapies to decrease the risk of infection per se, not to decrease the risk of neutropenic fevers. It is clear that the window of neutropenia is reliably more narrow in the treated population. Thus, it is equally clear, as shown by Crawford et al., [192] that the number of neutropenic fevers will be reduced even if the number of fevers is not. G-CSF is also used in neutropenic patients with AIDS, an issue that also requires further study. [196] [197] [198] G-CSF, when combined with EPO, is effective in the management of selected patients with myelodysplastic syndromes.[199]

GM-CSF has also been used effectively in bone marrow failure states, [162] [200] and to accelerate recovery after marrow transplantation[201] [202] and cytotoxic chemotherapy.[203] It is approved for use in the bone marrow transplant setting and to shorten the duration of drug-induced neutropenia in elderly patients with acute nonlymphocytic leukemia. The use of GM-CSF in the management of patients receiving cytotoxic antineoplastic therapy is associated with the same uncertainties as with G-CSF. The GM-CSF knockout mouse does not have neutropenia, so it is likely that GM-CSF has an indirect effect on the production of neutrophils and eosinophils. It is likely that GM-CSF accomplishes this by inducing IL-1 release, [204] which probably accounts for the incidence of myalgia, flushing, and fever in some patients who receive this agent.

Since most acute myeloid leukemic clones are responsive to GM-CSF, some investigators have hypothesized that the administration of GM-CSF either immediately before or during cytotoxic inductive chemotherapy might put more leukemic cells into cycle and enhance the susceptibility of the leukemic cells to chemotherapeutic agents. Results from a large European trial involving 253 young and middle-aged patients with newly diagnosed acute myeloid leukemia indicated no improvement in outcome.[205] GM-CSF has also been used in patients with AIDS. Although it reduces the incidence and severity of neutropenia in patients treated with interferon and zidovudine,[196] it should be used with antiretroviral therapy [196] because of its potential to enhance the human immunodeficiency virus-1 (HIV-1) load [206] in some patients by inducing proviral gene transcription in latently infected cells.

In summary, in selected cases, G-CSF or GM-CSF treatment is of substantial value and, no doubt, saves lives. However, considering the attendant costs of growth factor therapy, the routine use of G-CSF or GM-CSF to prevent infection in neutropenic cancer patients cannot be encouraged outside the setting of well-designed controlled clinical trials. For nontransplant patients not participating in such studies, it seems most rational to us to utilize these granulopoietic factors in patients undergoing cytotoxic chemotherapy only if the dose-intensity of the chemotherapeutic agents has a demonstrated impact on overall survival (e.g., Hodgkins disease, germ cell neoplasms) and one of the following three criteria apply:

1. The patient has developed, in prior rounds of therapy, potentially life-threatening complications of neutropenia (e.g., documented bacterial infection)
2. The potential for prolonged myelosuppression is high (e.g., HIV-1-seropositive patients [207] [208])
3. The patient has persistent neutropenia between cycles. [209]

Monocytes/Macrophages

Mononuclear phagocytes are phylogenetically the most primitive elements of the blood, being closely related functionally to the phagocytic coloemocytes of invertebrates.[210] [211] In vitro, both GM-CSF and M-CSF regulate survival and function of monocytes, but only M-CSF-deficient mice have monocytopenia and macrophage deficiency.[4] [212] A complete deficiency of mononuclear phagocytes is probably incompatible with life.

Macrophage Colony-Stimulating Factor

M-CSF is encoded by a gene originally assigned to the long arm of chromosome 5, [144] but subsequently reassigned to the short arm of chromosome 1.[213] M-CSF mRNA gives rise to two glycoprotein species (7090 kDa and 4050 kDa) as a result of alternative splicing [144] [214] and stimulates monocyte/macrophage proliferation.[172] M-CSF also activates secretory[215] and phagocytic [216] [217] function. M-CSF also regulates the genesis of osteoclasts and seems to regulate tissue remodeling [218] and placental function.[219] It may also have an auto- or paracrine role in a variety of cancers. [218] M-CSF can be secreted or expressed as an integral membrane glycoprotein on the surface of cells that express the gene. The mononuclear phagocyte is an essential regulatory cell for hematopoietic cells of many lineages. [220] It is, therefore, no surprise that osteopetrotic (op/op) mice with a naturally occurring M-CSF deficiency [4] [212] [221] routinely exhibit bone marrow failure. [212] As is the case with G-CSF for neutrophils and EPO for erythroid cells, M-CSF serves as the major survival factor for mononuclear phagocytes. [222] Specifically, marrow failure and osteopetrosis in M-CSF-deficient mice can be restored by enforcing expression of the anti-apoptotic protein Bcl-2 in mononuclear phagocytes of op/op mice. [222] Consequently, M-CSF augments monocyte survival, permitting them to respond to internal and external cues for their differentiation.

M-CSF
Also known as: CSF-1 *Chromosome:* 1p21-p13 *Gene product:* 4090 kDa *Produced by:* monocytes, macrophages, fibroblasts, epithelial cells, vascular endothelial cells, osteoblasts *Induced by:* IL-3, IL-4, TNF-, endotoxin *Receptor:* a 165 kDa cell-surface receptor tyrosine kinase, encoded by c-fms, a cellular proto-oncogene located on human chromosome 5q33-34, is the cellular homologue of the v-fms oncogene of the McDonough strain of feline sarcoma virus *Bioactivity:* see Table 14-2 *Deficiency:* severe deficiency of macrophages and osteoclasts, hematopoietic failure, osteopetrosis

The M-CSF receptor, the c-fms proto-oncogene product encoded by a gene on human chromosome 5q32-33 and murine chromosome 18, is a type III tyrosine kinase family member. On ligand binding, it forms homodimers that then activate intrinsic tyrosine kinase activity. Activation of the receptor serves to transduce survival, [222] activation, and growth signals to mononuclear phagocytes and their precursors, at least in part by activating c-cbl and protein tyrosine phosphatase-phi. [218]

Eosinophils

Eosinophil production depends on GM-CSF, IL-3, and IL-5, [223] the latter being the more cell-type-specific of the three, at least in granulopoiesis (IL-5 exerts effects in lymphoid cells too). Again, just as G-CSF and EPO are survival factors for their respective lineages, IL-5 prolongs the survival of eosinophils, [12] and incubation of human bone marrow cells in suspension culture with IL-5 induces production of a greater fraction of eosinophils. [224] [225]

Interleukin-5

Interleukin-5, [224] [226] [227] [228] [229] the gene for which is also located on the long arm of chromosome 5, [227] [229] serves as a final example of the notion that growth factors stimulate both proliferation of progenitors and function of the progeny (Fig. 14-10) IL-5 was known as T-cell-replacing factor and eosinophil differentiation factor. [224] [226] [228] IL-5 is produced by T lymphocytes induced by antigen, mitogens, and phorbol esters. [224] [226] [228] [230] [231] The high-affinity IL-5 receptor is a dimer composed of an IL-5-specific ligand-binding chain and a chain also common to the GM-CSF and IL-3 receptors. [17] [18] IL-5 activates cytotoxic T cells [232] and induces immunoglobulin secretion. [233] [234] IL-5 also induces eosinophil production in vitro [226] and activates the functional activity of eosinophils. [235] [236] [237] The role of IL-5 in the production and migration of eosinophils is clearly demonstrated by experiments in which anti-IL-5 antibodies inhibit parasite-induced eosinophilia in mice, [238] and in which mice with IL-5R chain deficiency also failed to mount an eosinophilic response to *N. brasiliensis*. [239]

IL-5
Also known as: T-cell-replacing factor, eosinophil differentiation factor *Chromosome:* 5q31.1 *Gene product:* 5060 kDa *Produced by:* T lymphocytes *Induced by:* antigen, mitogen, phorbol esters *Receptor:* heterodimer composed of IL-5-specific subunit (CDw125, human chromosome 3p26-p24) and subunit (CDw131, human chromosome 22q12.2-q13.1, shared with the high-affinity GM-CSF and IL-3 receptors) *Bioactivity:* see Table 14-2 *Deficiency:* failure to mount an appropriate eosinophilic response

Basophils

The production of basophils and mast cells is induced by IL-3 (reviewed following) and SF (reviewed previously), which seem to be sufficient in vitro to stimulate the production and viability of this cell type, although the relation between these factors and IL-4 (which some investigators find can also induce mast cell production in vitro) has not been clarified. [240] IL-3, capable on its own of inducing both eosinophils and basophils in suspension cultures of bone marrow, when combined with TGF- synergistically induces the specific outgrowth of basophils, at least in part because TGF- inhibits eosinophil production in IL-3-stimulated marrow. [241] The TGF- family is reviewed below under mitotic inhibitory factors.

Megakaryocytopoiesis

IL-3, [242] [243] IL-6, [244] [245] IL-11, [246] [247] [248] LIF, [249] SF, [111] [250] [251] and EPO [74] [252] have been reported to influence the production and/or maturation of megakaryocytes (Fig. 14-11). However, the most profound effects on platelet counts have been seen using TPO and IL-11; while there are likely other stimulators of platelet production, these are the best current candidates for therapeutic agents designed to enhance platelet production. [253] [254] In fact, IL-11 has been recently released for therapeutic use; unlike TPO, levels are consistently elevated in the serum of thrombocytopenic patients. [255]

Thrombopoietin

Thrombopoietin, a 36-kDa protein (6585 kDa when fully glycosylated) [256] encoded by a gene on the long arm of chromosome 3, [256] [257] is constitutively produced by a variety of organs/cell types including hepatocytes, proximal convoluted tubule cells of the kidney, bone marrow stromal cells, muscle, brain, and spleen cells. [258] [259] [260] [261] [262] The TPO receptor is the gene product of c-*mpl*, the human homolog of the murine myeloproliferative leukemia virus, encoded by a gene on human chromosome 1 (1p34) and the D band of murine chromosome 4. [263] The extracellular domain of c-mpl resembles the hematopoietic growth factor superfamily, [264] and the cytoplasmic domain is capable of signal transduction but, like the other members of the family, contains no protein kinase or phosphatase motifs. The TPO receptor can mediate proliferation without activation of the JAK/STAT pathway through the activation of phosphatidylinositol 3 kinase, which pathway is capable of phosphorylating Shc, Vav, and mitogen-activated protein kinase (MAPK) and Raf-1 and induction of c- *fos* and c-*myc* cells expressing the TPO receptor. [16]

Hepatocytes are the primary source of serum TPO in humans. Indeed, serum TPO levels are low to undetectable in patients with cirrhosis and thrombocytopenia and increase within 2 days after orthotopic liver transplantation. [265] [266] Circulating TPO binds via the c-mpl protein to platelets and to a

Figure 14-11 Humoral control of megakaryocyte and platelet production. The two humoral factors that influence this process directly include IL-11 (currently approved for clinical use) and

thrombopoietin (TPO), both of which induce more rapid recovery of platelets after bone marrow injury.

lesser extent megakaryocytes and is internalized and then degraded. [267] [268] [269] TPO levels are inversely related to the platelet count in patients with thrombocytopenia and can be decreased by platelet transfusion. [270] [271] [272] Serum TPO is also inversely related to megakaryocyte mass. [260] [273] The increase in TPO levels seen in thrombocytopenia does not appear to be due to any increase in TPO production but instead results from a decrease in TPO binding to platelets and/or megakaryocytes. [260] [269] [271]

Thrombopoietin stimulates the in vitro growth and differentiation of CFU-Mk, mature megakaryocytes, and even pro-platelets. [274] [275] [276] Megakaryocytes grown in the presence of TPO have increased ploidy. [276] [277] TPO primes mature platelets to respond to aggregation-inducing stimuli such as adenosine diphosphate (ADP), epinephrine, and thrombin and also increases platelet release of adenosine triphosphate (ATP) and thromboxane B_2. [278] [279] [280] In addition to its effects on stimulating in vitro megakaryocytopoiesis, TPO also synergizes with a variety of other hematopoietic growth factors (HGFs), especially SF, IL-3, and FL, to stimulate nonmegakaryocytic progenitor growth. [281] [282] For example, sorted individual CD34+CD38 cells have a limited proliferative response to TPO, but the addition of TPO to SF and FL increases proliferation of BFU-E, CFU-GM, and CFU-MIX by 1040 fold. The addition of IL-3, IL-6, and EPO did not significantly increase colony growth above that seen with the three-factor combination of TPO, SF, and FL. [283] [284] The addition of TPO increased clonal growth in response to SF, FL, IL-3, IL-6, and EPO by as much as 80%;. [283] The primary effect of TPO on these primitive progenitors seems to be in maintaining viability and suppressing apoptosis. [283] [284] [285] [286]

The in vivo role of TPO in regulating hematopoiesis has been demonstrated in mice nullizygous for TPO or its receptor. Such mice have marked thrombocytopenia (platelet counts 510% of normal) but have normal hematocrit levels, white blood cell counts, and peripheral numbers of neutrophils, lymphocytes, monocytes, and eosinophils. [287] [288] [289] The platelets in such knockout mice seem to function normally, demonstrating that TPO/c-*mpl* is not required for the production of normal platelets but that TPO is the primary regulator of platelet mass in vivo. Treatment of TPO ligand- or receptor-deficient mice with IL-6, IL-11, or SF increased platelet counts 0.351.2 fold. [287] TPO- or c-*mpl*-deficient mice had reduced numbers of megakaryocyte, erythroid, granulocyte-macrophage, and multilineage progenitors in bone marrow, peripheral blood, and the spleen. Treatment of TPO knockout mice with recombinant TPO increased the absolute number of bone marrow hematopoietic progenitors. [287] It is not known whether these mice have deficiencies in colony forming units-spleen (CFU-S) or pluripotent stem cells.

Thrombopoietin has been used to date in a limited number of human clinical trials. Treatment with a single dose or with daily doses of TPO results in a dose-dependent increase in platelet count associated with an increase in bone marrow megakaryocytes. [290] [291] [292] No effect of TPO on red cell or white cell counts has been found in these human studies. There are conflicting data on the effect of TPO on bone marrow progenitors, but it is clear that TPO treatment causes mobilization of hematopoietic progenitors. [290] [291] [292]

Preclinical and clinical studies to date have suggested several possible clinical uses for TPO. Although further study is needed, it seems likely that TPO will be useful in the treatment of radiation- or chemotherapy-induced thrombocytopenia, as in the setting of bone marrow transplantation or high-dose chemotherapy. [253] [293] [294] [295] [296] TPO may also be useful in mobilizing peripheral blood progenitors for use in transplantation. [290] [291] [296] Murine models suggest that TPO treatment of donors before stem cell harvest results in more rapid platelet recovery after transplantation. [294] [297] Other potential clinical uses of TPO include pretreatment of platelet apheresis donors to increase the collection yield and treatment of cirrhosis patients with thrombocytopenia due to TPO deficiency. [265] [266] Two human studies have examined the effect of TPO on ameliorating thrombocytopenia after chemotherapy. In a randomized, blinded, placebo-controlled trial, TPO and G-CSF or G-CSF alone was given after treatment with carboplatin and cyclophosphamide. Patients treated with TPO plus G-CSF had faster platelet recovery (day 17 vs. day 22) but no difference in the depth of the platelet nadir compared with patients receiving G-CSF alone. [296] In another randomized, double-blind, placebo-controlled study, TPO or placebo was administered to lung cancer patients being treated with carboplatin and paclitaxel. In the TPO-treated patients, the median platelet nadir was 188,000, versus 111,000 in the placebo-treated patients. The TPO-treated patients also had a faster recovery of platelets to baseline (14 days vs. 21 days) (Fig. 14-12). [253]

One concern in the clinical use of TPO has been the potential for peripheral blood platelet activation and iatrogenic thromboembolic complications. Studies in nonhuman primates and humans have not shown any evidence of platelet activation as assessed by platelet aggregation, ATP release, expression of the platelet activation marker CD62 (P-selectin), or expression of glycoprotein IIb/IIIa. [291] [292] [296] TPO treatment of baboons increased platelet deposition on segments of homologous endarterectomized aorta and vascular grafts in direct proportion to circulating platelet numbers but without significant fibrin accumulation. [296] The reports of a low incidence (<5%) of thrombotic complications in TPO-treated cancer patients suggest a need for further studies to define the risk factors for thromboembolic side effects of therapeutic TPO usage, [253] [296] but the prothrombotic potential of neoplastic cells in cancer patients must also be carefully considered as well.

Another unresolved concern is that TPO may induce myelofibrosis. Myelofibrosis and megakaryocytic hyperplasia are commonly linked, and while short-term TPO therapy does not cause myelofibrosis, [299] lethally radiated mice transplanted with murine marrow transduced with a retroviral vector expressing murine TPO cDNA developed a fatal myeloproliferative disorder that included myelofibrosis. [300] This approach is not a fair test of the long-term consequences of chronic TPO therapy because the levels of TPO were high and uncontrollable and because the model included lethal radiation. Nonetheless, it will be essential for us to rule out myelofibrosis as a complication of long-term therapy in the future.

TPO

Also known as: megakaryocyte growth and development factor (MGDF), *mpl* ligand
Chromosome: human 3q27-28, mouse chromosome 16
Gene product: 6585 kDa
Produced by: wide variety of somatic cells including those of bone marrow stroma, spleen, renal tubule, liver, muscle, brain
Receptor: c-*mpl*, chromosome 1p34
Bioactivity: see Table 14-2
Deficiency: marked thrombocytopenia but no anemia or leukopenia

Interleukin-11

The IL-11 cDNA was isolated from the primate bone marrow stromal cell line PU-34 using an expression cloning strategy based on the capacity of the encoded protein to stimulate the proliferation of a murine plasmacytoma cell line. [247] The 19 kDa protein is encoded by a gene on human chromosome 19. [301] IL-11 is produced by fibroblasts and bone marrow stromal cells, and its production is markedly increased by IL-1. [247] [302] [303] The IL-11 receptor is a type I cytokine receptor heterodimer consisting of IL-11R, structurally related to CD126 (IL-6R) and gp130, [304] [305] the latter being shared with the chains of LIF,

Figure 14-12 In vivo activity of thrombopoietic factors, thrombopoietin, and IL-11. **(A)** Thrombopoietin treatment of baboons. A truncated, pegylated version of human TPO (MGDF) or saline was given by daily subcutaneous injection for 14 days beginning 48 hours after a single dose of 120 mg/kg of 5-FU. [299] Administration of MGDF stimulated more rapid recovery of platelets (closed boxes) than saline alone (closed circles), although the depth of platelet nadir was not affected. The overshoot thrombocytosis seen in the MGDF-treated animals can be abrogated by shorter courses of treatment. Unfortunately, evidence that this particular formulation is immunogenic (neutralizing antibodies have developed in some treated patients) has resulted in a discontinuation of MGDF development. **(B)** IL-11, administrated at two different doses to patients following cancer chemotherapy, reduced the number of patients requiring platelet transfusion. All patients had received platelet transfusions because of severe thrombocytopenia following their previous cycle of chemotherapy. IL-11 (filled bars) or placebo (open bar) was administered subcutaneously beginning one day after

chemotherapy and continued for 1421 days or until the platelet count was 100,000 l.

oncostatin M (OSM), CNTF, and IL-6 (Fig. 14-2). As is the case with the IL-6 receptor, the IL-11R chain binds to IL-11 with low (kDa = 10 nM) affinity and does not activate a signaling pathway. When co-expressed with CD130, the heterodimeric receptor has high-affinity IL-11 binding activity (kDa = 400800 pM), and ligand binding sets off a signaling cascade. [306]

IL-11 is a pleiotropic cytokine with growth stimulatory effects that overlap those of IL-6 on multiple classes of lymphoid and myeloid cells. [303] [307] IL-11 is mitogenic for a number of murine plasmacytoma and hybridoma cell lines, [247] [303] enhances CD4+ T-cell-dependent proliferation of antigen-specific plaque-forming B cells, [247] [308] [309] and shortens the duration of G_0 of primitive hematopoietic progenitor cells, as measured in the blast cell colony assay of Ogawa et al. [310] [311] It acts synergistically with IL-3 or SF to support the clonal growth of erythroid (BFU-E and CFU-E) and primitive megakaryocytic (BFU-Mk) progenitor cells. [53] [105] [246] In combination with IL-3, IL-11 induces an upward shift in the ploidy values of cultured megakaryocytes. [312] In vivo, IL-11 administration stimulates megakaryocytopoiesis, increases peripheral platelet and neutrophil counts, and increases the numbers and cycling activity of all classes of committed hematopoietic progenitor cells. [248] [313] [314] IL-11 hastens hematopoietic recovery after treatment with cytotoxic agents or ionizing radiation and accelerates hematopoietic reconstitution after bone marrow transplantation. [314] [315] In mice, IL-11 stimulates multipotential progenitor cells but not stem cells, [316] but in combination with either SF or FL is capable of inducing in vitro expansion of progenitor cells and can maintain survival of hematopoietic stem cells for up to 21 days in vitro. [317] Taking these important bioactivities into account, it is surprising that IL-11R knockout mice have no hematologic defect, indicating that IL-11 is completely dispensable for hematopoiesis, at least in mice. [318]

Notwithstanding its dispensability, the clear influence of IL-11 on megakaryocytes underscores the potential therapeutic value of this cytokine in the management of thrombocytopenia and chemotherapy- or radiation-induced myelosuppression. Indeed, IL-11 has been approved for the prevention of severe thrombocytopenia and to reduce platelet transfusion requirements for patients receiving cytotoxic chemotherapy for nonmyeloid malignancies (Fig. 14-12B). Studies suggest that IL-11 may act as an autocrine growth factor for certain megakaryoblastic cell lines. [319] Outside the hematopoietic system, IL-11 stimulates hepatic production of acute-phase reactant proteins, [320] suppresses adipogenesis and heparin-releasable lipoprotein lipase activity in murine pre-adipocytes, [302] and, like its homolog IL-6, stimulates neuronal differentiation; however, its most substantial nonhematopoietic function, at least from the standpoint of future therapeutic potential, is its capacity to stimulate recovery of gastrointestinal epithelial cells after cytotoxic therapies. [321]

IL-11

Also known as: adipogenesis inhibitory factor
Chromosome: 19q13.3-13.4
Gene product: 1924 kDa
Produced by: fibroblasts, bone marrow stromal cells
Induced by: IL-1, phorbol 12-myristate 13-acetate (PMA), calcium ionophore A23187
Receptor: heterodimer consisting of the 43 kDa IL-11R chain encoded by a gene on human chromosome 9p13 and the CD130 (gp130) molecule (Fig. 14-2 **B**) encoded by a gene on chromosome 5q11
Bioactivity: see Table 14-2
Deficiency: no hematologic defect detected [318]

Figure 14-13 Humoral control of B lymphopoiesis. Some of the many factors involved in regulating the growth and differentiation of lymphoid cells are sufficient to induce growth or differentiation or both. However, most of the factors act synergistically; some always need help (IL-6 induces B-cell differentiation only in the presence of IL-2, and IL-10 enhances pro-B-cell differentiation only in the presence of flt3 ligand and IL-7).

Lymphopoiesis

The growth and development of lymphoid cells from the common lymphoid progenitor [322] occurs in multiple anatomic locations, where different factors may influence these processes. Many of the hematopoietic growth factors and interleukins have been shown to play a role in the growth and development of B cells (Fig. 14-13) and T lymphocytes. Natural killer cell control is less well understood, although the role of IL-12 and IL-15 in this process seems clear.

Interleukin-7

Interleukin-7 is a true lymphopoietic factor. A 17 kDa protein encoded by a gene on human chromosome 8q12-13, [323] IL-7 is produced by bone marrow stromal cells [324] and intestinal epithelial cells [325] and binds to a heteromeric receptor that shares a common chain with the receptors for IL-2, 4, 7, 9, and 15 (Fig. 14-2C). The IL-7R chain (CD127) is a type I cytokine receptor expressed on bone marrow lymphoid progenitor cells, thymocytes, mature T cells, and mononuclear phagocytes. The biologic activity of IL-7 is heavily weighted toward the lymphoid lineage, inducing the clonal growth of normal pre-B cells, [324] [326] [327] pre-T cells, [327] and various types of neoplastic lymphoid cells. [328] [329] It enhances differentiation of T-cell-receptor- cells selectively to the CD8+ subset. [330] It acts synergistically with flt3-ligand and IL-10 to augment the growth of primitive B lymphocytes. [331] Like other hematopoietic growth factors, it can act indirectly as well by enhancing the production of other growth factors (IL-3 and GM-CSF production by activated T cells [332] and IL-6, IL-1, TNF-, and IL-8 production by peripheral blood monocytes, [333] [334] for example).

The clear lymphopoietic function of this cytokine is best clarified by findings of lymphopenia and severe combined immunodeficiency in IL-7 [335] or IL-7R [336] knockout mice. Mutant mice have lymphocytopenia and reduced B-cell and T-cell numbers in lymphoid organs, including the spleen and thymus. Marrow B cells could not move from the pro-B stage to the pre-B stage. The lymphoid cells that do exist in these mice respond normally to mitogenic stimuli [335] but have functional defects, including cell-mediated immunity against allogeneic tumor cells. [336] Failure of aging stromal cells to release IL-7 when cocultured with IL-7-dependent murine B cells may serve as a model for B-cell failure in aging. [337] As with most lineage-specific factors, a major biologic effect of IL-7 on lymphoid cells is to prevent programmed cell death. In the case of IL-7, this was confirmed by demonstrating that Bcl-2 can rescue T cells in IL-7R / mice. [338] Finally, IL-7 acts synergistically with earlier-acting factors, in particular FL, which when combined with IL-7 very potently promotes B-cell commitment and differentiation of multipotential murine bone marrow progenitor cells. [339]

IL-7

Also known as: pre-B cell CSF
Chromosome: 8q12-13
Gene product: 17 kDa
Produced by: marrow stromal cells, spleen, and thymus tissue
Receptor: class I cytokine heterodimeric receptor, unique 49 kDa chain (CD127, chromosome 5p13) and a 40 kDa common chain, c (CD132, chromosome Xq13), which the chain shares with those of IL-2, IL-4, IL-9, IL-13, and IL-15
Bioactivity: see Table 14-2
Deficiency: lymphopenia and severe reductions in B-cell and T-cell cellularity of all lymphoid organs including nodes, spleen, marrow, and thymus

Interleukin-2

Interleukin-2 is encoded by a gene on chromosome 4.[340] The 23 kDa gene product is produced by T lymphocytes induced by mitogens, antigens, certain antibodies, phorbol esters, and lectins.[341] [342] [343] The IL-2 receptor (IL-2R), a heterotrimer of 55 ()-, 75 ()-, and 64 ()-kDa subunits, [161] [342] [344] is expressed by T cells,[345] B cells,[346] [347] [348] and natural killer (NK) cells.[349] The biologic activities of IL-2 include induction of growth and activation of T lymphocytes, [341] [342] [345] B lymphocytes,[346] [347] [348] and NK cells[349] both in vitro and in vivo. Intense interest in IL-2 and IL-2-stimulated lymphocytes as effectors of clinical tumor cytotoxicity have provided unambiguous evidence of in vivo immunomodulatory activity of IL-2 in humans.[350] [351] [352] [353] However, it is equally clear that this cytokine is not required for lymphopoiesis per se because IL-2 knockout mice do not suffer lymphopenia or immune deficiency;[354] in fact, the mice develop a syndrome of generalized inflammatory disease that involves multiple organs,[355] [356] often with severe fatal colitis. These surprising results indicate that IL-2 functions most prominently as a modulator or negative regulator of the immune response, and its absence, marked by uncontrolled activation and expansion of CD4+ T cells, [355] disrupts the management of self-tolerance.[355] [356]

IL-2

Also known as: T-cell growth factor
Chromosome: 4q
Gene product: 23 kDa
Produced by: T lymphocytes
Induced by: mitogens, antigens, some antibodies, phorbol esters, lectins, and IL-1
Receptor and subunits: // heterotrimer on T lymphocytes, B lymphocytes, and NK cells. (CD25, chromosome 10p14-p15); (CD122, chromosome 22q11.2-q13); (CD132, chromosome Xq13)
Bioactivity: see Table 14-2
Deficiency: generalized fatal immunoproliferative disorder involving multiple organs; loss of self-tolerance

Responses induced by IL-2 vary among lineages of cells bearing the receptor because permissible gene programs in those cells are different; some of them are also lineage-specific. Each chain of the trimeric IL-2 receptor has been fully characterized. The (p75) chain and the (p64) chain are shared with the receptor for IL-15 (Fig. 14-2C), but the IL-2R chain is unique (as is the IL-15R chain).[357] [358] [359] There is no evidence that differential expression of intermediate- or high-affinity receptors accounts for lineage-specific responses.

Interleukin-15

Interleukin-15 is a 14 kDa polypeptide produced by a variety of cells, including monocytes, macrophages, epithelial cells, muscle cells, fibroblasts, keratinocytes, and hematopoietic stromal cells.[360] [361] The gene for human IL-15 maps to chromosome 4q31, in close proximity to the IL-2 gene (4q26-27).[362] IL-15 and IL-2 exert overlapping effects in lymphopoiesis despite a lack of significant homologies between the IL-2 and IL-15 coding sequences.[361] [362] Instead, the overlapping activities result from receptor homologies and shared domains. The receptors for IL-15 and IL-2 share two subunits (the IL-2R and common chain). Murine and human IL-15-specific subunits have substantial homology (including intron-exon organization) with IL-2R.[359] These two cytokines also swap two receptor subunits. The IL-15 receptor complex is a heterotrimeric complex consisting of an IL-15-specific subunit and the IL-2R and IL-2R subunits.[357] [361] As noted previously, the IL-2R subunit is also used in the receptor complexes for IL-2, IL-4, and IL-7.[363] Not surprisingly, IL-2 and IL-15 induce many of the same biologic responses. IL-15 release is induced by ultraviolet light, Bacillus Calmette-Guerin (BCG), LPS, IL-10, and infection by intracellular organisms.[360] [364] [365] It protects multiple cell types, including T cells and hepatocytes, from apoptosis in vivo[366] resulting from either factor deprivation or fas-dependent programmed cell death. It induces maturation of human natural killer (NK) cells from thymic progenitors.[367]

IL-15, like IL-2, is a potent modulator of NK cell activity. IL-15, used as a single agent, induces differentiation of CD3-CD56+ NK cells from CD34+ hematopoietic progenitor cells. SF synergizes with IL-15 to increase this expansion without altering the differentiation state of expanded NK cells.[368] Indeed, recombinant IL-15 can replace bone marrow stromal cells in the in vitro generation of lytic NK cell activity and is 1050 fold more potent than IL-2.[369] IL-15 induces NK cell activity in peripheral blood mononuclear cell (PBMC) and splenocytes in vitro and in vivo and is chemotactic for NK cells.[361] [370] [371] NK cells are found in IL-2 / mice, whereas IL-2R / mice (lacking the capacity to transduce both an IL-1 and an IL-15 signal) have a marked reduction in circulating NK cells and a total absence of NK lytic activity in vitro.[372] [373] Likewise, in vivo treatment of mice with blocking antibodies to IL-2R results in the disappearance of NK cells. Thus, IL-15 may be required for the generation of functional murine NK cells.[374] Definitive testing of this hypothesis will require the generation of IL-15 / mice or the use of blocking antibodies to the IL-15-specific subunit of the IL-15 receptor complex.

IL-15, like IL-2, is a chemoattractant and growth factor for T cells. IL-15 induces the proliferation of memory (CD45RO+) CD4+ and CD8+ T cells and also of naïve (CD45RO) CD8+ but not naïve CD4+ cells.[375] IL-12 synergizes with IL-15 to increase the proliferation of memory CD4+ T cells.[376] Addition of IL-15 to mixed lymphocyte reactions augments the generation of cytotoxic lymphocytes (CTL) and lymphocyte-activated killer (LAK) cells, and treatment of mice with IL-15 generates CTL and LAK cell activity in vivo. IL-15 also augments antitumor responses in animal models where responses to IL-2 are also seen.[371] [377]

Like IL-2, IL-15 supports the proliferation and maturation of B cells and is costimulatory with anti-m antibody, phorbol ester, or CD40 ligand. B cells treated with IL-15 and CD40 ligand are induced to produce polyclonal IgM, IgG_1, and IgA antibodies, but not IgG_4 or IgE. Indeed, IL-15 can replace IL-2 as a costimulator of B cells and augments the in vitro production of antigen-specific antibodies.[378]

While the bioactivities of IL-2 and IL-15 are similar, there are several important differences between them. First, IL-2 is produced exclusively by activated T cells, whereas IL-15 is secreted by a much broader range of cell types, but not by T cells. The widespread production of constitutive and inducible IL-15 protein may serve to target immune effector cells to sites of peripheral inflammation and infection.[364] [379] Second, only T cells, monocytes, and B cells express mRNA for the IL-2R subunit, whereas expression of mRNA for the IL-15R subunit is fairly ubiquitous. However, it is not clear whether all the cells that express the IL-15R subunit can, under any circumstance, also co-express IL-2R and IL-2R subunits and assemble functional IL-15R complexes,[357] [380] so the biologic meaning of this difference is unclear. The effects of IL-2 are restricted to hematopoietic cells, whereas there is evidence that IL-15 can directly modulate some types of nonhematopoietic cells.[381] For example, IL-15 induces tryosine phosphorylation of endothelial cell proteins in vitro and stimulates angiogenesis in vivo.[382]

IL-15 may be involved in the pathophysiology of certain autoimmune disorders. Elevated levels of IL-15 have been found in the serum and in peripheral blood cells of patients with inflammatory bowel disease and in the synovial fluid of patients with rheumatoid arthritis.[383] [384] TNF-, a central mediator of the inflammation in rheumatoid arthritis, is released by macrophages induced by contact with IL-15-activated T cells. Freshly isolated T cells from rheumatoid synovial fluid also can induce macrophage TNF-, but exogenous IL-15 is required for sustained production of TNF-.[383] Thus, IL-15 may be critical in maintaining synovial inflammation in patients with this disease, and agents designed to modulate IL-15 production may have therapeutic potential for rheumatoid arthritis and other autoimmune disorders.[383]

IL-15

Also known as: IL-T
Gene: human chromosome 4q31 (in close proximity to IL-2 [4q26-27])
Gene product: 14 kDa
Produced by: monocytes, macrophages, epithelial cells, skeletal muscle cells, bone marrow and thymic stromal cells[361]
Induced by: ultraviolet light, BCG, LPS, IL-10
Receptor: heterotrimeric complex consisting of IL-15 specific subunit (chromosome 10p14-p15), IL-2R (CD122, 70 kDa, chromosome 22q11.2-q13), and IL-2R (CD132, 64 kDa, chromosome Xq13) subunits
Bioactivity: see Table 14-2

IL-15 may also function to preserve immune function in HIV-1-seropositive patients. HIV-1 infection results in a decrease in Th1 cells, with an associated loss of IL-2 production. Consequently, peripheral production of IL-15 may be responsible for the maintenance of cell-mediated immunity during the early phases of infection. [379] IL-15 stimulates the NK activity of peripheral blood mononuclear cells in HIV-1-infected patients, enhances mitogen- and antigen-independent lymphocyte proliferation, restores PBMC production of IL-12, augments microbicidal activity of monocytes against *Candida albicans*, [385] and stimulates the expansion of HIV-specific CTL.[386] [387] Is there therapeutic potential for IL-15? IL-15 treatment of mice produces fewer side effects than with IL-2 administration. [371] However,

this finding has not been confirmed in humans. The clinical utility of IL-15 in patients with HIV-1 infections or cancer will depend on an acceptable side effect profile and induction of in vivo responses similar to those produced in vitro.

Interleukin-4

Interleukin-4 was formerly known as B-cell stimulatory factor-1, B-cell differentiation factor, T-cell growth factor-2, and mast cell growth factor-2. The IL-4 gene resides on the long arm of chromosome 5[229] [388] [389] and encodes an 18 kDa protein[390] [391] produced by T lymphocytes induced by phorbol esters, lectins, and certain antigens.[392] There are two receptors for IL-4. The first is a heterodimeric member of the cytokine superfamily consisting of CD124 (87 kDa, chromosome 16p11.2-p12.1) and CD132 (40 kDa, chromosome Xq13). The second consists of CD124 associated with IL-13R (Fig. 142 **C**). [393] IL-4 induces proliferation of activated B cells,[394] T cells,[395] mast cells,[240] and fibroblasts.[396] It induces expression of its own receptor in B cells and T cells, [397] [398] induces isotype switching to IgG and IgE in activated B cells,[234] [399] induces expression of the IL-2 receptor in T cells exposed to phorbol esters, [400] suppresses IL-2-induced B-cell proliferation, [401] [402] and suppresses IL-2-induced IgM secretion.[403] IL-4 can influence nonlymphoid lineages. It induces expression of M-CSF and G-CSF genes in human monocytes[404] and induces expression of TNF- and an inhibitor of hematopoiesis (they may be the same factor) in mixed murine marrow stromal cells. [405] The effects of IL-4 on lymphopoiesis seem most clear when acting in synergy with other factors (Table 14-3).

IL-4 deficient mice are viable and have defective T_H2 cytokine production after nematode infections. IL-4 may be required for induction of optimal gut mucosal antibody responses,[406] although compensatory mechanisms do exist for infections caused by specific challenges, such as *Salmonella* or cholera toxins. [407] In some cases IL-4-deficient mice are more resistant to infectious agents, including schistosomes [408] and immunodeficiency virus. [409] Although IL-4 is capable of inducing IL-9 gene expression, IL-9 secretion in IL-4 knockout mice is only partly suppressed, indicating that IL-9 release is under the control of other factors as well. [410]

IL-4

Also known as: B-cell stimulatory factor-1, B-cell differentiation factor, T-cell growth factor-2, mast cell growth factor-2
Chromosome: 5q23-q21
Gene product: 18 kDa
Produced by: T lymphocytes (both CD4+ and CD8+)
Induced by: phorbol esters, calcium ionophore A23187
Receptor: heterodimeric member of the cytokine receptor superfamily; 87 kDa chain (CD124, chromosome 16p11.2-p12.1) and the 40 kDa c chain (CD132, chromosome Xq13), which is shared with the complex receptors for IL-2, IL-7, IL-9, and IL-15
Bioactivity: see Table 14-2
Deficiency: defective T_H2 cytokine responses, resistance to murine retroviral immunodeficiency syndrome

Interleukin-10

Human IL-10 is an 18 kDa protein[411] that is expressed as a noncovalent homodimer[412] and is encoded by a gene on chromosome 1.[413] The IL-10 receptor is a 90110 kDa class II cytokine receptor family member (Fig. 14-5), consisting of two extracellular fibronectin type III domains but no WSXWS motif and a 318 amino acid cytoplasmic region. IL-10 is truly pleiotropic. It was originally identified as a cytokine elaborated by murine

TABLE 14-3 -- Interleukins, Interferons, and Hematopoietic Growth Factors: Examples of Synergy

1.IL-2, IL-4, and IL-5 synergistically stimulate immunoglobulin isotype switching in B lymphocytes. [346]
2.IL-1 and TNF- stimulate prostaglandin production by fibroblasts. [775]
3.TNF- and IFN- synergistically suppress hematopoiesis in vitro. [645]
4.IL-1 and IL-2 induce interferon production in T lymphocytes. [776]
5.IL-3 and M-CSF stimulate proliferation of murine progenitor cells in clonal assays. [777]
6.IL-1 and TNF- induce differentiation of murine myeloid leukemic cells. [778]
7.IL-4 and IL-2 induce T-lymphocyte proliferation. [779]
8.IL-3 and G-CSF induce proliferation in multipotential progenitor cells. [780]
9.IL-6 and IL-1 activate T lymphocytes. [781]
10.IL-3 and both G-CSF and GM-CSF synergistically stimulate granulocyte and granulocyte-macrophage colony growth. [782]
11.IL-4 and IL-6 induce T-lymphocyte proliferation. [615]
12.IFN- and TNF- induce G-CSF and GM-CSF release from T lymphocytes. [783]

13.IL-3 and IL-2 stimulate T-cell proliferation. [529]
14.GM-CSF and IFN- induce TNF- gene expression by monocytes.[784]
15.IL-3 and EPO stimulate BFU-E growth in vitro.[524]
16.G-CSF and IL-3 synergistically induce megakaryocyte colony growth. [785]
17.IL-1 and TNF- induce IL-1 gene expression in vascular endothelial cells. [786]
18.M-CSF and IL-6 induce macrophage colony growth of human marrow cells.[787]
19.GM-CSF and IL-6 promote granulocyte differentiation. [617]
20.IL-1, IL-3, and M-CSF synergistically support clonal growth of macrophages [788] and primitive myeloid progenitor cells. [789]
21.IL-6, IL-3, EPO, and IL-4 support erythroid and megakaryocytic colony growth. [614]
22.IL-9 augments EPO-induced BFU-E growth,[790] IL-4-induced immunoglobulin production by B lymphocytes, [791] [792] and IL-3-induced growth of murine mast cells. [604]
23.IL-11 acts synergistically with IL-3 and SF to stimulate clonal growth of erythroid (BFU-E and CFU-E) and megakaryocytic (BFU-Mk) progenitor cells. [246] [247]
24.IL-12 synergizes with TNF- to stimulate IFN- production by NK cells. [418]
25.SF acts synergistically with IL-3, GM-CSF, and EPO to support optimal clonal growth of hematopoietic progenitor cells of all lineages [793] [794] [795] and also synergistically functions with IL-6 to augment CFU-S [119] and with IL-9 to stimulate proliferation of the human leukemic cell line MO7E. [796]
26.TPO synergizes with G-CSF in mobilizing hematopoietic progenitor cells in primates. [580]
27.TPO synergizes with SF and IL-3 in vitro to support proliferation of primitive hematopoietic cells. [282]
28.IL-1 and IFN- synergize to induce mip1 gene expression in fibroblasts. [797]
29.Simultaneous administration of FL and G-CSF increases peripheral blood CFU 12- to 20-fold over that seen with either agent alone. [583]
30.TPO and EPO synergistically enhance self-renewal of CFU-E and BFU-E in vitro. [798]
31.FL synergizes with G-CSF to mobilize peripheral blood stem cells. [582]

T_H 2 clones that inhibits the production of cytokines such as interferon-gamma (IFN-) by T_H 1 clones.[414] IL-10 is expressed by all classes of CD4+ T cells, CD8+ T cells, mononuclear phagocytes, and activated B cells. [412]

While IL-10 is in certain circumstances a mitogen, the overall effect of IL-10 on immune function is suppressive. IL-10 knockout mice challenged with *Aspergillus fumigatus* have an exaggerated immune response, including increased release of IL-4, IL-5,

and IFN- and a higher than normal mortality rate. Similar results are found in the same murine model challenged with *Toxoplasma*. [415] Some strains of IL-10-deficient mice also develop chronic enterocolitis, followed by carcinoma of the colon. [416] These findings confirmed earlier studies that first characterized IL-10 as cytokine synthesis inhibitory factor (CSIF) because of its capacity to inhibit the production of cytokines by T lymphocytes. [414] Whereas the murine protein seems to inhibit specifically the production of cytokines (IL-2, IFN-, and lymphotoxin) by T_H 1 cells,[414] [417] human IL-10 inhibits, in addition, the production of T_H 2-type cytokines (IL-3, IL-4, and IL-5)[412] and NK cell-derived cytokines (IFN- and TNF-). [418] [419] [420] This effect is largely indirect, reflecting IL-10-induced inhibition of mononuclear phagocyte antigen-presenting cell function (due, in part, to downregulation of MHC class II antigen expression). [421] [422] In systems in which cells other than mononuclear phagocytes, such as B cells, present antigen, IL-10 is devoid of CSIF activity. IL-10 inhibits mononuclear phagocyte-dependent T-cell proliferation [421] [422] but can also directly inhibit the proliferation of highly purified T cells (due primarily to suppression of IL-2 production). [423] IL-10 is a potent inhibitor of mononuclear phagocyte function, suppressing MHC class II antigen expression, [421] monokine (IL-1, IL-1, TNF-, IL-6, IL-8, G-CSF, GM-CSF, and IL-10 itself) [424] [425] synthesis, and production of reactive oxygen species and NO.[426] [427] As a result of its inhibitory effects on T_H 1-type immune functions, IL-10 appears to play an important role, at least in murine models, in the maintenance and progression of infections by obligate intracellular pathogens that infect macrophages (e.g., *Listeria, Schistosoma mansoni*, and mycobacteria).[428] [429] [430] In such infections, T_H 1-derived cytokines and efficient macrophage function may be crucial in reducing the microbial burden. [431]

Human IL-10 can act as a co-stimulator (e.g., with IL-4) of human B-lymphocyte proliferation. [432] It also plays a major role in regulating B-lymphocyte development in different ways at different differentiation stages. Specifically, IL-10, in concert with FL and IL-7, enhances the generation of CD19 ProB cells from uncommitted bone marrow progenitors but functions to inhibit growth of CDE19+ ProB cells.

IL-10

Also known as: cytokine synthesis inhibitory factor
Chromosome: 1q31-q32
Gene product: 18 kDa
Produced by: T cells, activated B cells and B-cell lymphomas, mononuclear phagocytes, keratinocytes
Induced by: LPS, anti-CD3, PMA
Receptor: class II receptor family, 90110 kDa, human chromosome 11
Bioactivity: see Table 14-2
Deficiency: exaggerated immune responses to obligate intracellular parasites, inflammatory bowel disease

Interleukin-12

Interleukin-12 is a 75 kDa heterodimer composed of disulfide-linked 35 and 40 kDa (p35 and p40, respectively) subunits. [433] [434] [435] Isolation of their respective cDNAs demonstrated that p35 and p40 are encoded by distinct genes and that expression of both is necessary for the production of the biologically active molecule. [436] [437] p35 bears minor sequence homology with IL-6 and G-CSF, while p40 demonstrates homology with the soluble IL-6 receptor, leading to the suggestion that IL-12 represents a cytokinesoluble receptor complex.[438] [439] The two subunits of the IL-12 receptor are IL-12RB2 (human chromosome 1p31.2) and IL-12B1 (human chromosome 19p13.1).[440] The IL-12RB1 chain contains five fibronectin III domains and has a high degree of homology to CD130. [441]

Interleukin-12 expression was originally demonstrated in Epstein-Barr virus (EBV)-transformed B-cell lines. [433] [435] Subsequently, mononuclear phagocytes were shown to be an important source of IL-12. A variety of pathogens or their products (LPS, *Staphylococcus aureus, Mycobacterium tuberculosis, Toxoplasma gondii, Listeria monocytogenes, Leishmania major*) induce IL-12 production by mononuclear phagocytes.[442] [443] [444] As suggested by its original name natural killer cell stimulatory factor, IL-12 has profound effects on NK cells. Exposure to IL-12 augments the functional activity of NK cells and induces LAK activity in NK cells. [433] [445] [446] [447] [448] IL-12 acts also synergistically with TNF- to induce IFN- production by NK cells. [418]

Recent studies have demonstrated the vital role of IL-12 in cell-mediated immunity. IL-12 induces the differentiation of naïve murine CD4+ T-helper cells into T_H 1 cells,[444] a process analogous to IL-4-induced differentiation of naïve T-helper cells into T_H 2 cells.[449] [450] IL-12-mediated generation of antigen-specific

IFN--producing T_H 1 cells is an essential component of the host response to infection by obligate intracellular pathogens, leading to reduction in the microbial burden in several experimental mouse models,[443] [444] [451] [452] and is also involved in the protection against malaria in rhesus monkeys treated, before challenge with sporozoites, with recombinant human IL-12.[453] Accordingly, it is not surprising that IL-12 knockout mice, viable and fertile, are immunologically compromised. Although they display no gross developmental abnormalities, the capacity of these mice to mount a T_H 1 response and to release IFN- in response to endotoxin is impaired, and murine strains ordinarily resistant to *Leishmania major* become sensitive to this organism when deficient in IL-12. [454] [455]

IL-12

Also known as: NK cell stimulatory factor, cytotoxic lymphocyte maturation factor
Chromosome: not reported
Gene product: 75 kDa heterodimer of 35 and 40 kDa subunits
Produced by: mononuclear phagocytes, EBV-transformed B-cell lines
Induced by: LPS, various pathogens
Receptor: single class of high-affinity receptors approximately 110 kDa
Bioactivity: see Table 14-2
Deficiency: unable to mount a T_H 1 response, cannot release IFN- in response to endotoxin, cannot resist leishmanial infection

Interleukin-13

Interleukin-13, a 10 kDa T_H 2 cytokine encoded by a gene on human chromosome 5q31 (in the cluster that also contains IL-3, IL-5, IL-4, and GM-CSF), [456] shares many biologic activities with IL-4. The similarity in biologic activity of IL-4 and IL-13 is probably due to shared signal transduction pathways and receptor structure. The IL-13 receptor complex is a heterodimer consisting of an IL-13-specific subunit, an IL-4-specific subunit, and possibly a third subunit. The c subunit shared by IL-2, -4, -7 , -9, and -15 is not required for IL-13 signal transduction. [457] Consistent with the current model of the IL-13 receptor, a mutant IL-4 protein has been described that competitively antagonizes the activity of both IL-4 and IL-13. [458] Both IL-4 and IL-13 regulate the functional activities of peripheral blood monocytes and bone marrow-derived macrophages. These include alterations in cell surface antigen expression, inhibition of antibody-dependent cytotoxicity, inhibition of nitrous oxide production,

down-regulating production of pro-inflammatory cytokines and chemokines (including IL-1, IL-1, IL-6, IL-8, macrophage inflammatory protein (MIP)-1, TNF-, IL-10, GM-CSF, G-CSF, and IL-12),[459] [460] and increasing production of the IL-1 receptor antagonist. [461] Additionally, IL-13 represses HIV-1 replication in alveolar- and peripheral blood-derived macrophages.[462] [463]

IL-13, like IL-4, increases B-cell expression of various lymphocyte antigens (including CD23, MHC class II and sIgM), enhances B-cell proliferation, promotes isotype switching to allow IgE expression, and enhances production of IgG_4 and IgM. These effects of IL-13 on B cells are seen only in the presence of additional stimuli such as CD4+ T cells and IL-7.[464] IL-13 shares with IL-4 the ability to inhibit IL-2-induced IFN- production by NK cells. Similar to IL-4, IL-13 induces endothelial cell expression of vascular cell adhesion molecule (VCAM)-1 but not that of E-selectin or intercellular adhesion molecule (ICAM)-1. IL-13 may help regulate VCAM-1-mediated accumulation of lymphocytes, basophils, and eosinophils, but not neutrophils at sites of inflammation. [465]

Although the actions of IL-4 and IL-13 are largely redundant, several distinctions can be made. First, IL-13, unlike IL-4, has no significant effect on T cells. [466] Second, the kinetics of IL-13 secretion following T-cell activation differ from those of IL-4. IL-13 production occurs earlier and persists significantly longer (by hours to days) than IL-4 production.[467] Third, IL-13, unlike IL-4, does not regulate pre-B-cell differentiation. This result is consistent with the hypothesis that functional IL-13R are expressed later in B-cell development than functional IL-4R. [468] Currently there is no knockout model of IL-13 deficiency.

IL-13 may have a role in the treatment of macrophage-mediated inflammatory conditions such as septic shock and some autoimmune diseases. In mice, in vivo treatment with IL-13 protects against LPS-induced lethal endotoxemia.[469] In a murine model of experimental autoimmune encephalitis, IL-13 suppressed the development of neurologic disease without altering T- or B-cell immunoreactivity. [470] Another clinical use for IL-13 may be in the treatment of HIV infection, possibly in combination with other immune modulators such as IL-16.[462] [471]

IL-13

Also known as: P600
Chromosome: 5q23-q21 (IL-4 and IL-13 are located within 12 kb in a head-to-tail orientation [472]
Gene product: isoforms of 9 and 17 kDa; 17 kDa probably represents an N-glycosylated isoform[473]
Produced by: T_H 2 T cells, basophils, stromal cells
Induced by: CD28 ligation,[473] Ionomycin, PMA,[474] anti-IgE[475]
Receptor: heterodimer consisting of IL-13-specific subunit, IL-4-specific subunit, and possibly a third subunit; c subunit shared by IL-2, IL-4, IL-7, IL-9, and IL-15 are not required for IL-13 signal transduction
Bioactivity: see Table 14-2

Interleukin-14

Interleukin-14 is a 60 kDa polypeptide produced by normal T cells, T-cell clones, and cell lines generated from patients with T- or B-cell lymphomas. [476] [477] IL-14 secretion is induced by phytohemagglutinin stimulation but not by treatment with LPS, phorbol ester, or concanavalin A. [478] [479] IL-14 binds to a 90 kDa receptor that is expressed only by cells of B-cell lineage. [476] [477] [480] As predicted by the cellular distribution of IL-14R expression, only cells of B-cell lineage respond to IL-14. The IL-14 protein is antigenically related to Bb, the activation fragment of complement factor B, and both are mitogenic for B cells and compete for binding to the IL-14R. However, the biologic responses of B cells to IL-14 and Bb are not identical. This difference may reflect differential activation of IL-14R by the two ligands or the possibility that Bb protein binds to other receptors besides IL-14R. [481] There are no known animal or human models of IL-14 or IL-14R deficiency.

Treatment of activated normal B cells with IL-14 stimulates proliferation but does not increase immunoglobulin secretion. In fact, addition of IL-14 to B cells treated with multicytokine combinations or pokeweed mitogen markedly inhibits immunoglobulin production. In cell fractionation studies, the sIgD-B-cell population is the most responsive to IL-14. Therefore, IL-14 may serve to expand B cells and divert them to a memory cell phenotype. [482] Resting B cells of tonsillar or peripheral blood origin express 50350 surface IL-14R per cell and do not proliferate in response to IL-14. In contrast, B cells activated by *Staphylococcus aureus* or anti-m antibody express 10,00050,000 surface IL-14R per cell and have a marked mitogenic response to IL-14. It is unclear if activation merely increases the IL-14R number to a critical threshold or whether other priming events are required for cellular response to IL-14. [481] [483]

In contrast to the results with normal B cells, neoplastic B cells are often responsive to IL-14 without the need for a comitogenic stimulus. In most cases of pre-B acute lymphocytic leukemia, hairy cell leukemia, prolymphocytic leukemia, or B-cell chronic lymphocytic leukemia, the malignant cells will be stimulated to proliferate in vitro by the addition of IL-14. [476] [480] IL-14 is secreted in some cases of B-cell non-Hodgkins lymphoma. In these cases the malignant cells also expressed functional IL-14R and proliferated in response to IL-14. Decreasing autocrine IL-14 production by neutralizing antibody or antisense IL-14 oligonucleotide inhibited cellular proliferation. Thus, in some patients, autocrine or paracrine production of IL-14 by malignant B cells may play a pathologic role. [484] Therapeutic strategies that block such an autocrine network may be useful in the treatment of certain B-cell neoplasms.

Abnormalities in IL-14R receptor signal transduction may also be involved in certain nonmalignant disease states. B cells isolated from patients with systemic lupus erythematosus are hyperresponsive to IL-14 and, unlike B cells from normal patients, will respond to IL-14 even in the absence of comitogenic stimuli. [485] In contrast, B cells from most patients with common variable immunodeficiency fail to respond to IL-14 even though cell surface expression of IL-14R appears normal. [486]

IL-14

Also known as: high-molecular-weight B-cell growth factor
Chromosome: not assigned
Gene product: 60 kDa
Produced by: T cells, T- and B-lineage lymphoma cells
Induced by: phytohemagglutinin
Receptor: 90 kDa
Bioactivity: see Table 14-2

Interleukin-16

Interleukin-16, formerly known as lymphocyte chemoattractant factor, is unique among the interleukins in that its cognate receptor (CD4) is an immune costimulatory molecule rather than a typical growth factor receptor. [487] IL-16 is a 1618 kDa protein that is formed by caspase 3 proteolytic cleavage of the pro-IL-16 polypeptide. [488] The main cellular source of IL-16 appears to be CD8+ T cells, although eosinophils and mast cells also produce IL-16 protein. [489] [490] [491] IL-16 is a potent chemotactic factor for

Figure 14-14 IL-16 and HIV. The receptor for IL-16 (CD4) is an immune costimulatory molecule, not a typical growth factor receptor. Produced in large part by CD8+ T cells, IL-16 induces cytosolic Ca^{++} and phosphatidylinositol 1,4,5 Tris phosphate (PI 1,4,5, TP) accumulation, activates p56lck, and induces protein kinase C (PKC) translocation to the membrane. IL-16 inhibits HIV-1 promoter activity (the integrated HIV-1 provirus is shown as a white rectangle flanked by black long terminal repeat sequences [LTR] and gray cellular DNA). When expressed in $CD4^{+}$ human cells, IL-16 renders them resistant to HIV-1 infection. IL-16 may have a potential role in treatment of HIV-1 infection.

CD4+ T cells, monocytes, and eosinophils. Additionally, IL-16 can inhibit T-cell activation induced by CD3 ligation or mixed lymphocyte reactions. [487] [492] Currently there are no animal models of IL-16 deficiency. IL-16 receptor-deficient mice (CD4 /) have been described, but the phenotype in these mice is more likely due to a loss of the costimulatory actions of CD4 in T-cell development than from a loss of IL-16 ligand binding activity. [493]

Many investigators have noted that production of CD8+ secreted soluble factor(s) is positively correlated with the clinical status of HIV-1-infected persons and is predictive of resistance to infection by simian immunodeficiency virus (SIV) in primate models. [494] [495] [496] Because IL-16 inhibits HIV-1 replication in vitro, [489] many have speculated that IL-16 is responsible for the bulk of the observed antiviral effect of CD8+ secreted factors. However, this hypothesis has not been rigorously tested.[489] [497] IL-16 does repress HIV-1 promoter activity (quantified using an HIV-1 LTR-reporter sequence), [498] and although IL-16 does not suppress HIV-1 replication in naturally infected peripheral blood mononuclear cells, [499] when expressed in CD4+ human cells, IL-16 renders these cells resistant to HIV-1 infection (Fig. 14-14).[500] The effect of IL-16 on HIV-1 replication does not appear to be related to the modulation of CD4 expression or interference with HIV-1 binding but rather to a direct inhibitory effect of IL-16 on the HIV-1 promoter. [471] [500] Based on studies to date, it appears that IL-16 may have a potential role in the treatment of HIV-1 infection.

IL-16

Also known as: lymphocyte chemoattractant factor[501]
Chromosome: unknown
Gene product: 1618 kDa; production of functional IL-16 requires cleavage of pro-IL-6 polypeptide by caspase 3[488]
Produced by: CD8+ T cells, mast cells
Induced by: serotonin, antigen challenge, C5, PMA, histamine
Receptor: CD4 (55 kDa, human chromosome 12pter-p12)
Bioactivity: see Table 14-2

FACTORS WITH MULTILINEAGE ACTIVITY (EARLY-ACTING FACTORS)

At least six growth factors, IL-3,[502] [503] GM-CSF,[504] [505] SF,[506] FL,[507] IL-9, IL-6, IL-10,[412] and TPO,[282] [508] have obvious direct effects on multilineage progenitor cells and are thus capable of stimulating hematopoietic precursors before they have become fully committed to one lineage or another. Because of the clear lymphopoietic effects of IL-10, thrombopoietic effects of TPO and IL-11, dominant erythropoietic effects of SF, and granulopoietic effects of GM-CSF, all have been reviewed previously. Only IL-3, FL, IL-9, and IL-6 are reviewed in the category of early-acting factors.

Interleukin-3

Interleukin-3 was one of the earliest recognized multipotential hematopoietic growth factors. [172] [173] [509] The human IL-3 gene (5q31.1, only 9 kb upstream of the gene for GM-CSF) encodes a 1428 kDa protein that influences the growth of multiple lineages. To date, only T lymphocytes (induced by mitogens, phorbol esters, and certain antigens),[510] mast cells, [511] and certain cell types in mouse brain tissue [512] have been found to express the IL-3 gene. Although the GM-CSF and IL-3 genes are separated by only 9 kb of intervening DNA, they are very differently regulated. GM-CSF is produced by stromal cells [168] and IL-3 is not.[149] [513] [514] Although T lymphocytes can be induced to produce both IL-3[510] [515] [516] and GM-CSF,[516] there is clear-cut evidence that each is regulated independently of the other. [517] The high-affinity IL-3 receptor is a heterodimer composed of an IL-3-specific ligand-binding subunit (CDw123, human chromosome Xp22.3, Yp13.3) and a -subunit (CDw131, chromosome 22q12.2-q13.1) shared with the IL-5 and GM-CSF receptors (Fig. 142 **A**). [17] [18] The receptor is expressed on bone marrow progenitor cells, neutrophils, eosinophils, megakaryocytes, BFU-E, and mast cells.[518] Binding of IL-3 to the high-affinity receptor results in rapid phosphorylation of the adaptor molecules CrkL, which associates with Shc, SHP-2, and Cbl.[519] Cbl is phosphorylated, which enhances Cbls association with Grb2, phosphatidylinositol 3-kinase, and fyn.[520] The apoptotic protein BAD is inactivated by phosphorylation in IL-3-stimulated cells. [521] The STAT pathway

may also be activated by binding of IL-3 to its receptor through the association of STAT5 with CDw131. [522]

The biologic activity of IL-3, outlined in Table 14-2 , like many of the hematopoietic growth factors, derives from direct effects on progenitors and from other more indirect effects. The direct growth-stimulatory effects of IL-3 seem to be largely limited to very primitive committed progenitors like BFU-E [147] [523] [524] and hematopoietic progenitor cells with multilineage potential, [147] [525] possibly even CFU-S,[526] but it may be a factor that induces differentiation of multilineage cells because it hastens the development of colony-forming cells from stem cell precursors and is incapable of maintaining stem cell viability in vitro. [527] When expressed by human stromal cells engineered to produce human IL-3, SF, FL, or IL-7, only IL-3-expressing cells were capable of supporting sustained human hematopoiesis in a murine xenograft model.[528]

The fact that IL-3 induces proliferation directly and indirectly by inducing expression of other hematopoietic factors [155] [179] has complicated efforts to clarify the roles of this factor in hematopoiesis. For example, although it is clear that IL-3 induces formation of multilineage colonies in cultured human bone marrow cells, the full biologic potential of the cytokine is apparent only when combined with other factors. Consequently, reports that IL-3 stimulates proliferation or function of certain mature hematopoietic cells[529] [530] [531] [532] may be a result of its ability to induce expression of other factors that actually do the real work. One particularly intriguing issue is the apparent ability of IL-3 to stimulate the full developmental potential of basophils and mast cells in vitro, [532] [533] a phenomenon that seems to be inconsistent in cultures of human marrow cells[534] but invariable in long-term cultures of rodent marrow cells. [535] In fact, administration of IL-3 to nude mice induces marked intestinal and splenic mastocytosis.[536] Nonetheless, the presence of accessory cells (including IL-3-responsive macrophages [155] [179] [537]) in such settings is universal, as is, therefore, the potential for a number of indirect effects. Notwithstanding all its direct and indirect hematopoietic effects, IL-3 is completely dispensible for normal steady-state hematopoiesis because no hematopoietic defects have been found in IL-3 knockout mice. [538]

The place of IL-3 in clinical therapeutics is unknown at this time. Trials of IL-3 therapy for myelodysplasia, acute nonlymphocytic leukemia, Diamond-Blackfan anemia, aplastic anemia, HIV-related cytopenias, and after bone marrow or peripheral stem cell transplantation have been either ineffective or no better than other factors currently approved for clinical use. [539] IL-3 may prove to be useful, however, in combination with other factors. Lemoli et al. [540] reported that the combination of IL-3 and G-CSF was better than G-CSF alone for hastening multilineage recovery, reducing transfusion requirements, shortening hospitalization time, and reducing the number of infections in patients undergoing autologous marrow transplantation for malignant lymphomas.

IL-3

Also known as: multi-CSF, mast cell growth factor-1
Chromosome: 5q31.1
Gene product: 1428 kDa
Produced by: T lymphocytes, mast cells
Induced by: mitogens, phorbol esters, calcium ionophore A23187, IgE receptor activation (mast cells)
Receptor: heterodimer of IL-3-specific subunit (CDw123, chromosome Xp22.3, Yp13.3) and a subunit (CDw131, chromosome 22q12.2-q13.1) shared with IL-5 and GM-CSF receptors
Bioactivity: see Table 14-2
Deficiency: no hematopoietic defect in steady state; deficient delayed-type hypersensitivity [538]

FLT3-Ligand

FLT3-ligand (FL) is the cognate ligand for the flt3/flk2 receptor tyrosine kinase. [541] Flt3/flk2 is a member of the type III receptor tyrosine kinase family that also includes c-*kit* (SF receptor), c-*fms* (M-CSF receptor) and the platelet-derived growth factor receptor.[542] Indeed, the flt3/flk2 gene shares a genomic structural organization with c-*kit* and c-*fms.* [543] Human flt3/flk2 is a 993 amino acid protein with a predicted molecular mass of 110 kDa and contains ten potential sites for

N-linked glycosylation. Cell-associated flt3/flk2 has a molecular mass of 155160 kDa; the difference in apparent versus predicted molecular mass is attributed to glycosylation.[544] [545]

Flt3/flk2 protein is widely expressed in lymphohematopoietic tissues but not in most extrahematopoietic tissues except brain and placenta. [544] [546] [547] Flt3/flk2 protein is not expressed by mature peripheral blood B cells, T cells, monocytes, eosinophils, nucleated red blood cells, or granulocytes, but is expressed by primitive hematopoietic progenitors, including about 20%; of lin-kit+sca-1+ murine bone marrow cells. [548] In humans, 6080% of CD34+ bone marrow cells are flt3/flk2+ and about 90%; of CD34+ umbilical cord blood cells are flt3/flk2+. B-cell precursors, CFU-GM, and HPP-CFC are flt3/flk2+, whereas BFU-E are flt3/flk2. [549] [550]

Flt3/flk2 protein and/or mRNA is expressed by malignant cells in most cases of acute myeloid leukemia (AML) or ALL, [551] [552] [553] but the expression of flt3/flk2 protein or mRNA does not always correlate with a proliferative response to FL. [553] Recently, mutations in the flt3/flk2 gene have been reported in some cases of AML or mylodysplasia (MDS). These mutations involve tandem duplication of sequences in exon 11, which encodes the juxtamembrane domain and the first residues of the N-terminal tyrosine kinase domain. These tandem duplications are translated in frame, always contain Y591 or Y599, and are somatic mutations associated with the leukemic clone. In several series, these mutations were found in up to 20%; of AML cases and 310% of patients with myelodysplasia. [554] [555] [556] The biologic significance of these mutations is unknown but could conceivably involve aberrant receptor activation and/or hypersensitivity to FL.

As might be predicted from the fact that M-CSF, SF, and FL bind to receptors with a common genomic structural organization, these ligands also share a protein structure. Although not homologous at the amino acid level, all are type I transmembrane proteins and have a four helix bundle structure. All three ligands exist as both membrane-bound and soluble isoforms, and some of the soluble isoforms are generated by proteolytic cleavage of membrane-bound precursors. [557] As is the case for M-CSF and SF, both soluble and membrane-bound FL protein isoforms have biologic activity. [558] [559] The relative biologic significance of membrane-bound and soluble isoforms of FL has not been determined.

Variable splicing of the FL gene generates several mRNA species. The most prevalent human mRNA species lacks exon 6 and encodes a transmembrane protein that can be proteolytically cleaved to generate a soluble FL isoform. [541] [559] Another human FL mRNA species contains exon 6 and generates an obligatorily soluble protein because the exon 6 sequence introduces a frame shift and introduction of a stop codon near the end of the extracellular domain. [560] Soluble human FL protein can also be translated from an mRNA in which the transmembrane domain has been spliced out. However, the relative abundance of this FL transcript has not been determined.[559] In mice, the most prevalent mRNA species encodes a membrane-bound protein that is not transmembrane and lacks the extracellular proteolytic cleavage site. To date, this species of FL transcript has not been identified in human cells.

Normal serum levels of FL in humans are <100 pg/ml. Levels of FL are not increased in patients with anemia only, but are

Figure 14-15 Serum FLT3 ligand levels in aplastic anemia (from Lyman, S.D. et al. [799]). Normal (N) serum levels of FL in humans are <100 pg/ml. Serum levels of FL are not increased in patients with anemia only, but increase substantially in patients with bone marrow failure (e.g., aplastic anemia [AA]). AA patients in complete remission (CR) have normal levels, but levels increase again in relapsed (RAA) patients. Little is known about the regulation of FL protein production, and it is not clear why levels increase in patients with pancytopenia, but the reliable increase of serum levels in bone marrow failure states is compatible with the idea that this factor may influence overall bone marrow cellularity in vivo.

increased dramatically in patients with pancytopenia, as seen with aplastic anemia, Fanconi anemia, or chemotherapy- or radiation-induced myelosuppression. [542] [561] For example, serum FL levels averaged 2654 pg/ml in patients with newly diagnosed aplastic anemia and fell to 100200 pg/ml in patients with hematologic remission. In relapsed patients, the FL serum levels increased to 15003000 pg/ml (Fig. 14-15). [561] Little is known about the regulation of FL protein production, and it is not clear why levels increase in patients with pancytopenia. One possibility is a loss of tissue binding sites and a displacement of FL protein into the peripheral circulation. This type of mechanism is believed to be the cause of increased thrombopoietin levels in patients with marrow failure. [269] Alternatively, progenitors or their progeny may produce feedback inhibitors of FL production; such inhibition is lost in marrow failure states, leading to increased FL production by stromal cells or other sources.

The biologic activity of FL is substantial. In general, FL has little in vitro colony-stimulating activity as a single agent but has potent synergism with a variety of other hemopoietins, including SF, [541] [562] IL-3, [541] [562] IL-7, [562] GM-CSF, [563] G-CSF, [563] [564] IL-6, [541] M-CSF, [563] and IL-11, [565] [566] as well as with multicytokine combinations. [567] [568] FL is not a universal hemopoietin: it augments the growth of only certain types of clonogenic colonies. In particular, FL has little or no effect in stimulating BFU-E, CFU-E, BFU-MK, CFU-MK, CFU-mast cell, or CFU-eosinophil. [564] [569] [570] [571] [572] However, FL is a potent stimulator of B lymphopoiesis and granulomonocytic proliferation and differentiation. [339] [551] [566] [573] Additionally, FL has a striking ability to augment dendritic cell proliferation and differentiation in vitro. [574] [575]

FL-responsive hematopoietic cells appear to be more primitive and to have greater lineage restriction than SF-responsive cells. For example, the growth- and differentiation-promoting effects of FL in humans appear to be largely confined to the CD34+CD38 fraction of bone marrow or cord blood. [567] [568] [576] Likewise, the FL-responsive population is contained in linsca-1+ but not linlowsca-1+ or lin-sca-1-purified murine bone marrow cells. [562] [565] Consistent with its action on primitive progenitors, FL supports the in vitro proliferation of long-term culture-initiating cells, CFU-S, and long-term repopulating cells. [317] [572] [576] [577] FL increases recruitment of primitive HPC into the cell cycle and inhibits apoptosis. [577] [578] [579]

The in vivo effects of FL administration have been studied using murine and primate models. FL-treated animals develop dose-related leukocytosis due to increases in lymphocytes, granulocytes, and especially monocytes. Associated with the leukocytosis is an increase in peripheral blood hematopoietic progenitors, especially CFU-GM and CFU-GEMM, with a smaller effect on peripheral blood BFU-E. Minimal decreases in hematocrit and platelet count were seen in mice receiving short courses of FL. Daily treatment with FL also increases peripheral blood primitive hematopoietic progenitors, including CFU-S (200-fold) and lin-kit+sca-1+ (170-fold) and long-term repopulating cells. [580] [581] [582] FL is synergistic with G- or GM-CSF in mobilizing stem cells. For example, simultaneous administration of FL and G-CSF increases peripheral blood CFU 12- to 20-fold over that seen with either agent alone. [583] FL treatment has no significant effect on bone marrow cellularity but does increase immature granulomonocytic cells and immature B cells (B220+sIgM). However, bone marrow immature erythroid cells decrease up to 90% during treatment.

FL has a potent effect on the proliferation and differentiation of dendritic cells in vitro and in vivo. Treatment of mice with FL increases the absolute number of dendritic cells in the spleen, lymph node, and peripheral blood compartments 17-, 4-, and 6-fold, respectively. These FL-stimulated dendritic cells are functionally active, as assessed by their ability to act as antigen presenting cells in vitro and to prime an antigen-specific immune response in vivo. [584] [585] Expansion of dendritic cells by FL administration may allow more effective utilization of dendritic cells in clinical immunotherapy protocols. [584] [586]

Considering the heterogeneous early-acting effects of this cytokine on hematopoiesis, it is surprising, just as it was with IL-11R knockout mice, that no marrow failure state is found in mice with targeted disruptions of the flk2/flt3 gene. [587] These mice, unlike mice nullizygous for SF or c-*kit*, were viable and had no gross abnormalities of bone marrow or spleen cellularity, peripheral blood counts, or morphology. Bone marrow progenitor frequencies for myeloid progenitors (granulocytic, monocytic, erythroid, and mixed colonies) are the same as in heterozygous mice. Disruption of the flt3/flk2 gene does not alter the frequency of day 13 CFU-S or pre-CFU-S. In addition, splenic and thymic cell populations were normal. Interestingly, however, although levels of differentiated bone marrow B cells (B220+CD43-IgM+ and $B220^{bright}$ CD43-IgM+) were normal in nullizygous mice, there was a 50% reduction in pro-B-cell ($B220^{dull}$ CD43+) and a 25% reduction in pre-B-cell (B220+CD43-IgM) populations. In addition, bone marrow from mutant mice generate fewer (by six-fold) B-cell colonies when cultured in the presence of IL-7 alone or IL-7 plus SF. LTCIC for B lymphopoiesis were proportionately reduced in nullizygous animals. [587] Thus, flt3/flk2 is not required for steady-state lymphohematopoiesis, but deficiency does lead to a subclinical defect in B lymphopoiesis.

There is an additional abnormality in these animals that involves hematopoietic stem cells. To assess the effects of flt3/flk2 disruption on stem cells, competitive repopulation studies were performed using homozygous and heterozygous bone marrow. Flt3/flk2 nullizygous marrow was 4.5-fold less efficient in repopulating peripheral blood, 2.5-fold less efficient in repopulating marrow and spleen, and 8-fold less efficient in thymic repopulation. When hematopoietic cell subsets were analyzed, the engraftment potential of mutant mice to generate B cells in marrow (3.6-fold less efficient) or spleen (16.7-fold less efficient) was reduced when compared with bone marrow granulocyte or macrophage repopulation (2.3-fold less efficient). Transplantation experiments utilizing a mutant to heterozygous marrow ratio of 4:1 resulted in an approximately 50% mutant cell engraftment in total bone marrow and peripheral blood cells, but in such mice only 17% of bone marrow B cells, 2% of thymocytes, and 3% of splenic B cells were derived from the

nullizygous donor.[587] Thus, the flt3/flk2 gene appears to be crucial for stem cell transplantation, especially for lymphoid reconstitution.

To assess further the functional role of flt3/flk2 in vivo, the flt3/flk2 nullizygous mice were crossed with W/Wv mice to generate mice nullizygous for flt3/flk2 and with impaired c-kit function. Viability was decreased in the double mutants and there was a 5- to 6-fold reduction in marrow, splenic, and thymic cellularity. The double mutant mice had a 16-fold decrease in bone marrow CFU-GM and a 56-fold decrease in B-cell colony-forming units. After age 3 weeks, the double mutant mice had a marked decrease in viability, with none surviving more than 6 weeks. The reason for the decreased viability is unknown. Combined deficiency of FL and c-*kit* exacerbates the hematopoietic defects seen with single receptor deficiency and is not compatible with long-term survival in mice.[587]

FL will likely prove to be of use in the clinic. In particular, for mobilization of peripheral blood stem cells, the combination of FL plus G- or GM-CSF seems superior to any of the three growth factors used alone.[580] [583] [588] Although preclinical data are lacking, the effects of FL in stimulating the proliferation of primitive progenitors suggest that it may have a role in treating bone marrow failure states such as seen with high-dose chemotherapy, stem cell transplantation, aplastic anemia, or myelodysplasia. FL in vitro synergistically enhances the activity of other growth factors, so optimal clinical use of FL may require tailored use of adjunctive cytokines. FL may also be useful in ex vivo maintenance of primitive progenitors and expansion of CFU for use in transplantation or gene therapy applications.[568] [589] [590] In addition to its use in expanding dendritic cells, FL may be useful clinically as an immune system modulator. In a murine model of syngeneic fibrosarcoma, FL induced complete regressions in more than half the cases and significantly reduced tumor growth in the other mice. Tumor response was dependent on FL dose and was mediated in part by CD8+ T cells.[591] Similar results were reported using a murine breast cancer model. In these studies the effect of FL was transient, as all animals with complete responses developed tumor after a secondary challenge (no FL was given during the rechallenge). FL was even more effective as a tumor vaccine, as it prevented tumors in nearly 90% of animals that were rechallenged with tumor. In 60% of cases, splenocytes harvested from tumor-free mice 4 weeks after the secondary challenge could adoptively transfer immunity to naïve mice. The effectiveness of FL as a tumor vaccine was superior to that of IL-2.[592]

FLT3-Ligand

Also known as: flk-2 (fetal liver kinase 2) ligand
Chromosome: 19q13.3
Gene product: Various isoforms are produced by alternative splicing. Membrane and soluble isoforms exist.
Produced by: mRNA expressed by most tissues examined, including spleen, lung, stromal cells, peripheral blood mononuclear cells, T-cell clones
Induced by: IL-1, pancytopenia
Receptor: Flt3/flk2, a type III receptor tyrosine kinase, human chromosome 13q12-13
Bioactivity: see Table 14-2
Deficiency: 50% reduction in pro-B cells, 25% reduction in pre-B cells, 6-fold reduction in B-cell colony-forming potential, reduced repopulating capacity of stem cells

Interleukin-9

Interleukin-9 [593] [594] was originally identified as a 40 kDa growth factor (P40) for certain murine T-cell clones.[595] [596] The human protein was identified as a factor produced by a human T-cell leukemia virus (HTLV)-1-transformed T-cell line that stimulates the proliferation of MO7E human megakaryoblastic leukemia cells.[597] Sequence comparison of the respective cDNAs[596] [597] demonstrated that P40 was the murine homolog of the human protein, both of which were subsequently designated IL-9. The murine gene is on chromosome 13 and the human IL-9 gene resides on the portion of the long arm of chromosome 5[598] [599] that also carries the genes that encode GM-CSF, IL-3, IL-4, IL-5, and the M-CSF receptor (c-*fms*), and a number of other cytokines and growth factor receptors (Fig. 14-16). IL-9 is produced by activated T lymphocytes, primarily CD4+ lymphocytes.[596] [600] Both IL-4 and IL-10 can induce IL-9 gene expression, but in vivo IL-10 is more important because IL-9 expression is low in IL-10 knockout mice but not low in IL-4 knockout mice.[410] The IL-9 receptor is a member of the hematopoietic growth factor superfamily (Fig. 14-2) and is expressed in membrane-bound and soluble forms.[601] Its unique chain (CD129, human chromosome Xq28, Yq12) consists of a fibronectin type III domain and WSXWS motif[601] and combines with the common chain (CD132, chromosome Xq13). The receptor is expressed on erythroid, myeloid, and lymphoid precursor cells, as well as activated T cells and T-cell lines.

In combination with erythropoietin, IL-9 supports BFU-E-derived colony growth from both unfractionated and highly progenitor-enriched marrow cells.[602] [603] In contrast to its effects on adult progenitors, which appear confined to the erythroid lineage, IL-9 supports the clonal growth of fetal erythroid, multipotential, and granulocyte-macrophage progenitors.[603] Despite its stimulatory effects on MO7E cells, IL-9 lacks megakaryocytopoietic

Figure 14-16 Chromosome 5. A number of hematopoietic growth factors and interleukins are found on the long arm of human chromosome 5. M-CSF, originally assigned to this chromosome, was reassigned to chromosome 1. C-fms is the M-CSF receptor. Other genes clustered in this region include the -2 adrenergic receptor, the monocyte differentiation antigen CD14, interferon response factor-1 (IRF-1), and the platelet-derived growth factor receptor (PDGF-R).

activity. IL-9 acts synergistically with IL-3 in promoting murine mast cell growth.[604] Although originally identified as a murine T-cell growth factor, it has been difficult to demonstrate comparable activity in the human system. Recently, however, IL-9 has been shown to stimulate the proliferation of human peripheral blood-derived T-cell lines and clones that had been preactivated with phytohemagglutinin, IL-2, and irradiated allogeneic feeder cells.[605]

IL-9 is also produced by certain lymphoid cell lines and neoplasms, including HTLV-1- and -2-transformed T lymphocytes,[597] Hodgkins disease cells (particularly by Reed-Sternberg cells),[606] and large cell anaplastic lymphoma cells.[606] It has been suggested that IL-9 may act as an autocrine growth factor in such cases.

IL-9

Also known as: T-cell growth factor P40, mast cell-enhancing activity
Chromosome: 5q31.2-31.3
Gene product: 2030 kDa
Produced by: T lymphocytes
Induced by: phytohemagglutinin, PMA, calcium ionophore A23187, anti-CD3, IL-1, IL-2, HTLV-1 or -2
Receptor: 522 amino acid member of hematopoietic growth factor receptor superfamily
Bioactivity: see Table 14-2

Interleukin-6

The IL-6 gene resides on the short arm of chromosome 7[389] [607] and encodes a 2126 kDa protein. [608] The expression of the gene is seen in heterogeneous cell types, including fibroblasts,[609] endothelial cells,[610] monocyte/macrophages,[609] and T lymphocytes, [611] and is induced by IL-1,[168] TNF-,[612] mitogens,[611] and endotoxin.[613] The IL-6 receptor is a heterodimer consisting of an 80 kDa subunit (CD126, chromosome 1q21) and a 130 kDa signal-transducing subunit (CD130, chromosome 5q11) (Fig. 14-2B). [20] [21] The biologic activity of IL-6 is exceedingly broad (Table 14-2). It functions synergistically with IL-3 in CFU-GEMM and BFU-E growth, [614] with IL-4 and G-CSF in GM colony growth, [614] with IL-4 in inducing T-cell proliferation, [615] and with IL-2 in inducing immunoglobulin secretion, [346] and increases the self-replicative potential of cells in M-CSF- and GM-CSF-stimulated colonies. [168] [614] IL-6 is a potent megakaryocytopoietic factor both in vitro and in vivo. It acts synergistically with IL-3 and GM-CSF in supporting CFU-Mk-derived colony growth, promotes megakaryocytic maturation, and increases peripheral platelet counts when administered to experimental animals.[245] IL-6 may be a humoral mediator of the reactive thrombocytosis that accompanies chronic inflammatory states. IL-6 also acts synergistically with many direct early-acting hematopoietic growth factors, including FL and SF. [616]

Largely a synergistic factor, recombinant human IL-6 has no clearly demonstrable direct effect on the proliferation of any human hematopoietic progenitor cell on its own, although it stimulates murine granulocyte/macrophage colony formation [617] [618] and is unambiguously an autocrine and paracrine growth factor for malignant lymphoid and myeloma cell lines.[619] [620] [621] [622] Thus, in vivo studies in rodents demonstrating that recombinant human IL-6 stimulates replication of CFU-S may reflect the ability of IL-6 to act in concert with other constitutively produced factors. IL-6 also mediates the acute phase response of hepatocytes [623] [624] [625] and influences differentiation of neural cells in vitro, [626] and is a major pyrogen in vivo, an effect that can be blocked by pretreatment with a recombinant soluble IL-6R. [627]

Had it not been for careful studies on IL-6-deficient mice, it would have been difficult to place IL-6 in a category of growth factors because it can act indirectly and can influence multiple hematopoietic lineages and nonhematopoietic cells. Nonetheless, IL-6 deficiency adversely affects survival of hematopoietic stem cells and early progenitor cells of multiple lineages. [628] Therefore, one of its dominant hematopoietic effects is on primitive multilineage cells. A recent study on IL-6-deficient mice suggests strongly that IL-6 also functions as an essential antiinflammatory cytokine that, like IL-10, modulates the intensity of the inflammatory response. [629] Consequently, the placement of this cytokine in one box is admittedly arbitrary.

IL-6

Chromosome: 7p
Gene product: 2126 kDa
Produced by: macrophages, endothelial cells, fibroblasts, T lymphocytes
Induced by: IL-1, mitogens, endotoxin
Receptor: heterodimer consisting of the ligand binding protein IL-6R (CD126), a 450 amino acid low-affinity binding protein encoded by a gene on 1q21, and the protein gp130 (CD130) encoded by a gene located on 5q11, which also serves as a chain for CNTF, IL-11, oncostatin M, and LIF
Bioactivity: see Table 14-2
Deficiency: reduced survival of hematopoietic stem cells and multilineage progenitors, reduced T-cell numbers, reduced proliferation and maturation of erythroid and myeloid cells

FACTORS THAT FUNCTION AS INDUCERS OF GROWTH FACTOR GENE EXPRESSION

Some proteins that regulate hematopoiesis in vivo and in vitro do so indirectly (Table 14-2). In other words, in some cases they incite bystander cells, also known as accessory or auxiliary cells, to release direct-acting factors.

Interleukin-1

Interleukin-1 was formerly known as endogenous pyrogen, lymphocyte-activating factor, and many other names. IL-1 exists in two molecular forms (IL-1 and IL-1), which are encoded by two genes on chromosome 2. Each of these genes encodes 31 kDa precursor molecules that are cleaved by IL-1-converting enzyme [630] to 17 kDa peptides. IL-1, originally thought to be produced only by monocytes and macrophages, is produced by almost all cells. Gene expression is induced by endotoxin, IL-1, GM-CSF, TNF-, and IL-2. There are two high-affinity IL-1 receptors, the 80 kDa type I receptor (CD121a) and the 68 kDa type II receptor (CDw121b), which show differential patterns of tissue expression. CD121a is expressed by T cells, synovial cells, hepatocytes, keratinocytes, and endothelial cells. CDw121b is largely expressed by macrophages, neutrophils, and B lymphocytes.[631] [632] Both are members of the immunoglobulin superfamily and share 28% amino acid homology in their extracellular ligand-binding domains. [631] [633] [634] The bioactivity of IL-1 is tremendously broad, and there is good evidence that it regulates expression of most genes encoding mediators of inflammation.

IL-1 has no colony-stimulating activity itself. However, when administered in vivo, IL-1 universally induces neutrophilic leukocytosis, which results from the induction of G-CSF and GM-CSF expression by other cells, including fibroblasts, [513] [635] endothelial cells,[168] thymic epithelial cells, [636] and T lymphocytes. The broad activity of IL-1 derives, in large part, from its ability to induce the expression of other interleukin and CSF genes, which themselves function as subordinate effector

molecules in the inflammatory process. The temporal pattern of IL-1 gene expression in the inflammatory response and its hierarchic dominance over a variety of other cytokines is shown graphically in Figure 14-18 , in which an activated macrophage produces IL-1 and thereby induces stromal cells (e.g., fibroblasts and endothelial cells) to express IL-1, IL-6, GM-CSF, and G-CSF.

IL-1 knockout mice are viable and do not have marrow failure. They do exhibit hyperresponsive febrile reactions after administration of IL-1 or , and early lethality after infection with influenza virus, but do not have defective immunity against *Listeria* challenges.[637] Because IL-1 is intact in these animals, a better test of the hematopoietic control function would be to knockout both the and forms. In effect, IL-1RI inactivation achieves this. Interestingly, IL-1RI knockout mice are protected against endotoxin-induced lethality [637] [638] but have no other gross defects in immune responses to date except failure to respond to IL-1 in vivo, [638] a finding that indicates the importance of this particular receptor and that other IL-1 receptor forms are insufficient to cover for the loss of IL-1RI.

IL-1 and

Chromosome: 2q
Gene product: 31 kDa precursor, mature 17 kDa cleavage product
Produced by: most cells
Induced by: endotoxin, IL-1, GM-CSF, TNF-, IL-2
Receptors: CDw121b, a 68 kDa protein encoded by a gene on 2q12-q22, and CD121a, an 80 kDa protein encoded by a gene on the same chromosome (2q12). Both are members of the immunoglobulin superfamily
Bioactivity: see Table 14-2
Deficiency: IL-1: minor defects. IL-1RI: no dramatic effects on immune system or hematopoiesis

Tumor Necrosis Factor-Alpha

Tumor necrosis factor-alpha, a 17 kDa protein (a cleavage product of a 29 kDa membrane-associated protein) encoded by a gene stationed on chromosome 6 [639] near the major histocompatibility complex,[640] shares with IL-1 a large number of heterogeneous biologic activities (Table 14-2) and, like IL-1, functions largely to induce the expression of other subordinate genes that, in turn, function as more specific regulators of hematopoietic responses to inflammation. TNF is a member of a family of molecules that influence cell growth and survival, including nerve growth factor (NGF, a 12.5 kDa neurotrophic peptide), CD40L (a 39 kDa integral membrane glycoprotein that forms natural trimeric structures, like TNF), OX40L (a 32 kDa peptide that naturally exists as a trimer), CD27L (CD70, a 50 kDa integral membrane glycoprotein), fas ligand (fasL, a 40 kDa transmembrane glycoprotein that, when bound to its receptor, fas, transduces apoptotic signals to a wide variety of cells), CD30L (a 40 kDa transmembrane glycoprotein that enhances the apoptotic effects of TNF by enhancing degradation of TRAF2 [47]), TNF-related apoptosis-inducing ligand (TRAIL, a 32 kDa molecule that, like fasL, mediates apoptosis), and TNF-like weak inducer of apoptosis (TWEAK). [641] [642] [643] [644]

Receptors for this family are also homologous. They are defined by the consistent presence of cysteine-rich repeats in the extracellular domains and frequently occurring soluble forms generated by proteolytic cleavage. Examples of signaling through this receptor family are shown in Figure 14-7 . Although a good deal of evidence demonstrates that TNF- itself is capable of functioning as a direct inhibitor of progenitor cell growth, [645] [646] [647] some evidence suggests that the ability of TNF to induce expression of other growth factor genes may be of equal importance, at least in the inflammatory response involving lymphopoiesis and granulopoiesis. For example, while TNF- can inhibit CFU-GM-derived colony growth, it also induces the expression of G-CSF and GM-CSF genes in accessory cells, [513] [648] which may function to override the inhibitory function. That EPO gene expression is not induced by TNF- may account for the vulnerability of erythroid cells in anemic patients with chronic inflammatory diseases in which the organism induces TNF- gene expression. [647] [649] Indeed, Roodman[649] has proposed that the anemia of chronic disease results from TNF- production. When factors such as TNF- have confusing double-edged biologic functions, we are obliged to assess the function of the molecule in vivo to assign weight to one or the other in vitro responses. This has been done recently, and it is clear that the stimulatory effect of TNF- dominates in granulopoiesis[650] [651] but inhibitory effects dominate in erythropoiesis. [649] [652] Other examples of the double-edged bioactivity of TNF- exist, some of which have been evaluated by in vivo studies. For example, while the growth of cultured vascular endothelial cells in vitro is inhibited by TNF, TNF administered in vivo is

angiogenic.[653] [654]

The full hematopoietic consequences of TNF-RI and II deficiency have not yet been evaluated, but it is clear that in cells of receptor-deficient mice, TNF- is incapable of inducing IL-6 or GM-CSF, ICAM-1 or VCAM-1, MHC class 1 expression, and CD44.[655] Consequently, it is likely that on-demand hematopoietic responses to inflammatory stimuli will be blunted in vivo as well. Further testing of receptor-deficient mice is clearly warranted, but some preliminary observations support this expectation. Specifically, TNF-RI is necessary for induction by endotoxin of nitric oxide synthase [656] and to prevent lethal complications of bacterial peritonitis. [657]

TNF-

Also known as: cachectin
Chromosome: 6p
Gene product: 17 kDa (cleaved by TNF converting enzyme from a 26 kDa precursor)
Produced by: macrophages, B lymphocytes, NK cells
Induced by: endotoxin, GM-CSF, IL-3, poly(I):poly(C), phorbol esters, calcium ionophore A23187
Receptor: 55 kDa protein homologous to nerve growth factor receptor
Bioactivity: see Table 14-2
Deficiency: TNF-RI-deficient mice: hypersensitive to bacterial infections, failure of endotoxin to induce iNOS, failure of TNF to induce IL-6, GM-CSF, ICAM-1, and VCAM-1

Interleukin-17

Interleukin-17 is a 22 kDa cytokine homologous to the predicted amino acid sequence of open reading frame 13 (ORF13) of Herpesvirus saimiri. This homology is analogous to the presence of an IL-10 homolog in the genome of EBV.[419] The gene encoding the receptor for the human IL-17R has recently been cloned and resides on chromosome 22q11.22-23.[658] The receptor is a transmembrane protein whose extracellular domain does not exhibit homology to other known proteins and whose 521 amino acid cytoplasmic portion lacks recognizable signal transduction domains. mRNA for the IL-17R is ubiquitously expressed, and protein is expressed by all hematopoietic and epithelial cell lines tested. [658] [659]

IL-17 is produced by activated memory T cells and induces stromal cells to secrete inflammatory and hematopoietic cytokines, including IL-6, IL-8, prostaglandin-E_2 (PGE_2), G-CSF and

GM-CSF,[660] and ICAM-1.[659] IL-17 has no direct effect on hematopoietic precursors, but the addition of IL-17 to cocultures of human CD34+ cells and irradiated fibroblasts results in enhanced cellular proliferation and augmented production of mature neutrophils. [660] Some of the indirect effects of T cells on hematopoiesis may be mediated by the capacity of IL-17 to alter stromal cell function.

IL-17

Also known as: CTLA
Chromosome: unknown
Gene product: 15 and 22 kDa isoforms. The 22 kDa protein is produced by glycosylation of the 15 kDa isoform.
Produced by: activated T cells; in mice, IL-17 is produced only by TCR ab+/CD4/CD8 cells.
Induced by: PMA, ionomycin, CD3 ligation, phytohemagglutinin
Receptor: predominant species 128132 kDa, minor species of 105107 kDa (nonglycosylated form); human chromosome 22q11.22-23
Bioactivity: see Table 14-2

Interleukin-18

Interleukin-18, an 18 kDa protein produced by macrophages and keratinocytes, [661] induces IFN- production from lymphoid cells, including unfractionated peripheral blood mononuclear cells as well as isolated populations of T_H1, B cells, and NK cells. IL-18 mRNA is translated to yield an inactive precursor, pro-IL-18, that is cleaved by the IL-1 converting enzyme (ICE, caspase-1) to yield the active protein. [662] [663] The receptor for IL-18 is a member of the IL-1 receptor family, also known as IL-1-receptor related protein (IL-1RRP).[664] IL-18 is one of a number of cytokines induced by endotoxin and may serve to prime the immune system through induction of inflammatory mediators such as TNF-, IFN-, and fas-ligand.[665] Caspase-1 cleavage of pro-IL-18 appears to be the only significant source of active IL-18, as lipopolysaccharide (LPS) treatment of caspase-1 / mice results in negligible induction of IFN-. [662] [663] IL-18 accounts for both TNF and FasL mediated hepatotoxicity in endotoxin-induced liver injury.[666] It activates NFB in murine T-helper cells[667] and induces activation and association of p56-lck and MAPK in murine T_H1 cells.[668] IL-18 induces apoptosis in myelomonocytic KG-1 cells via the fas pathway by inducing expression of p53, IFN-, and fas ligand. [669] No animal models of isolated IL-18 deficiency have been described to date. In vivo administration of IL-18 to animals produces immunologically mediated (primarily NK) antitumor responses. If these studies can be confirmed in humans, IL-18 may be useful in cancer immunotherapy treatment protocols.[670] Pharmacologic inhibition of IL-18 may be useful in treatment of inflammatory and/or autoimmune disorders.

IL-18

Also known as: Interferon--inducing factor, IL-1
Chromosome: unknown
Gene product: 18 kDa
Produced by: keratinocytes, Kupffer cells, activated macrophages, osteoblastic stromal cells
Induced by: LPS
Receptor: 60100 kDa protein (previously known as IL-1R-related protein) [664]
Bioactivity: see Table 14-2

A HEMATOPOIETIC FACTOR THAT IS DIFFICULT TO CATEGORIZE

Leukemia Inhibitory Factor

The murine cDNA encoding leukemia inhibitory factor[671] (also known as human interleukin for DA cells [HILDA]), a protein first identified by its capacity to induce differentiation and inhibit self-renewal simultaneously in certain murine leukemic cells, [671] [672] [673] was used as a hybridization probe to identify the human homolog [674] located on chromosome 22q12.[675] LIF is expressed by marrow stromal cells,[676] [677] monocytes,[678] and blastocysts,[677] [679] and expression is augmented by IL-1 and TGF. The human gene encodes a glycoprotein with 78% amino acid sequence identity with murine LIF, which, like the murine factor, induces differentiation of murine M1 leukemic cells.[674] Although it has no inhibitory activity on its own against the leukemic cell lines HL60 and U937, LIF, when combined with GM-CSF or G-CSF, reduces the in vitro clonal proliferative capacity of these cell lines [680] and induces differentiation.[681] LIF enhances the efficiency of retroviral mediated gene transfer in hematopoietic cells,[682] expands megakaryocyte mass in mice, [683] and exerts additional in vitro activities. For example, when added to cultures of totipotential embryonic stem cells, LIF suppresses the natural tendency of these cells to commit to differentiation. [684] [685] Whether LIF will function to inhibit commitment in other types of cells remains to be seen. It may prove to play an essential role in regulating the self-replication of not only hematopoietic stem cells, but other progenitors as well. The LIF receptor is a heterodimer consisting of an chain and a second chain, gp130 (CD130) shared with the IL-6R chain. [20] The LIF-R/gp130 heterodimer is also a receptor for oncostatin M (Fig. 14-2B). [20]

Based on the activities described previously, it is difficult to classify this cytokine based on its hematopoietic activity. The difficulty did not improve at all when the LIF knockout mouse was described. These mice have abnormalities of liver function, disrupted placental architecture, decreased bone volume (possibly because of increased osteoclasts), and neural defects, but no hematopoietic defects have been detected to date. [686]

LIF

Also known as: human interleukin for DA cells (HILDA)
Chromosome: 22q
Gene product: 58 kDa
Produced by: peripheral blood mononuclear leukocytes and Krebs II ascites tumor cells
Induced by: IL-1, TGF-
Receptor: a heterodimer consisting of gp130 and LIF-R subunits
Bioactivity: see Table 14-2
Deficiency: no hematopoietic defect

BRAKING MECHANISMS FOR BLOOD CELL PRODUCTION

Just as mammals have ways of accelerating blood cell production when they need extra cells, there are mechanisms for stepping on the brakes when the need no longer exists. This is accomplished by highly specific internal inactivation steps and two types of environmental cues.

Internal Controls; Signal Modulation Mechanisms

The capacity of growth factor receptors to activate adapter proteins is defined previously. The EPO-R, for example, when bound to EPO, dimerizes, resulting in transphosphorylation of

Figure 14-17 Modulation of growth signal transduction in cells of the erythroid lineage.[72] The erythropoietin receptor (EPO-R) dimerizes on ligand binding, resulting in transphosphorylation of Jak2 molecules. Jak2 activation results in phosphorylation of the EPO-R chains, creating docking sites for STAT molecules (also see Fig. 14-5). Signal termination results, at least in part, from: (a) phosphorylation of the protein tyrosine phosphatase, SHPTP1; (b) binding of SH-PTP1 to a domain on the EPO-R, followed by (c) SH-PTP1-mediated dephosphorylation of the JAK molecules, thus terminating the signal induced by the initial ligand binding event.

Jak molecules, which phosphorylate the EPO-R chains, creating docking sites for STAT molecules. Signal termination results, at least in part, from the subsequent binding of the protein tyrosine phosphatase SH-PTP1 to a domain on the EPO-R, followed by S-PTP1-mediated dephosphorylation of the JAK molecule (Fig. 14-17).[72] STAT molecules themselves are degraded in somewhat similar ways that involve phosphatases[687] and ubiquitin-dependent proteasome-mediated degradation of activated STATs.[688] In addition, a new and very interesting molecular family has been identified that contains STAT-inducible inhibitors of STAT activation. [688] [689] [690] [691] [692] [693] The specific action of these molecules is variable: some clearly function to inhibit Jak kinases, [690] [691] while others bind to STAT molecules themselves (e.g., inhibition of STAT3 activity by PIAS3[693]). Numerous examples of phosphatase-mediated inactivation of activated adaptor molecules can be found in the literature, indicating that the braking capacity of any signaling chain is very broad and set at a high fail-safe level. Phosphatase inhibitors enhance signaling through cytokine receptors.[694] [695] In fact, there are examples in which the failure of regulatory phosphatases results in oncogenic transformation (mitotic signals in cells lacking the capacity for signal termination usually result in tumorigenesis). [696]

Extracellular Cues

The easiest cue to understand is a downturn in growth factor production that deprives the proliferating population of the mitogenic signal. There are, however, occasions when high-level proliferation must be terminated promptly. To effect this, extracellular factors can repress expression of cytokine genes, induce programmed cell death of the proliferating cell population, or inhibit progression through the cell cycle of the proliferating cells. A number of factors can effect one or more of these modulatory responses. Some have already been reviewed. TNF, IL-4, and IL-10, for example, all inhibit cytokine and growth factor release under various circumstances. Three families of factors that modulate hematopoiesis are the interferons (the most clearly suppressive of which are IFN- and -), the TGF- family, and the chemokine family. One example of each family will be presented following.

Interferons

The interferons, a family of related cytokines initially discovered as glycoproteins produced by cells after infection by certain viruses, [697] [698] suppress hematopoietic progenitor cells, largely by inhibiting proliferation or inducing programmed cell death in that population. Since they are capable of inducing expression or release of other biologically active hematopoietic factors, [699] [700] the interferons can accomplish this in two ways. The receptors for each of the three types of interferons (, , and) are members of the cytokine receptor superfamily and after ligand binding cells transduce the IFN signals, at least in part, through the JAK/STAT pathway (Fig. 14-5). Much of the recent work done on the hematopoietic effects of interferons has been done on IFN- and this factor will be discussed in greater detail as a paradigm of the family.

The lymphokine IFN-, a 34 kDa homodimeric protein, directly suppresses the growth of committed progenitor cells and long-term culture-initiating cells (LTCIC) [645] [701] [702] and has even been proposed as a mediator of aplastic anemia.[703] [704] Fairly compelling indirect evidence supports this notion. First, parenteral administration of IFN- suppresses hematopoiesis in vivo.[705] Second, in patients with aplastic anemia, production of IFN- by cultured peripheral blood [706] and bone marrow lymphocytes is increased,[707] [708] [709] and when IFN- gene expression is enforced in bone marrow stromal cells, profound in vitro hematopoietic suppression occurs. [704] Finally, immunosuppressive therapy is often effective in patients with aplastic anemia, [710] [711] and response rates seem to be highest in patients whose bone marrow cells express the IFN- gene.[707]

IFN- induces progenitor cells to undergo programmed cell death, [704] [712] at least in part through its capacity to induce fas expression in these cells. [41] [43] [704] Fas, a 4348 kDa membrane glycoprotein, is a member of the TNF/nerve growth factor receptor superfamily[642] [713] that induces apoptosis when engaged by either its ligand (fas-L, a type II membrane protein homologous to

Figure 14-18 Orchestration of the inflammatory response. **(A)** Establishment of infection. Tissue macrophages are critical for the initiation of the inflammatory response. Macrophages engulf organisms (bacteria in this diagram) and kill them, but while doing so, they release cytokines that begin to induce the early phagocytic phase of the immune response. Release of G-CSF and IL-6 influences phagocyte production and activation in marrow. Release of IL-1 and TNF- also occurs. These indirect-acting cytokines induce expression of additional granulopoietic factors, G-CSF, GM-CSF, IL-6, IL-11, and IL-9, by other mesenchymal cells in the infected tissues and possibly in bone marrow stroma as well. Finally, neutrophil chemotactic factors are released by stromal cells induced by IL-1 and TNF. **(B)** Early phagocytic response. Under the influence of the granulopoietic factors, the chemotactic factor IL-8, and cytokines that induce release of storage-pool granulocytes, neutrophils come onto the scene and more effectively than macrophages begin to kill bacteria and at the same time augment the secretory response by synthesizing more IL-1 in response to GM-CSF. The increase in IL-1 further augments production of granulopoietic and chemotactic factors. G-CSF released from stromal cells and macrophages in the infected tissue activates the functional capacity of neutrophils in situ. **(C)** Multilineage immune response. Immunogenic peptides presented to $CD4^+$ (T_H 1 and T_H 2) and $CD8^+$ T cells result in release of additional granulopoietic

(IL-3, GM-CSF) and macrophage-activating (IFN-, TNF-, GM-CSF) factors, and T $_H$ 2 cells influence the outgrowth of antigen-specific B cells in inflammatory foci and nearby lymph nodes by intercellular communication through CD40/CD40L interactions and by secretion of cytokines (IL-4, -5, -6, -10, and 15) that induce B-cell production and maturation and T-cell expansion. CD8 cells are also influenced by macrophages to release macrophage activating factors and the lymphocyte specific factor, IL-16. **(D)** Late immune response and suppression of phagocyte production. Once the offending bacteria are cleared, production of granulopoietic factors declines but elements of immune stimulation persist through instructed T cells, resulting in suppression of phagocyte production via the inhibitory factors IFN-, TNF-, IL-10, IL-4, and TGF-. B-cell expansion persists for many days beyond the resolution of the infection.

members of the TNF family)[714] [715] or by specific anti-fas antibodies that mimic the effects of fas-L. [716] [717] [718] Fas expression alone is insufficient to account for an apoptotic phenotype. It requires a number of other intact elements, including FADD, [719] [720] a protein that binds to the death domain of fas, and FLICE, [721] an IL-1-converting enzyme (ICE)-like protein that binds to the death domain of FADD and subsequently initiates the caspase [722] cascade that, at least in certain lymphocytes, includes ICE and CPP32.[723] [724] The ordered activation of these death mediators is less well defined in hematopoietic progenitor cells, but the pathway is clearly involved in the high level of programmed cell death found in progenitor cells of children or mice with Fanconi anemia. [45]

Could this family play a modulatory role in the production of cells during infections? We think so, but the issue has not been fully tested yet. In the hypothetical model described in Figure 14-18 , IFN production develops during the recovery phase of infections, at which point the need for highly proliferative progenitor cells has diminished but the need for activated macrophages has not because the organisms are dead but the debris is still present (IFN- is a potent macrophage activator [725] [726]). In this context, IFN molecules may play an important role as a braking factor for neutrophil production. Failure of certain neoplastic hematopoietic clones to respond to braking factors such as IFN might account for the sustained hyperleukocytosis some leukemic patients develop during and after bacterial infections.

Transforming Growth Factor-Beta Family

There are about 30 members of the TGF-1 superfamily, all of which are functionally related. The superfamily has three subfamilies: the TGFs, inhibins and activins, and bone morphogenetic proteins. Most of these molecules act as homodimers joined by disulfide bonds. Although a good number of these molecules may modulate hematopoiesis, the most well studied is TGF-1. This molecule is a disulfide-linked homodimer, each chain of which is processed from a 390 amino acid precursor

to the mature 112 amino acid molecule. The binding molecules and pathways for TGF-1 signaling are reviewed in the previous sections. The effects of TGF on hematopoietic cells are complex. It can inhibit expression of growth factors and their receptors (e.g., c- *kit* and SF[90]) and induce expression of mitotic inhibitory genes. TGF- inhibits mitotic progression in hematopoietic cells and may also induce apoptosis. [727] It governs the activity of cyclin-Cdk complexes by inhibiting Cdk4; inducing p27/Kip1, an inhibitor of cyclinCdk complexes; inducing p21/Cip1/Waf1, an inhibitor of cyclinECdk2 complexes; [728] [729] inducing p16INK4a and p15INK4b expression, [730] inhibitors of Cdks 4 and 6; and by repressing the phosphorylation of the retinoblastoma (Rb) protein (Fig. 14-6). [731] The importance of the TGF receptor family as braking factors for a variety of cells is clarified by the capacity of inactivated receptors to permit autonomous growth and the frequency with which these receptors or their downstream targets are inactivated by somatic mutation in a variety of cancers, [33] [34] [35] and the markedly enhanced inflammatory response and early death seen in mice with targeted disruptions of the TGF-1 gene. [732] [733]

Chemokine Family

Chemokines are a large family of molecules that are distinguished among the cytokines for being the only ones that bind to seven transmembrane-spanning G protein-linked receptors.[36] The chemokines are divided into three families (or CXC, or CC, and or C) [37] on the basis of differences in the content and location of their component cysteine residues. These proteins were originally defined biologically as cytokines that exert effects on chemotaxis. While there are some exceptions, generally the chemotactic activities of the chemokines also sort with the

subtype. In other words, members of the family are chemotactic for granulocytes (neutrophils, eosinophils, and basophils), the family for mononuclear phagocytes and lymphocytes, and the family for lymphoid cells only.[734] Clearly, other activities have been identified for these molecules, including cell adhesion, angiogenesis, HIV-1 suppressive factors, and feedback control of hematopoiesis and the inflammatory response. [36] [734] It is this latter issue that will be reviewed in more detail, using as a paradigm of this family, the chemokine, IL-8.

IL-8 is an 11 kDa chemokine produced by most cells under the influence of inductive cytokines. After its secretion, extracellular N-terminal processing of the mature IL-8 polypeptide yields several active species, ranging from 69 to 79 amino acids in length, with the predominant species consisting of 72 amino acids. [735] [736] IL-8 is produced by mononuclear phagocytes, endothelial cells, fibroblasts, other connective tissue cells, and by neutrophils themselves in response to IL-1, TNF, and a variety of other inflammatory stimuli and proinflammatory cytokines. [737] [738] [739] [740] IL-8 is repressed by cytokines that modulate the inflammatory response (e.g., IL-10 [424]). Neutrophils express two closely related G-protein-coupled IL-8 receptor molecules, which each possess seven membrane-spanning domains and share significant sequence homology with receptors for the neutrophil chemoattractants fMet-Leu-Phe and C5a. [741] [742]

IL-8 is a potent neutrophil agonist, inducing neutrophil chemotaxis, [743] [744] shape change,[745] exocytosis of storage granule proteins,[746] [747] and the respiratory burst.[745] [748] NAP-2, the GRO proteins, and ENA-78 also bind IL-8 receptors and induce similar neutrophil responses. [742] [749] [750] IL-8 is also chemotactic for T lymphocytes, [751] basophils,[752] and endothelial cells[753] and is a potent angiogenic agent. [753] In addition to playing a role in host defense by promoting neutrophil activation and directed migration to sites of infection, IL-8 is also an important mediator of the destructive inflammatory processes that characterize such disease states as rheumatoid arthritis and psoriasis. [754] [755] [756] Observations of extreme neutrophilic leukocytosis in IL-8 receptor knockout mice [39] support the notion that IL-8 is an essential feedback regulator of neutrophil production. [757]

IL-8

Also known as: neutrophil attractant/activation peptide-1
Chromosome: 4q12-21
Gene product: 8 kDa
Produced by: mononuclear phagocytes, fibroblasts, endothelial cells, neutrophils, keratinocytes, synovial cells, chondrocytes
Induced by: IL-1, TNF, LPS, IL-3, GM-CSF, immune complexes, phorbol esters
Receptor: two G protein-coupled receptors (350 and 355 amino acids in length), both on human chromosome 2q35[758]
Bioactivity: see Table 14-2
Deficiency: expansion of lymph nodes, plasmacytosis, and neutrophilia

ORCHESTRATION OF THE INFLAMMATORY RESPONSE

New students of hematopoiesis are rightly dismayed at the complexity of the growth factor network, with all its synergies and feedback loops. One rule that seems to place the networks into some understandable framework is that most cytokine responses are hierarchic.[166] The central roles of IL-1 and TNF- in hematopoietic regulation, particularly of the inflammatory response, serve as particularly obvious examples of this.[168] Both IL-1 and TNF- genes are expressed early in the inflammatory response (Fig. 14-18). These two gene products induce the expression of a wide variety of subordinate interleukin and growth factor genes that call forth phagocytes by inducing granulopoietic factors, activate the phagocytes through phagocyte activating factors, some of which are the same as the lineage-specific granulopoietic factor that got them circulating in the first place, and then call them to the site of inflammation through the chemotactic factors and adhesion molecules induced by the same orchestrators, IL-1 and TNF. These master switch molecules are also capable of autoamplifying their own signals by enhancing the expression of their own genes[168] and each other (e.g., TNF- induces IL-1 gene expression).[759] More trying complexities exist. IL-1 gene expression is induced by proteins that IL-1 itself induces.[166] Thus, such signal amplification mechanisms can be autocrine, paracrine, or both. Finally, as the need for large numbers of sticky, fast-moving, hungry phagocytes declines during the course of a resolving infection, a set of factors come into play that repress growth factor production and inhibit the response of progenitor cells to such growth factors by causing either apoptosis (e.g., in the case of IFN-) or mitotic inhibition (e.g., TGF-).

HEMOPOIETINS: AUTOCRINE LOOPS IN NEOPLASTIC CELLS

Certain elements of the hierarchic network of hematopoietic growth factors and interleukins can fail. When cells produce their own growth factor, they are said to exhibit autocrine growth. While there exist some autocrine functions in normal cells, [760] [761] [762] [763] [764] rarely are these functions that directly affect cell growth. For the most part, cells that produce their own growth factors are transformed or neoplastic. An increasing number of neoplastic cells or cell lines, either of the wild type or molecularly engineered, have been found to depend on autocrine growth factors, including IL-1, [765] IL-2,[766] [767] IL-3,[768] [769] IL-4,[395] IL-6,[770] [771] IL-11,[319] IL-14,[484] GM-CSF,[768] [772] M-CSF,[773] [774] and EPO.[2]

SUMMARY

Our knowledge of hematopoietic control derives, in large part, from five pathways of laboratory and clinical investigation, each of which informs and sometimes surprises us:

1. Cell culture methods that permit studies on hematopoietic regulation in vitro
2. The comprehensive characterization of lineage- and stage-specific cell surface molecules
3. Cloning and characterization of genes encoding proteins with direct and indirect effects on blood cell growth and differentiation
4. The development of mice with targeted disruptions of growth factor and growth factor receptor genes
5. Clinical trials of recombinant hematopoietic growth factors.

As a result of these approaches, we know that cells empowered to produce these soluble regulatory factors do so in response to early inductive stimuli, and these inductive signals are quite predictably responsive to environmental influences. Some are even simple; hypoxia induces EPO gene expression but inflammatory stimuli do not. Most other responses to environmental stressors are more complex, especially those induced by microbial assault. These are met by a multipronged inflammatory response orchestrated by hematopoietic cells under the influence of a complex network of hematopoietic growth factors and interleukins, some of which are expressed early in the response and others of which are expressed late. Despite its complexity, cause-and-effect relationships are clearly testable using a combination of the five approaches. Because many of these

cells and hematopoietic factors have homologs in primitive organisms, and because disruptions of selected components of the control system can result in a wide variety of clinical disorders, from leukemia to aplastic anemia, this extraordinarily efficient molecular network is a paradigm with profound implications for clinicians, developmental biologists, cell biologists, and molecular biologists alike.

Chapter 15 - Biology of Erythropoiesis, Erythroid Differentiation, and Maturation

Thalia Papayannopoulou
Janis Abkowitz
Alan DAndrea

INTRODUCTION

The production of erythroid cells is a dynamic and exquisitely regulated process. The mature red cell is the final phase of a complex but orderly series of genetic events that initiates at the time a multipotent stem cell commits to the erythroid program. Expression of the erythroid program occurs several divisions later in a greatly amplified population of erythroid cells, which have a characteristic morphology, maturation sequence, and function. These maturing cells are termed erythroid precursor cells and reticulocytes. As terminally differentiated cells have a finite life span, they are constantly replenished by influx from earlier compartments of progenitor cells that are irreversibly committed to express the erythroid phenotype. During ontogeny these are successive waves of erythropoiesis in distinct anatomic sites. The erythroid cells developing in these sites have distinguishable phenotypes and intrinsic programs that are dependent on gestational time and their microenvironment. At each site erythroid cells are in intimate contact with other cells (stromal cells and hematopoietic accessory cells) comprising their microenvironment. Within this microenvironment, erythroid development is influenced by cytokines, which are either elaborated by microenvironmental cells or produced elsewhere and then entrapped in the extracellular matrix.

An understanding of the properties of erythroid progenitor and precursor cells and their complex interactions with the microenvironment is essential for understanding the pathophysiology of erythropoiesis. Aberrations either in the generation and/or amplification of fully mature and functional erythroid cells or in the regulatory influences of microenvironmental cells or their cytokines form the basis for various clinical disorders, including aplasias, dysplasias, and neoplasias of the erythroid tissue.

TABLE 15-1 -- Erythroid Progenitors: General Properties

	CFU-GEMM	BFU-E	CFU-E
Self-renewal	++	+	0
Differentiation potential	Multipotent	Committed to erythropoiesis	Committed to erythropoiesis
Cycling status % suicide with ^{3}H Thymidine	1520	3040	6080
Cell density (g/ml)	<1.077	<1.077	<1.077

ERYTHROID PROGENITOR CELL COMPARTMENT

The erythroid progenitor cell compartment, situated functionally between the multipotent stem cell and the morphologically distinguishable erythroid precursor cells, contains a spectrum of cells with a parent-to-progeny relationship, all irreversibly committed to erythroid differentiation. A complete understanding of how erythroid commitment is achieved at the biochemical or molecular level is lacking, although some recent attempts for understanding the molecular basis have been made. [1] [2] [3] Evidence from in vitro cultures of single multipotent progenitor cells allowed to differentiate in competent environments, as well as evidence obtained by studying the phenotype of leukemic cells, suggests that commitment to a specific hematopoietic lineage is accomplished not by acquisition of new genetic information but rather by restriction (probably on a stochastic basis) to specific programs from a wider repertoire available to pluripotent progenitor cells. [4] [5] Recent molecular evidence supports this view. [3] [6] Although the irreversible commitment to express the erythroid phenotype is a feature common to all erythroid progenitor cells, their properties progressively diverge as they become separated by several divisions.

Erythroid progenitor cells are both sparse (Table 15-1) and difficult to isolate in sufficient purity and numbers for study. Their existence and characteristics have been inferred from their ability to generate hemoglobinized progeny in vitro in clonal erythroid cultures (Fig. 15-1). Through this approach two classes of progenitors have been identified. [7] The first, more primitive, class consists of the BFU-E, named for their ability to give rise to multiclustered colonies (erythroid bursts) of hemoglobin-containing cells. BFU-E represent the earliest progenitors committed exclusively to erythroid differentiation and a quiescent reserve, because only 1020% are in cycle at any given time. However, once stimulated to proliferate in the presence of appropriate cytokines, they demonstrate a significant proliferative capacity in vitro, giving rise to colonies of 30,00040,000 cells, which become fully hemoglobinized after 24 weeks, with a peak incidence at 14 to 16 days. They also have a limited self-renewal capacity, because at least a subset of BFU-E is capable of generating secondary bursts, upon replating. In contrast to this class of progenitor cells, a second, more differentiated class of progenitors consists of the CFU-E. Most (6080%) of these progenitors are already in cycle and thus proliferate immediately after initiation of culture to form erythroid colonies within 7 days. Because CFU-E are more differentiated than BFU-E, they require fewer divisions to generate colonies of hemoglobinized cells, and the colonies are small (865 cells).

Although the two classes of committed erythroid progenitors, BFU-E and CFU-E, appear distinct from each other, in reality progenitor cells constitute a continuum, with graded changes in their properties. Only progenitor cells at both ends of the differentiation spectrum have distinct properties. Perhaps

Figure 15-1 Erythroid differentiation. BFU-E and CFU-E occur infrequently in the marrow (approximately 0.3% of mononuclear cells) and cannot be distinguished by morphologic or cytochemical techniques. Their existence is inferred by their ability to differentiate in culture. If marrow is placed in semisolid medium (e.g., methylcellulose) to decrease cell motility, with appropriate nutrients and growth factors (e.g., transferrin, insulin, EPO, and IL-3), CFU-E (after approximately 7 days) differentiate into small clusters of hemoglobinized or red cells termed erythroid colonies. Most BFU-E present in the inoculum differentiate to form multiclustered colonies of hemoglobinized cells, or erythroid bursts, by days 1416. Each erythroid colony or burst derives from one CFU-E or BFU-E, respectively.

TABLE 15-2 -- Erythroid Progenitors: Surface Antigen/Receptors

Receptor/Antigen	CFU-GEMM	BFU-E	CFU-E
CD34	++	++	
CD33	+	+	0
c-kit	++	++	+
HLA-DR (-DP, -DQ)	++	++	+
EPO receptor	+	+	++
Tumor necrosis factor receptor	+	+	++
Ep-1[242]	+	+	++
23.6[243] [a]	0	0	+
CD36	0	±	+
Glycophorin A	0	0	+
ABH, iI[b]	0	+	+
Adhesion Molecules			
VLA-4 (CD49d/CD29)	++	++	++
VLA-5 (CD49e/CD29)	+	+	++
CD41	+	+	
CD11a/CD18	+	+	
CD44	+	+	
HCAM[c]	+	+	

[a] 23.6 (SFL 23.6) is a monoclonal antibody reactive with CFU-E, erythroblasts, and erythrocytes.
[b] ABH and iI are blood group antigens.
[c] Presence of other cytoadhesion molecules, i.e. CD31, L-selectin, P-selectin, E-cadherin, has been described in progenitors (see text). However, the extent of their presence in BFU-E as compared to other cells is not clear.

the earliest cell with the potential to generate hemoglobinized progeny is an oligopotent progenitor, which is capable of giving rise to mature cells of at least one other

lineage (granulocytic, macrophage, or megakaryocytic) in addition to the erythroid. This progenitor, a multilineage CFU called CFU-granulocyte/erythrocyte/macrophage/megakaryocyte (GEMM), and the most primitive BFU-E have physical and functional properties that are shared by both pluripotent stem cells and progenitor cells committed to nonerythroid lineages. These properties include high proliferative potential, low rate of cycling, response to a combination of cytokines, and presence of specific surface antigens or surface receptors (Tables 15-1 and 15-2). In contrast, the latest CFU-E have many similarities to erythroid precursor cells and little in common with primitive BFU-E. Their proliferative potential is limited, they cannot self-renew, they lack the cell surface antigens common to all early progenitors, and they are exquisitely sensitive to erythropoietin (EPO) (Tables 15-1 and 15-2).

Although clonal erythroid cultures are indispensable for the study of erythroid progenitors, they do not faithfully reproduce the in vivo kinetics of red cell differentiation/maturation, and many maturing cells have a megaloblastic appearance and lyse before they reach the end stage of red cell development. In vivo, erythropoiesis probably occurs faster than would be predicted from culture data. For example, studies in dogs with cyclic hematopoiesis, a genetic stem cell defect leading to pulses of hematopoiesis, provide evidence that BFU-E mature to CFU-E over 23 days in vivo (Fig. 15-2), although this process may require 56 days in canine marrow cultures.[8] Erythroid progenitors can be cultured under serum-depleted conditions, [9] as well as in serum-containing media. The effects of recombinant growth factors can be studied in serum-depleted cultures without the complicating influences of multiple or unknown factors present in serum. Conditions that imitate the lower oxygen pressures, found in bone marrow in vivo, favorably influence erythroid development in culture and may be advantageous. [10]

As BFU-E are generated from the multipotent or oligopotent progenitors within the marrow, they are dependent for their survival and proliferation on the presence of cytokines, elaborated by either stromal cells or accessory cells within the microenvironment. A number of cytokines have been shown to influence proliferation and/or survival of early progenitors. Among them kit-ligand, produced by stromal cells and IL-3 produced by a subset of T cells, alone and in synergy, has a profound proliferative effect on BFU-E and its progeny. Other cytokines, such as GM-CSF, IL-11 and thrombopoietin (Tpo) stimulate a subset of BFU-E. [11] [12] [13] Cytokines exert their effects through interaction with specific receptors present on the BFU-E surface. The presence of such receptors has also been documented in the leukemic counterparts of normal BFU-E and in leukemic cell lines. [14] BFU-E cannot survive in the absence of cytokines for more than a few days in culture, and if they are deprived of cytokines for >6 days, >80% of them are lost.[15] In addition to positive regulators (IL-3, GM-CSF, Tpo, KL, or IL-11), substances with negative influences on BFU-E proliferation have been identified. These include tumor necrosis factor- (TNF), transforming growth factor- (TGF-), and interferon- (Inf-). [16] [17]

BFU-E and immediate progeny (but not CFU-E) are motile cells and are found in significant numbers in peripheral blood. As with BFU-E, the ability of stem cells and progenitor cells to circulate is physiologically important for the redistribution of marrow cells when there is local damage to the microenvironment and for the reconstitution of hematopoiesis after transplantation. The spectrum of BFU-E in circulation is probably narrower (consisting mostly of early, quiescent BFU-E) than that of BFU-E in the bone marrow, but otherwise their properties are similar to those of marrow BFU-E. The number of circulating BFU-E (along with other progenitors and stem cells) can be increased to significant levels after cytokine/chemokine treatments and following chemotherapy, and this has been exploited for transplantation purposes.[18]

Surface antigens of BFU-E have been defined through the use of monoclonal antibodies. [19] [20] The antibodies tested thus far include two broad categories: antibodies raised against leukemic cells or cell lines with progenitor cell properties, and antibodies raised against normal, terminally differentiated red cells. Enrichment in BFU-E (or CFU-E) following labeling with these antibodies, or their loss after complement-dependent lysis, have been considered indicative of the presence of test antigens on the BFU-E surface. Reactivities of BFU-E with several antibodies directed against defined surface antigens are listed in Table 15-2 . Like other hematopoietic progenitors, BFU-E display HLA class I (A, B, C) and class II (DP, DQ, DR) antigens on their surface, but class II antigens, especially the products of DR locus, are, in contrast to class I, variably expressed among BFU-E. This may relate to variations in their cycling status, as myeloid progenitors in S phase have been shown to have relatively higher expression of class II antigens. [21] The presence of HLA class II antigens (DR and, to a lesser extent, DP and DQ) most likely allows BFU-E to recognize and interact with the immunoregulatory cells (e.g., T cells, monocytes), which also express class II determinants. [22] In addition to HLA antigens, several other antigenic structures have been found on cells within the BFU-E compartment (Table 15-2). The best representative of these is the CD34 molecule (identified through monoclonal antibodies MY10, 12.3, or HPCA1), which has been successfully exploited for the isolation of BFU-E and other progenitors. CD34 is a highly O-glycosylated cell surface glycoprotein and is expressed in all hematopoietic progenitors and vascular endothelial cells. [23] Its role in hematopoiesis is not clearly defined. A reduction in the number of all hematopoietic progenitors was present in CD34 null murine embryos and adult animals, but no other abnormalities identified.[24] Recently it was shown that expression of CD34 is low or absent in a population of adult long-term repopulating cells in the mouse and man. [25] Furthermore,

Figure 15-2 Studies in a gray collie dog with cyclic hematopoiesis, an inherited disorder of hematopoietic stem cells in which granulocytes, monocytes, platelets, and reticulocyte counts fluctuate (or cycle) at 12-day intervals. It is thought that multipotent stem cells intermittently contribute to hematopoiesis, thus giving rise to pulses of differentiating cells. As shown here, the peak frequency of BFU-E (cycle day 10) occurs 3 days before the peak of CFU-E (cycle day 1), that in turn precedes the peak in the reticulocyte count (cycle day 4). These data confirm that BFU-E are the precursors of CFU-E in vivo and suggest that erythroid differentiation in vivo may occur more quickly than would be predicted from maturation time in culture. *(From Abkowitz et al.,[6] with permission.)*

through the use of antibodies or conjugated ligands it was determined that BFU-E present in enriched progenitor preparations display receptors for KL, EPO, TPO, GM-CSF, IL-3, IL-6, and IL-11 receptors. The great majority of BFU-E, however, in contrast to myeloid progenitors (CFU-GM) do not express the restricted hematopoietic phosphatase CD45RA.[26] [27] Furthermore, BFU-E appear to share with late CFU-MK progenitors the expression of glycoprotein IIb/IIIa (CD41) and of the megakaryocytic receptor c-Mpl.[27] [28]

As BFU-E mature to the CFU-E stage, they begin to express surface proteins characteristic of the morphologically recognizable erythroid cells, the erythroblasts. For example, CFU-E express the erythroid-specific sialoglycoprotein, glycophorin A, and Rh antigens. Blood group antigens of the ABH,iI type are also detectable at least in a subset of CFU-E. In contrast, CD34 molecules and class II antigens and certain growth factor receptors (i.e., IL-3R, c-kit) are greatly diminished or virtually absent at the CFU-E stage (Table 15-2). The most important functional difference between BFU-E and CFU-E is the abundance of EPO receptors on CFU-E and their dependence on EPO for cell survival. CFU-E, in contrast to BFU-E, cannot survive in vitro even for a few hours in the absence of EPO. Although >80% of CFU-E have detectable EPO receptors,[29] only a small proportion of BFU-E have receptors [30] [31] and can terminally differentiate in culture in the presence of EPO alone. [32] Direct binding studies show that the number of EPO receptors peaks at the CFU-E/proerythroblast level and progressively declines when cells mature further [30] (Table 15-2), reflecting the decline in the influence of EPO. In addition to the abundance of EPO receptors, erythroid progenitors are distinguished from other marrow progenitors by the presence of high levels of transferrin receptors. [31] [33] [34] The latter play a unique role in iron transport and in hemoglobin synthesis. Peak levels of transferrin receptors are seen on CFU-E and erythroid precursors, and lower levels are present on reticulocytes. [28] [33] (For a detailed review on iron metabolism and heme synthesis in erythroid cells, see reference [35] .)

ERYTHROID PRECURSOR CELL COMPARTMENT

The erythroid precursor cell compartment, also termed the erythron, includes cells that, in contrast to the erythroid progenitor cells (BFU-E and CFU-E), are defined by morphologic criteria. The earliest recognizable erythroid cell is the proerythroblast, which after four to five mitotic divisions and serial morphologic changes gives rise to mature erythroid cells. Its progeny include basophilic erythroblasts, which are the earliest daughter cells, followed by polychromatophilic and orthochromatic erythroblasts. Their morphologic characteristics reflect the accumulation of erythroid-specific proteins (i.e., hemoglobin) and the decline in nuclear activity (Fig. 15-3). After the last mitotic division, the inactive, dense nucleus of the orthochromatic erythroblast moves to one side of the cell and is extruded encased by a thin cytoplasmic layer. Expelled nuclei are ingested by marrow macrophages, and the resulting enucleated cell is a reticulocyte. Although all mammals have enucleated cells in their circulation, the evolutionary advantage of enucleation is not readily apparent. It may allow for more red cell deformability when

Figure 15-3 Erythroid maturation sequence. As proliferation parameters (i.e., rates of DNA and RNA synthesis) and cell size decrease, accumulation of erythroid-specific proteins (i.e., heme and globin) increases, and the cells adapt their characteristic morphology. *(Adapted from Granick and Levere, [245] with permission.)*

traveling through the small vasculature or it may minimize the cardiac workload.

It is unlikely that maturation from the proerythroblast to the reticulocyte always adheres to a rigid sequence in which each division is associated with the production of two more differentiated and morphologically distinct daughter cells (i.e., with a basophilic erythroblast giving rise to two polychromatophilic ones). Rather, significant flexibility may be allowed, both in the number and rate of divisions and in the rate of enucleation. Such deviations from the normal, orderly maturation sequence may be dictated by the level of EPO. Thus, when there is an acute demand for red cell production (because of blood loss or hemolysis), the kinetics of formation of new reticulocytes are significantly more rapid. Resulting red cells may be larger (i.e., with increased mean corpuscular volume). This has led to the concept of skipped divisions. [36]

The alterations in cell morphology as erythroid precursor cells mature (Fig. 15-3) are determined by complex biochemical changes, which accommodate the accumulation of erythroid-specific proteins and the progressive decline in proliferation. Compared to erythroid progenitor cells, erythroid precursor cells have been more accessible to study, and considerable information is available about their maturation-related biochemical changes.

The shape and deformability of the red cell is determined by its membrane proteins. Most membrane cytoskeletal proteins (spectrin, glycophorin, band 3, band 4.1, and ankyrin) accumulate after the CFU-E stage (i.e., within the precursor cell compartment). Specifically, expression of membrane glycoproteins such as band 3 and band 4.1 is greatly enhanced at the later stages of erythroid maturation. [37] [38] [39] Likewise, the quantity of polylactosaminoglycan, a specific carbohydrate chain that carries blood group ABH and iI antigenic determinants, is much higher in mature erythrocytes than in erythroblasts. [40] Whereas

a linear, virtually unbranched polylactosamine structure is present in fetal and newborn erythroid cells (reflected by i antigenic reactivity), a branched polylactosaminyl structure is present in adult erythroblasts (reflected by I antigenic reactivity), and branching increases further as maturation progresses. [40] Glycophorins, especially glycophorin A, are expressed fully at the CFU-E or proerythroblast level just before the expression of globin, and there are few changes during maturation. [20] In contrast, the membrane glycoproteins p105 and p95 decline during the later stages of maturation [40] and yet other membrane glycoproteins, such as vimentin (an intermediate filament protein) are totally lost. [37] The loss of vimentin expression at the late erythroblastic stages most likely facilitates enucleation.

In addition to quantitative changes during maturation, there are gradual switches in subunit composition of some cytoskeletal proteins. For example, exclusively erythroid subunits of - and -spectrin are displayed only in end-stage cells. [38] Likewise, multiple transcripts of ankyrin or protein 4.1 have been identified, and the ratios of these transcripts changes during maturation. [41] It is likely that the initial expression of many of these membrane components begins at the progenitor cell level. In these cells, however, final assembly may be discouraged because of the higher turnover of these proteins, which minimizes mutual interactions, or because of asynchrony in their synthesis. Prevention of cytoskeletal assembly at these early stages may secure more membrane fluidity and cell motility needed during this proliferative phase of differentiation. Because molecular probes for many of the red cell cytoskeletal components have been developed, detailed information about the transcription and processing of most of these proteins is beginning to emerge. [39]

Gene activity during erythroid maturation is dominated by the expression of globin. Although globin represents <0.1% of protein at the proerythroblast level, it reaches 95% of all protein at the level of reticulocytes. [42] Its expression has been extensively studied, and its gene regulation is well understood in molecular terms. Major steps in its transcription and processing are now known in considerable detail and are summarized elsewhere in this volume. The globin type synthesized by the adult precursors is hemoglobin (Hb) A($_2$ $_2$). In addition, two other minor globin components, Hb A$_2$ ($_2$ $_2$) and Hb F ($_2$ $_2$) are present. Of significant biologic interest are the low amounts of Hb F that continue to be synthesized throughout life.

This small amount of Hb F, which is present in all normal individuals, has the following characteristics [43] : (1) It is confined to a small fraction of red cells, called F cells, which are detected by sensitive immunofluorescence assays or acid elution techniques and usually constitute 25% of all red cells. Within each F cell, Hb F or -globin constitutes 1425% of total globin. (2) The number of F cells is genetically determined, and gene(s) linked or nonlinked to the -locus are responsible for F-cell formation. (3) F cells do not display other features of fetalness, because their membrane components and enzymes are characteristically adult. (4) Synthesis of Hb F peaks earlier than that of Hb A, so the proportion of fetal hemoglobin is higher in immature cells compared with mature, fully hemoglobinized cells. (5) F cells and cells that contain only Hb A are not derived from distinct stem cell populations but from a common adult stem cell. Whether this cell will form F or non-F (i.e., A) cells is determined at the BFU-E and throughout the CFU-E level. In vitro the great majority of BFU-E have the potential to express Hb F, whereas in vivo only a very small proportion of red cells contain Hb F; this potential appears to be lost during normal cell differentiation and maturation in vivo. This concept links the potential for Hb F expression to the pathway of erythroid differentiation and thus may have implications for interpreting the reactivation of Hb F that occurs in adults under diverse circumstances (e.g., after chemotherapy or with acute bleeding) [43] Many of these circumstances seem to influence Hb F levels by directly or indirectly modifying the kinetics of the normal differentiation/maturation process. [44] [45]

The synthesis of globin appears to be coordinated with the synthesis of heme throughout erythroid maturation, so that functional hemoglobin tetramers are formed

rapidly and spontaneously after the release of newly synthesized globins from polysomes. Information about the accumulation of heme and its synthetic intermediaries has been provided thus far by crude biochemical approaches (Fig. 15-3). However, as the genes for several enzymes in the heme synthetic pathway have now been cloned (i.e., genes for -aminolevulinic acid synthetase, porphobilinogen deaminase, and heme synthetase), information about their regulation is rapidly emerging. [35]

Crucial to the functional response of erythroid precursors is the expression of EPO receptors and transferrin receptors. EPO receptors decrease progressively (from about 1,000 to <300 receptors/per cell) as proerythroblasts mature, and they are undetectable at the reticulocyte level. [29] [46] Through these receptors, EPO exerts its proliferative influence on proerythroblasts and basophilic erythroblasts, but maturation beyond these stages can proceed in the absence of EPO.

Transferrin receptors are found in characteristic abundance in erythroid cells (300800,000/cell). [47] This is a reflection not only of the proliferative needs of erythroid cells but also of their extreme requirements for iron uptake for hemoglobin synthesis. It is for this reason that transferrin receptors persist in maturing, nondividing erythroblasts and in reticulocytes. Transferrin receptors belong to a large group of receptors that internalize their ligand through receptor-mediated endocytosis. This cycle allows for reuse both of the ligand (transferrin) to be resaturated with iron and of the receptor to enter an additional route of endocytosis. [48] Transferrin receptor density decreases with maturation, and after the reticulocyte stage, receptors appear to be shed as small lipid vesicles. [49] There is an inverse relationship between receptor density and the availability of iron. Deprivation of iron results in receptor induction, and excess iron results in receptor suppression. [48] However, the mechanisms that regulate the number of transferrin receptors throughout the maturation of precursors (even within progenitors) are largely unknown. Erythroid precursor cells differ from nonerythroid cells not only by requiring a higher number and higher occupancy of transferrin receptors but by displaying immunologically distinct receptor isoforms. [34] Whether the antigenically distinct form of transferrin receptor in erythroid cells is of physiologic significance to the unique role of erythroid cells in iron metabolism remains to be seen. However, monoclonal antibodies recognizing distinct receptor isoforms are useful in the isolation of erythroid cells from bone marrow. [34] [50]

ERYTHROPOIETIN AND THE ERYTHROPOIETIN RECEPTOR

EPO, a 35-kd glycoprotein, [51] is the physiologically obligatory growth factor for erythroid development. It is produced in the kidney, by peritubular cells. [52] A heme-containing protein senses oxygen need and then triggers the synthesis of EPO and its release into the bloodstream. [53] Through the interaction of EPO with receptor-bearing cells within the bone marrow, physiologic oxygen demands are translated into increased red cell production. Thus, EPO is a true hormone, manufactured at one anatomic site and transported through the bloodstream to the site of activity.

According to the prevailing model of hematopoiesis, progenitor cells committed to erythroid differentiation (i.e., BFU-E) are generated in a stochastic fashion from pluripotent stem cells.[3] [4] Neither EPO nor other lineage-restricted regulators play any role in determining lineage commitment. According to this model, EPO influences erythroid differentiation by rescuing (from apoptosis) cells that express the EPO receptor and amplifying

---

them further. Whether EPO receptors are present on all BFU-E (although only detectable on a subset of BFU-E) is not clear. [30] Thus, it is not known whether the presence of the EPO receptor in BFU-E is synchronous with the initial commitment event or follows it. In addition to the permissive role that the stochastic theory ascribes to EPO, experiments in vivo, in anemic states, or after pharmacologic doses of EPO, suggest that high levels of EPO may hasten the transition from BFU-E to hemoglobin-synthesizing cells either by decreasing the number of divisions required for this transition [36] or by decreasing the resting periods between cell divisions.[54] Autoradiographic studies in purified BFU-E populations indicate that EPO receptors increase as BFU-E mature to CFU-E, with the highest level observed at the CFU-E/proerythroblast boundary.[30] As the transition from BFU-E to CFU-E occurs under the influence of EPO, it may suggest ligand (EPO)-induced receptor up-regulation. Whether the magnitude of such up-regulation is EPO dose-dependent and whether it can modulate the rate of entry of these cells into the maturing compartment is unclear.

BFU-E and CFU-E can be generated in vitro [55] and in vivo,[56] in the absence of EPO or EPO receptor (in EPO or EPO-R null mice), but their survival and terminal maturation is normally dependent on EPO. For CFU-E EPO seems to stimulate all the biochemical processes characterizing erythroid cells (i.e., heme synthesis, globin synthesis, and synthesis of cytoskeletal proteins). However, the precise role of EPO in these processes has not been delineated. Whether EPO only increases the number of cells engaged in these biochemical functions or directly influences the intracellular mechanism of transcription of erythroid-specific proteins is unclear. Indeed, experiments in vitro showing complete maturation of BFU-E in the absence of EPO suggest that other factors or combinations of factors can influence red cell maturation. Activation of gp130 signaling pathway through the use of soluble IL-6 receptor and IL-6 leads to full terminal erythroid maturation (in the presence of SCF and IL-3 but in the absence of EPO), suggesting some form of cross-circuiting in signaling pathways among hematopoietic growth factor receptors. [57] [58] Furthermore, the stimulation by thrombopoietin of erythroid colony formation from yolk sac cells in the absence of EPO-R (in EPO-R / embryos) [59] can be explained by the same reasoning and the fact that there is a very high proportion of bipotent erythroid/megakaryocytic progenitors in yolk sac carrying both EPO and Tpo receptors (c-mpl) compared to adult bone marrow.[60] [61]

Whatever the precise mode of EPO action, it directly affects the number of CFU-E and the maturation of their progeny. This control is achieved by influencing CFU-E survival and not their cycling status.[62] CFU-E are irrevocably lost after one cycle of DNA synthesis if EPO is not present. [63]

With the availability of radiolabeled recombinant EPO and of purified or enriched populations of progenitors and precursors, information about the characteristics of EPO receptors in erythroid cells is continuously emerging. Direct binding studies have shown that as CFU-E and proerythroblasts mature to reticulocytes, there is a progressive decrease in the number of EPO receptors. [30] [31] [46] Pure reticulocyte populations show no detectable binding to EPO. The maturation-associated decline in the number of EPO receptors parallels the declining influence of EPO on erythroid cells during the terminal phase of maturation.

The cloning and expression of the erythropoietin receptor (EPO-R) has allowed a better understanding of the role of EPO in the regulation of erythroid development. The EPO-R polypeptide is a 66 kilodalton membrane protein, which is a member of the cytokine receptor superfamily. [64] [65] Many of the structural features of the cell surface EPO-R have been previously reviewed.[66] Like other members of the cytokine receptor superfamily, which includes the receptors for IL-3, GM-CSF, and IL-5, the EPO-R polypeptide contains four conserved cysteine residues and a WSXWS motif in the extracellular region. Additional extracytoplasmic sequences of the EPO-R determine the specificity for EPO binding. The cytoplasmic region of the EPO-R does not contain a tyrosine kinase catalytic domain, but instead interacts with cytoplasmic tyrosine kinases. Crosslinking of radiolabeled EPO to the cell surface EPO-R results in the formation of at least two major crosslinked protein complexes of 140 kD and 120 kD.[67] The molecular composition of these complexes remains unsolved but suggests that the EPO-R may contain additional subunits or accessory proteins.[68] The extracytoplasmic region of the EPO-R polypeptide contains the EPO binding activity of the receptor. [69] [70] [71] Additional EPO-R subunits may therefore provide other structural and functional elements of the receptor but are not required for high-affinity EPO binding. The extracytoplasmic region of the EPO-R polypeptide has also recently been crystalized. [72] [73] [74] [75] The crystal structure confirms the dimeric structure of the activated receptor. Interestingly, small synthetic peptides are capable of inducing EPO-R dimerization, suggesting a possible avenue of research for EPO-mimetic and EPO antagonist drug design. [75]

The EPO-R mRNA originally isolated from murine erythroblasts cell lines (MEL and HCD57) [76] and from a human erythroid cell line (OCIMI)[77] was found to be present in nonerythroid cells as well. EPO promotes the differentiation of megakaryocytes at physiological concentrations of hormone, suggesting that megakaryocytes have functional cell surface EPO receptors. Rat and mouse placenta also have cell surface EPO-R, detected by radiolabeled EPO crosslinking. EPO promotes a chemotactic effect on endothelial cells,[78] [79] suggesting the presence of a cell surface receptor in these cells as well. Other studies suggest that the EPO-R is expressed in neural cells[80] and smooth muscle cells,[81] though the functional importance of this expression remains unclear. The existence of naturally-occuring splice variants of the EPO-R gene encoding EPO-R polypeptides of variable length and activity [82] [83] [84] [85] has been shown. The soluble secreted form of the EPO receptor[86] binds EPO and thereby competes with the cell surface receptor isoform. The biological function of alternative forms of the cell surface EPO-R, including a truncated form of EPO-R found in early progenitors, [87] remains largely unknown, but may be related to differential EPO signaling and responses (survival, proliferation, differentiation) at different stages in erythroid development.

Signal Transduction by the EPO-R

Considerable progress over the last few years has been made in our understanding of EPO-R-mediated signal transduction. Early studies demonstrated that stimulation of the EPO-R on primary erythroid cells resulted in increased calcium ion flux and increased globin mRNA synthesis. [88] Since the cloning of the EPO-R polypeptide and its stable expression in heterologous cell systems, such as the Ba/F3 cell system, [89] considerable molecular insight has been gained. [90] For instance, it is now clear that EPO induces the homodimerization of the EPO-R polypeptide. [91] [92] Following receptor dimerization at the cell surface, a series of tyrosine phosphorylation events occurs, resulting in a mitogenic signal and a differentiative signal. [93] [94]

Initial studies of the EPO-R signal transduction pathway made use of mutant forms of the EPO-R stably expressed in the indicator cell line, Ba/F3. Ba/F3 cells are a

murine IL-3-dependent pro-B lymphocyte cell line. These cells can be readily transfected with the cDNA for the EPO-R, resulting in stable expression of the receptor on the cell surface. Expression of the full-length, wild-type EPO-R polypeptide in these cells resulted in EPO-dependent growth and partial EPO-induced erythroid differentiation.[93] [94] Expression of truncated forms of the EPO-R polypeptide in these cells resulted in variable growth responses. For instance, truncation of the membrane proximal region of the EPO-R demonstrated a critical positive regulatory domain

of the EPO-R, required for mitogenesis. [89] Furthermore, truncation of the carboxy terminal 40 amino acids of the EPO-R resulted in increased EPO-dependent growth, suggesting that the carboxy terminal region contained a negative regulatory domain normally required for down-modulating EPO-R mitogenic signals. [89]

The biochemical basis for these positive and negative regulatory domains has been elucidated. On the one hand, the membrane proximal positive regulatory region of the EPO-R binds constitutively to the cytoplasmic tyrosine kinase, JAK2. [95] Upon EPO binding to the receptor, the receptor dimerizes, resulting in activation of the prebound JAK2 kinase. The JAK2 kinase next tyrosine phosphorylates multiple signaling proteins in the cell, leading to various mitogenic and differentiative responses. The negative regulatory domain of the EPO-R, on the other hand, is required for recruiting the phosphatase, SHP1, to the EPO receptor. [96] SHP1 binds to an activated tyrosine phosphate on the EPO-R polypeptide and functions to rapidly down-regulate JAK2 kinase activity and to dephosphorylate the EPO-R polypeptide.

Activated JAK2 kinase initiates several events in EPO-R mediated signal transduction. JAK2 initially activates the tyrosine phosphorylation of several tyrosine residues of the cytoplasmic tail of the EPO receptor. These phosphorylated tyrosine residues next serve as docking sites for the binding of other cytoplasmic effector proteins containing SH2 domains, such as the p85 subunit of PI3 kinase, [97] the adaptor protein *Shc*, [98] [99] and the STAT transcription factor, STAT5. [100] [101] Once these proteins have docked on the EPO-R, they become tyrosine phosphorylated and activated for other downstream signaling events. In addition, JAK2 activates the Ras/Raf/MAPKinase pathway, further contributing to the EPO-induced mitogenic signal. [102] [103] The molecular mechanism of Ras activation by JAK2 remains unknown, but may entail direct binding of the proteins and tyrosine phosphorylation. [103] Activation of the JAK2/STAT5 signaling pathway has been studied in considerable detail. Upon EPO-R tyrosine phosphorylation, STAT5 protein binds to a specific phosphorylated tyrosine residue of the EPO-R. [100] [104] Binding is mediated by the SH2 domain of STAT5. Following EPO-R binding, STAT5 itself becomes tyrosine phosphorylated at amino acid Y694. [105] Activated STAT5 then disengages from the EPO-R, undergoes homodimerization, and translocates to the cell nucleus where it activates transcription of EPO-inducible genes. Some EPO-inducible genes, such as *myc* and *fos,* are common to other hematopoietic growth factor signaling pathways. Other EPO-inducible genes are specifically expressed in erythroid cells and are not shared by other growth factor responses. [106]

Other signal transduction pathways downstream from cytokine receptors have also been identified. For instance, EPO and IL-3 activate the tyrosine phosphorylation of the signaling protein, *cbl*, and the subsequent binding and tyrosine phosphorylation of the signal protein, CrkL. [107] The mechanism of activation of this pathway by the EPO-R is not known and the relative role of this pathway in EPO-induced growth and erythroid differentiation remains largely unexplored.

A critical question in the field of EPO-R signal transduction is the mechanism of EPO specificity. Most if not all of the signal transduction pathways activated by the EPO-R (i.e., Ras/Raf/MAPKinase and JAK/STAT pathways) are shared by other hematopoietic cytokine receptors, such as the receptors for IL-3, GM-CSF, and IL-5. How the EPO-R triggers a specific growth factor response resulting in erythroid differentiation remains unclear. Several models are possible. First, the EPO-R may activate a unique but still unknown signaling pathway specific to the EPO-R and distinct from other cytokine receptors. Alternatively, the EPO-R may activate the identical pathways, activated by other cytokine receptors. In this latter model, the specificity of the EPO signal is derived not from the EPO-R itself but instead from interactions with other developmentally programmed events in the erythroid cell, such as the expression of erythroid specific transcription factors.

Activation of the EPO-R in the murine IL-3 dependent cell line, Ba/F3, results in induction of both mitogenesis and -globin accumulation. [93] In contrast, the murine IL-2 dependent cell line, CTLL-2, when engineered to express the heterologous EPO-R, grows in EPO but does not differentiate into globin bearing cells. These data suggest that the expression of the EPO-R is necessary for erythroid differentiation but is not sufficient alone. It is likely that other erythroid-specific markers, such as GATA-1 and NFE-2, or EKLF, are required for cells to differentiate down the erythroid pathway. Other cytokine receptors, such as the IL-3R and the IL-2R, do not drive -globin synthesis in these cell lines. Taken together, these results suggest that the EPO-R generates a differentiation-specific signaling within the context of a proper cellular environment.

Regardless of the mechanism of cytokine specificity, it is clear that each cytokine receptor activates a similar but not identical pattern of signaling events. For instance, the EPO-R shows a preferential activation of the JAK2/STAT5 pathway in cultured erythroid cells in vitro. In contrast, the interleukin-2 receptor shows a preferential activation of the JAK1/JAK3/STAT6 pathway. [105] [108] [109] Interestingly, although EPO activates STAT5a and STAT5b in cultured cells, knockout of the STAT5a or STAT5b gene by homologous recombination results in a normal mouse phenotype with normal erythroid development. [110] This result suggests that, in vivo, other STAT proteins are capable of substituting for STAT5 and functioning downstream of the EPO-R and emphasizes the importance of in vivo studies to confirm the phenotypic relevance of in vitro studies.

Previous studies have also suggested that EPO functions synergistically with other multilineage growth factors, such as KL and IL-3. As discussed in previous sections, EPO and KL function together, resulting in increased erythroid colony cell growth in methylcellulose culture. Recent studies with the EPO-R polypeptide suggest a molecular mechanism for such synergy.[111] Activation of the kit receptor by KL results in a transphosphorylation of the EPO-R at the cell surface. Also, a direct interaction between the EPO-R and the kit receptor has been demonstrated. Taken together, these results suggest that receptor cross-talk at the cell surface may account, at least in part, for the physiologic interaction of some cytokines in controlling hematopoietic cell growth.

The Erythropoietin Receptor in Disorders of Erythropoiesis

As discussed above, the normal role of EPO is to stimulate the cell surface EPO-R in developing erythroid cells. The latter respond to EPO via a proliferative and differentiation response. The EPO-activated signal transduction of the EPO-R is quickly down-regulated in the cell, and continuing presence of EPO is required for optimal differentiation.

In some cells, the EPO-R may become constitutively activated. In these cases, erythroid progenitor cells are placed into a sustained proliferative state. Interestingly, these mechanisms underlie several murine and human examples of erythrocytosis (erythroid overproduction). Multiple mechanisms exist by which the EPO-R may become constitutively activated. First, the Friend Spleen Focus-Forming Virus (SFFV) of the Friend erythroleukemia complex encodes a glycoprotein, F-gp55, which binds and activates the murine EPO-R.[112] [113] [114] F-gp55 appears to bind to the EPO-R via its transmembrane region. The EPO binding site and the F-gp55 binding site are discrete; tertiary complexes of EPO-R, EPO, and F-gp55 have been detected on the surface of Friend Virus-infected cells. [115] Second, the EPO-R can be constitutively activated by a point mutation

(R129C) in the extracytoplasmic region of the polypeptide. [116] This mutation occurs in the dimerization domain of the EPO-R and results in the constitutive homodimerization of the EPO-R polypeptide, presumably through a disulfide bond. This mutation further underscores the importance of receptor dimerization in the initiation of a receptor signaling response. Third, the EPO-R can be constitutively activated in an autocrine manner. Murine erythroleukemia cell lines have been established that coexpress EPO-R and EPO. A fourth mechanism of EPO-R constitutive activation results from EPO-R overexpression. For instance, some murine erythroleukemia cell lines have increased EPO-R mRNA, resulting from SFFV proviral integration within the first intron of the murine EPO-R gene. [117] Overexpression of the normal murine EPO-R polypeptide may thereby contribute to oncogenesis.

Soon after the cloning of the cDNA for the mouse and human EPO-R, the mouse and human genomic structures were identified. The gene for the mouse EPO-R was found to map to mouse chromosome 9, whereas the human gene was found on human chromosome 19p.[118] [119] The mapping of the EPO-R genes led to their implication in various human disease states. For instance, recent studies have demonstrated that a chromosomal breakpoint 3 to the human EPO-R gene results in increased EPO-R expression.[120] The rearranged EPO-R allele appears to encode a mutated EPO-R polypeptide with increased activity, perhaps secondary to loss of the carboxy terminal negative regulatory domain. More recently, the EPO-R has been found to play a role in a rare congenital disease, Familial Erythrocytosis (FE). FE refers to a heterogeneous group of hereditary conditions characterized by an increase in red blood cell mass in the setting of low serum EPO levels. A few families have been identified that demonstrate autosomal dominant inheritance. [121] Interestingly, a linkage has been established between the EPO-R gene and FE. More

recent evidence demonstrates that, in one FE kindred, a mutant EPO-R allele that segregates with the disease contains a nonsense mutation in the coding region of the gene. This mutation results in the synthesis of a truncated EPO-R that lacks the previously described negative regulatory domain of its carboxy terminal region. [122] [123] Additional mutations within the EPO-R gene have also been found, resulting in FE, [124] but have not been identified in acquired disorders of erythropoietin, such as PV (polycythemia vera).

TRANSCRIPTIONAL CONTROL OF ERYTHROPOIESIS

It is widely believed that lineage-specific transcriptional factors are responsible for regulating the expression of erythroid genes both during ontogeny and the course of erythroid differentiation. Early experiments with somatic cell fusions and with transgenic mice have provided compelling evidence for this belief. [125] [126] [127] More recent studies in mice with targeted gene disruption have provided key insights into the complex molecular pathways that regulate hematopoiesis in general and erythropoiesis in particular.[1] These studies, complemented by in vitro differentiation of mutated ES cells into different lineages, have also provided clear evidence about distinct regulatory requirements of primitive (yolk sac) versus definitive (fetal liver and bone marrow) erythropoiesis, or of early versus late stages of erythroid differentiation.

As erythropoiesis is the first differentiated lineage in embryonic yolk sac hematopoiesis and the predominant lineage in fetal liver hematopoiesis, factors that affect hematopoiesis in general will disturb erythropoiesis during early stages of development and will lead to lethality at different gestational days depending on the defect. Mice lacking the bHLH factor Tal-1/SCL are bloodless and die very early with abrogation of both yolk sac and fetal liver erythropoiesis. [128] Because Tal-1/SCL is preferentially complexed in erythroid cells with the nuclear protein Rbtn2/LMO2, it is not surprising that the targeted disruption of the latter gene also produces a bloodless phenotype,[129] similar to the one seen in Tal-1/SCL knockouts. Furthermore, mice lacking GATA-2 expression , a member of the GATA family of transcriptional factors, also exhibit an early and severe quantitative defect in hematopoiesis that influences all lineages. [130] Other regulatory factors seem to totally spare embryonic (yolk sac) hematopoiesis and have a specific effect only on fetal liver hematopoiesis with death occurring at later days (12.5 days post conception). In this category are the proto oncogene c-myb and the core-binding factors CBF $_2$ /AML-1 and CBF.[131] [132] [133] Embryonic erythropoiesis is spared in mice with targeted ablation of these genes. Both c-myb, the cellular homolog of v-myb proto oncogene and the heterodimeric transcription factor core binding factor (CBF), are abundantly expressed early in normal myelolymphoid cells, decreasing as differentiation proceeds. This expression pattern and their functional influence on growth factor receptor genes (i.e., IL-3, GM-CSF, CSF-1, TCR,) may underlie their importance in the development of all hematopoietic lineages. [1]

Of specific importance for erythropoiesis, however, is the transcription factor, GATA-1, the founder of the GATA family of factors. [1] This protein interacts with the WGATAR DNA motif frequently found in erythroid genes and influences their expression. Both GATA-1 and GATA-2 are expressed early in multipotential progenitors; however, their expression ratios change as the cells differentiate, suggesting that the ratio of these two factors may be important at specific stages of erythroid differentiation. Knockout experiments with both of these genes have borne this out. Thus, in contrast to GATA-2, expressed at high levels in early cells and affecting expansion of all hematopoietic lineages, [130] GATA-1 expression increases as differentiation advances and seems to be the obligatory factor required for survival and terminal differentiation of erythroid cells. In mice with targeted disruption of GATA-1, erythropoiesis proceeds only up to the stage of proerythroblasts, which die early and fail to mature further.[134] [135] Furthermore, transgenic mice with partial loss of function (knockdown alleles) of GATA-1 show that erythroid differentiation is dose-dependent with respect to GATA-1.[136] High levels of GATA-1 may be necessary to form complexes with its co-factor FOG [137] and perhaps with other interacting zinc-finger proteins during terminal erythroid differentiation. Another factor with special importance in the erythroid lineage is the CACCC binding protein, designated erythroid Krüppel-like factor (EKLF), which is expressed at all stages of erythropoiesis, but binds preferentially to CACCC sites in globin promoter. Mice lacking EKLF die from a thalassemic-like defect, because of severe deficiency of globin expression. [138] Other erythroid genes are largely unaffected.

As common transcriptional factors are present in erythroid and megakaryocytic cells, and bipotent erythroid/megakaryocytic progenitors exist both in vitro, in the form of cell lines, and in vivo,[27] recent exciting insights regarding subtleties in the molecular control of these two lineages by the same transcriptional factors have surfaced. By modified gene targeting strategy (knockdown) of GATA-1, a largely unanticipated role for this transcriptional factor in the control of proliferation and maturation of megakaryocytes was uncovered.[139] In addition to GATA-1 other important transcriptional factors essential for terminal megakaryocytic development are NFE2[140] and its partner MatG.[141]

Despite the affiliation of specific transcriptional factors, such as GATA-1, with certain lineages (erythropoiesis, megakaryocytopoiesis), their role in lineage commitment decisions has not been established. Several in vitro experiments would suggest that a dose-related influence of GATA-1 in lineage selection exists. [1] However, these experiments concern only oligopotent or bipotent cell lines with phenotypic plasticity, and the data may

not apply to decisions faced by the hematopoietic stem cells. Nevertheless, the fact that several regulators are necessary for primitive (yolk sac), as opposed to definitive (fetal liver and bone marrow) erythropoiesis, provide evidence that the molecular control between these two hemopoietic sites is indeed different and it may include both ubiquitous and hematopoietic specific factors. In fact, recent evidence suggests that GATA-1 transcription is differentially regulated in yolk sac cells compared to fetal liver erythroid cells, with alternative promoter use and an additional intron element requirement for promoter activation in fetal liver cells. [142]

In addition to transcriptional factors/oncogenes influencing erythropoiesis, targeted ablation and naturally existing mutations of hematopoietic growth factor receptors, especially of the tyrosine kinase family, have disclosed important insights in the control of erythropoiesis. Whereas deletion of the VEGF/flk-1 receptor affects both endothelial and hematopoietic development[143] through its presumed presence in the common endothelial/hematopoietic stem cell, the hemangioblast, mutations affecting the tyrosine kinase kit-receptor (present in hematopoietic cells) or of its ligand (kit ligand, KL, present in stromal cells) seem to predominately affect erythropoiesis in the fetal liver and the adult animal. Mice with kit-mutations (W mutations) leading to absence of or compromised kinase activity, and Steel mice with mutations of KL have disproportionate and severe abrogation of the late erythroid progenitors, CFU-E, and differentiated erythroid precursors resulting in anemia. [144] Recent studies showing cross-phosphorylation of EPO-R following activation of kit/kit ligand signaling may be relevant to the above effect. [111] Mutations or targeted ablations of some downstream signaling substrates for kit or other receptors (i.e., Shp-2 phosphatase or gp 130) seem to produce a hematopoietic picture not unlike the one produced by receptor mutations.[145] [146]

Taken together, these recent studies have significantly expanded our understanding at the molecular level of hematopoietic development in general and of erythropoiesis in particular. The emerging picture is that certain genes, such as SCL, are absolutely required for hematopoietic development, whereas others, such as GATA-2, c-myb, CBF, TEL, and some downstream signal transducing molecules, such as gp130 and Shp-2, are responsible for expansion and maintenance of a normal pool of fetal liver and adult hematopoietic progenitors. The participation of many of these molecules in multicomponent molecular complexes with protein/protein and protein/DNA interactions (i.e., LM02/Lbd1/SCL/E2A/GATA), during the early, proliferative stages of hematopoiesis [147] may underlie their role in the proliferation and maintenance of immature progenitor/precursor pools in erythropoiesis. Other genes such as GATA-1, its partner FOG, and EKLF are necessary to direct high levels of function of erythroid-specific genes in cells already committed to terminal differentiation. Thus, a hierarchical requirement in the expression of specific regulators during early versus late erythroid differentiation or during yolk sac versus fetal liver/adult erythropoiesis is demonstrated. This, however, does not exclude the involvement of some factors (i.e., SCL, TEL) both at early and late stages of erythropoiesis. As information from innovative applications of molecular approaches is becoming available at a fast pace, the list of regulators with a biologic impact on hematopoiesis/erythropoiesis is continuously expanding.

HEMATOPOIETIC MICROENVIRONMENT

In invertebrates such as worms and sessile marine creatures, erythropoiesis takes place adjacent to peritoneal and endothelial cells. In premammalian species, the spleen is the primary site of erythropoiesis, and with evolutionary advancement, this gradually shifts to the liver and the sinusoidal cavities of bones. [148] These observations suggest that sufficient oxygen, a stagnated flow of blood to avoid the dispersion of factors produced locally, and extensive and redundant surfaces for cell-cell interactions are essential to support red cell production. Similar sites support erythropoiesis during human development, as discussed following. During both phylogeny and ontogeny, the liver and spleen are primarily erythropoietic organs, while granulocytic cells dominate in the bone marrow. [148] Within the bone marrow, hematopoiesis is restricted to the extravascular space, where compact collections of cells are interspersed among venous sinuses. These sinuses originate adjacent to the endosteal bone surface and empty into a central longitudinal vein. Studies in mice demonstrate that BFU-E follow a bimodal distribution with peaks adjacent to the periosteum and midcavity, whereas CFU-E and later erythroid cells have a broad distribution with highest incidence toward the axis of the femur, adjacent to the central vein, [148] [149] and thus suggest that the local anatomy influences the maturation of erythroid cells.

The bone marrow microenvironment consists of three components; stromal cells (e.g., fibroblasts, endothelial cells), accessory cells (monocytes, macrophages, T cells), and extracellular matrix (a protein-carbohydrate scaffold). Accessory cells are progeny of hematopoietic stem cells, and hence after marrow transplantation, these cells are of donor origin, whereas stromal cells are host-derived. [150] [151] Extracellular matrix molecules are synthesized and secreted by microenvironmental cells and include collagens (types I, III, IV, and V), glycoproteins (fibronectin, laminin, thrombospondin, hemonectin, and tenascin), and glycosaminoglycans (hyaluronic acid and chondroitin, dermatan, and heparan sulfate). [152] [153] Besides providing structure to the marrow space, and a surface for cell adhesion, the microenvironment is important for hematopoietic cell homing, engraftment, migration, and the response to physiologic stress and homeostasis.

Although the functional consequences of the microenvironment must ultimately be defined by in vivo studies in mice, dissection of the cellular components of the microenvironment, definition of the cytokines that are produced by individual cells, and the nature of cell-cell interactions have been aided by in vitro models. Long-term bone marrow cultures provide an experimental approach for such studies. [154] [155] In these in vitro conditions, murine hematopoiesis can be maintained for 810 months, and human hematopoiesis for 2 to 3 months.[154] An adherent layer consisting of fibroblasts, adipocytes, and macrophages is a crucial component of the culture system. Progenitor cells adherent to stroma are generally quiescent (dormant) whereas those in the nonadherent cell compartment are in active cell cycle. [155] [156]

With in vitro studies, it has been demonstrated that stromal cells, including endothelial cells and fibroblasts, elaborate cytokines such as GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-11, KL, flt-3 ligand, activin A, and basic fibroblast growth factor, which influence, alone or in combination, the growth of adjacent marrow progenitors. [154] [155] [156] [157] In addition to positive regulators of replication and differentiation, stromal cells elaborate factors, such as transforming growth factor-beta (TGF), interferon-, and tumor necrosis factor (TNF), which exert a negative influence on proliferation and may help maintain a dormant (noncycling) state. [155] [156] Because some regulators inhibit differentiation along certain lineages, but not others, there is an intriguing possibility that lineage-specific regulation within the microenvironment may be achieved through negative, rather than positive, factors. [158] Several cytokines are expressed in a transmembrane form as well as a soluble (secreted) product. Others bind extracellular matrix, a mechanism that allows for the retention of high concentrations of factor within the microenvironment adjacent to developing progenitors, and that metabolically stabilizes these factors.

Among the factors elaborated by stromal cells, KL has the

most profound effect on erythropoiesis. Mice unable to synthesize KL die in utero because of severe anemia. Steel-Dickie (Sl^{d}) mice that are unable to make the membrane-restricted form of KL are viable, but severely anemic, whereas other lineages in these animals are marginally affected or not affected by this defect. [159] The fact that erythropoiesis is abnormal, despite high levels of circulating Epo and the presence of soluble KL, suggests that normal erythroid differentiation and maturation require both a functional membrane restricted KL/kit and an EPO signaling pathway. Cross-phosphorylation of the EPO receptor by KL may provide a basis for the predominately erythroid effect. [160] Furthermore, recent data suggest that tyrosine cross-phosphorylation of the Epo receptor is sustained longer when cells are cultured on Steel stromal cells engineered to express the membrane restricted form of KL than cells expressing the soluble form. [161]

Besides cell/cytokine (paracrine) interactions, cell/cell adhesion and the adhesion of cells to the extracellular matrix are important functions of the microenvironment. [162] [163] Perhaps most important are the 1 integrins, VLA-4 and VLA-5, which mediate the adherence of hematopoietic cells to stromal cells, to fibronectin, or other components of the extracellular matrix. [163] [164] In mice lacking 1 integrins, hematopoietic stem cells fail to colonize the fetal liver during embryonic development. [165] Antibodies to VLA4 or to the vascular adhesion molecule VCAM-1 (a VLA-4 ligand on endothelial cells) impair homing and lead to the mobilization of progenitor cells and stem cells in adult mice and primates. [166] [167] [168] [169] In in vitro studies, hematopoietic progenitors bind to specific domains of fibronectin in a differentiation-dependent manner (LTCIC and CFU-S12 in mice adhere mainly through the heparin-binding domain and CS-1). BFU-E and other progenitor cells adhere to both the cell-binding (RGDS) and heparin-binding domain, whereas CFU-E preferentially bind the RGDS sequence, and reticulocytes fail to adhere to fibronectin. [153] [170] [171] [172] [173] This differential binding could influence the proliferation and maturation of erythroid progenitor cells, as well as the migration of these cells in and out of the bone marrow cavity. Hematopoietic cytokines present in the microenvironment can also modulate the affinity of 1 integrins for ligand, [174] [175] adding a further complexity to the regulation of erythropoiesis within the marrow microenvironment. In addition, other molecules on hematopoietic cells (e.g., c-kit, [176] CD31, [177] CD44, [178] L-selectin, [179] sialomycins [CD34, [180] CD43 [181]]) may have adhesive functions, but their physiologic roles have not been delineated.

Many observations suggest that hematopoietic progenitor cells at one stage of fetal development may not be supported by a hematopoietic microenvironment of a different ontogenetic stage. For example, cells present in the murine yolk sac are not able to repopulate adult recipients, [182] although they can repopulate newborn recipients with active fetal liver hematopoiesis. [183] Targeted disruption of PBSF/SDF-1, a member of the CXC chemokine family that is constitutively expressed by bone marrow stromal cells, leads to the inhibition of marrow hematopoiesis, although fetal liver hematopoiesis is unaffected, [184] suggesting that this chemokine has a role in the colonization of bone marrow from fetal liver. Recently it was also shown that TEL (translocation-Ets-leukemia) transcriptional factor is critical in the establishment of stable bone marrow hematopoiesis, but was not required for embryonic and fetal liver hematopoiesis. [185]

Accessory cells, such as stromal cells, secrete cytokines and express adhesion molecules, and also may influence marrow hematopoiesis by their nonrandom distribution in the marrow cavity. T cells (along with mast cells) are the only source for IL-3, and through the secretion of TNF- and interferon- may also negatively impact erythropoiesis. In histologic sections of normal marrow, islands of maturing erythroblasts often surround a central macrophage, termed a nurse cell. [186] Adhesion may be mediated through the binding of VLA-4 (on erythroid cells) to VCAM-1 (on central macrophages). [187] Although the specific interactions between macrophages and erythroid cells that promote erythroid differentiation are unknown, tissue macrophages express RNA for erythropoietin, [188] and may influence erythropoiesis through this mechanism.

It is clear that the microenvironment is not only a passive surface for the adherence of progenitor cells, but also exerts a crucial and interactive role in development and maturation. Some interactions are lineage- (red cell-) specific, whereas other interactions affect hematopoiesis more broadly. Stromal and accessory cells secrete cytokines and/or express them in a transmembrane form on their cell surface. Cytokines are retained via binding to components of the extracellular matrix. All components of the microenvironment are involved in adhesive interactions, some of which maintain quiescence, whereas other cell-cell interactions or interactions of cells with matrix components induce proliferation and/or differentiation. It is likely that an individual progenitor cell, in an anatomic niche adjacent to certain stromal cells, accessory cells, and extracellular matrix molecules, responds to the sum of the signals that it uniquely receives. In this way, hematopoiesis, including erythropoiesis, is stochastic, which is in effect a statement of the complexity of the interaction network.

ONTOGENY OF ERYTHROPOIESIS

During human development distinct anatomic areas for production of erythroid cells are recruited sequentially, in a temporal succession that allows overlap (Fig. 15-4). In addition, there are parallel changes in the morphology and functional properties of the erythroid cells themselves.

During the phase of embryonic erythropoiesis in the blood islands of yolk sac, aggregates of immature erythroid cells undergo maturation synchronously as a single cohort. Before their maturation is completed, they begin to circulate, and by the fifth gestational week they are found in the vascular spaces of the rudimentary liver (Fig. 15-5). At about the same time, foci of immature erythroid cells emerge within the fetal liver as the fetal, or hepatic phase of erythropoiesis commences. [189] From the seventh week onward, the liver is progressively filled with erythroid precursors and becomes the dominant site of erythroid cell production until about the 30th gestational week. Although some red cell production can be found in the thymus, the spleen, or occasionally in the lymph nodes, these other sites are never dominant. From the sixth month onward, the cavities of long bones are invaded by vascular sprouts and become competent to support red cell development. At birth all bone cavities are actively engaged in erythroid production, and the hepatic (fetal) phase of erythropoiesis comes to an end, as the final (adult) phase of erythropoiesis unfolds exclusively within the bone marrow.

In addition to the anatomic shifts in the sites of erythropoiesis, there are associated shifts in the phenotypic characteristics of erythroid cells. Embryonic erythroid cells (derived from the yolk sac) are large (about 200 mm), retain their nuclei at terminal stages of maturation, and have a megaloblastic appearance (Fig. 15-5). Fetal erythroid cells (produced in the fetal liver and later in fetal bone marrow spaces) are smaller than embryonic cells (about 125 m) but have a macrocytic appearance when compared with adult, normocytic red cells (about 80 m). Like adult cells, however, they eject their nuclei during maturation.

Apart from variations in size and morphology, embryonic and fetal erythroid cells differ from each other and from their adult counterparts in several other characteristics, including hormonal or growth factor requirements and proliferative and transplantation potential. For example, whereas fetal erythropoiesis is under the control of EPO,[190] the extent of EPOs influence on embryonic erythropoiesis has been under dispute. Most

Figure 15-4 Sites of hematopoiesis during fetal development and after birth. Only erythroid cells, and possibly lymphocytes, are generated by the yolk sac and early embryo. Significant megakaryopoiesis and granulopoiesis develop at 4 to 5 months. After birth, hematopoiesis occurs in the sinusoidal cavities of the tibias, femurs, and axial skeleton. *(Adapted from Erslev and Gabuzda,[246] with permission.)*

convincing are the results of EPO/EPO-R knockouts[56] that showed only partial effects on embryonic erythropoiesis, in contrast to fetal erythropoiesis. Recent evidence suggests that precursor cells from the extraembryonic mesoderm are dependent on EPO for their proliferation and erythroid differentiation. [191] EPO levels increase between the 9th and the 32nd week of gestation, and fetuses respond to hypoxia or anemia with increased EPO as early as 24 weeks. Fetal erythroid progenitors when studied in vitro appear more sensitive to EPO and kit-ligand than adult progenitors; in contrast, their in vitro response to

Figure 15-5 (A) Section of an 8-mm embryo depicting a portion of hepatic parenchymal cells with embryonic erythroblasts present within primitive sinusoidal cavities. **(B)** At 6 to 8 weeks, discrete aggregates of definitive erythroblasts appear within the liver parenchyma, whereas mature embryonic erythroblasts persist in well-developed sinusoids (PAS stain). **(C)** Later, definitive erythroblasts are spread throughout the liver (100-day fetus) (PAS stain). **(D)**

lymphokines (e.g., IL-3 or G-CSFM) is minimal compared to that of adult erythroid progenitors. [192] [193] It is noteworthy that in the early stages of fetal liver erythropoiesis, mainly erythroid differentiation/maturation is promoted. [194] Although progenitors committed to other lineages are abundant in the fetal liver, very few mature cells (granulocytes, megakaryocytes) from other lineages are seen. In addition to their heightened sensitivity to EPO, fetal erythroid progenitors and precursors are characterized by high proliferative potential and shorter doubling times than adult cells when cultured in vitro. [193] [194] The dependency of stem/progenitor cells on KL also changes during ontogeny. Although the generation of repopulating stem cells (ckit+/Sca-1±/Thy ^{lo} /Lin) and of CFU-S is minimally affected during fetal life in mice that cannot produce KL, adult Steel-Dickie (Sl/Sld) mutant mice (which only produce some soluble KL) display greatly impaired erythropoiesis and hematopoiesis, suggesting that KL/c-kit pathway plays a role in the recruitment and self-renewal behavior of adult stem cells in vivo. [195] [196] Also, the long term transplantation potential is impaired in cells with mutations of c-kit kinase activity. [196] Furthermore, transplantable stem cells from the yolk sac, in contrast to fetal liver cells, cannot engraft adult recipients, either because of altered homing behavior or inability of bone marrow to support their development. [183] Finally, the enzymatic activity of several enzymes in the glycolytic pathway is greater in fetal than in adult red cells. [197] In contrast, carbonic anhydrase levels are very low during intrauterine and early neonatal life. [198] Distinct isozyme patterns for several enzymes (phosphoglycerate kinase, acetylcholinesterase, etc.) also distinguish fetal from adult red cells. [199] [200]

The surface antigenic profiles of erythroid progenitors and precursors are distinct at each ontogenic stage. For example, HLA class I and class II antigens are not detected in embryonic erythroid progenitor cells, but reach adult levels about the ninth week of gestation. [201] In addition, CD34(+) hematopoietic progenitors present in yolk sac express Mac-1, but are negative for the stem cell antigen Sca-1, which is expresed in fetal and adult CD34+ progenitor cells. [202] Adult 34+ progenitors, on the other hand, lack Mac-1 and AA4.1, expressed in fetal CD34+ progenitor cells. Furthermore, fetal BFU-E and CFU-E express similar levels of HLA class II antigens, whereas adult CFU-E are largely devoid of these antigens. [201] [203] Fetal red cells display on their surface a straight, unbranched polylactosaminyl chain (i antigen), whereas this structure, which bears ABH blood group determinants, is highly branched in adult cells (i antigen). [39]

The most widely studied changes during red cell ontogeny are the shifts or switches in globin types. Embryonic erythroblasts are characterized by their avid accumulation of iron, which is stored as ferritin [204] (0.31% of total protein) and by the synthesis of the unique hemoglobins Gower I ($_2$ epsilon$_2$), Gower II ($_2$ epsilon$_2$), and Hb Portland ($_2$ epsilon$_2$). The - and epsilon-globin chains are embryonic -like and -like chains, respectively. [43] These three embryonic types of hemoglobin are most likely synthesized in succession, as the concentration of Gower I is highest in smaller embryos. Thus, a switch from - to - and epsilon- to -globin gene production begins during the embryonic phase of erythropoiesis but is not complete until fetal erythropoiesis is well established. During the transition from yolk sac to fetal liver erythropoiesis (69 weeks), erythroid precursors within the fetal liver co-express embryonic (- or epsilon-) and fetal (- or -) globin both in vivo and in vitro. [205] [206] The

predominant type of hemoglobin synthesized during fetal liver erythropoiesis is Hb F ($_{2}$ $_{2}$), with a high proportion of ^{G} :^{A} = 7:3). Adult hemoglobin A ($_{2}$ $_{2}$), detectable at the earliest stages of fetal liver erythropoiesis, is also synthesized as a minor component throughout this period, but Hb A $_{2}$ ($_{2}$ $_{2}$), a minor hemoglobin in the adult, is undetectable in these early stages. From about the 30th gestational week onward, -globin synthesis steadily increases, so that by term 50%55% of hemoglobin synthesized is Hb A. By 4 to 5 weeks of postnatal age, 75% of the hemoglobin is Hb A, this percentage increasing to 95% by 4 months as the fetal-to-adult hemoglobin switch is completed. Hb F levels in circulating red cells are in a plateau for the first 23 weeks (as a result of the decline in total erythropoiesis that follows birth), but Hb F gradually declines, so that normal levels (<1%) are achieved by 200 days after birth. [207]

Several in vitro and in vivo approaches have been used to study the basis of globin switching through development. Beyond its biologic interest, rigorous research in this area was propelled by the possibility of manipulating globin switching to increase Hb F production in adults and ameliorate the clinical symptoms of disorders of the -globin locus (e.g., sickle cell anemia, thalassemia). Transplantation experiments and ablative endocrine maneuvers in the sheep model have failed to provide convincing support for effects of environmental or humoral factors on the switching process, although some modulation of the rate of switching was seen in these models.[208] [209] The most important determinant of fetal to adult hemoglobin switching seems to be postconceptual age, with the sharpest period for transition between 30 and 52 weeks.[210] The fetal-to-adult switch appears to be unaffected by the time at which birth occurs or by changes in the kinetics of erythropoiesis induced by perinatal hemolysis.[210] A delay in switching is usually observed in cases of general developmental retardation, in patients with certain chromosomal abnormalities (e.g., trisomy 13), and in diabetic infants because of increase in circulating levels of -aminobutyric acid, which directly affects hemoglobin F synthesis. [211] Integration of the data available from in vitro and in vivo approaches indicates that control of globin switching is intrinsic to erythroid cells. Stage-specific transcriptional forces with negative or positive influences (or both) on specific globin genes may provide the molecular basis for differential transcriptional activity during development. This view is favored by experiments in transgenic mice[212] and in heterokaryons (produced by fusion of human with mouse cells),[213] as well as by the isolation of stage-specific transcriptional factors in other erythroid systems (e.g., avian). [214] Furthermore, as -like and -like globin genes are activated sequentially in the order of their location in chromosome 11 or chromosome 16, respectively, it is possible that polarity of the transcriptional activity and globin promoter competition for the locus control region (LCR) and developmental stage-specific transcriptional factors contribute to this regulation. [215]

In summary, throughout human development waves of hematopoiesis are initiated sequentially in newly recruited sites. The first wave of erythropoiesis is seen in yolk sac between days 15 and 18 (7.5 days after conception in mice). In addition to erythroid cells, uncommitted progenitors and progenitors for nonerythroid cells are present in the yolk sac and are thought to be the source of cells colonizing the fetal liver. [216] [217] [218] However, in addition to yolk sac foci of hematopoietic activity have been detected within the embryo around the developing aorta (in Paraortic-Splachnopleura, P-Sp, and the aorta/gonad/mesonephros, AGM, area). [219] [220] [221] In fact, the P-Sp/AGM site in mice was shown to harbor progenitor cells before circulation begins and one day before these cells are found in the yolk sac. Long-term repopulating cells were only detected in the AGM area, leading to speculation that this intraembryonic site is the main or only source of fetal liver colonization, [221] in contrast to earlier experiments implicating the yolk sac for that role. [216] [217] [218] Presence of mesodermally-derived hematopoietic cells in two distinct anatomic sites, one intra-, the other extra-embryonic, has also been seen with explant studies in Xenopus and after analysis of chick-quail chimeras. [222] More recent experiments with human cells have led to similar conclusions. [223] Although the presence of progenitors for definitive hematopoiesis (fetal liver and bone marrow) in two independent sites is indisputable, the extent to which these two sites contribute to fetal liver colonization has been a matter of dispute. The conclusion that only the AGM

area contributes to fetal liver colonization was based on transplantation experiments in adult recipients and has recently been challenged. [183] Transplantation experiments using as recipients newborn mice with active fetal liver hematopoiesis have shown that adult long-term repopulating cells are detectable in the yolk sac at day 9 post-conception and were 37-fold higher than repopulating cells present in the P-Sp/AGM area at the same time. Therefore, failure of yolk sac cells (or AGM cells before day 10 post-conception) to engraft adult recipients may be caused by either compromised homing or impaired survival and proliferation within the adult bone marrow environment (either because of positive regulators or inhibition by negative regulators). In light of this new information, a 30-year-old theory that yolk sac colonizes the fetal liver[216] has been revived. A question that remains unanswered is whether the stem cell activity in 9 days post conception in yolk sac and P-Sp/AGM is generated autonomously and independently or is derived from a common precursor cell with migratory properties. Further murine studies comparing newborn transplant outcomes before the onset of systemic circulation between the yolk sac site and the intra-embryonic AGM site will resolve this issue.

A common precursor cell giving rise to erythroid cells with either yolk sac or fetal liver characteristics has been recently identified during culture of ES in vitro. [224] Also in Zenopus it was recently shown that specification to the primitive or definitive lineages is environmentally regulated. [225] However, since BFU-E present in yolk sac, in fetal liver, and within fetal bone marrow all have a non-yolk sac (non-embryonic) phenotype and these progenitors were not present after ablation of CBF, [226] despite the presence of normal embryonic erythropoiesis, the derivation of embryonic erythroblasts from a distinct progenitor, not present in subsequent life, remains a viable hypothesis.

CELLULAR DYNAMICS IN ERYTHROPOIESIS

The primary function of the end product of erythropoiesis, the mature red cell, is to transport oxygen efficiently through the circulation to the tissues. To achieve this goal the adult marrow must release approximately 3×10^9 new red cells, or reticulocytes/kg/day.[227] This number of reticulocytes represents 1/100th of the total red cell mass and is derived from an estimated 5×10^9 erythroid precursor/kg. [227] In addition to maintaining homeostasis (i.e., a stable hematocrit), the erythron must be able to respond quickly and appropriately to increased oxygen demands, either acute (e.g., following red cell loss) or chronic (e.g., with hypoxia from pulmonary disease or a right-to-left cardiac shunt). It is now well established that EPO is responsible both for maintaining normal erythropoiesis and for increasing red cell production in response to oxygen needs. The overall marrow response, however, is complex and requires not only the participation of erythroid cells responsive to EPO but also a structurally intact microenvironment and an optimal iron supply within the marrow.

EPO stimulation elicits two types of measurable responses: changes in proliferative activity (including improved survival) and changes in maturation rates. The first detectable response to increased serum EPO is amplification of CFU-E and erythroid precursors, cells that are extremely sensitive to EPO. Because virtually all these cells are already in cycle, increases in their numbers cannot be achieved by increasing their fraction in cycle. Either additional divisions are involved or new cells are recruited to the CFU-E pool (from a pre-CFU-E pool). Additional divisions of CFU-E or precursor cells would increase their transit time within the marrow and potentially delay the delivery of new red cells to the periphery. Because a shortened maturation time has been observed instead and the proliferative potentials of CFU-E and proerythroblasts are finite, high levels of amplification cannot be achieved through this mechanism. Therefore, such needs are met by influx into the CFU-E and precursor pools of newly differentiating cells from earlier progenitor compartments.

Such a surge of newly produced cells has been observed in all previous experiments. [54] [228] [229] A rapid influx of fresh cells was particularly notable in polycythemic mice that were experimentally depleted of CFU-E and erythroid precursors at the time the stimulus was applied. [37] [54] Because of the rapidity of response (e.g., within 24 hours in the polycythemic animals), it appeared that the orderly progression from BFU-E to CFU-E to proerythroblast had been compressed. Such acceleration of differentiation is possible through shortened intermitotic intervals, fewer mitotic divisions, or differentiation without divisions. This short circuiting in differentiation requires high serum levels of EPO and adequate numbers of BFU-E (e.g., these conditions are met in a previously hypertransfused, polycythemic animal stimulated by EPO or in marrow suddenly recovering from acquired pure erythroid aplasia). Once CFU-E and precursors are expanded through this mechanism, most persisting erythropoietic demands can be met through this pool without excess input from pre-CFU-E pools. Thus, acute demands for erythropoiesis are met by influx from pre-CFU-E pools through an accelerated differentiation and maturation sequence. In contrast, chronic demands (i.e., demands in chronic hemolytic anemia) are mainly satisfied through a greatly amplified late erythroid pool and with a minimum distortion in the differentiation sequence. [43] [230] That the kinetics of erythroid differentiation/maturation are different in acute versus chronic marrow regeneration is supported by differing qualitative changes in the newly formed red cells. An increase in i antigen and Hb F expression as well as an increase in cells with higher mean corpuscular volumes is seen with an acute response, whereas these are minimal or less pronounced with chronic responses.[43] [231] When severe anemia persists from birth onwards, erythroid production can increase up to 10-fold above baseline.[230] This is possible not only because of maximally expanded erythropoietic pools but also because the sites of active erythropoiesis may extend to include those that support red cell differentiation during fetal life. Thus, although the marrow space in axial bones (vertebrae, pelvis, ribs, sternum, clavicles) is sufficient for normal erythropoiesis or to respond to moderate anemia, the femur, humerus, spleen and/or liver, and (rarely) thymus may support red cell production in children with congenital hemolytic anemia (e.g., thalassemia major). Expanded erythropoiesis may lead to skeletal deformities, hepatosplenomegaly, or erythropoiesis in the soft tissues adjacent to bone.

Quantitative assessments of changes in erythroid progenitor cell pools in response to EPO stimulation can be made through cultures of bone marrow cells. Despite sampling errors, erythroid cultures can provide rough estimates of relative progenitor abundance within an aspirated marrow specimen and have shown consistent increases in the frequency of CFU-E in proportion to the level of EPO stimulation. [232] [233] Conversely, with increases in the hematocrit or in polycythemic animals, a decrease in CFU-E frequency has been observed.[234] [235] In contrast to CFU-E, the incidence of BFU-E was found to fluctuate less with either acute or chronic expansion of erythropoiesis, probably because a few BFU-E can generate progeny of several thousand cells. Furthermore, BFU-E can increase their fraction in cycle and thus increase the number of differentiated progeny without a significant change in their total numbers. Most BFU-E detectable in marrow or blood erythroid cultures probably represent a reservoir of progenitors not normally participating in day-to-day erythropoiesis. The parameters needed to maintain a healthy or appropriate BFU-E pool in hematopoiesis are not defined. As hematopoietic expansion is curtailed in mice with Steel mutations and anemia develops in mice treated with anti-c-kit Ab antibody,[236] one may suggest that adequate levels of normal KL may be crucial for early erythropoietic expansion. [237]

The rate of red cell production also can be accurately evaluated

through ferrokinetics (i.e., the study of iron incorporation into developing red cells). In addition, a marrow scan, typically with ^{99m}Tc, can document the extent of active erythropoiesis. These approaches, however, are seldom necessary in clinical practice, because estimates of erythropoiesis can be obtained from the reticulocyte index.[230] First, the observed percentage of reticulocytes is normalized for the hematocrit to calculate the total marrow output of reticulocytes. Alternatively, the absolute number of reticulocytes/L can be counted directly, using fluorescent RNA labeling. However, because under conditions of acute need, younger reticulocytes are prematurely released into the circulation, the total number of reticulocytes overestimates the true level of red cell production as measured by iron kinetics. [230] Therefore, a second correction is made to account for the maturation of early circulating reticulocytes, or shift cells (polychromatophilic red cells) when present in the blood smear. The resulting reticulocyte index gives excellent estimates of effective red cell production.

Although the presence or density (or both) of EPO receptors on developing erythroid cells determines the responses to EPO, other properties (e.g., surface antigens on BFU-E versus CFU-E versus end-stage red cells) may provide the basis for selective suppression of CFU-E versus BFU-E or selective immune destruction of red cells versus erythroblasts. For example, suppression of CFU-E or erythroblasts can occur in acquired pure red cell aplasia [238] or B19 parvovirus infection,[239] respectively, whereas BFU-E in both these conditions remain largely unperturbed. Thus, the boundary from BFU-E to CFU-E and erythroblast may be biologically important for the pathophysiology of these disease states. Furthermore, in acquired hemolytic anemia selective destruction at a given stage of maturation (of red cells only or of both erythroblasts and red cells) can be observed depending on the type of antibody produced and the density of its antigen on maturing erythroid cells. Qualitative aberrations in the response of erythroid progenitors to cytokines or EPO may underlie the abnormalities of congenital erythroid aplasia (Diamond-Blackfan syndrome).[240] Analogous qualitative or functional defects can be observed in neoplastic erythropoiesis, as erythroid progenitors from patients with polycythemia vera and other myeloproliferative syndromes have altered sensitivities to EPO. [241]

Therefore, detailed knowledge of the structural and functional properties of erythroid cells throughout their differentiation may provide significant insights into the pathogenesis of hematopoietic disorders affecting the red cell lineage.

Chapter 16 - Granulopoiesis and Monocytopoiesis

Camille N. Abboud
Jane L. Liesveld

This chapter describes the process of granulopoiesis (production of neutrophils, eosinophils, and basophils) and monocytopoiesis (production of monocytes and tissue-fixed macrophages). The enormous number of short-lived mature cells that must be produced each day to sustain baseline granulopoiesis, as well as the need for rapid adjustment in rates of production of these cell types in response to acute stress, have necessitated the development of a very intricate cytokine network and a series of progenitor compartments to meet those requirements.[1] [2] The hematopoietic growth factor combinations required for the proliferation, survival, and maturation of these cells are detailed, and the functional similarities in signaling of colony-stimulating factor receptors (CSFR) and interleukin receptors (IL-Rs) are highlighted. Mechanisms of lineage commitment to the granulocyte versus monocyte differentiation pathways are delineated, and the interactions of cytokines with mature cellular elements as well as other accessory cells demonstrated, as are the paracrine and autocrine feedback loops that regulate this complex process. Understanding the properties and regulatory cytokine networks affecting each progenitor compartment within the marrow microenvironment facilitates an understanding of the pathophysiology of disorders of granulopoiesis and monocytopoiesis. These may include aberrant cell proliferation and impaired differentiation in leukemic disorders, excessive precursor production in the setting of inflammation, infectious or allergic diseases, impaired cellular production as in congenital neutropenia, or excessive precursor destruction (or both) due to apoptosis in myelodysplastic diseases.

STEM CELL AND PROGENITOR HIERARCHY

Growth factors important for myelopoiesis exert their effects at the level of the stem cell or the progenitor cell, or both. Stem cells are defined by their capacity for long-term self-renewal and by their ability to differentiate along multiple lineage pathways. [2] [3] Progenitor cells, on the other hand, retain proliferative potential but are committed to the production of cells from a limited array of lineages. [2] [3] [4] Progenitor cells are often defined as colony-forming cells (CFCs) because of their ability to generate hematopoietic colonies in vitro; such colonies consist of red cells, granulocytes, monocytes/macrophages, eosinophils, basophils, mast cells, megakaryocytes, dendritic cells, natural killer (NK) cells, and T or B lymphocytes. [5] [6] [7] [8] [9] [10] [11] In humans, stem cells are defined by surrogate assays such as the high-proliferative-potential CFC (HPP-CFC), [12] the so-called CFC-blast, [13] the long-term culture-initiating cell assay (LTC-IC), [14] and extended LTCI-C assay. [15] For obvious reasons, an in vivo definition of such a population is not feasible in humans, but studies using transplantation of early human progenitor cells into sublethally irradiated immunodeficient mice can serve as surrogate stem cell assays. [16] [17] [18] Similarly, a human/sheep xenograft model allows the long-term detection of transplanted stem cell progeny, thereby providing the means to study early events in hematopoiesis. [19] [20] [21]

Multipotential cells are largely unresponsive to single growth factors, but they often respond synergistically to combinations of growth factors. [3] For example, the combination of macrophage colony-stimulating factor (M-CSF, CSF-1) and IL-1 stimulates the proliferation of HPP-CFC, [22] [23] whereas the combination of IL-3, IL-6, and granulocyte colony-stimulating factor (G-CSF) is one of many cytokine combinations that promote the proliferation of CFC-blast. [24] [25] Although cytokines influence the growth of these cells, they do not alter the proportion of stem cells that self-renew or differentiate along a given hematopoietic lineage, leading to a stochastic model for hematopoiesis in which a cell randomly becomes committed to differentiate along any given myeloid lineage pathway. [3]

Progenitor Characterization

Early hematopoietic progenitors are CD34+/CD33 and are negative for lineage-specific markers. [26] When CD34+ cells are isolated from bone marrow or blood, most express CD13 and human leukocyte antigen (HLA)-DR surface antigens. Only a minor subset co-express CD33. [27] After 7 days in culture in the presence of GM-CSF and IL-3, CD33 is expressed by 50% of these cells. Concurrently, CD34 expression is lost, and CD13 and HLA-DR expression also diminishes. By 14 days of culture, most cells are CD33+. [28] Patients receiving marrow grafts purged with anti-CD33 have been found to require a significantly longer time to achieve polymorphonuclear neutrophils (PMNs) >500/mm^3 , underscoring the importance of these committed granulocytic progenitors during the early phase of hematopoietic reconstitution after bone marrow transplantation. [29] Marrow grafts depleted of CD33-bearing cells result in durable engraftment after myeloablative treatment, implying that this antigen is absent or expressed in very low amounts on reconstituting stem cells. [29]

The pluripotent stem cell can be found in bone marrow as well as fetal liver and cord and adult peripheral blood, and has been defined by long-term in vivo repopulating assays; it belongs to the CD34+ cell compartment. [30] [31] [32] [33] An earlier stem cell has recently been tentatively described in CD34 cells. [18] [34] Stem cells display the multidrug resistance gene (*mdr-1*) [35] and have a low fluorescent staining using the mitochondrial dye rhodamine 123. [36] [37] They are also characterized by low levels of the Thy-1 antigen (CD90), [38] and display no lineage commitment markers (CD38, CD33, CD20, CD14). [39] [40] [41] [42] These early stem cells display receptors for several hematopoietic growth factors: IL-3R chain (CD123), *c-kit* (CD117) and *FLK-2/FLT3* (CD135), as shown in Figure 16-1 . Surrogate in vitro assays, developed in lieu of reconstitution assays, have also established the presence of a whole continuum of myeloid progenitors of decreasing proliferative potential and multilineage commitment. [2] These include the long-term culture-initiating cells, [15] [43] HPP-CFC-1 and -2, [12] [44] the colony-forming unit (CFU)-blast, [13] [45] and the mixed progenitor assay (CFUgranulocyte/erythroid/ macrophage/megakaryocyte [CFU-GEMM]). [46] Subsets of committed granulocyte and macrophage progenitors can be enumerated in vitro after 714 days in culture, using semisolid

Figure 16-1 Schematic diagram illustrating some of the significant surface antigen features of both progenitor colony-forming cells and of morphologically distinguishable precursors of monocytes and neutrophils. The pluripotent stem cell, which can give rise to both lymphoid and myelocytic progenitors, is CD34 and CD45RO positive but negative for CD45RA. Also shown are natural killer cell precursors and lymphoid and myeloid dendritic precursor differentiation pathways. At the myeloid progenitor level, CD34 persists, but CD33, CD64, and CD13 expression eventually emerges, as do RNA and protein production of myeloperoxidase (MPO). Monocytic precursors develop CD14 expression. The characteristics of the various CD antigens are more extensively defined in the text. CD90, Thy-1; CD123, IL3R; CD117, *c-kit;* CD135, *FLK-2/FLT3;* CD80, B7-1; CD86, B7-2; CD64, FcRI; CD16, FcRIII; CFU, colony-forming unit; GEMM, granulocyte/erythroid/macrophage/megakaryocyte; GM, granulocyte/macrophage; HLA, human leukocyte antigen; LAP, leukocyte alkaline phosphatase.

colony assays and specific histochemical staining techniques, [47] allowing identification of CFUgranulocyte/macrophage (CFU-GM), granulocyte (CFU-G), macrophage (CFU-M), eosinophil (CFU-Eo), and basophil (CFU-Baso). [5] [6] [7] Mast cell and dendritic cell colonies have also been described. Figure 16-2 shows examples of HPP-CFC, CFU-GM, and CFU-M colonies assayed in semisolid media.

The advent of sophisticated flow cytometric cell separation techniques, coupled with improved progenitor and long-term reconstitution assays, has established that the earliest CD34+ stem cell compartment appears not to express CD45RA, as well as antigens associated with lineage commitment (CD33, CD38), but is CD45RO positive. [48] [49] CD34+ cells that express low levels of *kit* protein have been found to be enriched for long-term marrow-engrafting cells. [50] CD34+ progenitors begin to lose myeloid potential and become lymphoid progenitors after acquiring CD10 and CD19 (B-cell lineage) or CD7 and CD45RA+ (T-cell lineage). [51] [52] More definite lineage commitment using a thymic stromal co-culture system has shown that only CD34+ cells expressing the CD20 antigen are destined to become B cells, because they failed to generate myeloid and T-cell progeny in vitro. Similarly, the CD34+, CD13 bright, and the CD34+, CD14+ and CD34+, CD15+ progenitors gave rise to myeloid cells, and were unable to differentiate into the B- or T-lymphoid lineages. [53] The CD34+, CD10, CD19 populations contain mostly LTC-ICs and myeloid progenitors, whereas the CD34+, CD10+, CD19 population gives rise to macrophage colonies and are CD33+. [51] This overlap in B-cell/macrophage lineage development is underscored by the plasticity of hematopoietic cells and is also validated by the identification of bipotential B-cell macrophage progenitors in fetal liver, [54] and by the observed lineage switching between early B cells to macrophages associated with expression of the proto-oncogene *c-fms*, which is the CSF-1 receptor. [55] The earliest bipotential myeloid progenitor, CFU-GM, has been characterized as CD34+, CD33+, CD13+, CD45RA+ and myeloperoxidase positive. [56] Granulomonocytic committed progenitors are CD34 and CD64 (FcRI) positive. [57]

Figure 16-1 recapitulates the salient phenotypic changes that human progenitors undergo as they differentiate into specialized lymphoid and myeloid precursors. A unique subset of marrow progenitor can generate T and B lymphocytes, NK cells, and lymphoid-derived dendritic cells, [58] [59] and a common developmental pathway for thymic NK cells and dendritic cells has been identified. [60] This linkage is further underscored by the dysregulated lymphopoiesis and lymphoid dendritic cell development seen in Ikaros gene knockout mice. [61] Primitive fetal liver progenitors that can give rise to NK progenitors as well as myeloid progenitors are also found in the CD34+, CD38, HLA-DR+ subset. [62] A similar developmental pathway for NK and B lymphocytes applies to embryonic stem cells exposed to vascular endothelial growth factor. [63] More complex differentiation pathways govern dendritic cell ontogeny. As shown in Figure 16-1 , these specialized antigen-presenting cells can arise

from both myeloid (monocyte, granulocyte) and lymphoid precursors. [64] [65] [66]

GROWTH FACTOR REGULATION

Synergistic Growth Factors

Hematopoietins exert their effects in concert on primitive stem cells (synergistic early-acting factors) and continue to influence progenitor expansion (intermediate-acting factors); later, one or two factors influence progenitor maturation along specific lineages (late-acting factors). [67] [68] These growth factors were initially defined by colony assays; hence the name colony-stimulating factors. These include G-CSF, GM-CSF, and M-CSF. [5] [69] [70] [71] Other myeloid-active cytokines include the ILs, such as IL-3,[72] IL-4,[73] IL-5,[74] IL-6,[75] IL-7,[76] IL-10,[77] IL-11,[78] IL-12,[79] and IL-13.[80] The *kit*-ligand/stem cell factor (SCF/KL) and the *FLT3* ligand are early-acting growth factors with tyrosine kinase activity and broad synergistic functionality. [81] [82] [83] [84] [85] Also, lineage-specific thrombopoietin (TPO) has shown activity on the early stem cell compartment in vitro [86] [87] and in vivo in TPO receptor-deficient knockout mice. [88]

Although the initial process of stem cell lineage commitment is stochastic (random), stem cells are likely to display multiple cytokine receptors, thereby explaining the synergistic and overlapping or redundant properties of hematopoietic growth factors. [3] [67] These early-acting factors are shown in Figure 16-3 and include G-CSF (produced by stromal cells, fibroblasts, endothelial cells, and monocyte/macrophages), [67] [89] IL-1 (produced by many cell types, including stromal cells, fibroblasts, endothelial cells, keratinocytes, epithelial cells, monocyte/macrophages, and B cells), [2] [90] IL-6 (produced by T and B cells, stromal cells, fibroblasts, endothelial cells, keratinocytes, and mast cells),[91] IL-11 (produced by stromal cells),[92] IL-12 (produced by B cells and macrophages),[93] IL-13 (produced by T cells),[94] and leukemia inhibitory factor (LIF; present in serum and produced by stromal cells, fibroblasts, T cells, astrocytes, and monocytes/macrophages). [95] [96] Other synergistic effects are provided by basic fibroblast growth factor (present in serum, megakaryocytes, platelets, immature granulocytes, and stromal cells, and within an extracellular matrix reservoir).[97] [98] This factor plays an important role in maintaining pluripotential embryonic stem cells together with KL and LIF, [99] and has been reported to act on early cells,[98] but other studies show no effect on CD34+ *c-kit*-positive stem cells,[99] [100] suggesting that its complex effects may depend on indirect stromal accessory cell-derived factors.[101] Last, tyrosine kinase receptor ligands, SCF/KL (produced by stromal cells, and synthesized in a soluble as well as membrane-bound form), [81] [102] and the *FLK-2/FLT3* ligand (stromal cells)[103] [104] are prominent in their ability to stimulate multilineage hematopoiesis [105] [106] [107] [108] as well as enhance granulocyte macrophage progenitor amplification in concert with other cytokines, [108] [109] [110] [111] as shown in Figure 16-3 , whereas hepatocyte growth factor (HGF; made by stromal cells, endothelial cells, fibroblasts, and keratinocytes), which signals through the *c-met* tyrosine kinase receptor, is synergistic in action primarily with IL-11, GM-CSF, G-CSF, and M-CSF against cord blood CD34+ cells. [112] Hepatocyte growth factor, in fact, has been shown to substitute for the defective

Figure 16-3 Various cytokines and chemokines that act at different levels of granulopoiesis and monocytopoiesis. Multiple cyto-kines regulate progenitor cells or mature effector cells at each stage of maturation/differentiation from the primitive pluripotent stem cell to nondividing, terminally differentiated precursors (monocytes, neutrophils, eosinophils, and basophils/mast cells). The cytokines and chemokines also have varying degrees of specificity; some, such as macrophage colony-stimulating factor (M-CSF) and interleukin (IL)-5, act predominantly on the monocytic and eosinophilic pathways, respectively, whereas others, such as granulocyte-macrophage (GM)-CSF, act on multiple granulocytic/monocytic (erythroid not shown) cell types. b-FGF, basic fibroblast growth factor; CFU, colony-forming unit; GEMM, granulocyte/erythroid/macrophage/megakaryocyte; HGF, hepatocyte growth factor; IP-10, interferon--inducible protein; KL, *kit*ligand; LIF, leukemia inhibitory factor; MCP-1, monocyte chemoattractant protein-1; MIP-1, macrophage inflammatory protein-1; NAP-2, neutrophil-activating peptide-2; NGF, nerve growth factor; RANTES, regulated on activation normal T expressed and secreted; SCF, stem cell factor; TPO, lineage-specific thrombopoietin.

SCF/KL signaling in W/W mice. [113] Oncostatin M (made by stroma, fibroblasts), which signals through the gp130 transducer, has been shown to affect early embryonic hematopoiesis.[114] Hematopoietic cytokines participate at various levels in the steady-state regulation of granulopoiesis and monocytopoiesis by promoting the survival of noncycling early progenitors, and by shortening the G0 period of early progenitors and triggering the proliferation and maturation of committed progenitors.[3] [115] These synergistic interactions have been deduced from in vitro early progenitor assays (LTC-IC, HPP-CFC, CFU-blast) as well as intermediate-to-late progenitor assays (CFU-GEMM and CFU-GM). [13] [116] [117] [118] [119] [120] [121] [122] [123] [124] [125] [126] [127] [128] Such interactions occur in vivo when more than one compartment of progenitors is stimulated (see Fig. 16-3).

Lineage-Specific Growth Factors and Chemokines

Cytokine receptor expression becomes more restricted as progenitors differentiate along separate granulocyte or monocyte pathways. Thus, at later stages of lineage commitment they express fewer cytokine receptors, and granulocytic maturation and differentiation is then governed by fewer growth factors, such as GM-CSF and G-CSF for neutrophil production, M-CSF and GM-CSF for monocyte precursor growth, IL-5 for eosinophil growth and maturation, and SCF, nerve growth factor, and IL-3 for basophil and mast cell growth[3] [129] (see Fig. 16-3).

Also as shown in Figure 16-3 , cellular trafficking of early and late leukocytes is regulated by members of a superfamily of chemoattractant proteins termed chemokines.[130] [131] [132] These are small proteins inducible by inflammatory signals and upon cell activation by bacterial, parasitic, or viral antigens. [133] They carry four conserved cysteines (Cys1-Cys3 and Cys2-Cys4) forming two essential disulfide bonds, with distinct structural motifs where the first two cysteine residues are adjacent (C-C branch), separated by an intervening residue (C-X-C branch) [134] or showing only a single cysteine residue, such as lymphotactin (C branch). [135] Yet another novel chemokine with a prominent mucin stalk (fractalkine) displays three amino acid residues between the first two cysteines (CX3C motif). [136] Chemokines direct the migration of mature granulocytic cells (monocyte, neutrophil, eosinophil, and basophil) to sites of inflammation or antigen presentation. [132] [137] Chemokine receptors are seven spanning domain, G-linked structures that mediate calcium flux, actin polymerization, and secondary signaling events. [138] [139] [140] [141] Chemokines have demonstrated activities on dendritic cells, [132] [142] [143] NK cells,[144] T-lymphocyte subsets,[145] [146] and B cells.[147]

Furthermore, chemokine receptors mediate human immunodeficiency virus entry into susceptible cells such as T lymphocytes, monocytes, macrophages, and dendritic and microglial cells. [132] [137] [148] [149] [150] [151] CD34+ hematopoietic stem cells have chemokine receptors such as CCR5 and CXCR4, the receptor for stromal-derived factor-1, which is important in B-cell growth and development and early myelopoiesis. [152] In addition to serving as co-receptor for entry of T-cell tropic human immunodeficiency virus-1, stromal-derived factor-1 is a powerful chemoattractant instrumental in CD34 mobilization and transendothelial migration. [153] [154] [155] [156] Table 16-1 illustrates the complexity of this evolving area, as we have shown positive migration with IL-8, monocyte

TABLE 16-1 -- Chemokine Receptors/Ligands and Cellular Selectivity

Chemokine Receptors	Receptor Cellular Distribution	Chemokine Ligands
CXCR1	Neutrophils	IL-8, GCP-2
CXCR2	Neutrophils, IL-5-primed eosinophils	IL-8, GRO//, NAP-2, ENA78, GCP-2, LIX
CXCR3	Activated T cells, natural killer cells	IP-10, MIG, I-TAC
CXCR4	Neutrophils, monocytes, CD34+ and pre-B-cell precursors, resting and activated T cells, dendritic cells, endothelial cells	SDF-1
CXCR5	B lymphocytes	BCA-1/BLC
CX3CR1	Monocytes, dendritic cells, CD34+ cells, natural killer cells, activated T cells	Fractalkine/neurotactin
CCR1	Monocytes, eosinophils, basophils, CD34+, activated T cells, and dendritic cells	RANTES, MIP-1, MIP-5, MCP-2, -3, -4
CCR2	Monocytes, basophils, activated T cells, dendritic cells, natural killer cells	MCP-1, -2, -3, -4, -5, RANTES, eotaxin-1, -2
CCR3	Eosinophils, basophils, dendritic cells, activated T cells	Eotaxin-1, -2, RANTES, MCP-2, -3, -4, MIP-5
CCR4	Activated T cells, dendritic cells, monocyte-derived dendritic cells, IL-2-activated natural killer cells	TARC MDC
CCR5	Monocytes, CD34+, activated T cells, dendritic cells, natural killer cells	RANTES, MIP-1, MIP-1
CCR6	T cells, dendritic cells	MIP-3/LARC/exodus-1
CCR7	Activated T cells, B cells	SLC/ELC/MIP-3
CCR8	Monocytes	I309, TARC, MIP-1
CCR10	Fetal liver, placenta	MCP-1, -3
Not known	Resting T cells	DC-CK1, PARC
Not known	Resting T cells, natural killer cells	Lymphotactin
CCR1 and CCR3	Broadly active on neutrophils, monocytes, and lymphocytes	Leukotactin-1

IL, interleukin; IP-10, interferon--inducible protein; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine; MIP, macrophage inflammatory protein; NAP, neutrophil-activating peptide; RANTES, regulated on activation normal T expressed and secreted.

chemoattractant protein (MCP)-1, RANTES (*r*egulated on *a*ctivation *n*ormal *T e*xpressed and *s*ecreted), macrophage inflammatory protein (MIP)1, and fractalkine.[155] [157]

Similarly, chemokines like MIP-1 have been shown to mediate in vitro and in vivo negative regulatory signals on myeloid and erythroid progenitor cells, underscoring a novel mechanism for the alteration in hematopoiesis seen in chronic inflammation and infections. [158] [159] [160] [161] However, their principal mode of action is to control cellular trafficking and tissue transmigration of mature effector cells. [131] Neutrophil migration is mediated by the soluble chemokines like IL-8, neutrophil-activating peptide-2, and Gro- (Gro = growth-related), [131] and membrane-bound neurotactin.[162] Eosinophils and basophils are recruited to sites of allergic stimulation by eotaxin-1 and eotaxin-2.[163] [164] [165] Monocytes are recruited principally by monocyte chemotactic protein(s) elaborated at sites of inflammation by fibroblasts and granulocytes,[166] [167] [168] by an interferon--inducible protein (IP-10), [169] and by T-cell-derived chemokines like RANTES. [170] [171] Table 16-1 illustrates the complexity of this system, and underscores the redundancy of receptors and ligand interactions that regulate the cellular trafficking of granulocytes, monocytes, and immune effector cells such as memory/naive T cells, NK cells, and dendritic cells in normal and pathologic states. [131] [132] [133] [172] [173] [174] [175] [176] [177] [178] [179] [180] [181] [182] [183] [184]

Granulocyte colony-stimulating factor leads to only weak in vitro colony growth by itself, but when it is combined with SCF or GM-CSF in vitro, larger colonies are stimulated.[67] [122] Similarly, G-CSF does not display its maximal range of in vivo activity when administered to W/W mice defective in their *c-kit* signaling, [67] [185] whereas appreciable circulating levels of SCF in normal subjects [186] amplify its effects in vivo, thus explaining its potent activity on neutrophil production and progenitor expansion.[187] This in vivo synergism also occurs on administration of SCF and G-CSF either alone or together, leading to early and committed progenitor expansion and mobilization.[188] [189] [190] Indeed, although commitment decisions of pluripotent cells have been shown to evolve from random asymmetric cell divisions not affected by external growth factors, it is evident that cytokine receptors with overlapping specificities and at times opposing effects govern in large part the lineage-specific maturation of intermediate and late progenitors by promoting the proliferation and survival of precursors expressing the appropriate growth factor receptors.[3] [191] These include the G-CSF receptor (G-CSFR) on neutrophils, the M-CSF receptor (M-CSFR, CSF-1R) on monocytes/macrophages, [192] [193] the IL-5 receptor (IL-5R) on eosinophils and basophils, [74] [194] [195] and the *c-kit* (SCF) receptor (SCF-R) on mast cells [102] (see Fig. 16-3).

Various modes of overexpression or underexpression of growth factors have aided in elucidating their role in lineage commitment. The in vivo lineage specificity of these factors is demonstrated in a canine model of neutropenia. Administration of G-CSF to dogs leads to the generation of neutralizing antibodies to their endogenous G-CSF and, consequently, neutropenia. [196] Transgenic mice expressing IL-5 display hypereosinophilia, [197]

whereas IL-5-blocking antibody administration inhibits helminth-induced eosinophilia in mice. [198] In the op/op mouse osteopetrosis model, the *op* locus encodes the CSF-1 gene on murine chromosome 3. These mice do not produce M-CSF because of a stop codon mutation in the CSF-1 gene; they also have a deficiency in their monocyte/macrophage compartment and suffer from osteopetrosis because of the absence of osteoclasts, which mediate bone resorption. [199] [200] M-CSF is essential for osteoclast proliferation and differentiation, [201] but, in addition, GM-CSF promotes the differentiation of these monocyte-derived precursors into multinucleated osteoclasts.[202] These op/op mice improve over time,[203] suggesting that other factors, such as IL-6, tumor necrosis factor- (TNF-), or GM-CSF, can stimulate macrophage progenitors in lieu of CSF-1. [204] [205] Recently, it has been reported that GM-CSF is not responsible for correction of hematopoietic deficiencies in maturing op/op mice. This was demonstrated in mice lacking both M-CSF and GM-CSF wherein the age-related corrections in hematopoiesis continued to occur. [206] Also, mice lacking the hematopoietic-transcription factor, PU.1, develop osteopetrosis. [207] Finally, animal models such as the W/W have a defective *c-kit* receptor and mast cell deficiency,[208] whereas activating mutations in *c-kit*, the SCFR, have been identified in mast cell leukemia, systemic mastocytosis, and myeloproliferative diseases,[209] [210] [211] underscoring the importance of SCF in terminal mast cell differentiation.

Last, production of knockout mice has served to elucidate the role of GM-CSF and G-CSF as well as that of other cytokines in granulocyte production. For example, mice homozygous for absence of the G-CSF gene[212] are viable, fertile, and superficially healthy but have a chronic neutropenia, CFU-GM deficiency, and impaired neutrophil mobilization. Mature neutrophils were still present in blood and marrow, suggesting that other factors can support neutrophil production in vivo, but that G-CSF may be involved in steady-state and GM-CSF in emergency granulopoiesis. Moreover, during infection, mice lacking G-CSF show impaired monocytopoiesis, underscoring the molecular cross-talk between these receptor/ligand pathways. [213] In contrast, mice lacking GM-CSF have normal hematopoiesis but develop pulmonary alveolar proteinosis. [214] Mice lacking the common chain for the GM-CSF, IL-3, and IL-5 receptors also show a pulmonary alveolar proteinosis [215] and reduced numbers of peripheral eosinophils and lung eosinophils after parasitic challenge. [216] Although they play a major role in expansion of hematopoietic cells in emergency states, the entire function of IL-3/GM-CSF/IL-5 is dispensable for hematopoiesis in both steady states.

GROWTH FACTOR RECEPTOR STRUCTURE AND FUNCTION

Receptor Structure

The hematopoietic growth factors that regulate granulopoiesis and monocytopoiesis are a diverse group of glycoproteins whose actions are mediated through lineage-restricted specific cytokine receptors. [217] Cytokine receptors can be placed in four subgroups based on their structural characteristics, as shown in Table 16-2 . [218] [219] [220] [221] [222] [223] [224] [225] [226] [227] [228] We restrict ourselves here to the two cytokine families that encompass most of the growth factors. The hematopoietin type I cytokine receptor family includes IL-2R, -3R, -4R, -5R, -6R, -7R, -9R, -11R, -12R , -13R, and -15R, the single-chain erythropoietin receptor (EPOR), G-CSFR, and the TPO receptor, the common signaling subunit KH97 that associates with receptor chains for human GM-CSF, IL-3 and IL-5, the gp130 signaling subunit for IL-6R, the LIF receptor, ciliary neurotrophic factor receptor, and oncostatin M receptor; [218] [219] [220] [221] [222] [223] [224] [225] [226] all of these factors share a structural similarity to the growth hormone/prolactin receptor family. The immunoglobulin superfamily includes the receptors for hematopoietic active growth factors, such as IL-1R, and the tyrosine kinase-containing receptors: CSF-1R, SCF/KLR, FL (*FLT3* ligand), fibroblast growth factor receptor, and platelet-derived growth factor receptor (PDGFR). [218] [226]

High-affinity receptor interactions require homodimeric ligand receptor interactions such as those for G-CSF, [229] M-CSF, [230] [231] SCF/KL,[232] TPO,[233] [234] and EPO,[235] or heterodimeric receptor ligand interactions through multichain receptors like PDGFR [236] as well as receptors with a common signal transducer such as the IL-3/IL-5/GM-CSF common chain,[226] or the gp130 receptor subunit shared by IL-6R, [225] LIF receptor,[225] [237] oncostatin M receptor,[238] ciliary neurotrophic factor receptor,[225] [239] and IL-11R.[240] In addition, shared signaling receptor subunits like the IL-2R subunit common to IL-2, IL-4, [241] IL-7,[242] IL-13,[243] [244] and IL-15[245] may partially account for the functional redundancy of these factors in hematopoiesis and immune regulation. Moreover, in vivo knockout experiments have uncovered a major role for IL-2 in myelopoiesis, highlighting the fundamental importance of T-cell-derived cytokines to normal hematopoietic functions (see Fig. 16-3). [246] The profound neutropenia seen in these IL-2/mice is indeed reminiscent of the leukopenia frequently seen in transplant recipients while on immunosuppressive therapy.

Most cytokines have pleiotropic activities and exhibit multiple functions on multiple cell types, and several CSFs may exert the same function when interacting with a given cell type.[67] [220] Growth factor receptors exist in high- and low-affinity forms on many hematopoietic and nonhematopoietic cells. [218] [223] [247] [248] [249] [250] [251] High-affinity GM-CSFRs are expressed in low numbers on progenitors (50100/cell) and increase as neutrophil and monocyte precursors undergo terminal maturation.[218] [252] All CSF interactions with high-affinity receptors at 37°C are associated with internalization and subsequent degradation of internalized CSF. [230] [248] [253] This can in effect serve as a negative feedback mechanism. [254] [255] Low-affinity receptors have a high rate of ligand dissociation; as such, they may serve as a reserve pool that can be used by new high-affinity receptors as they become available. [256]

Another common growth factor receptor theme is receptor transmodulation.[257] [258] Such modulation of receptor number can occur through a variety of mechanisms.[259] [260] [261] [262] [263] First, several ligands that do not directly interact at the CSF-binding domains of receptors can down-modulate CSFRs. With the M-CSFR, such modulators include lipopolysaccharide, phorbol esters 12-0-tetradecanoyl-phorbol-13-acetate (TPA), and TNF-; for G-CSFR, they include lipopolysaccharide, TPA, and the chemotactic peptide f-met-leu-phe; and for GM-CSFR, they include TPA, f-met-leu-phe, and TNF-. Second, the loss of high-affinity binding sites through internalization is a mode of receptor down-regulation. Third, CSFs can transmodulate other CSFRs. This means that the binding of one CSF to its own receptor at 37°C results in a loss of high-affinity binding sites for another CSF. In the mouse, IL-3R can transmodulate M-CSFR, G-CSFR, and GM-CSFR; GM-CSFRs can modulate M-CSFR and G-CSFR; G-CSFRs can transmodulate M-CSFRs; and M-CSFRs can transmodulate GM-CSFRs. In mice, the multipotential CSFs (IL-3/GM-CSF) seem able to down-modulate lineage-specific CSFRs (G-CSF/GM-CSF), but not vice versa. [218] In humans, the transmodulation between IL-3, GM-CSF, and IL-5 is reciprocal. [256] [260]

Unlike the IL-2R subunit, the GM-CSF/IL-5/IL-3 common subunit does not bind ligand but rather alters the affinity of the ligand for subunits. This finding might help to explain receptor transmodulation: if subunits are limiting, then binding of ligand (IL-3) to its subunit will deplete subunits because the / high-affinity receptor complex will be internalized. [256] The possession of common receptor subunits may help to explain some overlapping activities of these growth factors, but it does not fully explain the unique spectrum of activities of each growth factor or their pleiotropic actions in a given cell

TABLE 16-2 -- Cytokine Receptor Subgroups

Type I Cytokine ReceptorsHematopoietin Receptor Family	Immunoglobulin Superfamily Receptors	Type II Cytokine Receptors	TNF-like Receptors
IL-2R	IL-1RI and II	IFN receptors	TNF receptors
IL-4R	*(Ig repeats)*	*(FBN III domains)*	*(Cys repeats)*
IL-7R			
IL-9R			
IL-15R	Fibroblast growth factor (FGFRs)	IFNR	TNF-R p75
(Shared c chain)			TNF-R p55
		IFNR	TNF-RP
Erythropoietin R	Flt3 (Flk-2)		(LT-R)
Granulocyte CSFR		IFNR	
Thrombopoietin R (Mpl)	*c-kit* (SCF/KLR)		CD40 (gp39)
(Single chain)	CSF-1 receptor (fms, CSFR)		CD27
Granulocyte-macrophage (GM)-CSFR	Platelet-derived growth factor (PDGFRs)		CD30
IL-3R			OX40
AIC2A (IL-3 murine receptor)			4-1BB

AIC2B (murine) or KH97 (human)			Fas
IL-5R			
(Common chain for GM-CSF, IL-3, IL-5)			Low-affinity nerve growth factor receptor
IL-6R			
IL-11R			
Leukemia inhibitory factor (LIFR)			
Oncostatin M (OSMR)			
Ciliary neurotrophic factor (CNTFR)			
Gp130 (common signal transducer)			
IL-12R			
IL-13R			
Growth hormone (GHR)			
Prolactin (PRLR)			

CSF, colony-stimulating factor; FBN, fibronectin; IFN, interferon; IL, interleukin; LT, lymphocyte; SCF/KL, stem cell factor/ *kit* ligand; TNF, tumor necrosis factor.

type. The subunits are responsible for GM-CSF/IL-3/IL-5 signal transduction in responsive cells. [223] [226] [256] It has been reported that mice have an additional subunit of the IL-3 receptor. In mice with a null mutation of the gene encoding the common subunit of GM-CSF, IL-3, and IL-5, high-affinity binding of GM-CSF is abolished whereas that of IL-3 is not.[215] As noted previously, such mice have decreased eosinophils and contract alveolar proteinosis. [216]

Indeed, cross-regulation of cytokine receptors by other factors is a constant theme in hematopoiesis and has been demonstrated with several early- and late-acting cytokines such as SCF, IL-1, IL-6, IL-3, GM-CSF, TNF-, and transforming growth factor- (TGF-). [129] [264] [265] [266] [267] [268] [269] [270] [271] This complex regulation serves as an additional checkpoint to regulate specific precursor survival and maturation after the initial commitment process. [3] [7C] [193] [194] All hematopoietin family receptors have common structural features: two fibronectin type III modules, four conserved cysteine residues in the N-terminal module, and a unique sequence, Trp-Ser-X-Trp-Ser (WSXWS), in the C-terminal module. [219] [226] These structural features ensure appropriate receptor dimerization and ligand-receptor three-dimensional interactions. [272] Last, these receptors have no intrinsic kinase activity of their own, and hence they require activation (phosphorylation of chains) and the additional docking action of intracellular serine threonine/tyrosine kinase(s)/signaling complexes to transduce a mitogenic signal effectively, [226] using a family of signal *t*ransducers and *a*ctivators of *t*ranscription (STATs) proteins that become phosphorylated on tyrosine on activation of the *J*anus *k*inases (JAKs), undergo dimerization by reciprocal *Src* homology domains (SH2), translocate from the cytoplasm to the nucleus, and activate gene transcription via DNA binding domains. [273] [274] [275] As shown in Figure 16-4 , the importance of both and chains to the signaling process has become more apparent as investigators have attempted to map out various regions of the receptor that transduce mitogenic or antiapoptotic signals. [276] [277] [278]

Receptor-Mediated Signaling

In contrast to type I cytokine receptors of the hematopoietin family, tyrosine kinase-containing receptors like M-CSFR (*c-fms*), [279] [280] PDGFR,[281] [282] *FLK-2/FLT3*,[66] [283] and *c-kit*[102] mediate signaling directly after ligand/receptor dimerization and interchain phosphorylation by interacting with multiple signaling molecules with adapter domains for *src*-homology regions (SH2/SH3). [282] M-CSF has also been found to induce STAT1 and STAT3 activation in conjunction with phosphorylation of the nonreceptor tyrosine kinase Tyk2 in macrophages, while leading to Tyk2 and JAK1 phosphorylation in fibroblasts. [284] Table 16-3 illustrates the family of JAK/STAT subtypes that each cytokine receptor activates along with some of the nonreceptor tyrosine kinases that have been associated with these signals. It is also important to note that some of these pathways differ between hematopoietic and nonhematopoietic target cells. [285] [286] [287] [288] [289] [290] [291] [292] [293] [294] [295] [296] [297] [298] [299] [300] [301] [302] [303] [304] [305] [306] [307] [308] [309] [310] [311]

Figure 16-4 Multiple signaling pathways involved in granulopoiesis, including the interleukin (IL)-6R/gp130 receptor and the IL-3R, IL-5R, and GM-CSFR receptors, which possess a common subunit (c). Also shown is the ability of IL-1 to act synergistically with these other growth factors. Complex intracytoplasmic cross-talk between mediators of these pathways occurs, and many aspects remain to be elucidated (denoted by question mark [?]). The chain of the IL-3/GM-CSF/IL-5 receptor family has no intrinsic protein tyrosine kinase (PTK)-activating capacity and can associate with the JAK2 tyrosine kinase. The common chain and gp130 interact with JAK2, and JAK1 and JAK2, respectively, resulting in receptor phosphorylation and activation of STAT5 and STAT3, which act as transcription factors into the nucleus. The chain of these receptors confers specificity for the individual cytokine signals, as shown by receptor reconstitution studies. AA, arachidonic acid; APP, acute-phase protein; DAG, diacylglycerol; ERK, extracellular signal-regulated kinase (also known as MAP, mitogen-activated protein); GM-CSF, granulocyte-macrophage colony-stimulating factor; Grb2-sos, growth factor receptor binding protein and mammalian son of sevenless; IL-1Racp, IL-1 receptor accessory protein; IRAK, IL-1 receptor-associated kinase; JAK, Janus kinase; LT, leukotriene; MEK, MAP kinase/ERK-activating kinase; NF, nuclear factor; PL, phospholipase; SHC, *src* homology domain containing protein adaptor; STAT, signal transducers and activators of transcription.

Cytokine receptor-mediated signal transduction results in cell activation, priming, proliferation, or maturation, depending on the particular target cell being analyzed. [3] [247] [269] [280] A complex cascade of events following GM-CSF/IL-3 high-affinity receptor engagement has been uncovered and includes (1) G-binding protein(s) translocation, [312] [313] [314] [315] [316] [317] (2) phosphatidylinositol pathway activation, [318] [319] [320] (3) phospholipase A_2 and D activation,[321] [322] [323] [324] (4) $p21^{ras}$ activation,[325] [326] [327] (5) *raf* kinase phosphorylation,[328] [329] (6) protein kinase C (PKC) activation, [330] [331] (7) Na^+ /H^+ antiporter activation,[332] [333] and (8) mitogen-associated activated protein kinase (MAPK) phosphorylation.[334] [335] [336] Similar events also occur with M-CSFR-(*fms*)-mediated signaling, leading to Na^+ antiporter activation,[279] [337] *raf* kinase phosphorylation and activation,[279] [338] cell proliferation,[280] and cyclin D1 expression, [339] and activation events such as enhanced phagocytosis, [340] chemotaxis,[341] [342] chemokine gene expression,[343] and integrin expression[344] of *c-fms*-positive target cells. The convergence of these various CSFR-mediated signaling pathways, involving PKC or MAPK (also termed ERK1 and 2, for *e*xtracellular *s*ignal-*r*egulated *k*inase), to the nucleus results in the transcriptional regulation of new genes, such as *EGR-1*, *c-jun*, and *AP1*, in both proliferating and terminally differentiated myeloid cells, [223] [345] [346] [347] [348] [349] with enhanced DNA-binding activity of the transcription factor AP-1, nuclear factor (NF)-AT, and NF-B after induction of MAPK in T cells. [350] The interaction of these signaling events is detailed in Figure 16-4 .

Another important signaling pathway is used by the synergistic factor IL-1. It involves the newly characterized IL-1 receptor accessory protein (IL-1RAcp) and two receptor-associated kinases (IRAK-1 and IRAK-2), which interact with a cytosolic protein, MyD88, and activate the adapter protein, TRAF6, which in turn leads to NF-B activation through the NF-B inducing kinase and two I-B kinases, IKK-1 and IKK-2 [351] [352] [353] [354] [355] (see Fig. 16-4). NF-B is a well characterized transcriptional activator for multiple cytokine and chemokine genes such as IL-6 and IL-8, triggered by proinflammatory cellular activators such as IL-1. [356] [357] [358] [359] [360]

Most hematopoietin receptors, such as G-CSFR and GM-CSFR, are devoid of tyrosine kinase activity and require additional molecules to mediate their mitogenic activity.[219] [223] For example, neither subunit of the GM-CSFR is a tyrosine kinase and neither has domains similar to those found in G-protein-associated receptors. The finding of common substrates phosphorylated on tyrosine residues after activation of several cytokine receptors, as well as the necessity of tyrosine kinase activity to activate $p21^{ras}$, suggested that these receptors were undergoing phosphorylation after ligand interaction by associating with intracytoplasmic signaling complexes with adapter

TABLE 16-3 -- JAKs, STATs, and Nonreceptor PTKs Mediating Signal Transduction

Cytokine	JAK Subtype	STAT Subtype	PTKs
Erythropoietin (EPO)	JAK2	STAT5, STAT1	Fes, Tec
G-CSF	JAK1, JAK2, Tyk2	STAT1, STAT3	Lyn, Syk, c-rel, Tec, PI3K
Thrombopoietin (TPO)	JAK2, Tyk2	STAT1, STAT3, STAT5	Tec
Growth hormone (GH)	JAK2	STAT1, STAT3, STAT5	Tec
Prolactin (PRL)	JAK1, JAK2	STAT1, STAT5	Lyn, Tec, PI3K
Ciliary neurotrophic factor (CNTF)	JAK1, JAK2, Tyk2	STAT1, STAT3, STAT5	
IL-6	JAK1, JAK2, Tyk2	STAT1, STAT3, STAT5	Hck, Btk, Tec, PI3K
IL-11	JAK1, JAK2, Tyk2	STAT1, STAT3	Yes, Src, PI3K
Leukemia inhibitory factor (LIF)	JAK1, JAK2, Tyk2	STAT1, STAT3, STAT5	Hck
Oncostatin M (OSM)	JAK1, JAK2, Tyk2	STAT1, STAT3, STAT5	
GM-CSF	JAK2	STAT5, STAT1, STAT3	Fes, Lyn, Yes, Tec, PI3K
IL-3	JAK2	STAT5, STAT1, STAT3	Lyn, Fyn, Fes, Tec, PI3K
IL-5	JAK2	STAT5, STAT1	Lyn, Syk, PI3K
IL-2	JAK1, JAK3	STAT1, STAT3, STAT5	Lck, Fyn
IL-4	JAK1, JAK3	STAT6	Lyn, Syk, PI3K
IL-7	JAK1, JAK3	STAT1, STAT5	Lyn, Syk
IL-9	JAK1, JAK3	STAT5	Lyn, Syk
IL-15	JAK1, JAK3	STAT5	Lyn, Syk
IL-12	JAK2, Tyk2	STAT3, STAT4	
IL-13	JAK1, JAK2, Tyk2	STAT6	
IFN-/	JAK1, Tyk2	STAT1, STAT2, STAT3	
IFN-	JAK1, JAK2	STAT1	
IL-10	JAK1, Tyk2	STAT1, STAT3, STAT5	
kit ligand (KL)	JAK2	STAT1, STAT2, STAT3	Lyn, PI3K
M-CSF	JAK1, Tyk2	STAT5	Fyn, Src, Yes, PI3K
FLT3 ligand		STAT1, STAT3	Fyn, Src, PI3K
Platelet-derived growth factor (PDGF)	JAK1, JAK2, Tyk2	STAT1, STAT3, STAT5	Fyn, Src, PI3K

CSF, colony-stimulating factor; G, granulocyte; IFN, interferon; IL, interleukin; JAK, Janus kinase; M, macrophage; PTK, protein tyrosine kinase; STAT, signal transducer and activator of transcription.

proteins containing 2 SH2 in a variety of cells. [223] [325] Furthermore, insights into the physiology of proteins with SH2 domains revealed their capacity to act as transducers of several tyrosine kinase signaling pathways. [361] The seminal discovery has been the isolation of an SH2 domain containing transforming protein with a unique sequence (SHC). [362] [363] The SHC cDNA encodes overlapping proteins of 46.8 and 51.7 kd, whereas antibodies recognize three components (46, 52, and 66 kd). SHC proteins are rapidly phosphorylated by *src* kinases and form a complex with the 23-kd polypeptide of the adapter molecule Grb2 with an SH3 domain and its partner binding protein sos (a guanine nucleotide exchange factor). [364] [365] This activated complex mediates ras activation after receptor/ligand interactions, as shown for the epidermal growth factor/erbB-2 receptor [356] [357] [358] [359] [360] [361] [362] [363] [364] [365] [366] [367] [368] [369] and for the insulin/insulin receptor substrate-1. [370] [371] [372] The demonstrated role of the SH2/SH3 domains of Grb2 in coupling epidermal growth factor signaling to the ras activator sos provided the final link for growth factor-mediated p21^{ras} activation. [373] Soon thereafter came the discovery of the JAK tyrosine kinase family and the realization that either JAK1 or JAK2 can serve as receptor-associated tyrosine kinases to transduce multiple growth factor/receptor proliferative signals, [374] as illustrated by the signaling mediated through growth hormone, interferon- (through JAK1), and interferon- (through both JAK1 or JAK2). [375] [376] [377]

This tyrosine kinase pathway linked to receptor subunits and Grb2/sos adapters offered the necessary explanation for the frequently seen p21 ^{ras} activation, which leads to the MAPK extracellular signal-regulated kinase activation [378] seen with GM-CSF, [223] [334] [335] SCF, and IL-3. [223] [325] [326] As shown in Figure 16-4 , hematopoietins such as IL-6, IL-3/GM-CSF/IL-5, and the immunoglobulin-like receptor for IL-1 use distinct but somewhat overlapping intracytoplasmic signaling pathways, eventually leading to new gene (*c-myc*, cyclin D2, *c-jun*, *c-fos*) transcription. [223] Multiple cytokines, with the exception of IL-4, stimulated the phosphorylation of a p97-kd protein (JAK2) and p42 MAPK. [379] [380] [381] [382] GM-CSF and IL-3 phosphorylated the same sets of proteins, including raf kinase and MAPK, in a factor-dependent cell line (MO7), whereas SCF, in addition, phosphorylated phospholipase C on tyrosine, [381] like the kinase-containing receptors such as PDGFR, M-CSFR, and *FLK-2/FLT3* receptor. [280] [281] [282] [283] Distinct cytoplasmic regions of the common subunit mediating the signaling for the IL-3/IL-5/GM-CSF ligands have been mapped by reconstitution experiments using a factor-dependent hematopoietic cell line of 3T3 fibroblasts. [383] [384] [385] [386] [387] [388] [389] [390] The importance of both and chains for GM-CSF, IL-3, and IL-5 signal transduction is illustrated in Figure 16-4 , [277] [292] [386] [388] [391] as is polypeptide signaling to the nucleus via JAK kinase. [392]

Mounting evidence implicating the IL-6 signal transducer gp130 protein in JAK2 kinase activation is now available. [393] In the event that this activation leads to tyrosine phosphorylation of an interferon-stimulated growth factor, this may provide a direct transcriptional signal to the nucleus without activating the *ras-raf*-MEK-MAPK cascade, which is reminiscent of the JAK1/2-mediated tyrosine phosphorylation of several cytoplasmic STAT proteins [393] [394] [395] (see Fig. 16-4). These transduction pathways have also been confirmed by the demonstration of JAK2 kinase association with several type I cytokine receptor/ligand complexes, such as IL-3, [396] [397] EPO, [398] [399] and GM-CSF, [400] [401] which have also been found to be associated with SHC and *sos*, leading to p21^{ras} activation. [384] [385] [386] Similarly, SCF [402] and the p210$^{bcr/ab}$ kinase [403] recapitulate the same events, leading to receptor

subunit phosphorylation and activation of the SHC signaling component of the p21 ^{ras} pathway by tyrosine phosphorylation, underscoring the importance of this cascade and its common utilization by several cytokine-receptor interactions. [362] [403] [404] [405]

Receptor reconstitution experiments showing a divergence in cellular signaling events between hematopoietic cells and nonhematopoietic cells such as 3T3 fibroblasts, as well as subtle differences between SCF, IL-3, and GM-CSF action on the same target cells, require additional explanation. [381] [385] [387] The discovery of the tyrosine phosphorylation of many endogenous cytoplasmic transcription factors with SH2/SH3 domains by JAK1 or JAK2 kinases [406] [407] at last provided a *ras*-independent growth factor signaling pathway. [408] The detailed analysis of signaling complexes has revealed a p80-kd component in cells stimulated by IL-3, GM-CSF, or IL-5, whereas interferon--treated cells activated several transcription factors containing the p91-kd component of epidermal growth factor-3. [407] Thus, the cellular specificity of signaling may be provided by individual receptor subunits (such as chains of CSFR) that activate unique cytoplasmic transcription factors. [406] In addition, the GM-CSFR subunit participates in glucose transport without requiring tyrosine phosphorylation, thus providing a link to the increased survival of precursors induced by GM-CSF. [409]

Another issue in cytokine receptors is the pleiotropic nonreceptor tyrosine kinases (e.g., src kinases) and transforming proto-oncogenes (e.g., *abl*, *myb*, *vav*) that have been identified in hematopoietic cells. [410] [411] Although the exact function of these molecules is far from being totally understood, gene knockout experiments have

started to shed some light on their role in hematopoiesis. [410] [411] For instance, Pim-1 kinase is induced in IL-3/GM-CSF-treated cells, [223] and its expression parallels the growth of cytokine-exposed cells. [412] The tyrosine kinase *c-fps/fes* has been implicated in GM-CSFR and EPOR signaling, [413] [414] [415] the *src* kinase *lyn*, normally associated with the high-affinity Fc receptor I, is regulated by IL-3 in myeloid cells, [416] and the *syk* kinase participates in GM-CSF/IL-5-induced eosinophil differentiation. [307] These potential regulatory kinase complexes are also illustrated in Figure 16-4 , and are highlighted in Table 16-3 .

Granulocyte colony-stimulating factor receptor, which is also devoid of kinase activity, by itself forms a three-component complex with *lyn* and *syk* protein kinases. [417] The study of patients with severe congenital neutropenia offers insights into the role of this receptor, because patients display normal G-CSFR on their neutrophils, [418] but their CFU-GM growth in response to G-CSF alone is poor, whereas a combination of SCF and G-CSF results in normal growth patterns. [419] Indeed, molecular characterization of G-CSFR showed distinct cytoplasmic regions involved in the induction of proliferation or differentiation, [420] and transfection analysis showed cross-phosphorylation of IL-3R by G-CSF stimulation of cells expressing both receptors, indicating potential functional redundancy of cytokine receptor signaling [421] [422] (see Fig. 16-4). Proliferative responses to G-CSF are associated with activation of the p21 ^{ras}/MAPK signaling pathway. [423] The identification of a truncated G-CSF receptor in a case of severe congenital neutropenia [424] offers an example of the important role of receptor-associated signaling complexes leading to p21 ^{ras} and MAPK activation in mediating cell proliferation. [423] [425] The importance of PKC in G-CSF-mediated neutrophil survival underscores the potential for this activation pathway in the cytokine receptor signaling process diagrammed in Figure 16-4 . [426] [427] G-CSF has been found rapidly to activate the STAT3 transcription factor, [428] [429] and distinct regions of the receptor are required for tyrosine phosphorylation of JAK2, STAT3, and p42,p44 ^{MAPK}. [430]

Along with the characterization of protein kinases came the realization that in these dynamic phosphorylation/dephosphorylation processes, distinct protein tyrosine phosphatases were an integral part of turning off or, in some instances, turning on a given signaling cascade. [431] In the case of hematopoiesis, the CD45-associated phosphatase has been shown to modulate IL-3-, GM-CSF-, and SCF-mediated progenitor growth, [432] whereas M-CSF phosphorylates [433] and SCF associates with a tyrosine phosphatase termed hematopoietic cell phosphatase (HCP or SHP-1). [434] This phosphatase associates with the IL-3 receptor chain, mediates the down-regulation of IL-3-induced tyrosine phosphorylation and cell proliferation, and regulates *c-jun* expression in monocytes. [435] [436] HCP is inactive in motheaten mice, [437] which are characterized by hyper-reactivity to multiple cytokines like G-CSF, GM-CSF and IL-3 in vitro, and in vivo suffer from marked hyperproliferation of granulocytes and macrophages. [438] [439] [440] Another negative regulator of cytokine signaling is a 145-kd, SH2-containing inositol-5-phosphatase (SHIP) [441] [442] that is widely expressed in hematopoietic cells and has been shown to down-regulate the antiapoptotic and proliferative signals triggered by several cytokines, including TPO, EPO, IL-3, KL, M-CSF, GM-CSF, and G-CSF. [441] [443] [444] [445] The central role of this phosphatase as a negative regulator of myelopoiesis is underscored by the phenotype of mice with targeted disruption of SHIP, which have increased numbers of GM progenitors in marrow and spleen and die prematurely from extensive lung consolidation by myeloid cells. [446]

Last, the regulation of myeloid proliferation and differentiation may also include small intracellular messenger molecules such as nitric oxide, which has been implicated in the modulation of cell differentiation and *c-myc* and *c-fos* gene expression in the HL60 human myeloid leukemia cell line, adding further complexity to the cytokine transduction pathways regulating myeloid cell proliferation or differentiation, or both. [447]

Lineage Commitment

The mechanisms of lineage commitment toward granulopoiesis and monocytopoiesis and the roles of cytokines, cytokine receptors, and specific myeloid genetic programs are still incompletely understood. [448] [449] In vitro studies of murine embryonic stem cells and embryoid bodies reveal a temporal coordinated expression of growth factor receptor genes during cell maturation. [450] Certain genes are expressed constitutively during development of these cells, such as *c-kit* and the subunits of the growth factor receptor genes. Expression of the common subunit of the IL-3/IL-5/GM-CSF receptors, as well as SCF, are induced early. By contrast, *c-fms*, G-CSFR, and CD34 are induced later, at an intermediate stage of development, reflecting the initiation of myeloid commitment. [450] The extent to which growth factors and cytokine receptor expression determine the differentiation pathway taken by GM progenitors remains largely unknown, as do the genes responsible for cell commitment. There is evidence that multilineage gene expression precedes commitment in the hematopoietic system. [451]

Several in vitro models of differentiation provide clues to the importance of various stimuli to lineage commitment. For instance, IL-3 and GM-CSF act dominantly in a factor concentration-dependent manner to suppress *c-fms* (M-CSFR) expression on their target cell. [452] Overexpression of *c-fms* in an IL-3/GM-CSF factor-dependent murine myeloid leukemia cell line (FDC-P1/MAC) leads to a CSF-1-dependent differentiation pattern. Also, a GM-CSF-activated ribonuclease system down-regulates *c-fms* mRNA in these cells. [453] Furthermore, TGF-1, a known cell growth inhibitor, increases *c-fms* expression in these cells, [454] implying that an important control point in regulating monocyte/macrophage lineage differentiation may be the expression of *c-fms* itself. [455] The HL60 cell line can mature along either granulocytic, monocytic, or eosinophilic pathways, allowing the identification of myeloid-specific genes involved in lineage commitment. [456] [457] HL60 cells exposed to phorbol esters (TPA) or vitamin D_3 are induced along the monocytic lineage, whereas dimethylsulfoxide causes granulocytic maturation, and retinoic

acid induces a biphenotypic maturation of these cells. [458] Such established cell lines are useful models for analyzing the developmental expression of CSFRs, chemokines, and novel genes that regulate or are temporally associated with lineage-specific differentiation. [455] [460] Using these models, cytokine combinations have been shown to inhibit proliferation and promote lineage commitment, [461] whereas sequential exposure to maturation inducers such as vitamin D_3 or retinoic acid and lineage-specific CSFs accelerates the differentiation process. [462] Similar studies have underscored the central role of specific genes in modulating myeloid commitment, such as the *c-myc*, [463] [464] *c-myb*, [465] *SCL*, [466] and *EGR-1* genes. [345] [467] Furthermore, they have demonstrated the importance of *c-myc* expression on cell proliferation [464] and the need to down-regulate its function before the induction of terminal differentiation. [468] [469] PU.1 but not *ets-2* has been found essential for macrophage development from embryonic stem cells, [470] and induction of PU.1 correlates with negative regulation of the *c-myb* promoter, which is essential for continued cell proliferation. [471] Moreover, myeloid development is selectively disrupted in PU.1 null mice. [472] The efficient survival and amplification of macrophage precursors depends on external signals (cytomatrix adhesion and cytokine receptor engagement) as well as the coordinate expression of PU.1 transcription factor, which in turn activates M-CSFR expression. [473]

Granulocyte-macrophage colony-stimulating factor concentration determines myeloid versus monocytic commitment by controlling *c-fms* expression. [204] At low concentrations of GM-CSF, macrophage colony formation is favored because of relatively high expression of *c-fms*, whereas at higher GM-CSF concentrations, mixed colony formation (GM) is preferred because of the lower levels of *c-fms* expression. [204] [452] Similarly, *EGR-1*, a DNA-binding zinc-finger transcription factor, is an early response gene up-regulated by macrophage inducers (TPA and CSFs); [280] [345] it functions by restricting myeloblast differentiation to the macrophage lineage. [467] The essential role of M-CSFR in monocyte/macrophage lineage commitment is also illustrated by a *c-fms*-dependent HL60 cell differentiation model in which monocytic differentiation and retinoblastoma (*Rb*) gene expression depend on the presence of active M-CSFR on the cell surface. [474]

Similar cross-regulation of CSFRs occurs in the 32DC13(G) IL-3-dependent murine cell line, which can be primed by G-CSF to express GM-CSFRs and thereby differentiate into monocytes and granulocytes. [475] Such findings are in keeping with the observed synergistic effects between GM-CSF and G-CSF on highly purified progenitor cells. [476] Moreover, as with *c-fms* and monocytic maturation, expression of G-CSFR promotes granulocytic differentiation in the WEHI-3B D+ cell line, [477] whereas the up-regulation of G-CSFR mRNA appears to be an early commitment event in normal myeloid differentiation that is often dysfunctional in leukemic cells. [478]

A common feature of hematopoietic cells is their capacity to switch lineages. [449] The introduction of *v-fms* into pre-B lymphocytes allows the generation of monocytic leukemic cell lines. [479] The bipotential capability of precursors of B cells and macrophages in murine fetal liver [54] and the expression of *c-fms* by B-transformed B cells such as hairy cell leukemia cells [342] suggest the presence of common transcriptional regulators in each cell type. [480] Hence, it is not surprising that common genes belonging to the *ets* family are active in early macrophage differentiation and B-cell development. These include *ets2* and *PU.1* proto-oncogene(s). [481] [482] Indeed, the *PU.1/Spi-1* proto-oncogene regulates the lymphoid-specific immunoglobulin heavy chain enhancer at the pre-B-cell stage. [483] Other genes such as *fes* and *MZF-1* appear to modulate granulocytic precursor proliferation and maturation. [484] [485]

Other mechanisms for lineage commitment have been identified in the HL60 leukemia model. Retinoic acid-induced cell differentiation can occur through the induction of TGF-1 protein and TGF-1 receptor expression, potentially triggering an autocrine inhibition loop. [486] Another mechanism regulating neutrophilic maturation can be the easing of the dominant negative effect (blocking maturation) exerted by retinoic acid -fusion transcripts in leukemic promyelocytes. [487] Alterations in inositol lipids and phosphates regulate neutrophilic or monocytic lineage maturation of HL60 cells. [488] Finally, whereas PKC activation promotes monocytic maturation of myeloblasts [489] and enhances CFU-GM growth in conjunction with cytokines (IL-6 and G-CSF), [490] inhibitors of myosin light chain kinase have been shown to differentiate the monoblastic leukemia U937 line, an effect antagonized by GM-CSF. [491]

The central role of transcriptional regulators in normal and leukemic cells has been increasingly appreciated as sites of chromosomal translocations have been characterized.[480] For example, embryonic lethality and impairment of hematopoiesis result in mice heterozygous for an *AML-1/ETO* fusion gene. [492] Homeobox genes have also been found to have individual roles in differentiation and proliferation of myeloid progenitors. Undoubtedly, complex regulatory signaling pathways involving receptor and nonreceptor kinases and phosphatases must affect specific genetic programs responsible for the lineage commitment process. [473]

CELLULAR PRODUCTION

Granulocytes are derived from a common myeloid stem cell and comprise neutrophils, eosinophils, basophil/mast cells, and dendritic cells. Neutrophils (PMNs) and monocytes/macrophages constitute two important elements of the host defense system. Basophils and mast cells contribute to mucosal immunity, and eosinophils, basophils, and mast cells aid in response to allergens and parasitic infections. In this role, they must have the capacity to migrate, phagocytize, and produce inflammation-inducing substances to achieve antimicrobial destruction or contribute to inflammatory reactions. In addition to combating microorganisms, tissue macrophages constitute the resident reticuloendothelial system of many organs such as liver, spleen, and bone marrow. [493] In these sites, they may also serve to eliminate debris and senescent cells, aid in antigen presentation and processing, and, in some cases, effect antitumor cytotoxicity. Because these effector cells are constantly used, the need to maintain appropriate cell numbers in an equilibrium state as well as to have the capacity for increased production in times of stress requires a finely controlled regulation of both neutrophil and monocyte production.

Neutrophil and Monocyte Production

In the adult, the marrow is the source of both neutrophils and monocytes, which circulate until they exit the vascular spaces to the tissues. In the marrow, the CFU-GM is the earliest cell type that can be identified in culture as having commitment to differentiate along the myeloid pathway. This cell type is distinguished by its ability to form hematopoietic colonies when assayed in vitro in semisolid media such as agar or methylcellulose in the presence of CSFs (see Fig. 16-2). CFU-GM, which numbers approximately $50100/10^6$ nucleated cells in a normal human marrow specimen, is a bipotential progenitor and can respond to GM-CSF differentially based on growth factor concentration. As discussed previously, at high concentrations of GM-CSF, the granulocytic pathway is favored, whereas at low concentrations, monocytic/macrophagic differentiation occurs preferentially (see Fig. 16-3). CSF-1 appears to control its own expression on maturing progenitor cells, providing another feedback regulatory pathway to limit unchecked monocyte production, [494] whereas anti-inflammatory agents such as cyclo-sporine and dexamethasone regulate CSF-1 and *c-fms* expression at a post-transcriptional level. [495]

Progenitor cells cannot be recognized morphologically in

marrow, but rather have the appearance of nondescript mononuclear cells (lymphoid appearance). The myeloblast is the first morphologically identifiable precursor. Myeloblasts, promyelocytes, and myelocytes are mitotic, but metamyelocytes, band neutrophils, and mature PMNs constitute what is known as the postmitotic compartment (see Fig. 16-1). Azurophilic granules appear at the promyelocyte stage, but the specific granules containing such substances as lactoferrin and cytochrome b do not appear until the myelocyte stage. The adult human harbors an estimated 7.7×10^9 PMNs/kg. In addition to neutrophils found in the vascular space and tissues, there is a large marginated pool and a large marrow reserve, allowing for rapid recruitment of effector cells in times of need. Neutrophils spend approximately 67 days in the marrow. On egress, they spend only a short time in the circulation (half-life 6.7 hours). The released PMN is differentiated and postmitotic, and neutrophils live in tissues for only a few days.

Monocytic cells, of which the promonocyte is the earliest recognizable stage, spend less time in the bone marrow than do PMNs, so they are released into the circulation with the ability to mature further. No marrow reserve exists. Monocytes spend 13 days in transit through the marrow and 872 hours in the blood. On entry into tissues, further maturation and possible proliferation can occur. Monocytes can survive in tissues for long periods, reportedly >80 days. The tissue-fixed macrophages derived from monocytes include alveolar macrophages, which can proliferate when exposed to IL-3 with M-CSF, [496] the Kupffer cells in the liver, splenic macrophages, [493] and oligodendrocytes/glial cells in the central nervous system, which elaborate cytokines and express GM-CSFRs. [497] [498]

Dendritic cells are specialized cells that appear to be derived from CD34+ progenitors, [499] [500] because colonies with a dendritic appearance appear in the same colonies as macrophages, suggesting a common origin. Dendritic cells are HLA-DR+ and CD4+, but they lack nonspecific esterase and other macrophage surface markers. They are HLA-DQ+ and are able to stimulate allogeneic mixed lymphocyte cultures. In the presence of TNF- and GM-CSF, these cells proliferate and acquire the characteristic morphologic appearance of dendritic cells. [501] Furthermore, dendritic cells in the lungs as well as pleural and peritoneal macrophages are subject to local control by GM-CSF, [502] a process also seen in transgenic mice expressing GM-CSF. [503]

To maintain steady-state hematopoiesis, it is estimated that 8.7×10^8 PMNs/kg and 5.7×10^6 monocytes/kg must be produced every day. The cytokine factors that influence the proliferation and maturation of these cells must thus be finely tuned to be able to accommodate ever-changing and sometimes urgent demands for increased production. CFU-M generally needs two factors, GM-CSF plus M-CSF or IL-6 plus M-CSF, to express full colony-forming potential. [476] GM-CSF synergizes with G-CSF in the formation of granulocytic colonies (CFU-G) with respect to number and size of the colonies. Also, GM-CSF synergizes with M-CSF to increase the number and size of macrophage colonies (CFU-M). [67] [476] A significant proportion of CFU-M growth requires the presence of IL-6, indicating that an intricate regulatory cytokine network probably influences marrow promonocyte production. [504] [505] Additional studies have also identified a monocyte-specific inducer elaborated by activated macrophages undergoing phagocytosis or at sites of inflammation. [506] This cytokine, termed factor-increasing monocytopoiesis, differs from IL-1 and CSF-1 and regulates marrow monocyte production in a specific long-range manner. [507] Its relationship to the newly identified monocyte-active chemokines such as MCP-1, -2, and -3 remains to be determined. [166] The cytopenias frequently associated with infections and other bone marrow disorders reflect a complex regulatory network of soluble factors such as positive regulatory cytokines, inhibitory cytokines (TGF-, TNF-), [271] [507] and chemokines (MIP-1, IP-10, MCP-1, stromal-derived factor and), [130] [158] [159] [508] [509] [510] soluble cytokine receptors, [511] and short-range regulatory signals mediated by leukotrienes, [512] [513] prostaglandins, [514] and cytomatrix-bound factors regulating the interactions between stromal cells and progenitor cells. [515] [516] [517] [518] Furthermore, macrophages developing in the marrow may differ in their function and phenotype. [519] [520] These complex cytokine/cell-cell interactions are illustrated in Figure 16-5 , which recapitulates intramedullary regulatory events occurring during active immune stimulation or chronic infections. [2] [521] Mature mononuclear cells including granulocytes, monocytes, and T lymphocytes release cytokines (Table 16-4) and chemokines (Table 16-5) when exposed to activating agents such as bacterial antigens or inflammatory stimuli, as shown in Figure 16-5 . Tables 16-4 and 16-5 underscore the potential for localized regulation of progenitor output and precursor tissue accumulation by mature cells. [522] [523] [524] [525] [526] [527] [528] [529] [530] [531]

Eosinophil Production

The eosinophil is a type of granulocyte characterized by distinct granules that become apparent at the early myelocyte stage of development. [195] Eosinophils are derived from CD34+ committed progenitors that proliferate and mature in the marrow. Mice deficient in CD34 have reduced eosinophil accumulation after allergen exposure, but otherwise have normal hematopoiesis. [532] As illustrated in Figure 16-3 , eosinophil production requires early-acting factors such as SCF, IL-3, and G-CSF, [533] [534] [535] as well as late-acting lineage-specific factors such as IL-5 [195] [535] and GM-CSF. [536] Eosinophilic colonies in culture have been identified by luxol fast blue or peroxidase staining. [6] [537] Their distinctive morphology and enzymatic granule content account for their staining properties, and are described in greater detail in Chapter 40 . The normal concentration of eosinophils in the blood is $<0.7 \times 10^9$ cells/L. Many diseases are associated with eosinophilia, including parasitic

infestation with tissue-invasive organisms, allergic states (bronchial asthma, allergic rhinitis, pulmonary aspergillosis), vasculitides, various collagen vascular diseases, and paraneoplastic conditions. [538] [539]

The sequential action of eosinophil-active cytokines and their cellular derivation are shown in detail in Figure 16-6 . Fibroblasts and bone marrow vascular endothelial cells release cytokines such as SCF/KL, GM-CSF, G-CSF, and IL-5, [540] all of which affect eosinophilopoiesis. Several growth factors act on early eosinophil progenitors in a synergistic fashion. These include factors such as G-CSF and *kit* ligand (SCF), both of which are not specific for this lineage. [533] [536] IL-3 is capable of inducing colonies from CD34+/CD33 cells, whereas IL-5 by itself does not have this capability. [536] When CD34+/CD33 cells are grown in IL-3 followed by IL-5, CFU-Eo emerge. CD34/CD33+ cells form CFU-Eo if first exposed to G-CSF or to IL-3 and then replated in IL-5. [536] IL-3, GM-CSF, and IL-5 have additional activity at intermediate stages of eosinophilopoiesis, and they are also active on mature eosinophils. [537] [541] It has also been found that hybrid eosinophil/basophil intermediates and immature mononuclear eosinophils exhibit autocrine regulation of viability because of constitutive production of GM-CSF. [542]

In vivo experiments in mice and humans infected with filarial parasites have shown IL-5 to be the principal regulator of eosinophil production. [198] [543] [544] IL-2 administration leads to eosinophilia, which can be blocked by a monoclonal antibody to IL-5. [545] This in vivo IL-2 administration is associated with increased IL-5 RNA expression in the spleens of treated mice. [545] Transgenic mice expressing IL-5 manifest eosinophilia and autoantibody production. [197] Moreover, IL-5 has also been found to be elevated in patients with hypereosinophilia, [546] and has been identified along with GM-CSF and IL-3 in the eosinophilia associated with T-cell lymphoma. [547] Expression of IL-5 in thymocytes/T cells leads to development of massive eosinophilopoiesis in tissues and consequent eosinophilia. [548] In IL-5R-deficient mice, basal levels of eosinophils were

Figure 16-5 Positive and negative regulators of monocytopoiesis and granulopoiesis (neutrophil component). Mediators of both a positive and negative nature are active at all levels of development. Also, certain cytokines at different concentrations and in different isoforms (e.g., transforming growth factor [TGF]-) can act in either inhibitory or stimulatory fashion at various levels of maturation. CFU, colony-forming unit; CSF, colony-stimulating factor; G, granulocyte; GEMM, granulocyte/erythroid/macrophage/megakaryocyte; SGMR, soluable granulocyte-macrophage colony-stimulating factor receptor; HPP-CFC, high-proliferative-potential colony-forming cells; IGF, insulin-like growth factor; IL, interleukin; IP-10, interferon--inducible protein; LIF, leukemia inhibitory factor; LPS, lipopolysaccharide; LTC-IC, long-term culture-initiating cell; M, macrophage; MCP, monocyte chemoattractant protein; MIP, macrophage inflammatory protein; PF4, platelet factor-4; ra, receptor agonist; SCF, stem cell factor; sIL-R, soluble interleukin receptor.

TABLE 16-4 -- Cytokines Released by Activated Mature Precursors

produced, but impaired eosinophilopoiesis enhanced the survival of *Angiostrongylus cantonensis*.[549]

T cells and eosinophils are implicated in the pathogenesis of many disease states such as asthma. [537] [538] [539] The role of human types 1 and 2 T-helper-derived cytokines in eosinophilic states is highlighted in Figure 16-6 .[550] [551] The activation of IL-5-producing T cells in atopic states may lead to eosinophilia; additional factors, some of which have not been cloned yet, are also operational in these conditions. [552] Also, in the hypereosinophilic syndrome, there is evidence in some patients for clonal proliferation of type 2 helper T cells. [553] [554] A case has been reported of a patient with hypereosinophilia who had T-cell clones that produced IL-4 and IL-5 and demonstrated clonal rearrangements of the chain of the T-cell receptor. [554] Moreover, the importance of cell-cell intercrine stimulation is illustrated by the finding that GM-CSF-induced LTB4 secretion can lead to increased IL-5 elaboration by T cells, thereby amplifying eosinophilic precursor maturation at the sites of antigenic stimulation.[555] Eosinophils in the circulation and at the sites of allergic inflammation express IL-5, GM-CSF, [556] [557] and eotaxin,[163] and elaborate a potent angiogenic factor, TGF-, as indicated in Tables 16-4 and 16-5 .[558]

Basophil and Mast Cell Production

Both mast cells and basophils develop from the hematopoietic stem cell.[559] Basophils complete their differentiation in the marrow, but precursors of mast cells leave the marrow, invade connective or mucosal tissue, proliferate, and differentiate into mast cells. Mechanisms regulating maturation of these two cell types are also different. The basophil is a granulocyte subtype derived from marrow progenitors that functions in allergic disease. In contrast, tissue mast cells do not circulate in the blood but complete their maturation in tissues, where they provide mucosal immunity as well as serve a source of cytokines and a variety of agents on activation by allergens.[560] Mast cells are derived from CD34+, *c-kit*-positive progenitors, and not from monocytes, as previously thought.[561] The production of basophils as well as tissue-fixed mast cells is regulated by a complex array of cytokines elaborated by T-cell subsets, macrophages, and stromal cells/fibroblasts (see Fig. 16-6). Basophilopoiesis is regulated by overlapping cytokines such as SCF, IL-3, [560] [562] [563] and IL-5,[7] [537] [564] which are active in eosinophilopoiesis, but it also relies on IL-4,[7] [565] IL-9,[566] and IL-10,[567] cytokines with anti-inflammatory roles that do not affect eosinophil production. [7]

Figure 16-6 Regulatory cytokines and accessory cells that modulate eosinophilopoiesis and basophilopoiesis. Factors produced by T-lymphocyte subsets, macrophages, fibroblasts, and bone marrow endothelial cells (BMEC) control the development of these cell types. These cytokines act individually or synergistically within each maturation pathway to promote cell proliferation or inhibit apoptosis. Several cytokines can activate mature precursors and thereby prime them for degranulation, migration, and enhanced effector function. CFU, colony-forming unit; CSF, colony-stimulating factor; IL, interleukin; NGF, nerve growth factor; SCF, stem cell factor; Th, T-helper.

Also, at later stages of development, mast cells are differentially influenced by IL-3 and SCF/KL, whereas basophils are regulated by IL-10, IL-3, and IL-4. [560] Recently, IL-3 has been shown to augment immunity after parasitic challenge.[568] Mouse basophils express little or no *c-kit* receptor on their surface, nor can they survive for long periods in SCF-supplemented cultures. Mast cells are also FcepsilonR+ but develop *c-kit* receptors during their maturation.[569] A rat model with an abnormal *W* locus has been developed that has no mast cells but has normal numbers of basophils, [570] implying that additional regulators such as nerve growth factor and IL-10 can substitute for SCF in basophil development [571] (see Fig. 16-6). SCF/KL also induces mast cell proliferation, maturation, and heparin synthesis. [572] SCF/KL also allows the emergence of mast cells from marrow mononuclear cells in long-term culture.[563] Signaling through the *c-kit* receptor tyrosine kinase is essential for development and survival of mast cells, but not of basophils. [573] SCF influences mast cell development only in the context of other cytokines.[574] Nerve growth factor promotes murine mast cell colony formation[575] and has been found to be synergistic with GM-CSF in normal and leukemic basophilic cell differentiation[564] [576] (see Figs. 16-3 and 16-6).

CELLULAR DYNAMICS

Cytokine Expression by Mature Cells

Macrophages synthesize and release GM-CSF and G-CSF and display a large spectrum of heterogeneity. [520] [522] Very little CSF is produced by resting macrophages, but stimulation with substances such as endotoxin can increase GM- or G-CSF production, whereas bone marrow-derived macrophages can elaborate SCF in small amounts.[519] Because tissue macrophages are separated from proliferating granulopoietic cells in the marrow, it is uncertain whether CSFs produced by these resident macrophages have any proliferative effects on the marrow progenitor compartment; they may serve only to activate granulocytes/macrophages locally. Monocytes also produce IL-1, IL-6, and TNF-, [577] as well as many chemokines that are instrumental in recruiting effector granulocytes and lymphocytes to areas of inflammation or antigen challenge (see Tables 16-4 and 16-5). Disruption of the microtubule network of human monocytes induces expression of IL-1 but not of IL-6 or TNF-.[578] The IL-1 production is mediated by the stimulation of protein kinase A. [384]

Neutrophils as well as eosinophils express IL-6 mRNA and secrete IL-6 protein. [556] This expression is rapidly down-regulated after cells are removed from the blood. Neutrophils can thus modulate T- and B-lymphocyte functions, granulocyte self-priming, and endothelial interactions through secretion of IL-6. GM-CSF has also been found to induce *c-fos*, *EGR-1*, IL-1, G-CSF, M-CSF, and TNF- genes in neutrophils, again suggesting that neutrophils can play a role in regulating the inflammatory response.[247] [579] [580] [581] [582] One can assume that there are active autocrine loops in both mature neutrophils and monocytes. [583] [584] Mast cells release IL-6 through *c-kit*. Mature eosinophils have been found negatively to regulate eosinophilopoiesis by decreasing IL-5 levels. Basophils produce IL-4 and IL-13 on FcepsilonR1 cross-linking. As with other granulocytic effector cells, eosinophils, basophils, and mast cells also express cytokines and chemokines on activation (see Tables 16-4 and 16-5).

Cytokine Modulation of Mature Effector Cell Function

Growth factors are released at sites of inflammation and can exert both priming and direct effects on mature monocytes and neutrophils. These influences can arm effectors for improved response to other physiologic substances that are also active at sites of inflammation and infection such as chemotactic factors, ILs, and leukotrienes. GM-CSF, as an example, can decrease random migration of macrophages and neutrophils, increase surface expression of Mo1, and increase leukocyte aggregation.[585] [586] These represent only a few of the many effects of GM-CSF on mature neutrophils, which in general include accentuating host defense mechanisms such as adhesion, chemotaxis, phagocytosis, superoxide production, antibody-dependent cell-mediated cytotoxicity, and synthesis and release of inflammatory mediators and cytokines. Many of these effects have clinical significance, such as the profound drop in neutrophil counts after intravenous boluses of GM-CSF and G-CSF, possibly due to sequestration of these activated cells in lungs. [586]

Numerous cytokines also have effects on the mature eosinophil. IL-5 can prevent apoptosis in mature human eosinophils. [566] GM-CSF, IL-5, and IL-3 can activate eosinophils, manifested in many ways. The FcRII is activated in human eosinophils in response to these cytokines, [587] and each one has a priming effect on the eosinophil respiratory burst [588] and on responses to FMLP and to platelet-activating growth factor. [589] Moreover, GM-CSF and IL-3 amplify leukotriene C4 production after Ca^2 + ionophore exposure.[590] Cytokines also modulate cell-surface expression of activation antigens on mature eosinophils. [591] [592] The chemokines RANTES and eotaxin 1 and 2 have been shown to be chemoattractants for eosinophils, [132] [593] a property not shared by MCP-1 MIP-1, or IL-8 [594] (see Fig. 16-3 and Table 16-1). Platelet-activating factor is another potent inflammatory mediator that can activate mature eosinophils and stimulate eosinophil production from precursor cells [595] (see Tables 16-4 and 16-5).

Granulocyte-macrophage colony-stimulating factor, IL-3, and IL-5 have been found to influence basophil functional activity. [7] [560] [596] IL-10 stimulates mast cells and their progenitors,[567] and also regulates cytokine production in mouse marrow-derived mast cells. [597] Finally, the chemokine MIP-1 has also been found to activate basophils and mast cells.[598] In addition to its effects on basophil and mast cell development, SCF/KL potentiates release of mediators from mast cells [599] and activates their adhesion to fibronectin. [600] Both cyclosporine and FK506 have been found to inhibit cytokine production from mast cells [601] [602] and basophils.[603] Tables 16-4 and 16-5 illustrate the panel of cytokines and chemokines released by basophil/mast cells on activation.

Chapter 17 - Thrombocytopoiesis

Michael W. Long
Ronald Hoffman

The clinical consequences of alterations in platelet levels are well known, ranging from severe thromboembolic episodes (occurring in some patients with primary thrombocytosis) to hemorrhage resulting from thrombocytopenia. With the exception of instances of increased peripheral destruction (e.g., trauma, infection), most quantitative and qualitative disorders of platelet function result from intrinsic errors occurring within the megakaryocyte. Platelets lack a nucleus and (for the most part) a rough endoplasmic reticulum, and therefore have little ability to alter their biochemical composition or structure. Consequently, an understanding of the biochemical and molecular mechanisms underlying thrombocytopoiesis rests on understanding the development of the platelet within its precursor cell, the megakaryocyte. Until recently, however, megakaryocyte differentiation was difficult to study because the low frequency and fragility of these cells make them difficult to purify in sufficient numbers for biochemical and molecular studies. Recent scientific advances, together with new developments in cytokine therapy and bone marrow transplantation, now provide therapeutic tools with which to alter platelet production.

Megakaryocyte development is a complex process in which a wide variety of regulatory signals work in concert to direct a highly specific response to thrombopoietic demand. The cells of the megakaryocyte lineage are the primitive, actively proliferating progenitor cells as well as the mature postmitotic megakaryocytes undergoing maturational development (Fig. 17-1). The complex nature of this developmental hierarchy is underscored by the wide variety of hematopoietic growth factors that stimulate these cells (i.e., the various colony-stimulating factors [CSFs], interleukins, and thrombopoietin [TPO]). Developing megakaryocytes also interact with surrounding extracellular molecules that further modulate the developmental process. Each of these key elementscells, growth factors, and extracellular moleculesthus defines a highly organized and localized regulatory system known as the megakaryocytic microenvironment. It is this system that coordinately regulates megakaryocyte development and the daily production of approximately 2×10^{11} platelets. [1]

Although the exact makeup of the megakaryocyte microenvironment is still unknown, many of its important elements have been defined. The cellular components are the parenchymal cells (i.e., cells committed to megakaryocyte lineage) and the neighboring stromal cells such as fibroblasts, endothelial cells, and macrophages. These stromal cells produce both membrane-associated and soluble cytokines (growth factors) as well as extracellular molecules important to megakaryocyte function. To date, over 25 hematopoietic growth factors have been identified and molecularly cloned, including interleukin (IL)-1-IL-18, granulocyte (G)-CSF, granulocyte-macrophage (GM)-CSF, macrophage (M)-CSF, leukemia inhibitory factor (LIF), c-kit ligand, erythropoietin, and TPO. A variety of other regulatory factors such as the interferons, tumor necrosis factor, and transforming growth factor- (TGF-) are capable of inhibiting or stimulating (or both) hematopoiesis. Among these 30 or so growth factors, at least four interleukins (IL-3, IL-6, IL-9, and IL-11) as well as c-kit ligand, GM-CSF, and possibly erythropoietin stimulate both in vivo and in vitro megakaryocyte

Figure 17-1 Cellular hierarchy of megakaryocyte development. Megakaryocytes can be conceptually divided into three stages: the proliferating progenitor cells, which have the typical 2C/4C DNA content, the immature megakaryocytes, which have an intermediate DNA content and are transitional between the progenitor cells and the more mature cells, and the mature, postmitotic cells, which have an 8C to 128C DNA content (see text). development (for a review, see Kaushansky[2]). The final component of the megakaryocytic microenvironment is the extracellular matrix (ECM). Once referred to as basement membrane, ECM is no longer thought to be an inert structural scaffold for various organs. Instead, it is a dynamic, complex cellular substrate whose components stimulate cells to proliferate, differentiate, or migrate (for a review, see Long [3]). Recent studies demonstrate that, like other lineages, megakaryocytes have unique developmental requirements that are modulated by interactions with specific ECM molecules. [4] [5] [6]

Interestingly, megakaryocytopoiesis occurs in a number of locations throughout the body. The primary site of megakaryocyte development (and hence platelet production) is the bone marrow. However, it is known that megakaryocyte precursors and some mature megakaryocytes circulate, [7] [8] which suggests that capillary beds might filter (trap) such cells. If the surrounding microenvironment is appropriate, then megakaryocytes may develop in such extramedullary tissue. This is true for both the spleen and lungs, each of which contains megakaryocytes and produces platelets. [9] [10] However, the contribution of these organs to total thrombocytopoiesis is on the order of only 715%. [1] [10]

An understanding of the disorders of platelet production requires knowledge of the complex regulatory events that occur during normal megakaryocytopoiesis. Moreover, a rational approach to therapeutic interventions that might alter the clinical course of megakaryocyte disorders must take into consideration the nature of the developmental control mechanism(s) being affected. This chapter focuses on current concepts of megakaryocyte/platelet development, examining the various types of megakaryocytic cells, their responses to cytokines and other extracellular influences, and recent observations on the biochemical and molecular control of lineage-specific gene expression.

BIOLOGY OF MEGAKARYOCYTES

Megakaryocyte Progenitor Cells

The cellular hierarchy of megakaryocytopoiesis is best understood if megakaryocyte development is artificially divided into three stages: progenitor cells, immature megakaryocytes (promegakaryoblasts [PMkB]), and mature megakaryocytes (Fig. 17-1). Megakaryocyte progenitor cells are responsible for the expansion of megakaryocyte numbers and proliferate in response to a number of mitotic growth factors. Promegakaryoblasts are transitional in nature, bridging between the progenitor cells and the more mature postmitotic cells. Mature megakaryocytes no longer proliferate but have the unique ability to continue or increase DNA synthesis, without undergoing mitosis, during maturation (see following). Mature megakaryocytes are markedly larger than other marrow cells and thus have a dramatically increased cell volume. As a result, an individual megakaryocyte produces on the order of 2,0003,000 platelets. [11]

Most of our knowledge concerning hematopoietic progenitor cells comes from in vitro assays of these cells. The most primitive hematopoietic progenitor cells are multi- or pluripotential, giving rise to cells of different lineages. These in turn give rise to committed progenitor cells, which are defined as proliferating cells capable of generating progeny of a given lineage(s). The development of either progenitor type in vitro thus results in a clonal expansion of cells, leading to the formation of a colony in semisolid media. Originally, the entity generating a colony was called a colony-forming unit (CFU) to reflect the concept that it was unclear whether a colony was derived from a single cell; this is now definitively proved.

In vitro studies demonstrate that megakaryocyte progenitor cells, like progenitor cells of other lineages, progressively lose proliferative potential as they develop. The proliferating cells of this lineage are themselves heterogeneous and are of at least three distinct cell populations, each marked by varying degrees of proliferative potential. Reports from animal studies suggest that the earliest detectable cell in this lineage, the megakaryocyte high-proliferative-potential colony-forming cell (Mk-HPP-CFC), is the most primitive progenitor cell of this lineage. Unlike most other progenitor cells, this cell proliferates in vitro to the extent that its colonies are macroscopically visible. The burst-forming unit-megakaryocyte (BFU-Mk) is more mature than the Mk-HPP-CFC but retains a high degree of proliferative potential, developing bursts of individual colony-forming cells (Fig. 17-2). The most mature proliferating cell is the colony-forming cell megakaryocyte (CFU-Mk), which has very limited proliferative potential.

The existence of Mk-HPP-CFC was first established by the groups of Long [12] [13] and Quesenberry. [14] Initially, these cells were observed in murine bone marrow; recently they have been observed in human fetal bone marrow. [15] Nonetheless, the murine data show that these cells are quite primitive and respond to a variety of hematopoietic regulators. Mk-HPP-CFC produce colonies of a few thousand megakaryocytes, demonstrating a proliferative potential of some eight to ten replicative divisions. Mk-HPP-CFC require a minimum of three different mitogenic signals for proliferation. Long and co-workers have demonstrated that these cells have an obligate requirement for IL-3 and simultaneously require co-activation of the protein kinase C- and cyclic adenosine monophosphate (cAMP)-mediated signal transduction pathways. [12] Quesenberrys group confirmed and extended these observations, showing that three to five recombinant hematopoietic growth factors are required to sustain the proliferation of these early megakaryocyte progenitor cells. Interestingly, colonies observed in these latter studies contained cells of multiple hematopoietic lineages, with large numbers of megakaryocytes present.

The BFU-Mk has a high proliferative potential, generating 100500 megakaryocytes per cell, representing a proliferative capacity of some five to seven replicative events. [16] These cells are believed to be the progeny of Mk-HPP-CFC and the immediate ancestors of the colony-forming cell. [13] BFU-Mk colonies morphologically resemble the erythroid burst-forming cell in that the BFU-Mk colonies consist of multiple foci of megakaryocyte development, each of which presumably is due to the presence of a single CFU-Mk (Fig. 17-2). Human BFU-Mk cells have in vitro characteristics similar to those of murine cells and, additionally, are resistant to treatment in vitro with 5-fluorouracil. [17] [18] Proliferation of these cells in chemically defined media (i.e., serum-free cultures) has allowed precise determination of their growth factor responsiveness. BFU-Mk require two categories of growth factors for in vitro development. They have an obligate requirement for mitogenic growth factors such as IL-3 or GM-CSF. Additionally, optimal development of BFU-Mk requires the presence of synergistic co-regulators that augment hematopoietic growth factor-driven proliferation and differentiation (see discussion under Megakaryocyte-Active Cytokines). [16] In humans, these cells respond to IL-3 and GM-CSF as proliferative stimuli. [18] In addition, c-kit ligand (also known as stem cell factor, or mast cell growth factor), IL-11, IL-1, and thrombopoietin synergize with IL-3 to augment BFU-Mk development. [18] [19] [20] A number of other putative megakaryocyte co-regulators (i.e., IL-6, erythropoietin, G-CSF, IL-4) fail to synergize with IL-3, GM-CSF, or Mk-CSF in stimulating BFU-Mk. [18]

The most differentiated of the megakaryocyte progenitor cells is the CFU-Mk cell. This was the first megakaryocyte progenitor cell to be assayed in vitro. This cell and its progenitors have relatively fastidious requirements for in vitro growth. As a result, the first murine CFU-Mk colony was not developed in vitro until 9 years [21] [22] [23] after the first hematopoietic progenitor

Figure 17-2 Megakaryocyte progenitor cells. **(A** & **B)** The cellular hierarchy of the megakaryocyte lineage is believed to begin with a primitive, highly proliferative burst-forming cell, BFU-Mk, which divides, migrates, and differentiates to generate multicentric clusters of megakaryocytes. **(C** & **D)** Each BFU-Mk gives rise to several nonmotile, less proliferative CFU-Mk, each of which generates a small cluster of megakaryocytes in culture. *(Reproduced from Long MW, Gragowski LL, Heffner CH et al.: Phorobol diesters stimulate the development of an early murine progenitor cell: the burst forming unit megakaryocyte. J Clin Invest 67:431, 1985, by copyright permission of the American Society for Clinical Investigation.)*

cell (the granulocyte progenitor cell), [24] and the first human megakaryocyte colony was not reported until 5 years later. [25] [26] The CFU-Mk cell has a restricted proliferative potential, generating only 432 megakaryocytes (i.e., 25 divisions). [27] This progenitor cell responds to a variety of single growth factors (e.g., IL-3, GM-CSF), and also interacts with co-regulators such as c-kit ligand, flt3/flk2-ligans, and thrombopoietin. [19] [28] [29] Interestingly, CFU-Mk cells are not the first cells in the lineage to respond to thrombocytopenia. In fact, increases in CFU-Mk numbers occur as a late response to decreased platelet numbers. [30] [31] This suggests that megakaryocyte progenitor cells somehow sense megakaryocyte (and not platelet) mass, thus increasing in number to supply an increased need for megakaryocytes. This type of regulatory network was first suggested by Ebbe and Phalen, who demonstrated that decreased megakaryocyte numbers resulted in a correcting stimulus that was independent of platelet level. [32]

A number of reports suggest that other types of multi- or pluripotential cells express megakaryocytic potential (e.g., the colony-forming unit-granulocyte/erythrocyte/megakaryo-cyte/macrophage [CFU-GEMM]). Notably, a developmental relationship seems to exist between the erythroid and megakaryocyte lineage. Early work by Nicola and Johnson documented the progressive loss of lineage potential by pluripotential progenitor cells, resulting in a bipotential erythroid/megakaryocytic progenitor cell. [33] This concept was strengthened by observations of Papayannopoulou et al., [34] [35] Long et al., [36] and others [37] [38] showing that cell lines derived from patients with erythroleukemia express some megakaryocyte phenotypic markers or can be induced to undergo megakaryocyte

commitment and differentiation (or both). Other investigators have documented the existence of transplantable megakaryocyte progenitors (Mk-CFC $_s$)[39] and cell size heterogeneity among in vitro colonies (large heterogeneous colonies). [40]

Immature Megakaryocytes (Promegakaryoblasts)

Promegakaryoblasts are transitional cells intermediate between proliferating progenitor cells and postmitotic, mature megakaryocytes. [41] [42] Morphologically, these immature cells are not readily observed in vitro or in bone marrow specimens, but they may be identified by their expression of megakaryocyte/

platelet-specific markers such as platelet peroxidase, platelet glycoprotein IIb/IIIa, von Willebrand factor (vWF), etc. [43] [44] Promegakaryoblasts are restricted in (or lack) proliferative potential. They thus are the developmental stage at which megakaryocytes cease to proliferate but continue to acquire an increased DNA content. As such, they are endomitotic (a mechanism of acquiring polyploid nuclei, see below) and contain an intermediate DNA content. PMkB respond to a variety of hematopoietic growth factors (IL-3, c-kit ligand, IL-6, TPO) in vitro, maturing into single large megakaryocytes. [45] [46] Observations of the early phases of CFU-Mk colony formation demonstrate that progenitor cells pass through a PMkB stage during development, thus confirming the parent-progeny relationship between PMkB and megakaryocytes.[41] Studies in animals document the responsiveness of these cells in vivo. Promegakaryoblasts are highly sensitive to thrombopoietic demand and are the first cells to increase in number after the induction of thrombocytopenia and to decrease under conditions of thrombocytosis. [42] [47] Subsequently, increases and reductions (respectively) are seen in megakaryocyte numbers, again confirming the kinetic and developmental relationship between PMkB and their more differentiated progeny. Promegakaryoblasts also are a heterogeneous group of cells that during development increase in nuclear and cytoplasmic complexity. [41] [46] [48] [49] Three distinct subpopulations of these cells exist, differing in their physicochemical characteristics, morphology, antigen expression, and enzymatic content.[43] [46] [48] [50]

Mature Megakaryocytes

Morphologically recognizable megakaryocytes exist in three maturational stages as defined by their morphology (Fig. 17-3). The megakaryoblast (stage I) is characterized by a high nucleus to cytoplasm ratio and scanty basophilic cytoplasm, reflecting the large amount of protein synthesis occurring in these cells. The promegakaryocyte (stage II) is the cell in which both the cytoplasmic volume and number of platelet-specific granules increase. The granular or platelet-shedding megakaryocyte (stages III and IV) is the most mature of the megakaryocytes and supposedly is the platelet-shedding cell. It should be understood that these morphologic classifications also represent a maturation progression and are themselves heterogeneous with respect to many other developmental characteristics such as antigenic expression, enzymatic content, and DNA content.

Platelets

The final event of megakaryocyte development is the release of platelets into the circulation. Interestingly, platelets were the first element of this lineage to be identified and among the first of the blood cells observed. In the late 1800s both William Oster (in 1874) and Georges Jayem (in 1878) described and illustrated blood platelets.[51] In 1882, Julius Bizzorzero coined the term platelet (*Blutplättchen*) and noted their shape change with activation and their involvement with hemostasis. [51] However, it was not until 1906 that Homer Wright linked platelets with the megakaryocyte, [52] [53] and not until the 1950s that this hypothesis was proved. [11] [54] Insofar as the existence of platelets has been recognized for over a century, it is surprising that the mechanisms by which platelets are produced and released remain poorly understood. During maturation, proliferation and invagination of the megakaryocyte plasma membrane occur, resulting in the development of a tubular network known as the demarcation membrane system (DMS). The DMS is thought to divide the megakaryocyte cytoplasm into platelet fields (Fig. 17-4), although its exact role in the formation of individual platelets remains obscure and controversial. Finally, megakaryocytes seem to extend pseudopods into the sinusoidal lumen, from which platelets are shed into the circulation. [55] Studies using TPO-based in vitro assays of platelet production have allowed the

REGULATION OF MEGAKARYOCYTE DEVELOPMENT

There are three areas in which physiologic control over the megakaryocyte lineage is relevant: the expansion of megakaryocyte numbers (proliferation), the regulation of megakaryocyte maturation, and control of platelet shedding. A large number of investigators have detailed the role of cytokines in the first two of these areas. Moreover, increasing evidence suggests the importance of ECM components to megakaryocyte and platelet production. The actual process of both platelet formation and shedding is poorly understood. Given the lack of definitive data, the regulation of platelet production per se will not be discussed. Instead, this section examines megakaryocyte antigenic expression and the regulation of megakaryocytes by cytokines and the ECM.

Markers of Megakaryocyte Development

Megakaryocytes and their precursors express antigenic determinants that are developmentally regulated. The expression of these cell-surface structures allows the isolation and purification of subpopulations of marrow cells that are enriched for the various megakaryocyte progenitor cells. One of the antigens on megakaryocytes and their precursors is CD34, a pan-hematopoietic cell antigen first identified by Civins group (Strauss et al. [56]). This antigen is expressed on all hematopoietic progenitor cells and allows their separation from other bone marrow cells by a variety of immunologic procedures. Subsequent examination of CD34+ subsets for other developmental markers has yielded the beginnings of an immunophenotypic analysis of the megakaryocytic lineage.

As expected, cells of the megakaryocyte lineage from the BFU-Mk to the mature cells express CD34, although its expression is reduced in mature cells. Subsequent characterization of CD34+ cells based on the expression of the human major histocompatibility (MHC) class II complex HLA-DR yields further segregation of progenitor cell phenotypes. In general, expression of the HLA-DR antigen characterizes a more mature subset of hematopoietic progenitor cells (i.e., CD34+ HLA-DR cells are more primitive than CD34+ HLA-DR+ cells). [4] Among megakaryocyte progenitors, this distinction separates BFU-Mk (which are CD34+ DR) from the more mature CFU-Mk (CD34+ HLA-DR+). [57] Importantly, CD34+ HLA-DR cells can sustain long-term megakaryocytopoiesis in growth factor-driven cultures for 1012 weeks, thus demonstrating the marked proliferative potential of these cells. [57] Megakaryocyte CD34+ HLA-DR burst-forming progenitor cells also express the c-kit receptor[58] (a tyrosine-kinase receptor that interacts with the c-kit ligand [KL]). It should be realized, however, that the progression of cells through a differentiation sequence results

in a spectrum of phenotypes (immunologic, morphologic, or otherwise) and that cells do not exist as compartments. Although the majority of cells of a given type may express (or lack) a given antigen, this does not mean that antigenic expression is phenotypically exclusive.

Platelet glycoprotein (GP)IIb/IIIa (CD41) is another important marker of the megakaryocyte lineage. This antigenic structure results from the interaction of two gene products (GPIIb and GPIIIa) on the surface of cells and is expressed on cells of this lineage from the progenitor cells through to the platelets. [43] [59] Co-expression studies demonstrate that CD41+ cells represent approximately 2% of the CD34+ cells subpopulation (i.e., 0.06% of total nucleated bone marrow cells). This number is consistent with the frequency of the assayable megakaryocyte progenitor cells in human bone marrow.

Studies of human PMkB by Vainchenkers group (Debili et al. [50]) show that these cells also express CD34. Three antigenically distinct subpopulations of human PMkB can be identified based on the co-expression of CD34 and platelet GPIIIa (i.e., CD34+ IIIa, CD34+ IIIa+, and CD34 IIIa+). These cells thus are transitional in antigenic expression, being the point at which megakaryocytes alter expression of CD34 and begin to express platelet GPIIIa. Based on proliferative capacity and granular content, CD34 IIIa+ cells are the most mature, having a high granular content and a low proliferative potential. CD34+ IIIa+ cells are intermediate, and the CD34+ IIIa cells are the most primitive, having a higher proliferative capacity and giving rise to more polyploid progeny. Nonetheless, the overall proliferative capacity of PMkB remains low because only 10% of these double-positive cells are capable of forming megakaryocyte colonies. [50] These studies show that CD34 is still expressed on the (polyploid) transitional PMkB, and suggest that CD34 expression occurs in those cells capable of some degree of DNA synthesis (mitosis or endomitosis). Also, platelet GPIIIa is present on both PMkB and those megakaryocyte progenitor cells with a low proliferative capacity.

Immunophenotypic analysis demonstrates that, although mature megakaryocytes express little if any CD34, they do express multiple markers associated with the platelet lineageplatelet factor 4, platelet GPIIb/IIIa, vWF, thrombospondin, and thrombomodulinbut are heterogeneous for the degree of expression of these antigens. The functional significance of such antigenic heterogeneity among the various subpopulations of mature megakaryocytes remains unresolved. Although the exact function of platelet antigen heterogeneity on megakaryocytes is unknown, it may be clinically relevant. For example, Stahl et al. have shown that expression of platelet epitopes on megakaryocytes is important in immune interactions. [60] Thus, not all antibodies to platelet antigens react with megakaryocytes, perhaps owing to lack of exposure of the target antigen. Also, expression of specific (but undefined) antigens occurs in megakaryocyte progenitor cells. [61] Such antigens may be the targets of antibodies that lead to certain autoimmune disorder such as acquired amegakaryocytic thrombocytopenias. [62]

Megakaryocyte-Active Cytokines

The ability to assay megakaryocyte progenitor cells in vitro has gone hand in hand with the ability to identify growth factors important to megakaryocyte development. In 1969, an elegant study by Harker and Finch demonstrated that, in vivo, thrombocytopoiesis was regulated by alterations in both megakaryocyte number and megakaryocyte volume (mass). [1] In the late 1970s and early 1980s, investigators struggling with crude sources of megakaryocyte growth factors (conditioned medium from various tissues or cell lines) discovered the in vitro correlates of the Harker and Finch hypothesis: that distinct factors (bioactivities) seem to regulate the proliferative and maturational events occurring during in vitro megakaryocyte development. [29] [46] [63] [64] The purification of these activities proved difficult, but the rapid identification and cloning of numerous human recombinant hematopoietic growth factors in the mid- to late 1980s and early 1990s markedly improved our understanding of the cytokine control of megakaryocytopoiesis.

A number of cytokines affect megakaryocyte proliferation in vitro, raising the questions of growth factor redundancy and combinatorial control. Given the importance of hematopoiesis it is not surprising that redundant control mechanisms exist for each of the lineages. The concept of combinatorial control is illustrated by studies in which multiple cytokines provide a better (in vitro) stimulus than single growth factors. Studies in which purified progenitor cells are cultured in defined serum-free media demonstrate that as many as 27 recombinant hematopoietic growth factors have additive proliferative effects on megakaryocyte progenitor cell proliferation. [28] [29] [65]

Among the many possible cytokine combinations, the most physiologically relevant class of interactions consists of growth factor combinations that are synergistic (i.e., pharmacologically nonadditive). This type of control is biologically important, as synergistic responses strongly suggest that differing intracellular signal transduction pathways are co-activated, leading to dramatic and rapid increases in proliferation. This has been clearly demonstrated in other developmental systems and for murine as well as human megakaryocytopoiesis. [12] [29] [66] Furthermore, the identification of such synergistic control mechanisms in vitro points to possibly more

effective forms of therapeutic intervention in platelet disorders.

Of the hematopoietic growth factors that affect megakaryocyte proliferation, IL-3 (a 1730-kd glycoprotein) is the most potent. [17] [18] [67] It stimulates each of the three classes of megakaryocyte progenitor cells, and immature cells as well as mature megakaryocytes. However, the physiologic role of IL-3 is not known. Exogenous IL-3 stimulates in vivo expansion of megakaryocyte progenitor cells, but by itself IL-3 has little significant effect on in vivo platelet production. [68] Moreover, IL-3 is produced only by antigen-activated T lymphocytes, which suggests that its role in maintaining basal hematopoiesis or platelet production is minimal. Another pleiotropic cytokine affecting megakaryocyte development is GM-CSF, a glycoprotein of approximately 23 kd. GM-CSF stimulates development of BFU-Mk and CFU-Mk. However, parallel cell culture experiments demonstrate that its megakaryocyte-stimulatory activity is approximately 1/100th that of IL-3. [67] Nonetheless, this protein functions as a megakaryocyte CSF, and its actions are additive to those of IL-3, [28] suggesting a single converging intracellular mitotic signaling pathway.

A number of growth factors have megakaryocyte maturational activities (e.g., TPO IL-6, IL-3, c-kit ligand, IL-1, IL-11, G-CSF, LIF). [18] [19] [67] [68] [69] [70] [71] [72] Although none of these purified or recombinant molecules is megakaryocyte lineage specific, some are synergistic co-regulators. Such auxiliary growth factors were first defined in vitro as cytokines that lack the ability to stimulate megakaryocyte proliferation but do function as co-regulators to augment megakaryocyte size, DNA content, antigen expression, and so forth. [18] [29] [73] Of the hematopoietic growth factors identified, only a few fall into this category: c-kit ligand (stem cell factor), IL-1, IL-6, and IL-11. [18] [20] [71] [74] Each of these growth factors is capable of augmenting the megakaryocytic activity of other growth factors such as IL-3, albeit at differing developmental levels. For example, IL-1, c-kit ligand, and IL-11 each interact with IL-3 at the level of BFU-Mk, [18] whereas IL-6 and c-kit ligand each synergize with IL-3 to modulate colony-forming cell development. [74] IL-11 has multiple effects on in vivo and in vitro megakaryocytopoiesis. [20] It not only affects IL-3-dependent megakaryocyte colony formation, but also has a potent effect

on megakaryocyte maturation. Neben et al. have shown that recombinant human IL-11 when administered in vivo to mice results in increased numbers of megakaryocyte progenitors, increased megakaryocyte DNA content (polyploidy), and increased peripheral platelet counts. [75] Recently, IL-11 was approved for use in humans for the treatment of chemotherapy-induced thrombocytopenia. Another megakaryocyte maturational promoter is IL-6. This cytokine stimulates megakaryocyte maturation and its actions (are partially) additive to those of IL-3. [65] [70] Although in vivo, IL-6 stimulates platelet production (and speeds recovery from thrombocytopenia in animals), its actions may occur via the secondary activation of accessory (stromal) cells. [74] [76]

Finally, a number of cytokines (e.g., TGF-, platelet factor 4, certain interferons) can inhibit megakaryocytopoiesis. Platelets release specific and general inhibitors of megakaryocytopoiesis such as TGF- [77] [78] and platelet factor 4. [79] However, the physiologic role for platelet-derived inhibitors is unclear. Theoretically, it may be hypothesized that increased platelet destruction should stimulate rather than inhibit platelet production, raising the paradoxical situation of increasing inhibitors with increased platelet destruction. Other inhibitors such as the interferons also inhibit megakaryocyte development. [80] [81] Again, the mechanism of action is unknown.

Thrombopoietin

The existence of TPO as a (putative) lineage-specific regulator of platelet production was proposed approximately 36 years ago. [82] [83] It was classically defined as an *activity* in the plasma of thrombocytopenic animals or humans that, when transferred to a secondary recipient, stimulates platelet production (as monitored by radiolabeled amino acid incorporation). [82] [83] [84] For three decades, multiple unsuccessful attempts were made to purify and clone TPO. The search for TPO began in earnest following observations by Wendling and colleagues that a rare and poorly understood member of an orphan-receptor family was involved in megakaryocytic development. Thus, Vigon et al. [85] [86] cloned the human and murine homologues of the v-*mpl* oncogene that is transduced by the *m*yelo*p*roliferative *l*eukemia virus. The c-*mpl* gene encodes a protein with strong homologies with the highly conserved hematopoietin receptor superfamily and is expressed in low levels in cells of hematopoietic origin. [86] As it pertains to thrombocytopoiesis, Methia et al. used reverse transcriptase-based PCR studies to demonstrate c- *mpl* expression in CD34+ cells, megakaryocytes, and platelets. [87] As well, they showed that antisense c-*mpl* oligonucleotides specifically inhibited in vitro megakaryocyte colony formation. These data clearly indicated a role for this receptor in megakaryocytopoiesis and further suggested that the as yet unidentified mpl ligand may be the elusive TPO.

Guided by the observations by Wendlings group, a number of teams finally cloned TPO in 1994. [88] [89] [90] [91] [92] [93] The TPO gene encodes a protein with a predicted molecular weight of 3135 kd that contains two domains, the amino terminal domain having homology with erythropoietin and a carboxyl-terminal domain containing a serine- and proline-rich region. [88] The genomic structure of TPO spans 68 kilobases [94] [95] and consists of approximately 7 exons and 6 introns, with the protein encoded by exons 37. [94] Localization studies have mapped human TPO to chromosome 3, within the region of 3q2628. [94] [96] Analysis of the promoter region of this gene shows binding sites for several important transcriptional activating factors, including GATA-1 (see following) and Ets family members. [97] A splice variant of the TPO gene exists as a result of a 4-amino-acid deletion within the erythropoietin homology domain. [93] [94] [96] These studies also demonstrated a profound effect of thrombopoietin on the megakaryocyte lineage. Administration of TPO results in an increase in the frequency of megakaryocytes in the bone marrow and spleen, an increase in megakaryocyte size and DNA content, an increase in megakaryocyte/platelet-specific antigenic markers, and a 3- to 10-fold increase in circulating platelet concentration.

Numerous studies over the past 30 years have demonstrated an inverse relationship between the levels of circulating TPO (i.e., TPO-like activities) and platelet mass. The arrival of TPO cloning, the availability of recombinant or purified protein, and the availability of gene knockout animals have allowed the dissection of this relationship at the cellular and molecular level. Data from these studies best fit the model in which the predominant feedback mechanism regulating TPO concentration is its binding to platelets or megakaryocytes (or both) (Fig. 17-5). Thus, during periods of normal homeostasis, platelet counts (i.e., mass) remain constant and circulating TPO is at its basal concentration. During thrombocytopenia, platelet mass drops, resulting in a reduction in the binding and degradation of TPO by c-mpl-positive cells and an increased concentration of free TPO. Conversely, during conditions such as rebound thrombocytosis or primary thrombocythemia (other than familial; see following) elevated platelet/megakaryocyte mass serves as a sink, reducing the levels of circulating TPO to achieve homeostasis. Thus, TPO production (in most circumstances) remains constant, and its concentration is regulated by the total mass of platelets/megakaryocytes available to bind and degrade this protein. Gene inactivation studies demonstrate that TPO and its receptor (c- *mpl*) are the primary regulators of megakaryothrombocytopoiesis. [98] [99] [100] [101] [102] Thus, TPO-deficient and c-mpl-deficient mice show an approximately 85% reduction in circulating platelets and markedly reduced bone marrow megakaryocyte numbers. [98] [99] Studies of TPO concentration in c-*mpl*-deficient mice show increased levels, [98] [103] and gene dosage effects in TPO-deficient animals (i.e., TPO+/ vs. TPO/) also demonstrate this relationship. [102] Confirming these in vivo observations, a number of studies demonstrate the interaction of TPO with platelets. Purified native TPO (rabbit) binds to platelets; conversely, its administration during conditions of thrombocytopenia results in a reduction in the elevated levels of TPO. [104] [105] Studies of platelets from c-*mpl*-deficient mice indicate that they fail to bind radiolabeled TPO, whereas normal platelets bind, internalize, and degrade this protein. [103] [104] [106] Likewise, the administration of washed, normal platelets to c- *mpl*-deficient animals causes a transient reduction in their high TPO levels. [103] Consistent with these observations, platelets express high-affinity TPO receptors (i.e., c-mpl) with an affinity of 200560 pM and between 20 and 200 receptors per platelet. [103] [107] Interestingly, TPO levels are low to intermediate in normal individuals as well as in individuals with idiopathic thrombocytopenic purpura at (ITP) and thrombotic thrombocytopenic purpura (TTP). [108] [109] However, they are markedly elevated after chemotherapy and in patients with aplastic anemia or acute lymphocytic anemia. These data, plus data acquired from NF-E2-null mice (see below), demonstrate that megakaryocyte mass also is a major determinant of TPO concentration. Thus, individuals with thrombocytopenia due to peripheral destruction have normal TPO concentrations owing to the presence of increased megakaryocyte numbers, as do NF-E2 mice. [108] [110] TPO is produced by the adult and fetal liver and the adult kidney, [88] [89] and its mRNA levels are not altered in these organs by changes in platelet concentration. [111] [112] [113] However, a secondary or alternative mechanism of regulating TPO concentration seems to exist in the bone marrow and spleen that is activated during conditions of thrombocytopenia. In these organs, TPO is transcriptionally activated during thrombocytopenia, resulting in an increase in TPO mRNA and (presumably) increased protein. [111] [114]

Four organs are reported to produce TPO: the liver, kidney, bone marrow, and spleen. Of these, the data are clearest regarding

Figure 17-5 Regulation of circulating thrombopoietin levels. TPO levels are inversely related to the combined platelet/megakaryocyte mass due to TPOs binding and degradation by these cells (see text).

constitutive production by the liver and kidney, where TPO mRNA is detectable by Northern blot analysis and in situ hybridization. [88] [89] [114] These two organs most

likely account for the greatest part of basal TPO production. In the bone marrow, the expression of TPO mRNA is detectable by semiquantitative RT-PCR [111] and in situ hybridization, [114] with both procedures demonstrating an increase during thrombocytopenia. In the spleen, TPO is undetectable by conventional Northern blot analysis,[88] but RT-PCR and in situ hybridization-based detection demonstrate the presence of TPO mRNA and increased levels during thrombocytopenia. [111] [114] The regulation of TPO concentration, therefore, can be thought of as having both constitutive and inducible components (Fig. 17-6). The liver, kidney, and perhaps the spleen constitutively produce TPO, and its levels are regulated by the total mass of platelets (primarily) and megakaryocytes. However, during times of thrombopoietic stress, increased TPO expression by the spleen and bone marrow presumably contributes to platelet production. The concept of megakaryocyte binding of TPO is important to understanding TPO regulation, as megakaryocyte disorders that affect platelet shedding would be predicted to have normal TPO concentrations in the face of profound thrombocytopenia. Such is the case in animals deficient in the NF-E2 transcription factor (see following).

The cellular targets of TPO are diverse, as c-mpl receptors are expressed on both megakaryocytes and platelets as well as on hematopoietic stem/progenitor cells. In mice, TPO effects on early stem/progenitor cells are shown by its stimulation of the expansion of very immature precursors both in vitro and in vivo. [92] [99] [115] [116] [117] TPO thus stimulates both murine long-term repopulating cells as well as phenotypically defined primitive hematopoietic stem cells. [117] In isolated populations of immunologically defined primitive human hematopoietic cells (i.e., CD34+, Lin, Thy1+ cells), TPO generates CD41+ megakaryocytes (alone or in conjunction with other pluripotent cytokines such as IL-3 or c-kit ligand). [116] This capacity is observed at the single cell level, thus demonstrating the direct effect of TPO on hematopoietic stem/progenitor cells.

Within the megakaryocyte lineage, TPO is required for full maturation, and TPO synergizes with other members of the hematopoietin-receptor superfamily to augment megakaryocyte development. Under serum-free conditions TPO stimulates CD34+ cells (either alone or in combination with other cytokines such as IL-3, erythropoietin, or c-kit ligand) to produce megakaryocytes. [118] [119] Megakaryocyte progenitor cells show variable response to TPO (alone or in combination with other cytokines), suggesting that these cells have a differential sensitivity to this growth factor. [118] [120] More mature progenitor cells (as defined by co-expression of CD34 and CD41) or the translational PMkB (in single cell culture) respond with either maturational development or a limited degree of proliferation. [121] Interestingly, although the resulting single megakaryocytes are mature and of high ploidy, 60% show ultrastructural defects in the formation of the DMS or in -granule synthesis, whereas

Figure 17-6 Regulation of thrombopoietin production. TPO is constitutively produced in the liver, kidney, and perhaps the spleen. During times of increased thrombocytopoietic demand, the bone marrow and spleen seem to increase their expression of TPO, thus contributing to platelet production. TPO in turn is bound by circulating platelets, as well as by megakaryocytes and other c-mpl-positive cells in the bone marrow and other sites of hemato-thrombocytopoiesis (see text).

the remainder are ultrastructurally indistinguishable from normal bone marrow megakaryocytes. It is interesting that, in serum-free culture, TPO fails to support full megakaryocyte polyploidization even when target cells are stimulated with high concentrations of TPO. Thus, a few TPO-stimulated human megakaryocytes reach ploidy levels of 16C or greater.[91] Even the use of more mature CD34+, CD41+ megakaryocytes as a starting population generates CD41+ cells predominantly having a low DNA content.[122] [123] The limited ability of human CD34+ stem/progenitor cells to generate high ploidy megakaryocytes is in sharp contrast to the murine system, where 3555% of megakaryocytes generated ex vivo are high-ploidy cells.[124] [125] [126] Such observations suggest that other growth factors or microenvironmental signals are required for full polyploidization of human megakaryocytes and, hence, for megakaryocyte maturation. The availability of recombinant TPO also allows the generation of intact, functional platelets in vitro, thus allowing studies of this poorly understood aspect of megakaryocyte development. [127] Interestingly, the administration of TPO to platelets in vitro does not stimulate platelet aggregation. [128] Rather, its preadministration (in vivo or in vitro) primes platelet aggregation, increasing platelet responsiveness to various agonists such as ADP, epinephrine, thrombin, and collagen. [129] [130]

Studies of the domain structure of the TPO receptor (i.e., c-mpl) and its ligand binding have determined both the important features of this receptor and the nature of its signal transduction cascade. Intracellular domains of c-mpl proximal to the transmembrane region are required for proliferative response, [131] and these regions also are necessary for activation of the Janus kinases/signal transducers and activators of transcription (JAK/STAT) signal transduction pathway. [131] [132] Conversely, C-terminal regions of the receptor activate both shc-mediated signal transduction and increase c- *fos* mRNA.[131] [133] They are also necessary for proliferative response, whereas a subdomain (amino acids 6983) appears to signal receptor-mediated differentiation. [134] As mentioned, TPO binding to its receptor activates JAK, leading to STAT transcriptional factor phosphorylation and subsequent gene activation. TPO activates JAK2 and STAT 1, 3, and 5, with STAT 5 perhaps being the major component of this signal transduction process,[133] [135] although its activation may be indirect. [134] Additionally, ligand binding of c-mpl results in phosphorylation of the c-mpl receptor itself,[133] as well as activation of phosphotidylinositol-3 kinase and phospholipase C . As mentioned, TPO interacts with a variety of cytokines, yielding additive or, often, synergistic effects on megakaryocyte development, or the proliferation of hematopoietic stem/progenitor cells. Such interacting cytokines often share the gp130 receptor chain, although gp130 is not required for TPO signaling. [135] [136]

A number of animal studies have documented the in vivo effectiveness of TPO administration in models of myelosuppression

or bone marrow/peripheral blood transplantation. The in vivo actions of TPO on megakaryocyte development are seen in the original cloning/function reports and gene inactivation studies (see above). These reports, plus the gene inactivation studies, clearly demonstrate that TPO and c-mpl function as the primary regulators of in vivo megakaryocytopoiesis and document their role in early hematopoiesis. These data predict that TPO administration should have clinical utility. In murine models of chemotherapy- or radiation-induced myelosuppression and in bone marrow transplantation models, TPO accelerates the recovery of hematopoietic progenitor cells, reticulocytes, RBCs, neutrophils, and platelet counts; it often also increases the cell concentration during cytopenic nadirs. [101] [119] [137] [138] [139] [140] Prior administration of TPO to donor or recipient mice increases platelet and erythrocyte recovery in bone marrow transplantation models, suggesting that TPO modulates both the transplanted donor cells as well as the recipients hematopoietic microenvironment. [141] [142] Encouraging results are also seen in TPO administration to nonhuman primates. In general, TPO results in a 3- to 5-fold increase in circulating platelets (in either normal or myelosuppressed animals). This appears to be the result of an increase in both megakaryocyte number and volume (thus yielding a marked increase in megakaryocyte mass). [143] [144] [145] As in mice, TPO decreases the thrombocytopenia and augments neutrophil recovery in nonhuman primates given -irradiation; [146] it has the same effect in other models of myelosuppression.[147] Finally, administration of TPO to human patients with solid tumors results in a 3- to 10-fold increase in circulating platelet concentration (mean elevation, 3-fold). [148] Ex vivo testing of the platelets from these individuals showed no apparent activation or priming of the platelets as a result of TPO administration.

Extracellular Influences and Cell Interactions

The cellular concentration of bone marrow is roughly 10^9 cells/ml. This suggests that blood cells develop within the context of their interactions with neighboring cells and extracellular molecules. In the past decade, a number of investigations have demonstrated that stromal cells and ECM are dynamic and inductive (or permissive) components of all developing cellular systems. With respect to hematopoiesis, numerous studies have shown that hematopoietic progenitor cells interact with growth factors, accessory cells such as T cells, stromal cells, and ECM components (for reviews, see Long [3]). This developmental network is further complicated by observations that stromal cells express membrane-associated growth factors, [149] [150] and that ECM both binds hematopoietic growth factors and presents these cytokines in a biologically functional manner. [151] [152]

Both cell-cell and cell-ECM communications among developing megakaryocytes are poorly understood. Structurally, mature (platelet-shedding) megakaryocytes are located on the abluminal surface of the bone marrow sinusoid. It is postulated that megakaryocytes extend pseudopods through or between sinusoidal endothelial cells, thus allowing shear forces to fragment platelets into the circulation. [55] Both the location and the putative mechanism of platelet shedding imply that megakaryocyte-ECM or megakaryocyte-(endothelial) cell interactions are important to thrombocytopoiesis. Isolated megakaryocytes adhere to bovine corneal endothelial cell-derived ECM and proplatelet-like structures are induced under these conditions. [153] As well, megakaryocytes adhere to collagen and secrete both a collagenase and a gelatinase,[5] [153] suggesting a possible mechanism for pseudopod infiltration of the surrounding ECM.

Studies of megakaryocyte progenitor cells show that cell-ECM relationships are important to megakaryocyte proliferation. Approximately 30% of CFU-Mk cells in bone marrow adhere to the ECM proteins fibronectin or thrombospondin (TSP).[154] Interestingly, 6080% of primitive CD34+, HLA DR BFC-Mk attach to TSP, whereas they fail to bind to fibronectin.[4] Therefore, primitive megakaryocyte progenitor cells show both altered expression of cytoadhesion molecule attachment and altered

responsiveness to complex matrix-cytokine regulatory signals.

MOLECULAR AND BIOCHEMICAL CONTROL OF MEGAKARYOCYTE COMMITMENT AND DIFFERENTIATION

Transcriptional Control of Megakaryocyte Gene Expression

One of the fundamental goals of molecular hematology is the identification of specific genes, or sets of genes, that direct the activation of lineage-specific differentiation events. A related and equally important aim is to identify the specific nuclear proteins (transcription factors) involved in the (trans-) activation of such master control genes. The activation of lineage-specific gene expression during the commitment of multi- or pluripotent progenitor cells requires a great deal of transcriptional specificity, which is complicated by the observation that DNA-binding transcription factors recognize short (68 bp) DNA sequences. [155] For example, cis-acting DNA regulatory sequences recognized by factors involved in transcription include TATA, which binds transcription factor IID, CCAAT, which is found in many gene promotor regions, and GATA, a regulatory element observed in genes of hematopoietic, endothelial, and neural cells. [155]

To date, the nature of megakaryocyte master control genes remains obscure. Nonetheless, a number of cis-regulatory elements have been identified, and their regulatory motifs are found within the control regions of specific genes. Of these, the GATA motif is an important control element for erythroid and, megakaryocyte development (for a review, see Orkin[155]). The GATA sequence was first observed in the promoter region of chicken globin genes, [156] and later in the enhancer region of the human -globin gene. [157] In fact, all currently identified erythroid genes contain GATA sequences within their control regions. [155] As well, the core regions of the locus control region (LCR) of the human - and -globin gene clusters contain GATA sequences. [155] There exists a family of nuclear DNA-binding proteins that interact with GATA sequences. GATA-1 (also known as NF-E1, GF-1, eryf-1) was the first such protein identified and is an abundant nuclear protein in erythroid cells and megakaryocytes.[158] [159] GATA-1 is a 413-amino acid, 50-kd polypeptide containing two highly conserved zinc finger regions, which are both necessary and sufficient for DNA binding. In hematopoietic tissue, expression of GATA-1 is observed in the erythroid, megakaryocyte, and mast cell lineages. [158] GATA-2 is present in megakaryocytes and mast cells,[155] and GATA-3 expression is restricted to T cells, being found in the enhancer region of the T-cell receptor gene. [160] Interestingly, GATA-1 expression is detectable in CD34+, CD38+ bone marrow cells but not in the more primitive CD34+, CD38 cells, suggesting a role for GATA-1 in the function of more differentiated progenitor cells. [161]

GATA-binding proteins are observed in various tissues or cell lines, but the mere presence of a transcriptional factor does not define its role in lineage-specific gene expression or hematopoietic differentiation. [155] The function of such transcription factors is best examined in animals in which the gene of interest is rendered inoperative. This has been achieved for GATA-1 by Pevny et al., who disrupted the GATA-1 gene in embryonic stem (ES) cells by homologous recombination. [162] The resultant knock-out cells were analyzed both in vitro and in vivo. In vitro differentiation of GATA-1-deficient ES cells failed to generate erythroid cells. Confirming its role in erythropoiesis, the

inoperative gene also failed to contribute to hematopoiesis in null animals. GATA-1-deficient mice either died in utero or had severe anemia. Importantly, these animals sustained white blood cell production and generated clonogenic myeloid progenitor cells, [162] indicating that GATA-1 has a predominant role in erythroid differentiation.

A number of other megakaryocyte/platelet specific genes (thrombomodulin, PF4, platelet GPIIb, platelet GPIX) have GATA sequences in their promoter regions, [163] [164] [165] as do megakaryocytes and megakaryocyte cell lines.[155] A recent study indicated that transfection and 50-fold overexpression of GATA-1 in the murine myeloid cell line 416B restored some of its previously lost megakaryocyte potential. [166] Cells expressing high levels of GATA-1 (re)acquired some, but not all, of the appropriate megakaryocyte characteristics. For example, consistent with the presence of GATA sequences in its promoter, PF4 levels were increased, as was the level of acetylcholinesterase (a marker for megakaryocytes in certain rodents and cats). Likewise, a limited number (2040%) of GATA-transfected cells increased their cell size and volume. In most of these cells the volume increase was modest, but a small proportion (38%) became both large and polyploid. However, the degree of polyploidy appeared to be limited to 8C. [166] These studies suggest that GATA-1 is important to certain aspects of megakaryocyte differentiation, but its solitary overexpression (even in 50-fold excess) is not sufficient to drive full megakaryocyte differentiation. However, the importance of GATA-1 to megakaryocyte development is shown in GATA-1-null mice in which the gene is selectively lost in the megakaryocytic lineage. [167] GATA-1-null mice have marked thrombocytopenia, deregulated megakaryocyte proliferation, and deficient cytoplasmic maturation.

Another transcription factor, NF-E2, is important to megakaryocyte development. NF-E2 is an obligate heterodimer composed of a 45-kd subunit restricted to hematopoietic cells and a widely expressed 18-kd subunit. [110] The p45 subunit is co-expressed with GATA-1 in hematopoietic cells, megakaryocytes, and mast cells. Mice lacking p45 have a high mortality from bleeding secondary to profound thrombocytopenia. [110] Moreover, they show a relative megakaryocytic hyperplasia in which the mature cells undergo a cytoplasmic maturational arrest, lack granules, and show reduced amounts and an abnormal structure of the DMS. Interestingly, the few null animals surviving birth are thrombocytopenic but do not show the expected increase in TPO concentration. Rather, they have normal TPO levels. This apparent paradox was resolved by Shivdasani et al., who used radiolabeled TPO to demonstrate that the megakaryocytes in both the bone marrow and spleen (which are increased in number) as well as large platelet-like particles in the spleen bind TPO and thus regulate TPO concentration. [168] These data also confirm the aforementioned studies demonstrating a role for megakaryocyte mass in regulating TPO. Recently, the role of GATA-1 and NF-E2 in megakaryocyte development has become clearer. GATA-1 specifically interacts with a novel zinc-finger protein known as Friend of GATA (FOG). [169] The high degree of specificity in this interaction suggests that the function of DNA-bound GATA-1 is to recruit FOG (and other factors) for the assembly of cell-specific transcriptional complexes. It is therefore noteworthy that FOG is co-expressed with GATA-1 in megakaryocytic (and erythroid), but not other cells, and that GATA-1 and FOG synergize in activating the p45 NF-E2 gene.[169]

Megakaryocyte Cell Cycle Control and Endomitosis

Unlike other cells, megakaryocytes continue to synthesize DNA during differentiation. During this process megakaryocytes become polyploid, [170] [171] [172] having a DNA content of 8C128C, where 2C is the DNA content of a somatic cell. Megakaryocytes are not multinucleate cells but contain this increased DNA content within a single, albeit highly lobulated, nucleus. [173] [174] Ebbes and Feingendins groups, using tritiated thymidine incorporation, demonstrated that mature (stages II and III) megakaryocytes do not take up this label, thus showing that they are not undergoing DNA synthesis. [175] [176] State I megakaryocytes are the only recognizable cells capable of synthesizing DNA, but only 2040% of these cells do so. On prolonged exposure to tritiated thymidine, 100% of the megakaryocytes become labeled, indicating that the majority of DNA synthesis occurs in the immediate precursor of the megakaryoblast (i.e., PMkB). The cell cycle of megakaryocytes thus is different from that of other cells in that the normal 2C4C2C cell cycle progression is abolished. However, this release from normal cell cycle control does not imply that megakaryocyte DNA synthesis is dysregulated. The acquisition of a polyploid nucleus is tightly or globally controlled, as megakaryocytes show progressive doublings of their DNA content and no intermediate ploidy classes (e.g., 3C, 6C) are seen.

Two observations indicate that formation of a polyploid nucleus requires alterations in the megakaryocyte cell cycle. First, the immediate precursors of the stage I

megakaryocytes (i.e., PMkB) actively synthesize DNA for a prolonged period. [175] [176] Second, morphologic observations of primary cells show that megakaryoblasts do not go through the usual processes of mitosis, as few if any cells reach metaphase and none progress into anaphase or telophase. [173] As important as these historical observations are, they are based either on morphologic evidence or on the analysis of a limited number of megakaryocytes. Indeed, the term that is usually applied to this type of polyploidization, endomitosis, is a morphologic classification. The definition of endomitosis refers to the replication of nuclear elements within an intact nuclear envelope without subsequent chromosomal movement or cytokinesis.[177] This term is best used to describe megakaryocyte polyploidization.[173] Frequently the term endo-reduplication is erroneously applied to megakaryocytes. Endo-reduplication is the mechanism that results in polytenic (diplo- and quatro-chromosome number) cells in insects, and is a chromosome duplication cycle not associated with endomitotic-like changes. [177]

Given that the polyploid nature of megakaryocytes is unique among mammalian bone marrow cells, the question arises as to the biologic significance of this altered DNA content. A related question is whether or not polyploidization occurs as a prerequisite to or as a consequence of the increase in megakaryocyte cell volume occurring within these cells. It is known that megakaryocyte DNA content is related to megakaryocyte cell size and thus to the eventual numbers of platelets produced.[173] [178] A number of studies have documented the effect of thrombocytopenic demand on megakaryocytes. For example, acute thrombocytopenia results in an increased DNA content prior to increased platelet production. [173] Likewise, increases in cytoplasmic volume and cytoplasmic maturation occur predominantly, if not completely, in stages II and III megakaryocytes,[173] [178] which do not appear to synthesize DNA. Therefore, whatever its functional significance, polyploidization precedes the increase in megakaryocyte cell volume. This association of increased DNA content and increased cell volume implies that the large DNA content in megakaryocytes is in some unknown manner relevant to the process of platelet formation. For example, increased DNA content may be associated with increased mRNA expression, which in turn drives the marked degree of biosynthesis required for platelet formation. Although this remains to be proved, it is clear that megakaryocytes synthesize increased amounts of DNA prior to increases in cytoplasmic volume and cytoplasmic maturation.

It is now recognized that two classes or families of proteins control the cell cycle in mammalian cells. These are the cell division kinases (also known as cyclin-dependent kinases, CDK),

and the cyclins, so named for their cyclical synthesis and degradation. Together, these two classes of proteins form a protein-kinase complex in which the catalytic unit is a CDK and the regulatory unit is a cyclin. These proteins are highly conserved, [179] [180] and different CDK complexes regulate cell cycle progression. The role of these kinase complexes in cell cycle control is complex. Currently, seven members of the cyclin gene family are known, [181] [182] as well as at least seven distinct CDK genes. [183] The role of the kinase known as cdc2 and its cognate cyclin (B) is best understood. Together, these proteins form a mitosis-initiating cdc2 kinase complex that is also known as maturation (or mitosis)-promoting factor. The cdc2-cyclin B kinase complex regulates the initiation of mitosis at the G_2/M transition as well as subsequent events such as spindle fiber formation and cytokinesis. [181] Among the CDK proteins, cdk2 plays an important role in regulating both G_1/S transit and S-phase progression. A number of regulatory cyclins are complexed with cdk2: cyclin E plays a role in G_1 progression and in G_1/S transit; cyclin A is essential for both S phase and the initiation of DNA replication. [184] [185] [186] [187] [188] The cdk2-cyclin E complex is assembled in mid-G_1 and its associated kinase activity peaks in late G_1 and early S phase, whereas cdk2-cyclin A activity is maximal in S phase. [184] [189] Another family of cyclins, the G_1 cyclins (D-type cyclins in mammals and the analogous Cln regulators in yeast), together with cdk4 or cdk6, are important in timing G_1 progression, as well as in G_1/S transit.[190] The D-cyclins are partially cell-type specific, and most cells express cyclin D_3 and either D_1 or D_2 .[191] Interestingly, the D-type cyclins also bind with cdk2. [192]

The precise role of CDK and cyclin proteins in megakaryocyte endomitosis is unknown. Nonetheless, a general hypothesis can be put forward concerning the biochemical control of the endomitotic cell cycle. That is that mitosis must be abrogated to retain an increased DNA content within a single nucleus, and that S phase must be modified to prevent (or weaken) its interdependency with the M phase. Not too surprisingly, megakaryocytes show demonstrable alterations at the two control (or restriction) points evident in all cycling cells. They have a prolonged S-phase period and synthesize increased amounts of DNA (i.e., they are altered in G_1 or S phase), and they undergo an abrogation of mitosis (M phase). Interestingly, in normal cells, the cdc2-cyclin B complex kinase activity peaks in early metaphase. [193] This is just the point at which megakaryocytes fail to progress through mitosis. Moreover, recent observations demonstrate that stabilizing mutations of the cyclin B gene (e.g., the loss of its N-terminal domain) results in persistence of this protein, and its sustained presence leads to mitotic arrest. [194] [195]

As mentioned, megakaryocytes are unique in that they leave the diploid (2C) state to differentiate, synthesizing 464 times the normal DNA content within a single nucleus, a process known as endomitosis. Human erythroleukemia (HEL) cells model this process, becoming megakaryocytic during phorbol diester-induced megakaryocyte differentiation.[36] Datta and co-workers have shown that the mitotic arrest occurring in these polyploid cells involves novel biochemical alterations in the cdc2-cyclin B1 complex: a marked reduction in cdc2 protein levels, and an elevated and sustained expression of cyclin B1. [196] As a result, endomitotic cells lack cdc2-cyclin B1-associated H1-histone kinase activity. Constitutive overexpression of cdc2 in endomitotic cells failed to reinitiate normal mitotic events, even though cdc2 was present in 10-fold excess. This was due to an inability of cyclin-B1 to physically associate with cdc2. Thus, during megakaryocytic differentiation of HEL cells, mitosis is abrogated during endomitosis owing to the absence of cdc2 and the failure to form active cdc2-cyclin B kinase complexes, resulting in a disassociation of mitosis from the completion of S phase. Similar results were reported by Zhang and co-workers, who demonstrated a decreased cdc2-cyclin B kinase activity in polyploid megakaryocytes.[197] Consistent with this, Garcia and Cales also demonstrated a lack of cdc2/cyclin B kinase activity in phorbol-stimulated megakaryocytic cell lines (HEL and MEG-01). [198] These data are consistent with studies showing that a loss of the cdc2-cyclin B complex in yeast results in multiple S phases, [199] that cyclin B is absent during multiple rounds of S phase in *Drosophila* embryos,[200] and that endoreduplication in maize endosperm involves both an increase in the amount and activity of S-phase-related protein kinases and active inhibition of cdc2-cyclin B activity. [201]

Polyploid HEL cells also are a useful model for examining endomitotic S-phase control, as their cell cycle machinery must be modulated in order to allow the acquisition of high levels of DNA content (ploidy) within a single nucleus and to allow the re-replication of newly synthesized DNA without an intervening mitosis. In order to evaluate the mechanisms of S-phase control during the process of polyploidization, Datta and Long also investigated the modulations occurring in CDK complexes during the induction of megakaryocyte differentiation in human HEL cells. During polyploidization, megakaryocytic HEL cells undergo a dramatic modulation in the subunit composition of G_1 - and S-phase-associated CDK complexes and an increase in their specific activities. In particular, cyclin D_3 protein levels are increased (owing to both a change in D_3 mRNA levels and a stabilization of its half-life), and there is a marked increase in cdk2-cyclin D_3 kinase activity throughout the period of endomitosis. [202] Moreover, these changes occur within the context of an up-regulated function of cdk2-cyclin E complexes that is associated with both G_1/S-phase transit and S-phase progression. [202] The cyclin D observations are consistent with studies by Wang et al. [203] showing that antisense cyclin D3 oligonucleotides abrogated megakaryocyte development (although ploidy of the megakaryocytes was not examined). Further studies regarding the regulation of these complex CDK interactions will be important to understanding the cell cycle control in such diverse processes as megakaryocyte differentiation or the types of genomic instability occurring in cancer cells. However, it should be noted that data derived from the study of cell lines may not exactly reflect the biochemical changes occurring in primary megakaryocytes. Recent preliminary observations (K. Kaushansky and W. Vainchenker, pers. commun.) indicate that megakaryocyte development (cytokine driven) in vitro differs somewhat from that of megakaryocytic cell lines: the mitotic arrest in cultured megakaryocytes seems to happen nearer to or following the anaphase. A paper by Vainchenker and co-workers demonstrates the similarities and differences between the cell line data and that of megakaryocytes produced ex vivo. Thus, HEL cells and cultured developing megakaryocytes both show an increase in cyclin B1 levels (in megakaryocytes only up to 8C cells, after which levels are sustained), as well as a cyclin B/associated H1 histone kinase activity. [196] [204] In contrast, cultured megakaryocytes do express cdc2, although their physical association with cyclin B or kinase activity was not tested. Nonetheless, this excellent paper clearly demonstrates that endomitosis of human megakaryocytes is due to abortive mitosis and that this is associated with nuclear envelope breakdown and the formation of complex mitotic spindles. It is clear that a better understanding of endomitotic events requires further analysis of the cell line data, data from cultured megakaryocytes, and, eventually, data from purified populations of primary megakaryocytes.

CONCLUSIONS AND PERSPECTIVE

Our increased understanding of the cellular and molecular basis of megakaryocytopoiesis has had an immediate impact on clinical medicine. There are numerous dyscrasias of megakaryocytopoiesis that result in abnormal platelet production, such as amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, and primary thrombocythemia. Although the molecular and biochemical basis of these disorders often remains

unknown, a number of preliminary studies have documented alterations in the frequency of megakaryocyte progenitor cells in these conditions. [205] [206] [207] [208] As well, amegakaryocytic thrombocytopenia is associated with increased levels of circulating regulatory factors, [62] [64] and familial forms of primary thrombocythemia have been described in which patients have increased megakaryocytes and thrombocytosis attributed to increased TPO production. [210] The marrow fibrosis that characterizes agnogenic myeloid metaplasia (myelofibrosis) is ascribed to mitogenic factors, released from abnormal mega-karyocytes, that stimulate fibroblast proliferation and ECM deposition.[211] Thrombocytopenias are associated with either high or normal TPO levels, depending on the remaining megakaryocyte mass. [108] [110] [168]

In order to effectively control platelet production, both normal and abnormal megakaryocyte development must be examined at the cellular and molecular levels. This requires that the interacting ECM-cytokine complexes that regulate platelet production be defined. Similarly, the megakaryocytic signal transduction pathways activated by these thrombopoietic signals must be understood. Ultimately, understanding megakaryocyte development will require identifying those genes that regulate megakaryocyte commitment and differentiation. This requirement notwithstanding, current clinical trials of IL-11 and of TPO have resulted in the development of effective strategies for the therapeutic management of the thrombocytopopenias.

Chapter 18 - Inherited Forms of Bone Marrow Failure

Melvin H. Freedman

INTRODUCTION

In the context of this chapter, bone marrow failure is defined as decreased production of one or more of the major hematopoietic lineages on an inherited basis (Table 18-1). The term constitutional is often used interchangeably with inherited and similarly implies that a genetic abnormality causes bone marrow dysfunction, especially when it occurs in two or more members of the same family or is associated with congenital physical abnormalities. The designation congenital has a looser connotation and refers to conditions that manifest early in life, often at birth, but does not connote a particular causation. Congenital marrow failure is not necessarily inherited or constitutional and may be caused by acquired factors such as viruses and environmental toxins.

Because hematopoiesis is an orderly but complex interplay of stem and progenitor cells, marrow stromal elements, and positive and negative cellular and humoral regulators, marrow failure can potentially occur at a number of critical points in the hematopoietic lineage pathways. For the inherited marrow disorders, current theory holds that genetic mutations interfere with hematopoiesis and cause the marrow failure, although the specific molecular basis is not yet known for any of these conditions. Acquired factors may also be operative and may interact with the putative genetic mutations to produce overt disease with varying clinical expression. Hence, the conditions shown in Table 18-1 can be transmitted as a simple Mendelian disorder determined primarily by a single mutant gene with inheritance patterns of autosomal dominant, autosomal recessive, or x-linked types. Alternatively, some or all of these can be multifactorial disorders caused by an interaction of multiple genes and multiple exogenous or environmental determinants.

The incidence of the inherited marrow failure disorders can

TABLE 18-1 -- Inherited Bone Marrow Failure Syndromes

Pancytopenia
Fanconi's anemia
Shwachman-Diamond syndrome
Dyskeratosis congenita
Amegakaryocytic thrombocytopenia
Other genetic syndromes
Down's syndrome
Dubowitz's syndrome
Seckel's syndrome
Reticular dysgenesis
Familial aplastic anemia (non-Fanconi's)
Unilineage Cytopenia
Diamond-Blackfan anemia
Kostmann's syndrome/Congenital neutropenia
Thrombocytopenia with absent radii
Congenital dyserythropoietic anemias
Types I, II, III
Variants

be roughly approximated from careful clinical observations compiled at large centers. For example, data from the Children's Hospital Medical Center, Boston, and the Prince of Wales Hospital, Australia, show that these syndromes comprise 3035% of cases of pediatric marrow failure, respectively, and Fanconi's anemia represents about two-thirds of the total.[1] [2]

PANCYTOPENIA

Fanconi's (Aplastic) Anemia

Introduction

This classical marrow failure disorder is inherited in an autosomal recessive manner with a heterozygote frequency of about 1 in 200 and is remarkable for its diversity in phenotype. It occurs in all racial and ethnic groups. Although the original report in 1927 by Professor Fanconi described pancytopenia combined with physical anomalies in three brothers, a summary of the large body of published information on approximately 1,000 cases [3] over the ensuing 70 years has underscored the clinical variability of the condition. [4] At presentation patients may have: (a) typical physical anomalies but normal hematology; (b) normal physical features but abnormal hematology; or (c) physical anomalies and abnormal hematology, the so-called classic phenotype that fits the original description. There can also be sibling heterogeneity in presentation with discordance in clinical and hematological findings, even in affected monozygotic twins. All patients show abnormal chromosome fragility, most easily seen in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin and enhanced by adding clastogenic agents (see Laboratory Evaluation).

About 75% of patients are between 3 and 14 years of age at the time of diagnosis of Fanconi's anemia, with a mean of about 8 years in males and almost 9 years in females.[4] It is noteworthy that 4% are diagnosed in the first year of life and 10% at 16 years of age or older.

Biologic and Molecular Aspects

A breakthrough in the search for Fanconi's anemia genes evolved from the important observation that hybrid cells formed from Fanconi's anemia and normal cells resulted in correction of the abnormal chromosome fragility, a process known as complementation. [5] [6] [7] [8] [9] It was further demonstrated that cell fusion studies from several unrelated Fanconi's patients could also produce the corrective effect on chromosomal fragility by complementation. [7] [8] [9] Currently, eight complementation groups and hence eight separate genes (termed types A, B, C, D, E, F, G, and H) have been distinguished on the basis of these somatic cell hybridization experiments,[6] [10] [11] with Fanconi's anemia type A (FA-A) accounting for over 65% of the cases analyzed. [12] A cDNA for the group C gene was identified in 1992 and localized to chromosome 9q22.3.[13] Using the same successful expression cloning method, a cDNA representing the group A gene on chromosome 16q24.3 has also been reported.[14] Even though the precise functions of the FA-C and FA-A proteins are unclear so far, complementation analysis suggests that they operate in concert with at least three to six additional proteinsthe products from the other Fanconi genes. Although FA-D has not been cloned yet, genetic mapping localizes it to 3p22-26. The FA-A protein localizes primarily to the cell nucleus, whereas the FA-C gene product is located in both the nucleus and cytoplasm. All of the FA proteins may thus control or participate in a conceptually novel biochemical process which must play an important role in the various physiological and cellular processes implicated in the Fanconi phenotype, such as skeletal development, blood cell formation, and maintenance of genomic integrity. Cloning the remaining genes should help researchers to eventually understand this process at the molecular level.

A knockout mouse model of FA-C has provided some insight into the role of that gene. [15] When mice were generated with targeted inactivation of the FA-C gene, the nullizygous genotype did not exhibit developmental abnormalities or gross hematologic defects for up to 9 months. Spleen cells from the knockout mice had increased numbers of chromosomal aberrations in response to two agents that enhance chromosome fragility, mitomycin C and diepoxybutane (DEB). Homozygous male and female mice also had compromised gametogenesis and markedly impaired fertility, mimicking some of the features of the human disease. Although the mice did not exhibit gross hematologic defects, FA-C nullizygous mouse hematopoietic progenitors were markedly sensitive to -interferon, a cytokine implicated in growth arrest and apoptosis. When mitomycin C was administered to homozygous mice they developed either pancytopenia or total bone marrow failure, depending on the dose of the drug.[16]

Further information regarding the importance of FA-C in hematopoiesis was provided by experiments in which normal human lymphocytes and bone marrow cells were exposed to an antisense oligodeoxynucleotide (ODN) complementary to bases 4 to +14 of FA-C mRNA.[17] The mitomycin C assay showed that the antisense ODN repressed FA-C gene expression in lymphocytes. Escalating doses of antisense ODN increasingly inhibited clonal growth of erythroid and granulocyte-macrophage progenitors, thereby demonstrating a seemingly important role for the gene in sustaining normal hematopoiesis.

A recent study [18] examined the phenotypic consequences of mutations of FA-C in patients. Kaplan-Meier analysis showed that IVS4 or exon 14 mutations define poor risk subgroups clinically, as they are associated with earlier onset of hematologic abnormalities and poorer survival compared to patients with the exon 1 mutation and to the non-FA-C population. The molecular biology of Fanconi's anemia and the implications for diagnosis and therapy have recently been reviewed. [19]

Etiology and Pathogenesis

The two theories of pathogenesis of Fanconi's anemia relate to either defective DNA repair or an inability of Fanconi's cells to remove oxygen-free radicals that damage cells. Despite an extensive body of published data, neither theory has prevailed. The strongest evidence supporting an oxygen metabolism deficiency is the G_2 phase cell cycle defect of Fanconi's cells, consisting of both a phase transit delay and/or a complete arrest. [20] This effect is reduced when Fanconi's cells are grown at low

oxygen levels, and a similar defect can be induced in normal cells grown at high oxygen levels. [21] [22] This phenotype cannot be induced by treatment with DNA cross-linking agents, suggesting that it is not related to a DNA repair defect.

The best evidence supporting the theory that the primary defect is in DNA repair comes from experiments in which the frequency of mutations induced by 8-methoxy psoralen (8-MOP) plus near ultraviolet light (320-360 mm) (UVA) at the hypoxanthine phosphoribosyl transferase and $Na^+ + K^+$ -ATPase loci was lower in FA-A and FA-D cells than in controls.[23] [24] These results could indicate that Fanconi's cells cannot repair cross-links through the normal pathway involving either mismatch repair or recombinational repair following bypass of the lesion, or both. Similar studies that assayed the repair of cross-linked herpes simplex virus DNA following transfection found that Fanconi's cells, unlike controls, were able to repair cross-linked DNA only under conditions of multiple infection. [25] Since multiplicity reactivation is dependent on recombinational repair, it can be inferred that Fanconi's cells are defective in an excision repair pathway.

To reconcile the evidence of defective oxygen metabolism with the data demonstrating the involvement of the DNA repair system in the pathology of Fanconi's cells, it may be possible that in Fanconi's anemia a set of proteins, closely involved in DNA repair, is particularly sensitive to oxidative damage. The Fanconi's anemia

mutation could either make the repair pathway sensitive to oxidative damage or cause a transient increase of oxidative damage to which the repair machinery is particularly sensitive.

The bone marrow dysfunction in Fanconi's anemia is evident at the hematopoietic progenitor level in bone marrow and peripheral blood. The frequencies of CFU-E, BFU-E and CFU-GM colony-forming cells are reduced fairly consistently in almost all patients after aplastic anemia ensues, [26] [27] [28] [29] [30] [31] [32] [33] [34] as well as in a few patients before the onset of aplastic anemia.[35] Although marrow cells from Fanconi's patients show normal transcripts for the -and -chains of the GM-CSF/IL-3 receptor and for c-kit protein, there is a deficient growth response in the majority of patients of CFU-GEMM, BFU-E and CFU-GM progenitors to GM-CSF plus stem cell factor (c-kit ligand) or IL-3 plus stem cell factor, a finding not seen in controls. [36] Because all hematopoietic lineages are affected in these studies, the basic defect probably involves the pluripotent stem cell compartment. Confirmatory data for this hypothesis using long-term bone marrow cultures were reported by one group [37] but contradicted by another.[38] Decreased colony numbers in these studies can be interpreted as the result of an absolute decrease in progenitors, or a result of adequate numbers of progenitors that have faulty proliferative properties and cannot form colonies in vitro. Both interpretations may be true.

Cytokine studies in Fanconi's patients have shown varied abnormalities. Although Fanconi's fibroblasts showed no deficiencies in stem cell factor or M-CSF production, variability ranging from diminished production to augmentation of production of IL-6, GM-CSF and G-CSF was seen in different patients. [39] A fairly consistent finding that may relate directly to pathogenesis is diminished IL-6 production in Fanconi's patients and markedly heightened abnormal TNF- generation. [40]

Clinical Manifestations

The presence of characteristic congenital physical anomalies alone or in combination in the setting of bone marrow failure makes a diagnosis of Fanconi's anemia straightforward (Fig. 18-1). It is important to note, however, that Fanconi's anemia patients may lack anomalies. The older historical terms Estren-Dameshek aplastic anemia[41] and constitutional aplastic anemia type II [42] referred to such patients. With the introduction of clastogenic stress-induced chromosomal breakage analysis as a confirmatory test for Fanconi's anemia, data from the International Fanconi's Anemia Registry (IFAR) showed that 39% of 202 patients tested had aplastic anemia and anomalies, but 30% had aplastic anemia only and were without anomalies.[43] Twenty-four percent had anomalies only and 7% had neither. Hence, the Estren-Dameshek cases that lack anomalies should not be considered as a separate entity but as part of the pleiotropic continuum of Fanconi's anemia.

Table 18-2 shows the categories of characteristic physical abnormalities and their approximate frequency. The most common anomaly is skin hyperpigmentation, a generalized brown melanin-like splattering, which is most prominent on the trunk, neck, and intertriginous areas and which becomes more obvious

Figure 18-1 Classical phenotype of Fanconi's anemia. Patient has pigmentary changes around the neck, shoulders and trunk, short stature, absent radii and absent thumbs bilaterally, microcephaly, and low-set ears.

TABLE 18-2 -- Characteristic Physical Anomalies in Fanconi's Anemia

Anomaly	Approximate Frequency (%)
Skin pigment changes	65
Short stature	60
Upper limb abnormalities (thumbs, hands, radii, ulnae)	50
Hypogonadal and genitalia changes (mostly male)	40
Other skeletal findings (head/face, neck, spine)	30
Eyes/lids/epicanthal fold anomalies	25
Renal malformations	25
Ear anomalies (external and internal), deafness	10
Hips, legs, feet, toes abnormalities	10
Gastrointestinal/cardiopulmonary malformations	10

Modified from data compiled by Dr. Blanche Alter, with permission.[4]

with age. Café-au-lait spots are common alone or in combination with the generalized hyperpigmentation, and sometimes with vitiligo or hypopigmentation. The skin pigmentation should not be confused with hemosiderosis-induced bronzing in transfusion-dependent patients who have not been adequately chelated.

The majority of patients are small and have short stature. As summarized by Alter, of 19 published cases who had growth hormone assays performed, 14 showed a deficiency, but only about half of those treated with growth hormone showed a growth response. [4]

Malformations involving the upper limbs are common, especially hypoplastic, supernumerary, bifid, or absent thumbs. Hypoplastic or absent radii are always associated with hypoplastic or absent thumbs in contrast to the thrombocytopenia with absent radii (TAR) syndrome in which thumbs are always present. Less often, anomalies of the feet are seen including toe syndactyly, short toes, a supernumerary toe, clubfoot, and flat feet. Congenital hip dislocation and leg abnormalities are occasionally seen.

Males often have gonadal and genital abnormalities including an underdeveloped penis or micropenis, undescended, atrophic, or absent testes, hypospadias, phimosis, and an abnormal urethra. Female patients occasionally have malformations or atresia of the vagina, uterus, and ovary.

Many patients have a Fanconi facies and unrelated patients can resemble each other almost as closely as siblings. The head and facial changes vary but commonly consist of microcephaly, small eyes, epicanthal folds, and abnormal shape, size or positioning of the ears. About 10% of Fanconi's patients are mentally retarded.

Renal anomalies occur but require imaging for documentation. Ectopic, pelvic, or horseshoe kidneys are detected often, as well as duplicated, hypoplastic, dysplastic, or absent organs. Occasionally, hydronephrosis or hydroureter is present.

Auerbach et al. developed a scoring system[43] for the probability of an accurate diagnosis of Fanconi's anemia using discriminating clinical and laboratory variables in patients enrolled in the IFAR whose diagnosis was confirmed by clastogenic stress-induced chromosomal breakage analysis. The variables used for scoring are shown in Table 18-3A and the scoring system in Table 18-3B . One point is added or subtracted for each variable with a positive or negative coefficient, respectively. A patient with a score of 4+ or greater has a 98% probability of having Fanconi's anemia.

Laboratory Evaluation

A cardinal feature is the gradual onset of bone marrow failure with declining values in one or more hematopoietic lineages. Thrombocytopenia usually develops initially, with subsequent onset of granulocytopenia and then anemia. Severe aplasia eventually develops in most cases but the full expression of pancytopenia is variable and ensues over a period of months to years. The development of aplastic anemia can be accelerated by intercurrent infections or by drugs such as chloramphenicol. Within families, there is a tendency for the hematologic changes to occur at about the same age in affected siblings. [44] Data from 388 patients reported to the IFAR showed that 332 developed hematologic abnormalities at a median of 7 years (range: birth31 years). [45] The actuarial risk of developing hematologic abnormalities rose progressively with age and was 98% by 40 years.

TABLE 18-3A -- Discriminating Clinical and Laboratory Variables in Fanconi's Anemia

Variable	Frequency (%)		Coefficient	Contribution
	FA	Non-FA		
Growth retardation	60.9	24.1	0.70	38.47
Skin pigmentation	58.4	22.2	0.78	27.09
Kidney, urinary	35.1	9.3	0.71	17.56
Thumb, radius	51.0	21.3	0.85	15.24
Microphthalmia	44.1	13.9	0.81	12.80
Learning disability	15.8	18.5	0.66	11.62
Other skeletal	30.2	26.9	0.57	8.47
Thrombocytopenia	80.2	61.1	0.73	7.43

TABLE 18-3B -- Probability of Having Fanconi's Anemia Based on Simplified Score

Simplified Score	FA (N)	Non-FA (N)	Probability
1	0	5	0.00
0	5	20	0.20
1	27	59	0.31
2	53	18	0.75
3	59	5	0.92
4	58	1	0.98
Total	202	108

The red cells are macrocytic with mean cell volumes often above 100 fl even before the onset of significant anemia. Erythropoiesis is characterized by increased Hb F and increased expression of i antigen, but not necessarily both features in individual cells. The increased Hb F production is not clonal and has a heterogeneous distribution. Ferrokinetic studies indicate that most patients have an element of ineffective erythropoiesis as part of the marrow failure. Red blood cell (RBC) lifespan may be slightly shortened but this is a minor component, if any, of the anemia.

In the early stages of the disease, the bone marrow can show erythroid hyperplasia, sometimes with dyserythropoiesis and even megaloblastic-appearing cells. As the disease progresses, the marrow becomes hypocellular and fatty, sometimes patchily, and shows a relative increase in lymphocytes, plasma cells, reticulum cells, and mast cells. With full-blown marrow failure, the morphology on biopsy is identical to that seen in severe acquired aplastic anemia.

A major finding is abnormal chromosome fragility, seen readily in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin. The karyotype shows spontaneously occurring chromatid breaks, rearrangements, gaps, endoreduplications and chromatid exchanges in cells from homozygote Fanconi's anemia patients. Cultured skin fibroblasts also show the abnormal karyotype underscoring the constitutional basis for the disorder. The abnormal lymphocyte chromosome pattern, the number of breaks per cell, and the variations in proportion of abnormal cells have no direct correlation with the hematological or clinical course of individual patients.

Spontaneous chromosomal breaks, as described, are occasionally absent in true cases of homozygote Fanconi's anemia. [43] The clastogenic stress-induced chromosomal breakage analysis was introduced, in part, to circumvent this problem and to bring specificity to testing for Fanconi's anemia. Chromosomal breakage is strikingly enhanced compared with controls if clastogenic agents such as DEB are added to the cultures. [46] Indeed, homozygote Fanconi cells are hypersensitive to many oncogenic and mutagenic inducers, such as ionizing radiation, SV40 viral transformation, and alkylating and chemical agents including mitomycin C, cyclophosphamide, nitrogen mustard, and platinum compounds.[4] For definitive diagnostic purposes, the IFAR has defined Fanconi's anemia as increased numbers of chromosome breaks/cell after exposure to DEB[43] [47] with a mean of 8.96 (range: 1.323.9) compared to normal controls of 0.06 (range: 00.36).

The abnormal chromosome picture can be used to make a prenatal diagnosis of Fanconi's anemia. [47] [48] Diagnostic testing can be performed on fetal amniotic fluid cells obtained at 16 weeks' gestation, or earlier on chorionic villus biopsy specimens at 912 weeks. A very high degree of prenatal diagnostic accuracy has been obtained by looking at both spontaneous and DEB-induced breaks. [47] [48]

Predisposition to Malignancy

A major feature of the Fanconi's anemia phenotype is the propensity for cancer. The karyotype data, the defects in DNA repair, and the cellular damage that occur in Fanconi's patients translate into an enormous predisposition for malignancy. More than 80 of 1,000 published patients have been reported with leukemia, about 30 with liver tumors, and 47 with other cancers, giving an overall incidence of malignant transformation of about 20%. [3] [49] Fanconi patients may also develop myelodysplastic syndromes (MDS). These are traditionally defined as clonal refractory cytopenias with characteristic dysplastic changes in marrow cells and a propensity to evolve into AML. Some patients also have clonal cytogenetic findings in marrow cells without overt MDS/AML. The clonal findings of deletions, translocations, and marker chromosomes often involve chromosomes 1 and 7.

To determine the risk of malignant myeloid transformation in Fanconi's anemia patients, Butturini et al. used the observational database of the IFAR in which most patients' diagnoses were confirmed by DEB testing. [45] They defined MDS as 5% to 30% myeloblasts in marrow or 5% to 20% myeloblasts in blood. AML was defined as more than 30% marrow blasts or more than 20% blasts in blood. Marrow dysplastic morphology was not used as a criterion. Of 332 patients in the IFAR who developed varying hematologic abnormalities, 59 subjects (18%) developed MDS or AML with a median interval of observation prior to the transformation of 13 years (1 month to 32 years). Using the authors' strict disease definitions, 34 patients had MDS and 25 had AML. It is noteworthy that 20 of the 59 patients initially presented at diagnosis with established MDS or AML and the diagnosis of Fanconi's anemia was made secondarily. Using the same IFAR data, the actuarial risk of MDS or AML developing over time could be determined. At 5, 10, 20, and 40 years of age, the probability of malignant transformation escalates from less than 5%, to approximately 8%, 25%, and 52%, respectively. The risk of MDS/AML was higher for patients in whom a prior clonal marrow cytogenetic abnormality had been detected. Loss of chromosome 7 (monosomy 7) or rearrangement or partial loss of 7q, rearrangements of 1p36 and 1q2434, and rearrangements of 11q2225 were the most frequently recurring cytogenetic changes.

Alter has compiled published data on 42 patients who developed one or more malignancies other than leukemia or liver tumors. [4] Almost all patients were at least 10 years old when the tumors presented; the average age was 23 years. Most of the tumors were squamous cell carcinomas involving the gastrointestinal tract at any site from the oropharynx to the anorectalcolonic area. Less frequently, gynecologic malignancies were also described, with primaries arising in vulva, cervix, and breast. Unusual combinations were occasionally described, such as Wilm's tumor with medulloblastoma, cancer of the vulva and of the tongue, hepatic carcinoma and cancer of the tongue, and hepatic carcinoma and esophageal carcinoma.

Liver tumors, benign and malignant, as well as peliosis hepatis consisting of blood-filled empty spaces in the liver, occur with increased frequency in Fanconi's anemia.[4] The most common tumors reported were hepatocellular carcinoma followed by hepatomas and adenomas. Because almost all patients reported in the

literature were taking androgen therapy at the time that the liver disease presented, androgens have been implicated in pathogenesis. Indeed, peliosis hepatis is reversible when androgens are stopped, and in three patients with tumors, discontinuation of androgens alone or coupled with bone marrow transplantation effected a regression of the tumors.

Differential Diagnosis

Patients with abnormal hematology and characteristic physical anomalies are not difficult to diagnose, especially if there are previously affected siblings. Distinguishing Fanconi's anemia from acquired aplastic anemia on clinical grounds can be difficult if the Fanconi's patient lacks physical anomalies. In this situation, the clastogenic stress-induced chromosomal breakage analysis using DEB will specifically identify Fanconi's anemia and lead to the correct diagnosis.

Although neutropenia is the consistent feature of Shwachman-Diamond syndrome, anemia and/or thrombocytopenia is seen in more than half the patients and can be confused with Fanconi's anemia. Since growth failure is also a manifestation of Shwachman-Diamond syndrome, differentiating between the two disorders can initially be difficult. The major difference between them is that Shwachman-Diamond syndrome is a disorder of exocrine pancreatic dysfunction which produces gut malabsorption.

This can be confirmed by fecal fat analysis and by pancreatic function studies using intravenous secretin and cholecystokinin, which confirm markedly impaired enzyme secretion. Computed tomography of the pancreas may also demonstrate fatty changes within the body of the pancreas. Other skeletal distinguishing features found in some Shwachman-Diamond patients are short flared ribs, thoracic dystrophy at birth, and metaphyseal dysostosis of the long bones. Chromosomes are normal in Shwachman-Diamond syndrome and no increased breakage is seen after clastogenic stress.

Dyskeratosis congenita shares some features with Fanconi's anemia including development of pancytopenia, a predisposition to cancer, and skin pigmentary changes. However, the pigmentation pattern is somewhat different in dyskeratosis congenita and manifests with a lacy reticulated pattern affecting the face, neck, chest, and arms, often with a telangiectatic component. At some point, usually in the first decade, dyskeratosis congenita patients also develop dystrophic nails of the hands and feet, and, somewhat later, leukoplakia involving the oral mucosa especially the tongue. Other findings, seen only in dyskeratosis congenita and not in Fanconi's anemia are teeth abnormalities with dental decay and early tooth loss, hair loss, and hyperhydrosis of the palms and soles. Although there are contradictory data regarding chromosomal fragility in dyskeratosis congenita, DEB testing has not shown any difference between patients and controls, which contrasts sharply with Fanconi's patients.

Amegakaryocytic thrombocytopenia and TAR syndrome both present in the neonatal period with an isolated decrease of platelets. A neonatal hematologic presentation is atypical for Fanconi's anemia since less than 5% of patients are diagnosed in the first year of life. Neither of the thrombocytopenic syndromes show chromosome fragility, which readily separates them from Fanconi's anemia. In the TAR syndrome, thumbs are always preserved and intact despite the absence of radii, whereas in Fanconi's anemia the thumbs are hypoplastic or absent when the radii are absent.

Therapy and Prognosis

Because of their clinical complexity, Fanconi's anemia patients should be supervised at a tertiary care center using a comprehensive and multidisciplinary approach. On the initial visit, the following should be performed: a careful physical examination with emphasis on physical anomalies; complete blood counts and chemistries, diepoxybutane (and/or mitomycin C) chromosome fragility testing on peripheral blood lymphocytes on patients and siblings; and, HLA tissue typing on patient and family members. Arrangements should then be made for diagnostic studies to search for any internal anomalies that are described herein. When all of the results are catalogued, a follow-up visit with the family is arranged to discuss management options and prognosis.

It is important to emphasize that the prognosis for patients with Fanconi's anemia is improving. Older literature describing an early demise of Fanconi's patients is flawed because it did not take into account the diversity in clinical and hematological phenotype. A diagnosis can now be made before the onset of serious marrow failure or malignant transformation and survival from the time of diagnosis is longer. Also, the newer forms of management, especially marrow transplantation, have dramatically changed prognosis. Data from the IFAR for the 1980s indicate that Fanconi's patients have a median survival of 25 years of age. [50] Indeed, older female Fanconi's patients can be sexually active; at least 17 patients have become pregnant, resulting in 19 births and 18 surviving children. [51]

If the patient is stable and has only minimal to moderate hematological changes and does not have transfusion requirements, a period of observation is indicated. Blood counts should be monitored every 13 months and bone marrow aspirates and biopsies should be performed annually for morphology and cancer cytogenetics to identify the emergence of a malignant clone or overt transformation to MDS/AML. Depending on the types of congenital anomalies, subspecialty consultations, for example with orthopedic surgery, can be arranged during this interval.

Bone Marrow Transplantation (BMT)

Bone marrow transplantation is currently the only curative therapy for the hematological abnormalities of Fanconi's anemia, and the best donor source is an HLA-matched sibling. Initial efforts to transplant Fanconi's patients using standard preparative regimens and graft-versus-host prophylaxis were plagued by two serious and often lethal problems: severe cytotoxicity to chemotherapy, and exaggerated graft-versus-host disease. BMT protocols were subsequently modified for Fanconi's patients and the outcomes improved substantially.

Gluckman et al. analyzed the data of HLA-identical sibling BMT performed on 151 Fanconi's patients from 42 institutions. [52] The two-year survival rate was 66%. Factors associated with a favorable outcome were younger patient age, higher pre-BMT platelet count, use of antithymocyte globulin, and use of low-dose cyclophosphamide (1525 mg/kg) with limited field irradiation for pre-BMT conditioning, and cyclosporine for graft-versus-host disease prophylaxis.

At the Children's Hospital Medical Center in Cincinnati, 30 Fanconi's patients received matched sibling donor BMT, and the survival rate with normal blood counts was about 85%, with a median follow-up of over three years. [53] The successful Cincinnati protocol is comprised of cyclophosphamide 5 mg/kg/day for four days before transplantation (days 5 to 2), followed by thoracoabdominal irradiation 400 cGy (day 1), with ATG (40 mg/kg days 6, 4, 2, and 20 mg/kg days +2, +4, +6, +8, +10, +12), and cyclosporine for six months after transplant for graft-versus-host disease prophylaxis. If a cytogenetic clone or MDS/AML is identified before BMT, the preparative therapy is escalated to cyclophosphamide 10 mg/kg/day for four days followed by total body irradiation 450 cGy. Methylprednisolone is also added post-BMT, 1 mg/kg/day for 33 days.

Excellent results can also be achieved with conditioning regimens that use a reduced dosage of cyclophosphamide but omit radiation and antithymocyte globulin. [54] The Kaplan-Meier survival estimate with this Seattle protocol was 89% with a median follow-up of 285 days.

Despite the clear-cut success in correcting the marrow failure of Fanconi's anemia with BMT, data from a joint Paris and Seattle study of 79 patients indicate that a subset of survivors will develop secondary cancers, particularly of the head and neck. [55] The occurrence of cancer of the tongue in one such patient illustrates the problem.[56] These malignancies reflect the ongoing genetic susceptibility of host non-hematopoietic tissue to cancer despite successful BMT for marrow failure.

For patients who do not have a matched sibling donor for BMT, a search for a matched unrelated donor can be initiated. Because of the heightened graft-versus-host response observed in Fanconi's patients, the survivals and cure rates have not been as good compared to matched sibling donor BMT. Even when matched unrelated marrow is fully compatible with the recipient at the DNA level (molecular match), these transplants are still problematic. In the analysis by Gluckman et al., [52] the two-year probability of survival for 48 Fanconi's patients transplanted with donor marrow comprised of matched unrelated or alternative related sources was only 29%. In another multicenter report of 49 cases of Fanconi's anemia who received unrelated stem cell transplants, survival was only 43% using HLA-matched marrow and 32% in mismatch recipients.[57]

Because of the increased risks associated with alternative donor marrow, it is not recommended that Fanconi's patients undergo

this type of BMT if their clinical and hematological status is stable. Criteria to proceed with an alternative donor BMT include: (a) failure to respond adequately to androgen therapy and/or cytokine treatment, resulting in an impending need for chronic transfusional support; (b) presence of a persistent cytogenetic clone in bone marrow cells, for example, monosomy 7; and (c) overt malignant transformation to MDS/AML.

Cord blood cells, naturally enriched with hematopoietic stem and progenitor cells, are being increasingly used as a donor source. The first cord blood transplantation was performed in 1988 for a Fanconi's anemia patient using a matched sibling donor. [56] Since then, cord blood collections and transplants have increased quickly for a variety of indications [59] [60] [61] [62] [63] including more Fanconi's anemia patients. [63] Using cord cells from related donors, engraftment in Fanconi's patients was about 78% and the incidence of graft-versus-host disease was reported to be lower than in allogeneic BMT. [63] Recently, cord cells from unrelated donors were transplanted into 5 Fanconi's patients. [64] Some of the donor specimens were mismatched at 1 or 2 loci, yet graft failure was only seen in 1 of the 5 cases, there were no instances of lethal graft-versus-host disease, and event-free-survival beyond day 60 after transplantation was 80% (4 of the 5 cases). To date, of 17 Fanconi's anemia patients who have received unrelated cord blood transplants in the United States, 10 are alive. [53]

Hematopoietic Growth Factors

The potential for recombinant growth factor (cytokine) therapy for Fanconi's anemia has not been fully explored but short-term data thus far are encouraging. An important multicenter clinical trial [65] examined the effect of prolonged administration of G-CSF in 12 Fanconi's patients with neutropenia. The patients were treated with varying subcutaneous dosages daily or every other day for 40 weeks. By week 8 of the study, all patients had an increase in absolute neutrophil numbers and 4 had an increase in platelet counts. Additionally, 4 patients who were not being transfused had a significant increment in hemoglobin levels and a fifth patient lost a transfusion requirement. Concurrent with the impressive improvements in hematology, 8 of 10 patients who finished 40 weeks of G-CSF treatment showed increases in the percentage of marrow and peripheral blood CD34+ cells.

Since genomic instability and a marked predisposition to leukemia and cancer are features of Fanconi's anemia, the wisdom of using a growth-promoting cytokine on a long-term basis for this disorder is a central issue. In the G-CSF study, 1 patient had a marrow clonal cytogenetic abnormality (48 XXY, +14) without MDS or AML at week 40 of treatment. Therapy was stopped and within 3 months the +X, +14 clone disappeared but monosomy 7 appeared in 11% of metaphases and increased over the ensuing months, prompting a bone marrow transplantation. Since monosomy 7 manifested and progressed after G-CSF was stopped, it seems unlikely that G-CSF was involved in the transformation event in this case. Also, the appearance of the +X, +14 clone while the patient was receiving G-CSF treatment and its disappearance when cytokine was discontinued must be put into the context of Fanconi anemia, per se, in which clones, seemingly unstable, are known to manifest and disappear spontaneously. [66] Thus, this pilot study showed overall that G-CSF is probably a safe and effective form of treatment for Fanconi anemia. One patient had a low-grade fever that resolved with dosage modification, and no other untoward clinical effects were noted in any patients.

At one institution, patients without a matched sibling donor who did not have a marrow cytogenetic clone were given combination cytokine therapy consisting of G-CSF 5 g/kg with erythropoietin 50 units/kg administered subcutaneously or intravenously three times a week. [53] Androgen therapy was added if the response was inadequate. Of 20 patients treated, all but 1 had improved neutrophil numbers, 20% achieved a sustained rise in platelets, and 33% had an increase in hemoglobin levels. Although more than half of the responders lost the response after one year due to progression of marrow failure, the requirement for androgen therapy could be delayed by about a year.

Androgens

Androgen therapy has been used to treat Fanconi's anemia for almost four decades. The overall response rate in the literature is about 50% [4] heralded by reticulocytosis and a rise in hemoglobin within 12 months. If the other lineages respond, white cells increase next, followed by platelets, but it may take many months to achieve the maximum response. When the response is deemed maximal, the androgens should be slowly tapered but not stopped entirely.

Oxymetholone, an oral 17- alkylated androgen, is used most frequently at 2 to 5 mg/kg/day with the lower dose preferred initially. Corticosteroids are commonly added to counter the androgen-induced growth acceleration and to prevent thrombocytopenic bleeding by promoting vascular stability. For this purpose, 510 mg of prednisone is given orally every second day. If an injectable androgen is preferred to decrease the risk of liver toxicity, nandrolone decanoate, 1 to 2 mg/kg/week is given intramuscularly followed by suitable pressure and ice packs to prevent hematomas.

Almost all patients relapse when androgens are stopped. Those few who successfully discontinue treatment are often in the puberty age range, when temporary spontaneous hematological remissions have been observed to occur. Many patients on long-term androgens eventually become refractory to therapy as marrow failure progresses. Potential side effects include masculinization, especially troublesome in female patients, and elevated hepatic enzymes, cholestasis, peliosis hepatis, and liver tumors. Those receiving androgens should be evaluated serially with liver chemistry profiles and ultrasonography and/or CT scan of liver.

Future Directions

The premise for gene therapy in Fanconi's anemia is based on the assumption that corrected hematopoietic cells have a growth advantage. Strengthening this supposition are recent descriptions of rare Fanconi's anemia patients who show spontaneous disappearance of cells with the Fanconi's phenotype. These so-called mosaic patients appear to have two populations of leukocytes, one sensitive to mitomycin C and the other with normal resistance to mitomycin C. [19] The phenotypically normal cells appear to have undergone an intragenic mitotic recombination generating one allele with both Fanconi's anemia mutations, whereas the other allele has none (equivalent to a heterozygous carrier). These mosaic patients go into hematologic remission suggesting that hematopoiesis was derived from progenitor cells spontaneously revertant to a normal phenotype.

Preclinical studies using retroviral vectors showed that the FA-C gene and the FA-A gene can be successfully integrated into normal cells and Fanconi's anemia cells. [67] [68] [69] This prompted a clinical trial in 3 FA-C patients. [70] The patients underwent peripheral blood stem cell harvesting and CD34+ cell fractionation following G-CSF administration. The CD34+ cells were admixed with a retrovirus containing the corrected copy of the FA-C gene and the cells were reintroduced into each patient intravenously. The stem cell harvesting and virus transduction were repeated every three months for a total of four procedures. Analysis of the peripheral blood and bone marrow cells demonstrated that the FA-C gene was transferred to a small percentage (0.1%) of the total cells but that various lineages expressed the FA-C gene.

Clinically, one patient had improvement in hemoglobin which increased from a pretreatment level of 89 g/dl to 12

A COMPREHENSIVE PLAN OF MANAGEMENT FOR FANCONI'S ANEMIA

Fanconi's anemia patients become complicated clinically, socially, and psychologically and therefore require a comprehensive multidisciplinary management plan. Ideally, the plan should be initiated in a tertiary care center by a consultant and support staff familiar with the disorder and its nuances. At the first visit, in addition to the detailed clinical, psychosocial, and hematological assessment, chromosome fragility testing should be performed on the patient and siblings using PHA-stimulated peripheral blood lymphocytes with and without added diepoxybutane and/or mitomycin C. HLA tissue typing on the patient and all family members should also be arranged to guide future planning. Imaging and other diagnostic investigations can be planned electively to determine the presence of internal anomalies.

If the hematological changes are mild to moderate and transfusional support is not needed, simple observation is appropriate. Blood counts are checked every 13 months, and marrow aspirates and biopsies performed annually to assess cellularity and morphology, and to obtain cytogenetics on hematopoietic cells. The goal of cytogenetic analysis is to identify the appearance of a malignant clone, or overt transformation to MDS/AML, early.

If transfusional support for red cells and/or platelets is imminent or has already started, further intervention is indicated. Bone marrow transplantation (BMT) is currently the only curative treatment for marrow failure. The results are best when the donor source is an HLA-matched sibling. In this setting, plans for BMT should be activated with the patient's and family's permission. There is nothing to gain by waiting if the patient requires transfusions and has a matched sibling donor. Platelet products should be derived from a single donor source, if possible, and show negative testing for cytomegalovirus.

For patients without a matched sibling donor, a search for an alternative donor source should be initiated after serious and detailed discussion with the family. The term alternative currently encompasses sources from matched unrelated donors, family members other than matched siblings, and umbilical cord cells, related and unrelated, matched and mismatched. Since an alternative donor transplantation is more problematic and has inferior survival data compared to a matched sibling BMT, a decision to go ahead has to be determined for each case by weighing risks and benefits. Criteria to proceed include a failure to respond adequately to androgens and/or cytokine therapy necessitating repeated transfusions, the presence of a persistent clonal cytogenetic abnormality in marrow cells such as monosomy 7, and overt transformation to MDS/AML.

If some form of transplantation is not an option, there are two choices for pharmacologic medical management. Androgen therapy is the historical choice but only affects a marrow response in about 50% of patients and is usually restricted to the erythroid lineage. The penalty is masculinization, which can be very troublesome esthetically in female patients. Oxymetholone is the most widely used oral formulation at doses of 25 mg/kg once a day with preference for the lower dose initially. Prednisone, 510 mg orally once every second day is usually added (but without solid evidence of efficacy) to offset the oxymetholoneinduced growth acceleration, and to stabilize vasculature which may prevent thrombocytopenic bleeding. Because oxymetholone is a 17- alkylated androgen and carries a risk of liver toxicity, a safer but much less popular injectable androgen, nandrolone decanoate, can be given intramuscularly once a week at a dose of 12 mg/kg. Suitable pressure and ice packs must follow the injections to prevent hematomas. When a response to androgens occurs, usually heralded by a rise in hemoglobin within 1 to 2 months, white cells and then platelets may increase but it may take several months to get the fullest response. When the effect is thought to be maximal, the androgen should be slowly tapered to the lowest dose that maintains the response. The androgen should not be stopped completely because almost all patients relapse on discontinuing the drug.

Recombinant growth factor therapy is a new option to androgens and has some advantages. G-CSF, 510 g/kg once a day by subcutaneous injection, will induce a neutrophil response in almost all patients within 48 weeks and has potential to effect a trilineage marrow response. Erythropoietin, 50 units/kg subcutaneously three times a week, can be given additionally but the advantage of this over using G-CSF alone has not been proven. When the effect of G-CSF is judged to be maximal, the schedule can be reduced in some patients to an every second day format with sustained results. The main disadvantage of growth factor therapy is the need for repeated injections. Also, G-CSF probably cannot offset progressive marrow failure indefinitely. However, while the cytokine response is operative, the need to commence androgens can be delayed. There have not been any randomized trials to prove that G-CSF plus androgen treatment is superior to G-CSF alone.

g/dl post-treatment. Although that patient received androgens and G-CSF during the initial period of the trial, both these medications were reduced without affecting blood counts. The other two patients demonstrated variable cell marking at lower levels without significant changes in blood counts.

These results, although crude and preliminary, underscore the potential of a futuristic approach to treating Fanconi's anemia.

Shwachman-Diamond Syndrome

Introduction

This is an inherited disorder of exocrine pancreatic dysfunction with additional features of short stature, variable hematological abnormalities and radiological skeletal changes.[71] [72] [73] The gene responsible for this complex, pleiotropic phenotype is not known and no unifying pathogenesis has been confirmed that can account for all of the multisystem features of the Shwachman-Diamond syndrome. Chromosomes are normal and no increased breakage is seen after clastogenic stress. None of these patients have cystic fibrosis, and sweat chloride levels are normal. Many families have been identified with at least two affected children, and published studies of segregation ratios and family pedigrees support an autosomal recessive mode of inheritance.

Etiology and Pathogenesis

Until the molecular genetics are defined for this syndrome, the pathophysiological link between exocrine pancreatic dysfunction, physical anomalies, and partial to complete marrow failure remains speculative. Copper deficiency in utero is one hypothetical unifying etiology for the various phenotypic manifestations of Shwachman syndrome, but has never been confirmed.[74]

Regarding the neutropenia, an early but informative study of marrow function was performed in which granulopoiesis was analyzed in 10 children from the Toronto series.[75] Marrow proliferative activity was normal, as assessed by determination of mitotic indices and tritiated thymidine uptake into granulocytic cells. Assay of bone marrow CFU-GM progenitors demonstrated normal numbers in four patients and reduced numbers in five. Morphologically, the granulocyte colonies were indistinguishable from normal colonies. Production of colony-stimulating activity from patients' peripheral blood leukocytes appeared normal when tested on control marrow. No serum inhibitors against CFU-GM or colony-stimulating activity could be demonstrated using both control and autologous marrow, and co-culture of patients' peripheral blood lymphocytes with control marrow did not inhibit CFU-GM growth. Thus, in ShwachmanDiamond syndrome, committed granulocytic progenitors were proliferative and their frequency in vitro varied widely, as did the clinical neutropenia. The proliferative activity of mitotic granulocytic cells was normal, and neither a deficiency of humoral stimulators nor the presence of serum or cellular inhibitors of granulopoiesis could be demonstrated. Other investigators in subsequent studies[76] [77] [78] [79] showed decreased CFU-GM and CFU-E compatible with a defective stem cell origin for the marrow failure in Shwachman-Diamond syndrome.

Clinical Manifestations

The many manifestations that occur in varying combinations are shown in Table 18-4 . Pancreatic dysfunction of variable severity is a consistent feature of the syndrome. The pancreatic lesion appears to be due to failure of pancreatic acinar development. Pathologic study reveals extensive fatty replacement of pancreatic acinar tissue and normal ductular architecture. Pancreatic function studies using intravenous secretin and cholecystokinin confirm the presence of markedly impaired enzyme secretion, averaging 1014% of normal, but with preserved ductal function. [80] [81]

The vast majority of patients have symptoms of maldigestion, caused by the pancreatic insufficiency, from birth. The absence of steatorrhea, however, does not exclude a diagnosis of Shwachman-Diamond syndrome. If the syndrome is suspected, a quantitative pancreatic function test should be performed. Alternatively, computed tomography of the pancreas may demonstrate

TABLE 18-4 -- Clinical Features of Shwachman-Diamond Syndrome

Pancreatic	Exocrine pancreatic hypoplasia
Hematologic	Neutropenia (persistent or intermittent)
	Red cell hypoplasia
	Thrombocytopenia
	Pancytopenia
	Elevated fetal hemoglobin
	Myelo-lymphoproliferative diseases
Skeletal	Metaphyseal dysplasia
	Long bone tubulation
	Short or flared ribs
	Thoracic dystrophy
	Clinodactyly
Growth	Short stature (normal growth velocity)
Other	Psychomotor delay
	Renal tubular dysfunction
	Diabetes mellitus
	Dental abnormalities
	Ichthyosis
	Hepatomegaly
	Hirschsprung's disease

fatty changes within the body of the pancreas. A low serum immunoreactive trypsinogen concentration is highly suggestive of severe pancreatic exocrine deficiency. [82] Approximately 50% of patients appear to exhibit a modest improvement in enzyme secretion with advancing age. [81] A number of older patients with Shwachman-Diamond syndrome actually develop pancreatic sufficiency with normal fat absorption when assessed by 72-hour fecal fat balance studies.

The most conspicuous physical findings relate to the pancreatic insufficiency and malabsorption, especially short stature, which is another consistent feature of the syndrome. When treated, most patients show a normal growth velocity, yet remain consistently below the third percentile for height and weight. Some patients have evidence of delayed puberty. The occasional adult achieves the 25th percentile for height.

Skeletal abnormalities are quite variable. Some patients present at birth with thoracic dystrophy, while others have short, flared ribs. Metaphyseal dysostosis of the long bones is a common radiological abnormality and is thought to be quite specific, particularly in the femoral head and the proximal tibia. These changes may not be detectable until after 12 months of age. The etiology of the metaphyseal changes is unclear. In most patients these bony lesions fail to produce any symptoms. However, the integrity of the growth plate may be affected, which in turn may result in skeletal growth disturbances and joint deformities, particularly in the knees and hips.

Additional, less frequent, manifestations felt to be associated with Shwachman-Diamond syndrome include psychomotor delay, hypotonia, massive hepatomegaly, elevated transaminase levels in the absence of hepatomegaly, dental abnormalities, endocardial fibrosis, renal tubular acidosis, and diabetes mellitus.

Laboratory Evaluation

Data from two large institutions have recently been published and probably represent the spectrum of hematologic findings fairly accurately. [81] [83] The combined data from 25 patients in the Toronto series and 21 patients in the London series confirmed that neutropenia is present in virtually all patients on at least one occasion and can be chronic, cyclic or intermittent. It has been identified early in some patients in the neonatal period during an episode of sepsis. Anemia, usually normochromic-normocytic, was recorded in up to 66% of patients, [83] and thrombocytopenia in up to 60%. [81] Fetal hemoglobin was elevated in 80% of patients at some stage during the disease course. [83] Whether this reflects stress hematopoiesis and/or ineffective erythropoiesis concomitant with chronic infections, or reflects MDS in transformation has not been clarified. Reticulocyte responses were inappropriately low for the levels of hemoglobin in 75% of patients. [83]

More than one lineage can be affected, and pancytopenia was observed in up to 44% of cases. [81] The pancytopenia can be severe as a result of full-blown aplastic anemia. However, bone marrow biopsies and aspirates vary widely with respect to cellularity; varying degrees of marrow hypoplasia and fat infiltration are the usual findings, but marrows showing normal or even increased cellularity have also been observed. [81] [83] The severity of neutropenia does not always correlate with bone marrow cellularity, nor is the severity of the pancreatic insufficiency concordant with the hematological abnormalities.

Patients with Shwachman-Diamond syndrome are particularly susceptible to severe infections, including otitis media, bronchopneumonia, osteomyelitis, septicemia, and recurrent furuncles. Overwhelming sepsis is a well-recognized fatal complication of this disorder, particularly early in life. Shwachman-Diamond neutrophils may have a defect in mobility, migration and chemotaxis that does not appear to be caused by malnutrition. [84] [85] [86] In the London series, all 13 patients tested showed

defective chemotaxis. [83] Lithium in some manner appears to restore chemotaxis when used in vitro [87] and in vivo. [88] Alterations in neutrophil cytoskeletal/microtubular function may play a prominent role in causing the defective chemotaxis. [86]

Predisposition to Leukemia

Like some other inherited bone marrow failure disorders, Shwachman-Diamond syndrome predisposes patients to MDS and leukemic transformation. [81] [83] [89] [90] [91] [92] [93] In the London series, [83] MDS developed in seven cases (33%). Five of these patients ultimately evolved into AML (M6 in two, M5 in two, and M2 in one) following a period of MDS (RAEBT in two, RA in two, and RAEB in one). During the MDS phase, five cases had clonal marrow cytogenetic abnormalities, mostly structural changes involving chromosome 7. In the Toronto series, [81] 11 of the 25 patients had pancytopenia and three of these developed AML (12%). In the published literature of 165 patients, [49] nine (5%) developed leukemia (three cases of ALL, two of AML [M2], one M4, one M5, one M6, and one JCML). These sporadic reports in the literature are likely a gross underestimate of the true incidence of malignant transformation judging from the London and Toronto data. Clearly, the propensity for leukemic conversion in Shwachman-Diamond syndrome is extremely high compared with the general population but is probably not as high as in Fanconi's anemia.

A new issue is the occurrence of MDS/AML in Shwachman-Diamond patients while receiving G-CSF therapy for severe neutropenia. In the report of 14 patients with congenital disorders of myelopoiesis who developed MDS/AML (n=13) or a clonal cytogenetic abnormality (n=1) while receiving G-CSF, two of the study group had Shwachman-Diamond syndrome. [93] The concern is that G-CSF therapy may have played a role in the malignant transformation. To date, there is no strong evidence to incriminate the cytokine directly in leukemogenesis (see detailed discussion in Malignant Myeloid Transformation in Kostmann's Syndrome/Congenital Neutropenia in this chapter).

Differential Diagnosis

The syndrome of refractory sideroblastic anemia with vacuolization of bone marrow precursors, or Pearson's syndrome, is clinically similar to Shwachman-Diamond syndrome but very different in bone marrow morphology.[94] [95] [96] [97] [98] [99] [100] [101] [102] [103] Severe anemia requiring transfusions rather than neutropenia is often present at birth and by 1 year of age in all cases. In contrast to Shwachman-Diamond syndrome, the major marrow morphologic findings are ringed sideroblasts with decreased erythroblasts, and prominent vacuolation of erythroid and myeloid precursors.

The disorder shares clinical similarities with Shwachman-Diamond syndrome because of exocrine pancreatic dysfunction in both. Malabsorption and resultant severe failure to thrive occurs in about one-half of cases within the first 12 months of life. Qualitative pancreatic function tests show depressed acinar function and reduced fluid and electrolyte secretion. About 50% of reported cases died early in life from sepsis, acidosis and liver failure; the others appeared to improve spontaneously with reduced transfusion requirements. At autopsy, the pancreas shows acinar cell atrophy and fibrosis; fatty infiltration as seen in Shwachman-Diamond syndrome is not a prominent feature. The need for long-term pancreatic enzyme replacement is unclear. These patients have abnormalities of mitochondrial deoxyribonucleic acid (mtDNA).[99] mtDNA encodes enzymes in the mitochondrial respiratory chain that are relevant to oxidative phosphorylation, including the reduced form of nicotinamide-adenine dinucleotide dehydrogenase (NADH), cytochrome oxidase, and adenosine triphosphatase (ATPase), as well as transfer ribonucleic acids (tRNAs) and ribosomal RNAs.

Shwachman-Diamond syndrome shares some manifestations with Fanconi's anemia such as marrow dysfunction and growth failure, but Shwachman-Diamond patients are readily distinguished because of pancreatic insufficiency with a resultant malabsorption syndrome, fatty changes within the pancreatic body that can be visualized by computed tomography, characteristic skeletal abnormalities not seen in Fanconi's patients, and no increase in chromosome breakage after clastogenic stress testing.

Therapy and Prognosis

Patient management is ideally shared by a hematologist and a gastroenterologist. The malabsorption component of Shwachman-Diamond syndrome responds to treatment with oral pancreatic enzyme replacement. When monitored over time, about 50% of patients convert from pancreatic insufficiency to sufficiency due to spontaneous improvement in pancreatic enzyme secretion.[75] This improvement is particularly evident after 4 years of age.

Growth Factors and Other Strategies

G-CSF has been given for profound neutropenia and has been very effective in inducing a clinically beneficial neutrophil response. [93] [104] [105] [106] [107] In one patient, crossover treatment using G-CSF initially, followed later by GM-CSF demonstrated that both cytokines could effect a neutrophil response. [107] Of nine Shwachman-Diamond patients enrolled in the Severe Chronic Neutropenia International Registry, Seattle, three patients have received G-CSF with good responses lasting from 6 months to more than 6 years (David Dale, MD, personal communication).

Patients have also been treated with corticosteroids with hematologic improvement noted in 6 of 12 patients. [4] A smaller number have received androgens plus steroids in the manner of treating Fanconi's anemia and improved marrow function was also noted. One patient improved on cyclosporin therapy. [108]

Bone Marrow Transplantation

At present, the only definitive therapy for severe marrow failure in Shwachman-Diamond syndrome is allogeneic BMT, although the experience has been very limited. As of 1996, only five patients with this disorder who received a marrow allograft had been reported. [109] [110] [111] [112] [113] The small number of transplanted patients is partly explained because the usual clinical presentation is isolated neutropenia, and if severe it can be successfully managed with antibiotics and growth factor therapy like G-CSF. Transfusional management can also be applied effectively on a long-term basis for patients with advanced bi- and trilineage marrow failure.

A note of caution is sounded regarding BMT for Shwachman-Diamond syndrome. Left ventricular fibrosis and necrosis without coronary arterial lesions have been reported in 50% of Shwachman-Diamond patients at autopsy[114] suggesting that there may be an increased risk of cardiotoxicity with the intensive preparatory chemotherapy used in BMT. Indeed, of two patients who underwent BMT, one died as a result of cardiotoxicity ascribed to cyclophosphamide [110] and the other had significant left ventricular dysfunction throughout the clinical course. [111] A third patient[109] and two others who received transplants in London[83] showed no cardiac dysfunction or cardiotoxicity using comparable conditioning protocols. Although these data are limited, it is recommended that cardiac function be carefully assessed before starting chemotherapy for BMT.

Dyskeratosis Congenita

Introduction

This is an inherited disorder of the mucocutaneous and hematopoietic systems. The diagnostic ectodermal component invariably

consists of the triad of reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy. [115] [116] [117] The skin and nail findings usually become apparent in the first 10 years of life, whereas the oral leukoplakia is seen later. These manifestations tend to progress as patients get older.

Dyskeratosis congenita is also an inherited bone marrow failure syndrome in which aplastic anemia occurs in about 50% of cases, usually in the second decade of life. Patients also have a predisposition to cancer. Because of the cluster of abnormalities involving skin and bone marrow and the predilection to cancer, dyskeratosis congenita resembles Fanconi's anemia. However, the genetics and physical abnormalities of patients with both conditions are quite different and the conditions should be considered as totally discrete entities. Two recent reviews highlight the salient features of dyskeratosis congenita. [118] [119]

The inheritance pattern is somewhat complicated. There are about 225 published cases of dyskeratosis congenita [3] and about 85% of the patients are male, compatible with an X-linked recessive trait. Linkage studies in one large family [120] using X-chromosome-specific restriction fragment length polymorphism markers have assigned a gene for the syndrome to Xq28, a finding confirmed in three additional families. [121] In X-linked families it is possible to identify female carriers using informative Xq28-specific polymorphic probes.

Approximately 15% of cases appear to have another mode of inheritance. Sporadic female cases, familial cases with affected male and female siblings in one generation, and cases with known parental consanguinity fit an autosomal recessive inheritance pattern. An autosomal dominant mode best fits other cases in families with affected male and female members in consecutive generations. Clinically, the autosomal dominant group seems to be milder in its manifestations, and the autosomal recessive group appears to have more physical anomalies and a higher incidence of aplastic anemia and cancer. [118] It seems likely that the dyskeratosis congenita phenotype is due to more than one gene.

Etiology and Pathogenesis

Most studies of the pathogenesis of the aplastic anemia in dyskeratosis congenita have been limited to clonogenic assays. A marked reduction or absence of CFU-GEMM, BFU-E, CFU-E and CFU-GM progenitors has been consistently reported. [26] [27] [122] [123] [124] The absence of a serum inhibitor of CFU-GM was documented in one case, and the absence of T-cell mediated hematopoietic suppression in another case. Although Hanada et al. reported one case of T-cell-mediated suppression of CFU-GM, but not of CFU-E, this effect was not seen after splenectomy or recurrence of the pancytopenia. [125]

Marsh et al.[124] used long-term bone marrow cultures to study hematopoiesis in three patients with dyskeratosis congenita. Two had aplastic anemia and the third had normal blood counts and normal marrow cellularity. Hematopoiesis was severely defective in all three patients with a low frequency of colony-forming cells and a low level of hematopoiesis in long-term cultures. The function of marrow stromal cells was normal in their ability to support growth of hematopoietic progenitors from normal marrow seeded onto them in all 3 cases, but generation of progenitors from patient marrow cells inoculated onto normal stroma was reduced, strongly

suggesting that the defect in dyskeratosis congenita is of stem cell origin.

Thus, the marrow failure in this disorder may be due to a progressive attrition and depletion of hematopoietic stem cells which manifests as pancytopenia when patients are in their mid-teens. Alternatively, the marrow dysfunction may not be a simple consequence of a limited stem cell pool but may represent a failure of replication and/or maturation.

Clinical Manifestations

Clinical manifestations in dyskeratosis congenita often appear during childhood. The skin pigmentation and nail changes typically appear first, mucosal leukoplakia and excessive ocular tearing appear later, and by the mid-teens the serious complications of bone marrow failure and malignancy begin to develop. In rare cases the marrow abnormalities may appear before the skin manifestations. The main causes of death relate either to bone marrow failure or to malignancy. The mean age of death is approximately 30 years.

Cutaneous findings are the most consistent feature of the syndrome. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding. The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next most common finding (Fig. 18-2). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa, especially the tongue (Fig. 18-3) but may also be seen in the conjunctiva, anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases. [126] Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia are seen in approximately 20% of cases.[127] [128] Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, hepatomegaly or cirrhosis, are seen in 10% of cases. [129]

Several physical findings can be used to distinguish Fanconi's anemia from dyskeratosis congenita clinically. The following abnormalities are seen only in patients with dyskeratosis congenita but not Fanconi's patients [49] : nail dystrophy, leukoplakia, teeth abnormalities, hyperhydrosis of palms and soles, and hair loss.

Laboratory Evaluation

About 50% of the X-linked male dyskeratosis congenita patients and 70% of the autosomal recessive patients develop aplastic anemia, usually in the teenage years. It occurs in the autosomal dominant patients as well, but much less frequently. Most of these patients already have manifestations of dyskeratosis congenita, but some younger patients can develop marrow failure before the clinical onset of the mucocutaneous manifestations. The initial hematological change is usually thrombocytopenia or anemia, or both, followed by full-blown pancytopenia caused by aplastic anemia. The red cells are often macrocytic and the fetal hemoglobin can be elevated. Oddly, early bone marrow aspirations and biopsies may be hypercellular; however, with time the cellular elements decline with a symmetrical decrease in all hematopoietic lineages. Ferrokinetic studies at this point are consistent with aplastic anemia.

As summarized by Dokal,[119] there is a large body of contradictory information regarding chromosomal fragility and instability in dyskeratosis congenita. Spontaneous chromosome breaks in patients' lymphocytes were reported in some studies but were not confirmed in others. Similarly, excessive spontaneous and clastogenic-induced sister chromatid exchange in patients' lymphocytes were observed by some investigators but not by others. However, standard clastogenic stress studies of dyskeratosis congenita cells using the DNA alkylating agents

Figure 18-2 Dystrophic nails in dyskeratosis congenita.

mitomycin C and DEB in several laboratories clearly have not shown any difference in chromosome breakage between patients and controls. [130] [131] [132] [133] [134] [135] This contrasts sharply with Fanconi's anemia cells and distinguishes one disorder from the other.

However, Dokal et al. argue strongly that dyskeratosis congenita is, indeed, a chromosome instability disorder of a somewhat different type than Fanconi's anemia. [136] Dokal et al. found that primary skin fibroblasts in culture were not only abnormal in morphology and doubling rate, but in some patients metaphases in peripheral blood cells, marrow cells, and fibroblasts

Figure 18-3 Leukoplakia of the tongue in dyskeratosis congenita.

in culture showed numerous unbalanced chromosome rearrangements such as dicentrics, tricentrics and translocations in the absence of clastogenic agents. These findings were confirmed by other investigators [119] and provide evidence for a defect that predisposes patient cells to developing chromosomal rearrangements.

Predisposition to Cancer

Cancer develops in about 10% of patients, usually in the third and fourth decades of life. In contrast with Fanconi's anemia in which both malignant tumors and MDS/AML are seen, dyskeratosis congenita patients are not predisposed to leukemia but only to solid tumors. Young and Alter have summarized the literature on cancers in 20 patients, including 15 X-linked males, four autosomal recessive cases, and one autosomal dominant patient. [137] Most of the cancers were squamous cell carcinoma or adenocarcinomas, and the oropharynx and gastrointestinal tract were involved most frequently. One patient had three separate primaries in the tongue, nasopharynx, and rectum, one had esophageal and cheek carcinomas, and one had separate nasal and tongue malignancies. Thus, the sites of most of the cancers involve areas known to be abnormal in dyskeratosis congenita such as mucous membranes and gastrointestinal tract.

Therapy and Prognosis

Management of aplastic anemia is similar to that for Fanconi's anemia. Androgens, usually combined with low-dose prednisone, can be expected to induce improved marrow function in about 50% of patients. If a response is seen and deemed to be maximal, the androgen dose can be slowly tapered but not stopped. As in Fanconi's anemia, patients can become refractory to androgens as the aplastic anemia progresses. There is no published information on the use of immunosuppressive therapy for this disorder.

Other Treatment Options

As recently summarized,[138] 16 patients with dyskeratosis congenita worldwide have been reported who received allogeneic BMT for marrow failure. [138] [139] [140] [141] [142] [143] [144] [145] Eight patients were less than 11 years of age at the time of the procedure; the others were in their twenties and thirties. All received cyclophosphamide-based preparative regimens with or without irradiation. The results were remarkably poor; only 3 of the 16 were alive and appeared cured by BMT, at 8 months, 15 months, and 5 years post-BMT, respectively. The others died of early, transplant-related complications or, notably, of very late complications. Lethal pulmonary fibrosis in four patients and renal failure in two others occurred years after BMT. Gluckman et al. [146] suggested that the epithelial and endothelial cells of these patients might be abnormally sensitive to the preconditioning agents without any relation to chromosomal fragility. This sensitivity may be reflected by raised von Willebrand factor levels in patients' plasma. [119] Gluckman et al. reported two dyskeratosis congenita patients treated with BMT who developed diffuse vasculitis

caused by endothelial activation several years after BMT. [146] Their renal histology at postmortem showed similar lesions characterized by alteration of the capillary walls of glomeruli, mesangiolysis, arteriolonecrosis, and occasional arteriolar luminal fibrosis.

Thus, judging from available information, strong endorsement cannot be made for BMT in dyskeratosis congenita, although there is usually no other recourse for life-threatening aplastic anemia. Perhaps modified conditioning similar to that used for Fanconi's anemia will ensure a safer procedure and a more optimistic outcome.

Three patients were reported who responded to G-CSF therapy with significant increases in absolute neutrophil counts. [147] [148] [149] Similarly, two other patients received GM-CSF therapy, which resulted in improved neutrophil numbers. [150] [151] G-CSF with erythropoietin resulted in a trilineage hematologic response in one patient.[3] Stem cell factor increased the in vitro growth of erythroid progenitors in some patients with dyskeratosis congenita [152] but it has not yet been used clinically. Although the reports are scanty, cytokine therapy appears to offer potential benefit, at least in the short-term, especially for improving granulopoiesis.

In the X-linked form of dyskeratosis congenita, the assignment of a gene to Xq28, and the availability of most of this region as contiguous yeast artificial chromosomes may facilitate positional cloning of the gene. Although this raises hope for gene therapy in the future, the prospects are not imminent.

Amegakaryocytic Thrombocytopenia

Introduction

Amegakaryocytic thrombocytopenia, or congenital amegakaryocytic thrombocytopenia (CAT) is a syndrome that presents in infancy with isolated thrombocytopenia due to reduced or absent marrow megakaryocytes with preservation initially of granulopoietic and erythroid lineages. Aplastic anemia subsequently ensues in about 45% of patients, usually in the first few years of life. The diagnosis depends on the exclusion of all other specific causes for thrombocytopenia in early life. Although most cases are sporadic, familial cases also occur and the syndrome is felt to be an inherited bone marrow failure disorder. Peripheral blood chromosomes do not show increased fragility, which distinguishes CAT from Fanconi's anemia.

Of reported cases, male cases outnumber female, suggesting that some cases may be X-linked and that others may have an autosomal recessive mode of inheritance. Examples of male-only affected sibships as well as mixed male-female affected sibships are reviewed by Alter. [49]

Etiology and Pathogenesis

Serial studies of bone marrow hematopoiesis using clonogenic assays were performed in an infant from Toronto with CAT. [153] Initially, when the only hematological abnormality was isolated thrombocytopenia, the number of clonogenic hematopoietic progenitors was comparable to controls, including the number of megakaryocyte precursors (CFU-Meg). As the disease evolved into aplastic anemia over an 11-month period, the peripheral blood counts declined, and colony numbers from four classes of progenitors also declined in parallel. When added to the marrow cultures, the patient's plasma was not inhibitory to control or to patient's colony growth. Similarly, no cellular inhibition of hematopoiesis was observed when the patient's marrow was cultured after depleting the sample of T lymphocytes or after adding them back. Furthermore, stromal cells established in short-term and long-term cultures of the patient's marrow showed normal proliferative activity and yielded a fertile marrow microenvironment for patient's and control colony growth. The data suggest that the central problem in CAT is an intrinsic hematopoietic stem cell defect rather than an abnormality of the marrow milieu. The findings are consistent with either a progressive, quantitative attrition of progenitors or their inability to proliferate into colonies in vitro and into differentiated, functional cells in vivo.

Guinan et al.[154] produced data that demonstrated assayable numbers of CFU-Meg progenitors in vitro from 5 patients with CAT in response to IL-3, GM-CSF or the combination of both. The presence of megakaryocyte progenitors in these patients fits

with the data from the Toronto patient when studied early in the course of the disease. [153]

Muraoka et al.[155] examined the effect of recombinant human thrombopoietin on CFU-meg colony formation from a patient with CAT and demonstrated a defective response. The patient's serum thrombopoietin level was significantly elevated compared to controls, and the patient's marrow cells did not express mRNA for c-mpl, the thrombopoietin receptor. The pathophysiology of CAT in this case appeared to be directly attributable to these findings.

Clinical Manifestations

Almost all patients present with a petechial rash, bruising, or bleeding in the first year of life. Most cases are obvious at birth or within the first 2 months. Roughly half of the patients have characteristic physical anomalies, although the others have normal physical and imaging features. Some affected sibships manifest both normal and abnormal physical findings in the same family. As in Fanconi's anemia, CAT patients with and without anomalies should be considered as part of the clinical spectrum of one entity.

The commonest manifestations in those with anomalies are neurologic and cardiac. Findings related to cerebellar and cerebral atrophy are a recurrent theme and developmental delay is a prominent feature in this group. Patients may also have microcephaly and an abnormal facies. Congenital heart disease with a variety of malformations can be detected, including atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these can occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate.

Laboratory Evaluation

Thrombocytopenia is the major laboratory finding with normal hemoglobin levels and white blood cell counts initially. Although there are usually measurable, albeit reduced, numbers of platelets, peripheral blood platelets may be totally absent. Similar to other inherited bone marrow failure syndromes, red cells may be macrocytic. Hb F can be increased and there may be increased expression of i antigen. Bone marrow specimens show normal cellularity with markedly reduced or absent megakaryocytes. In patients who develop aplastic anemia, marrow cellularity is decreased with fatty replacement; the erythroid and granulopoietic lineages are also symmetrically reduced.

Predisposition to Leukemia

Alter described two patients with CAT who developed leukemia. [49] One male with a normal physical appearance had amegakaryocytic thrombocytopenia from day 1 of life, developed aplastic anemia at 5 years of age, responded poorly to androgens and steroids, and then evolved into AMML at age 16 with death at age 17. A female had thrombocytopenia at 2 months of age, pancytopenia at 5 months, and thereafter developed a preleukemic picture with clonal abnormalities involving chromosome 19. The Toronto patient described herein had thrombocytopenia at 6 months of age, developed progressive aplastic anemia over the next 2 years, acquired monosomy 7 in marrow cells at 5 years of age, and then evolved into MDS with an activating ras oncogene mutation in hematopoietic cells. [153] Hence, the current evidence shows that CAT is another inherited marrow failure disorder that is preleukemic. The risk or incidence of malignant conversion is difficult to determine because of the rarity of the disease and paucity of published data dealing with this issue.

Therapy and Prognosis

Historically, treatment has been unsatisfactory and the mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or from malignant myeloid transformation has been very close to 100%. For that reason, HLA typing of family members should be performed as soon as the diagnosis is confirmed to see if a matched related donor for BMT exists. If not, a search for a matched unrelated donor should ensue as soon as the seriousness of the clinical picture dictates. The need for transfusional support is a cogent indication.

Platelet transfusions should be used discretely. Platelet numbers should not be a sole indication; clinical bleeding is a more appropriate trigger for the use of platelets. Single-donor platelets are preferred to multiple unfiltered random donor platelets in order to minimize sensitization, and if BMT is a realistic possibility all blood

products should be negative in testing for cytomegalovirus.

Corticosteroids have been used for thrombocytopenia with no apparent efficacy. For aplastic anemia, androgens in combination with corticosteroids may induce a temporary partial response but the effect is short-lived and does not prevent mortality.

Based on the in vitro augmentation of megakaryocyte progenitor colony growth in response to IL-3, GM-CSF or both, a phase I/II clinical trial was initiated for five patients with CAT.[154] IL-3 but not GM-CSF resulted in improved platelet counts in two patients, and decreased bleeding and transfusion requirements in the other three. GM-CSF had no observable benefit when given after IL-3 pretreatment. Prolonged IL-3 administration in two additional patients also resulted in platelet increments. This pilot study illustrates that IL-3 may be an important adjunct to the medical management of CAT. Thrombopoietin has not been tried yet for the treatment of CAT.

There is curative potential using BMT. In the original Toronto series of patients with inherited marrow failure studied by clonogenic assays, [26] [27] [156] a case of familial CAT in the aplastic anemia phase received a BMT from his sister in 1974 and is currently alive and cured. More recently, two infants of 22 and 42 months of age, respectively, underwent allogeneic BMT, one of them with an unrelated donor marrow.[157] Both patients were well with good engraftment of donor marrow and normal blood counts at 12 and 31 months after BMT, respectively.

An additional male patient with familial CAT who had a robust response to IL-3 initially and then later to the IL-3:GM-CSF fusion product underwent a matched unrelated BMT when he became refractory to cytokine therapy. He appeared cured 1 year after BMT (Laurence Boxer, MD, personal communication, 1997). The Toronto patient described in the Etiology and Pathogenesis and Predisposition to Leukemia sections received a one antigen mismatched T-cell depleted unrelated donor BMT in desperation because of clinical deterioration. Engraftment ensued readily but the patient died several months after BMT from complications of grade IV graft-versus-host disease (unpublished data). Despite this negative experience, the other successful BMTs described here illustrate the potential for cure by the procedure.

OTHER GENETIC SYNDROMES

Bone marrow failure can occur in the context of several specific non-hematological syndromes, and also in familial settings that do not exactly correspond with the entities already described.

Down Syndrome

Down syndrome, or trisomy 21, has a unique association with aberrant hematology. Three seemingly related events can occur.

---

[158] In the neonatal period, a myeloproliferative blood picture with large numbers of circulating blast cells has been observed in many of these infants. The blasts apparently are clonal but, remarkably, disappear spontaneously over several weeks in most cases. The term transient leukemia is often used to reflect this unusual natural history.

Second, in about 20% of cases, true leukemia recurs and requires oncologic management. Acute lymphoblastic and myeloblastic leukemias are both seen in Down's syndrome, and acute megakaryoblastic leukemia (M7) is the most common form of the myeloblastic leukemias. It has been estimated that the incidence of M7 is 500 times greater in children with Down's syndrome than in normal children. [158] Third, the onset of M7 is frequently preceded by an interval of MDS characterized by thrombocytopenia, abnormal megakaryocytopoiesis, megakaryoblasts in the marrow, and an abnormal karyotype, commonly trisomy 8. [159] In addition to the propensity for leukemia, a few patients have been reported with aplastic anemia. Alter has summarized five of these cases, three of whom died of marrow failure and two who responded to androgen therapy. [49]

Dubowitz's Syndrome

This is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. [160] This is a rare disorder and incidence rates for complications are difficult to establish; however, as reviewed recently, there appears to be a predilection to cancer as well as to bone marrow dysfunction in patients with Dubowitz's syndrome. [161] Patients have developed ALL, AML, neuroblastoma, and lymphoma. [161] [162] [163] About 10% of patients also develop hematopoietic disorders varying from hypoplastic anemia, moderate pancytopenia, and full-blown aplastic anemia. [161] [164]

Seckel's Syndrome

Sometimes called bird-headed dwarfs, patients with this autosomal recessive developmental disorder have marked growth failure and mental deficiency, microcephaly, a hypoplastic face with a prominent nose, and low-set and/or malformed ears. [165] These patients can be distinguished from those with Fanconi's anemia on the basis of a negative DEB clastogenic chromosome stress test. About 10% of cases develop aplastic anemia, usually severe. [166] [167] [168]

Reticular Dysgenesis

This is an immunologic deficiency syndrome coupled with congenital agranulocytosis. [169] The mode of inheritance is probably autosomal recessive but an X-linked mode is also possible in some cases. The disorder is a variant of severe combined immune deficiency (SCID) in which cellular and humoral immunity are absent and patients also have severe lymphopenia and neutropenia. Because of profoundly compromised immunity, the syndrome presents early with severe infection at birth or shortly thereafter. A striking feature is absent lymph nodes and tonsils, and an absent thymic shadow on radiograph. In addition to lymphopenia and neutropenia, anemia and thrombocytopenia may be present. Bone marrow specimens are hypocellular with markedly reduced myeloid and lymphoid elements. Clonogenic assays of hematopoietic progenitors consistently show reduced to absent colony growth, indicating that the disorder has its origins at the pluripotential lympho-hematopoietic stem cell level. [170] [171] [172] [173] The only curative therapy is BMT. [172]

Familial Aplastic Anemia

Bone marrow failure can cluster in families, but many of these cases cannot be readily classified into discrete diagnostic entities such as Fanconi's anemia. The phenotype of these conditions can be complex, with varying combinations of hematologic abnormalities, immunologic deficiency, physical malformations, and development of leukemia. One approach to nosology is to divide the disorders into inheritance patterns, and then subdivide them into those with and without physical anomalies. [4]

Some families show an autosomal dominant mode of inheritance of marrow dysfunction associated with physical anomalies. The *WT syndrome* is characterized by successive generations of affected family members who have radial-ulnar hypoplasia, abnormal thumbs, short fingers, and fifth finger clinodactyly. [174] Pancytopenia or thrombocytopenia, sometimes with leukemia, occurs in some of the affected. The *IVIC syndrome* [175] or *oculo-otoradial syndrome* [176] manifests with radial ray hypoplasia, absent thumbs or hypoplastic radial carpal bones, impaired hearing, strabismus, and sometimes imperforate anus. Mild thrombocytopenia is seen in about 50% of cases. The *ataxia-pancytopenia syndrome* is a combination of cerebellar atrophy and ataxia associated in affected family members with varied manifestations of anemia, aplastic anemia, MDS, AML, monosomy 7 in marrow cells, and immune deficiency. [177] [178] Other autosomal dominant syndromes with anomalies include: a family with marrow failure, ALL, skin pigmentation, warts, immune dysfunction and multiple spontaneous abortions; [179] successive generations of family members with unilineage cytopenia or pancytopenia with vascular occlusions; [180] and, proximal fusion of the radius and ulna, and aplastic anemia or leukemia. [181]

Autosomal recessive inheritance of anomalies and marrow dysfunction also occurs. Consanguinity can result in a syndrome of microcephaly, mental retardation, skin pigmentation, short stature, and pancytopenia, possibly with a clonal cytogenetic marker in bone marrow cells. [182] A second example of this inheritance mode presents with central nervous system anomalies, such as the Dandy-Walker syndrome or ventricular dilatation and asymmetry, and aplastic anemia. [183]

Autosomal dominant inheritance of a wide-ranging pattern of disordered marrow function can be seen without physical anomalies. Successive generations have been described with the following: acquired aplastic anemia in 4 families comprised of 9 patients, with an affected parent, aunt or uncle [184] ; aplastic anemia in a mother and neutropenia and thrombocytopenia in her offspring [185] ; aplastic anemia, AML and monosomy 7 in various family members [186] ; and hypoplastic anemia in a parent and offspring with either myelofibrosis, AML, MDS, or pancytopenia, all associated with the acquired Pelger-Huet anomaly. [187]

Marrow dysfunction can also be inherited without anomalies in an autosomal recessive pattern. One example encompasses pancytopenia, immune deficiency, multiple cutaneous basal cell and squamous cell carcinomas, oral telangiectasias, and neck and chest poikiloderma. [188] Another pattern includes immune deficiency, pure red cell aplasia and/or neutropenia, and unusual crystalloid structures seen by electron microscopy in neutrophils. [189]

An X-linked inheritance is suggested by a syndrome affecting males in successive generations with one or more of pancytopenia, AML, ALL, and light chain disease but without physical anomalies.[190]

Laboratory Evaluation

These genetic disorders are very heterogeneous clinically and hematologically and only generic descriptives can be used in their characterization. These patients have variable manifestations

of cytopenia involving one or more hematopoietic lineages, usually with hypocellular marrows. In the familial syndromes, additional findings such as physical malformations, immunologic deficiency, and marrow cytogenetic markers such as monosomy 7 distinguish them from cases of sporadic acquired bone marrow failure. Patients' marrows generally show reduced numbers of hematopoietic progenitors in clonogenic assays but this is common to almost all marrow failure disorders and does not distinguish genetic and familial cases from acquired aplastic anemia.

Therapy

Because these disorders are rare, broad conclusions about management are difficult to formulate. For full-blown aplastic anemia with a hypocellular, fatty marrow, curative therapy with BMT if a matched donor is identified remains the first choice. In the familial cases, potential marrow donors must be thoroughly assessed clinically, hematologically and by marrow morphology, clonogenic activity, and cytogenetics to ensure that latent or masked marrow dysfunction is not present. If a matched donor is not available, principles of medical management used for Fanconi's anemia and for acquired aplastic anemia should be used.

UNILINEAGE CYTOPENIAS

Diamond-Blackfan Anemia

Introduction

Diamond-Blackfan anemia (DBA), or congenital hypoplastic anemia, is a constitutional form of pure red cell aplasia. [191] The syndrome is heterogeneous with respect to inheritance patterns, clinical and laboratory findings, in vitro data, and therapeutic outcome. About 80% of cases are sporadic, suggesting new mutations or acquired disease, but there are examples of recessive inheritance (autosomal and possibly X-linked), as well as autosomal dominant patterns. [192] There is suspicion that DBA represents a family of disorders with different etiologies that share the common hematological phenotype of pure red cell aplasia. Based on data from the DBA registries in France[193] and in the United Kingdom,[194] the suspected incidence of the disorder in Europe is 5 to 7 cases per million live births.

The uniform diagnostic criteria for all cases are: (1) normochromic-macrocytic anemia presenting in 90% of cases in the first 12 months of life; (2) profound reticulocytopenia; (3) normocellular marrow with a selective, marked deficiency of red cell precursors; (4) increased serum levels of erythropoietin; (5) normal or slightly decreased white cell counts; and (6) normal or increased platelet counts. Fetal hemoglobin is usually increased with a fetal G/A pattern, is distributed heterogeneously, and is associated with increased expression of red cell i antigen as well as with fetal levels of red cell glycolytic and hexose monophosphate shunt enzyme activities.

Biologic and Molecular Aspects

Most cases of DBA are sporadic. In contrast with Fanconi's anemia, cytogenetic findings are usually normal, although morphologic alterations of chromosomes 1 and 16 have been reported in a few children. [195] [196] A significant proportion of patients, as many as 1020%, have a family history suggestive of a genetic disorder. Out of 21 patients in the Toronto series, 3 presented clear evidence of familial transmission of the disease. [192] Three of four sisters were affected in one family; an affected father and his son were found in another family; and there was an affected mother and her son in the third family. In addition, occasional histories were revealed of anemia in one or both parents of 5 other patients. Although this could not be documented in most cases, bone marrow examination of one mother who was slightly anemic revealed a reduced number of erythroid precursors (7%), which was suggestive of a mild form of DBA. Autosomal recessive transmission is postulated in families in which there is consanguinity, presence of several affected children, or both. Autosomal dominant inheritance is assumed in those kindreds in which cases of DBA have been documented in two or more successive generations.

Sporadic and familial cases do not differ by clinical criteria. Long-term demographic analysis on a large number of families has been hampered by several factors including the rarity of the syndrome, its relatively recent description, its historically fatal outcome, and the limited number of successive generations available for study. Whether the variable pattern of inheritance observed in pedigrees of DBA reflects different genetic determinants of the disease is still uncertain, but there has been progress in the search for the DBA gene.[197] A female patient was identified with a translocation involving 19q. Linkage analysis with chromosome 19 microsatellite markers in DBA families revealed significant linkage to 19q13 for both dominant and recessive modes of DBA inheritance. Within this region, a submicroscopic de novo deletion of 3.3 Mb was identified in a DBA patient. The deletion coincides with the translocation breakpoint and together with key recombinations restricts the putative DBA gene to a 1.8 Mb region. The results suggest that despite its clinical heterogeneity, DBA is genetically homogeneous for a gene in 19q13.

Etiology and Pathogenesis

The cellular basis for most cases of DBA is becoming much clearer due to improved cell fractionation techniques, chemically defined tissue culture medium, recombinant growth factors, and molecular technology. Initial reports [198] [199] [200] [201] [202] [203] of humoral, cellular, or microenvironmental inhibitors of erythropoiesis in DBA could not be confirmed.[192] [204] [205] [206] [207] [208] [209] [210] [211] [212] Claims for immune-mediated erythroid suppression in DBA would need to satisfy these strict criteria: patients must be newly diagnosed, untreated, and not previously transfused; the in vitro testing system must be completely autologous using only patient cells and serum; and any degree of inhibition must be totally selective for the erythroid lineage. Since almost none of the reports met these criteria, the notion of an immune pathogenesis of DBA shifted to alternate possibilities.

A large body of evidence indicates that the erythroid progenitor compartment is intrinsically defective in DBA. [194] [204] [205] [206] [207] [208] [209] [210] [211] [212] Cultures of DBA marrow using standard clonogenic assays for CFU-E and BFU-E progenitors consistently have shown reduced or absent colonies in most DBA patients, and intermediate, normal, or occasionally increased numbers in the rest. The DBA erythroid progenitors are relatively insensitive to EPO in vitro [209] and to burst-promoting activity,[213] but the hyporesponsiveness to EPO can be corrected in some cases by the addition of glucocorticoids in vitro [214] or by clinically administering prednisone.[215]

The data underscore the fact that the intrinsic defect of DBA erythroid progenitors is an inability to respond normally to inducers of erythroid proliferation and/or differentiation. Confirmation of the overall defect was demonstrated by Bagnara et al. who showed that CD34+ DBA progenitors differentiated normally along megakaryocytic and granulocytic pathways but aberrantly along the erythroid lineage. [216] Accelerated programmed cell death (apoptosis) may play a role in this pathogenesis.[217] Based on the various patterns of erythroid colony growth seen with DBA patients, a model [192] for the aberrant erythropoiesis was developed that proposes maturational arrests at varying sites along the differentiation pathway.

Studies indicate that recombinant interleukin-3 (IL-3) [218] and Steel factor (SCF) in combination with EPO[219] [220] [221] may increase

the in vitro clonogenicity of DBA bone marrow progenitors from unfractionated cell preparations. Halperin et al. reported that the size and number of DBA BFU-E colonies were dramatically increased by adding IL-3 to the cultures, [218] and Abkowitz et al.[219] showed a growth response of BFU-E from 4 patients to SCF alone or in combination with IL-3, GM-CSF, or conditioned media. Bagnara et al. [216] described a lack of response of enriched CD34+ progenitors to IL-3, GM-CSF and erythroid potentiating activity (EPA) in 10 DBA patients, but SCF in combination with IL-3 promoted BFU-E colony growth in 3 patients. Olivieri et al. [220] observed heterogeneity in vitro in 10 patients with normal, intermediate or absent responses to SCF. Alter et al. [221] found that 15 of 16 DBA marrow cultures had increased erythropoiesis, often to normal levels, in the presence of SCF compared to cultures lacking SCF. The human ligand for flt-3 apparently has no effect on DBA marrow colony growth. However, addition of IL-9 to SCF, IL-3 and EPO does potentiate DBA BFU-E growth. [222]

Casadevall et al. discovered that there are significant age-related changes in erythroid and granulopoietic progenitors in a large series of DBA patients. [223] Despite profound anemia, 7 of 10 patients studied within 1 year of diagnosis had normal numbers of CFU-E and BFU-E that showed a normal response to cytokines. In contrast, 12 of 14 patients followed for more than 3 years had decreased erythroid progenitors and, in 7 cases, decreased CFU-GM. The data are consistent with the idea that the DBA defect involves a pluripotent progenitor and worsens with time.

Strong support for this conclusion comes from a detailed study that examined the interaction between DBA CD34+ cells and the hematopoietic microenvironment using long-term bone marrow cultures.[224] Stromal adherent layers from DBA patients did not show evidence of any morphological, phenotypic, or functional abnormality and the stroma sustained the proliferation of normal control CD34+ cells. A major finding in this study was an impaired capacity of DBA CD34+ cells in the presence of normal stromal cells to proliferate and differentiate along not only the erythroid pathway but also along the granulocytic-macrophage pathway. These results indicate an intrinsic defect of a hematopoietic progenitor with at least bi-lineage potential that places it earlier than previously suspected and which was only unmasked by testing in long-term cultures. The findings broaden the definition of DBA and can explain some generalized hematological abnormalities and marrow dysfunction in DBA that have puzzled investigators for years.

These in vitro findings raised speculation that DBA is due to one or more receptor-ligand abnormalities involving various growth-promoting cytokines such as EPO, IL-3 and SCF. Thus far, studies have failed to identify any of these putative abnormalities. DBA lymphocytes produce high levels of IL-3, DBA marrow stromal cells express mRNA for SCF, and DBA patients have measurable serum levels of SCF and have SCF receptors on marrow cells.[225] Moreover, molecular studies have not disclosed mutations in genes for c-kit (SCF receptor) or SCF.[226] [227] [228] Thus, a revised hypothesis is that an intracellular defect exists in signal transduction or in a transcription factor acting early in differentiation. Such anomalies could account for the increased tendency of DBA erythroid progenitors to undergo apoptosis upon EPO deprivation in vitro.[217] A role for induction of apoptosis by the fas-fas ligand system in DBA was also recently suggested because of elevated serum soluble fas ligand in patients compared to controls.[229]

Clinical Manifestations

Aside from findings associated with anemia, about one-half of infants at presentation look healthy otherwise and normal physically. Unless the patient develops cardiac failure as a result of anemia, hepatosplenomegaly and edema are absent.

Both sexes are equally affected. Although the majority of reported patients are white, DBA has been recognized in several ethnic groups, including African Blacks, Arabs, East Indians, and Japanese. Pregnancy, birth history, or both are often abnormal. There is a slightly higher incidence of previous stillbirths or miscarriages among patients' mothers than in the general population. Approximately 10% of the mothers present with obstetrical complications, such as preeclampsia, premature separation of the placenta, or breech presentation. Intrauterine growth retardation has been found in more than 10% of reported patients.

Approximately 50% of the patients present with one or more congenital defects.[193] [194] Most of these phenotypic abnormalities belong to the following categories: (a) craniofacial dysmorphism, including hypertelorism, microcephaly, microphthalmos, congenital cataract or glaucoma, strabismus, microretrognathism, and a high-arched palate or cleft palate; (b) prenatal or postnatal growth failure, independent of steroid therapy; (c) neck anomalies; these may consist of a pterygium coli, or the fusion of cervical vertebrae with flaring of the trapezius muscle (Klippel-Feil syndrome) giving a Turner's syndrome appearance; there may also be the Sprengel deformity (congenital elevation of the scapula) as an isolated anomaly, or a combination of the two anomalies; and (d) thumb malformations, such as bifid thumb (Fig. 18-4), duplication, subluxation, hypoplasia, or absence of the thumb. The characteristic association of triphalangeal thumbs with congenital red cell aplasia has been described in a dozen patients (Fig. 18-5). Although often referred to as Aase syndrome or Aase-Smith syndrome, [230] [231] [232] [233] [234] this entity clearly belongs within the clinicohematologic framework of

Figure 18-4 Bifid thumb in Diamond-Blackfan anemia.

Figure 18-5 Radiograph of a triphalangeal thumb in Diamond-Blackfan anemia.

DBA. In addition, some patients have a flat, hypoplastic thenar eminence, weak or absent radial pulses, or both, which probably represent variations of the thumb malformations.

Some patients have a characteristic facial appearance. The facies of DBA is said to consist of tow-colored hair, snub nose, wide set eyes, thick upper lip, and an intelligent expression. Another facies[192] observed in two unrelated girls of markedly different ancestries consists of small heads, almond-shaped eyes with a slight antimongoloid slant, a carp-like smile, and pointed chins. These patients resemble each other more than they resemble their own family members (Figs. 18-6 A and 18-6 B).

Various other anomalies are occasionally reported in association with DBA. There may be urogenital malformations, such as dysplastic or horseshoe kidneys, duplication of ureters, or renal tubular acidosis. There may also be congenital heart disease, mainly ventricular and atrial septal defects, or hypogonadism, ear malformations, mental retardation, congenital hip dislocation, cartilage-hair hypoplasia with T-cell dysfunction, or tracheoesophageal fistula.

Laboratory Evaluation

The main hematological findings in DBA are summarized in Table 18-5 . The anemia is usually profound at the time of diagnosis. Hemoglobin levels average 6.5 g/dl in patients diagnosed in the first 2 months of life (range of 1.79.1 g/dl) and 4.0 g/dl (range of 1.87.4 g/dl) in those diagnosed later. Macrocytosis is seen in the vast majority of patients, the mean corpuscular volume (MCV) being above the expected values for age. The peripheral blood smear may show, in addition to macrocytes, a mild degree of anisocytosis and poikilocytosis, but these findings are not specific. The aregenerative component of the anemia is reflected by the absence of both polychromasia and nucleated red cells on the blood film. Decreased red cell production is confirmed by absence of a reticulocyte response and by characteristic findings on bone marrow examination.

In over 90% of the patients, the bone marrow aspirate is normocellular, but erythroblasts are markedly decreased or absent.

Figure 18-6 Similar Diamond-Blackfan facies in two unrelated girls of different ancestries consisting of a small head, almond-shaped eyes with slight antimongoloid slant, a carp-like smile, and a pointed chin.

TABLE 18-5 -- Hematological Features of Diamond-Blackfan Anemia at Diagnosis

Hematological Parameters	Findings in DBA
Mean (range)	
Hemoglobin value	

Newborns under 2 months of age[a]	6.5 g/dl (range of 1.79.1 g/dl)
Children 2 months of age or older[a]	4.0 g/dl (range of 1.87.4 g/dl)
Mean corpuscular volume (MCV)	Usually increased for age
Reticulocytes	Markedly decreased (<1%)
White cell count	Normal or slightly decreased
Platelet count	Normal or increased
Fetal hemoglobin	Increased (>5% after 6 months of age)
Red cell i antigen	Expression increased beyond first year of life
Red cell enzymes	Fetal pattern
Red cell adenosine deaminase activity	Elevated in 4090% of cases
Bone marrow morphology	
In >90% of cases	Marked reduction or absence of erythroid precursors
In 510% of cases	Slightly reduced or normal number of proerythroblasts with or without maturation arrest
In all patients	Normal cellularity; normal myeloid and megakaryocytic lineages

[a]Toronto series (n = 21).

Proerythroblasts, if present, account for less than 3% of all nucleated elements, with a myeloid to erythroid ratio of >10:1. In 510% of cases, proerythroblasts may be present in normal numbers, with or without a maturation arrest. The other cell lines are normal. White cell counts and platelet counts are usually normal at diagnosis but platelets may be increased and with normal function.[235] Mild to moderate neutropenia, thrombocytopenia, or both may occur later in the course of the disease, particularly in multitransfused patients who have hemosiderosis and secondary hypersplenism. Progression of the single-lineage erythroid deficiency of DBA into pancytopenia and severe aplastic anemia is rare but occurs.[194] [236] In the Toronto series,[192] one patient met all criteria for DBA during the first 2 years of life. This child later developed severe aplastic anemia and succumbed at 3½ years of age after two unsuccessful attempts at bone marrow transplantation.

Erythrocytes in DBA express a number of fetal characteristics.[237] The level of hemoglobin F (Hb F) is increased persistently, even during remission. It remains at a level of 510% after the age of 6 months and has a heterogeneous distribution in red cells. The HbF has a specifically fetal amino-acid profile, with a high glycine to alanine ratio (G to A). Similarly, the i antigen, which normally disappears from the erythrocyte surface by 1 year of age, is expressed at near fetal levels in older patients with DBA. The i antigen, however, can be detected simultaneously at normal adult levels.

The precise cause of this fetal-like erythropoiesis still requires clarification.[238] [239] It is clearly distinct from the fetal erythropoiesis implicated in various types of leukemia, notably in juvenile chronic myelogenous leukemia, in which the fetal red cells presumably arise from the leukemic clone. The situation in DBA may be analogous to that in other forms of bone marrow failure and in the hematological recovery phase following bone marrow transplantation.[238] In all of these conditions, the fetal (or stress) erythropoiesis may represent an accelerated recapitulation of red cell ontogeny in the face of an increased demand for new red cells in peripheral blood.

Red cell enzymes often display an abnormal pattern of activity.[240] Enzymes, such as enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, or glutathione peroxidase have increased activity in patients with DBA compared to those in normal children and adults or in patients with transient erythroblastopenia of childhood. For some enzymes, this increased activity is comparable to that in cord blood red cells. In apparent contradiction, carbonic anhydrase isoenzyme B, which is not normally present in fetal red cells, was detected in hemolysates from three patients with DBA.[237] Also, the red cells of two of the three patients had adult hexokinase isoenzyme distribution by isoelectric focusing.

Abnormalities in purine and pyrimidine metabolism are reflected by increased activity of red cell adenosine deaminase (ADA) in many patients with DBA.[241] [242] [243] [244] Also, increased orotidine decarboxylase (ODC) activity is seen in some patients.[244] ADA activity is raised in DBA erythrocytes, but not in cord blood red cells from normal newborns or from patients with any of several hematologic conditions associated with stress erythropoiesis. Thus, this enzymatic abnormality cannot be due simply to a reversion to fetal erythropoiesis. Red cell ADA activity was initially reported to be elevated in up to 90% of patients with DBA and to be elevated occasionally in some of their nonanemic relatives. However, in subsequent studies, ADA levels were found to be raised in only 40% of patients. Raised ADA activity may also be detected in some hemolytic anemias and acute leukemias, which limits the utility of this assay as a specific diagnostic marker for DBA. However, increased ADA activity does appear to be useful in differentiating DBA from transient erythroblastopenia of childhood on a biochemical basis.[240] [241] [242] [243] [244]

Serum levels of various factors involved in red cell production, such as erythropoietin, iron, vitamin B_{12}, and folate are appropriately elevated in DBA. These findings are compatible with any form of chronic hypoplastic anemia. Riboflavin levels are normal in the serum, but not in the erythrocytes. This observation initially aroused interest since experimental riboflavin deficiency may be corrected by corticosteroids similar to DBA. However, administration of large doses of riboflavin to several DBA patients did not result in a hematopoietic response.

Red cell serology is usually unremarkable at the time of diagnosis, but alloantibodies are frequently detected in chronically transfused patients. Two infants developed hypoplastic anemia, either in conjunction with or following a bout of Rh hemolytic disease.[245] [246] In one of them,[245] the hypoplastic anemia was transient. It was proposed that the Rh antibody had specificity not only for mature red cells but also for reticulocytes and erythroid progenitors, thereby causing temporary erythropoietic suppression of the bone marrow. The second patient[246] presented with a brisk hemolytic anemia that initially masked the presence of DBA. DBA became manifest 5 weeks postnatally when the Rh hemolytic disease had resolved.

Differential Diagnosis

In clinical practice, after excluding a viral etiology, particularly parvovirus B_{19}, transient erythroblastopenia of childhood (TEC) is usually the only diagnosis that is confused with DBA (Table 18-6). Both entities share the same morphologic findings in the bone marrow. However, TEC is a self-limited disorder with an excellent prognosis and needs no specific therapy except for red cell transfusions in the most profoundly anemic patients.[247]

The definition of TEC includes the following features: (1) gradual onset of pallor in previously healthy children 14 years of age (85% of cases), with older and younger exceptions; (2) normochromic-normocytic anemia with varying reticulocytopenia unless recovery has already ensued; (3) marrow erythroid hypoplasia (60% of cases), or aplasia (10% of cases), or a recovery picture (30% of cases); (4) spontaneous recovery usually

TABLE 18-6 -- Distinguishing Features Between Diamond-Blackfan Anemia (DBA) and Transient Erythroblastopenia of Childhood (TEC)

	DBA	TEC
Cause	Congenital/inherited	Acquired
Previous history	None	Viral infection
Anomalies	30%	0%
Neurological findings	None	Occasional

Immune-mediated	Rare	Common
Course	Chronic	Transient
Risk of leukemia	Increased	Not increased
Mean age (range)	6 months (172)	27 months (1192)
Laboratory findings at diagnosis		
RBC size	Macrocytic	Normocytic
Hb F	Increased	Normal[a]
i antigen	Increased	Normal[a]
RBC enzyme activities	Fetal levels	Adult levels[a]
RBC adenosine deaminase	Increased	Normal

[a]During recovery, values may be increased.

within 48 weeks without recurrence, with rare exceptions. [248]

There are some additional important features of TEC. It can occur in siblings simultaneously and in seasonal clusters from June to October and from November to March. Of concern are the transient neurologic changes that can occur with TEC and which appear to be linked to the disorder. Affected children may have one or more of the following: hemiparesis, papilledema, abnormal extraocular movements, seizures, and unsteadiness of gait. The affected patients in the published reports recovered without sequelae, and the precise relationship of these neurologic changes to the pathogenesis of TEC has not been determined.

It was claimed initially that only the erythroid lineage was affected in TEC and all other hematopoietic lineages were normal. Although the mechanism is not clear, significant neutropenia also occurs in many patients with TEC, being associated in some with hypocellular marrows or with a granulopoietic maturational arrest. The neutropenia may be due to a common pathogenetic mechanism that produces anemia. Increased numbers of CD10+ (CALLA) lymphoid cells have been observed in bone marrow of some TEC patients but the interpretation of this finding is not clear. [249] [250] An unusual presentation of TEC as a leukoerythroblastic anemia has been recorded.[251]

There are no data that firmly incriminate parvovirus or other infectious agents in the etiology of TEC, although a history of a preceding viral-like illness can be obtained in more than half of the patients. The most plausible explanation proposed to date is that TEC is due to transient immunosuppression of erythropoiesis, [252] and possibly of granulopoiesis in those with neutropenia. Most supportive evidence for this thesis comes from in vitro studies. Both Koenig et al. [253] and Dessypris et al.[254] demonstrated an inhibitory effect of TEC serum and fractionated IgG on erythroid colony growth that disappeared as TEC improved. Freedman and Saunders also demonstrated an IgG inhibitor of erythropoiesis in one case, but also an IgM inhibitor in a second patient. [252] A summary of other published studies[255] suggests that over 60% of TEC patients have autologous or allogeneic serum inhibitors of erythroid colony formation. Autologous or allogeneic cell-mediated immune suppression of erythropoiesis has also been identified in about 25% of cases. [252] [255] [256] All of the in vitro studies have generated varying patterns of erythroid colony growth in TEC. Colony numbers can be normal, but reduced numbers of BFU-E and CFU-E progenitors have been recorded in 30% and 50% of cases, respectively.

Therefore, TEC is likely to have an immune etiology. The transient nature of TEC is similar to other autoimmune hematological disorders of childhood, such as idiopathic thrombocytopenic purpura and some cases of autoimmune hemolytic anemia. The decreased activities of virtually all red cell enzymes in TEC compared to normal levels probably relate to the aged population of peripheral blood erythrocytes being tested. [247]

Regarding viral causes of red cell aplasia, Epstein-Barr virus, hepatitis virus, human T-cell leukemia virus-1, and human immunodeficiency virus-1 have all been implicated and should be excluded if the etiology of the anemia remains unclear. Parvovirus B_{19} stands out as a major causal agent of red cell aplasia in the context of an underlying chronic hemolytic anemia in infants and children with chronic congenital and acquired forms of immunosuppression. The fetus is uniquely susceptible to parvovirus infection and in utero transmission is a well-documented cause of nonimmune hydrops fetalis. Parvovirus infection should be ruled out in every case of childhood red cell aplasia by serial measurements of serum IgM and IgG, and by bone marrow examination for the characteristic giant pronormoblasts. Parvovirus may also be detected in marrow by gene amplification using the polymerase chain reaction and confirmed by direct in situ hybridization.

Predisposition to Leukemia

Although not generally regarded as a pre-leukemic condition, DBA is also associated with malignant myeloid transformation, like some of the other inherited marrow failure syndromes.[236] As summarized by Lipton and Alter,[257] acute leukemia and/or MDS have been reported in eight patients with DBA. One girl developed ALL at age 13 after a spontaneous remission of DBA at 5 years of age; the leukemia also remitted completely with therapy, and neither disorder was present at age 17. Two patients originally described by Diamond had intermittent remission of DBA but died of AML at ages 31 and 43, respectively. One of them had received thymic and skeletal irradiation during childhood as therapy for DBA. A girl who received cyclophosphamide for treatment of DBA died of acute promyelocytic leukemia at age 13. A boy who developed acute megakaryoblastic leukemia at age 14 months had anemia at 2 months of age; this may have been a long preleukemic phase. Three male steroid-nonresponders developed MDS at ages 13, 21, and 22 years, respectively. One evolved into AMML, one into AML, and the third patient died of complications of MDS. Eight additional patients developed various other cancers. [3]

Thus, of 379 published cases of DBA,[49] the number of cases of myeloid malignant transformation (eight cases, 2% incidence) is inordinately high and may even be higher as new cases[258] are diagnosed and reported. The link between disordered erythropoiesis and myeloid malignant disease is more understandable

now with the advent of new information, described in this chapter, implicating an earlier marrow progenitor than was previously thought in the pathogenesis of DBA.

Therapy and Prognosis

In younger children and infants, it is important to determine whether the red cell aplasia is DBA or TEC (Table 18-6). Until a firm diagnosis is established, initial treatment in children is almost always transfusional. This allows the flexibility to complete the viral work-up and other investigations, and to observe for a spontaneous remission if the anemia is due to TEC or another self-limited condition. The principle to follow if transfusions are used is to aim for a moderate but not full correction of anemia so that erythropoiesis is not suppressed and recovery from TEC not delayed. Most patients with TEC usually recover within a few weeks after receiving only one transfusion. Occasionally, recovery from TEC is slow and starts to mimic DBA in chronicity. If there is confusion about the proper diagnosis, it is appropriate to withhold corticosteroids in favor of a further transfusion in order to allow more observation time.

Transfusions

Before the first transfusion it is recommended that a full red cell phenotype be performed on patients' cells. This information will be valuable for prevention and management of alloantibody formation due to sensitization.

For patients in whom corticosteroids are either ineffective or excessively toxic, a regular program of periodic red cell transfusions is usually required. During the course of this program, a small number of patients may recover sensitivity to corticosteroids, or even proceed to a spontaneous transient or prolonged remission. Packed red cells are given monthly and this treatment is aimed at keeping the hemoglobin concentration at a level compatible with normal activity. Several complications may arise from transfusions, such as cytomegalovirus or other viral infections and sensitization, but the major long-term threat is iron overload which causes delayed puberty, growth retardation, diabetes mellitus, hypoparathyroidism, and eventually liver cirrhosis and cardiac failure. These complications can be

delayed, and possibly prevented, by the early administration of an iron chelator. Deferoxamine, administered as a daily 12-hour subcutaneous infusion, is the main chelator in use today.

There are uncertainties about the optimal age at which to start deferoxamine for patients with transfusion-dependent anemia. There have been reports of abnormal linear growth and metaphyseal dysplasia in thalassemia major patients treated with deferoxamine before the age of 3 years. [259] This adverse event has prompted recommendations for starting therapy later. However, a progressively rising serum ferritin level or, more accurately, excessive hepatic iron concentration obtained by biopsy after 1 year of regular transfusions would be appropriate indications to commence chelation. The daily starting subcutaneous infusion dose of deferoxamine should not exceed 50 mg/kg. Ascorbate supplementation should be considered if there is sustained loss of efficacy of deferoxamine, especially if tissue ascorbate concentrations are reduced. [260]

Corticosteroids

It is estimated that steroid responsiveness is present in 5075% of DBA patients. Upon administration of prednisone at a dose of 2 mg/kg/day in three divided doses, reticulocytosis is usually seen within 14 weeks, and is followed by a rise in hemoglobin concentration. Once the hemoglobin level reaches 9.010.0 g/dl, prednisone can be slowly tapered by reducing the number of daily doses. If a single daily dose of prednisone maintains the desired hemoglobin level, the dose can be doubled and given on alternate days. This schedule presents less risk of steroid-induced growth retardation.

The dose of prednisone can be further reduced by small decrements on a weekly basis, or more slowly, until the minimal effective dose is determined. This dose is extremely variable. A few patients can be maintained on minute, nonpharmacologic doses, whereas other patients need large doses that preclude long-term therapy because of side effects. There is no known predictor of steroid responsiveness, nor any way to anticipate the type of individual responses.

Alter recognized several patterns of response to corticosteroid therapy, some of which may occur at different times in the same patient. [49] Most children who respond to steroids cannot be completely weaned off the medication and become steroid-dependent. A few of these patients, however, enter steroid-free remission after a prolonged period of treatment. Between 15% of cases promptly respond to therapy and enter a durable steroid-independent remission. However, later relapses, sometimes precipitated by an infectious illness or by hormonal changes such as in pregnancy or with the use of birth control pills, are not uncommon. In other cases, a progressive resistance to steroids occurs, requiring escalating doses of prednisone or alternative therapy. Following a relapse, some patients are responsive to steroids again, whereas others are refractory to subsequent trials. Initial insensitivity to steroids is observed in 25% of cases, and in as many as 60% of patients long-term steroid therapy is hampered by the development of resistance or by side effects of the treatment.

High-Dose Methylprednisolone

Long-term experience with megadose steroid therapy for patients refractory to conventional prednisone treatment has been largely confined to a single center, which reported a sustained erythroid response leading to transfusion independence in 8 of 13 DBA patients. [261] Eleven had been treated with 100 mg/kg/day intravenously, and 2 additional patients with 30 mg/kg/day orally. Another study at a second center [262] showed a transient response in 1 of 8 patients after intravenous treatment with 30 mg/kg/day and a sustained response after a higher dosage (100 mg/kg/day) in 3 of 8 patients. In the latter study, side effects were weight gain, oral moniliasis, increase in hepatic transaminases, transient hyperglycemia, and bacteremia related to central venous access. Thus, high-dose steroid therapy may have a therapeutic role but is not without risk.

Cytokine Therapy

Because of the corrective effect on erythropoiesis by IL-3 in vitro cited herein, clinical trials were introduced for steroid-refractory and steroid-dependent DBA patients and for those in whom BMT was considered too risky. [263] [264] [265] [266] [267] The early enthusiasm generated by sustained remissions in some patients [263] has largely been tempered by the realization that IL-3 is likely to be effective in only a very small number of cases of steroid-refractory, transfusion-dependent DBA. [264] [265] [266] [267] To definitively answer questions regarding the therapeutic role of IL-3 for DBA, 49 patients were treated with the cytokine in a European multicenter compassionate-need study. [266] IL-3 was given as a daily subcutaneous injection at a starting dose of 2.5 g/kg, escalating at day 21 to 5 g/kg, and then to 10 g/kg if there was no response, for a total duration of 12 weeks. Three children had a significant response, achieving sustained remissions off therapy. At the time of entry into the study, one was steroid-responsive and transfusion-independent and two were transfusion-dependent. Two adults had a transient reduction in transfusion requirements but could not tolerate the complete course of therapy. Eosinophilia was common; neutrophil and platelet counts were unaffected except in three patients in whom previously-noted mild thrombocytopenia was transiently exacerbated. Clinical response to IL-3 did not correlate with in vitro culture results. A comparison of individual patient

STANDARD TREATMENT OF DIAMOND-BLACKFAN ANEMIA (DBA)

Until the diagnosis of DBA is certain, the initial approach is to transfuse packed red cells for a moderate but not full correction of anemia. If the diagnosis is TEC and not DBA, full correction of anemia may suppress erythropoiesis and delay recovery of TEC. A red cell phenotype should be performed on patients' cells before the first transfusion to guide in the management of potential alloantibody formation in transfusion-dependent patients at a later date.

Oral corticosteroids are the mainstay of therapy for DBA. Initial treatment is usually prednisone, 2 mg/kg/day in three divided doses and should be maintained for at least 4 weeks. A prednisone-equivalent preparation can also be used because no difference in efficacy has been observed with different formulations, but this is a less popular approach. A reticulocytosis is usually seen within 14 weeks, followed by a rise in hemoglobin. The increment in hemoglobin may be partial, whereby transfusion requirements are decreased but not eliminated, or complete. When the hemoglobin value reaches 9.010.0 g/dl, the steroid dose should be gradually reduced to determine the minimum dosage required to sustain the response. If a single daily dose of prednisone is effective, the dose can be doubled and given on alternate days. Prednisone should be stopped in non-and partial-responders as well as full-responders who require a high daily maintenance dose of >0.5 mg/kg/day. Long-term treatment of responders may be precluded by unacceptable side effects including growth retardation, which already can be a concern as part of the clinical phenotype of DBA. Growth curves should be closely monitored and the occurrence of a plateau should prompt substitution of steroid therapy with a transfusion program in order to allow catch-up growth, especially in the first year of life and at puberty.

For DBA patients in whom steroids are too toxic or ineffective, a regular program of periodic red cell transfusions should be introduced. Packed cells, 15 cc/kg, are given monthly, on average, to maintain a hemoglobin level that allows optimal growth and normal activity. Body iron stores must be monitored by serum ferritin levels every 3 months. A progressively rising ferritin level or, more accurately, an excessive liver iron concentration obtained by biopsy after 1 year of regular transfusions, is an appropriate indication to start iron chelation. Deferoxamine, 50 mg/kg, is given daily for this purpose by subcutaneous infusion over 812 hours using a battery-powered infusion pump. Oral vitamin C supplements should be considered (100 mg/day) if there is sustained loss of efficacy of deferoxamine, especially if tissue ascorbate concentrations are reduced.

Except for conventional prednisone therapy or chronic transfusion-chelation management, the other treatments described in the text should still be considered experimental. These include high-dose methylprednisolone intravenously and orally, subcutaneous IL-3 therapy, and BMT. For all of these options, risks must be weighed against benefits on a case-by-case basis.

characteristics with previously reported series confirmed earlier impressions that patients who had never achieved significant in vivo erythropoiesis in response to steroids or during a spontaneous remission were highly unlikely to respond to IL-3. Thus, the overall response rate in all published studies averages 1020%, and there may be a sustained remission off steroids in children who are steroid-dependent and transfusionindependent at the time of IL-3 therapy, suggesting a possible role for a short course of IL-3 earlier in the treatment of children with steroid-responsive DBA.

Trials with recombinant stem cell factor are awaited on the basis of in vitro culture results. However, to extrapolate from experience with IL-3, it is unwise to assume that in vitro results can predict clinical response. It is also likely that the presence of low-level in vivo erythroid activity is a prerequisite for a clinical response to SCF. EPO serum levels are elevated in DBA and attempts at treatment with high-dose EPO have been ineffective.

Bone Marrow Transplantation

BMT is a therapeutic option for DBA but risks must be weighed against benefits on a case-by-case basis. The fundamental issue centers on the defined mortality rate with BMT when used for a non-lethal medical condition, at least one that is non-lethal in the short-term. In steroid-responsive patients on low-dose maintenance, and in properly transfused and adequately chelated patients, quality of life is not threatened by life-threatening complications. Thus, the decision for intervention with BMT in this setting is difficult.

Nevertheless, experience has broadened since the first BMT was introduced for DBA in 1976. [268] Preparative regimens, supportive measures, and graft-versus-host disease management have progressively become more refined, thereby reducing overall risks of the procedure. But there are still major risks. Of 16 reported DBA cases receiving BMT, [268] [269] [270] [271] [272] [273] [274] [275] four patients died. Of these, two had interstitial pneumonia, one had cardiac failure, and one developed lethal complications associated with chronic graft-versus-host disease. Of the survivors, acute and chronic graft-versus-host disease was observed in nine and seven patients, respectively. To circumvent the graft-versus-host disease complications, there have been recent attempts to use cord blood stem cells from HLA-matched siblings as a donor source with apparent success. [276] [277]

Other Therapeutic Options

A number of uncontrolled therapeutic trials have been performed in steroid-refractory patients using various medications and treatments with varying success in a few patients. [278] [279] [280] [281] [282] [283] [284] The medications include: androgens, riboflavin, vitamin B_{12}, folate, iron and other hematinic agents, 6-mercaptopurine, [278] cyclophosphamide with antilymphocyte globulin, [280] antithymocyte globulin alone, [282] and cyclosporin A. [283] [284] Plasmapheresis has also been tried. [281] Splenectomy, employed in the past, shows no effect on erythropoiesis but may be helpful in transfused patients with proven hypersplenism.

Kostmann's Syndrome/Congenital Neutropenia

Introduction

Severe chronic neutropenia (SCN) and recurrent serious infections are features of a heterogeneous group of disorders of myelopoiesis including congenital neutropenia, cyclic neutropenia, and idiopathic neutropenia. Kostmann's syndrome (KS) is a subtype of congenital neutropenia inherited in an autosomal recessive manner with onset in early childhood of profound neutropenia (absolute neutrophil count <200/L), recurrent life-threatening infections, and a maturation arrest of myeloid precursors at the promyelocyte-myelocyte stage of differentiation. Congenital neutropenia and KS have the same hematologic phenotype and clinical presentation. The recessive inheritance of KS is deduced by inference when there is more than one affected child in a family. Congenital neutropenia is the proper designation used for a single sporadic case in a family, and may or may not be inherited in an autosomal recessive manner

like KS. Since the molecular defect is not known for either diagnostic category, the option to lump or split the two disorders remains a subject of argument. In this chapter, the terms KS and congenital neutropenia are used interchangeably.

The Severe Chronic Neutropenia International Registry (SCNIR) was established in 1994 to catalogue the clinical features and to monitor the clinical course, treatment, and disease outcomes in patients with SCN.[285] [286] [287] [288] [289] [290] [291] [292] [293] [294] The Registry is a valuable resource for clinical data because of the large numbers of patients entered into its worldwide database. Patient data are submitted internationally to the coordinating centers at the University of Washington, Seattle, and the Medizinische Hochschule, Hannover. In late 1996, short-term and long-term information dating back to 1987 on a total of 506 patients was available for analysis. Of the total, 249 patients were classified as having congenital neutropenia including KS.

Etiology and Pathogenesis

Initial studies of KS CFU-GM progenitor growth in vitro yielded variable data. [295] [296] [297] [298] [299] [300] [301] [302] [303] [304] [305] [306] [307] [308] [309] [310] [311] [312] [313] [314] [315] [316] [317] [318] [319] CFU-GM numbers can be decreased or increased, but are usually normal, and the colonies are comprised of myeloid elements arrested in differentiation, thereby mimicking the disease in vitro. Some patients, however, yield CFU-GM colonies with mature neutrophils. [301] [304] KS serum is not inhibitory to CFU-GM growth. Long-term cultures from some patients also show decreased myeloid differentiation. [307]

More recent studies of stromal and marrow mononuclear cells from patients with KS suggest that the primary defect is at the level of the myeloid progenitor. In particular, these experiments have shown normal serum G-CSF levels, normal G-CSF production by marrow stromal cells ex vivo, a normal or increased number of G-CSF receptors on hematopoietic cells, and defective myeloid colony growth. [312] [315] [316] [317] The G-CSF receptor contains discrete cytoplasmic domains that transduce proliferative and differentiating signals. [318] [319] [320] Dong et al. found a mutation that removed the carboxy tail of the G-CSF receptor in a congenital neutropenia patient after developing MDS [321] (see section, Predisposition to Leukemia). This truncated receptor retained the ability to stimulate cell growth, but deleted the differentiation domain. The G-CSF receptor mutation was restricted to the myeloid lineage and was not detected in DNA extracted from other tissues. The absence of germ-line mutations of the G-CSF receptor gene is consistent with the concept that the neutropenia of KS is not caused by this mechanism.

Clinical Manifestations

KS, or infantile genetic agranulocytosis as described in 1956 [322] was recognized in an original cohort of 14 cases and in a subsequent 10 additional patients [323] belonging to a large intermarried kinship in northern Sweden. The mode of inheritance in these original patients was clearly autosomal recessive. Subsequently, the disorder has been recognized widely despite its rarity and in various ethnic groups including Asians, American Indians, and Blacks. Consanguinity is not a uniform finding in cases enrolled in the SCNIR.

About half the patients develop clinically impressive infections within the first month of life and almost all others develop them by 6 months. Skin abscesses are common but deep-seated tissue infections and blood-borne septicemia also occur. SCNIR data illustrate examples of every conceivable form of bacterial and sometimes fungal infection in the pre-cytokine era. Especially troublesome in survivors were recurrent episodes of otitis media and pneumonia, advanced gingival-stomatitis, and, in the extreme, gut bacterial flora overgrowth leading to malabsorption requiring total parenteral nutritional therapy. In contrast to some of the other inherited bone marrow failure syndromes, physical malformations are not a feature. Birth weights are generally unremarkable and physical examinations are normal. There are a small number of reports of short stature, microcephaly, mental retardation, and cataracts but the association with KS does not appear to be strong. Data from the SCNIR indicate that some patients with KS develop bone demineralization before and during G-CSF therapy. The underlying pathogenesis is unclear but patients can develop bone pain and unusual fractures.

Laboratory Evaluation

Neutropenia is profound in KS, usually less than 200/L but often absolute. Compensatory monocytosis and sometimes eosinophilia is seen. At diagnosis, platelet numbers and hemoglobin values are normal. In survivors in the pre-cytokine era, anemia of chronic disease associated with recurrent infections and inflammation was common. Aside from neutropenia, humoral and cellular immunology is completely normal.

Bone marrow specimens are usually normocellular. The striking classical finding is a maturation arrest at the promyelocyte or myelocyte stage of granulocytic differentiation. Cellular elements beyond are markedly reduced or totally absent. The other hematopoietic lineages are normal, active, and undisturbed.

Predisposition to Leukemia

There is concern regarding the phenomenon of malignant myeloid transformation in KS patients receiving G-CSF therapy. Of 249 patients in the SCNIR in late 1996 classified as having congenital neutropenia, including KS, 24 developed MDS/AML yielding an overall incidence or crude rate of about 10% with an average follow-up of 5 years. No cases of MDS/AML occurred in the subgroup of congenital neutropenia patients with glycogen storage disease type 1b, nor among those with cyclic or idiopathic neutropenia.

Conversion to MDS/AML in the KS patients was associated with one or more cellular genetic abnormalities which may be useful to identify a subgroup of patients at high risk.[324] Of 24 who transformed in the Registry series, 14 developed partial or complete loss of chromosome 7 (7q- or monosomy 7) in marrow cells; none of the patients who were tested prior to G-CSF therapy had loss of chromosome 7. Activating ras oncogene mutations were discovered in 5 of 10 patients from the series of 24 after the transformation to MDS/AML but not before. Four of these also had monosomy 7. The mutated fragments were cloned and sequenced and showed GGT (glycine) to GAT (aspartic acid) substitutions at codon 12 in all of them (K12ASP in 2 patients and N12ASP in 3 patients). Marrow cells from 5 transformed patients also showed point mutations in the gene for G-CSF receptor resulting in a truncated C-terminal cytoplasmic region of the receptor that is crucial for maturation signalling.[325] [326] Twenty patients without receptor mutations showed no evidence of progression to MDS/AML; however, 4 additional patients have been identified with mutations but without MDS/AML[325] and are currently being closely monitored.

Can G-CSF be implicated in the malignant conversion of congenital neutropenic patients? Development of MDS/AML must be put in the context of the underlying primary problem. Before the availability of G-CSF therapy, it was recognized that leukemic transformation occurs occasionally in patients with KS/congenital neutropenia.[327] [328] [329] [330] However, in the pre-cytokine era, many KS/congenital neutropenia patients died in the first years of life from other causes. Of published cases, 42% of patients died at a mean age of two years secondary to sepsis and pneumonia. [49] Thus, the true risk of congenital neutropenia patients developing MDS/AML was not defined. Currently with G-CSF therapy, most of these patients do not develop life-threatening

---

infections and are surviving, but it is not known whether longer survival will allow for the natural expression of leukemogenesis in this population. Moreover, since the long-term effects of G-CSF are barely known beyond 10 years of observation, it is still unclear whether MDS or AML will occur with increased frequency in patients who receive prolonged therapy of G-CSF to correct the neutropenia.

Differential Diagnosis

The commonest cause of isolated neutropenia in very young children is viral-induced marrow suppression. An antecedent history of good health, the occurrence of a viral illness, and the transient nature of the neutropenia distinguishes this disorder from KS/congenital neutropenia. Autoimmune neutropenia of infancy is being recognized more frequently as a fairly specific syndrome of early childhood. Low neutrophil numbers are often discovered during the course of routine investigation for a benign febrile illness. The illness abates but the neutropenia persists, sometimes for months and occasionally longer than a year. A marrow biopsy is normocellular and an aspirate shows active granulopoiesis up to the band stage; neutrophils may be normally represented or reduced. The neutropenia is due to increased peripheral destruction and the diagnosis is confirmed serologically by demonstrating anti-granulocyte antibodies. The prognosis is good, the neutropenia is self-limited albeit protracted, and patients seldom develop serious bacterial infections as a result of it. Other infrequent acquired causes of severe, isolated

neutropenia in this age group include marrow suppression from a drug or toxin, and neutrophil sequestration as part of a hypersplenism syndrome.

Of the inherited forms of neutropenia, Shwachman-Diamond syndrome can also manifest as isolated neutropenia but can be identified because of growth failure, the malabsorption component due to pancreatic insufficiency, fatty changes in the pancreas seen on computed tomography scanning, and characteristic skeletal abnormalities. Neutropenia can also be a prominent part of antibody deficiency syndromes, dysgammaglobulinemia, and agammaglobulinemia; investigation of chronic neutropenia of childhood should include an immunoglobulin electrophoresis. Cyclic neutropenia is distinguished by predictable symptomatology, especially mouth sores every 21 days in classic cases, often associated with chronic gingivitis. A complete blood count three times a week for a month will demonstrate the diagnostic oscillation pattern with the 21 day nadir. Familial cases of neutropenia with an autosomal dominant mode of inheritance are also described; parents of all cases should be screened with a complete blood count.

Therapy and Prognosis

Before the introduction of G-CSF as a specific therapy of KS and other forms of severe chronic neutropenia, there was limited treatment. Antibiotics were the mainstay of management for active infection and for prophylaxis. Attempts to mobilize neutrophils in KS with lithium had limited application. [331] [332]

Cytokine Therapy

G-CSF has supplanted all other forms of management and should be initiated as front-line treatment when the diagnosis is established. [333] GM-CSF in crossover trials with G-CSF for KS is not as effective and does not induce a neutrophil response consistently. The starting dose of G-CSF is 5 g/kg/day subcutaneously and can be escalated until the desired neutrophil number is achieved. Neutrophils higher than 500/L generally afford some protection from infection but counts greater than 1000/L are clearly safer.

Documentation of the efficacy of G-CSF for SCN is described in a definitive phase III randomized controlled trial. [334] The trial enrolled 123 patients (60 congenital, 21 cyclic and 42 idiopathic) of which 120 had evaluable responses. Defining a complete response over the 4 month treatment period and beyond as the maintenance of median neutrophil numbers greater than 1,500/L, 90% of patients showed a complete response to G-CSF therapy, and infection-related events and antibiotic use were significantly decreased. Safety data were analyzed [335] and events related to the treatment were generally mild and consisted of headache, general musculoskeletal pain, transient bone pain, and rash. None of these required the discontinuation of G-CSF. Thus, the vast majority of patients in this phase III trial benefited substantially from G-CSF therapy with minimal adverse or toxic effects and almost all of the originally-treated patients entered a long-term G-CSF maintenance program. The reduction in fevers, infections, and inflammation translated into a well-documented improvement in the quality of life for these patients.

In the SCNIR 1996 annual report (on file at Clinical Safety, AMGEN Boulder Inc., 3200 Walnut Street, Boulder, CO, 80301), the consistent sustained hematological response in patients treated with G-CSF for more than 8 years was confirmed. With therapy, neutrophil counts rose in more than 90% of SCN patients and were maintained at a plateau for protracted periods resulting in vast clinical benefits. In no instance has there been marrow or hematopoietic lineage exhaustion or depletion with G-CSF therapy. The overall safety of long-term administration of G-CSF is reviewed in detail. [333]

Bone Marrow Transplantation

Prior to the use of G-CSF, BMT was tried in a small number of KS patients with mixed success. Data from the International Bone Marrow Transplantation Registry are limited; the small series is heterogeneous with regard to donor source and clinical status of patients at the time of the procedure.

In the SCNIR database, 13 KS patients who developed MDS/AML were transplanted after the transformation. Only three appeared to be cured of MDS/AML and KS. Results may have been better but nine of the procedures were from matched unrelated donors or were performed in desperation using mismatched donors. One of the three who appeared cured by BMT died of liver failure secondary to chronic hepatitis from type C virus infection.

Thrombocytopenia with Absent Radii

Introduction

TAR syndrome was first described in 1929, [336] defined by Hall et al. in 1969, [337] and subsequently reviewed. [338] The two essential features of TAR syndrome are hypomegakaryocytic thrombocytopenia and bilateral radial aplasia. The rest of the phenotype varies widely and can manifest with abnormalities involving skeletal, skin, gastrointestinal, and cardiac systems.

Most of the genetic evidence supports an autosomal recessive mode of inheritance for TAR syndrome because many families have been observed with more than one affected sibling. The possibility of other modes of inheritance for TAR syndrome has been raised. [338] Almost always, parents of TAR patients are phenotypically normal. Females with TAR syndrome can conceive and give birth to hematologically and phenotypically normal offspring.

Aside from the occurrence of one case of acute lymphoid leukemia in a child with TAR syndrome, [339] there is no predisposition to leukemia nor to other bone marrow dysfunction or cancer in this disorder.

Etiology and Pathogenesis

Thrombocytopenia in TAR syndrome is the result of a defect in megakaryocytopoiesis/thrombocytopoiesis. [340] [341] Initial contradictory

data claiming either high levels of megakaryocyte-CSA in sera of TAR patients, [340] [342] or normal levels, [341] have been resolved. Thrombopoietin levels in serum are consistently elevated in TAR syndrome, thereby excluding a cytokine production defect as a cause for thrombocytopenia in this disorder. [343] Also, expression studies of the thrombopoietin receptor, c-mpl, on the surface of platelets from TAR patients is normal and with a similar molecular weight of the receptor compared to controls. [343] Marrow CFU-Meg progenitors are either absent, [340] [342] or are present in normal frequencies but are comprised of colonies in vitro with abnormal morphology. [341] Cells within these colonies are smaller and the number of cells per colony is much higher than in normal CFU-Meg colonies. CFU-GM and BFU-E colony growth is often increased.

Platelet response to adenosine diphosphate or to the thrombin receptor agonist peptide, SFLLRN (TRAP), is normal in TAR patients. [343] However, in contrast to controls there is no in vitro reactivity of platelets from TAR patients to recombinant thrombopoietin as measured by testing thrombopoietin-synergism to ADP and TRAP in platelet activation. [343] Thrombopoietin-induced tyrosine phosphorylation of platelet proteins in this setting is completely absent or markedly decreased. The results indicate that defective megakaryocytopoiesis/thrombocytopoiesis in TAR syndrome is due to a lack of response to thrombopoietin in the signal transduction pathway of c-mpl.

Clinical Manifestations

The diagnosis is made in the newborn period because of the absent radii, and in about half of patients becuase of a petechial rash and overt hemorrhage such as bloody diarrhea. Patients have bilateral radial aplasia (Fig. 18-7) with preservation of thumbs and fingers on both sides. Additional upper extremity deformities include radial clubhands, hypoplastic carpals and phalanages, and hypoplastic ulnae, humeri, and shoulder girdles. Syndactyly and clinodactyly of toes and fingers are also seen. Characteristic findings include a selective hypoplasia of the middle phalanx of the fifth finger and altered palmar contours. Upper extremity involvement ranges from isolated absent radii to true phocomelia, often asymmetric. The lower extremities are involved in about half of cases. Malformations include hip dislocation, coxa valga, femoral torsion, tibial torsion, abnormal tibiofibular joints, small feet, and valgus and varus foot deformities. Abnormal toe placement is commonly seen, especially the fifth toe overlapping the fourth. Like upper limb involvement, lower extremity deformities range from minimal involvement to complete phocomelia. An asymmetric first rib, a cervical rib, cervical spina bifida, and a fused cervical spine can occur, but trunk involvement is usually minimal. Micrognathia

has been associated with the TAR syndrome in up to 65% of cases.

Cardiac abnormalities occur in one-third of the patients. The commonest are atrial septal defect, tetralogy of Fallot, and ventricular septal defect. Facial hemangiomas are common, as well as redundant nuchal folds. Hays et al. [344] described three additional findings in TAR syndrome: dorsal pedal edema, hyperhydrosis, and gastrointestinal disturbances such as diarrhea and feeding intolerance.

There are important clinical differences that distinguish TAR syndrome from Fanconi's anemia. In Fanconi's patients, when radii are absent thumbs are hypoplastic or absent. Fanconi's patients do not have skin hemangiomas like some TAR patients, whereas TAR patients do not show abnormal skin pigmentation like 65% of Fanconi's patients. Confirmation of Fanconi's anemia is made by the clastogenic chromosome stress test showing increased fragility. TAR patients do not have increased chromosomal breakage.

Prenatal diagnosis has been demonstrated readily both by quantitating platelet numbers obtained by fetoscopy or cordocentesis,

Figure 18-7 Radial aplasia with preservation of the thumb in a newborn with TAR syndrome.

and by imaging. In one case after the diagnosis was made, a prenatal in utero platelet transfusion was given to effect a safe delivery. [345]

Laboratory Evaluation

Thrombocytopenia due to bone marrow underproduction is a consistent finding. Marrow specimens show normal to increased cellularity with decreased to absent megakaryocytes. The erythroid and myeloid lineages are normally represented. When a few megakaryocytes can be identified in biopsies they are small, contain few nuclear segments, and show immature nongranular cytoplasm. If platelet counts increase spontaneously in patients after the first year of life, megakaryocytes increase in parallel and appear more mature morphologically. At diagnosis, leukocytosis is seen in the majority of patients and is sometimes extreme to over 100,000/L with a left shift to immature myeloid forms. The cause of this leukemoid reaction is unclear but it is usually transient and subsides spontaneously. If anemia is present, the likeliest etiology is from blood loss due to thrombocytopenia. When platelet numbers are adequate for study, their size is generally normal, with rare exception,[346] and function is unremarkable, [347] [348] [349] although some patients may show abnormal platelet aggregation and storage pool defects. [350] [351] [352] Unlike some of the other inherited marrow failure syndromes, red cell size and fetal hemoglobin levels are normal. Studies of spontaneous and clastogenic-induced chromosome breakage are also normal.

Therapy

The risk of hemorrhage is greatest in the first year of life. Deaths are usually due to intracranial or gatrointestinal bleeding. If patients survive the first year of life, platelet counts spontaneously increase inexplicably to levels that are hemostatically safe and which do not require platelet transfusional support. A minority of patients have sustained, profound thrombocytopenia that does not improve spontaneously.

As in other inherited marrow failure disorders associated with thrombocytopenia, platelet transfusions should be used judiciously. Clinical bleeding or prophylaxis for orthopedic surgical procedures are appropriate indications. Persistent platelet counts below 10,000/L may require preventative platelet transfusions on a regular basis, especially in the first year of life when the expectation is that a spontaneous improvement in platelet number will ensue with time in most infants. Single donor platelets are preferred to multiple unfiltered random donor platelets to minimize the risk of alloimmunization. HLA-partially-matched donors for platelets may be required if patients become refractory to transfusions.

Other Therapies

Because the overall prognosis for survival is good and because patients do not develop aplastic anemia, or leukemia with rare exception, [339] supportive management is the mainstay. In exceptional situations, profound persistent life-threatening thrombocytopenia can be successfully treated by BMT. [353] The role of thrombopoietin in the management of TAR patients is unclear. Elevated serum thrombopoietin levels at baseline [343] may predict for a poor response to cytokine therapy. IL-11, another thrombopoietic cytokine, is yet to be studied in clinical trials; however, endogenous IL-11 serum levels in TAR patients are also elevated. [343] Androgens, corticosteroids, and splenectomy are ineffective therapies for TAR syndrome.

INHERITED MARROW FAILURE AND MALIGNANT HEMATOPOIETIC TRANSFORMATION

Historically, the inherited marrow failure syndromes were classified as enign hematology, which contrasted sharply with the malignant myeloid disorders. Patients with Kostmann's syndrome/congenital neutropenia, Shwachman-Diamond syndrome, Fanconi's anemia, congenital amegakaryocytic thrombocytopenia, and Diamond-Blackfan anemia often died early in life from complications of their respective disorders. However, in the current era of advanced supportive care and availability of recombinant cytokines and other effective therapeutics, patients with these conditions usually survive the early years of life and beyond. With the extended lifespan of patients, a new natural history for some of these disorders is evident. As recently reviewed, [354] one of the most sobering observations is that most of these benign disorders confer an inordinately high predisposition to MDS/AML. Thus, the distinction between benign and malignant hematology in the context of the inherited marrow failure disorders has become blurred, and a new clinical and hematological continuum is evident.

Carcinogenesis occurs as a sequence of events that is driven by genetic damage and by epigenetic changes. In the traditional view, the initiation of cancer starts in a normal cell through mutations from exposure to carcinogens. In the promotion phase that follows, the genetically altered, initiated cell undergoes selective clonal expansion that enhances the probability of additional genetic damage from endogenous mutations or DNA-damaging agents. Finally, during cancer progression, malignant cells show phenotypic changes, gene amplification, chromosomal alterations, and altered gene expression.

In the inherited marrow failure syndromes described herein, the first hit or cancer-initiating step may be the constitutional genetic abnormality itself that initially manifests as the single-lineage or multiple-lineage myelopathy. The predisposed progenitor, already initiated, could conceptually show decreased responsiveness to the signals that regulate homeostatic growth, terminal cell differentiation, or programmed cell death. The leukemic promotion and progression steps leading to MDS/AML could then ensue readily in the initiated pool of progenitors or stem cells. When the molecular defects that produce the marrow failure syndromes are discovered, the nature of the leukemogenic-initiating events in these conditions should become evident.

Congenital Dyserythropoietic Anemias

Introduction

The designation congenital dyserythropoietic anemia (CDA) refers to a family of inherited refractory anemias characterized by marrow erythroid multinuclearity, ineffective erythropoiesis, and secondary hemosiderosis. [355] [356] The ineffective erythropoiesis is reflected by marrow erythroid hyperplasia, inappropriately low reticulocyte counts for the level of hemoglobin, and intramedullary red cell destruction. Although these disorders are not bone marrow failure syndromes per se, they are genetically transmitted and result in anemia with a blunted erythropoietic response.

Three forms of CDA have been described, as well as a number of variants. An arbitrary classification used in practice is based on the morphologic features and the serologic findings in each case. [357] [358] The distinguishing features of the three main types of CDA are as follows:

Type I: Megaloblastoid changes, macrocytosis, and internuclear bridges.
Type II: Binuclearity, multinuclearity, pluripolar mitoses, karyorrhexis, and positive acidified serum test.
Type III: Multinuclearity with up to 12 nuclei, gigantoblasts, and macrocytosis.

The designation, Type IV, is sometimes used to classify cases of morphologic Type II CDA but with a negative acidified serum test. [359] [360] Reports of some of the variants[361] [362] [363] [364] [365] [366] underscore the complex nature of CDA and the need to reclassify these disorders accurately when the molecular basis for the various types becomes clear. A recent review addresses this issue and other aspects of CDA. [367]

Etiology and Pathogenesis

The defect that accounts for each type of CDA is found in all of the erythroid progenitors rather than in a subpopulation of cells. [368] [369] [370] Some pertinent biochemical abnormalities are related to the etiology of CDA I and CDA III, [371] [372] [373] [374] [375] but little more is known about pathogenesis. A putative gene for CDA III has recently been localized and maps to an 11cM interval within 15q21q25. [376]

In comparison, the pathogenesis of CDA II has been almost completely clarified. At the stem cell level, in vitro culture of CDA II erythroid progenitors produces CFU-E and BFU-E colonies with erythroblast multinuclearity. [368] Initially, studies of peripheral blood CDA II red cells identified a number of chemical abnormalities including unbalanced globin chain synthesis, [373] increased membrane glycolipids, [377] and altered red cell membrane protein patterns demonstrated by two-dimensional electrophoresis. [375] Furthermore, glycoproteins on CDA II red cells were found to have an abnormal carbohydrate structure leading to aberrant reactivity with anti-i sera. [378] Additional data suggested that the IgM antibody responsible for hemolysis in the acidified-serum lysis test recognizes an abnormal glycolipid structure sharing homology with the i and I antigens. [379] Thus, a

variety of data predicted that abnormalities in the glycosylation pathway were involved in the etiology of CDA II.

Fukuda et al. [380] [381] reported two distinct defects in this glycosylation enzymatic pathway that occur in CDA II: alpha-mannosidase II deficiency and N-acetylglucosaminyltransferase II deficiency. As a result of the former abnormality, addition of new sugar moieties to the oligosaccharide core structure is impaired. A defect, probably in the promoter region of the gene encoding for alpha-mannosidase II, has been identified, thus linking a molecular defect with CDA II. Fukuda et al. [380] also claim that multinucleated erythroblasts are formed in vitro when normal bone marrow is cultured with an inhibitor of alpha-mannosidase II. Also, low levels of N-acetylglucosaminyltransferase II, the enzyme responsible for addition of an N-acetylglucosamine residue to one of the arms of the core, results in glycoproteins with truncated oligosaccharides.

A third enzymatic defect has been described in a variant case of CDA II. Low levels of the membrane-bound form of galactosyltransferase, involved at various stages of oligosaccharide synthesis, severely affect processing and lead to the presence of primitive high-mannose core structures on glycoproteins. [382] All three of these enzymatic deficiencies lead to abnormal oligosaccharides on major erythrocyte proteins such as the anion transporter Band 3. [383] [384] In addition to its other functions, this glycoprotein plays a critical role in the organization of the membrane skeleton that determines normal red cell strength, flexibility, and shape. Abnormal glycosylation of Band 3 may cause it to cluster on the cell surface. [385] Such clustering could cause disruption of the structural network of the erythrocyte and its

precursors, thereby leading to their premature demise.

Defective glycosylation on the red blood cell surface may also affect the regulation of complement on the surface of erythrocytes. Enhanced functional activity of the alternative pathway C3 convertase and of the membrane attack complex may result from the improper glycosylation of glycophorin A, which has been proposed to serve as a complement regulatory protein.[386]

Clinical Manifestations

Some features are shared by all forms of CDA and some features are specific for each type (Table 18-7). In general, there is a wide variation in age of onset of clinical problems related to CDA. Most patients are diagnosed in late childhood or adolescence; however, a few CDA cases have now been reported in newborn infants presenting with hydrops fetalis.[387] [388] [389] Clinical manifestations may include intermittent jaundice and dark urine due to increased hemoglobin catabolism, or signs and symptoms of anemia may be present. Rarely, hyperbilirubinemia without anemia may be the initial presentation of CDA patients. The degree of splenomegaly and hepatomegaly is quite variable. Cholelithiasis may be present as a consequence of chronic hyperbilirubinemia. In some older patients, evidence of hemosiderosis (skin hyperpigmentation, diabetes mellitus, hypogonadism, or delay of secondary sexual characteristics) is often present. It is noteworthy that hemosiderosis occurs in both transfused and nontransfused CDA patients. In the latter, iron overload is a direct consequence of ineffective erythropoiesis and increased gastrointestinal absorption of iron.[390] Two recent reports of a large series of patients with CDA I and CDA II, respectively, illustrate the spectrum of clinical manifestations of these disorders.[391] [392]

Laboratory Evaluation

There is a wide range in severity of the anemia in the CDAs. Some patients are completely asymptomatic, whereas others require blood transfusion. Most commonly, however, the anemia is mild to moderate, with hemoglobin concentrations between 8 and 11 g/dl. Normocytic or macrocytic indices are typical (Table 18-7). Abnormalities of mature erythrocytes, including anisocytosis, poikilocytosis, anisochromasia, and punctate basophilic stippling, can be pronounced and may serve as the first clue to an underlying CDA. Reticulocytes are normal to slightly elevated but less than expected for the degree of anemia, reflecting ineffective erythropoiesis. Red cell life span may be normal to moderately shortened. White cells and platelets are quantitatively normal except on rare occasions when cytopenias can be attributed to splenic sequestration. Infrequently, quantitative abnormalities can also be seen, such as abnormal segmentation of neutrophils, cytoplasmic cisternae in both granulocytes and platelets, and budding of nuclei in megakaryocytes.[393] [394] [395]

TABLE 18-7 -- Distinguishing Features of the Congenital Dyserythropoietic Anemias

Feature	CDA Type I	CDA Type II (HEMPAS)	CDA Type III
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal dominant
Organomegaly	Splenomegaly	Splenomegaly, hepatomegaly	Minimal organomegaly
Anemia	Mild-moderate	Mild-severe	Mild
Mean corpuscular volume	Mild-moderate increase	Normal-mild increase	Normal-mild increase
Bone marrow erythroids			
Light microscopy	Megaloblastoid changes; large cells with incompletely divided nuclear segments; double nuclei, internuclear chromatin bridges	Late polychromatophilic and orthochromic erythroblasts often contain two to seven normal-appearing nuclei	Giant erythroblasts, with up to 12 nuclei; prominent basophilic stippling
Electron microscopy	Widened nuclear pores, cytoplasmic invasion of nucleus, spongy appearance of nuclei, disaggregation of ribosomes, and presence of cytoplasmic microtubules	Excess endoplasmic reticulum appearing as a double cell membrane	Clefts and blebs within nuclear region, autolytic areas in cytoplasm, some iron-filled mitochondria, and myelin figures
Acid serum hemolysis	Negative	Positive	Negative
Sugar water test	Negative	Negative	Negative
Red cell agglutination/lysis			
with anti-i serum	±	++++	±
with anti-I serum	+	++++	±

The bone marrow shows marked erythroid hyperplasia, reversal of the M:E ratio, dyserythropoiesis, and a degree of red cell multinuclearity. No specific cytogenetic finding is associated with the CDAs; however, erythroblasts are frequently hyperdiploid reflecting ineffective cell division with a resultant increased complement of chromosomes within the cells.[396] Increased stainable iron is evident in the marrow, but ringed sideroblasts are not a feature. Ferritin concentration is elevated and correlates with iron stores. Ferrokinetic studies similarly reflect the ineffective erythropoiesis with a shortened plasma iron clearance, an increase of plasma iron turnover as much as 10 times normal, and increased retention of marrow iron, but without evidence of impaired iron utilization as occurs in the thalassemia syndromes.[397] Because excess iron is present even in the absence of transfusions or therapeutic supplementation, it is thought to be due to an increased absorption that occurs in the presence of accelerated, but ineffective, erythropoiesis. Reflecting this, elevation of serum lactate dehydrogenase and unconjugated bilirubin along with depression of serum haptoglobin are frequently noted, but most consistently in CDA II.

Differential Diagnosis

Dyserythropoiesis with erythroblast multinuclearity is seen with other hematologic disorders but these can be readily distinguished from CDA. The megaloblastic anemias have a different clinical presentation and are identified in the laboratory by the presence of hypersegmented neutrophils, decreased red cell folate values, or reduced serum levels of vitamin B_{12} . The myelodysplastic syndromes may manifest as an isolated refractory anemia, but they often present with bi- or tri-lineage cytopenias that contrast sharply with the CDAs. The FAB myelodysplastic syndrome subsets may also show marrow granulocytic and megakaryocytic morphologic abnormalities, the presence of myeloblasts, ringed sideroblasts, and clonal cytogenetic changes. Erythroleukemia (AML, M6) is another cause of marked dyserythropoiesis but typically there is pancytopenia, the erythroblasts are avidly positive for the periodic acid-Schiff stain, and the marrow cells may show a clonal cytogenetic marker. The beta-thalassemia syndromes differ from the CDAs by the presence of marked microcytosis with elevated levels of either hemoglobin A_2 or fetal hemoglobin, or both.

Specific Features of Major Types of Congenital Dyserythropoietic Anemia

Type I

CDA I is inherited in an autosomal recessive manner. In several reported families more than one sibling was affected, and the disorder has been seen in fraternal and identical twins. The onset of anemia, jaundice, or other symptoms may be noted at any age. Affected patients often manifest some degree of icterus and splenomegaly. Recently, CDA I has been associated with skeletal malformations of the limbs in four unrelated patients.[398] [399] The abnormalities consist of absence of nails, short or absent phalanges, and polysyndactyly of the fourth metacarpal. One of the patients also had areas of depigmentation. These anomalies are not

common in CDA I patients but do appear to be quite specific for this subtype.

The degree of anemia is usually mild to moderate (hemoglobin in the range of 8 to 12 g/dl), and red cells are macrocytic. Peripheral blood red cell morphology is characterized by anisocytosis and poikilocytosis, and occasionally Cabot rings are seen. Cabot rings appear to be unique to CDA I and are not seen in types II and III. White blood cells and platelets are normal. Examination of the bone marrow reveals erythroid hyperplasia with some megaloblastic erythropoiesis, and a small number of erythroblasts with dyserythropoietic features. The unique morphologic abnormality seen in type I CDA is the presence of interchromatin bridges between nuclei of two separate erythroblasts, a reflection of impaired cellular division (Fig. 18-8). This internuclear bridging of erythroblasts seen with light microscopy is also a common feature in myelodysplastic syndromes. Electron microscopy reveals additional abnormalities that include widening of the nuclear membrane pore space with cytoplasmic invagination into the nucleus, separation of nuclear chromatin, and chromatin condensation, all of which give the general appearance of a spongy nucleus (Fig. 18-9). Dyserythropoiesis seems limited mostly to more mature red cell precursors. In contrast to type II CDA, there are no unique serologic features.

The defect in CDA I is at the stem cell level. The numbers of CFU-E and BFU-E are normal, but the colonies contain a mixture of normal and abnormal cells when examined by electron

microscopy. [400] This suggests that the abnormality is expressed variably in the mature progeny of each stem cell.

Type II (HEMPAS)

CDA II is commonly known as HEMPAS, an acronym for *H*ereditary *E*rythroblastic *M*ultinuclearity with a *P*ositive *A*cidified *S*erum test. [401] There is overlap of some clinical and laboratory manifestations between CDA I and CDA II, but there are three major differences. The first difference is that the magnitude of anemia is usually more severe, and patients with CDA II often require red cell transfusions. Peripheral blood red cells are usually normocytic but with anisocytosis and poikilocytosis (Fig. 18-10). The second difference is that the bone marrow in type II CDA reveals more abnormal erythroblasts (30%), with binuclearity, multinuclearity, and abnormal lobulation (Fig. 18-11). These nuclear abnormalities are seen only in the late erythroblasts, not in basophilic erythroblasts. Karyorrhexis is commonly observed, and pseudo-Gaucher cells may be present, representing the ingestion of debris by histiocytic cells from ineffective erythropoiesis. Electron microscopy of late erythroblasts also reveals an excess of endoplasmic reticulum parallel to the cell membrane, giving the appearance of a double cell membrane [402] [403] (Fig. 18-12). A third difference, which is also a pathognomonic finding, is that type II CDA red cells are lysed by acidified (pH 6.8) sera obtained from approximately 30% of normal persons, but there is no lysis when red cells are incubated with the patient's own acidified serum. This lysis is due to a naturally occurring IgM antibody that binds complement, and this antibody can be removed by preincubating normal sera with HEMPAS erythrocytes. However, the specific HEMPAS antigen recognized by this antibody is not known. In contrast to HEMPAS, the erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (PNH) undergo lysis when the acidified serum is from the PNH patient or from normal donors. Another difference is that PNH erythrocytes undergo lysis in isotonic sucrose, whereas HEMPAS red cells do not lyse in sucrose solution.

The erythrocytes from patients with CDA II also exhibit an increased agglutinability and lysis to anti-i and anti-I sera and manifest increased expression of both antigens. These surface antigens are complex carbohydrate structures found predominantly on fetal and adult red cells, respectively. Increased expression of i antigen can be demonstrated on all red cells in CDA II using fluorescent labels. Relatives of patients with CDA II who have normal marrows but increased agglutinability to anti-i appear to be heterozygote carriers of this disorder. [404] HEMPAS erythrocytes bind a normal amount of complement (C1), but more antibody and less C4 than normals.[405] This causes binding of an excess of C3 and hemolysis.

The number of erythroid progenitors is probably normal in marrow and blood. Although one study found only normal

Figure 18-10 Peripheral blood smear from patient with CDA type II. Note the marked variation in size and shape.

Figure 18-11 Bone marrow aspirate from a patient with HEMPAS (type II CDA) showing erythroid hyperplasia and multinucleated erythroblasts. (*Provided by Dr. Jean Shafer, Rochester, NY.*)

morphology of the erythroblasts produced in culture, [406] subsequent studies reported multinuclearity similar to that seen in the bone marrow. [368] [407] As in type I CDA, the defect in type II CDA is in the erythroid stem cell and is expressed variably in more mature erythroblasts.

A number of clinical associations with CDA II have been reported such as mental retardation, Sweet's syndrome, von Willebrand's disease, and Dubin-Johnson syndrome, among others.[408] [409] [410] Rather than true associations, it is likely that the majority represent coincidental occurrence. An adult patient was recently reported with an extramedullary hematopoietic

Figure 18-12 Electron micrograph of bone marrow erythroblast from patients with HEMPAS (type II CDA). Note the appearance of a double cell membrane reflecting an excess of endoplasmic reticulum. (*Provided by Dr. Raoul Fresco, Loyola University, Maywood, IL.*)

mass in the posterior mediastinum that was a result of marrow expansion associated with ineffective erythropoiesis. [411]

Type III

Based on reported CDA cases, type II is the most common, type I is next, and CDA III is the rarest of the three major forms. As of the mid-1990s, only about 30 cases of CDA III have been described,[49] 15 of which come from a single Swedish family.[412] In contrast to the other major forms, CDA III is inherited as an autosomal dominant disorder although sporadic cases have also been described. [413] [414] These latter cases may represent spontaneous dominant mutations.[415] In the Swedish family, an excess number of cases of monoclonal gammopathy and myeloma have occurred.[416] Also, an adult patient with CDA III was recently described with T-cell non-Hodgkin's lymphoma.[417] These cases, plus a case of Hodgkin's disease occurring in an additional patient, may indicate an increased incidence of lymphoproliferative disease in CDA III.

In CDA III, splenomegaly is usually minimal or absent. The anemia is usually mild to moderate, but transfusion-dependent patients have been observed. [418] The circulating red cells can be normal or mildly macrocytic. Bone marrow examination shows erythroid hyperplasia. Giant erythroblasts with up to 12 nuclei are the most distinctive feature of CDA III observed on light microscopic examination of the bone marrow. These may appear similar to some of the large multinucleated cells seen in CDA II (Fig. 18-11). Abnormally large lobulated nuclei and discordance in nuclear maturation are also found. While they are hallmarks of CDA III, these findings

are not pathognomonic and may be seen in erythroleukemia. Electron microscopy demonstrates nuclear clefts and autolytic areas within the cytoplasm.

The acidified-serum lysis test is negative in CDA III. Agglutination and lysis of erythrocytes to anti-i antibody has only been examined in a few cases of CDA III with conflicting findings.[413] [415] Serum thymidine kinase was measured in 20 CDA III patients and 10 healthy siblings.[419] Elevated thymidine kinase was found in all 20 cases but was normal in the siblings. It is suggested that testing thymidine kinase levels can allow clinicians to discriminate between affected individuals and healthy siblings without performing a marrow aspirate.

Precipitation of beta chains has been observed within abnormal CDA III erythroblasts.[420] The defect in the erythroid precursors is intrinsic to the stem cell and can be reproduced in tissue culture in which morphologically normal as well as giant multinuclear erythroblasts are found.[421]

Variants

Cases of CDA have been reported that do not conform with the classification of types I, II, and III,[359] [422] [423] [424] [425] [426] [427] [428] [429] [430] [431] [432] and it has been recommended that one of these variants be termed type IV.[359] [429] The major features of some of the earlier variant cases were reviewed.[426] In two kindreds, CDA was inherited in an autosomal dominant mode. In some cases marrow erythroid multinuclearity resembled that of HEMPAS, but the acidified serum lysis test was negative.[428] [429] Long-lasting erythroblastosis occurring after splenectomy of such patients has been attributed to impairment of the denucleation of erythroblasts.[428] Unbalanced globin-chain synthesis with excess production of -chains was documented in several patients. In one kindred, a disorder with features of both thalassemia and hereditary erythroid multinuclearity was dominantly transmitted.[425] In variant syndromes, there were also differences in the degree of agglutination by anti-i antibodies and in the concentrations of hemoglobins F and A_2. In one case of CDA, the acidified serum lysis test was positive, but erythroid multinuclearity was absent.

A number of other poorly-defined CDA variants probably exist. Cases of lifelong anemia, probably inherited, have been observed.[427] These were characterized by marked aniso- and poikilocytosis and occasional teardrop and fragmented erythrocytes in the blood. Hyperplastic marrows showed megaloblastoid features without multinuclearity or ringed sideroblasts,[427] but a case with prominent ringed sideroblasts was also described.[430] Neutropenia is commonly present and thrombocytopenia has been observed in some patients. Cytogenetic studies of marrow revealed no chromosomal abnormalities. Reticulocyte response to anemia was absent or inappropriately low in all. Most case studies of parents failed to reveal abnormalities, suggesting an autosomal recessive mode of transmission.

Therapy and Prognosis

In general, the CDAs are associated with a favorable long-term prognosis. For example, CDA I was diagnosed for the first time late in life,[433] and followed a relatively benign course in another case over a 30-year follow-up.[434] Anemia is typically mild in most cases of CDA and requires no intervention, but in more severe presentations, especially those requiring transfusional support, splenectomy may be beneficial. Most of the experience showing an improvement in hemoglobin levels after splenectomy has been in CDA II; the benefit of splenectomy in CDA I is less clear.[418] [435] [436] In planning splenectomy, erythrokinetic studies beforehand may be useful to quantitate the magnitude of splenic sequestration and shortened red cell survival.

Treatment of all forms of CDA with androgens, corticosteroids, vitamin E, vitamin B_{12}, folid acid, pyridoxine, or iron is ineffective in ameliorating the anemia. Iron therapy is also contraindicated because of the underlying propensity for hemosiderosis secondary to increased gut iron absorption. Even if regular red cell transfusions are not initiated, patients should be routinely monitored for evidence of iron overload. Iron chelation with daily subcutaneous infusions of deferoxamine has been underused in the CDAs even though deaths have been recorded from hemochromatosis. A solitary case report on the successful use of deferoxamine in CDA I illustrates the potential benefit.[437] Phlebotomy has been carried out to remove iron in CDA patients, but this could result in a worsening of the anemia and theoretically enhance gut iron absorption. An additional concern is that CDA patients seem predisposed to hepatic cirrhosis irrespective of body iron burden.[367] The pathogenesis of this is unclear.

Interferon alpha-2a was recently reported to increase hemoglobin levels to normal in a CDA I patient who required repeated transfusions for moderately severe anemia.[438] Erythrokinetic studies demonstrated a striking reduction of ineffective erythropoiesis while patients were receiving interferon, and electron microscopy showed a reduction in nuclear structure abnormalities.

Asymptomatic extramedullary hematopoiesis may mimic tumors of the mediastinum, abdomen, and vertebral column.[411] [439] [440] Because of the increased red cell production that occurs, the development of sites of extramedullary hematopoiesis may result in an amelioration of the degree of anemia.[441] Technetium-99m sulfur colloid scintigraphy is useful in delineating the extent of these regions.[440]

INTRODUCTION

Aplastic anemia (AA), the paradigm of bone marrow failure syndromes, is most simply defined as peripheral blood pancytopenia and a hypocellular bone marrow (Plate 19-1A, B). From epidemiologic and clinical features, pathophysiologic studies, and response to therapy, AA is a distinctive disease. However, the proper diagnosis of AA requires excluding other causes of pancytopenia (Table 19-1). In addition, AA may occur as a primary hematologic disorder, most often idiopathic, or apparently secondary to various proximate causes, including obvious physical and chemical toxins but also medicinal agents and viruses that may act indirectly. Although AA is usually characterized by a severe diminution in bone marrow function that affects all the hematopoietic lineages, granulocyte, platelet, and red blood cell (RBC) levels may not be depressed uniformly, and less severe degrees of marrow hypoplasia and odd combinations of bicytopenias and even monocytopenias may be observed. Aplastic anemia can be especially difficult to distinguish from hypocellular forms of myelodysplasia, a diagnostic confusion that may rest on real biologic similarities. Even typical AA may vary in its clinical presentation and course, from a fulminant illness marked by continuous or recurrent hemorrhage and major infections to an indolent process manageable by transfusions alone.

History

The study of bone marrow failure is traditionally dated to 1888, when Paul Ehrlich described a young woman who died after an explosive short illness marked by severe anemia, bleeding, and high fever.[1] As a pathologist, Erhlich was struck by the absence of nucleated RBCs and the fatty quality of the femoral marrow, opposite findings from the physiologic response to severe anemia, and he inferred from the morphology a mechanism of failed blood cell regeneration. Vaquez and Aubertin in their 1904 case report of pernicious anemia with yellow marrow first named the disease and emphasized a pathophysiology of failed hematopoiesis (anhematopoiesis).[2] Cabot stressed the marrows distinctive pathology and emphasized the need for its examination in diagnosis. [3] Tissue from patients with early cases of AA could only be examined at autopsy, and in practice, as reflected in the medical literature of the early 20th century, pancytopenia was often equated with aplastic anemia. The etymologic root of the term aplastique

TABLE 19-1 -- Differential Diagnosis of Pancytopenia

Pancytopenia with Hypocellular Bone Marrow
Acquired aplastic anemia
Inherited aplastic anemia (Fanconi anemia and others)
Some myelodysplasia syndromes
Rare aleukemic leukemia (acute myelogenous leukemia)
Some acute lymphoblastic leukemias
Some lymphomas of bone marrow
Pancytopenia with Cellular Bone Marrow
Primary bone marrow diseases
Myelodysplasia syndromes
Paroxysmal nocturnal hemoglobinuria
Myelofibrosis
Some aleukemic leukemias
Myelophthisis
Bone marrow lymphoma
Hairy cell leukemia
Secondary to systemic diseases
Systemic lupus erythematosus, Sjögrens syndrome
Hypersplenism
B_{12} , folate deficiency (familial defect)
Overwhelming infection
Alcohol
Brucellosis
Ehrlichiosis
Sarcoidosis

Tuberculosis and atypical mycobacteria
Hypocellular Bone Marrow ± Cytopenia
Q fever
Legionnaires disease
Mycobacteria
Tuberculosis[a]
Anorexia nervosa, starvation
Hypothyroidism

[a]Pancytopenia in tuberculosis only rarely is associated with a hypocellular bone marrow at biopsy or autopsy. Marrow failure in the setting of tuberculosis is almost always fatal; exceptional patients probably had underlying myelodysplasia or acute leukemia.

is the Greek verb ´theta, to create and give shape to (´eta, the adjective, unformed). Of course, inferences about the etiology of the disease were made from the bone marrow appearance. The aplastic variety of pancytopenia was distinguishable from secondary cellular or regenerative pernicious anemias, and AA was recognized as primary and due to failed blood cell production. [2] Pathologically, the watery yellow marrow seen at autopsy uniquely characterized the aplasia, but the limited and rather general clinical signs were less helpful in distinguishing this type of aregenerative marrow failure from other anemias. [4] Inability of the marrow to produce hematopoietic cells is a common feature of many hematologic diseases, many of which are not classified as bone marrow failure states. Conversely, the concept of AA as an intrinsic marrow disorder may be more applicable to inherited marrow failure than to the immunologically mediated form of the disease observed in adults. Some of the early speculation about marrow failure being a consequence of an environmental insult, either infectious or chemical in nature, or occurring indirectly through altered regulation of hematopoiesis may not have been far off the mark.

Classification

AA is a major sequela of radiation and exposure to chemical agents. It has been associated with use of chemicals and drugs, with viral infections, and with other diseases (Table 19-2). Most patients have an idiopathic form of the disease, meaning only that the cause is unknown. Too strict a division of cases into categories can obscure important pathophysiologic relationships. In any event, the relation between clinical associations and causation is neither direct nor reliable. The basis for assigning

TABLE 19-2 -- A Classification of Aplastic Anemia

Acquired Aplastic Anemia
Secondary aplastic anemia
Irradiation
Drugs and chemicals
Regular effects
Cytotoxic agents
Benzene
Idiosyncratic reactions
Chloramphenicol
Nonsteroidal antiinflammatories
Antiepileptics
Gold
Other drugs and chemicals
Viruses
Epstein-Barr virus (infectious mononucleosis)
Hepatitis virus (non-A, non-B, non-C, non-G hepatitis)
Parvovirus (transient aplastic crisis, some pure red cell aplasia)
Human immunodeficiency virus (acquired immunodeficiency syndrome)
Immune diseases
Eosinophilic fasciitis
Hypoimmunoglobulinemia
Thymoma and thymic carcinoma
Graft-versus-host disease in immunodeficiency
Paroxysmal nocturnal hemoglobinuria
Pregnancy
Idiopathic aplastic anemia
Inherited Aplastic Anemia
Fanconi anemia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Reticular dysgenesis
Amegakaryocytic thrombocytopenia
Familial aplastic anemias
Preleukemia (monosomy 7, etc.)
Nonhematologic syndromes (Down, Dubowitz, Seckel)

a particular case to a particular cause depends on the history. How closely is the patient questioned? How biased are the inquiries? How conscientiously is a possibly significant but distant toxic exposure sought? How exaggerated is a brief episode? Ultimately, patients with idiopathic and secondary disease require similar support and definitive therapies; with a few exceptions, there is little basis for major differences in their clinical management.

EPIDEMIOLOGY

Incidence

The largest and most comprehensive study of the epidemiology of bone marrow failure is the International Aplastic Anemia and Agranulocytosis Study (IAAAS) conducted in Europe and Israel from 1980 to 1984.[5] This study was performed prospectively and applied strict case definition to pathologically confirmed cases. Using stringent criteria, the overall annual incidence of AA was 2 cases/10^6. Other subsequent studies of similar design have confirmed this figure.[6] The incidence rates reported in the IAAAS study are considerably lower (by 3-to 4-fold) than rates reported in many earlier, mainly retrospective and far less well-designed surveys. Although an apparent increase in the incidence of AA during the 1950s and 1960s was reported by some groups, such a trend has not been supported by data collected in the past 20 years, during which the incidence rates have been stable.[5] [7] [8]

Age Distribution

AA has been identified as a disease of the young. Histograms showing the age distribution of patients (Fig. 19-1) demonstrate

Figure 19-1 Distribution of aplastic anemia by age. For the patients at the University of Washington (a major transplantation center), age is at first treatment; for the patients at the National Institutes of Health (where immunosuppressive therapy is offered), age is at the time of diagnostic bone marrow biopsy. Acute disease is defined as <3 months between diagnosis and presentation at NIH, and chronic as >3 months. *(Seattle statistics made available courtesy of Rainer Storb).*

two peaks, with most patients presenting at age 1525 or after age 60, and with a trough in middle life.[9] [10] The peak of occurrence conflicts with mortality data indicating a single major rise in deaths from AA in late middle age;[11] the explanation for this discrepancy is probably misdiagnosis of AA through confusion of AA with myelodysplasia in older people.[12]

Geographic Distribution

The most remarkable feature of the epidemiology of AA is the unexplained geographic variation in its incidence. The long-standing impression of physicians in Asia and their European and American visitors is that AA is far more common in Asia than in the West. The frequency of AA as an admission diagnosis may rival that of acute myeloid leukemia (AML) in these centers;[13] by contrast, in most American hospitals, AML is five to ten times more common as an admitting diagnosis than AA. National surveys in Japan[14] [15] and China[16] [17] published in the 1970s and 1980s suggested very high prevalence and incidence figures for AA. Autopsy series [18] and mortality statistics[19] suggested that the annual death rate from AA might be more than three times higher in the Far East than in the West. More recently, the incidence of AA in Bangkok and two rural regions of Thailand has been accurately determined using the same methods as employed by the IAAAS researchers in Europe and Israel; the annual incidence was 4.0/10^6 in the capital and 5.6/10^6 in the northeastern province of Khonkaen.[20] The incidence in 21 Chinese provinces has been estimated to be 7.4/10^6 annually,[21] and in the Sabah province of Malaysia a retrospective analysis suggested a rate of 5/10^6.[22] From published, hospital-based series, personal communications, and first-hand observations, AA appears most prevalent in specific regions of the world, including Vietnam, Indonesia, Russia, the former Soviet republics, Iran, Iraq, Pakistan, India, Mexico, other regions of Latin America, [23] and Africa, where it is likely underdiagnosed. [24] In these developing countries the rate of AA appears to be two to three times higher than in Europe.

In the United States, there are no major sex or racial differences in the occurrence of AA.[7]

Epidemiologic Clues to Causality

Population-based studies have investigated possible causal associations. Drugs are implicated in only about 25% of cases of AA. [5] The major drug associations in the IAAAS study were with gold salts (relative risk [RR] of 29), antithyroid drugs (RR = 11), and nonsteroidal anti-inflammatory agents (e.g., RR = 8.2 for indomethacin). Benzene, insecticides, and petrochemicals were only modestly related. Other smaller studies have shown associations with chemical exposures, exposures to viruses, hepatitis, and occupation.[25] In Thailand, significant and high RR ratios have been established for a number of independent variables, including low income, [26] rural residence, and prior exposure to hepatitis A virus; perhaps most provocative is a link to rice farming. [27] AA was attributed to drug exposure in only about 15% of cases. Clusters of AA provide further evidence of an environmental etiology. [28] Japanese in Hawaii seem to have a similar incidence of AA as non-Orientals born in North America.[19] Conversely, a high incidence of AA was reported in the Pacific theater during World War II, an observation that was attributed to quinacrine exposure.[29] Thus, the geographic variation in AA is probably due mainly to environmental causes rather than being based on a genetic predisposition.

GENETIC ASPECTS

More than one case of acquired AA in a single family is a rare occurrence. In children and young adults, acquired AA should be distinguished from the inherited forms of bone marrow failure such as Fanconi anemia. Identification of patients with Fanconi anemia has important therapeutic implications. Patients with Fanconi anemia may lack typical physical anomalies, and the pancytopenia may develop after childhood (see Chap. 18). Occasionally, AA that is not due to Fanconi anemia has been observed in multiple family members.[30]

The host immune response is genetically restricted, as exemplified by familial susceptibility for autoimmune disease based on HLA linkage. A few histocompatibility types have also been associated with AA, most consistently HLA-DR2:[31] in one study of 75 patients, HLA-DR2 was twice as frequent in AA patients as expected in the population.[32] Other associated antigens include A2 and HLA-B14 class I loci and DR4 and Dpw class II antigens. [33] [34] [35] [36] [37] An analysis of 106 AA patients typed for HLA-A and B loci showed an increased frequency of HLA-B7 and HLA-B14 antigens. Typing for HLA-C loci in 96 AA patients revealed an increased representation of HLA-C7 antigens, while in 82 patients in whom class II typing was performed a previously described increased frequency of HLA-DR2 and HLA-DR15 antigens was observed.[38] HLA-DR subtypes have proved useful in predicting response to immunosuppressive therapy in some studies. In Japanese patients, a class II haplotype (DRB*1501) that determines HLA-DR2 presentation has been recorded to be strongly associated with hematologic responses to cyclosporine (CsA),[39] as well as with the probability of relapse[31] and CsA dependence.[40] However, HLA-DR2 has been inconsistently associated with response to immunosuppression in other studies. The haplotypes associated with clozapine-induced agrannlocytosis have been linked to the heat-shock protein variants encoded within the large major histocompatibility gene region.[41] Genetic predisposition may be responsible for some idiosyncratic reactions to drugs and chemicals leading to the development of AA.

ETIOLOGY AND PATHOGENESIS

Hematopoiesis in Bone Marrow Failure

Stem Cells

A consistent laboratory finding in AA is the very low numbers of assayable blood and bone marrow progenitor cells. [42] [43] [44] Colony formation by bone marrow cells of patients with severe disease remains unresponsive, even to high levels of hematopoietic growth factors. [45] [46] This defect can persist long after successful treatment of the underlying AA. [43] [47] [48] Not only is the total number of progenitors in a marrow sample reduced, but the number of colony progenitor cells assayed from a purified CD34+ population is also low. [43] In humans, a stem cell surrogate assay that assesses cells capable of colony formation after more than a month in long-term bone marrow culture is available; these long-term culture-initiating cells (LTC-IC) share the frequency, phenotype, and kinetic properties of true stem cells. Studies indicate a profound deficiency in LTC-IC numbers in all patients with severe AA. [49] [50] At clinical presentation, the number of LTC-IC is usually <10% of normal; combined with a reduction in total marrow cellularity to 10%, the stem cell number is estimated to be reduced to 1% of normal in AA (Fig. 19-2).

Figure 19-2 CD34+ cells, primary colony-forming cells, and LTC-IC numbers measured in bone marrow of aplastic anemia patients. Each dot represents an individual patients sample studied. Severe AA (sAA) includes patients at presentation, cases refractory to immunosuppressive therapy, and patients who relapsed after a period of recovery. N, controls; mAA, moderate aplastic anemia; rAA, recovered from aplastic anemia; CFC, colony-forming cells. Primary CFCs were measured in short-term methylcellulose cultures. Secondary CFCs after long-term bone marrow culture reflect LTC-IC numbers.

Figure 19-3 Normal stromal cell function in long-term culture of aplastic anemia bone marrow. *(Courtesy of Dr. Judith Marsh).*

The CD34+ cell marrow population contains most of the committed progenitor cells and stem cells. CD34+ cell numbers are also dramatically reduced in most patients with AA. [43] Patients who have recovered from moderate AA may have higher CD34+ counts, but CD34+ cell levels often remain low despite hematologic recovery. [43] [51]

Stroma and Hematopoietic Growth Factors

The survival and proliferation of hematopoietic cells are dependent on stromal cells. Stromal cell function is usually not defective in AA. [42] For example, adherent cells from patients support hematopoiesis by normal CD34+ cells, whereas no hematopoietic colonies develop when patients CD34+ cells are cultured in the presence of normal stroma (Fig. 19-3). [52] [53] Stromal cells cultured from patients bone marrow generally produce normal quantities of hematopoietic growth factors. [54] [55] [56] A few studies have suggested deficiencies in some factors, an observation of uncertain pathophysiologic significance. Stroma isolated from a minority of patients may poorly manufacture granulocyte-macrophage colony-stimulating factor (GM-CSF), [57] interleukin-3 (IL-3), and granulocyte colony-stimulating factor (G-CSF) [58] or interleukin-1. [59] However, serum levels of erythropoietin, [60] thrombopoietin, [61] G-CSF, [62] and GM-CSF are significantly elevated. [63] Cytokines that act at very early stages of hematopoiesis have been studied as possible etiologic factors in the pathobiology of AA. Flt-3 ligand blood levels are highly elevated in AA, [64] while stem cell factor (SCF) levels are modestly decreased, [65] [66] SCF stromal cell production has been reported to be normal. [66] Adequate stroma function is implicit in the success of marrow transplantation in AA because important stromal elements remain of host origin. Treatment with hematopoietic growth factorseven those putatively deficient in patientshas not been very effective in restoring hematopoiesis in severely affected patients. Thus, the combination of clinical and laboratory observations argues against a defect in stroma function as being responsible for AA.

Pathophysiologic Pathways Leading to Aplastic Anemia

Direct Hematopoietic Injury

Although the commonest form of AA is iatrogenic, transient marrow failure often follows treatment with cytotoxic chemotherapeutic drugs or irradiation (Fig. 19-4). Certain chemical or physical agents directly injure both proliferating and quiescent hematopoietic cells. Such agents cause sufficient damage to DNA to result in apoptosis. However, patients with community-acquired AA rarely have a history of exposure to such physicochemical agents. Even benzene, which may act as particularly inefficient cytotoxic chemical, is an infrequent cause of AA in developed countries. [5] As discussed later, medical drugs are frequently associated with acquired AA, and at least in some instances they may directly cause marrow damage. However, in comparison to conventional therapeutic agents, which are delivered in high doses, relatively low total quantities of ingested drug can cause idiosyncratic hematologic reactions.

Although the causes of idiopathic AA remain unclear, viruses have also been hypothesized to be involved in the pathophysiology of AA. In addition to their direct toxic effects, chemicals and viruses may induce complex immune reactions leading to bone marrow failure in AA (Fig. 19-4). Different etiologic factors may serve as inciting events, resulting in a common pathophysiologic pathway leading to marrow aplasia.

Immune-Mediated Marrow Failure
