The role of membrane lipids in the acanthocyte shape transformation was first established by findings of restoration of biconcave shape after extraction of lipids from the cell membrane by detergents.[390] The molecular basis of the acanthocytic shape is unknown, but several indirect observations suggest that it is related to an increase of the surface area of the outer hemileaflet of the lipid bilayer relative to the inner leaflet. In normal red cells, sphingomyelin is present predominantly in the outer bilayer leaflet; thus, it is likely that the extra sphingomyelin is located in the same leaflet. [391] This conclusion is supported by the observation of shape transformation of acanthocytes to discocytes on incubation with chlorpromazine, a compound that preferentially accumulates in the inner half of the lipid bilayer, leading to its expansion, thus normalizing the surface area asymmetry between the two bilayer halves. Furthermore, sphingomyelin is less fluid than the other phospholipids, which presumably accounts for the overall decrease in acanthocyte membrane fluidity. [392]

Several other abnormalities have been noted in abetalipoproteinemia, including a decrease in plasma lecithin cholesterol transferase activity and an increased susceptibility of membrane and plasma lipids to oxidation as a result of malabsorption-induced deficiency of vitamin E. [363] [393] [394] The contributions of these abnormalities to the acanthocyte red cell lesions is unknown. It should be noted that the membrane lesion in abetalipoproteinemia is considerably milder than that in spur cells of severe liver disease, as evidenced by only mild anemia and a moderately shortened red cell half-life of abetalipoproteinemic acanthocytes. [377] [385]

Clinical Manifestations

This autosomal recessive disease may become evident in the first few months of life, manifested by fat malabsorption with normal absorption of other nutrients. [377] [384] Intestinal biopsy is diagnostic, revealing engorgement of mucosal cells with lipid droplets. [352] [377] [384] [395] [396] Other features include retinitis pigmentosa, which may result in blindness, and a progressive ataxia with intention tremors that usually develops at between 5 and 10 years of age, progressing to death in the second or third decade.[396] [397] Occasionally, ocular manifestations are absent. [398] The hematologic manifestations are relatively mild and include mild normocytic anemia with acanthocytosis (5090%) and normal or slightly elevated reticulocyte counts. [350] [351] [376] [377] [388] Occasional patients may have more severe anemia resulting from the nutritional deficiencies (iron and folate) that accompany fat malabsorption. [376] [377] The treatment includes dietary restriction of triglycerides and supplementation with the lipid-soluble vitamins A, K, D, and E. Vitamin E may stabilize or even improve both the retinal and neuromuscular abnormalities. [377]

Autosomal recessive abetalipoproteinemia should be distinguished from the homozygous form of familial hypobetalipoproteinemia. [376] [377] Although the clinical presentation of both disorders is similar, the latter disorder is milder and the parents have occasional acanthocytes on the peripheral blood film and their plasma low-density lipoproteins are decreased. The molecular lesions in familial hypobetalipoproteinemia involve a variety of apoprotein B gene mutations, leading to aberrant apoprotein B gene transcription or translation. [376] [399] [400] [401] [402] [403]

Variable degrees of acanthocytosis without anemia have also been described with isolated deficiency of apoprotein B100. [402] [403] One of two patients reported was ataxic, while the other had some degree of fat malabsorption. Neither had evidence of retinopathy, and plasma triglyceride levels were normal.

Chorea-Acanthocytosis Syndrome

This autosomal recessive syndrome of adult onset is manifest by multiple neurologic abnormalities, including limb chorea, progressive orofacial dyskinesia with tics, tongue-biting neurogenic muscle hypotonia, and atrophy. [354] [355] [404] [405] [406] [407] The hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral blood film without anemia and normal or only slightly decreased red cell survival. [354] [408]

Some patients have developed parkinsonism or pigmentary retinopathy. [409] [410] One patient with acanthocytosis had a stroke-like syndrome due to encephalopathy, chronic lactic acidosis (possibly related to mitochondrial abnormalities of the muscle), and pellagra-like changes on neuropathologic examination.

The mechanism of acanthocytosis in this syndrome is unknown. Studies of plasma and red cell membrane lipids have revealed no abnormalities [354] [404] [408] [411] except for a high content of unsaturated fatty acids, presumably accounting for a reduced red cell membrane fluidity. [411] [412] Additional abnormalities of uncertain significance include an uneven distribution of intramembrane particles, impaired phosphorylation of the erythrocyte actin-bundling protein dematin, and, in one report, altered function and structure of the erythrocyte anion-exchange protein. [413] [414] Recently, a genome screen of 11 families with chorea-acanthocytosis localized a candidate region to a 6-cM region of chromosome 9q21. [415]

McLeod Phenotype

The McLeod syndrome is characterized by a mild compensated hemolytic anemia with a variable percentage of acanthocytes on the peripheral blood film and, in some patients, late-onset myopathy or chorea.[356] [416] [417] The McLeod blood group phenotype is an X-linked anomaly of the Kell blood group system in which red cells, white cells, or both react poorly with Kell antisera. The affected cells lack Kx, the product of the *XK* gene, which appears to be a membrane precursor of the Kell antigens.[418] [419] The *XK* gene encodes a novel 444-amino acid integral membrane transporter. [420] As expected, Kx is defective in McLeod patients.[420] [421] [422] Male hemizygotes who lack Kx have variable acanthocytosis (885%) and mild, compensated hemolysis.

Because of the red cell mosaicism predicted by the Lyon hypothesis of X chromosome inactivation, female heterozygote carriers may have occasional acanthocytes on the peripheral blood film.[417] [423] Lyonized women with more severe symptoms have been described.[421]

The McLeod syndrome has been reported in association with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne muscular dystrophy.[423] [424] [425] This association is due to the close proximity of the genetic loci for the above disorders in the p21 region of the X chromosome (Xp21),

suggesting the occurrence of variable manifestations due to contiguous gene syndromes. [424] [425] [426] [427] [428] This may explain the occasional findings of either echinocytes or stomatocytes in Duchenne dystrophy, or a choreiform disorder in some subjects with McLeod phenotype. [429] [430] [431]

The Kell antigen appears to consist of two protein components: a 37-kd protein that carries the Kx antigen, a precursor molecule necessary for the Kell antigen expression, and a 93-kd protein that carries the Kell blood group antigen. [418] [432] Red cells with the McLeod phenotype have no detectable Kx antigen, and they have a marked deficiency of the 93-kd protein that carries the Kell antigen. McLeod red cells should be distinguished from Kell null (K_0) red cells, which have a normal shape. In K_0 cells, only the Kell antigen carrying 93-kd glycoprotein is absent, while these cells have twice the amount of the Kx antigen. [418] As in the other acanthocytic disorders, the surface projections of acanthocytes may be related to asymmetry of the surface area of the two lipid bilayer hemileaflets, as indicated by correction of the acanthocytosis by agents that expand the inner lipid layer, [433] [434] as well as the finding of an increased rate of exchange of phosphatidylcholine (localized preferentially in the outer lipid hemileaflet) with an exogenous source. [391] [435] Studies of membrane lipid and protein composition, membrane fluidity, and intracellular enzyme and ATP levels were all normal. [430] [436] In contrast, abnormalities were found in the phosphorylation of certain membrane proteins and phospholipids, in the density of intramembrane particles, and in water permeability, along with reduced deformability and mechanical stability of red cells, but the contribution of these abnormalities to the cell lesion is unknown. [437] [438]

Acanthocytosis in Other Conditions

Two of eight subjects carrying the In phenotype, characterized by decreased expression of the Lutheran P1, I, and Aua blood group antigens, were reported to have acanthocytes on their peripheral blood smears. [439] In one report, a dominantly inherited acanthocytosis was found in association with structural alterations of the anion channel protein involving increased molecular size, restricted rotational diffusion, and a decrease in high-affinity binding sites for ankyrin. [440]

Acanthocytes have also been noted in malnourished patients, including those with anorexia nervosa and cystic fibrosis. In these patients, red cell shape normalizes after restoration of the nutritional status. [357] [359] [367] Likewise, a small number of cells with long spicules resembling acanthocytes are found in hypothyroidism, [360] after splenectomy, [361] and in myelodysplasia.

Differentiation of Acanthocytes from Other Spiculated Red Cells

Echinocytes (Burr Cells)

In contrast to acanthocytes, echinocytes, also called burr cells, have rather uniform surface projections. Although early echinocytic forms have a regularly scalloped cell contour, advanced forms of echinocytes have a spheroidal shape and the surface projections appear as short, narrow spikes (Fig. 33-12 (Figure Not Available)). Although the finding of echinocytes on a peripheral blood film is often an artifact related to blood storage, contact with glass, or an elevated pH, [349] [361] several hemolytic anemias have been reported in association with echinocytosis on peripheral blood films. These conditions include mild hemolytic anemia in long-distance runners[441] and in patients with hypomagnesemia and hypophosphatemia (presumably because of decreased intracellular ATP stores), [375] uremia due to an unknown plasma factor,[442] and pyruvate kinase deficiency. [361]

Inspection of wet blood preparations (but not dried blood films) reveals echinocytosis in most patients with liver disease. [443] In contrast to spur cells in patients with severe liver disease, these echinocytes have a normal cholesterol content, and the molecular abnormality may be related to the binding of abnormal echinocytogenic high-density lipoproteins to the red cell surface. [443]

The mechanisms of echinocytosis in these diverse disorders are likely to be heterogeneous, as suggested by findings that many diverse factors, such as exposure of red cells to certain drugs, calcium loading, or ATP depletion, can induce the transformation of discocytes to echinocytes in vitro. [444] [445] [446] However, in vitro studies of the discocyte-echinocyte-stomatocyte equilibrium have suggested a possible common denominator. As discussed in the Introduction, the lipid bilayer of normal red cells is asymmetric in lipid composition: the outer half of the lipid bilayer is relatively enriched in sphingomyelin and phosphatidylcholine, whereas the inner half is preferentially enriched in the negatively charged phosphatidylserine and phosphatidylethanolamine. [391] [435] Agents that preferentially bind to one or another class of these phospholipids dramatically influence red cell shape. Consequently, agents that preferentially accumulate in the outer half of the red cell lipid bilayer, expanding this lipid bilayer, produce an echinocytic shape, presumably by creating an asymmetry between the two surface areas of the two halves of the lipid bilayer (see Fig. 33-2). Conversely, agents that asymmetrically expand the inner half of the lipid bilayer, such as chlorpromazine, lead to stomatocytic shape transformation. [11] In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution between the two bilayer hemileaflets may be a consequence of calcium-induced phospholipid scrambling or a decrease in the activity of aminophospholipid translocase, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer leaflet to the inner hemileaflet. [12]

Keratocytes, Bizarre Poikilocytes, and Schistocytes

Mechanical trauma of circulating red cells has occasionally produced bizarre shapes resembling acanthocytes, such as cells with horny projections (keratocytes). Some acanthocyte-like cells are also seen in splenectomized HE and HS subjects. Similar shape changes are seen in heated red cells, in which spectrin has been damaged by thermal denaturation, suggesting that these cells are bizarre poikilocytes rather than true acanthocytes. [210] Similar shape abnormalities have been described as an asymptomatic trait (Woronets trait). [447]

RED CELL MEMBRANE DISORDERS MANIFESTED BY TARGET CELL FORMATION

The common feature of target cells is an increase in the ratio of the cell surface area to cell volume. In microcytic red cells of patients with various forms of thalassemia and hemoglobinopathies, the increased surface/volume ratio, and consequently the target cell shape, reflects, at least in part, the relative abundance of cell-surface area. In liver disease and other disorders discussed below, the target cell formation reflects an absolute expansion of the cell-surface area because of a net accumulation of membrane phospholipids and cholesterol.

Liver Disease

The presence of target cells in association with either normal or slightly increased cell volume is characteristically found in patients with obstructive jaundice, including various forms of liver disease associated with intrahepatic cholestasis. [364] [368] These target cells have a normal survival in the peripheral circulation and do not typically account for the anemias often encountered in patients with liver disease.

In these patients, target cell formation is a consequence of a net uptake of both free cholesterol and phospholipids into the red cell membrane from the plasma because of abnormalities in the cholesterol/phospholipid/protein ratios of low-density lipoproteins. [364] [368] Target cells have a decreased osmotic fragility, as the excess of membrane surface area leads to an increase in the critical hemolytic volume.

Lecithin Cholesterol Acyltransferase Deficiency

The lecithin cholesterol acyltransferase (LCAT) enzyme catalyzes the transfer of fatty acids from phosphatidylcholine to cholesterol. [448] It circulates in plasma as a complex with components of high-density lipoproteins. LCAT deficiency is a rare autosomal dominant disorder manifested by hyperlipidemia, premature atherosclerosis, corneal opacities, chronic nephritis, proteinuria, mild anemia, and the presence of target cells on the blood film. The anemia is due to mild hemolysis together with a diminished compensatory erythropoiesis. [448] As in obstructive jaundice, the target cells in LCAT deficiency have a marked increase in both cholesterol and phospholipids. In addition, the membrane phosphatidylcholine is increased at the expense of sphingomyelin and phosphatidylethanolamine. [448] [449] Bone marrow aspiration and biopsy reveals the presence of sea blue histiocytes. Analysis of plasma lipoproteins reveals multiple abnormalities secondary to the underlying enzyme deficiency. Inherited LCAT deficiency should be distinguished from an acquired deficiency of this enzyme, which is found in patients with severe liver disease. [363] [393]

STOMATOCYTOSIS AND RELATED DISORDERS

Stomatocytes were first described in a girl with dominantly inherited hemolytic anemia. [450] On blood films, her red cells contained a wide transverse slit or stoma (Fig. 33-14). In a three-dimensional view, these cells have a shape of a cup or a bowl. [451] The slitlike appearance is an artifact that results from folding of the cells during blood smear preparation.

Stomatocytes are seen in a variety of acquired and inherited disorders. The latter are often associated with abnormalities in red cell cation permeability that lead to changes in red cell volume, which may be either increased (hence the designation hydrocytosis) [452] [453] [454] or decreased (dessicocytosis or xerocytosis), [455] or, in some cases, near normal.

There is no unifying theory to explain this morphologic abnormality. In vitro, stomatocytes can be produced by drugs that preferentially intercalate into the inner half of the asymmetric lipid bilayer, expanding its surface area relative to that of the outer half of the bilayer. [11]

Hereditary StomatocytosisHydrocytosis

Hereditary hydrocytosis designates a seemingly heterogeneous group of hereditary hemolytic anemias that are transmitted in an autosomal dominant mode in most patients. [453] [456] [457] [458] The disorder is characterized by a moderate to severe hemolytic anemia with 1030% stomatocytes, an elevated MCV, and a reduced MCHC. Osmotic fragility of red cells is markedly increased, as some of the swollen red cells approach their critical

Figure 33-14 Peripheral blood smear of a patient with hereditary **(A)** xerocytosis (dessicocytosis) and **(B)** stomatocytosis (hydrocytosis). *(From Lande and Mentzer,[452] with permission.)*

hemolytic volume. For unexplained reasons, red cell membrane lipids and, consequently, membrane surface area are also increased, [454] but this increase in surface area is insufficient to correct the osmotic fragility of the red cells. Red cell deformability is decreased. [454] [459]

The principal cellular lesion involves a marked increase in intracellular sodium and water content with a mild decrease in intracellular potassium as a result of a marked sodium influx into the red cells. [452] [454] [456] [457] [458] [459] Despite a marked compensatory increase in active transport of sodium and potassium by the Na^+/K^+-ATPase (which normally maintains the low sodium and high concentrations in the cells) and an ensuing increase in glycolysis, the pump hyperactivity is unable to compensate for the vastly increased sodium leak. [408] [452] [454] [456] [457] [458] [459] [460] [461] The molecular basis of this permeability defect is unknown. In vitro, the defect is corrected by a bifunctional cross-linking agent, [462] [463] suggesting the involvement of a membrane protein. Analysis of membrane protein was normal in some patients, [452] [454] [456] [457] [458] [459] but in others the presence of a 25-kd protein of an unknown function was reported. [464] However, this protein was also present in subjects with other disorders who had undergone splenectomy and who had elevated reticulocyte counts. [464] Band 7.2b (stomatin), an integral membrane protein, has been reported to be decreased or absent from the erythrocyte membranes of affected patients. [465] [466] [467] [468] This protein has now been cloned and sequenced, but no mutations have been found in two unrelated patients deficient in this protein. [469] [470]

BLOOD FILM EVALUATION: A CLUE TO PATHOPHYSIOLOGY AND DIAGNOSIS OF A RED CELL MEMBRANE DISORDER

Advances in the understanding of the structure and function of red cell membrane have highlighted the importance of blood film evaluation in the diagnosis of a red cell membrane disorder. Red cell shape abnormalities may provide clues both to disease pathobiology and to diagnosis (see table on opposite page).

MICROSPHEROCYTES

The finding of microspherocytes indicates a deficiency of red cell surface area. In autoimmune hemolytic anemia, the IgG-coated red cells attach to macrophages, which remove parts of the membrane material from the cells. In hemolytic anemias associated with the presence of Heinz bodies, membrane material is removed together with the membrane-associated Heinz bodies as a result of the pitting function of the spleen. In the context of a lifelong hemolytic anemia or a positive family history, the finding of spherocytes leads to the diagnosis of hereditary spherocytosis (HS). The surface area deficiency of HS red cells reflects a lipid loss resulting from the underlying deficiency of spectrin or other major membrane proteins.

ELLIPTOCYTES, POIKILOCYTES, AND FRAGMENTS

Elliptocytes and poikilocytes are found both in hereditary elliptocytosis (HE) and in many acquired conditions, including iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, and myelodysplastic syndromes. The molecular basis of acquired elliptocytosis is unclear; in our experience, laboratory evaluation of the underlying molecular defect yields negative results. In contrast, many molecular defects have been detected in HE, and the laboratory evaluation is useful both in establishing the diagnosis and in detecting asymptomatic carriers. In more severe forms of the disorder, elliptocytosis is invariably associated with the presence of poikilocytes and red cell fragments. These findings indicate that the membrane is markedly unstable, as in hemolytic forms of HE or hereditary pyropoikilocytosis (HPP), in which a skeletal protein defect alters the two-dimensional integrity of the membrane skeleton. In severe hemolytic forms of HE and in HPP, the mean corpuscular volume is markedly reduced, since many red cells circulate in the form of fragments, which implies a severe defect in the stress-supporting horizontal interactions of the membrane skeleton. The red cell size distribution index is high, indicating a considerable size heterogeneity of the circulating red cell fragments. Such fragments differ from schistocytes produced by a mechanical trauma to the red cells: the former fragments are round, often seen budding from the red cell membrane, whereas schistocytes appear as cuts with sharp edges and often bizarre shapes, while the remaining red cells are relatively intact. Elliptocytes are also seen in the peripheral blood smears of some patients with -thalassemia syndromes.

ECHINOCYTE/DISCOCYTE/STOMATOCYTE EQUILIBRIUM

Echinocytescells with fine, multiple, and uniform spiculesare found in many conditions, including malnutrition associated with mild hemolysis due to hypomagnesemia and hypophosphatemia, uremia, and hemolytic anemia in long-distance runners. They are also a common artifact of elevated pH, blood storage, or contact with glass. Although the mechanism of echinocyte formation in vivo is not clear, studies in vitro suggest that echinocytosis is caused by an expansion of the outer hemileaflet of the lipid bilayer relative to the inner bilayer hemileaflet. By contrast, expansion of the inner lipid bilayer leaflet relative to the outer leaflet leads to cup shape formation (stomatocytosis) and surface invaginations. Stomatocytosis is seen either as an inherited hemolytic anemia associated with cell volume changes or as an acquired condition, particularly in alcohol-induced liver disease.

ACANTHOCYTES

In contrast to echinocytes, acanthocytes contain long, irregular protrusions that suggest both a net accumulation of lipids in the red cell membrane and an asymmetry between the two lipid bilayer hemileaflets with a preferential expansion of the outer hemileaflet. In the spur cell hemolytic anemia associated with severe liver disease, these spurs reflect a net gain of free (unesterified) cholesterol that preferentially accumulates in the outer half of the lipid bilayer. Because of the conditioning effect of the spleen, the cells are also spheroidal, indicating a secondary loss of surface area, yet their surface protuberances are very prominent. In abetalipoproteinemia, acanthocytes contain excess sphingomyelin in the outer lipid bilayer hemileaflet. The mechanisms of acanthocytosis in other conditions (chorea-acanthocytosis syndrome, malnutrition, hypothyroidism, and McLeod phenotype) are unknown.

TARGET CELLS

In contrast to spherocytes, target cells have either a relative or an absolute excess of surface for a given red cell volume. A relative excess of the surface area is typically found in microcytic red cells in most patients with thalassaemia minor and some hemoglobinopathies (hemoglobin C, D, and E). In red cells having normal or even slightly increased volume, targeting indicates an absolute excess of surface area. For example, in a patient with liver disease or obstructive jaundice, red cell surface area is expanded because both phospholipids and cholesterol are transferred from the abnormal plasma lipoproteins into the red cell membrane.

DEHYDRATED RED CELLS

Changes in red cell density, as reflected by increased mean corpuscular hemoglobin concentration, can likewise be appreciated on the blood film. The staining intensity of intracellular hemoglobin of spherocytes, regardless of the mechanism of their formation, is greater than that of normal discocytes, because the hemoglobin layer that is in the optical path between the light source and the observers eye is thicker than in the normal discocyte. However, the staining intensity of intracellular hemoglobin and, hence, the density of hereditary spherocytes are typically greater than that of spherocytes in autoimmune hemolytic anemia, because hereditary spherocytes are also somewhat dehydrated. In some inherited disorders associated with cellular dehydration (xerocytosis), cells may be either stomatocytic or appear as bizarre targets with intracellular hemoglobin puddled into distinct clumps.

Peripheral Blood Film Evaluation in a Patient with a Red Cell Membrane Disorder

Shape	Pathobiology	Diagnosis
Microspherocytes	Loss of membrane lipids leading to a reduction of surface area resulting from deficiencies of spectrin, ankyrin, or band 3 and protein 4.2	HS
	Removal of membrane material from antibody-coated red cells by macrophages	Immunohemolytic anemias
	Removal of membrane-associated Heinz bodies, with the adjacent membrane lipids, by the spleen	Heinz body hemolytic anemias
Elliptocytes	Permanent red cell deformation resulting from a weakening of skeletal protein interactions (such as the spectrin dimer-dimer contact). This facilitates disruption of existing protein contacts during shear stress induced elliptical deformation. Subsequently, new protein contacts are formed that stabilize the elliptical shape	Mild common HE
	Unknown	Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Poikilocytes/fragments	Weakening of skeletal protein contacts resulting from skeletal protein mutations	Hemolytic HE/HPP
	Unknown	Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Schistocytes, fragmented red cells	Red cells torn by mechanical trauma (fibrin strands, turbulent flow)	Microangiopathic hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses

Schistocytes, fragmented red cells	Red cells torn by mechanical trauma (fibrin strands, turbulent flow)	Microangiopathic hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses
Acanthocytes	Uptake of cholesterol and its preferential accumulation in the outer leaflet of the lipid bilayer	Spur cell hemolytic anemia in severe liver disease
	Selective accumulation of sphingomyelin in the outer lipid leaflet	Abetalipoproteinemia
	Unknown	Chorea-acanthocytosis syndrome, malnutrition, hypothyroidism McLeod phenotype
Echinocytes	Expansion of the surface area of the outer hemileaflet of lipid bilayer relative to the inner hemileaflet	Hemolytic anemia associated with hypomagnesemia and hypophosphatemia in malnourished patients, pyruvate kinase deficiency; in vitro, artifact of low blood storage (ATP depletion), contact with glass or elevated pH
	Unknown	Hemolysis in long-distance runners, renal failure
Stomatocytes	Expansion of the surface area of the inner hemileaflet of the bilayer relative to the outer leaflet	Exposure of red cells to cationic anesthetics in vitro; in vivo, the drug concentrations may not be sufficient to produce similar effect
	Unknown	Alcoholism, inherited disorders of membrane permeability (hereditary stomatocytosis)
Target cells	Absolute excess of membrane lipids (both cholesterol and phospholipids: symmetric lipid gain), followed by an increase in cell surface area	Obstructive jaundice, liver disease with intrahepatic cholestasis
	Relative excess of surface area because of a decrease in cell volume	Thalassemias and some hemoglobinopathies (C,D,E)

Splenectomy may improve, but not fully correct, the hemolysis.[454] [459] [460] In some patients, splenectomy may be deleterious or even contraindicated (see following discussion).[471] [472] [473]

Hereditary Xerocytosis and the Intermediate Syndromes

Hereditary xerocytosis or dessicocytosis describes an autosomal dominant hemolytic anemia characterized by red cell dehydration and decreased osmotic fragility. [455] [474] [475] [476] [477] [478] Affected individuals have characteristically moderate to severe hemolysis with an increased MCHC, reflecting cellular dehydration. Hydrops fetalis with fetal anemia has been reported in a number of xerocytosis kindreds.[476] Frequently, the MCV is mildly increased. In Coulter-type electronic counters, the conversion of pulse height (from the resistance of a cell passing through an electric field) to a cellular volume is dependent on cell shape. Xerocytes do not deform to the same degree as normal cells, which causes the MCV to be about 10% too high. The peripheral blood film does not always reveal stomatocytes (which are more prominent on wet films), but frequently target cells, dessicocytes, and spiculated cells are seen. In some of the cells, hemoglobin is concentrated (puddled) in discrete areas on the cell periphery (Fig. 33-14).

The mechanism of cellular dehydration is unclear and complex, involving a net potassium loss from the cells that is not accompanied by a proportional gain of sodium.[455] [474] [475] [477] Consequently, the net intracellular cation content and cell water are decreased. In some reports, a decrease in red cell 2,3-DPG has also been noted.[478] [479] Analysis of membrane lipids and proteins failed to detect any abnormalities except for an increase in membrane-associated glyceraldehyde-3-phosphate dehydrogenase.[480] This enzyme binds to the band 3 protein.[481]

Some of the reported cases of hereditary stomatocytosis share features of both hereditary stomatocytosis and xerocytosis. Lux and Becker categorized these disorders as intermediate syndromes.[305] These patients characteristically have both stomatocytes and some target cells on the peripheral blood smear. Osmotic fragility is either normal or slightly increased. Sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the red cell volume are either normal or slightly reduced. These cells were reported to have subnormal glutathione content. [482] [483] In two other reported patients, red cells underwent in vitro hemolysis at 5°C;[483] [484] hence, the disorder was designated cryohydrocytosis. In one patient, hemolysis was worsened by swimming, and the red cells hemolyzed when exposed to shear stress.[485]

Several investigators have also reported a dominantly inherited hemolytic anemia with stomatocytosis, occasional target cells, spherocytes, and a decreased osmotic fragility in which the main red cell membrane abnormality involved a nearly 50% increase in phosphatidylcholine and a corresponding decrease in phosphatidylethanolamine. [452] [486] [487] [488] In wet preparations, 30% of the cells were stomatocytes.[487] The molecular basis of this syndrome is unclear. Because abnormalities in membrane phospholipid composition have not been systematically investigated, it is uncertain whether the disorder represents a distinct disease entity.[489] For additional details on this rare group of disorders, the reader is referred to reviews in the literature. [452] [488]

The results of splenectomy in this group of disorders are variable. In some patients the hemolytic anemia is improved, although often not fully corrected, by splenectomy,[454] [459] [460] [475] [479] while in others the severity of the hemolysis is unchanged. [490] Splenectomy should be carefully considered in patients with hereditary stomatocytosis. Several patients with stomatocytosis (both hydrocytosis and xerocytosis) have developed hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes.[472] [473] In vitro, stomatocytic erythrocytes from an individual with xerocytosis who had undergone splenectomy demonstrated increased endothelial adherence when compared with stomatocytic erythrocytes from unsplenectomized family members without hypercoagulability. [473] In one hypercoagulable stomatocytosis patient, pentoxifylline decreased red cell adherence. [473] Fortunately, the majority of persons with hereditary stomatocytosis are able to maintain an adequate hemoglobin level, so that splenectomy is not required.

Rh Deficiency Syndrome

Rh deficiency syndrome designates rare individuals who have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression, mild to moderate hemolytic anemia associated with the presence of stomatocytes, and occasional spherocytes on the peripheral blood film. [430] [491]

The Rh antigens are present in about 20,00030,000 copies per cell and reside on minor transmembrane proteins with an electrophoretic mobility of 2833 kd on SDS-PAGE.[492] Immunoprecipitation of Rh polypeptides by c, D, and E antigen-specific antibodies followed by two-dimensional mapping of the iodine-labeled chymotryptic peptides indicates that these proteins are distinct but closely related, a conclusion further verified by analysis of their cDNA. Furthermore, recent studies of the Rh gene locus are consistent with the existence of two closely linked genes, one encoding the D polypeptide and the other encoding the Cc, Ee proteins, the antigenic expression of which is a consequence of alternate splicing of their pre-mRNA. [493] [494]

Prediction of their structure from hydropathy plots revealed that the Rh proteins span the lipid bilayer multiple times, with the C- and N-termini located at outer and inner surfaces, respectively.[493] The Rh proteins are heavily palmitoylated, forming dimers or oligomers in solutions and, presumably, in the membrane as well. They are linked to the red cell membrane skeleton,[495] [496] but their function is unknown. A previous suggestion that Rh proteins may be involved in the translocation of aminophospholipids across the membrane has been excluded by the finding of normal phosphatidylserine transport in these cells. [497] In Rh_{null} human red cells, two proteins (32 kd and 34 kd) containing extracellular thiol groups are absent.

The genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups can be defined. The amorph type is thought to be related to defects

involving the *RH30* locus encoding the RhD and RhE polypeptides, but its precise genetic basis is unknown. [493] [498] The regulatory type of Rh_{null} and Rh_{mod} phenotypes results from suppressor or modifier mutations independent of the *RH30* locus. Abnormalities of *RH50* have recently been described in Rh_{null} individuals. These have included deletion, splicing, and missense mutations of the Rh50 glycoprotein gene. [499] [500] [501]

Red cells of some Rh_{null} patients have increased osmotic fragility, reflecting a marked reduction in membrane surface area. [502] These cells are also dehydrated, as indicated by decreased cell cation and water content and increased cell density. [502] The potassium transport and the Na^+/K^+ pump activity are increased, possibly because of reticulocytosis. [503] [504] Hemolytic anemia is improved by splenectomy. [491] Additional serologic aberrations involve a weakened expression of Ss and U antigens, [505] [506] which, unlike the Rh antigen system, reside on one of the transmembrane glycoproteins, glycophorin B, [507] the level of which is reduced in Rh_{null} cells by 30%, possibly because glycophorin B is, in part, present as a complex with the Rh proteins.

Familial Deficiency of High-Density Lipoproteins

Severe deficiency or absence of high-density lipoproteins leads to accumulation of cholesteryl esters in many tissues, leading to the clinical findings of large orange tonsils and hepatosplenomegaly. [449] Reported hematologic manifestations include a moderately

severe hemolytic anemia with stomatocytosis. [508] Membrane lipid analyses revealed a low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine at the expense of sphingomyelin. [508]

Acquired Stomatocytosis

Stomatocytes have been noted in diverse acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic in vitro. [509] [510] In some of these conditions, the percentage of stomatocytes on the peripheral blood smear may approach 100%. However, the clinical significance of the above observation is unclear because stomatocytes are absent in most patients with the conditions listed. Furthermore, some stomatocytes may be found in normal individuals (35%). [511] [512] The most consistent association is that of stomatocytosis and heavy alcohol consumption. [511] [512] Stomatocytosis has also been reported in Mediterranean immigrants in Australia. Its cause is unknown, but it may be related to alcoholism. [513] [514]

Chapter 34 - Autoimmune Hemolytic Anemias

Robert S. Schwartz
Eugene M. Berkman
Leslie E. Silberstein

INTRODUCTION

The autoimmune hemolytic anemias are a group of disorders in which autoantibodies against antigens on the erythrocyte membrane cause a shortened red blood cell (RBC) life span. The antierythrocyte autoantibodies of these diseases fall into three generic types, each of which has distinctive serologic properties: (1) cold agglutinins, almost always of the IgM isotype, clump RBCs at cold temperatures; (2) the IgG Donath-Landsteiner antibody fixes to RBC membranes in the cold and activates the hemolytic complement cascade when the cells are warmed to 37°C; and (3) IgG warm autoantibodies bind to erythrocytes at 37°C but fail to agglutinate the cells. Each of these three categories of autoantibodies delineates one or more characteristic clinical disorders, known collectively as autoimmune hemolytic anemia. Autoimmune hemolytic anemia may occur as a primary (idiopathic) disorder, may coexist with another disease (secondary autoimmune hemolytic anemia), or may follow administration of certain drugs (Table 34-1). The nomenclature of these conditions is imprecise and sometimes confusing. This chapter refers to the hemolytic diseases associated with warm-reactive IgG autoantibodies as autoimmune hemolytic anemia, to the hemolytic anemias caused by cold-reactive IgM autoantibodies as cold agglutinin disease, and to the syndromes associated with the Donath-Landsteiner antibody as paroxysmal cold hemoglobinuria.

HISTORICAL BACKGROUND

Any reader interested in the origins of hematology should seek out Dacies superb review of the history of autoimmune hemolytic anemia. [1] Much of this section follows his scholarly account.

TABLE 34-1 -- Classification of Autoimmune Hemolytic Anemia

Warm autoimmune hemolytic anemia
Primary (idiopathic)
Secondary
Lymphoproliferative diseases
Connective tissue diseases
Miscellaneous diseases
Drugs
Hapten type
Immune complex type
Autoantibody type
Cold autoimmune hemolytic anemia
Primary (idiopathic)
Secondary
Lymphoproliferative diseases
Infections
Mycoplasma pneumoniae
Infectious mononucleosis
Other
Miscellaneous diseases
Paroxysmal cold hemoglobinuria
Associated with tertiary syphilis
Postviral infection (self-limited)

An earlier historical analysis by Dameshek and Schwartz is a classic. [2] Rosenfields personal narrative of the history of immunohematology is also strongly recommended.[3]

Paroxysmal cold hemoglobinuria was the first recognized form of hemolytic anemia, probably because its clinical manifestations are so striking; the principal sign of the disease, the passage of black urine after exposure to the cold, can hardly be ignored. Descriptions of patients with attacks of hemoglobinuria after exposure to cold temperatures, including the case of a 10-year-old boy with *chromaturie*,[4] began to appear between 1854 and 1865 in the medical literature. [4] [5] [6] In 1879, Rosenbach reported inducing hemoglobinuria by immersing his patients feet in ice water; [7] 2 years later, Ehrlich reported his observation of hemolysis and erythrophagocytosis in blood obtained from a chilled finger of a patient with the disease. [8]

The association of paroxysmal cold hemoglobinuria with syphilis was first noted in 1884 by Götze, [9] but nothing else was known of the cause of the disease until 1904, when Donath and Landsteiner published their landmark work. [10] They described three cases of paroxysmal cold hemoglobinuria in which (1) an autolysin bound to the patients RBCs in the cold, and (2) a heat-labile serum factor (now known to be hemolytic complement components) lysed the sensitized erythrocytes when the temperature was raised to 37°C. This classic paper presents the first description of an autoimmune disease.

Less obvious forms of hemolytic anemia were not identified until the end of the 19th century, when Le Gendre [11] and Hayem [12] distinguished a form of jaundice with bile in the plasma, but not in the urine (acholuric jaundice). Widal and Abrami were among the first to recognize congenital and acquired forms of hemolytic anemia; in 1907 they reported autoagglutination of erythrocytes in patients with *lictère hémolytique acquis*.[13] The following year, Chauffard and Troisier [14] described cases of severe hemolytic anemia with serum hemolysins, but progress in delineating autoimmune hemolytic anemia ceased until 1938, when Dameshek and Schwartz revived interest in the topic with their report of similar cases. [15] Dameshek and Schwartz also demonstrated that injection of heterologous antierythrocyte antibodies into guinea pigs induced hemolytic anemia, with spherocytosis and increased osmotic fragility of RBCs, thereby establishing the first experimental model of immune hemolytic anemia.[16] Even so, the idea of an autoimmune form of hemolytic anemia was resisted for several reasons, not the least of which was the difficulty in making the diagnosis. Only cold-reactive antibodies, which directly agglutinate erythrocytes, and rare forms of lytic autoantibodies could be recognized in the laboratory. In 1918, the first example of cold agglutinin disease was described, [17] but the validity of such cases was suspect because cold-reactive autoantibodies were also found in normal serum, an observation made 15 years earlier by Landsteiner. [18] Not until 1937 was it recognized that the serum of patients with cold agglutinin disease had markedly elevated titers of cold agglutinins. [19]

The antiglobulin test, designed to detect nonagglutinating antierythrocyte antibodies, was introduced into clinical medicine by Coombs et al. in 1945. [20] The Coombs test revolutionized immunohematology; within 1 year it was applied to the diagnosis

of autoimmune hemolytic anemia. [21] Ironically, essentially the same procedure, developed in 1908 by Moreschi, [22] was ignored for almost 40 years, perhaps because

Moreschis report dealt with animal RBCs.

In 1954, autoimmune hemolytic anemia in dogs was reported,[23] and in 1958, the first easily bred animal model of the disease, the NZB mouse, was described. [24] This discovery was a turning point in the development of a scientific basis for the study of autoimmunization.

The first recorded attempt to treat acquired hemolytic anemia with splenectomy was carried out in 1911, [25] and in 1950 the beneficial effect of corticotropin on autoimmune hemolytic anemia in two patients with lymphoma was reported by Dameshek[26] and in a 5-year-old girl by Gardner. [27]

IMMUNOLOGIC MECHANISMS OF RED CELL DESTRUCTION

Immunologic Tolerance

Regardless of their underlying cause, autoimmune hemolytic anemias ultimately result from derangement of the mechanism of immunologic tolerance. An understanding of this mechanism is essential. At the end of its life, when it transforms from a biconcave disk to a sphere, the RBC undergoes the initial steps required to trigger an immune response, namely, phagocytosis and proteolysis by a macrophage. There is no reason to doubt that macrophages produce potentially immunogenic peptide fragments from those worn-out spheres and offer them to lymphocytes. This, after all, is a major function of macrophages, and it applies to virtually any particle or molecule they can ingest and digest. However, the lymphocytes of the immune system specifically ignore the numerous self-antigenic determinants on the RBC membrane. Those same antigens would nonetheless engender an immune response if injected into another person with a different constellation of blood groups. The complex mechanisms that prevent autoimmunization, while simultaneously permitting alloimmunization, are known collectively as immunologic tolerance. The rules governing immunologic tolerance are essential aspects of the mechanisms of immune recognition of erythrocytes.

Owens[28] classic study of the RBCs of dizygotic cattle twins, published in 1945, was the first to uncover evidence of this remarkable aspect of the immune system. Owen observed that such twins had in their circulation a mixture of erythrocytes, some with self blood groups and others with the blood groups of the allogeneic twin. These cattle twins were erythrocyte chimeras, a condition caused by the exchange of hematopoietic stem cells through the vascular anastomoses of the common placenta that nourished both fetuses in utero. The immunologic consequences of chimerism did not escape Owen, who emphasized the lack of any alloantibodies in the twins despite the presence of foreign erythrocytes in their blood.

Owens work was a key element in the theory of immunologic tolerance and was advanced 4 years later by Burnet and Fenner. [29] Their sweeping new idea was that contact with any antigen during embryonic life would result in immunologic tolerance (their original term). They attributed self-tolerance to clonal deletion, the lethal consequence of an embryonic lymphocyte that contacts an antigen. One of the main predictions of this theory was substantiated in 1953 by Billingham et al., [30] who showed that fetal mice injected with foreign cells would later tolerate skin grafts from the donors of those cells. The principle established by that historic experiment has been reaffirmed by recent experiments with transgenic mice, which carry a foreign gene implanted in their germline DNA. A foreign protein encoded by the gene, if expressed early in embryonic life, fails to induce any immune response in the transgenic animal. [31]

The thymus is an important seat of this mechanism (see Chap. 11). There is now convincing evidence that the fetal thymus inactivates T cells with the potential to respond to self antigens.[32] The fetal thymus contains macrophages, epithelial cells, and dendritic cells that not only ingest and degrade (process) antigenic material but also bind the resulting peptide fragments to class II MHC molecules. [33] The latter are membrane glycoproteins required for antigen recognition by T cells; the T-cell receptor for antigen recognizes a configuration consisting of an immunogenic peptide and a portion of the class II MHC glycoprotein (Fig. 34-1).[34] Intrathymic antigen-presenting cells can, for example, ingest and digest RBCs within the thymus and bind degraded fragments of self-hemoglobin to their class II MHC molecules.[35]

Each T-cell clone arising within the thymus expresses its own unique receptor, the result of random recombinations of V and V or V and V gene segments. [32] This stochastic mechanism will inevitably yield clones with receptors capable of recognizing a self-peptide/class II MHC complex. Such clones are destined for deletion from the immune repertoire; the fetal thymus eliminates any thymocyte whose receptor binds with high affinity to an antigen-presenting cell. [36]

Tolerance of Blood Group Antigens

The immune systems solution to the problem of distinguishing self from foreign requires an about-face late in fetal development. The dominant function of the immune system during early embryonic life is the acquisition of immunologic tolerance of the antigens bathing its milieu, but as birth approaches, the fetus begins to acquire the capacity to respond to immunogens. This principle is clearly evident in the case of the ABO blood group antigens, oligosaccharides not only expressed on the membranes of erythrocytes and many other kinds of cells, but also circulating in soluble form in the plasma. The immunodominant sugar of the A antigen is *N*-acetylglucosamine; the B determinant, galactose, differs from the A sugar only by a single acetyl group. The core of transfusion therapy is the infallible ability of the immune system to recognize that minute difference. The extreme rarity of autoimmune hemolytic anemia due to anti-A or anti-B antibodies attests to the deletion from the immune repertoire of lymphocytes with the capacity to produce such autoantibodies. Such clones are probably eliminated or inactivated very early in ontogeny, since the embryo begins to synthesize A or B substances within 5 weeks of its implantation in the uterine wall. [37]

Another telling example of the fetal acquisition of immunologic

Figure 34-1 Antigen-specific receptors. Antigen recognition by immunoglobulin variable regions and T-cell receptors. The antibody molecule typically recognizes a three-dimensional configuration on the antigen, whereas the T-cell receptor binds to a compound structure consisting of a peptide fragment of the antigen (produced as the result of antigen processing by macrophages) and a portion of an MHC structure. $CD4^+$ T cells recognize an antigen fragment plus a class II MHC structure; $CD8^+$ T cells bind to processed peptides plus a class I MHC structure.

Figure 34-2 The I/i blood group system in **(A)** the fetus and **(B)** the adult. The fetus lacks the enzymes (branching enzymes) required to produce the branched forms of ceramide and the I antigen. The unbranched (fetal) and branched (adult) variants of the I antigen are immunochemically distinct structures. Shaded structure represents the erythrocyte membrane. The modified N-terminus of band 3 faces the interior of the RBC. *(From Hakomori,[40] with permission.)*

tolerance is the I/i blood group system, originally discovered by Wiener et al. [38] in a case of cold-reactive autoimmune hemolytic anemia. The serum of their patient contained high titers of an autoantibody with a specificity they denoted I. Its counterpart antigen, i, is typical of fetal erythrocytes (Fig. 34-2).[39] The fetus with I $/i^+$ erythrocytes presumably lacks the enzymatic capacity to convert the unbranched ioligosaccharide to the antigenically different branched oligosaccharide structure of I.[40] Thus, the fetus has no opportunity to acquire immunologic tolerance of the branched I ganglioside, and B-cell clones capable of producing anti-I autoantibodies persist in the immune system throughout life. This explains why Landsteiner so easily found anti-I cold-reactive antibody (cold agglutinins) in the samples of normal serum he tested in 1903. By contrast, he never found anti-A or anti-B autoantibodies when he discovered the ABO blood groups. [41] Further evidence of the failure of the immune system to delete anti-I B-cell clones is the occurrence of monoclonal cold-reactive antibodies in 10% of cases of Waldenström macroglobulinemia; [42] such malignant cells presumably arise from their counterparts in the normal B-cell repertoire.

Self-reactive Lymphocytes

It is highly unlikely that the fetal thymus can purge all self-reactive lymphocytes from the immune system. In the first place, B cells do not differentiate in the thymus and their receptors for antigensurface immunoglobulinsdo not depend on recognition of an antigen-MHC complex. Indeed, self-reactive B cells occur in a surprisingly high frequency; about 1 in 10^4 B cells from healthy young mice produce anti-DNA antibodies.[43] B cells from normal humans, when activated by mitogens in vitro, also produce autoantibodies.[44] [45] Furthermore, it is improbable that all the bodys different proteins, estimated at 100,000 in number, [32] find their way into the fetal thymus. Some, like the I antigen, are expressed only after birth; others are sequestered in the brain and other internal organs. The peripheral lymphocyte population must, therefore, contain at least some antiself T cells and B cells. The existence of such cells accounts for the success of the classic experiment of Rose and Witebsky, [46] who were able to induce autoimmune thyroiditis in rabbits by immunization with rabbit thyroglobulin. If all lymphocytes capable of responding to self-thyroglobulin had been deleted, the animals would have been unresponsive to the injected thyroglobulin. With respect to autoimmune hemolytic anemia, the role of helper T cells with anti-RBC autospecificity has been suggested by a recent study demonstrating the existence of T-cell epitopes on Rhesus polypeptides corresponding to antigens commonly involved in autoimmune hemolytic anemia.[47]

Immunoregulation

Growing evidence shows that the antiself immune repertoire is normally constrained by suppressor T cells. In humans, the mature T-cell population consists of $CD4^+$ helper cells, which augment the activity of B cells, and $CD8^+$ cytotoxic and suppressor cells. Two subsets of $CD4^+$ cells have been identified: helper-inducer T cells, identified by the 4B4 membrane glycoprotein, and suppressor-inducer T cells, marked by the 2H4 (or CD45R) glycoprotein. [48] The latter regulate a subset of $CD8^+$ T cells that have been shown to suppress antibody formation in vitro. [49] An imbalance in suppressor (or suppressor-inducer) T cells is a plausible explanation of the origins of some autoimmune diseases.[50] How such an impairment occurs in the first place is enigmatic, but clinical and experimental findings support the concept. Two children with autoimmune hemolytic anemia and a profound deficiency of suppressor cells, probably due to a thymic defect, have been reported. [51] Removal of the thymus from mice within a few days after birth can result in a variety of T-cell-mediated organ-specific autoimmune diseases. The thymectomy apparently prevents entrance of newly formed suppressor cells into the periphery; administration of T cells from intact mice prevents the autoimmune process. [52] Cyclosporine, a potent immunosuppressive drug, can have the paradoxical effect of causing autoimmune diseases,[53] [54] [55] [56] presumably by disrupting immunoregulatory T-cell populations.

Antigen-independent polyclonal activation of self-reactive B cells, another possible mechanism of autoimmunization, could result from an inherent abnormality of B cells, as has been demonstrated in some patients with systemic lupus erythematosus (SLE),[57] or from the excessive production of B-cell-stimulatory lymphokines (e.g., interleukin [IL]-6) by T cells. The case of a patient with an IL-6-secreting atrial myxoma who produced large amounts of immunoglobulins and autoantibodies [58] is instructive, as is the development of thyroiditis and antithyroglobulin autoantibodies in cancer patients treated with large doses of IL-2. [59] [60] The hypergammaglobulinemia and production of autoantibodies in parasitic diseases [61] and in patients with human immunodeficiency virus (HIV) infection[62] [63] [64] [65] probably also originate as a consequence of polyclonal B-cell activation.

ANIMAL MODELS OF AUTOIMMUNE HEMOLYTIC ANEMIA

Evidence for Genetic Factors

NZB Mice

The inbred NZB mouse is genetically programmed to develop autoimmune hemolytic anemia at around the age of 68 months (the life span of a normal mouse is 2 years). Antierythrocyte

Figure 34-3 Development of autoimmune hemolytic anemia in NZB mice. Splenic enlargement is due to the effects of the hemolytic anemia and also to marked polyclonal proliferation of $CD5^+$ B cells. As the animals age, the polyclonal population of $CD5^+$ B cells converts to a monoclonal population (see text).

autoantibodies begin to appear at around the age of 3 months, and by 9 months the direct antiglobulin test (DAT) is positive in 6080% of the animals. Typical signs of hemolytic anemia develop, with reticulocytosis, spherocytosis, a shortened RBC survival time, and splenomegaly (Fig. 34-3).[66] The autoantibodies are of two types: anti-X, an IgG autoantibody, reacts with the X antigen exposed on the erythrocyte membrane and causes the hemolytic anemia; anti-HB, an IgM autoantibody, reacts with a hidden phosphorylcholine erythrocyte antigen revealed by in vitro enzyme (bromelain) treatment of the RBCs. Both the X and the HB antigens circulate in the plasma.[67] Anti-HB antibodies, found in virtually all normal strains of mice, are not pathogenic. They are produced by $CD5^+$ B cells;[68] their high levels in NZB serum undoubtedly stem from the marked increase in $CD5^+$ B cells in NZB mice.[69] Other antierythrocyte autoantibodies in NZB mice include an IgG antibody with probable specificity for spectrin,[70] and cold-reactive antibodies with a resemblance to anti-I autoantibodies in humans. [71]

The F_1 progeny of crosses between NZB and NZW mice or between NZB and SWR mice do not develop autoimmune hemolytic anemia, and the antiglobulin test is negative. Instead, lupus nephritis and high levels of anti-DNA antibodies dominate the disease in these animals. [72] Mice of the SWR strain are normalthey never develop any evidence of SLE or any other autoimmune disease. Yet in the (NZB × SWR) cross, a substantial fraction of the anti-DNA antibodies arises from genes inherited from the SWR parent.[73] In the (NZB × SWR)F_1 hybrid, therefore, the inherent immunologic abnormalities of the NZB strain [66] can induce pathogenic autoantibodies that originate from the genome of a normal animal. The shift from autoimmune hemolytic anemia in the NZB parent to nephritis in the F_1 hybrid demonstrates that genetic factors influence not only susceptibility to autoimmunization but also its clinical manifestations.

Graft-versus-Host Disease: Graft-versus-Host Model

Conditions are ripe for a graft-versus-host reaction when foreign lymphocytes are injected into hosts that cannot reject them. In the classic graft-versus-host reaction, the grafted T lymphocytes respond to MHC antigens of the host. A chronic graft-versus-host reaction can occur in F_1 hybrid mice following injection of lymphocytes from one of the parental strains: A (A × B)F_1 . The strain A T cells respond to class II MHC antigens inherited by the F_1 animal from its B parent.

Several different autoimmune diseases can develop in mice or rats as a result of a chronic graft-versus-host reaction. The particulars of the outcome depend on the donor host combination.[73] For example, when lymphocytes from BALB/c mice are injected into (BALB/c × A/J)F_1 animals, the recipients develop typical autoimmune hemolytic anemia (Fig. 34-4).[74] If, however, DBA/2 lymphocytes are injected into (DBA/2 × C57B1/6)F_1 mice, the result is severe glomerulonephritis of the type seen in SLE.[75] In each of these examples, both the donors and the F_1 recipients are normal strains of mice.

The principal requirement for triggering the autoimmune disease is a difference in class II MHC antigens between the donor and the recipient. [76] This intense immunogenic stimulus causes a marked activation of the donors T cells, which release large amounts of IL-4 and IL-6, potent polyclonal activators of B cells. [77] The hosts B cells can respond in two ways: by the production of autoantibodies and, in some cases, by a persistent lymphoproliferative reaction that culminates in malignant lymphoma.[78] The graft-versus-host model provides ample evidence of the importance of polyclonal B-cell activation in autoimmunization, but the genetic factors that determine the particulars of disease a given F_1 hybrid develops are unknown.

Several complications of chronic graft-versus-host disease in humans, including immune thrombocytopenia, [79] the sicca syndrome, and scleroderma,[80] may arise on a similar basis, but since bone marrow transplantation is rarely carried out when there is a class II HLA mismatch, other factors are probably involved. The development of autoimmune hemolytic anemia in recipients of renal allografts could be associated with a graft-versus-host reaction caused by donor lymphocytes in the organ graft.[81] However, the role of cyclosporine, which has been associated with the induction of autoimmunization, cannot be discounted in these cases. [82] [83] [84]

Figure 34-4 Autoimmune hemolytic anemia in F_1 hybrid mice, (A × B)F_1 , injected with parental strain (A) T cells. The two lines compare survival of ^{51}Cr-tagged syngenic erythrocytes in control and experimental animals. Red cell life span is markedly reduced, and the antiglobulin tests are positive in animals with the chronic graft-versus-host reaction.

Autoimmune Hemolytic Anemia in Transgenic Mice

Okamoto et al.[85] developed transgenic mice by inserting the V_H or V_L genes for an NZB antierythrocyte autoantibody into the germline of a normal strain of mice. * The NZB V genes were linked to B-cell-specific promoters, restricting their expression to the B cells of the new hosts. Mice harboring either the V_H or the V_L transgenes had no detectable abnormalities. When these two transgenic lines were bred, all their F_1 offspring bore both NZB immunoglobulin V genes, and many had autoimmune hemolytic anemia due to the transgenic NZB antierythrocyte autoantibody. In some doubly transgenic animals, autoimmune hemolytic anemia appeared, only to remit spontaneously, whereas in others the anemia was fatal. It was apparent that not all the antiself B-cell clones in the F_1 animals were deleted, a surprising result in light of other experimental models in which deletion or inactivation of B-cell clones with the potential to secrete pathogenic autoantibodies has been demonstrated.[86] Deletion, anergy, and autoimmunizationall involving the same autoantibodyappeared and disappeared, apparently at random, in individual

transgenic mice. Even more confounding was the finding of severe autoimmune hemolytic anemia in some transgenics.

This interesting model shows some of the features of autoimmune hemolytic anemia in humans; the tendency toward spontaneous remissions and relapses in the F_1 transgenic mice is noteworthy. In subsequent work, Murakami et al.[87] found that the $CD5^+$ B cell is the main source of the hemolytic autoantibody in the F_1 transgenic mice (see Chap. 8 for a discussion of $CD5^+$ B cells). In adult mice, $CD5^+$ B cells reside mainly in the peritoneal cavity. The peritoneal fluid contains many $CD5^+$ B cells but only a few erythrocytes. The transgenic $CD5^+$ B cells in the peritoneum would thus be isolated from self RBCs and would not be susceptible to clonal deletion by autoantigen. However, death of those antiself $CD5^+$ B cells occurs within 12 hours of an intraperitoneal injection of autologous red cells.[87] It is plausible that the erratic course of autoimmune hemolytic anemia in the F_1 transgenics was due to the chance entrance of red cells into the peritoneal cavity, perhaps as the result of casual injury when the animals were handled by the investigators. This model emphasizes the importance of antigen in maintaining self-tolerance: no antigen, no tolerance.

Origins of Antierythrocyte Autoantibodies

The vast improvement in our understanding of what prevents autoimmunization has not yet informed us of the mechanism that causes autoimmunization. Virtually nothing is known of the origins of warm-reactive IgG antierythrocyte autoantibodies, despite the availability of a thoroughly investigated, spontaneous animal model of the disease (the NZB mouse) and stocks of pathogenic autoantibodies, readily obtained from patients with the disease. A major impediment to advances in our perceptions of how autoimmune hemolytic anemia originates is that the autoantigens are for the most part unknown. Even in those cases in which blood group specificity of the autoantibodies has been identified, the relevant structures have not been elucidated. Leddy et al.[88] have succeeded in identifying four proteins on the red cell membrane that bind to antierythrocyte autoantibodies: the band 3 anion transporter, glycophorin A, and two polypeptides, probably related to the Rh family of antigens. Various combinations of those four autoantibody specificities were found in a group of 20 patients with autoimmune hemolytic anemia.

The association of autoimmune hemolytic anemia with SLE and with immune thrombocytopenia (Evans syndrome, see later), the induction of the disease by drugs that seem to perturb immune regulation (see later), and the graft-versus-host model of autoimmune hemolytic anemia all suggest that at least in some cases there is antigen-independent activation of clones of B cells with the capacity to produce IgG anti-RBC autoantibodies. Such polyclonal B-cell activation may account for the production of antierythrocyte autoantibodies in patients with the acquired immunodeficiency syndrome (AIDS).[89] [90] Hypergammaglobulinemia and other signs of nonspecific activation of B cells are prominent in HIV infection.[91]

The immunologic basis of autoimmune hemolytic anemia in patients with chronic lymphocytic leukemia (CLL) or a B-cell lymphoma is equally obscure.[92] In CLL, the autoantibodies are IgG and often polyclonal,[93] whereas the malignant $CD5^+$ B cells of that disease generally produce only IgM antibodies that are monoclonal. It is therefore likely that B cells other than those constituting the leukemia produce the autoantibodies. The large mass of $CD5^+$ B cells in CLL might induce non-neoplastic CD5 B cells to produce IgG autoantibodies, perhaps by a disturbance of immunoregulatory idiotypic networks (Fig. 34-5). The demonstration of the simultaneous presence of autoantibodies and anti-idiotypic antibodies on red cells in autoimmune hemolytic anemia[94] suggests that such networks may indeed have a role in the disease.

By contrast with the autoantigens that bind to warm-reactive autoantibodies, the structures of the autoantigens of cold agglutinin disease, the I/i system, are known (Fig. 34-2);[40] this has clarified our thinking about the immunology of this group of disorders. There is little reason to doubt that the very high levels of monoclonal cold agglutinins found in some patients with B-cell neoplasms are produced by the malignant cells. The demonstration that an idiotypic marker on monoclonal cold agglutinins could be detected not only on the patients neoplastic B cells but also on 310% of normal B cells[95] supports the view that these autoantibodies are part of the normal immune repertoire; malignant transformation of a cold agglutinin-producing B cell results in a lymphoma complicated by chronic cold agglutinin disease.

The basis of the association of paroxysmal cold hemoglobinuria with syphilis may be antigenic mimicry, in which structural similarities between a microbial antigen and a self-antigen trigger an autoantibody response. In the case of paroxysmal cold hemoglobinuria, the infecting organism, *Treponema pallidum*, should possess two antigenic determinants (epitopes): one recognized by T cells (the foreign epitope), the other by self-reactive B cells (the mimicking epitope). Donath-Landsteiner antibodies would be produced only by syphilitic patients whose class II MHC glycoproteins could present the foreign epitope in an immunogenic form to T cells (Fig. 34-6). A similar mechanism could apply to postinfectious acute cold agglutinin disease, in which a cross-reaction involving antigenic determinants of *Mycoplasma pneumoniae* and the I blood group substance has been incriminated.[96]

Structural analyses of monoclonal anti-I and anti-i autoantibodies from patients with B-cell neoplasms are beginning to yield important clues about the origins of chronic cold agglutinin disease. A striking observation is the repetitive use of the same immunoglobulin V_H gene, $V_{H4\text{-}34}$, in monoclonal IgM cold agglutinins, regardless of the anti-I or anti-i specificity of the autoantibody.[97] [98] In each case, the $V_{H4\text{-}34}$ heavy chain gene had a different CDR3 (see Chap. 8 for a discussion of the structure of immunoglobulin-coding regions); the light chains of cold agglutinins with anti-I or anti-i specificity differed as well. The $V_{H4\text{-}34}$ genes of these cold agglutinins contained few or no somatic mutations of the type that would lead to amino acid substitutions (replacement mutations). This, together with the variations in their CDR3s and in the light chains, implies that the

*The DNA constructs for either the heavy or light chain genes were miscroinjected into fertlized eggs of C55B1/6 mice; the eggs were then transferred to pseudopregnant moce. The presence of the transgenes in the newborn animals was verified by Southern blot analysis.

Figure 34-5 Hypothetical link between $CD5^+$ B cells and the immunologic complications of CLL. The idiotype displayed by the IgM surface immunoglobulins of the large mass of monoclonal $CD5^+$ B cells stimulates a population of T cells with a complementary anti-idiotype. In turn, the anti-idiotypic T cells affect normal CD5 B cells, either by inducing suppression (with resulting hypogammaglobulinemia) or polyclonal activation (resulting in autoimmune hemolytic anemia due to IgG autoantibodies).

$V_{H4\text{-}34}$ germline gene segment itself encodes a binding site for the I and i antigens. In contrast to the heavy chain gene, the light chain genes of the cold agglutinins did contain replacement mutations, especially in their hypervariable regions.[98]

It appears from these results that (1) the germline $V_{H4\text{-}34}$ heavy chain encodes the dominant specificity of monoclonal cold agglutinins; (2) the somatic mutations of the light chain genes of the cold agglutinins are the result of an immune response; and (3) the V_H CDR3 and the light chain confer fine specificity (e.g., for I or i) on the cold agglutinin and influence

Figure 34-6 Induction of autoimmunization by antigenic mimicry. **(A)** The usual foreign antigen contains antigenic determinants (epitopes) recognized by both T cells and B cells. The result is a cooperative interaction between helper T cells and B cells. **(B)** A self-antigen may be recognized by B cells, but T/B collaboration does not occur because of the deletion from the immune repertoire of T cells with receptors for the autoantigen. **(C)** A microbe with a self-mimicking epitope could engender T/B collaboration because T cells would recognize the foreign epitope and B cells would bind to the self-mimicking structure.

its affinity. These data make a convincing case that monoclonal cold agglutinins arise as the result of an immune response, perhaps an autoimmune response to an autoantigen on erythrocytes. The results of these molecular studies of cold agglutinins complement other evidence favoring a role for antigen-mediated clonal selection in some types of B-cell neoplasms (see Chap. 66 for a discussion of clonal selection in B-cell neoplasms).

In contrast to monoclonal cold agglutinins associated with chronic cold agglutinin disease, the naturally occurring IgM cold agglutinins that are present in low titers in normal serum are not restricted to the $V_{H4\text{-}34}$ gene segment. They are associated with different genes of the V_{H3} family as well as the $V_{H4\text{-}34}$ gene.[99] It therefore appears that B-cell neoplasia is an important, but not exclusive, element in the association between $V_{H4\text{-}34}$ and cold agglutinins. The correlation with lymphomas has added interest because $V_{H4\text{-}34}$ has been independently linked to B-cell lymphomas that do not secrete cold agglutinins.[100] Both kinds of V_{H434} -related B-cell tumors may originate from an uncontrolled autoimmune response against I or i RBC antigens, one type lacking the capacity for secreting the cold agglutinin, the other able to

secrete it as a monoclonal IgM immunoglobulin.

AUTOIMMUNE HEMOLYTIC ANEMIA

Epidemiology

The incidence of autoimmune hemolytic anemia is estimated to be approximately 10 cases per million population; for comparison, the incidence of acute myeloid leukemia is about 50 cases per million. [101] Autoimmune hemolytic anemia is more common in women than in men. It occurs at all ages, but usually in midlife. About one-half of cases are idiopathic (i.e., they are unassociated with any other disease). Some cases are induced by drugs, and others occur simultaneously with another autoimmune disease, especially SLE. That disorder may begin with Evans syndrome, a rare combination of autoimmune hemolytic anemia and immune thrombocytopenia. [102] A substantial proportion of cases develop in patients with B-cell lymphomas or

TABLE 34-2 -- Diseases Rarely Associated with Autoimmune Hemolytic Anemia

Collagen vascular disease
Rheumatoid arthritis
Scleroderma
Polyarteritis nodosa
Serum sickness
Sjögren syndrome
Lymphoreticular malignancy
Macroglobulinemia
Hodgkin disease
Multiple myeloma
Mycosis fungoides
Other malignancy
Acute leukemia
Thymoma
Carcinoma: colon, kidney, lung, ovary
Miscellaneous diseases
Myelofibrosis with myeloid metaplasia
Ulcerative colitis
Pernicious anemia
Thyroid disease
Ovarian cysts
Mucocutaneous lymph node syndrome (Kawasaki disease)
Evans syndrome (thrombocytopenia and hemolytic anemia)
Congenital immunodeficiency syndromes
Guillain-Barré syndrome
Primary biliary cirrhosis
Multiply transfused patients with hemoglobinopathies

CLL. Treatment of CLL with drugs such as cladribine (2-CdA) and fludarabine can either control or trigger the onset of autoimmune hemolytic anemia. It is theorized that by affecting T cells more than B cells, these types of drugs induce a disturbance in immunoregulatory T cells. [103] [104] A number of other diseases have also been complicated by autoimmune hemolytic anemia, but only as unusual exceptions (Table 34-2). [105]

Clinical Findings

The clinical findings in autoimmune hemolytic anemia are variable. They include jaundice (usually mild) and symptoms and signs of anemia. The spleen may be palpable 28 cm below the costal margin, especially after several months of unremitting hemolytic anemia. The spleen is enlarged in about one-third of patients. The disease can make its appearance acutely, with symptoms due to rapidly developing anemia, or it can develop gradually in a relatively asymptomatic form. Occasionally the blood bank provides the diagnosis through a positive antiglobulin test in a patient referred for transfusion therapy. The physical examination may reveal only pallor or slight jaundice, but signs of congestive heart failure are not unusual in patients with rapidly developing, severe autoimmune hemolytic anemia. Lymphadenopathy, fever, hypertension, renal failure, a rash, petechiae, or ecchymoses should alert the physician to the possibility of an underlying disease.

Laboratory Evaluation

Laboratory findings reflect the intensity of the hemolytic process and the bone marrows response to the anemia. In fulminant cases, with an RBC life span of <5 days, the anemia is severe and erythropoiesis increases 810-fold. As a result, the reticulocyte count rises, sometimes to levels >40%. In less severe cases, the regenerative

capacity of the bone marrow lags only slightly behind the rate of RBC destruction; hence a mild anemia but an elevated reticulocyte count. Between these extremes are many variations. Inspection of the blood smear in a typical case will reveal polychromatophilia, spherocytes, a few fragmented RBCs, nucleated RBCs, and occasionally erythrophagocytosis. Examination of the bone marrow shows erythroid hyperplasia, often with megaloblastoid features.

Patients with severe hemolytic anemia and markedly increased erythropoiesis occasionally develop folate deficiency and frank megaloblastosis. The growth of hematopoietic tissue in the bone marrow also leads to moderate increases in the white blood cell and platelet counts. The absence of reticulocytosis does not exclude the diagnosis of autoimmune hemolytic anemia but portends a serious prognosis. [106] [107] [108] [109] Presumably due to destruction of young erythrocytes by the autoantibody, the reticulocytopenia aggravates the severity of the anemia and increases the need for RBC transfusions; it may last several weeks despite therapy.

Rapid destruction of erythrocytes leads to other laboratory changes, which, like the preceding abnormalities, are not specific for autoimmune hemolytic anemia (see Chap. 23). These changes include increased serum levels of unconjugated bilirubin and lactate dehydrogenase and a reduction in plasma haptoglobin levels. In rare cases with intravascular destruction of erythrocytes, the plasma hemoglobin is elevated and there is hemoglobinuria; hemosiderinuria follows in 7 days, when renal tubular epithelial cells containing absorbed iron defoliate into the urine. Tests of osmotic fragility and autohemolysis are unnecessary for diagnosis and management; measurements of RBC survival are rarely indicated.

The distinction between autoimmune hemolytic anemia and other forms of hemolytic anemia depends on the DAT, often termed the direct Coombs test. This assay detects the hallmark of autoimmune hemolytic anemia, the presence of IgG or complement bound to the RBC membrane (Fig. 34-7). It is performed by washing the patients RBCs free of plasma, adding the antiglobulin reagent, centrifuging, and reading for the presence or absence of agglutination. The DAT thus tests for the presence of immunoglobulin or complement on the patients RBCs. In patients with severe autoimmune hemolytic anemia, the DAT results are usually strongly positive, but the titer of the autoantibody and the strength of the reaction do not always predict the severity of disease.

The IgG autoantibodies in autoimmune hemolytic anemia are predominantly of the IgG1 and IgG3 subclasses, both of which are capable of activating complement. In most cases, either

Figure 34-7 DAT for detection of **(A)** erythrocyte-bound C3d or **(B)** IgG. Hemagglutination occurs when anti-C3d or anti-IgG can create a lattice structure by bridging sensitized RBCs.

IgG or C3d (a proteolytic fragment of C3; see below) is bound to the RBC membrane. Therefore, the screening antiglobulin reagent, made by immunizing rabbits or by blending murine monoclonal antibodies, must contain antibodies against IgG (including IgG1 and IgG3 subclasses) and C3d. [110] [111] [112] [113] [114] [115] [116] [117] Broad-spectrum antiglobulin test reagents may also contain antibodies against other serum proteins that can bind nonspecifically to RBCs. Therefore, when the routine antiglobulin test is positive, it should be repeated using reagents specific for IgG and C3d. IgA and IgM autoantibodies are rare causes of warm autoimmune hemolytic anemia[118] [119] [120] [121] and need not be considered in usual routine tests. [122]

A positive antiglobulin test, confirmed with a specific anti-IgG reagent, is occasionally found in healthy people; approximately 1 in 10,000 blood donors has a positive antiglobulin test without anemia or evidence of increased hemolysis. [123] A positive antiglobulin test with a monospecific anti-C3d reagent is also seen occasionally in healthy subjects,[124] but such a result almost always points to either warm- or cold-reactive autoantibodies. In about 10% of cases of autoimmune hemolytic anemia, erythrocyte-bound C3d occurs in the absence of erythrocyte-bound IgG, whereas in all cases of cold agglutinin disease, erythrocyte-bound C3d is detected. SLE should be suspected in cases of autoimmune hemolytic anemia in which both IgG and C3d are detected. By contrast, -methyldopa-induced autoimmune hemolytic anemia is rarely associated with erythrocyte-bound C3d; only IgG is present.

The unexpected report of a negative antiglobulin test in a patient suspected of having autoimmune hemolytic anemia, although uncommon, may have several explanations. Technical error is infrequent, but it can occur. Other rare causes are IgA autoantibodies or low-affinity IgG autoantibodies. [125] More commonly, the test is not sensitive enough to detect small numbers of erythrocyte-bound IgG molecules; this occurs most often in autoimmune hemolytic anemia associated with a lymphoma or CLL. Manual antiglobulin tests detect 200500 molecules of IgG per cell; amounts below this level, although undetectable, may be clinically important. In such cases, sensitive assays such as the antiglobulin consumption assay [126] or tests with ^{125} I-staphylococcal protein A, which binds avidly to IgG, can reveal the autoantibodies.[127]

The DAT, like any other laboratory test, requires interpretation. As already noted, a positive antiglobulin test can occur in healthy subjects and patients with autoimmune hemolytic anemia can have a negative antiglobulin test. Of equal importance, a positive antiglobulin test does not always signify erythrocyte-bound IgG antibody or complement, nor does a positive result necessarily imply that the individual has hemolytic anemia. The frequency of false-positive tests in hospitalized patients can be as high as 15%.[128] They can stem from tests performed on clotted blood,[129] from the use of silicone gel tubes,[130] from collection of samples from intravenous lines containing low ionic strength solutions, [131] from medications (e.g., cephalin) that cause nonspecific attachment of plasma protein to the RBC surface,[132] [133] and from hypergammaglobulinemia.[134] [135] If the DAT is positive, specific reagents are required to identify the erythrocyte-bound protein.

In 80% of patients with autoimmune hemolytic anemia, the autoantibodies are present in the serum as well as on the red cell membrane. [136] The indirect antiglobulin test (indirect Coombs test) detects the presence of these serum antibodies in the patients serum (Fig. 34-8). The procedure entails incubating the test serum and normal RBCs, usually at 37°C for 1 hour, washing the cells free of serum, adding the antiglobulin reagent, and reading for agglutination. The antibodies detected by the indirect antiglobulin test may be autoantibodies in a patient with autoimmune hemolytic anemia, or they may be alloantibodies induced by blood transfusion or maternal/fetal incompatibility. Alloantibodies, present only in the serum, have specificity for RBC antigens not present on the patients erythrocytes. The DAT is therefore negative in alloimmunization; exceptions may occur if the alloantibodies bind to recently transfused RBCs.

The specificity of the antibodies detected by the indirect antiglobulin test can be assessed by reacting the test serum with a panel of erythrocytes of known antigenic composition. Alloantibodies have definable specificities, whereas the serum autoantibodies of autoimmune hemolytic anemia usually react with all RBCs except those that contain no Rh antigens, the so-called Rh_{null} RBCs.[137] Even so, the identity of the Rh-associated determinant implied by the lack of reactivity of the autoantibodies with Rh_{null} cells is unknown. Occasionally (12% of cases), relative specificity within the Rh system can be demonstrated, and RBCs lacking the corresponding Rh antigen survive better in vivo than those that express the antigen. [138] [139] [140] [141] Specificities of IgG autoantibodies for other blood groups have been described. [142] [143] [144] [145] [146] [147] [148] [149] [150] Specificity for different subunits of the RBC membrane has recently been reported. [151] [152] [153] [154] [155] In Evans syndrome in patients with the lupus anticoagulant (antiphospholipid antibody syndrome), the erythrocyte-bound autoantibody can react with phospholipids. [156] [157] [158] [159] [160] An important practical point is that, with rare exceptions, the autoantigens are present on all normal erythrocytes; in practice, all RBCs are incompatible (see discussion under TherapyTransfusion).

Pathophysiology

Immune Clearance of Erythrocytes

The autoantibodies that cause RBC destruction in autoimmune hemolytic anemia and the antierythrocyte autoantibodies in healthy persons with no discernible signs of abnormal hemolysis may have the same isotype and even identical serologic specificities. Therefore, the pathogenicity of anti-red cell autoantibodies must depend on additional considerations. The amount of the autoantibody, its avidity for the erythrocyte autoantigen, and its ability to fix complement are of particular importance.[161] Each of these factors probably contributes independently and cumulatively to the erythrocyte lesion.

Figure 34-8 Indirect antiglobulin test for detection of antierythrocyte antibodies in serum. The patients serum is mixed with a panel of normal RBCs, some (or all) of which express the antigen(s) recognized by the serum antibodies. After the antibody-coated erythrocytes are washed, an anti-IgG reagent is added. Hemagglutination occurs, as in Figure 34-7 .

Immune hemolysis in vivo begins with opsonization by autoantibodies. The terminal effect can be destruction of the RBC directly within the circulation (intravascular hemolysis) or removal of the cell from the circulation by tissue macrophages (extravascular hemolysis), or both. Opsonized RBCs are recognized and cleared from the circulation by macrophages located primarily in the spleen, and to a lesser extent in the liver. [162] The interaction of macrophages with RBCs coated with IgG or C3b (or both) occurs through receptors specific for the Fc portion of IgG (especially IgG1 and IgG3) and for C3b. [163] [164] Initiation of the events that culminate in the deposition of C3b on the erythrocyte surface requires at least two IgG molecules bound in close proximity on the RBC membrane. Furthermore, the subclass of the IgG autoantibodies is important not only for binding to macrophage Fc receptors (IgG3 > IgG1) but also for complement activation. The potency of subclasses for complement activation is as follows: IgG1 > IgG3 > IgG2 > IgG4. [162] [163] [164] [165] [166] [167]

The presence on the erythrocyte membrane of both IgG and C3b accelerates immune clearance, [168] [169] [170] suggesting that the Fc and C3b macrophage receptors act synergistically. Sequential studies in one subject of the clearance of RBCs coated in vitro with different amounts of the same antibody showed that the amount of erythrocyte-bound IgG is another factor influencing the rate of hemolysis. Little information is available on the minimum number of erythrocyte-bound IgG molecules required for interaction with macrophages; in some cases of autoimmune hemolytic anemia, <200 IgG molecules per erythrocyte (too few for detection by the DAT) is sufficient to cause in vivo hemolysis. [167]

The splenic environment is especially conductive to immune clearance. IgG-coated RBCs are efficiently trapped from the hemoconcentrated circulation within the spleen. The relatively low plasma concentration in splenic sinusoids tends to alleviate competition between plasma IgG and IgG-coated RBCs for Fc receptors, thus providing optimal interactions between opsonized erythrocytes and macrophages. [163] [169] Rarely, RBC autoantibodies cause reticulocytopenia and dyserythropoiesis, thereby contributing to the severity of anemia. [171]

Red Blood Cell Lesion

The macrophage may ingest an opsonized RBC entirely; more likely, proteolytic ectoenzymes on its surface digest away bits of the erythrocyte membrane, producing a spherocyte, an RBC with the lowest possible surface area/volume ratio. [164] Spherocytes are less deformable and more susceptible to osmotic lysis than disk-shaped red cells, so they are especially susceptible to hemolysis during their travels through the sluggish circulation of the splenic sinusoids. This is why the predominant mechanism of destruction of erythrocytes coated with IgG with or without C3b occurs extravascularly in autoimmune hemolytic anemia (Fig. 34-9). By contrast, intravascular hemolysis is rare because regulatory proteins of the complement system (C3b inactivator and $_1$H globulin limit completion of the complement cascade on the surface of the opsonized erythrocyte. [172] The C3b inactivator system contributes to the local arrest of the complement cascade by degrading C3b to C3d; spontaneous elution of the autoantibody (a measure of its avidity for the RBC) leaves an erythrocyte coated only with C3d.

Macrophage-mediated mechanisms predominate in causing the lesion of autoimmune hemolytic anemia, but the participation of cytotoxic lymphocytes (natural killer cells), which cause antibody-dependent cell lysis, has not been excluded. The efficiency of reticuloendothelial function probably also contributes to the degree of immune clearance and may account for exacerbations of autoimmune hemolytic anemia by viral or bacterial infections. In vitro assays of the ability of blood monocytes from patients with viral infections to phagocytose Ig-coated RBCs have shown marked deviations from normal. [173] [174]

Therapy

General Principles

Because the severity of autoimmune hemolytic anemia may range from indolent to life-threatening, the impetus to initiate treatment must begin with a thorough appraisal of symptoms and the extent of the damage. Rapidly developing anemia with

Figure 34-9 Mechanism of extravascular hemolysis in autoimmune hemolytic anemia. **(A)** Macrophage encounters an IgG-coated erythrocyte and binds to it via its Fc receptors. Thus entrapped, the RBC loses bits of its membrane as a result of digestion by the macrophages ectoenzymes. The discoid erythrocyte transforms into a sphere. **(B)** RBC lightly coated with IgG (and therefore incapable of activating the complement cascade) is preferentially removed in the sluggish circulation of the spleen. **(C)** RBC with a heavy coat of IgG; thus, C3b (black circles) can be removed both by the spleen and the liver.

Box 34-1. HAZARDS OF TRANSFUSION THERAPY

The idea that transfusion therapy represents a special hazard in patients with autoimmune hemolytic anemia[183] [184] [185] [186] has been overemphasized; nevertheless, transfusions are not to be undertaken lightly in such patients. The decision to transfuse requires that the clinician and the blood bank work together. The clinician must supervise the transfusions and insist on close observation of the patient. An adverse reaction dictates additional laboratory tests, but even sophisticated serologic techniques do not ensure uneventful transfusions; acute intravascular hemolysis can occur with no evidence of serologic incompatibility. In vivo compatibility testing with ^{51}Cr-tagged RBCs is of no value in the management of most patients.

Transfusion is warranted without delay and, if necessary, before all the serologic tests are completed when cardiac or cerebral function is threatened. Alleviation of signs and symptoms of anemia can usually be accomplished with relatively small quantities of RBCsas little as 0.51 U of RBCs. Overtransfusion in the presence of high-output cardiac failure can easily lead to circulatory overload, another reason to justify careful observation of the patient during the transfusion.

a hematocrit of <20 requires urgent management, but in the less aggressive forms of the disease, especially in the elderly, it may be more prudent to allow mild anemia than to institute risky treatment.

The management of autoimmune hemolytic anemia depends in part on whether the disease is primary or whether it is secondary to such disorders as B-cell malignancies or SLE. [175] [176] This, too, demands a careful assessment before any treatment begins. In some cases of autoimmune hemolytic anemia secondary to lymphoma or CLL, the pathogenic autoantibody (usually monoclonal) is secreted by the neoplastic B cells. Combination chemotherapy or irradiation of the underlying malignancy often brings the hemolytic anemia under control. [177] [178] [179] In other cases, however, the autoantibodies (usually polyclonal) do not originate from the B-cell neoplasm but probably result from abnormal immune regulation instigated by the neoplastic B cells. Treatment of the latter type of secondary autoimmune hemolytic anemia with immunosuppressive agents may improve the anemia, but it may also trigger an exacerbation. [180]

The ultimate goal of therapy is control of the B-cell populations that secrete pathogenic autoantibodies. However, so little is known about such cells [181] [182] that the currently available therapy is, by default, nonspecific. The desired therapeutic effect is eradication of the abnormal hemolytic process, not reversal of the serologic

abnormalities. Indeed, the DAT often remains positive in the face of a hematologic response.

Transfusion

Severe anemia may cause pulmonary edema (in the setting of high-output cardiac failure), somnolence, and even obtundation. These manifestations occur when the hemoglobin falls to <4 g/dl. They are life-threatening and necessitate transfusion with RBCs. [183] [184] [185] [186] The persistence of tachycardia, postural hypotension, dyspnea, and angina also calls for transfusion. Oxygen therapy may be prescribed, but it is no substitute for transfusion.

Alloantibodies, usually with specificity for the Rh or Kell blood group systems, occur in 30% of patients with autoimmune hemolytic anemia who have a history of blood group immunization by maternal/fetal incompatibility or previous transfusions. [187] [188] [189] These alloantibodies can escape notice in a patient with a positive result on the indirect antiglobulin test because of the concomitant presence in the serum of autoantibodies that react with virtually all normal RBCs. Nevertheless, several techniques may help detect suspected alloantibodies. [190] [191] [192] Absorption of the autoantibodies with the patients own RBCs can permit recognition of residual alloantibodies. Before absorption, the autoantibody must be eluted from the patients RBCs; enzyme treatment of the patients cells increases autoantibody absorption. Another method involves absorption of the patients serum with normal RBCs of selected phenotypes and then retesting of the absorbed serum.

The preceding techniques should not be required as pretransfusion tests in patients with autoimmune hemolytic anemia. Transfusions should never be delayed if the tests are not readily available. However, standard antibody detection and identification tests with both the patients serum and an elute prepared from the patients cells should be performed whenever possible. Titration of the eluate and the serum against RBCs of various Rh phenotypes can indicate an auto-antibody specificity (or preference) within the Rh system. Any such specificity should be respected in selecting donors units. [193] [194]

Corticosteroids

Corticosteroids are the mainstay of treatment for patients with symptomatic, unstable autoimmune hemolytic anemia of either

Box 34-2. PREDNISONE THERAPY

Therapy can begin with prednisone (there is no clear advantage to alternative forms of corticosteroids) in a dose of 12 mg/kg/day in divided doses, depending on the severity of the disease. The physician can consider beginning with a lower dose (e.g., 0.6 mg/kg/day) in elderly patients, especially those who are immobilized or who already have osteoporosis, or when faced with infection or other mitigating complications. Whatever the amount selected, it should be continued until a response becomes evident, usually within 3 weeks, by a rise in the hematocrit and a fall in the reticulocyte count.

Autoimmune hemolytic anemia in children is likely to respond to prednisone with a durable remission. By contrast, permanent remissions are infrequent in adults. Therapy for adults therefore requires a plan to manage (or avoid) relapse. Essential elements to consider in formulating the long-term management of a patient with autoimmune hemolytic anemia are the duration of treatment with the initial dose of prednisone and the rate of dosage reduction after a response has been achieved. The tapering schedule depends, in part, on the severity of the initial presentation and on the prominence of side effects of the treatment. In the absence of contraindications, prednisone is continued at the initial dose until the hemoglobin reaches a level of 10 g/dl, by which time transfusions should no longer be necessary. Thereafter, gradual reduction in the dose can begin, usually at a rate of 510 mg/wk. During this second phase of treatment, the divided daily prednisone dose can be consolidated into a single daily dose. If the remission remains stable after a dose of 10 mg/day is reached, further tapering over a 34-month period can proceed cautiously. Some hematologists will continue treatment for many months, at low doses (e.g., 10 mg every other day), but the efficacy of this practice has not been investigated.

the idiopathic or the secondary forms. The clinical response to prednisone results primarily from its ability to disable macrophages from clearing IgG-or C3b-coated erythrocytes. Corticosteroids interfere with both the expression and function of macrophage Fc receptors. This is probably the earliest, and perhaps even the primary, mechanism of the ability of steroids to diminish the immune clearance of blood cells. [195] [196] [197] [198] Prednisone can also reduce autoantibody production, but only after several weeks of therapy.

Splenectomy

Indications for splenectomy in autoimmune hemolytic anemia include failure to respond to prednisone, dependence on prednisone dosages that are >1020 mg/day, or intractable side effects of the corticosteroid. The procedure can be highly effective because along with the removal of the spleen go its phagocytosing macrophages and autoantibody-producing B cells. In most young adults with primary autoimmune hemolytic anemia, the question of splenectomy arises almost inevitably. However, in an elderly patient with a stable but incomplete remission, maintenance therapy with prednisone at a dose of 10 mg/day for an indefinite period may be the better alternative. There is a slight risk that the overwhelming sepsis syndrome may develop immediately following splenectomy, but systemic bacterial infections can occur long after the postoperative period as well. [199] These risks are lessened by immunization with pneumococcal and meningococcal vaccines, always given preoperatively, and by the prompt use of antibiotics for febrile illness.

The response to splenectomy does not correlate with the age of the patient, the presence or absence of an underlying B-cell disorder, the strength of the antiglobulin test, prior response to prednisone, or pattern of sequestration of ^{51}Cr-labeled red cells; these criteria cannot be used to predict the response to splenectomy. [200] About 5060% of patients with classic autoimmune hemolytic anemia will have a good to excellent initial response to splenectomy. They will need <15 mg/day of prednisone to maintain an adequate level of hemoglobin. [201] Information regarding the clinical implications of an accessory spleen in autoimmune hemolytic anemia is meager. Faced with such a rare finding in a patient with relapse, many hematologists would recommend its removal. The role of splenectomy in patients with mixed IgG, IgM, or mixed cold- and warm-reactive IgG antibodies is unclear.

Box 34-3. CYTOTOXIC DRUG THERAPY

The administration of cytotoxic drugs is best reserved for refractory cases: symptomatic patients who have not responded to splenectomy, those in whom splenectomy is an unacceptable medical risk, those who refuse the operation, or patients who have serious side effects from corticosteroids. Cyclophosphamide (2 mg/kg/day) or azathioprine (1.5 mg/kg/day) should be continued for 3 months to ensure maximal inhibition of autoantibody synthesis. Less than one-half of patients treated with these drugs will respond with a rise in the hemoglobin that can be maintained in the face of substantially reduced doses of prednisone. Indeed, this estimate may be overly optimistic, since negative or unfavorable results seldom reach publication. Unfortunately, no controlled clinical trials of cytostatic agents in the treatment of autoimmune hemolytic anemia have been conducted.

Immunosuppressive Therapy

Most experience with immunosuppressive drugs in the treatment of autoimmune hemolytic anemia has been with alkylating agents (cyclophosphamide and chlorambucil) and thiopurines (azathioprine and 6-mercaptopurine). [202] The basis for the clinical use of these drugs is their inhibitory effect on the immune system, possibly affecting both B cells and T cells. [203] [204]

Cyclophosphamide and azathioprine, like prednisone, can induce numerous side effects. Some of these occur concomitantly with their use; others become evident only after sustained administration. The early side effects include bone marrow suppression and impairment of the immune response (particularly T-cell-mediated immunity). In addition, cyclophosphamide damages ovarian function, inhibits spermatogenesis, [205] [206] [207] [208] and causes bladder fibrosis. [209] Acute myeloid leukemia can develop years after sustained use. [203] By contrast, the prolonged use of azathioprine has not been associated with a statistically significant increase in malignant diseases. All these considerations mandate careful monitoring of any patient treated with either cyclophosphamide or azathioprine.

Plasma Exchange

In a normal person, plasma exchange of 11.5 plasma volumes is effective in lowering the serum level of IgG by 50%. However, continuous antibody production and the large extravascular distribution of IgG limit the efficacy of plasma exchange in autoimmune hemolytic anemia. On cessation of therapy, the rate of return of pretreatment levels of autoantibody depends on the rate of autoantibody production. [210] Occasional dramatic responses have been reported in patients being prepared for surgery or when plasma exchange was a temporizing measure following the initiation of immunosuppressive therapy. [211] [212]

Vinca Alkaloids

Responses in a few patients with autoimmune hemolytic anemia have been reported following infusion of vincristine-laden IgG-coated platelets; the platelets serve the drug directly to macrophages, presumably interfering with the ability of the macrophages to bind or ingest IgG-coated RBCs. Reported responses have been of long duration and associated with a delayed fall in titer on the DAT. The therapeutic effects of vinca alkaloids alone in autoimmune hemolytic anemia have not been systematically investigated. [213]

Danazol

Danazol, an attenuated synthetic androgen, is useful in patients with autoimmune thrombocytopenic purpura when given in a dose of 400600 mg/day orally. It has benefited a limited number of patients with refractory autoimmune hemolytic anemia. Remissions of 1 year have been reported. [214] In view of the relatively low risk of long-term side effects (the drug can cause abnormal liver function), danazol may find a secure place in the management of prednisone-dependent patients.

Intravenous -Globulin

Intravenous -globulin has been found effective in managing selected cases of autoimmune thrombocytopenia. The recommended dose is 400 mg/kg/day for 5 days. The soluble IgG in the material may increase the life span of IgG-coated RBCs by saturating Fc receptors on macrophages. In a recent study of patients with autoimmune hemolytic anemia associated with lymphoproliferative disorders, a long-term benefit was observed with a maintenance dose schedule of intravenous IgG every 21 days. A decrease in antiglobulin titer was found in

these patients, suggesting a mechanism other than blockade of Fc receptors by intravenous IgG. [215]

COLD AGGLUTININ DISEASE

Cold agglutinin disease refers to a group of disorders caused by antierythrocyte autoantibodies (e.g., cold agglutinins) that preferentially bind RBCs at cold temperatures (418°C). Virtually all sera from healthy individuals contain low-titer cold agglutinins, regarded as benign or harmless RBC autoantibodies and considered polyclonal. Similarly, cold agglutinins that arise following certain infections are also polyclonal and usually benign; in rare cases, a transient form of cold agglutinin disease ensues (see following sections). By contrast, monoclonal cold agglutinins are generally pathogenic and are derived from clonal B-cell expansions (as in idiopathic/chronic cold agglutin disease), which may progress to frank lymphoma (Table 34-3).

Chronic Cold Agglutinin Disease

The most common type of cold agglutinin disease, a chronic form characterized principally by a stable anemia of moderate severity and attacks of acrocyanosis precipitated by exposure to cold, constitutes about one-third of all cases of immunohemolytic anemia. Cold agglutinins cause the cardinal abnormalities of the disease. The acrocyanosis stems from intra-arteriolar agglutination of erythrocytes in the relatively cool tips of the fingers, feet, earlobes, and nose. The hemolytic anemia depends on the capacity of the cold agglutinins to initiate activation of the complement cascade on the surface of the RBC (see discussion under Pathophysiology). Most patients with chronic cold agglutinin disease are in the fifth to eighth decades of life, and many of them have a B-cell neoplasmlymphoma, Waldenström macroglobulinemia, or CLL. The cold agglutinin in those latter cases is monoclonal, almost always IgM-, and may show up as a monoclonal band in the region of the serum protein electrophoretic pattern. In the absence of a B-cell neoplasm, the spleen and lymph nodes are rarely enlarged; such findings warrant a search for the neoplasm.

Laboratory Evaluation

The usual laboratory findings of hemolytic anemia (i.e., anemia, reticulocytosis, polychromatophilia, spherocytosis, erythroid hyperplasia in the bone marrow, and elevations in serum bilirubin and lactate dehydrogenase levels) are generally not striking in chronic cold agglutinin disease. Hemagglutination may be visible to the unaided eye in blood drawn from a patient with cold agglutinin disease and can interfere with automated blood counts. The anemia is often mild and stable because the C3b inactivator in serum limits the extent of cold agglutinin-induced complement activation on the erythrocyte membrane. However, exposure to cold may greatly augment the binding of cold agglutinins, exceeding the restraints of the inactivator system. This can result in a sudden drop in hematocrit, with complement-mediated intravascular hemolysis and renal failure. In a

distinctive subset of patients with aggressive cold agglutinin disease, the cold agglutinin titer is relatively low, but the autoantibody has a high thermal amplitude. Recognition of patients with this variant of cold agglutinin disease is important because they may respond to prednisone, [216] whereas patients with high-titer cold agglutinin disease usually do not.

In typical cases of chronic cold agglutinin disease, the cold agglutinin titer is very high (>1:10 ^{5} , and occasionally >1:10^{6}). The antibodies are most reactive in the cold, and hemagglutination disappears as the temperature rises toward 37°C. In some cases, however, the antibody is reactive at relatively high temperatures, and occasionally even at 37°C. The reactivity of the cold agglutinin at high temperatures (i.e., its thermal amplitude), not the titer of the antibody, most accurately predicts the severity of the disease. The DAT is positive because of erythrocyte-bound C3d (see discussion under Pathophysiology), but tests with anti-IgG reagents are negative. The indirect antiglobulin test, conducted at 37°C, is negative. In addition to monoclonal IgM cold agglutinins, IgG/IgM mixed cold agglutinins have been reported. [217] [218] [219] Besides the usual high titers of IgM cold agglutinins, some cases of cold agglutinin disease have low titers of IgG and IgA cold agglutinins.

Cold agglutinins are not cryoglobulins. The latter are most often monoclonal IgM immunoglobulins that, in the cold, either self-associate and precipitate from solution (type I cryoglobulinemia) or precipitate as complexes with polyclonal IgG molecules (type II cryoglobulinemia, often due to a monoclonal IgM rheumatoid factor). Type III cryoglobulins consist of a mixture of polyclonal IgM and polyclonal IgG immunoglobulins. The clinical manifestations of the cryoglobulinemic syndromes are highly variable: types I and II cryoglobulinemia occur in B-cell neoplasms (Waldenström macroglobulinemia, multiple myeloma, lymphoma, and CLL); types II and III cryoglobulinemia can produce a picture of immune complex-mediated vasculitis, with vascular purpura, arthritis, and nephritis as the dominant complications. In occasional patients, the cryoglobulin can also be a cold agglutinin. [220] [221] [222] [223]

Transient Cold Agglutinin Disease

A second type of cold agglutinin disease, usually acute and always self-limited, occurs as a rare complication of several infectious diseases, most notably *M. pneumoniae* infection and infectious mononucleosis. Patients with this form of cold agglutinin disease are therefore much younger than those with chronic cold agglutinin disease. The onset is abrupt, appearing as the infection wanes, and the anemia can be severe. Cold agglutinin titers are moderately elevated, and the cold agglutinins are polyclonal. Often these polyclonal cold agglutinins coincide with high-titer warm-reactive IgG RBC autoantibodies.

Targets of Cold Agglutinin Disease

The antigenic specificity of cold agglutinins is usually identified by their degree of reactivity with RBCs from adults (blood group I) and cord blood (blood group i). The cold-reactive autoantibody produced after some cases of *M. pneumoniae* infection has anti-I specificity, [90] whereas the antibody in infectious mononucleosis frequently, but not always, has anti-i specificity. [224] [225] Additional specificities have been identified by tests with rare adult RBCs that lack the I antigen, or with enzyme-treated erythrocytes. Cold agglutinins with these antigenic specificities (I(T), I(F), Pr, Gd, Sa, Lud, Fl) have no distinguishing clinical features. [226] [227] [228] [229]

[230] [231] [232] [233] [234] Rarely cold agglutinins will be specific for the A blood group antigen. [235]

Pathophysiology

The pathogenic IgM autoantibody in cold agglutinin disease is highly efficient in activating the classical complement pathway

---

Box 34-4. TRANSFUSIONS AND COLD AGGLUTININ DISEASE

Transfusion in a patient with cold agglutinin disease requires the same prudent safeguards observed with transfusions in autoimmune hemolytic anemia. All compatibility tests must be carried out at 37°C and with IgG-specific antiglobulin reagents to avoid confusion with the serum cold agglutinin and the erythrocyte-bound C3d. The use of inline blood warmers is advisable, and more elaborate measures to perform the entire transfusion process at 37°C are occasionally required.[248] Hypothermia must be avoided during cardiac surgery, and special techniques must be used to avoid lowering the temperature of blood in the coronary arteries.[249]

on the erythrocyte membrane.[236] [237] However, the thermal dependency of the antibody constrains its pathogenic effects. The autoantibody rapidly elutes off red cells at the 37°C temperature of the visceral circulation, but in the cool peripheral circulation of the hands and feet the cold agglutinin remains on the erythrocyte membrane for at least a few seconds. That amount of time is sufficient to activate the complement cascade to the stage of C3b, which adheres to the RBC after it re-enters the central circulation. In the hepatic circulation, $C3b^+$ RBCs encounter macrophages with receptors specific for C3b;[161] [169] [233] however, C3b sensitization is only a weak signal for the activation of phagocytosisthe hepatic clearance of C3b-coated RBCs requires 500800 C3b molecules per RBC. As a result, many $C3b^+$ RBCs escape unharmed into the systemic circulation, where they come under the influence of the regulatory proteins of the complement system. The C3b inactivator system degrades C3b into C3dg or C3d, or both. The result is a cohort of erythrocytes coated with C3d, but not with the IgM autoantibody. [162] Since macrophages bind to C3d with even lower avidity than to C3b, the $C3d^+$ erythrocytes tend to have a near normal survival in vivo despite a heavy coating with that degradation product of C3. [166] [238]

These limits on the pathogenicity of cold agglutinins account for the subdued hematologic picture in most patients with cold agglutinin disease. If, however, the regulatory C3b inactivator proteins are impaired, limiting cleavage of RBC-bound C3b, or if the production of IgM autoantibodies with a high thermal amplitude is impaired, permitting completion of the complement cascade in the visceral circulation, severe extravascular hemolysis can occur. Several patients with high titers of IgA cold agglutinins have been reported. These cases are not associated with cold agglutinin disease, which may relate to the lack of complement activation by IgA antibodies.[239] [240] [241] [242] [243] [244] [245] [246] [247]

Therapy

Chronic Cold Agglutinin Disease

Therapy for the cold agglutinin syndromes depends on the gravity of the symptoms, the serologic characteristics of the autoantibody, and any underlying disease. In the idiopathic, or primary, form of chronic cold agglutinin disease, prolonged survival and spontaneous remissions and exacerbations are not unusual. The anemia is generally mild, and the simple measure of avoiding exposure to cold temperatures can avoid exacerbations, especially when the cold agglutinin has a low thermal amplitude. Prednisone has been beneficial in rare cases showing relatively low titers of cold agglutinins of a high thermal amplitude or in which an IgG cold-reactive antibody is produced. However, prednisone is not useful therapy in most patients with primary IgM-induced cold agglutinin disease, and its administration should not be undertaken lightly, given the chronicity of the disease. [248] [249] Plasma exchange may help as a temporary measure in acute situations.[210] Splenectomy is usually ineffective because the liver is the dominant site of sequestration of red cells heavily sensitized with C3b. However, rare cases with an enlarged spleen have responded to splenectomy; in some of these patients, a localized splenic lymphoma was found, whereas in others only lymphoid hyperplasia was evident.

It is essential to seek evidence of a B-cell neoplasm before initiating therapy for chronic cold agglutinin disease. Oral alkylating agents (chlorambucil or cyclophosphamide) help many patients with the secondary form of cold agglutinin disease because of their effect on the B-cell neoplasm, but only occasionally do they benefit patients with the primary form of the disease. [250] [251] When cold agglutinin disease is part of an established B-cell malignancy, the severity of hemolysis often waxes and wanes in parallel with the activity of the neoplasm.

Transient Cold Agglutinin Disease

Transient cold agglutinin disease is a rare form that is always self-limited. Supportive measures, including transfusions and avoidance of cold, may suffice to tide the patient over the bout of hemolysis. Corticosteroids are usually not helpful, and splenectomy is almost never indicated.

PAROXYSMAL COLD HEMOGLOBINURIA

Clinical Manifestations

There are two distinct groups of patients with paroxysmal cold hemoglobinuria: persons with tertiary or congenital syphilis, and children or young adults who develop the disease after a viral illness. The syphilitic variant is rarely seen today. Although the Donath-Landsteiner antibody often occurs in tertiary or congenital syphilis, it generally does not cause hemolytic disease. On exposure to cold, an occasional patient experiences paroxysms of hemoglobinuria and constitutional symptoms: fever, back pain, leg pain, abdominal cramps, and rigors, followed by hemoglobinuria. The infrequent postviral form of paroxysmal cold hemoglobinuria [252] [253] [254] is characterized by constitutional symptoms with fulminant intravascular hemolysis and its associated signs of hemoglobinemia, hemoglobinuria, jaundice, severe anemia, and sometimes renal failure. The disease is self-limited, usually lasting 23 weeks.

Laboratory Evaluation

The IgG antibody responsible for paroxysmal cold hemoglobinuria is found in the patients serum by incubation of normal erythrocytes, fresh normal serum as a source of complement, and the patients serum, first at 4°C and then at 37°C, with appropriate controls. The Donath-Landsteiner antibody fixes the first two components of complement in the cold and completes the cascade on warming to 37°C. [255] The DAT is almost always negative, but occasionally weak reactions for erythrocyte-bound complement are manifested. The indirect antiglobulin test is negative. Most Donath-Landsteiner antibodies have specificity for the P blood group system,[256] [257] but other specificities have been described. [258] [259] [260] The diagnosis depends on recognition of the clinical picture, since tests for the Donath-Landsteiner antibody are not routinely performed.

Therapy

No specific treatment for paroxysmal cold hemoglobinuria has been found. Prednisone is not useful. The best approach is supportive care, transfusions to alleviate symptoms, and avoidance of cold temperatures.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Drug-induced immune hemolytic anemia was commonly seen when penicillin was administered in large doses (i.e., >20 million U/day) and when -methyldopa was widely used in the treatment of hypertension. [261] [262] However, the disease is unusual in present-day clinical practice. [263]

Four distinct mechanisms are associated with the disorder. In the first, the patient makes antibodies against a drug (e.g., penicillin) that can bind to the RBC membrane, exposing its haptenic determinant. The antidrug antibodies combine with the erythrocyte-bound drug, opsonizing and preparing the RBC for destruction. In the case of penicillin, [264] hemolytic anemia occurs only when large amounts are administered; in patients treated with lower doses, a positive DAT result without hemolytic anemia is not unusual because the production of low-avidity IgG antipenicillin antibodies is a common event. Discontinuation of the drug brings the hemolytic anemia to a rapid halt. Clues to the diagnosis are the appropriate clinical setting: a positive DAT result, a negative result on the indirect antiglobulin test, and failure of antibodies eluted from the patients RBCs to bind to normal erythrocyte. The diagnosis is established when both the eluate and the patients serum react with penicillin-coated cells.

The second mechanism involves immune complexes. The offending drug, or drug metabolite, binds to a plasma protein, forming an immunogenic conjugate. The resulting antidrug antibody binds to the drug-plasma protein conjugate, forming an immune complex that adheres to RBCs. The antidrug antibody, usually IgM, causes a clinical picture of intravascular hemolysis, hemoglobinemia, hemoglobinuria, and even renal failure by efficiently activating complement on the erythrocyte membrane. This chain of events accounts for most reported examples of drug-induced immune hemolytic anemia. Recent reports concerning the nonsteroidal drug diclofenac have shown that autoimmune hemolytic anemia is induced by sensitization to the glucuronide conjugate of the drug. [265]

Serologic findings with erythrocyte-bound immune complexes are similar to those of the first mechanism, except that

[a]Mechanism and serologic findings are summarized.

the DAT reveals complement only bound to the RBC; the IgM antibody is presumed to be no longer present after complement activation. The patients serum reacts with RBCs (lacking antidrug antibody) in the presence of the offending drug, and the eluate from the patients RBCs generally does not react with normal erythrocytes.

The third mechanism involves in vivo sensitization to drugs by the formation of immunogenic drug-RBC complexes. In these cases, the specificity of the drug-induced antibodies is contributed not only by the drug (or its metabolites), but also by defined RBC antigens, particularly of the Rhesus and I/i systems. [266]

The fourth mechanism involves the induction of authentic autoantibodies against RBCs by a drug. -Methyldopa is the classic example (Fig. 34-10).[267] In as many as 20% of patients treated with -methyldopa the DAT result turns positive, but few develop hemolytic anemia. The antiglobulin test result may take several months to a year or more after the start of drug therapy to become positive. In patients with hemolytic anemia, discontinuation of the drug results in the gradual cessation of the hemolytic anemia and disappearance of the autoantibody. Curiously, the autoantibody is usually specific for antigens of the Rh system. The serologic findings are indistinguishable from those of primary autoimmune hemolytic anemia; they include a positive DAT result, usually a positive result on the indirect antiglobulin test, and an eluate that reacts with normal erythrocytes. In contrast to the preceding examples, in this case the drug is not required in the test system to demonstrate the presence of the antibodies. Patients taking -methyldopa often have antinuclear antibodies, rheumatoid factor, and antibodies to gastric parietal cells, in addition to the RBC autoantibodies. The mechanism by which -methyldopa induces autoantibodies

Figure 34-10 Drug-induced hemolytic anemia. **(A)** The planted antigen mechanism, of which penicillin-induced hemolytic anemia is the paradigm, entails binding of a drug to the RBC membrane, followed by binding of antidrug antibody to the planted antigen. **(B)** By contrast, in the autoimmune mechanism, the patient produces authentic antierythrocyte autoantibodies.

is unknown but may involve effects on immunoregulatory T cells.

UNUSUAL FORMS OF IMMUNE HEMOLYTIC ANEMIA

Hemolytic anemia due to heteroantibodies or alloantibodies may be confused with autoimmune hemolytic anemia in certain cases. Some lots of antithymocyte globulin contain heterologous anti-human RBC antibodies, which can precipitate attacks of immune hemolysis. [268] Anti-A alloantibodies in some preparations of intravenous human -globulin have resulted in RBC destruction, [269] [270] and the synthesis of alloantibodies by B cells in transplanted livers and kidneys may cause a hemolytic anemia that masquerades as autoimmune hemolytic anemia.[271]

FUTURE DIRECTIONS

The lifelong symbiotic relationship between the immune system and erythrocytes begins to unfold during the early stages of embryonic life. Lymphocytes and macrophages supply immature erythrocytes with growth-promoting lymphokines and with iron; in turn, mature RBCs furnish the immune system with oxygen. Old erythrocytes, no longer disks but spheres, end their lives within antigen-presenting macrophages. Even so, lymphocytes ignore virtually all the proteins, glycoproteins, and glycolipids on the RBC membrane. Those same components can trigger the production of antibodies with a lethal potential when injected into another person with a different constellation of blood groups, even if the difference is but a single sugar molecule. The molecular biology of this striking aspect of lymphocyte physiologyimmunologic toleranceis not understood, nor are the mechanisms responsible for its induction and maintenance. The developmental immunology of structurally defined human blood groups is an untapped mine of information with considerable relevance to the phenomenon of immunologic tolerance in humans. The advantages of such studies over experiments on specially bred transgeneic mouse for immunologic investigations should be self-evident.

Virtually nothing is known about how the immunologic tolerance of erythrocyte autoantigens breaks downthe cause of autoimmune hemolytic anemia. Research on this question needs to focus on three topics: the structures of the autoantibodies, molecular identification of the autoantigens, and elucidation of the networks of lymphocytes and idiotypes that enforce unresponsiveness to erythrocyte autoantigens. Modern techniques of molecular biology (gene analysis, protein microsequencing, and cell cloning, in particular) are ripe for application to the problem. A particularly fruitful line for future investigations is the mechanism of the production of IgG warm-reactive antierythrocyte autoantibodies in CLL. This is one of the few cases in which a monoclonal population of B cells with obvious relevance to polyclonal autoantibodies can be cloned in vitro and analyzed with the armamentarium of molecular immunology.

The present classification of the autoimmune hemolytic anemias does not accommodate all variants of these disorders, but it is generally useful. Our terminology reflects current practice: most clinicians recognize that the unembellished term *autoimmune hemolytic anemia* refers to hemolytic anemia due to warm-reactive IgG autoantibodies and that cold agglutinin disease means hemolytic anemia associated with cold-reactive IgM autoantibodies. Not all cases fit into these neat categories, however. The thermal behavior of the autoantibody, or its isotype, may not correspond to arbitrary rules, and some patients produce mixtures of IgG, IgM, and even IgA autoantibodies. Furthermore, the serologic specificity of the autoantibody in autoimmune hemolytic anemia is highly variable. Some autoantibodies bind to well-defined blood group antigens, whereas

others show much broader patterns of reactivity. Still others bind to structural membrane proteins or phospholipids with no known relationship to blood group antigens. Additional contributions to the heterogeneity of the autoimmune hemolytic anemias include the complement-fixing ability of the autoantibody and its avidity for the erythrocyte autoantigen. A realistic classification of the autoimmune hemolytic anemias would take this extensive heterogeneity into account, but it might prove too cumbersome for practical application.

The physician encounters additional layers of complexity in deciding about treatment. Is the disorder primary or secondary? Does the patient have SLE or a lymphoma? Could a drug be involved? Are transfusions warranted if a compatible donor cannot be identified? Management of the patient with autoimmune hemolytic anemia in relapse remains a major problem. None of the available tests accurately predicts the efficacy of splenectomy in an individual case. This research problem has a useful potential, not only in the autoimmune hemolytic anemias but in other immune-mediated cytopenias as well. Despite the plausible and detailed description of the in vivo mechanism of antibody-mediated destruction of RBCs, effective therapeutic advances based on this knowledge have made slow progress.

Every patient with an autoimmune hemolytic anemia tests the knowledge, skill, and art of the physician. These qualities are, to be sure, of singular importance, but common sense and good judgment count above all. They make the difference in any rare disease for which the outcome is unpredictable.

Chapter 35 - Extrinsic Nonimmune Hemolytic Anemias

Stanley L. Schrier

INTRODUCTION

By definition, extrinsic causes of hemolysis are abnormalities in the environment in which the red cells, usually normal themselves, circulate. These abnormalities may occur acutely or may be chronic in nature. These conditions can arise from either congenital or acquired lesions, but mostly the latter. The decision that a patient has an anemia belonging to this category is made by using the approaches described in Chapter 23 and determining that hemolysis with varying levels of compensation is the cause of the anemia. Signs of extrinsic hemolysis with minimal or no anemia can also be valuable clues to diseases of other organ systems. It should be emphasized that among the most important forms of extrinsic hemolytic anemia are those caused by immune mechanisms; these are discussed in Chapter 34 .

Clinical and morphologic findings suggest the many misfortunes that can befall red cells in their travels. They can be trapped in an abnormal marrow stroma network, sheared by jets in an abnormal heart, cut and fragmented by fibrin strands stretched across damaged areas in the microvasculature, or attacked by parasites. They also can undergo stasis and perhaps metabolic depletion in giant hemangiomas or in an enlarged spleen. An abnormally functioning liver or kidney can cause a buildup of substances in plasma that can alter red cell shape and metabolism. Drugs can cause oxidation or other metabolic damage. Oxidant injury provokes degradation of hemoglobin with the formation of hemichromes. Degraded hemoglobin and hemichromes bind avidly to the cytoplasmic tail of the major transmembrane protein, band 3 (see Chaps. 4 and 33) and cause the clustering of band 3 oligomers.[1] Immunoglobulins and complement then bind to the external membrane face over clusters of band 3, promoting immune destruction. Other membrane proteins may be subject to oxidative attack. Toxins, venoms, heat, and mechanical trauma can directly destroy the membrane. These agents may also cause an alteration in the asymmetry of the phospholipid bilayer, causing phosphatidylserine to move from the inner leaflet of the membrane bilayer to the outer leaflet where it can be recognized by macrophages.

In general, only the most devastating damage leads to direct intravascular destruction. Usually, the initial insult leads to an eventual change in the external portion of the red blood cell (RBC) membrane that in turn causes macrophages to retard, hold, remove, or otherwise modify these RBCs. Infection or inflammation can activate these macrophages. Moreover, some RBC changes are accompanied by a decrease in RBC deformability, which retards flow and thereby facilitates the action of macrophages on the affected RBC. All of these changes lead to extravascular hemolysis.

FRAGMENTATION HEMOLYSISMICROANGIOPATHY

Clinical Manifestations

Patients present with varying degrees of hemolytic anemia and compensation, with evidence of red cell fragmentation on smear (Plate 35-1). Red cell removal is generally extravascular, with minimal or moderately decreased levels of haptoglobin, but if red cell damage is severe, signs of intravascular hemolysis may also be present. Because of the underlying pathology, some of these syndromes may show evidence of platelet removal, leading to thrombocytopenia. Occasionally the underlying cause may also produce procoagulant activation and depletion with consequent activation of the fibrinolytic system, consistent with disseminated intravascular coagulation (DIC) (Table 35-1).

Pathophysiology

Fragmentation hemolysis occurs when mechanical forces disrupt the physical integrity of the red cell membrane. Brain et al. [2] noted a possible relationship between vascular lesions and cases of RBC fragmentation. They postulated that the lesions either produced shearing forces sufficiently strong to fragment the red cells or incited inflammation of small vessel walls, which in turn would generate the fibrin strands that literally cut the passing red cell into irregular pieces. Subsequent studies have documented the shearing forces required to fragment RBCs. In vitro shear stresses in excess of 3,000 dynes/cm ^{2} cause RBC fragmentation. In vivo studies in patients with mitral prosthetic regurgitation and hemolysis show either high peak shear stresses of 4,500 dynes/cm ^{2} or very rapid acceleration or deceleration, or both. [3] A recent report described a baboon model in which injection of C4b-binding proteins and *Escherichia coli* produced a picture of DIC with microangiopathic hemolysis and thromobocytopenia; treatment with the F(ab)$_2$ monoclonal antibody against platelet glycoprotein (GP) IIb/IIIa (7E3) reduced both the microangiopathic hemolysis and renal disease. [4] This result suggests an alternative mechanism for producing

TABLE 35-1 -- Causes of Red Blood Cell Fragmentation Hemolysis

Damaged microvasculature	
	TTP-HUS
	Associated with pregnancy: pre-eclampsia/eclampsia, HELLP
	Associated with malignancy: with or without mitomycin C
	Vasculitis: polyarteritis, Wegeners granulomatosis, acute glomerulonephritis, *Rickettsia*-like infections
	Abnormalities of renal vasculature: malignant hypertension, acute glomerulonephritis, scleroderma, allograft rejection with or without cyclosporine
	Disseminated intravascular coagulation
Atrioventricular malformations	
	Kasabach-Merritt syndrome
	Hemangioendotheliomas
	Atrioventricular shunts, congenital and acquired (stents, coils, TIPS, Levine shunts)
Cardiac abnormalities	
	Replaced valve, prosthesis, grafts, patches
	Aortic stenosis, regurgitant jets (as in ruptured sinus of Valsalva)
	Drugs
	Cyclosporine, mitomycin, ticlopidine, tacrolimus, cocaine

Abbreviations: TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome; HELLP, hemolysis plus elevated liver enzymes plus low platelet count.

microangiopathic hemolysis that involves platelets and small vessel thrombi in the kidney.

The red cell membrane is viscoelastic and has self-sealing properties (see Chaps. 4 and 33), so that little hemoglobin leaks out as the cell is being cut. However, prolonged distortion of the membrane produces a plastic change; therefore, the smaller red cell fragments usually do not become microspheres or microdisks but continue to display evidence of the shearing event or distortion in the form of the typical irregular shapes. These irregular shapes and the rigidity that they reflect subsequently interfere with the ability of red cells to fold, elongate, and deform sufficiently to pass through 3-m capillaries and even smaller slits in the walls of the sinusoids of the reticuloendothelial system. This sequence leads to their destruction.

DIFFERENTIAL DIAGNOSIS OF EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

There is no simplistic approach to the differential diagnosis of this type of hemolysis; the physician must pay close attention to the clinical setting. Useful clues come from a determination of whether red cell breakdown is predominantly extravascular or intravascular. However, most important in the analysis is the observation of red cell morphology, because an accurate appreciation of morphology focuses and limits the differential diagnosis. Such nonhelpful terms as *aniso* and *poik* should be discarded. The RBCs are spherocytic, stomatocytic, fragmented, echinocytic, acanthocytic, spurred, or bite cells, or mixtures of these. When necessary, the standard Wright-Giemsa-stained peripheral blood smear should be supplemented with a wet preparation in which 1020 l of freshly drawn heparinized whole blood is added to 200 l of 1% glutaraldehyde in phosphate-buffered saline. After several moments to allow for fixation, the RBCs are examined by phase microscopy (phase 2, ×400 or phase 3, ×1,000), and the three-dimensional appearance of the cells can be appreciated. Subtle degrees of stomatocytosis (spherocytes are really stomatocytes), red cell budding, and acanthocytosis become apparent, and artifacts in smear preparation are avoided.

Differential Diagnosis

Generally, the differential diagnosis of fragmentation hemolysis can be deduced from the clinical setting. The presence of a prosthetic heart valve (Waring blender syndrome) can be readily discerned. The clinical picture of thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) is generally dramatic and acute (see Chap. 126). Atrioventricular malformations may be associated with DIC and platelet removal; the diagnosis requires a high index of suspicion and imaging studies. The presence of pre-eclampsia in a pregnant woman with microangiopathic hemolysis is usually obvious, but the HELLP syndrome (hemolysis, elevated liver enzymes, and a low platelet count) is a serious complication of pregnancy that can occur without other signs of pre-eclampsia or hypertension. [5] [6] This syndrome can produce hepatic rupture, visual failure, DIC, seizures, and congestive heart failure and needs to be treated by prompt delivery of the fetus (see Chap. 149); cancer can be an underlying cause. Vessels supplying malignant tumors are thought to be structurally abnormal. They exhibit the same sort of fibrin stranding that produces fragmentation hemolysis in DIC and TTP/HUS.

The continued utilization of invasive methods for diagnosis and treatment with the insertion of foreign bodies into the circulation has brought with it complications of microangiopathic hemolysis. Transjugular intrahepatic portosystemic shunts (TIPS) can cause the syndrome in 10% of patients. [7] The hemolysis apears to disappear after 1215 weeks. Similarly, the use of coil embolization to seal off a patent ductus arteriosus produced a fall in hemoglobin from 11.6 to 6 g in one patient. [8] Vasculitis has been implicated as a cause.[9]

It now appears that some drugs can produce microangiopathic hemolysis. Cyclosporine [10] and mitomycin C have been implicated as causing an HUS picture. However, for mitomycin C at least, it is frequently difficult to distinguish the action of the drug from that of the cancer being treated. [11] The new antiplatelet agent ticlopidine also seems to be capable of producing a TTP-like syndrome. There are few preliminary reports, and the incidence is probably quite low. [12] The newer immunosuppressive agent tacrolimus (FK506) seems to be as capable as cyclosporine of causing microangiopathic hemolysis. [13] One patient is thought to have had microangiopathic hemolysis following cocaine use. [14] Therapy for cancer may play a role. Of 581 patients treated for breast cancer with cyclophosphamide, cisplatin, and carmustine, 2.6% developed microangiopathic hemolysis.[15]

Therapy

Management is primarily directed toward the underlying disease or event. In addition, compensation of red cell production should be optimized by replacing iron or folic acid if the patient is deficient in these nutrients. Occasionally it is necessary to remove or replace a prosthetic heart valve when the hemolysis produces a disabling transfusion requirement. The HUS of mitomycin C/adenocarcinoma is said to respond reasonably well to use of the staphylococcal protein A immunoperfusion column[16] or to infusion of vincristine, [11] but it may be necessary to proceed to apheresis with fresh frozen plasma replacement.

OTHER FORMS OF MECHANICAL DAMAGE TO RED CELLS

Heat Denaturation

Normal RBCs will undergo budding and fragmentation when exposed to a temperature of 49°C in vitro. In some of the hereditary hemolytic anemias this occurs at temperatures as low as 46°C (see Chap. 33). Some clinical circumstances have been identified in which temperatures sufficient to cause heat denaturation

Figure 35-1 Change in RBC morphology produced by heating normal RBCs at the indicated temperatures. Note the budding that begins abruptly at 50°C, leading eventually to spherocytosis.

of RBCs have been generated. Occasionally, cell warmers used to bring transfused red cells to body temperature before infusion in treatment of cold agglutinin disease have malfunctioned and cooked the red cells about to be transfused. In one case, a patients mother decided to warm red cells with a hot water bottle, reasoning that such cells would cause less vein irritation to her child. Such transfusion was followed by evidence of both intra- and extravascular hemolysis, and the peripheral smear showed red cell budding and fragmentation (Fig. 35-1). Presumably, similar events can lead to hemolysis in patients who have sustained very extensive burns. In patients suffering from heat stroke, the temperature is usually below 42°C; at this temperature little RBC denaturation occurs.

Mechanical Trauma

The classic example of red cell damage due to mechanical trauma is march hemoglobinuria, which occurs in soldiers after a long march, in joggers after running on a hard road, or in karate or conga drumming enthusiasts following practice. Anemia is rare, and reticulocytosis is uncommon. Evidence of typical intravascular red cell destruction is present and is thought to be caused by direct trauma to the red cells in the vessels of the feet or hands. Switching jogging paths or using better footwear often relieves the problem. In some cases there is evidence of an underlying red cell membrane abnormality. [17] Occasionally, malfunction of the cell savers used during abdominal or thoracic surgery can mechanically injure red cells.

Cardiopulmonary Bypass

The postperfusion syndrome occurs in some patients following cardiopulmonary bypass. The syndrome includes acute intravascular hemolysis and leukopenia as part of a febrile inflammatory clinical picture. Affected patients may go on to develop pulmonary distress and even adult respiratory distress syndrome. Visible hemoglobinemia occurs, with rising plasma hemoglobin levels, associated with an increase in lysed red cell ghosts seen in the whole blood and plasma. These ghosts have been shown to be coated with the complement complex C5bC9 (see Chap. 37). Presumably, the complement pathway is activated as the blood is passed through the oxygenator. Why the complement activation results in lytic attack on red cells (and also granulocytes) is not known. Treatment involves knowledge of the process and requisite support [18] until the situation corrects itself.

Osmotic Attack

Abrupt changes in osmolality can also cause hemolysis. Freshwater drowning may be associated with so much water in the lungs that the red cells swell as they undergo an in vivo osmotic fragility test in the lung vessels. Saltwater drowning, conversely, can cause profound dehydration of red cells, producing a situation analogous to xerocytosis (see Chap. 33). Very rarely, acute hemolysis may occur from mistaken infusion of or exposure to concentrated hypertonic solutions such as those used in hemodialysis. To manage such an event, the physician must recognize its cause, appreciate the shrunken RBCs on peripheral smear, and restore isotonicity as quickly as possible. The use of a hemodialysis device, if available, may be helpful in this regard. [19]

HYPERSPLENISM

In all organs of the monocyte-macrophage system (reticulo-endothelial system), blood cells leaving the arterial bed are generally unloaded into channels such that the red cell must pass through the wall of the sinus to re-enter the circulation. The sinusoidal wall has slits 23 m in size and is usually endothelialized on one side and has a macrophagic lining on the other. The normal human adult RBC is a discocyte, having a surface area 40% larger than a sphere of that volume (see Chap. 4). It is this excess surface area that allows a red cell of approximately 8 m in diameter to twist, elongate, and deform sufficiently to squeeze through these 2- to 3-m slits. This excess of surface area is critical and is occasionally referred to as the ratio of surface area to volume (SA/V); it is normally about 1.4. Any condition that reduces the SA/V reduces the ability of the red cell to traverse these sinusoidal slits because a plump sphere cannot deform sufficiently.

Factors that interfere with the interaction of the cytosol and the membrane will also impair the red cells ability to deform. Oxidant attack may produce Heinz bodies that come to lie adjacent to the membrane. They interfere with the smooth movement of the membrane over the cytosol, called tank treading. Such cells are selectively blocked from leaving the splenic cords and entering the sinuses. [20] Inflammation or infection may enhance the ability of splenic macrophages to attack and ingest red cells. Although not strictly a mechanism of hypersplenism, Kupffer cell erythrophagocytosis is a prominent finding in patients undergoing the graft-versus-host hemolysis seen after liver transplantation. [21]

The spleen is somewhat more complicated than other RE organs in that the afferent arterioles pass through lymphoid nodules (the white pulp) and then terminate in the cords of Billroth (the red pulp), into which the blood cells are discharged. In the slow flow of the cords of Billroth, the blood cells are selectively attacked by macrophages and are in direct contact with several classes of lymphocytes. The blood cells must then pass through the cordal walls before they can approach the sinus wall, which they must pass through to re-enter the circulation. Thus, the spleen provides a double filter, and the blood cells must be

TABLE 35-2 -- Pathophysiologic Mechanisms of Splenomegaly

Mechanisms	Examples
Neoplasia	Lymphoma, hairy cell leukemia
Infections	Bacterial endocarditis
	Malaria, schistosomiasis
	Tuberculosis
Portal bed obstruction	Alcoholic cirrhosis
	Splenic vein thrombosis
Collagen-vascular disease	Systemic lupus erythematosus, rheumatoid arthritismalignant phase

Chronic hereditary or acquired hemolytic anemias	Severe -thalassemia
	Autoimmune hemolytic anemia
Miscellaneous disorders	
Lipoidosis	Gaucher disease
Amyloidosis	AL and AA types
Tropical splenomegaly syndrome	Hyperreactive malarial splenomegaly syndrome

remarkably deformable to pass through it. Furthermore, this slow passage permits highly selective action by macrophages, which have receptors that can detect several sorts of alterations in these blood cells. These receptors include the Fc receptor for the appropriate portion of the immunoglobulin molecule, receptors for complement components such as C3b, and perhaps receptors that detect alterations in the outer portion of the phospholipid bilayer or in the externally oriented glycopeptides. The macrophage then holds, retards, modifies (pitting function), or removes (culling function) the blood cells so identified. Normally, the pitting function of the spleen allows it to remove Howell-Jolly bodies and normally occurring endocytic vacuoles (called pocks because of their appearance on phase interference or Nomarski microscopy). The normal culling function of the spleen is exemplified by its removal of senescent RBCs. [22]

All the activities of the spleen are presumably markedly accentuated in a large spleen, and if the increased activity is extensive enough, hypersplenism ensues. It is the size of the spleen, not the portal pressure, that is important in determining the degree of red cell sequestration that occurs. [23] Other factors that may play a role are the state of activation of the splenic macrophages and the size of the small slits between the splenic cords and sinuses. Both macrophages and slits seem to be under a degree of control, as evidenced by variations in the splenic removal of red cells in patients with malaria. [24] [25]

The clinical picture of hypersplenic hemolysis is dominated by the specific cause of the splenomegaly. Although causes of splenomegaly are legion, there are several general mechanisms (Table 35-2). Generally, there is a varying degree of anemia, with varying evidence of a compensatory increase in red cell production. Because stasis and trapping in the spleen are associated with macrophagic attack and remodeling of the red cell surface, the reduction in SA/V leads to spherocytosis. If the red cells undergo a prolonged period of distortion in traversing the cordal-sinus barrier, then tailed red cells will be present as the red cell membranes undergo a plastic change (Plate 35-2) (see Chaps. 4 and 33). Presumably, the enlarged spleen can also trap and remove platelets and white blood cells (WBCs), so that variable thrombocytopenia and leukopenia may occur. The bone marrow may show normal to increased cellularity, with erythroid hyperplasia.

Management depends on the causes of the splenic enlargement. The anemia or pancytopenia usually is not very profound, but if the anemia is very severe, splenectomy may be contemplated. In most situations, recognition of the possibility of hypersplenism is most important in guiding the approach to diagnosis of an unexplained anemia. Massive splenomegaly is frequently associated with expansion of the plasma compartment, so that measurement of hemoglobin, hematocrit, or red cell count may give a falsely low value of the actual red cell mass present. In that circumstance the true RBC mass can be determined by a ^{51} Cr assay.

A good example of the previous situation is the tropical splenomegaly syndrome, now renamed hyperreactive malarial splenomegaly syndrome. [26] Diagnostic criteria

include massive splenomegaly, >10 cm below the costal margin, with no other cause identified; immunity to malaria; elevated serum IgM levels; and clinical response to treatment with the antimalarials like chloroquine, proguanil, or pyrimethamine and folic acid. [26] The pathophysiology of the splenomegaly seems to be a poorly controlled B-lymphocytic production of antibodies, and the IgM stimulation may be a response to malarial antigens or an unidentified mitogen. Malarial parasites are almost never found. The apparent anemia is in large part due to plasma volume expansion, although red cell survival is reported to be slightly attenuated. Splenectomy is unnecessary; antimalarial therapy for several months results in a reduction in spleen size.

INFECTION

Pathophysiologically, there are several mechanisms by which infection can cause hemolytic anemia (Table 35-3).

Direct Parasitization

The classic example of direct parasitization is *Plasmodium falciparum, P. vivax,* or *P. malariae* infection. In each of the malarias, sporozoites injected by the mosquito in its saliva make their way to liver cells, where after 12 weeks they become merozoites, which burst out of the liver cells and into the bloodstream. Then, in a remarkable process, the parasite via its apical end and related organelles called rhopteries attaches to a specific receptor on the red cell surface. For *P. vivax,* the Duffy blood group antigen appears to be involved. *P. falciparum* binds to sialic acid residues on the red cell surface that are on glycophorin A. Following specific attachment, a convulsive movement occurs during which the red cell engulfs the parasite by a process resembling receptor-mediated endocytosis. The parasite then immediately co-opts the red cells metabolic machinery, degrades and ingests hemoglobin, and grows, eventually bursting out of the red cell, and the cycle begins again. The red cells are lysed, both intravascularly as a consequence of direct parasitic destruction, and extravascularly, as a consequence of changes in the splenic microvasculature and in the activation state of the monocyte-macrophage system. In addition, acute malarial infection, particularly with P. falciparum, leads to alteration in splenic function and in the structure of nonparasitized red cells that incites their premature destruction. [24] [25] [27] Treatment consists

TABLE 35-3 -- Mechanisms by Which Infection Can Cause Hemolysis

Direct parasitization of red cells
Examples: malaria, babesiosis
Immune mechanisms
Example: cold agglutinin hemolysis following infectious mononucleosis or mycoplasmal pneumonia (see Chap. 34)
Induction of hypersplenism
Examples: malaria, schistosomiasis
Altered red cell surface topology
Example: *Hemophilus influenzae*
Release of toxins and enzymes
Example: clostridial infection causing TTP/HUS; *E. coli* 0197; HIV(?)

of the use of appropriate antimalarials and the support of erythropoiesis.

Other infections that have somewhat similar pathophysiologies include Carrión disease (bartonellosis), in which a bite from the sandfly injects *Bartonella bacilliformis,* which attaches to the red cell surface and somehow causes lysis. It appears that the invasion of red cells is partly dependent on the flagella of bartonellae. Incubation with antiflagellin antiserum reduces invasion of red cells. [28] In babesiosis the parasite is transmitted by ticks and directly invades red cells, producing fever and hemolytic anemia. On the East Coast the disorder occurs in continental Massachusetts and on Nantucket Island. Most cases occur on the West Coast, particularly Washington and California, and in the northern portion of the Midwest. The organisms can be seen invading red cells on smear examination, somewhat like *P. falciparum* malaria, but these organisms produce no pigment. Babesiosis has been described in an immunocompromised patient with AIDS and thus must be considered in the differential diagnosis of such patients in endemic areas who present with persistent fever and evidence of hemolysis. [29] In addition, there are sporadic reports indicating that acquired chronic toxoplasmosis can occasionally be associated with hemolytic anemia. [30]

Alteration of Red Cell Surface by Bacterial Products

Infection can produce hemolysis by altering the red cell surface. An example is the hemolysis caused by *Hemophilus influenzae* type b.[31] Severely affected patients, particularly those with meningitis, have developed hemolytic anemias requiring red cell transfusions. The capsular polysaccharide of the bacterium, composed of polyribosyl ribosyl phosphate (PRP), is released during infection and binds to the red cell surface. Infected patients develop antibodies to PRP. When the balance between PRP-coated red cells and anti-PRP antibodies is correct, an immune sort of hemolysis, requiring complement, occurs. Red cell destruction is thought to be both intra- and extravascular.

Bacterial Products Causing Hemolysis by Direct Damage to Red Cells

The most dramatic example of hemolysis due to bacterial action is clostridial infection, during which the organism releases enzymes that acutely degrade the phospholipids of the membrane bilayer and the structural membrane proteins. In one case the serum phospholipase C level increased 5-fold over 4 hours as the patient died.[32] The setting can be any infection, but my personal experience is limited to acute cholecystitis, surgery of the biliary tree, and infections surrounding an obstetric event, including criminal or self-induced abortion or other infection of the gravid uterus. The signs of infections may be obvious, but fever may be unimpressive.[33] [34] Signs of collapse appear acutely, and the clue is profound intravascular hemolysis, with a spherocytic anemia developing with shocking suddenness. A clue to the severity of the process may be the inability of the laboratory to perform chemical determinations or to type and cross-match the blood because the sample is hemolyzed. With even the slightest suspicion, the physician immediately starts full doses of penicillin, evaluates the patient for DIC (see Chap. 117), and prepares to support the patient for shock, DIC, acute renal failure, and hemolytic anemia. In the case of septic abortion it is not clear that hysterectomy is lifesaving.[34]

Hemolysis Caused by Less Well Understood Infections

HIV infection can cause Coombs-positive autoimmune hemolytic anemia and a TTP-like syndrome and microangiopathic hemolysis. Cytomegalovirus infection has been reported to cause hemolysis associated with thrombocytopenia in an immunocompetent woman by unknown mechanisms.[35] The hemolytic anemia in visceral

leishmaniasis may be in part caused by the generation of oxidative metabolic products. [36]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

HEMOLYSIS ASSOCIATED WITH LIVER DISEASE

Hemolysis in liver disease is usually not of overwhelming clinical importance by itself but might contribute to the severity of anemia when coupled with defects in red cell production and the type of gastrointestinal (GI) blood loss that occurs in several sorts of liver disease. There are several causes of hemolysis in patients with liver disease. The spleen may be enlarged as a consequence of portal hypertension [37] and produce a hypersplenic picture, a phenomenon seen quite commonly in hepatic cirrhosis.

The literature concerning red cell shape change in liver disease is considerable. The target cell in cirrhosis has an increased SA/V that appears to be a consequence of an increase in both the cholesterol and the phospholipid content of the membrane bilayer. The cholesterol increase is usually proportionately greater, resulting in an increase in the cholesterol/phospholipid ratio. It is this increase in lipid that probably accounts for the increase in red cell surface area, which means there is more membrane than usual for the cellular contents. These red cells probably circulate as bell-shaped red cells called codocytes, but on dried blood films they assume the appearance of target cells. Target cells per se do not have a shortened red cell survival. [37] [38] The red cells of patients with liver disease are frequently echinocytes when wet preparations are examined, but these echinocytes are not easily apparent on dried blood smears. [38] The echinocytes seem to be produced by a material in a patients plasma that causes normal red cells to become echinocytic; this material is an abnormal echinocytogenic high-density lipoprotein. Echinocytes per se do not necessarily have a shortened red cell survival. Some forms of echinocytic red cells are normally deformable when studied in the ektacytometer or rheoscope.

A brisk, clinically important hemolysis can occur in some patients with severe liver disease. The peripheral smear in these individuals usually shows acanthocytes (distorted red cells), extreme forms of which are called spur cells. Spur cells are probably acanthocytes additionally remodeled by an enlarged spleen (Plate 35-3) and are considerably enriched in cholesterol. [37] They are rapidly removed in the spleen, which is usually enlarged.

It may be that increased red cell membrane proteolytic activity is a partial explanation of the differences between acanthocytosis and spur cells. [39] Additional pathophysiologic mechanisms may be involved. Although the adult red cell cannot synthesize phospholipids de novo, it can identify and remove peroxidized fatty acid chains that interfere with normal membrane lipid fluidity. [40] When the fatty acid is removed a lyso-derivative remains, which is lytic, and therefore the missing fatty acid chain must be replaced. A store of acyl groups exists in red cell membranes in the form of acylcarnitine. When needed, the fatty acid (acyl group) is transferred to acyl-CoA and the fatty acid is then inserted into the potentially lytic lysophospholipid by the enzyme lysophosphocholine acyl transferase (LAT). LAT is inhibited in spur red cells, and the same inhibition can be produced by heavily loading red cells with cholesterol in vitro. [40]

Thus, in spur cell anemia the red cells have an abnormal membrane SA/V ratio, their membrane fluidity is impaired, and they are unable to remove and repair peroxidatively damaged fatty acids. On occasion, spur cell hemolytic anemia is severe enough to necessitate consideration of splenectomy. The operative morbidity in such cases is considerable, because the underlying alcoholism usually produces problems with thrombocytopenia and leukopenia, while the severity of the liver disease

can cause problems with procoagulants and intolerance to anesthesia.

Acute alcoholism can be associated with hypophosphatemia, defined as levels of <0.2 mg/dl. Such hypophosphatemia presumably interferes with red cell intermediary metabolism (see Chaps. 22 and 32), and red cell ATP levels fall. Very low ATP levels are associated with red cell rigidity. This rigidity leads to fragmentation, loss of surface area, and spheroidicity. These red cells are then further trapped in the spleen. This hypophosphatemia syndrome can also cause neuromuscular disorders, including weakness, paresthesias, tremors, and seizures. It should be treated aggressively with orally and intravenously administered phosphate supplements. Hypophosphatemia also occurs in cirrhotic patients, patients receiving total parenteral nutrition whose phosphate intake is not carefully monitored, and patients taking large amounts of phosphate-binding antacids. [41] [42]

Stomatocytosis can occur in severe liver disease and is also thought to be a sign of acute alcoholic intoxication. This change in red cell shape can also be seen in acute pancreatitis. The stomatocyte is a cell well on its way to becoming a spherocyte. The reduction in SA/V leads to trapping in the microvasculature of the spleen and other organs of the monocyte-macrophage system, producing varying degrees of hemolysis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

RENAL DISEASE

The anemia in renal disease is multifactorial, with a major component being impaired red cell, production, which is now well-controlled with erythropoietin. The renal disease also impairs platelet function, which may lead to occult blood loss. However, hemolysis can also occur and is also multifactorial. Disease of the small renal arterioles can produce fragmentation hemolysis of the sort seen in TTP/HUS, pre-eclampsia, and malignant hypertension (Table 35-1). In the past, some patients on chronic hemodialysis were exposed to unusual concentrations of chloramine in the tap water and underwent acute oxidative hemolysis. [43] This occurrence has become very rare, if it even still exists. Otherwise it is not clear that uremia per se produces significant shortening of red cell survival. Patients with chronic renal failure on hemodialysis may be particularly susceptible to oxidative damage to their red cells. Red cell GSH is reduced in some patients, and the activity of the enzymes glucose-6-phosphate dehydrogenase (G6PD) and glutathione peroxidase was found to be relatively low. The ability of these red cells to deal with generation of peroxides is probably impaired. [44]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

VENOMS, BITES, STINGS, AND TOXINS

The best-known example of toxin-caused hemolysis was discussed earlier under clostridial sepsis.

Insect, Spider, and Snake Bites

Hemolysis has occurred after bee and wasp stings, snake bites, and spider bites. Isolated cases of acute intravascular hemolysis have been reported after bee and wasp stings. Two kinds of dangerous spiders live in the United States: the southern black widow and the brown recluse spider. Both sexes of the black widow produce the venom, but only the female has fangs capable of penetrating human skin. Black widow spider bites produce generalized muscle pain and muscular rigidity. Hemolysis, if it occurs at all, is not common. Brown recluse spider bites cause a considerable local reaction, called the volcano lesion. Both DIC and hemolysis may occur after a 24- to 48-hour lag period. Corticosteroids may be beneficial. The hemolysis appears to be self-limiting, but in one case red cell transfusion support was needed.[45]

In some parts of the world, cobra bites can cause intravascular hemolysis because the venom contains phospholipases. In the United States the two classes of venomous snakes are pit vipers (rattlesnakes, cottonmouths, moccasins, and copperheads) and coral snakes. Pit viper venom affects hemostasis and may produce DIC with bleeding, but rarely hemolysis. Coral snake venom produces severe neurologic impairment. Therapy consists of support and use of the appropriate antivenin and prophylactic antimicrobials and tetanus injections.

Drugs and Chemicals (Exclusive of Those Producing Oxidative Hemolysis)

Potassium Chlorate

Potassium chlorate ingestion is listed as a cause of hemolysis, but this compound is no longer available in hospital pharmacies and has no currently recognized medical use. Arsine gas (AsH_3) is generated in industrial plants that engage in lead plating, galvanizing, etching, and soldering. Inhalation of a toxic amount produces a severe intravascular hemolysis[46] of unknown pathogenesis.

Copper

The idea that copper can produce human hemolytic disease is best supported by observations of episodes of severe hemolysis in patients with Wilson disease. The patient is usually a child, adolescent, or young adult in whom the diagnosis of Wilson disease has not yet been made. [47] [48] The initial clinical presentation usually is dominated by the hemolytic anemia, accompanied by weakness and dark urine. The red cell morphology has not been well described, but reticulocytosis is present, with an increased serum bilirubin level partly attributable to the underlying liver disease. Because of the hereditary deficiency in the copper-binding protein ceruloplasmin, serum and urine copper levels in patients with hemolysis are very high. Curiously, in one report hemoglobin A_2 levels were also elevated.[47]

Free copper can interfere with glucose metabolism by hexokinase inhibition and alternatively can generate oxidative hemolysis, perhaps by acting as a Fenton reagent. It is important to establish the diagnosis promptly suspecting this possibility, looking for the Kayser-Fleischer rings on physical examination, and measuring serum and urine copper and ceruloplasmin levels. Treatment with penicillamine reduces the serum copper level and stops the hemolysis. Other forms of copper poisoning also may cause hemolysis in patients who do not have underlying Wilson disease. The amount of copper ingested would have to exceed the normal copper-binding capacity of normal ceruloplasmin.

Lead Poisoning

There are at least two general forms of lead intoxication. Occupational exposure is an example of chronic, slow cumulative poisoning (saturnism). The symptoms are predominantly neurologic and nephrologic, with variable degrees of anemia, which may be due to a production defect combined with hemolysis. Relatively acute poisoning occurs when lead inadvertently finds its way into a food source [49] or is consumed as part of an exotic medication. Such subacute lead poisoning leads to central nervous system symptoms, hepatitis, nephrotoxicity, hypertension, and abdominal colic, along with seizures and severe hemolytic anemia. Physical examination may reveal the lead line on the gums. The peripheral smear shows extensive coarse basophilic stippling and reticulocytosis; however, red cell morphology is not otherwise characteristic. Some authors state that intravascular destruction occurs, but no proof has been provided. Bilirubin levels are not significantly elevated.

The diagnosis of lead-related hemolysis can be made from

THERAPY FOR LEAD-RELATED HEMOLYSIS

In an acute situation with multiple organ malfunctions and hemolysis, lead ingestion is immediately stopped and therapy is begun with 0.51.0 g of edetate calcium disodium administered intravenously over 6 to 8 hours every day for a 5-day course, while monitoring urine lead levels. If the symptoms improve and the urine levels fall satisfactorily, the patient can then be started on a regimen of 500 mg/day of oral penicilamine, which is continued for 60 days. If the symptoms do not improve satisfactorily another course of edetate calcium disodium is given.

the history and physical examination finding of the lead line on the gingiva, and from the coarse basophilic stippling on red cells, which reflects the pathologic aggregation of ribosomes. The diagnosis is confirmed by measuring of blood and urine lead levels. The level of acuity determines the therapy.

The cause of the anemia is complex. Lead interferes with several steps in heme synthesis, particularly those involving heme synthetase and -aminolevulinic acid dehydratase (see Chap. 27). The inhibition of heme synthetase probably accounts for the elevation in free erythrocyte protoporphyrin, which provides a useful corroborative diagnostic test for lead toxicity. Inhibition of heme synthesis also probably accounts for the elevated urinary levels of -aminolevulinic acid and coproporphyrin. Lead poisoning mimics the basophilic stippling and accumulation of pyrimidines seen in hereditary deficiency of the enzyme pyrimidine 5-nucleotidase,[50] probably because lead attacks the enzyme (see Chap. 32).

DRUG-INDUCED OXIDATIVE HEMOLYSIS

General Concepts

The potential for normal red cells to undergo auto-oxidative destruction is great because the cell is loaded with 20 mM hemoglobin, most of which is bonded to oxygen at the iron(II) atom in heme. The bond that allows the reversible association and dissociation of oxygen from the heme moiety of hemoglobin involves partial transfer of an electron from iron(II) to oxygen. That oxygen now has an extra electron, which makes it a superoxide radical. Ordinarily, when oxygen leaves hemoglobin, it returns the electron, but if it does not, a highly reactive superoxide ion is released, leaving behind it an iron(III) moiety otherwise called methemoglobin.

$Hb\ Fe^{2+}\ 0_2\ Hb\ Fe^{3+} + O_2$ [1]

Methemoglobin cannot reversibly bind oxygen. It is not in itself harmful to red cells, but if the oxidative assault persists, methemoglobin is converted to hemichromes, which are variably denatured hemoglobin intermediates in which the distal histidine unit binds to the oxidized heme. This step is associated with conversion of a high to a low spin state, as measured by electron spin resonance. Continued oxidation leads to irreversibility of the hemichrome oxidation, to precipitation, and eventually to the formation of Heinz bodies. Hemichromes and Heinz bodies can destroy membrane function directly or by causing oxidation of membrane proteins and lipids. [51]

It is estimated that each day 3% of hemoglobin is converted to methemoglobin, but since only 1% of hemoglobin normally is in the form of methemoglobin, this indicates that a mechanism that prevents oxidation in red cells is in effect. This mechanism involves the NADH and NADPH-dependent reducing systems, catalase, glutathione, and the glutathione reductase and peroxidase systems. Defects in this defense system against oxidation lead to an enhanced tendency to oxidative hemolysis. An example is the several G6PD deficiency states. Any agent or event that interferes with the smooth offloading of oxygen will enhance the generation of O_2 [1] and methemoglobin (see equation). If the reducing power of the red cell is inadequate, hemichromes and Heinz bodies will subsequently be generated. In fact, many agents appear to cause oxidative hemolysis by interfering with the smooth functioning of the heme cleft.

Pathophysiology

Once the oxidative attack has been initiated, the sequence proceeds along a recognizable track. The oxidative attack is directed at hemoglobin and the red cell membrane. However, these are not clearly separable because the precipitated hemichrome and Heinz bodies come to lie against the cytosolic face of the membrane. Methemoglobin may be detectably elevated, with levels as high as 5060% of total hemoglobin. The hemichromes, by themselves or with their iron portions acting as a Fenton reagent, mediate the generation of hydroxyl free radicals, which add their effect to that of superoxide and hydrogen peroxide. Lipid peroxidation may take place, membrane proteins may be cross-linked, and adducts between spectrin and denatured globin may form. [52] Such red cells are rigid and are susceptible to trapping in sinusoidal structures whether or not they have Heinz bodies lying against the membrane. In addition, in vitro evidence suggests that such oxidized red cells are increasingly susceptible to phagocytosis by macrophages. These features may account for the extravascular destruction. The oxidative lesions can be so severe as to cause intravascular destruction as well, with hemoglobinemia and hemoglobinuria.

The smear may show bite cells (Plate 35-4), which look as if a macrophage had taken a bite, removing a Heinz body- containing segment of membrane. Red cell rigidity may result in irregularly shaped cells, since these undeformable cells are unable to undergo elastic recoil after fighting their way through the sinus wall. Recurrent loss of membrane material may produce spherocytes. Severe hemolysis may produce the kind of circulating ghost or hemighost called a blister cell or bite cell. These red cells have an empty veil of membrane on one side and puddled hemoglobin on the other. [53] [54] A Heinz body preparation may be positive.

The clinical picture is determined by the specific agent used. It may be useful to screen for G6PD deficiency or a related disorder by using an enzyme assay or the ascorbate cyanide test. Although any defect in the anti-oxidant defense mechanisms, such as G6PD deficiency, considerably increases the susceptibility to hemolysis, the agents listed in Table 35-4 can produce oxidant hemolysis even in persons with normal defense mechanisms. Paraquat ingestion has occurred inadvertently and in suicide attempts.[55] Profound cyanosis with methemoglobinemia can occur within hours, with levels of 120%. This can be succeeded

REDUCTION OF DANGEROUS METHEMOGLOBIN LEVELS

Levels of methemoglobin in excess of 2030% can be dangerous in themselves but can be easily treated with methylene blue (12 mg/kg) infused intravenously over 5 minutes as a 1-g/dl solution. In the presence of a functioning intact NADPH-methemoglobin reductase system, methylene blue is reduced to leuko-methylene blue, which in turn reduces methemoglobin to hemoglobin.

TABLE 35-4 -- Agents That Cause Oxidative Hemolysis

Therapeutic agents
Nitrofurantoin (Furadantin)
Sulfasalaine (Azulfidine)
p-Aminosalicylic acid
Phenazopyridine (Pyridium)
Phenacetin
Dapsone and other sulfones
Recreational drugs
Isobutyl nitrate
Amyl nitrite

Miscellaneous
Naphthalene mothballs
Paraquat
Hydrogen peroxide

by hemolysis, with Heinz bodies seen in appropriate preparations of red cells.

Nitrites have been used in suicide attempts,[56] and there have been industrial exposures as well. More recently nitrites have also been inhaled or swallowed as recreational agents.[57] [58] The nitrite may be sold in sex shops under the name locker room, sweat, or rush. Nitrites bind to hemoglobin,[59] producing methemoglobinemia, which may be so profound as to produce coma. If methylene blue infusion does not quickly turn the chocolate color of blood back to normal, one must consider the possibility that the patient is G6PD deficient and therefore unable to generate adequate amounts of NADPH (see previous discussion). In that case, exchange transfusion may be lifesaving.[59] [60] Benzocaine topical anesthesia in the form of a spray or cream can cause methemoglobin levels of 23% with cyanosis and dyspnea requiring methylene blue treatment.[59] [61] [62]

Pyridium (Phenazopyridine) can cause oxidative hemolysis,[63] even in the absence of renal disease.[64] This agent is in common use for the treatment of bladder irritation and the *Physicians Desk Reference* recommends a maximum of 2 days of therapy. However, it is not uncommon to see patients who have been given a prescription for 14 weeks of therapy.[65]

I have recently seen a case of almost fatal oxidative hemolysis, in which a patient with AIDS had injected hydrogen peroxide directly into his Hickman catheter. (Some persons infected with HIV had circulated a pamphlet suggesting that hydrogen peroxide could be used therapeutically to control the HIV infection.)

It has been recognized for more than 130 years that therapy with dapsone causes oxidative hemolysis.[66] In the past, dapsone was used primarily to treat leprosy and dermatitis herpetiformis and thus was not often encountered as a cause of oxidative hemolysis. More recently, dapsone has come into more widespread use in some communities as a very effective prophylactic agent against *Pneumocystis carinii* pneumonia in patients with AIDS. The reduced levels of GSH described in patients with AIDS may enhance dapsone toxicity. In some clinics

We are now seeing AIDS patients with dapsone-induced methemoglobinemia and hemolytic anemia. The methemoglobinemia, if severe, is treated as described previously and in Chapter 31 . One study suggests that the severity of the oxidative attack can be partially ameliorated by administration of 800 U/day of vitamin E, an agent that has antioxidant action.[69]

HEMOLYTIC ANEMIA IN CHRONIC LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Although large granular lymphocytic leukemia (LGL) usually presents with neutropenia and a rheumatoid-like picture, several patients have been described with a severe Coombs-negative hemolytic anemia in the absence of splenomegaly and, in a case seen by this author, LGL leukemia occurred in a splenectomized subject (see Chap. 66). The mechanism is unknown, but one report identified direct cytotoxicity against red cells by the LGL cell lines.[70] There are no formal studies on therapy. One patient had a partial response to therapy with 60 mg of Prednisone/day and two patients responded well to weekly doses of methotrexate begun at 10 mg/week.[71]

it is the practice to screen potential recipients for the G6PD deficiency (see Chap. 32) and if negative proceed with dapsone therapy. However, dapsone can cause oxidative attack on normal red cells, leading sequentially to methemoglobinemia, then Heinz bodies, and finally hemolysis, all at generally accepted standard doses.[67] Dapsone is metabolized to a hydroxylamine derivative that is directly toxic to red cells.[68]

MISCELLANEOUS, POORLY CHARACTERIZED CAUSES OF EXTRINSIC HEMOLYTIC ANEMIAS

Interferon- as a Cause of Hemolytic Anemia

There are two case reports of acute and severe hemolytic anemia occurring in patients being treated with interferon- for chronic myeloid leukemia and hepatitis C. The Coombs test was negative in one case that seemed to respond to withdrawal of interferon and treatment with methylprednisolone. The other case underwent severe intravascular hemolysis. No mechanism is described. [72] [73]

Hemolysis with Intravenous Immune Globin G

Strictly speaking, this is a form of immune hemolysis. It is useful to remember, however, that preparations of IgG contain anti-A and anti-B antibodies and rarely cause an alloimmune hemolytic anemia, as described in two young women being treated for idiopathic thrombocytopenic purpua. If this situation occurs and more IV IgG is needed, performing a minor cross-match choosing a preparation of IV IgG that gives no reaction is recommended. [74]

Chapter 36 - Immunoglobulins: Polyclonal and Monoclonal Antibodies

Jack Ballantyne
Robert Mandle
David H. Bing

INTRODUCTION

In 1845 Dr. Watson, a general practitioner, sent a urine sample obtained from a patient suffering from mollities ossium with the following letter to Professor H. Bence Jones, an English pathologist:

> Saturday, Nov. 1st, 1845
>
> Dear Dr. Jones,The tube contains urine of very high specific gravity. When boiled it becomes slightly opaque. On addition of nitric acid it effervesces, assumes a reddish hue, and becomes quite clear; but as it cools, assumes the consistence and appearance which you see. Heat reliquifies it. What is it?
>
> (Signed) Dr. Watson

In 1847, Jones published the results of his analysis of the specimen. He confirmed Dr. Watsons observation and reported that the sample contained a protein substance (an oxide albumen) that was distinguished from albumin by its solubility in nitric acid and lack of heat coagulability. He demonstrated that a protein in the sample purified by alcohol precipitation retained the properties of solubility in cold water: increased solubility in boiling water, coagulation with continued boiling, and return to solution with further boiling. Acid precipitated the substance, heating solubilized the acid precipitate, but cooling led to reprecipitation. Jones concluded his analysis by noting: Each oz. of this urine contained as much nutritive matter as an oz. of blood. No supply of food could compensate for such a loss. [1]

Over the years the presence of such proteins, subsequently named Bence Jones proteins, became a diagnostic test for multiple myeloma because of the high association between the plasma cell disease and the urinary pattern. One hundred and ten years lapsed, however, before Jones original insight about a possible relationship between the urinary substances and plasma proteins was confirmed by Korngold and Lipari [2] and Deutsch, Kratovil, and Reif[3] who used immunologic techniques to demonstrate the relationship of the urinary microglobulins (Bence Jones proteins) to normal and myeloma immunoglobulins.

IMMUNOGLOBULINS

Properties and Structure

The mammalian immune system responds to the almost unlimited array of antigens by producing specific antibodies, each of which reacts specifically with the molecule that induced its production. During the immune response, the structure of the inducing antigen is imprinted on the immune system, as subsequent challenges with the same or structurally related molecule(s) will cause a more rapid rise in antibody levels to much greater concentrations than were achieved following the primary antigenic challenge. Thus, the hallmarks of the immune system include induction, specific protein interaction, and memory.

Antibodies belong to the family of proteins called the immunoglobulins. The basic structure of all immunoglobulins consists of a monomer that contains four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains covalently linked by disulfide bonds (Fig. 36-1).[4] A model of the monomeric form of immunoglobulin has been prepared based on x-ray crystallographic data obtained on the IgG myeloma protein Dob (Plate 36-1). [5] The immunoglobulin monomer consists of a Y- or T-like structure. The size of the arms, called Fab (fragment antigen binding) domain of the Y or T, is 80 × 50 × 40 nm and the size of base, called Fc (fragment crystallizable), is 70 × 45 × 40 nm according to models based on x-ray diffraction data. [6] The immunoglobulin molecule exhibits considerable flexibility; the angle between the Fab domains has been observed in electron microscopic, low-angle x-ray scattering, transient electric birefringence, and resonance energy transfer studies to vary from 0° to 180°. All antibodies have two identical combining sites for each antigen located at the ends of the Fab domains.

The Fab and Fc represent functional domains in immunoglobulins.

Figure 36-1 Diagrammatic representation of the structural features of an IgG molecule. NH_2 indicates the NH_2 -terminus and COOH the C-terminus. The V_H , C_{H1} , V_L , and C_L homology domains are shown as boxes. Only the disulfide linkages that join H and L chains are shown. **(Left)** Approximate boundaries of the CDR regions in the V_L and V_H regions. **(Right)** Sequences encoded by V_H , D, J_H , V_L , and J_L segments in the V_H and V_L regions.

These were discovered by performing limited proteolytic digestion of the molecule. Both the H and L chains contribute amino acids that constitute the antigen-binding site in Fab. The Fab will combine with, but will not precipitate, multivalent antigens, in contrast to native IgG. A fragment can be prepared, called Fab2, which is devoid of Fc but still precipitates antigen. This form of immunoglobulin consists of two Fabs disulfide bonded at a part of the molecule called the hinge region. The hinge region is the part of the immunoglobulin molecule that is responsible for the molecular flexibility exhibited by all immunoglobulins. Every immunoglobulin is a glycoprotein, and the carbohydrate is always found attached to the H chain in the Fc domain. The other major function of immunoglobulins, binding to specific receptors on cells and certain effector proteins such as protein A and C1q, is associated with binding site(s) also found in Fc.

The chain structure of immunoglobulins explains neither antibody structural diversity nor antibody binding to antigen. The discovery that there were variable and constant regions of amino acid sequence formed the basis for understanding both phenomena. Thus, in the L chain, the 100 or so amino acids in amino-terminal half of the protein (V_L) vary between antibody molecules, but in the second half (C_L) there is virtual complete correspondence in amino acids, position for position, to the carboxy-terminus. The H chains exhibit the same pattern and can be divided likewise into V_H and C_H . Comparison of the amino acid sequence of many V_L s has revealed that certain parts of the variable region exhibit excess variability, whereas others have lesser variability. The former are called hypervariable (CDR) regions and the latter framework regions. The H chains exhibit the same pattern in the V_H regions. Amino acid sequence analysis of the C_H region, has shown three homologous regions where the amino acid sequences show more similarity than could have occurred by chance. These are called C_H 1, C_H 2, and C_H 3. The Fab region consists of the intact L chain, and the Fd region of the H chain consists of V_H C_H (Fig. 36-1). The combining site for antigen is a trough or a cavity composed of parts of the hypervariable regions of both the H and L chains. It is a small region, representing only 25% of the antibody V region. The region that interacts directly with the epitope on the antigen is even smaller and is formed by the association of the CDR regions, each of which consists of about 20 amino acids. Thus, the variation in a few amino acids accounts for the specificity and diversity of antibodies with respect to antigen binding. [4]

In addition to the amino acid sequence variations at the binding site, immunoglobulins can exhibit additional physical heterogeneity, and this imparts to each immunoglobulin a special effector function that is reflected in unique biologic properties that are additional to the antigen-binding activity. Heterologous and autologous antisera raised against immunoglobulins have been used to classify three types of physical heterogeneity. The first kind is based on the antigenic heterogeneity exhibited by immunoglobulin when it is used as an immunogen in other species. This is called class or isotypic variation. In humans five isotypes can be distinguished based on unique antigenic (isotypic) determinants found on the H chain. These are designated by capital Roman letters: IgG, IgM, IgA, IgD, and IgE. The H chain of each class is designated by the small Greek letter corresponding to the Roman letter of the class. Thus the H chain for IgG is , for IgM is , for IgA is , for IgD is , and for IgE is . Some of the immunoglobulin classes are composed of polymers of the basic monomer. In humans there are two antigenic varieties of the L chain, called kappa, , and lambda, . Each immunoglobulin will have two identical L chains; the and are shared by all classes. The monomeric form of any immunoglobulin is described by its chain structure. The molecular mass of the immunoglobulins can vary from 150 kd to 10^3 kd. This variation is due to polymerization of the basic monomer form. None of the immunoglobulins, however, are polymeric forms of another class. IgG is the most prevalent, constituting 75% of the total immunoglobulin in blood. It is present in normal adults at concentrations of 6001,500 mg/dL. IgG is designated $_{2\,2}$ or $_{2\,2}$. It is the only class of immunoglobulin that will cross the placenta (Fig. 36-2). [7]

The isotype IgM is a pentamer consisting of five monomeric units disulfide linked at the C-terminus of the H chain; each monomer of IgM is 180 kd due to the presence of an additional C_H domain. The complete protein has a sedimentation coefficient of 19 S, which corresponds to a molecular mass of 850 kd. IgM is designated $(_{2\,2})_5$ or $(_{2\,2})_5$. IgM also contains a 15-kd protein called the J chain. In the current structural model of IgM, the J chain forms a disulfide-bonded clasp at the C-terminus of two H chains (Fig. 36-2). [7]

The structure of the other isotypes of immunoglobulins are summarized as follows. The isotype IgA has a variable number of monomeric units and is designated $(_{2\,2})_n$ or $(_{2\,2})_n$ where n is 25. Serum IgA constitutes 20% of the total serum immunoglobulin, and 80% of this is monomeric. The remainder exists as polymers where n is 25. The other form of IgA is found in external secretions such as saliva, tracheobronchial secretions, colostrum, milk, and genitourinary secretions. Secretory IgA consists of four components: a dimer of two monomeric molecules, a 70-kd secretory component that binds noncovalently to the IgA dimer, and the 15-kd J chain that is believed to form a disulfide-bonded clasp at the C-terminus of the H chains (Fig. 36-2). The isotype IgD has a molecular mass of 180 kd. Its serum concentration is very low, approximately 3 mg/dL. IgD apparently functions as a membrane molecule, being associated on mature but unstimulated B cells in association with IgM. IgE

is the homocytotropic or reaginic immunoglobulin and mediates immediate hypersensitivity. It has a molecular mass of 180 kd and, like IgM, has four C domains. The Fc portion of IgE binds strongly to a receptor on mast cells, and this is how this immunoglobulin exerts its particular activity. The overall properties of the immunoglobulins are summarized in Table 36-1 .[7]

In addition, subclasses of the isotypes IgG, IgA, and IgM have been identified. The structural basis for this heterogeneity is antigenic variation (e.g., amino acid sequence differences) in the Fc portion of the H chain of a given class. The subclasses of IgG are the best characterized. These are called IgG1, IgG2, IgG3, and IgG4. Each has a slightly different structure, the most notable difference being the interchain disulfide-bonding pattern (Fig. 36-2 and Table 36-1). IgG1 comprises 70% of the total IgG and IgG2 20%. IgG3 and IgG4 make up 8% and 2%, respectively, of the total IgG. The subclasses of IgG exhibit different catabolic rates, and IgG2 crosses the placenta slightly more slowly than the other three. The other known subclasses of immunoglobulin isotypes are associated with IgM (IgM1 and IgM2) and IgA (IgA1 and IgA2). The properties and function of these subclasses are less well known.

The second type of variation is called allotypic variation. It is due to genetically controlled antigenic determinants found on both the H and L chains. Although each human has all immunoglobulin isotypes, an individual has only one form of each allotype on their immunoglobulin molecules. Allotypes are co-dominantly expressed, but an individual B lymphocyte secretes only one of the parental forms. This phenomenon is called allelic exclusion.

The third type of variation is due to antigenic determinants that are unique to each particular antibody molecule produced by an individual. These markers are called idiotypic determinants and they are associated with a single species of antibody. The anti-idiotypic antibodies that recognize a particular idiotype will not react with any other immunoglobulins in the donor other than the purified antibody that was used to raise the anti-idiotype antibody. In most cases, the immune response to an antigen results in a mixture of several antibodies each of which has identical binding specificity but distinct idiotypic

Figure 36-2 (A) Structure of the four subclasses of human IgG. Constant region domains are indicated by CnN, where n is the subclass and N is the domain. (B) Structure of human IgM. The J chain is shown in this model as being disulfide linked to two -chains. Other models have been proposed. Filled circle () carbohydrate. (C) Structure of human secretory IgA. This model shows the possible arrangement of the two IgA monomers in relationship to the secretory component and J chain. As the IgA molecule passes through the epithelial cells, the secretory components are synthesized and attached covalently to the Fc domain of the -chains that have previously been joined to the J chain with disulfide links. determinants. Thus, there can be many idiotypes for a given antigenic specificity, and this has been interpreted as being a reflection of physical heterogeneity in or near the antibody combining site, for example, in the variable region domains. In some species (notably certain strains of mice), the response to antigen results in a predominant idiotype on all antibodies of a given specificity. Because this is an inherited quality, they are called major, cross-reactive, or public idiotypes. Finally, some public idiotypes have been found in certain species (again most notably mice) to be genetically linked to allotypes. Three kinds of

anti-idiotype antibodies have been described: those that function as an internal image of the original antigen by mimicking the antigen structure, those that recognize antibody combining site-associated idiotypes, and those that are specific for framework-associated determinants. These three types of anti-idiotype antibodies are diagrammatically illustrated in Figure 36-3 . The first type, internal image antibodies, are the ones of clinical interest. The criteria for an internal image anti-idiotype is that the antibody is an immunogen in other species, that the antibody response to the antibody binds as specifically as the mimicked antigen, and that the antibody should be able to act like a natural ligand for a cellular receptor for the antigen.

Genetic Basis for Diversity

The origin of antibody diversity and heterogeneity is found in the genes that code for these molecules. Before the introduction of molecular biologic approaches to the investigation of the immunoglobulins, there was considerable controversy as to how much information for antibody specificity was carried in the germline and how much originated at the level of somatic cells. This question was resolved by the discovery that in antibodies two genes code for a single polypeptide chain. Two kinds of data support this conclusion. The first was the discovery of the V and C regions. The second was the observation that in DNA

Figure 36-3 Types of anti-idiotype antibodies. 1. paratope; 2. idiotope; 3. framework.

isolated from embryos that make no antibody, the coding sequences for the V and C regions for a given antibody were located at separate sites in the DNA but in mature antibody-producing cells for the same antibody, the V and C regions were found in the same part of the DNA.[4] [6] [8] Detailed analysis of the organization of the L and H chain genes has shown that the genes for L chains are located on chromosome 2, for L chains on chromosome 22, and for H chains on chromosome 14.

The organization of the L chain genes is shown in Figure 36-4 . In addition to the V and C genes, there is a set of genes called J segment (for joining) separated from the germline V genes. Each V region is preceded by a leader sequence (L_1 , L_2 . . . L_N). In the antibody molecule the V_L contains three hypervariable regions (CDR_1 ,

CDR_2 , and CDR_3) and three framework regions (FR_1 , FR_2 , and FR_3 ; Fig. 36-1). The CDR_3 region arises from the region where gene segments are joined. [4] The H chain gene likewise has a tandem array of 100200 V_H segments preceded by leader sequences. At an undetermined distance from the V_H and leader sequences, 30 segments of DNA known as diversity (D) regions code for 10 amino acids not found in L chains. Further downstream of the D regions are located six functional joining (J) segments that impart additional variability (Fig. 36-5).

The main function of B cells is to produce antibodies against an almost infinite variety of antigens that might be harmful to the organism. They comprise a clonally diverse population in which each cell has a monospecific antibody receptor bound to its surface. A foreign antigen encounters its cognate antibody receptor bound to a B cell and, with the cooperation of helper T cells, causes the clonal proliferation and subsequent differentiation of this subset of B cells into antibody-secreting plasma cells. A unique feature of B-cell ontogeny is the creation of a functional antibody molecule by somatic recombination of multiple noncontiguous germline gene segments at both the V and C gene loci. In the case of the H chain, two distinct types of somatic DNA rearrangements take place. [9]

V(D)J Recombination

The first wave of somatic DNA rearrangements involves developmentally regulated, site-specific recombination events that fuse V (variable), D (diversity), and J (joining) coding segments

Figure 36-4 Organization of chain gene. The germline DNA is rearranged in a -producing cell so that one V region is brought together with one J region. The mRNA that encodes the protein has the C region adjoined to the V-J region and yields a complete chain. This same motif is used in the organization of the chains. L_1 , L_2 , L_n , leader sequences. CDR, hypervariable regions; FR, framework regions. *(Data from Golub,[7] with permission.)*

to create a functional VDJ gene.[4] Diversity in this case is generated by selection of any one of the 100200 V_H genes (contributing the CDR_1 and CDR_2 regions) as well as the recombinatorial assortment of different D and J regions (resulting in the CDR_3 region). V(D)J recombination is mediated through conserved recombination signal sequences that flank the coding segments and comprise a palindromic heptamer and an A/T rich nonamer separated by a spacer region of either 12 bp or 23 bp. Coding segments can recombine only if they possess recombination signal sequence spacers of opposite type (the 12/23 rule). The mechanism involves a looping out and deletion of the intervening noncoding DNA resulting in the creation of a coding joint between the D and J segments and, subsequent to a second round of recombination, a coding joint between the V and the recombined DJ segments. Prior to ligation of the coding joints, modification of the ends is carried out by an endonuclease activity and the enzyme terminal deoxynucleotidyl transferase, resulting in further diversification.

Substantial progress has been made in establishing the biochemical components of the V(D)J recombination machinery and in understanding the underlying molecular mechanism of recombination. The proteins encoded by the recombination activation genes, RAG1 and RAG2, are essential for V(D)J recombination and are able to impart such activity to nonlymphoid cells. [10] RAG1 and RAG2 are responsible for the initial endonucleolytic cleavage that generates a 3OH at the coding end and a 5P at the signal end, followed by a nucleophilic attack of the 3OH on the phosphodiester backbone of the other strand, resulting in the formation of a hairpin joint at the coding end. This hairpin joint must then be resolved by an endonuclease, the ends processed and ligated. Other gene products have been implicated including components of the DNA-dependent protein kinase (DNA-PK), which is a multimolecular complex comprising a large catalytic domain (PK_{CS}) and two Ku subunits (Ku70 and Ku80). PK_{CS} possesses a serine/threonine protein kinase activity, whereas Ku binds DNA nonspecifically at double-strand

Figure 36-5 Organization and rearrangement of the H chain gene. Developmentally regulated site-specific recombination occurs initially between D and J segments, and is followed by a V to DJ rearrangement. Controlling elements for the VDJ recombination process include the intronic enhancer (E), which is subtended at both its 5 and 3 ends with a matrix attachment region (MAR), and the 3 enhancer complex (3E) located downstream at the C_H genes.

breaks, nicks, and hairpins, possesses helicase activity, and recruits and activates PK_{CS} . SCID mice, which are mutated at the PK_{CS} locus, display defects in coding joints, whereas Ku-deficient mice adversely affect the formation of functional coding and signal joints. The XRCC4 protein involved in double-strand break repair is also implicated in signal and coding joint formation. [11]

Antibody diversity is not completely accounted for by multiple germline V_H genes, V(D)J recombination, imprecise coding joint formation, and the combinatorial assortment of different H and L chains, although calculations indicate that the number of possible different antigen-binding sites is of the order of 10. [11] Additional variation in the V_H and V_L regions of already-expressed antibody molecules is effected by a process known as somatic hypermutation. This refers to a mechanism, the molecular details of which are largely unknown, by which point mutations are introduced into CDR_1 , CDR_2 , and CDR_3 regions of antibody molecules at a very high rate in the germinal centers of secondary lymphoid organs. Thus the ability to mount an antibody challenge to an almost infinite variety of antigens originates from a number of developmentally regulated somatic recombination and mutation events acting on a finite complement of germline gene segments. [12]

The organization of the human C-region genes is now understood. There are four C genes and one C gene and as many C_H genes as there are classes and subclasses. The location of the C-region genes is on the 3 side of the V, D, and J regions. During the proliferation of the lymphocytes in an immune response, there is usually a class switch. This phenomenon refers to the mechanism by which the isotype switches from to another class while retaining the same rearranged V region. The switch occurs in a stretch of DNA called the S region. There are also enhancer elements in the DNA that are tissue specific and function to increase the level of transcription of the DNA to mRNA (Fig. 36-6).

Antibody Class Switching

The second type of somatic rearrangement is the principal mediator of antibody class (or isotype) switching, by which antibodies of a given specificity acquire different effector functions.[13] [14] [15] In contrast to V(D)J recombination none of the

Figure 36-6 The structural dynamics of antibody class switch recombination (using IgG1 as an example). The murine germ line C_H locus comprises eight different isotype sequences (, , 3, 2, 2, epsilon, and) represented as shaded boxes. Upstream of each isotype (except for) is a block of switch sequences (S) that range in length from 1 to 10 kb. The donor S and acceptor S sequences are represented by open and hatched boxes, respectively. The intronic and IgH 3 enhancers are labeled as E and 3E, respectively. The V(D)J recombination process has already occurred in the pictured chromosome as evinced by the juxtaposition of the V, D, and J segments. The upper panel represents the IgC $_H$ germline configuration. On activation (by CD40L:CD40 interaction, for example) and targeting by switch commitment factors (in this case by the cytokine interleukin-4), I_H transcripts are produced at both the C_H and C_H 1 loci, and subsequently processed. The extent to which the 3E is responsible for transcriptional activation of the I_H locus remains to be determined (middle panel). Switch recombination mediated by the S and S2 sequences leads to the reciprocal production of a switch circle and a novel chromosomal configuration (lower panel).

components of the switch recombinase enzymatic machinery have been cloned, and the molecular mechanism of recombination remains to be elucidated. Antibody class switching typically occurs during the secondary immune response that effectively results in the transfer of effector function from IgM to IgG, IgA, or IgE antibodies.[14] The nature of the antigenic challenge defines the particular immunoglobulin isotype or isotypes produced and, as described above, different immunoglobulin classes have different functions. Class switching to non-IgM isotypes is important to good health as evinced by those individuals suffering from

X-linked hyper IgM syndrome. In this condition, which is due to genetic defects in the CD40L:CD40 signaling pathway essential for isotype switching, [15] individuals display an almost complete lack of serum and non-IgM isotypes (except for small amounts of IgG3) and suffer from a variety of opportunistic infections that severely impair their ability to lead normal lives.

The mechanisms for this class switching in the H chain have been most thoroughly studied in mice and are described as follows. The murine CH locus consists of eight functional genes arranged as 5-C-C-C3-C1-C2b-C2a-C-C-3 at the telomeric end of chromosome 12 (Fig. 36-6). Recombinagenic switch (S) sequences are positioned 14 kb upstream of each of these functional C_H gene segments with the exception of C (Fig. 36-6). Switch recombinations within or nearby these S sequences have been documented in a large number of hybridomas, plasmacytomas, and A-MuLV-transformed pre-B lines. S sequences are composed of direct tandem repeats of a basic core structure, which often contains the pentamers GAGCT and GGGGT although other repeats such as TGAGC, GAGCTG (S, S, and S) and GCAGC, ACCAG (S) are also prevalent. S regions vary in length and repeat unit sequence and display different degrees of homology with one another. [16]

Class switch recombination (CSR) occurs when an illegitimate nonhomologous DNA rearrangement event juxtaposes a functional VDJ gene (initially 5 of the C gene in an IgM-bearing B cell) in close proximity to a downstream C_H gene. This occurs (with the exception of IgD switching) by a looping out and deletion mechanism resulting in the loss of all the intervening C_H genes (Fig. 36-6).[13] [15] Although other mechanisms of isotype switching have been proposed, including RNA-mediated events such as processing of long pan-locus transcripts or trans-splicing, these are not believed to represent the physiologically relevant principal mode of isotype switching. An exception to this is IgD, in which the C locus does not possess S sequences, [16] and switching occurs by differential processing of long transcripts or by recombination between specific homologous non-S sequences upstream of C and C. [15]

It is unclear how the tandem repetitive S regions mediate switching and how switching is regulated at the molecular level. It may be that these sequences represent a structural motif that is directly recognized by the DNA-binding domain of a common switch recombinase [14] [17] or there may even be a class of isotype-specific switch recombinases whose substrate activities are under independent control. Alternatively, or in addition, S region binding proteins may act as accessory molecules to recruit the recombination machinery by specific protein-protein interactions. Switching can be regulated in vivo to yield a specific or limited set of isotypes and important regulators of this process include several T-cell-derived cytokines. These include interleukin (IL)-4, IL-5, IL-10, interferon- and tumor growth factor (TGF)-. [18]

Directed class switching may be manifested by the differential transcriptional competence of the C_H genes.[15] Prior to class switch recombination sterile or so-called germline transcripts encompassing a short I_H exon (residing 5 to every S region) spliced to an adjacent C_H region are expressed in a regulated inducible fashion. [17] [19] Initially, transcription initiates within a promoter 5 of the downstream acceptor I_H exon, continues through the S region and terminates at the 3 end of the C_H gene. The S sequences are then spliced out (Fig. 36-6). Similar RNA structures are formed at the donor C locus by the intronic enhancer, E, which acts as a promoter for an initial transcript, which encompasses I, S, and C and subsequently yields an IC moiety after RNA processing (Fig. 36-6).

A number of cytokines are known to modulate germline transcripts (GT).[15] These results are consistent with the notion that transcriptional activity at the donor and acceptor C_H loci are prerequisites for targeting of switch recombination to these loci. This transcribed status is believed to engender a particular C_H gene with the accessibility to undergo switch recombination (hence the so-called accessibility model of CSR [17] [19]) by facilitating the binding of the catalytic or regulatory units of the switch recombination apparatus or activators thereof. Either the change in chromatin configuration induced by transcription or the transcripts themselves may be responsible for the increased accessibility of the S sequences to the recombinase. Switching to a particular isotype is always preceded by the presence of C_H germline transcripts at that C_H locus[13] [15] and there is a direct correlation between cytokine-mediated induction of germline RNAs and enhanced transcriptional rate at a particular locus.[13] Apart from germline transcriptional control by I exon promoters, IgH locus transcriptional control of CSR is also mediated by the E enhancer and a developmentally regulated enhancer complex located 3 of the C gene (3E) and comprising four distinct enhancers (3E; 3E-HS(1,2); 3E-HS3; 3E-HS4) (Fig. 36-6).[20] The E enhancer, on the other hand, is responsible for the generation of the heterogeneously initiating germline I transcripts that are prerequisites for isotype switching from C to downstream C_H loci. [15]

THERAPEUTIC USE

Immunoglobulin G was one of the first plasma proteins prepared in a purified state as a therapeutic drug for the treatment of clinical disorders. It remains, along with albumin and factor VIII (antihemophilic factor), the most widely therapeutically used plasma derivative. The method for purifying IgG has remained essentially unchanged from the cold ethanol method developed by Dr. Edwin J. Cohn and his colleagues from 1935 through 1945. The Cohn method for purifying IgG yields a 15% protein solution that can only be given intramuscularly. Over the past 15 years, methods have been developed for preparing IgG in a form suitable for intravenous administration. [21] [22]

Intravenous immunoglobulin (IVIG) is prepared from pooled human plasma by the Cohn-Oncley cold ethanol fractionation procedure and retains the antibody repertoire reflecting the combined immunologic experience of the donors. [23] Aggregates and anticomplementary activity must be removed by any of several approaches including limited enzyme digestion or chemical modification. IVIG contains concentrated IgG with normal plasma ratios of IgG1 and 2 but lower percentages of IgG3 and 4, and only trace amounts of IgA and IgM. IVIG products and manufacturers are listed in Table 36-2 .

Intravenous immunoglobulin has proven both safe and effective in restoring protective immunity to patients with agammaglobulinemia for the past two decades. The major risks associated with IVIG administration are the possibility of transmission of disease and the potential risk of anaphylactoid reactions. Standardized testing of donor units and the fractionation procedure have reduced virus load. In addition, many producers of IVIG now add a heat or detergent viral inactivation step to reduce the risk of disease vector transmission to a very small possibility. Aseptic meningitis with severe headache was reported for 11% of recipients of high-dose IVIG and was associated with patient history of migraine headaches. Other complications include pain, chills, fever, headache, nausea, or vomiting. Most adverse events are self-limiting and improve

with a slower infusion rate. Selective IgA deficiency or previous anaphylactic response to IVIG are the only contraindications for the use of IVIG. The relative safety of IVIG and the effectiveness of treatment in obvious and not so obvious diseases had led to widespread use of IVIG for a variety of abnormalities, often without sufficient evidence to justify efficacy. Indications for IVIG are listed in Table 36-3 . [24] [25] Controlled studies will be required to define appropriate use of IVIG in areas in which clinical experience has suggested promise. There is a significant drug cost (approximately $10,000 annually for patients with primary immunodeficiency) and because administration is intravenous and requires 23 hours in a clinical setting, added costs are associated with IVIG administration.

The effects of IVIG are explained by mechanisms beyond antibody

TABLE 36-3 -- Clinical Indications for Use of IVIG

Labeled use for all US-licensed IVIG
Primary immunodeficiencies
Labeled uses for selected IVIG products
Kawasaki syndrome
Chronic lymphoid leukemia
Prophylaxis of bacterial infection in children with human immunodeficiency virus infection
Prevention of graft-versus-host and bacterial infection in bone marrow transplantation
Idiopathic thrombocytopenic purpura
Off-label uses for which efficacy as a primary treatment has been demonstrated
Post-transfusion purpura
Guillain-Barré syndrome
Chronic inflammatory demyelinating polyneuropathy
Off-label uses indicated only after standard interventions have not been effective
Autoimmune hemolytic anemia

Dermatomyositis
Epilepsy
Immune-mediated neutropenia
Infectious disease prophylaxis in high-risk neonates
Myasthenia gravis
Polymyositis
Solid organ transplantation to prevent cytomegalovirus infection
Systemic vasculitis
Systemic lupus erythematosus
Thrombocytopenia
Other applications from pilot trials or clinical experience
Multiple sclerosis
Asthma
Juvenile rheumatoid arthritis
Insulin-dependent diabetes
Crohns disease
Recurrent abortions
Acquired von Willebrand disease

recognition of pathogen antigens. IVIG preparations contain up to 30% dimers composed of idiotype-anti-idiotype antibody pairs. These dimers appear to be very effective as a sink for activated complement and can inhibit complement activation. [26] In immune thrombocytopenia purpura the effects of IVIG seem to be mediated by Fc-receptor blockade of reticuloendothelial cells combined with an anti-idiotypic neutralization of antiplatelet antibody. Other indications of antibody neutralization can be seen in IVIG treatment of myasthenia gravis. The dramatic success of IVIG in treating Kawasaki syndrome may be due to several mechanisms, including anti-idiotypic neutralization of antiendothelial antibodies, inhibition of cytokine production and function, and elimination of causative superantigens. [27] [28] IVIG inhibits B-cell activation and autoantibody production by enhancing CD8+ suppressor T-cell function. Cell-mediated immunity is also affected. Hyperimmune IGIV is made from donor plasma selected for high titer for specific antigens. Prophylaxis for cytomegalovirus and respiratory syncytial virus has been successfully demonstrated using hyperimmune IVIG.[28] [29] Future progress with IVIG will include antigen selection and augmentation with monoclonal antibodies. [30]

Possible therapeutic and diagnostic uses for anti-idiotype antibodies are as prophylactic vaccines. Table 36-4 is a list of viruses and bacteria to which immunity has been induced in mice with an anti-idiotype antibody (see review by Walter, Friesen, and Harthus [31]). Recent efforts have been devoted to using this method to make a vaccine against human immunodeficiency virus based on its ability to mimic CD4, the receptor on T cells for the virus. Such antibodies would also prove useful in developing tumor-specific vaccines. Similar efforts are being devoted to developing such antibodies for use in both in vivo and in vitro immunodiagnostic assays where a purified antigen is not readily available.

POLYCLONAL AND MONOCLONAL ANTIBODIES

A fundamental concept in the immune system is the clonal nature and function of the B lymphocytes, the cell type responsible for synthesis of immunoglobulins (Chap. 8). The constant production by the mammalian immune system of large numbers of B lymphocyte clones that recognize different antigenic structures on different, as well as single, molecules leads to the production of a vast array of antibody proteins. Thus, an antiserum raised by immunization with a single cell type or a homogeneous, purified antigen contains many different antibodies that have in common, specific reactivity with the immunizing cell or antigen, but that are also a mixture of immunoglobulins that are heterogeneous by other criteria such as size, charge, amino acid sequence, and binding affinity. Because such an antiserum represents a mixture of antibodies derived from many clones of B lymphocytes, all of which have produced an antibody reactive with the immunizing antigen, this is called a polyclonal antiserum and purified immunoglobulins with a single antigen specificity derived from such an antiserum are called polyclonal antibodies.

Monoclonal antibody technology as described in 1975 by Kohler and Milstein combines the clonal properties of B lymphocytes with the random segregation of chromosomes in hybrids formed between two cells.[32] [33] This procedure results in a hybrid cell in which there is immortalization of an individual antibody-producing B lymphocyte. Thus, each cell line derived from the hybrid produces a unique or monoclonal, constant antibody molecule. Such cell lines are called hybridomas. The method for obtaining a monoclonal antibody was first developed in a murine system and is summarized as follows.

Following immunization of the mouse, the B lymphocytes are harvested from the spleen or lymph nodes as a single cell suspension, and fused with a mouse myeloma cell (plasmacytoma cellsee Chap. 76). The myeloma cell is immortal and

TABLE 36-4 -- Immunity of Mice Against Viruses and Bacteria Following Immunization with Anti-idiotype Antibodies

Virus/Bacteria	Anti-idiotype Antibodies Produced In	Class	Immunity of Mice Immunized with-Idiotype

has the cytoplasmic machinery to produce large quantities of immunoglobulin. The tumor cell used for fusion also contains an enzyme deletion that can be used to select for cells that do not have the deletion. In the murine system this is usually hypoxanthine guanine phosphoribosyl transferase (HGPRT), an enzyme required for survival of the cell in the presence of the folic acid antagonist aminopterine. Fusion of the immunized spleen cells with the myeloma cells is triggered by Sendai virus, polyethylene glycol, electric current, or directed fusion. [34] [35] This mixed cell suspension is separated into small aliquots (usually by dilution into a 96-well microtiter plate holding about 200 L/well) and each aliquot is grown in the presence of the selecting agent, hypoxanthine-aminopterine-thymidine (HAT). Only those hybridoma cells that have acquired the HGPRT from the immunized lymphocytes will survive. The hybrids are then cloned by limited dilution, such that there is one cell per well. The growth of the newly fused hybridoma can be initially facilitated by the addition of IL-6, which can be added exogenously or provided by feeder cells. The individual clones, once they have been grown, are characterized for the antibody of desired specificity, titer, and binding affinity before propagation in large-scale tissue culture production or by propagation in the peritoneal cavity of a mouse as an ascites tumor. Once established, the B-cell hybridomas will exhibit autonomous growth and can be adapted to growth in synthetic media containing no serum. Because these cultures produce a single species of immunoglobulin, the antibodies can be purified by standard column chromatographic methods, although frequently immunoaffinity purification methods are used to obtain highly purified antibody devoid of any contaminating proteins. The basic steps in the production of a monoclonal antibody from an immunized mouse are summarized in Figure 36-7 .

The most widely used species for the production of monoclonal antibodies is the mouse, but hybridoma cell lines can also be obtained from rats and humans. Compared with human immunoglobulin purified from pooled plasma, human monoclonal antibodies would be particularly useful as potential therapeutic reagents for the treatment of human disease, because they would have the added advantage of antigen specificity. There are serious ethical considerations about the immunization of humans with potential toxins or tumor cells, and the lack of a suitable, reproducible source of antigen-activated human lymphocytes has been, and still is, the major difficulty in the preparation of human monoclonal antibodies. An early approach to this problem was to use Epstein-Barr virus to transform human B cells obtained from the peripheral circulation, thus allowing for an expansion of the B cells before fusion. This approach depends on first finding an individual who is

Figure 36-7 General scheme for the production of murine monoclonal antibodies.

producing an antibody of the desired specificity and isotype. Another difficulty in producing human monoclonal antibodies is that a human-mouse hybridoma cell (called a heterohybridoma cell) resulting from fusion of mouse myeloma cells with human B cells tends to lose human chromosomes, and this results eventually in the loss of the ability to secrete human immunoglobulin. A mouse cell line has been developed that fuses efficiently with human B cells and has been used to produce stable human monoclonal-secreting heterohybridomas. Simultaneously, several suitable human myeloma fusion partner cell lines have been developed, as well as a human-mouse heterohybridoma cell line.[35]

Production of Human Monoclonal Antibodies by Gene Technologies

Technical achievements in cellular immunology have led to the ability to produce human monoclonal antibodies, but the general approach for production of monoclonal antibodies still does not address the potential problem of using tumor-derived proteins in humans. Attention has turned, therefore, to the use of gene manipulation methods to produce immunoglobulins that potentially overcome the conceptual and practical difficulties of using human tumor cell lines as a source of human therapeutic agents. In this approach, hybridoma technology is combined with molecular biology techniques for the design and development of immunoglobulins that are specifically targeted for use as human therapeutic and diagnostic reagents. The expansion of the repertoire of monoclonal antibody technologies has resulted in a molecular diversification of routine hybridoma technologies.

First, the use of the polymerase chain reaction technique [36] has allowed for the generation of complete V-region gene libraries. This is accomplished by using a 3 primer in the C region and a degenerated 5 primer that corresponds to homologous sequences at the 5 end of most V-region cDNAs. The amplified DNA is then used to construct, in *Escherichia coli*, a V_H library that has been previously screened by antigen binding and found to produce V fragments that exhibited good antigen binding. [37] [38]

Second, the problem of H-L chain pairing has been solved using in vitro recombined lambda phage libraries, where separate V_H and V_L fragments (inserted respectively on the left and right arm of the phage) are randomly combined in vitro using a unique restriction site located near the center of the phage genome. The diversity generated by this system is probably as large as that generated by the immune system (>10^8 antibodies). The resulting antibodies will not be the same as those generated in mammals because phage do not have mechanisms such as the use of alternative V gene fragments (V, D, or J) to form the V regions. Thus, the phage combinatorial library system is most effective when the starting animal has been immunized with the antigen of interest. It is possible, however, to obtain specific antibodies from phage libraries made from nonimmunized animals by enriching for antigen binding by panning the phage-derived immunoglobulin population on immobilized antigen. [38] Thus, the combinatorial phage library methodology represents a significant advance in monoclonal antibody technology.

Third, the problem of modifying an existing antibody to retain desired characteristics, and introduce other characteristics required for the intended use, forms the basis for engineering monoclonal antibody genes. The high somatic mutation rate of V regions in H and L chains during maturation of the immune response is operative in B-cell hybridomas, and this has led to the development of positive screening and selective methods for the detection and enrichment of hybridoma-secreted monoclonal antibodies that have altered characteristics. [39] Another approach to engineering monoclonal antibodies is based on recombinant DNA technology. The H and L chain plasmid cDNAs expressed in hybridoma cells are cloned, sequenced, and appropriately modified by replacing nucleotide sequences. These plasmids are then transfected into nonimmunoglobulin-secreting myeloma cells and the new cell, called a transfectoma, will secrete the engineered antibody. [40] This is the approach used to humanize murine monoclonal antibodies (e.g., to convert a murine immunoglobulin to resemble a human immunoglobulin). [41] Such engineered antibodies are designed to overcome the problem that murine monoclonal antibodies cannot be repeatedly injected into humans without the eventual development of an immune response to the foreign protein. Finally, the combination of the somatic cell method with this type of recombinant DNA method forms the basis of specific gene therapies for the treatment of genetic diseases. [35]

Therapeutic Use of Monoclonal Antibodies

The potential use of monoclonal antibodies as diagnostic reagents and therapeutics is just beginning to be realized, and no attempt will be made here to summarize all of these emerging developments. Two examples, however, of how monoclonal antibodies have proven useful in hematology are the use of monoclonal antibodies to identify cell types that have a common myeloid cell progenitor and their use in the understanding of human myeloid cell differentiation, as revealed by identification of cell surface marker phenotypes.

At one level, monoclonal antibodies have been found that detect antigens expressed uniquely, not only by T and B lymphocytes, but also as more general markers of peripheral blood monocytes or neutrophils. Thus, certain reagents identify cell surface antigens common to (1) monocytes and neutrophils; (2) monocytes, neutrophils, and large granular lymphoid cells; (3) monocytes and platelets; and (4) neutrophils and large granular lymphoid cells (see review by Foon and Todd [42]).

At a second level, monoclonal antibodies have been used to correlate the presence of cell surface antigens with pathways of normal differentiation within the myeloid lineage. The stage in differentiation where a variety of monoclonal antibodies to cell surface markers react is illustrated in Figure 36-8. Detection of the cell surface antigens is based either on complement-dependent monoclonal antibody-mediated cell lysis (negative selection) or on techniques such as fluorescence-activated cell sorting or immune rosetting (positive selection). These methods allow for determination of antigen expression by multipotent stem cells (CFU-GEMM) and stem cells committed to the myeloid (CFU-GM), erythroid (BFU-E, CFU-E), or megakaryocyte/platelet (CFU-Mega) pathways of differentiation. Certain monoclonal antibodies have been used to prepare 50- to 100-fold enriched preparations of myeloid progenitor cells from pooled bone marrow mononuclear cells. Certain determinants have been found to be expressed uniquely by progenitor cells; other cell surface antigens are found on myeloid, erythroid, or platelet precursors that correspond morphologically and histochemically to distinct stages of maturation; some antigens are either lost or acquired as cells progress from myeloblasts to mature neutrophils; and finally, some antigens are maintained on all recognized myeloid cells. [42]

In addition to serving as differentiation markers, many of the cell surface antigens represent functionally significant plasma membrane proteins, glycoproteins, and glycolipids. Cell surface antigens have been given cluster designations (CD or CDw) followed by a number. The complete listing of all cluster designations for cell surface antigens is listed in Chapter 7. This systematic classification of monoclonal antibodies has made these reagents invaluable tools, not only for the understanding of the development of cellular aspects of hematopoiesis, but in the

Figure 36-8 Schematic representation of human myeloid differentiation indicating the phenotype of cell-surface markers as defined by monoclonal antibody reagents.

diagnosis and classification of hematopoietic disorders and have allowed for guidance on therapeutic decisions.

SUMMARY

The immunoglobulins modulate and mediate many physiologic functions and serve as diagnostic markers of disease and monitors of changing health. The study of these molecules continues to yield new insights about fundamental biologic, biochemical, and genetic mechanisms controlling hematopoiesis and host defense mechanisms. There is currently a rapid increase in new information on the immunoglobulins based on both biologic and physical/biochemical studies as illustrated by the advances in knowledge on immunoglobulin structure and function and monoclonal antibody technology. This may result in further diagnostic and therapeutic uses of immunoglobulins.

Chapter 37 - Complement Biology

Peter J. Sims
Therese Wiedmer

INTRODUCTION

The complement system includes more than 20 plasma proteins that interact through two enzymatic pathways to generate products with distinct immunoregulatory, opsonic, and inflammatory activity (Table 37-1 and Fig. 37-1 (Figure Not Available)). In addition to these fluid-phase proteins, the complement system also encompasses a variety of cell-surface proteins with receptor function. These membrane complement receptors recognize activated fragments derived from the complement components in plasma, and through this interaction initiate immune adherence and cell activation. Additionally, cellular receptors that bind activated components of complement can function as inhibitors that serve to limit dissemination of the complement reaction cascades and to protect autologous cell membranes from damage by the complement system. In concert, these plasma proteins and cell membrane receptors play a central role in host defense against infection and contribute to virtually every aspect of the inflammatory response. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12]

OVERVIEW OF PROTEIN STRUCTURE AND FUNCTION

Table 37-1 summarizes the main components of the complement system. Shared structural motifs and related functions among several of these proteins permit a number of distinct protein superfamilies to be identified. [5] [10] [13] Common structural elements include collagen-like domains of the collectin protein family, common to proteins that initiate complement activation, including C1q, C-reactive protein (CRP), and mannose-binding protein (MBP); a serine protease domain (SPD) that is shared among many of the complement enzymes, including C1r, C1s, MASP, C2, factor B, factor D, and factor I; [14] short cysteine-rich consensus repeats (SCRs), representing highly conserved globular domains of approximately 60 amino acids each that confer binding affinity for C3b/C4b (SCRs are found predominantly in those complement proteins and receptors that bind C3b or C4b, but they are also found in several unrelated proteins); [15] [16] and a cytolytic peptide motif (found in C6, C7, C8, and C9) consisting of a putative membrane-spanning domain and a cysteine-rich domain characteristic of the epidermal growth factor receptor precursor. [8] [17] This latter motif is also shared by perforin, a pore-forming cytolytic polypeptide that is contained in the intracellular granules of cytotoxic T cells. [18]

Shared structural and functional homology is also apparent when the reaction mechanisms of the classical and alternative activation pathways are compared (Fig. 37-1 (Figure Not Available)). This homology is most evident for the C3/C5 convertases of both pathways. [3] [5] [13] These enzyme complexes (C4b2a of the classical pathway and C3bBb of the alternative pathway) each represent a Mg^{2+} -stabilized heterodimer formed between a serine protease (C2a or Bb) and a surface-bound cofactor (C4b or C3b, respectively). C2 and factor B are proenzymes containing SPDs and SCRs. When proteolytically activated, they each share specificity for the same substrates (i.e., C3 and C5). C3 and C4 also derive from homologous precursor polypeptides, and each contains an internal thioester bond (between a cysteinyl sulfhydryl and -glutamyl carbonyl) that is destabilized upon peptide cleavage of their -chains. [19] [20] [21] Transacetylation through nucleophilic attack by surface amino or hydroxyl groups provides a mechanism by which the C3b and C4b domains of these components covalently attach to membrane surfaces, thereby localizing the C3/C5 convertase enzyme complexes to the target membrane of complement attack. Membrane-bound C3b also serves an important opsonic function, labeling the target for removal by the reticuloendothelial system.

Common structure and function can also be discerned among the complement regulatory proteins and cellular complement receptors (Tables 37-1 and 37-2). Certain of the cellular C1q receptors (C1qR) are closely related to cellular collagen receptors. [22] [23] The cellular anaphylatoxin receptors for C3a, C4a, and C5a peptides are related to other G-protein-coupled receptors. [24] The cellular C3b/C4b receptors CR1 and CR2 as well as the C3/C4 regulatory proteins factor H, C4b-binding protein

TABLE 37-1 -- Components and Regulatory Proteins of the Complement System

Protein	Serum Concentration (g/ml)	Number of Peptide Chains	Structural Motifs
Components of Activation Pathways			
C1q	100	18 (6 × 3)	Collagen-type helix
C1r	50	1	Serine protease, SCR
C1s	40	1	Serine protease, SCR
C4	640	3	Internal thioester
C2	25	1	Serine protease, SCR
C3	1,200	2	Internal thioester
Factor B	200	1	Serine protease, SCR
Factor D	1	1	Serine protease, SCR
Factor I	35	1	Serine protease, SCR
Components of Membrane Attack Complex			
C5	70	2	Homologous to C3, C4
C6	65	1	Pore-forming protein, SCR
C7	55	1	Pore-forming protein, SCR
C8	55	3	Pore-forming protein
C9	60	1	Pore-forming protein
Plasma Regulatory Proteins			
C1 inhibitor	200	1	Serpin-type inhibitor
Properdin	25	4	
C4b-binding protein	250	8 (7 and 1)	SCR
Factor H	500	1	SCR
S protein (vitronectin)	500	1	Adhesive protein (RGD sequence)
Membrane Regulatory Proteins			
Decay-accelerating factor (DAF, CD55)		1	SCR, GPI anchor
Membrane cofactor protein (MCP, CD46)		1	SCR
20-kd homologous restriction factor (HRF-20, CD59)		1	GPI anchor
Membrane Receptors			
CR1 (CD35)		1	SCR

CR2 (CD21)		1	SCR
CR3 (CD11b/CD18)		2	Leukocyte $_2$ -integrin
CR4 (CD11c/CD18)		2	Leukocyte $_2$ -integrin
C1q receptor		1	
C3a receptor		1	G-protein coupling
C5a receptor		1	G-protein coupling

Abbreviations: SCR, short consensus repeat; GPI, glycosyl phosphatidylinositol; DAF, decay-accelerating factor; MCP, membrane cofactor protein; HRF, homologous restriction factor.

(C4b-bp), membrane cofactor protein (MCP), and decay-accelerating factor (DAF) all share the SCR motif that confers ability to bind C3b and C4b. The genes for these proteins cluster as a linkage group that has been designated regulators of complement activation (RCAs). [15] [16] Two other cellular C3 receptors, CR3 and CR4, belong to the Leu-CAM $_2$ -integrin family of cellular adhesion receptors, which includes LFA-1. [25]

COMPLEMENT ACTIVATION PATHWAYS

Expression of the biologic activity of the complement system requires proteolytic processing of C3 and C5. Accordingly, the reaction mechanisms of this system are focused on the assembly and control of the C3/C5 convertases (Fig. 37-1 (Figure Not Available)). The alternative pathway C3/C5 convertase (C3bBb) is phylogenetically oldest and remains the most important enzyme mechanism for C3/C5 activation. The classical activation pathway utilizing C2 and C4 appears to reflect evolutionary adaptation, initially to utilize the specificity of a lectin as provided through the interaction of MBP with the mannose-rich lipopolysaccharides common to many microbial pathogens, and subsequently for precise immune recognition as provided through C1qs interaction with antigen-bound immunoglobulin. [5] [10] [26]

Classical Pathway

The classical pathway is initiated through the conformational activation of C1q, one of the components of the C1 enzyme complex. [27] [28] C1 is present in plasma largely as a Ca^{2+} -dependent complex between C1q and the proenzymes C1r and C1s with the stoichiometry $C1q,r_2,s_2$. Ultrastructurally, C1q exhibits six globular heads joined by filamentous segments to a helical stem-like core. This helical core is compositionally and structurally similar to collagen and can compete with collagen for binding to plasma membrane collagen receptors. [22] [29] The C1r and C1s enzyme dimers bind to the collagen-like tail of C1q, whereas the

Figure 37-1 (Figure Not Available) Reaction scheme of the complement activation pathways. Components displaying enzymatic activity are denoted by a solid bar above symbol. $C3{*}H_2O$ is generated from C3 by spontaneous hydrolysis of an internal thiol ester bond in the C3 -chain (see Fig. 37-2). Dashed arrow denotes crossover between classical and alternative pathways, through which C3b generated by the classical pathway C3 convertase (C4b2a) serves as the membrane cofactor for assembly of the alternative pathway C3 convertase (C3bBb). Also note potential for self-propagation of the C3bBb enzyme complex through the cycle of the amplification convertase. See text for details. *(From Sims,[244] with permission.)*

TABLE 37-2 -- Specificity and Cellular Distribution of Major Complement Receptors

Receptor	Ligand Specificity	Structural Motifs	Cellular Distribution in Humans
C1qR	C1q (collagen)		Platelets, PMN, B lymphocytes, monocytes, fibroblasts, endothelial cells
C3aR	C3a (C4a)	G-protein coupling	Mast cells, basophils, eosinophils, PMN, monocytes, many tissues
C5aR	C5a, $C5a_{des\ arg}$	G-protein coupling	Mast cells, basophils, eosinophils, PMN, monocytes, many tissues
CR1 (CD35)	C3b (C4b, iC3b, C3c) SCR	SCR	Erythrocytes, B cells, certain T cells, neutrophils, eosinophils, macrophages, follicular dendritic cells
CR2 (CD21)	C3d, C3dg, (iC3b)	SCR	B cells, T cells, follicular dendritic cells
CR3 (CD11b/CD18)	iC3b (C3d)	Leukocyte $_2$ -integrin	Neutrophils, eosinophils, macrophages, K and (CD11b/CD18) NK cells, follicular dendritic cells
CR4 (CD11c/CD18, p150, 95)	iC3b	Leukocyte $_2$ -integrin	Neutrophils, macrophages, monocytes, K and CD11c/CD18, NK cells

C1qR, C1q receptor; C3aR, C3a receptor; C5aR, C5a receptor; CR1CR4, complement receptors 14.

binding of C1 activators generally occurs through the globular heads of C1q. Activation of C1 requires multipoint attachment of at least two globular heads of C1q to the Fc domains of immunoglobulin within immune complexes.[27] [28] This can be achieved by simultaneous attachment to either two closely spaced IgG molecules or to multiple Fc of a single antigen-complexed molecule of IgM. The conformational change induced in C1q upon binding multiple immunoglobulin Fc is transmitted to the $C1r_2\ s_2$ subunits, resulting in proteolytic autoactivation of the C1r dimer, which then proteolytically activates C1s. Activated C1s possess the catalytic site for proteolytic activation of C4 and C2.

In addition to antigen-antibody complexes and IgG aggregates, C1 activation can be initiated by CRP, certain viral and bacterial membranes, endotoxin, DNA, monosodium urate crystals, cytoskeletal proteins, and heart mitochondrial membranes. [28] Whereas immunoglobulins bind to the globular region of C1q, C1 activation by CRP occurs through the binding of this protein to the collagen-like core of C1q. Two domains on the C1q -chain have been identified as the CRP-binding sites. These same sites have been implicated as the binding sites for DNA, which can also initiate the classical pathway by activation of C1. [30] In addition to C1, human plasma contains another enzyme complex that can initiate the reaction cascade of the classical pathway. MBP, a C-type lectin in plasma that binds to glycosidic residues expressed by bacteria and other pathogens, has a structure similar to that of C1q and binds to C1q receptors, enhancing phagocytosis. Upon binding to mannose-rich surfaces, MBP initiates proteolytic activation of C4 and C2 through an associated C1s-like serine protease (see the following sections). [10]

Proteolytic cleavage of the -chain of C4 by C1s generates two fragments, C4a and C4b. C4a is a vasoactive peptide of 77 amino acids, removed from the amino-terminal end of the C4 -chain.[31] [32] In addition to liberating the C4a peptide, C1s cleavage of the -chain of C4 exposes an intrachain thioester bond within the -chain of the C4b domain of the molecule that provides a short-lived and highly reactive carbonyl for covalent attachment of C4b to suitable acceptor residues (primary amines and hydroxyl groups) of the antigen-antibody complex or the target cell surface. [19] [21] [33] Polymorphism of the C4 gene is reflected in two common isotypes, C4A and C4B.[34] [35] These isotypes differ in the reactivity of the internal thioester bond for amines versus hydroxyl groups, which is reflected in functional differences in hemolytic activity and in their interaction with immune complexes. [21] Once covalently bound to the cell surface or immune complex, C4b can bind C2 into a Mg^{2+} -dependent complex. When complexed to C4b, C2 is proteolytically cleaved by C1s to liberate the C2b fragment, the C2a domain of the molecule remaining attached to C4b. C2a complexed to C4b provides the catalytic site for subsequent proteolytic activation of C3 and C5.

Peptide cleavage of the -chain of C3 by the C4b2a enzyme complex liberates the vasoactive peptide C3a and exposes a reactive intrachain thioester bond within the -chain of the C3b portion of the molecule (Fig. 37-2).[19] [21] [31] [32] [33] [36] Multiple C3b molecules are deposited on the cell surface (or within the immune

Figure 37-2 Schematic diagram of the proteolytic processing of C3 through enzyme reactions of the complement system. Native C3 lacks biologic activity. C3*H_2O is a C3b-like molecule that is generated by spontaneous hydrolysis of the internal thiol ester bond of the C3 -chain. C3-to-C3b conversion is mediated by either classical or alternative pathway C3 convertase through proteolytic cleavage between amino acid residues 77 and 78 of the C3 -chain. In addition to generating C3b, this proteolysis liberates the peptide anaphylatoxin C3a. The formation of C3b exposes the carbonyl of the -chain thiol ester, which freely reacts either with H_2O or with residues on the target surface to attach C3b covalently. Inactivation of C3b is initiated by the protease factor I, which cleaves a 3-kd fragment from the C3b -chain to generate iC3b. Proteolysis by factor I requires binding of C3b either to plasma component factor H or to the membrane receptors CR1 or MCP. Further proteolysis by factor I liberates the larger fragment C3c, leaving C3dg (43 kd) covalently bound to the target surface via the carbonyl of the internal thioester. See text for details. R, residue; SS, disulfide bonds.

complex) through reaction of this thioester bond with nearby residues containing primary amines or hydroxyl groups. [21] [33] Those molecules of nascent C3b that fail to react with acceptor residues undergo spontaneous hydrolysis of the internal thioester bond, thereby losing their capacity for covalent attachment to the target surface. The covalently bound C3b functions as a cofactor for subsequent activation of C5, and as cofactor for assembly of the alternative pathway C3/C5 convertase (the C3bBb complex, described following). On permissive surfaces, the recruitment of this amplification convertase of C3bBb provides a positive feedback mechanism for propagating the activation of C3 and C5.

The next step in the classical pathway is the activation of C5, which is also initiated by the C4b2a enzyme complex through proteolytic cleavage of the -chain of C5. C3b that is covalently bound to the C4b subunit of the C4b2a enzyme complex is thought to facilitate presentation of C5 to the active site in C2a, conferring enhanced specificity of the enzyme for C5.[5] Proteolytic cleavage of C5 liberates the chemotactic peptide C5a, leaving the C5b portion of the molecule weakly attached to C3b. Interaction of C5b with C6 initiates assembly of the membrane attack complex, composed of components C5b, C6, C7, C8, and C9. The resulting C5b9 complex has the potential to insert into lipid bilayers and to initiate plasma membrane damage (see discussion under Assembly of the Membrane Attack Complex).

Alternative Pathway

In contrast to the sequentially ordered enzyme cascade of the classical pathway, the alternative pathway entails a positive feedback interaction in which the principal activation product, C3b, serves as the cofactor of the C3-cleaving enzyme complex (C3bBb) that is responsible for its own production (Fig. 37-1 (Figure Not Available)).[1] [5] [37] This system is therefore continuously primed for explosive C3 activation, the rate of C3 activation governed by the stability of the C3bBb enzyme complex (which, analogously to the C4b2a complex, also serves to activate C5). Activators of this pathway, which include immune complexes, bacterial lipopolysaccharides and yeast cell walls, certain viral membranes and virally infected cell lines, and the autoantibody C3 nephritic factor, share the common property of facilitating stability of the assembled C3bBb enzyme, sequestered from the regulatory control of inhibitors found in plasma.

Initiation of the alternative pathway involves the conformational activation of C3, which is thought to be closely linked to rupture of the internal thioester bond within the C3b domain of the protein.[21] [33] [37] One pathway for activation of C3 is by peptide cleavage to C3b (e.g., as initiated by the classical pathway enzyme C4b2a). In this manner, C3b formed through the classical pathway can directly initiate assembly of the alternative pathway enzyme complex (Fig. 37-1 (Figure Not Available)). In the absence of classical pathway activation, C3 conversion to an activated state can also occur by spontaneous hydrolysis of the thioester bond within the intact protein, resulting in a molecule (C3*H_2O) that is conformationally similar to C3b. Slow conversion of C3 to C3*H_2O is believed to proceed continuously under normal plasma conditions. Conversion of C3 to either C3*H_2O or C3b results in expression of a binding site for factor B, the proenzyme of the alternative pathway C3/C5 convertase.

When bound to C3*H_2O or C3b, factor B becomes sensitive to proteolytic cleavage by factor D, a trace plasma enzyme. [5] [38] Factor D is a unique enzyme as it neither requires enzyme cleavage for activation nor is regulated by plasma serine protease inhibitors (serpins). Rather, the activity of factor D is conformationally regulated through binding to its substrate, factor B in complex with C3*H_2O or C3b. [38] Proteolysis of factor B by factor D liberates a 30-kd fragment (Ba), leaving the larger Bb fragment (80 kd) attached to C3*H_2O or C3b. Through a catalytic site in Bb, the complex of C3*H_2O,Bb can proteolytically convert C3 to C3a and C3b. Nascent C3b generated by this mechanism is capable of binding additional factor B (which is then converted by factor D to active C3bBb), thereby amplifying the reaction. Activation of C5 by the alternative pathway convertase occurs by identical peptide cleavage to that initiated by C4b2a, resulting in formation of C5a and C5b. Again, C3b covalently deposited in the vicinity of the C3bBb complex is thought to be required for proper presentation of C5 to the catalytic site of the enzyme.

The Lectin Pathway of Complement Activation in Innate Immunity

An element of humoral immune defense with particular significance in the neonatal period is the capacity to recognize and clear microbial pathogens during the months before development of a full repertoire of immunoglobulin-secreting memory B lymphocytes. It is now recognized that a key element of this innate immunity is a C1-like serum enzyme complex that can activate C4 and C2 and is triggered through interaction with the mannose-rich lipopolysaccharide commonly found on the surfaces of microorganisms.[10] [39] [40] The first component of this complex is designated serum mannose (or mannan)-binding protein (MBP), a Ca^{2+} -dependent lectin that is structurally related to two other serum lectins, conglutinin and CL-43, and to two pulmonary surfactant proteins, SP-A and SP-D. These proteins all exhibit structural similarity to C1q, having globular and collagen-like domains, and collectively make up the collectin protein family. A C-terminal carbohydrate recognition domain with affinity for N-acetylglucosamine confers the capacity for MBP to directly opsonize microorganisms expressing mannose-rich surface coats. In blood, MBP circulates as a stable complex with a C1s-like proenzyme (designated MBP-associated serine protease, or MASP), a 93-kd polypeptide with sequence homology to both C1r and C1s. Binding of the MBP-MASP complex to the appropriate carbohydrate surface results in autoactivation of MASP by internal peptide cleavage, converting MASP to an active serine protease. Like C1s, active MASP exhibits the capacity to proteolytically activate both C4 and C2 to initiate assembly of the C4bC2a enzyme complex. In contrast to C1s, active MASP also exhibits direct C3-cleaving activity, thereby accelerating C3b generation and the recruitment of the alternative complement pathway through assembly of C3bBb. MBP has also been found to associate with the $C1r_2C1s_2$ complex and support C4/C2 activation by this enzyme , although the physiologic significance of the C1 proteases in MBP-initiated activation of complement remains unclear.

MBP-mediated opsonization and complement activation have been demonstrated for a wide range of microorganisms, including both gram-negative and gram-positive bacteria, fungi, mycobacteria, and parasites, as well as certain enveloped viruses, including influenza virus, HIV-1, and HIV-2. The importance of this pathway of complement activation to innate immunity in man is suggested by accumulating evidence that patients with inherited MBP deficiency have increased susceptibility to recurrent infection as a result of a complement-dependent opsonic defect. [10] [39] [40]

Assembly of the Membrane Attack Complex

Membrane damage by the complement system is initiated through the interaction of C5b (generated by either the classical pathway or alternative pathway C3/C5 convertase) with plasma proteins C6, C7, C8, and C9.[8] [41] [42] [43] C5 shares homology with C3 and C4 but does not contain the internal thioester bond that is found in those proteins. C6, C7, C8, and C9 share structural motifs that are also found in the cytolytic polypeptide perforin, a membrane pore-forming protein contained in the intracellular dense granules of cytotoxic lymphocytes. The first step

in assembly of the C5b9 complex is the formation of a complex between C5b and C6, through a short-lived interactional site that is expressed by nascent C5b. Association of C6 with C5b is thought to occur while C5b remains in contact with membrane-bound C3b. Upon reaction of C7 with the C5b6 complex, a membrane interactional site is transiently expressed (primarily by the C7 subunit), enabling the C5b67 complex to deposit directly onto membrane surfaces. Once bound to a membrane surface, the C5b67 complex expresses a stable binding site for a single molecule of C8. Association of C8 with the complex results in insertion of a portion of the molecule into the hydrophobic core of the membrane and expression of a binding site for C9. The interaction of C9 with membrane-bound C5b8 results in its elongation and insertion into the membrane interior, concomitant with a polymerization of multiple C9 into a large torus-ringed tubular structure. This tubule of polymerized C9 is readily detected projecting from the membrane surface in electron micrographs of complement-damaged cells.

Insertion of the C5b9 proteins affects both the structural and the functional properties of the plasma membrane. [41] [42] [43] [44] [45] [46] [47] Intercalation of hydrophobic

domains of C8 and C9 alters the bilayer arrangement of membrane lipid and can thereby increase cell-surface exposure of phosphatidylserine and other acidic phospholipids that are normally sequestered to the inner surface of the plasma membrane. By exposing these phospholipids, the C5b9 complex can potentially provide catalytic membrane surfaces for assembly of those enzymes of the coagulation pathway that are stabilized by binding to acidic phospholipid. In addition to altering membrane structure, the inserted C5b9 proteins increase membrane permeability to electrolytes and other small molecules. In the absence of compensatory mechanisms, insertion of these proteins ultimately leads to a complete collapse of transmembrane electrochemical gradients and lytic rupture of the plasma membrane.

REGULATORY PROTEINS OF THE COMPLEMENT SYSTEM

The classical and alternative activation pathways are under strict control designed to limit dissemination of the reactions in plasma and to inhibit activation of the membrane attack complexes at the surface of blood cells and on other autologous membranes that are normally exposed to complement. Inhibitors identified to date include specific binding proteins and proteases present in plasma, as well as several important cell-surface proteins. [48] [49] [50]

C1-INH

C1-INH is a serpin that binds irreversibly to activated C1r and C1s, blocking their enzymatic activity and dissociating their attachment to C1q. [51] [52] This inhibitor also plays important enzyme regulatory roles in the kinin-generating, intrinsic coagulation, and fibrinolytic pathways through interaction with plasmin, kallikrein, and factors XIa and XIIa.[5] Inherited deficiency of C1-INH underlies the syndrome of hereditary angioedema. [52] Antibodies to C1-INH have been observed in certain lymphoproliferative disorders and can give rise to an acquired syndrome of angioedema that is analogous to the hereditary angioedema seen in C1-INH-deficient patients.

Carboxypeptidase N

The biologic activity of C3a, C4a, and C5a is regulated by carboxypeptidase N, a plasma enzyme that rapidly removes the carboxyl-terminal arginine residue from each of the anaphylatoxins.[53] In the case of C3a, removal of this amino acid abolishes its biologic activity. By contrast, carboxypeptidase N-treated C5a (designated $C5a_{desarg}$) retains about 510% of its chemotactic and neutrophil-stimulating activity. [54]

C3b/C4b-Binding Proteins

The C3b/C4b-binding proteins serve to bind C3b or C4b and to regulate assembly of the C3/C5 convertases. [15] [16] [48] [55] [56] Additionally, several of these proteins serve as physiologically important plasma membrane receptors (Tables 37-1 and 37-2). The genes for factor H, C4b-bp, DAF, MCP, CR1, and CR2 are all localized to the long arm of chromosome 1 and compose a family of closely related genes designated regulators of complement activation (RCAs). [15] [16] [48] These proteins share a common globular structure consisting of homologous cysteine-rich repeating units (SCRs), each of approximately 60 amino acids. This characteristic structure is also found in enzymes that interact with C3 or C4, including C1s, C2, and factor B, as well as in a number of unrelated proteins. CR3 and CR4 are C3 receptors that belong to the Leu-CAM family of $_2$ -integrin cell adhesion receptors. [25] These receptors do not contain the SCR motif.

Factor H

Factor H is a plasma protein comprised of 20 SCRs that binds C3b and serves to inhibit association of either C3b or C3*H2O with factor B (restricting assembly of the C3bB proenzyme).[48] [57] Additionally, factor H promotes the dissociation of the assembled C3bBb enzyme complexes and serves as a cofactor for proteolytic degradation of C3b by factor I. [58] Limited intrachain proteolysis by factor I initially converts C3b to inactivated C3b (iC3b), which remains covalently bound to its original acceptor surface (Fig. 37-2). Subsequent degradation of the iC3b -chain by factor I releases the large C3c fragment (150 kd), leaving C3dg (41 kd) still attached to the acceptor surface through the C3d domain of the fragment. Bound C3dg is normally the final C3b degradation product remaining on circulating cells in vivo. In contrast to factor H (which promotes dissociation of the C3bBb), factor P (properdin), another regulatory protein found in plasma, acts to stabilize the alternative pathway enzyme complex.[59] [60]

C4b-Binding Protein

C4b-bp is an acute phase reactant protein found in plasma that binds to C4b, serving both to block its association with C2 and to accelerate dissociation of the assembled C4b2a enzyme complex.[61] [62] Additionally, C4b-bp serves as a cofactor to facilitate proteolytic degradation of C4b by the serine protease factor I, which splits the larger C4c fragment from the molecule, leaving C4d bound to the original acceptor surface. [58] [63] Approximately 50% of C4b-bp normally circulates in plasma as a complex with protein S, a vitamin K-dependent protein with regulatory function in the coagulation system. Thus an elevation in circulating C4b-bp, as can occur during the acute phase response to injury, has potential to increase the risk of plasma clotting. [64] C4b-bp is composed of seven -chains, each with eight SCRs that contain the binding site for C4b, and of a single -chain with three SCRs that form the binding site for protein S. [65] [66] [67] [68]

Regulation at Cell Surfaces

Surfaces that promote activation of the alternative pathway are distinguished by their capacity to stabilize the C3bBb enzyme complex, away from regulatory control by factor H in plasma, whereas nonactivating surfaces facilitate factor H binding to C3b. Although the exact chemical and physical properties that distinguish complement-activating from nonactivating surfaces remain to be elucidated, it appears that the total content and chemical modification of cell surface sialic acid residues can be

determining factors.[69] [70] [71] The inhibitory activity of factor H is increased when C3b is bound to a surface containing polyanions such as sialic acid, reflecting an increase in the apparent affinity of factor H for C3b under these conditions. [70] [72] Consistent with these data, a specific polyanion-binding site in factor H has been localized to the 13th SCR domain of the protein. [73] In addition to the nature of the glycosidic residues presented by the cell surface, the propensity for complement activation is also governed by the expression of specific membrane proteins that exhibit avidity for C3b and C4b and that exert complement regulatory function through their interaction with these membrane-bound components of the C3/C5 convertases. [16] [49] [50] [74] [75]

Decay-Accelerating Factor

Decay-accelerating factor (DAF, CD55) is a 70-kd single chain glycoprotein normally expressed on the surface of red cells, platelets, leukocytes, endothelium, and other cells that serves to accelerate the dissociation of the subunits of the membrane-assembled C4b2a and C3bBb enzyme complexes. [49] [50] [74] [75] DAF does not function as a cofactor for the inactivation of C4b or C3b by factor I. [76] The protein is composed of four SCRs, three of which are essential to its function. [77] In addition to containing the SCR motif, DAF belongs to a class of membrane proteins (examples of which include erythrocyte acetylcholinesterase, lymphocyte LFA-1, leukocyte 5-ectonucleotidase, leukocyte Fc III receptors, neutrophil alkaline phosphatase, and complement regulatory protein CD59) that are attached to the cell surface by glycosidic linkage to the membrane lipid phosphatidylinositol. [78] [79] [80] Defective biosynthesis of the glycosyl phosphatidylinositol (GPI) anchor that normally attaches

DAF, CD59, and other GPI-anchored proteins to the cell surface underlies the syndrome of paroxysmal nocturnal hemoglobinuria (PNH; see Chap. 20),[80] [81] [82] whereas polymorphisms in the DAF gene itself account for the Cromer blood group antigens (see Chap. 132).[83]

Membrane Cofactor Protein

Membrane cofactor protein (MCP, CD46) is a 45- to 70-kd glycoprotein distributed on all human leukocytes and platelets but absent on erythrocytes. [16] [48] [84] This protein contains four SCRs that function in binding C3b, C4b, and iC3b. Additionally, MCP exhibits potent cofactor activity for factor I-mediated proteolysis of C3b and C4b. DAF and MCP act in concert on the membrane surface and are complementary in their activity: DAF exhibits only decay-accelerating activity but no cofactor activity for factor I, while MCP serves as cofactor for factor I but does not promote decay of the C3 convertase enzymes.

CR1

CR1 (CD35), the principal cellular receptor for C3b, also serves as an important cofactor for proteolysis of C3b and C4b by factor I. In contrast to MCP, CR1 exhibits DAF-like function and contributes to the decay of the C3 convertases. [48] [49] [85] [86] [87] Recombinant forms of CR1, MCP, and other complement regulatory proteins may have future therapeutic application as inhibitors of complement activation. [48] [50] [88] [89]

Inhibitors of the Membrane Attack Complex

Formation of C5b on human blood cells is regulated through control of the C3/C5 convertases, exerted by DAF and other inhibitors. Furthermore, the C6-binding site that is exposed when C5 is activated to C5b is highly unstable, limiting the rate of formation of C5b6. Once formed, diffusion of the C5b67 complex to innocent bystander cells is limited by the very short lifetime of the membrane-interactional site exposed in this complex. [1] [90] Membrane damage to autologous cells exposed to activated complement is also restricted by inhibitory proteins found in plasma and on cell surfaces.

Vitronectin (S-Protein) and Clusterin

The diffusion of functional C5b9 complexes from the initial target of complement activation to other cells is restricted by several scavenger proteins in plasma that bind newly formed C5b67, thereby preventing its dissemination to other cells. Proteins with this property include vitronectin (also referred to as S-protein), as well as certain serum lipoproteins, including clusterin (SP40,40). [91] [92] [93] [94] [95] Upon binding one molecule each of C8 and C9, the vitronectin-C5b9 complex (SC5b9) circulates inactive in plasma until cleared, providing a serologic marker of intravascular complement activation that has proceeded to assembly of the C5b9 complex. Vitronectin also contains the RGD (Arg-Gly-Asp) peptide sequence found in fibrinogen, fibronectin, and other integrin-binding proteins, which provides a mechanism for interaction of SC5b9 complexes with plasma membrane integrin receptors on a variety of cells. [96] [97]

CD59 (HRF-20) and Other Homologous Complement Restriction Factors

In addition to the protection afforded by vitronectin and other C5b9 scavenger proteins in plasma, human blood cells, vascular endothelial cells, and many other tissues are also protected from lytic damage by human complement through the cell-surface expression of a protein(s) that specifically serves to inhibit intercalation of C9 into the plasma membrane.[49] [98] [99] [100] [101] [102] [103] [104] This cell-surface inhibitor of the membrane attack complex appears to recognize specific domains contained within the human C8 -chain and human C9 that are involved in the transformation of C9 from its globular conformation in plasma to a membrane-embedded homopolymer with cytolytic activity.[102] [105] [106] [107] [108] Proteins with this function have been termed homologous restriction factors, because of their apparent specificity for human C8 and C9, as opposed to these same complement proteins derived from the serum of other species. The best-characterized human complement homologous restriction factor, designated CD59, is an 18- to 22-kd cell-surface glycoprotein that was first isolated from the erythrocyte membrane. [100] [101] [102] [103] [104] [106] In its mature form, this protein is comprised of a 77-residue polypeptide that is folded through five disulfide bonds, the resulting structure showing similarity to that identified in a group of unrelated proteins, designated the Ly6 superfamily. [109] Like DAF, CD59 is tethered at the carboxyl-terminus of the polypeptide to the cell surface by glycosidic linkage to phosphatidylinositol. [110] Deletion of CD59 from the surface of erythrocytes and other blood cells can occur as the consequence of the GPI-anchoring defect that underlies PNH, which accounts for the unusual sensitivity of the defective blood cells that arise in this disorder to lysis by the C5b9 proteins. A putative 64-kd human erythrocyte membrane protein (commonly referred to as HRF, or C8-binding protein) had been reported to exhibit many of the complement-inhibitory properties that are now recognized to reside in CD59. [111] [112] [113] The capacity of nonprimate cells to resist injury by the human C5b9 complex when transfected with cDNA encoding CD59 suggests one potential strategy for genetic engineering of tissues and organs that are inherently protected from the lytic action of complement in human serum.[114] [115] [116]

CELLULAR RESPONSES MEDIATED BY COMPLEMENT RECEPTORS

Activated components of the complement system contribute to virtually every aspect of inflammatory response, including increased vascular permeability, leukocyte chemotaxis, leukocyte activation, immune adherence and phagocytosis, solubilization

and clearance of immune complexes, and regulation of the lymphocytic immune response. [1] [2] [3] [4] [7] [48] [117] These proteins also play a direct role in mediating cell lysis through both intravascular and extravascular mechanisms. In addition to their role in host defense and inflammation, there is evidence that complement proteins can also interact with components of the coagulation, fibrinolytic, and kinin systems to alter vascular hemostatic mechanisms. [5] [46] [118] [119] In general, the biologic effects of complement are initiated through binding of activated components to specific complement receptors distributed on the surface of various blood and vascular cells. This binding interaction can serve to remove immune complexes and other complement-coated particles from plasma, through direct adherence to circulating blood cells. In many cases, binding of a complement protein to its cell-surface receptor elicits specific cellular responses that are evoked by receptor-coupled signaling across the plasma membrane.

Responses Mediated by C1q Receptors

Two types of widely expressed plasma membrane receptors for the C1q subunit of C1 have been described: a 60-kd calreticulin homolog, designated cC1qR, that binds to the collagen-like stalk of C1q, and gC1qR, a 33-kd glycoprotein with affinity for the globular heads of C1q. [120] [121] [122] [123] [124] [125] [126] Binding of C1q to these receptors prevents the formation of C1 and can be inhibited by either type 1 collagen or the $C1r_2C1s_2$ enzyme complex. In addition to C1q, gC1qR has been shown to bind vitronectin and thus may participate in the clearance of opsonized particles or cooperate with vitronectin in the inhibition of complement-mediated cytolysis. [127] C1q has been shown to bind to blood platelets and to inhibit collagen-induced platelet aggregation by competing with collagen at the platelet collagen receptor. By contrast, multimeric aggregates of C1q can initiate platelet activation and aggregation. Aggregates of C1q have also been shown to elicit oxidative bursts in neutrophils and to potentiate antibody-dependent cellular killing by peripheral blood lymphocytes. These interactions potentially contribute to the inflammatory responses elicited by C1q-containing immune complexes.

Anaphylatoxin Receptors

The amino-terminal peptide fragments that are released from the -chains of C3, C4, and C5 during complement activation, collectively referred to as complement anaphylatoxins, share considerable structural and functional homology and exhibit a spectrum of biologic effects during an inflammatory response. These effects include smooth muscle contraction, histamine release from mast cells, vasodilation, and increased vascular permeability.

C3a/C4a Receptor

C3a, a 77-amino acid peptide, causes increased vascular permeability and stimulates the degranulation of mast cells and basophils, resulting in the release of histamine and other vasoactive compounds. [24] [53] [54] [128] The C3a receptor has recently been cloned. The cDNA encodes a 53-kd G-protein-coupled receptor with 37% nucleotide identity with the C5a receptor. [129] Because many of the biologic effects of C3a are also shared by C4a (77 amino acids), it has been suggested that they bind to the same receptor, although evidence for a separate C4a receptor has also been presented. [130] [131]

C5a Receptor

C5a, a 74-amino acid peptide, interacts with cell-surface receptors that are specific for C5a (and distinct from the C3a/C4a receptors) to stimulate degranulation of mast cells and basophils. [24] [132] C5a also plays a major role in the recruitment and activation of human neutrophils and macrophages at sites of complement activation. C3a and C5a receptors can undergo internalization after stimulation, resulting in a desensitization of the cells to further stimulation. Like the receptor for C3a, the C5a receptor is G protein coupled and is a member of the superfamily of rhodopsin-type receptors that contain seven transmembrane loops. [132] The deduced amino acid sequence of the C5a receptor shows homology with the leukocyte N-formyl peptide receptor, and the gene for the C5a receptor is closely linked to the formyl peptide receptor genes on chromosome 19. [24]

Through activation of its cellular receptors, C5a initiates several important inflammatory responses. First, C5a serves as a potent chemotactic agent for human neutrophil and mononuclear phagocyte migration. Stimulation by C5a has been shown to increase neutrophil adhesiveness and to initiate neutrophil aggregation. C5a also elicits oxidative metabolism, leading to free radical formation and the secretory release of lysosomal enzymes from neutrophils and a variety of phagocytic cells. These pro-inflammatory changes in C5a-stimulated neutrophils are accompanied by increased surface expression and activity of both CR1 (CD35) and CR3 (CD11b/CD18), thereby promoting leukocyte adhesion as well as phagocytosis of opsonized particles. [24] [133] It has been reported that C5a induces rapid expression of endothelial P-selectin, secretion of endothelial von Willebrand factor, and increased adhesiveness of neutrophils to endothelial cells. [134] [135] The putative role of C5a in mediating neutrophil rolling, attachment, and adhesion is of particular interest in light of its implicated role in the pathogenesis of lung disease. Recent evidence also suggests that inflammatory and immunoregulatory responses to C5a may be mediated through induction of interleukin-6 (IL-6) synthesis by human monocytes. [136] The potent chemotactic and leukocyte-activating properties of C5a (and $C5a_{desarg}$) suggest an important role in the vascular response to complement activation in humans. In particular, these peptides have been implicated as mediators of the neutropenia associated with hemodialysis and cardiopulmonary bypass and may give rise to the pulmonary leukostasis associated with adult respiratory distress syndrome and acute transfusion reactions. [137] [138] The role of C5a in the pathogenesis of endotoxic shock syndrome is suggested by studies in primates, in which functionally blocking antibodies against C5a have been shown to attenuate respiratory distress and enhance survival after gram-negative bacteremia. [139]

Expression of receptors for C3a and C5a had generally been thought to be limited primarily to myeloid cells. The recent cloning of both receptors has made it possible to examine cellular expression of mRNA encoding these receptors in greater detail, which has revealed that both receptors are expressed in many tissues distributed throughout the body and are not restricted to blood leukocytes. [24] [129] [140]

C3b Receptors

As noted, cellular receptors that bind C3b and C4b play an important role in the inactivation of these proteins by providing cofactor function for the serum protease, factor I. By contributing to the degradation of C3b deposited onto the plasma membrane, these receptors serve to limit the accumulation of C3b on circulating blood cells and restrict dissemination of the C3/C5 convertase reaction. In addition to this function, it is now recognized that these cellular receptors for C3b (and its

degradation products) play a central role in mediating cellular adherence and ultimate clearance of immune complexes and other C3b-coated particles and cells. [48] [141] [142] [143]

The cellular distribution and ligand specificities of the various C3 receptors are summarized in Table 37-2 . Although it is distributed in the plasma membrane of nearly all blood cells, the preponderance of CR1 found in the blood of humans and other primates is expressed on the surface of erythrocytes.

In humans, the clearance of immune complexes from the circulation is principally mediated by an initial adsorption to red cells that is mediated via interaction of multiple C3b and/or C4b incorporated into the immune complex with erythrocyte CR1 receptors. [48] [144] [145] After adsorption to the erythrocyte surface, proteolytic processing of C3b provides a mechanism for transfer of the bound immune complex to cells of the reticuloendothelial system: Upon conversion of C3b to iC3b and C3dg (by factor I), the reduced affinity of these degraded C3b fragments for CR1 promotes release of the immune complex from the erythrocyte surface (which contains only the CR1 receptor), followed by endocytic uptake of the complexes by phagocytic cells that express CR3 and CR4. Studies with radiolabeled C3b-coated immune complexes suggest that these immune complexes are stripped from the erythrocyte surface during passage through the liver and, to a lesser extent, the spleen. These data implicate hepatic Kupffer cells as the principal scavenger of C3b-containing immune complexes that are initially transported by red cells. [146]

In addition to serving as receptors for cellular adherence to immune complexes (and other C3-containing particles), these complement receptors are also known to provide stimulatory signals for leukocyte activation. [141] [143] [147] [148] Binding of C3b aggregates to leukocyte membrane CR1, either alone or in concert with occupancy of cell surface Fc receptors by IgG, is known to trigger an endocytic response from neutrophils and mononuclear phagocytes, which is accompanied by enzyme secretion and a cell respiratory burst. The capacity of iC3b-coated particles to trigger similar responses from neutrophils and monocytes suggests a similar role for CR3 and CR4. The distribution of CR1 (the C3b receptor) and CR2 (the C3dg receptor) on B lymphocytes suggests possible roles for these receptors in modulating immune responses. For example, interaction of CR1 and CR2 with their respective ligands has been shown to promote B-lymphocyte proliferation and differentiation into memory B cells, although the physiologic significance of these responses remains to be clarified. [7] [149] Aggregated C3-split products have also been reported to augment the response of IL-2-treated helper T lymphocytes, suggesting a co-stimulatory function. [149] [150] Decreased numbers of erythrocyte CR1 receptors have been documented in patients with systemic lupus erythematosus (SLE), AIDS, and lepromatous leprosy, diseases that are also associated with increased levels of circulating immune complexes, reflecting polyclonal B-cell activation. As indicated, CR2 has been identified as the B-lymphocyte receptor for the Epstein-Barr virus, implicating this receptor in the pathogenesis of infectious mononucleosis and Burkitt lymphoma. [7] [151] [152] Finally, CR3 distributed on natural killer lymphocytes has been implicated in promoting adhesion and enhancing the cytotoxic response to target cells bearing surface iC3b. [153] [154]

CR1

CR1 (CD35), also known as the immune adherence receptor, is the principal cellular receptor for C3b. It is a single-chain membrane glycoprotein that is distributed on erythrocytes, neutrophils, eosinophils, monocytes, B lymphocytes, subsets of T lymphocytes, macrophages, follicular dendritic cells, and glomerular podocytes. [48] [142] CR1 is not found on human platelets. Four polymorphic variants (160250 kd) encoded by four codominantly inherited alleles have been identified, and the cellular concentration of this receptor also exhibits genetic polymorphism. [155] [156] [157] [158] [159] The primary role of CR1 is to mediate binding of particles coated (opsonized) with C3b or iC3b to neutrophils and monocytes that express this receptor, for subsequent phagocytosis. In addition to its role in immune adherence and clearance, CR1 also contributes to the regulation of complement by acting as cofactor for the proteolytic degradation of both C3b and C4b by factor I and by accelerating decay of the C3 convertases.[86] [87] The most common allotype of CR1 (220 kd) contains 30 SCRs. The ligand-binding sites have been localized to SCRs 13 for C4b and to SCRs 810 (duplicated in SCRs 1517) for C3b and C4b.[160] More recent studies have further defined amino acids within these regions that are critical for C3b versus C4b binding.[161] [162] [163]

CR2

CR2 (CD21) is a 145-kd glycoprotein found primarily on B lymphocytes, T lymphocytes, and follicular dendritic cells, but not on phagocytic cell types. This protein functions as a receptor for C3d, C3dg, and iC3b, and is the plasma membrane receptor of the Epstein-Barr virus. [7] [142] [143] [164] [165] CR2 contains 15 SCRs. The binding sites for both the Epstein-Barr virus and C3dg have been mapped to a common domain on CR2, which includes the first two SCRs. [151] [152] [166] CR2 on follicular dendritic cells binds C3d- or C3dg-bearing immune complexes. On B lymphocytes, stimulation through CR2 is thought to play a role in proliferation and differentiation. CR2 exerts an important co-stimulatory function within a noncovalent complex with CD19 and CD81, lowering the amount of specific antigen required for optimal activation through the B-cell receptor when the antigen is coated with C3dg. [148] Recent evidence also implicates CR2 in the infection of B lymphocytes by HIV-1 (see discussion under Acquired Immunodeficiency Syndrome).[167] [168]

CR3, CR4

CR3 (CD11b/CD18, Mac-1) and CR4 (CD11c/CD18) belong to the Leu-CAM family of leukocyte adhesion molecules, which also includes LFA-1 (CD11a/CD18). They constitute the $_2$ subfamily of membrane integrin receptors, two-chain glycoproteins consisting of a common -chain (CD18 antigen) and a noncovalently associated -subunit. [25] [169] [170] These receptors do not contain the SCR motif that is common to CR1, CR2, and other C3b-binding proteins. Of note, CR4 originally designated another C3 receptor (the platelet C3dg receptor) that is not related to CD11c/CD18. [171] CR3 and CR4 are cellular receptors for iC3b, and are distributed on neutrophils, monocytes, and other mononuclear phagocytes and natural killer lymphocytes. They are not found on B lymphocytes, glomerular podocytes, or erythrocytes. CR3 participates in immune adherence and phagocytosis by promoting adhesion of granulocytes and monocytes to iC3b-coated cells and particles, and plays a role in lymphocyte-mediated antibody-dependent cellular toxicity. [170] [172] CR4 shares these functions and has been implicated in granulocyte-mediated lysis of erythrocytes.[172] Additionally, CR3 is involved in polymorphonuclear leukocyte homotypic aggregation through an unidentified counter-receptor, in cellular adherence to activated endothelial cells via ICAM-1, and in cellular adhesion to fibrinogen and coagulation factor X. [173] These functions and recognition of iC3b have been attributed to the so-called I-domain of CR3.[174] CR3 also expresses a lectin-like domain that binds certain polysaccharides, including -glucan, providing a recognition site for phagocyte attachment and phagocytosis of unopsonized yeast cells. [175] [176] A lectin-carbohydrate bridge clustering CR3 and certain GPI-anchored receptor glycoproteins (including FcRIIIb and the receptors for urokinase plasminogen activator) has been demonstrated in which CR3 is stimulated when ligand binds to these GPI-anchored receptors.[177] Expression of the receptor function of CR3 and CR4 requires cell activation, which entails both redistribution to the cell surface and increased affinity for their ligand, possibly through phosphorylation of cytoplasmic domains of the CD18 subunits. [131] [178] [179] Congenital deficiency of these receptors gives rise to the disorder leukocyte adherence deficiency, which is associated with defective chemotaxis, reduced adhesion with impaired transmigration across endothelium, and impaired cell-mediated killing of microbial pathogens. [170] [180] [181] Neutrophils from patients with

complete leukocyte adhesion deficiency fail to amplify the phagocytic function in response to stimulation. [182]

Cellular Responses to the C5b9 Complex

The cytolytic activity of the complement system resides in the capacity of the C5b9 proteins to insert into phospholipid bilayers, thereby increasing membrane permeability to aqueous solute. This membrane permeability-inducing function of the C5b9 complex can be observed for a variety of cellular and synthetic lipid membranes, suggesting that it is directly mediated through interaction of these proteins with the lipid bilayer and does not require binding to specific receptors on the surface of the target cell. The affinity of activated C5b9 for phospholipid bilayers confers a capacity to interact with the membrane envelope of virtually every biologic cell, a feature that at least in principle enables the complement system to defend against a limitless variety of potential pathogens.

Although the cytolytic function of these proteins is consistent with their role in immunologic defense and is a prominent feature of their interaction with nonhuman cells, accumulating evidence suggests that some of the biologic manifestations of complement activation relate to the capacity of the assembled C5b9 proteins to evoke specific cellular responses, without lytic consequence for the target cell. [41] [44] [46] [118] [183] [184] [185] It is now recognized that specific inhibitors of this protein complex are expressed on the surface of human blood cells and vascular endothelium. By limiting the extent of activation and membrane insertion of C9, the cytolytic activity of the complement system is markedly attenuated on these cell membranes. In addition to protecting these cells from lysis during intravascular complement activation, the resistance to complement-mediated cytolysis conferred by these plasma membrane inhibitors may have other biologic consequences. For example, it

has been shown that insertion of the C5b9 proteins into the plasma membrane of human platelets, neutrophils, cultured vascular endothelium, and numerous other cells elicits activation-related responses, indicating that these proteins trigger stimulatory intracellular metabolic pathways without lytic breakdown of the plasma membrane. Among the cellular changes that have been reported to result from sublytic plasma membrane damage by C5b9 proteins are initiation of arachidonate metabolism (leading to the biosynthesis of various active prostanoids), activation of intracellular C-kinases, induction of shape change, secretory exocytosis of the contents of intracellular storage granules, an oxidative respiratory burst, induction of mitogenic responses, induction of IL-8 and monocyte chemoattractant protein-1 synthesis, expression of receptor sites for serum lipoproteins, cell binding and activation of plasminogen, vesiculation of cell-surface components from the plasma membrane, and the induction of a transbilayer migration of plasma membrane phospholipids with exposure of membrane-binding sites for coagulation factors and other plasma proteins that exhibit affinity for anionic phospholipid surfaces. [183] [186] [187] [188] [189] [190] [191] [192] [193] [194] The cellular changes initiated by the C5b9 proteins generally show a dependence on the level of extracellular calcium, suggesting that the stimulatory effects observed reflect increased cytoplasmic [Ca^{2+} +], mediated through the influx of this ion across the complement pore formed in the plasma membrane. [195]

COMPLEMENT IN DISEASE

Genetic Polymorphism and Deficiency States

Insight into the functional importance of individual complement components in man has come from the study of complement deficiency states. Additionally, genetic polymorphisms of many of the complement proteins have now been identified. In several cases these polymorphisms have proved to be of serologic and immunohematologic interest, and have also provided clues to specific protein structure-function relationships. cDNA and genomic clones for most of the complement proteins and receptors have been isolated and the chromosomal location of the genes identified (Table 37-3). The discussion in this section is limited to selected examples of complement deficiency states and allelic variants that are of particular hematologic interest. For extensive review of the structure and regulation of the complement genes and of the known complement deficiency states, the reader is referred to the literature. [7] [196] [197] [198] [199] [200] [201]

C1-INH Deficiency

Inherited deficiency of C1-INH underlies the syndrome of hereditary angioedema. The gene for this serpin protease inhibitor is localized to p11.2q.13 of chromosome 11. Deficiency states can arise through subnormal production of functional C1-INH, or by production of dysfunctional protein. [52] [200]

Class III Genes and C4 Polymorphism

The genes for C4, C2, and factor B form a tight cluster (with the gene for enzyme 21-hydroxylase) in the MHC on the short arm of chromosome 6, a region designated MHC class III.[202] Class III lies between the class I and class II genes of the HLA system. C2 deficiency is commonly associated with SLE and is one of the most common complement deficiency states. Deficiency of factor B has not been described, which may reflect a requirement of this primary C3 activator for survival. Whereas genetic polymorphisms of several of the complement proteins have now been described, that of C4 is of greatest immunohematologic interest. Two isotypes, C4A and C4B, with distinct functional and serologic properties have been characterized. [35] The functional distinction between C4A and C4B isotypes relates to differences in the reaction mechanism and the type of bond that is preferentially formed by the internal -chain thioester group. [203] The C4A isotype preferentially transacylates onto amino group nucleophiles, while the C4B isotype reacts with equal efficiency toward amino or hydroxyl groups. The C4B variant shows greater hemolytic activity owing to increased binding to the red cell surface, whereas the C4A variant binds more efficiently to C1-containing immune aggregates, which serves to inhibit immune precipitation of these complexes. [204] The haplotype C4AQO is linked to SLE and other autoimmune diseases, which may reflect this differential processing of immune complexes. An increased incidence of SLE is also associated with other complement gene defects that would potentially affect clearance of immune complexes, including quantitative or functional defects in the classical pathway components C1q, C4, or C2, or in the plasma membrane receptors that function in the clearance of opsonized immune complexes, particularly CR1. [196] [197] [205] [206] [207] At a serologic level, the C4A and C4B isotypes give rise to the Rodgers (Rg) and Chido (Ch) immune serotypes detected in red cell cross-matching. These antisera detect the antigenic differences of the erythrocyte-bound C4d fragment that originate from the C4A and C4B isotypes: most simply, C4A-coated red cells type Rg+, Ch, while C4B-coated cells type Rg, Ch+. For each, numerous allotypic and isotypic variants have been identified, several of which have been characterized at the molecular level, permitting precise epitope mapping. [35] [208]

Deficiencies and Polymorphisms of Plasma Membrane Complement Receptors and Regulatory Proteins

CR1/CR2

The gene for CR1 is located within the RCA group on the long arm of chromosome 1. [205] [209] Several CR1 allotypes (ranging from

TABLE 37-3 -- Complement Components: Gene Location and Deficiency States

Component	Chromosomal Gene Location	Disease Associated with Deficiency
Components of Activation Pathways		
C1q	1	SLE; pyogenic infection; glomerulonephritis
C1r/C1s	12	SLE; infection; nephritis
C4	6 (MHC class III)	SLE; infection; immune complex disease
C2	6 (MHC class III)	SLE; infection; nephritis
C3	19	SLE; infection; nephritis
Factor B	6 (MHC class III)	
Factor D	19	Neisserial infection
Factor I	4	Pyogenic infection
Components of Membrane Attack Complex		
C5	9	Neisserial infection; SLE
C6/C7	5	Neisserial infection; SLE, Sjögrens
C8	and : 1; : 9	Neisserial infection
C9	5	Neisserial infection; also asymptomatic
Plasma Regulatory Proteins		
C1 Inh	11	Hereditary angioedema
Properdin	X	Neisserial infection; other pyogenic infection

C4bp	1 (RCA gene cluster)	
Factor H	1 (RCA gene cluster)	Infection; hemolytic uremic syndrome; glomerulonephritis
Vitronectin (S protein)	17	
Membrane Regulatory Proteins		
DAF (CD55)	1 (RCA cluster)	No symptoms with isolated deficiency Inab phenotype[a]
MCP (CD46)	1 (RCA cluster)	
HRF-20 (CD59)	11	PNH-like symptoms with isolated deficiency[a]
Membrane Receptors		
CR1 (CD35)	1 (RCA cluster)	SLE
CR2 (CD21)	1 (RCA cluster)	
CR3 (CD11b/CD18)	16	LAD
CR4 (CD11c/CD18)	21	LAD

Abbreviations: SLE, systemic lupus erythematosus; RCA, regulators of complement; C1 Inh, C1 inhibitor; C4bp, C4b-binding protein; DAF, decay-accelerating factor; MCP, membrane cofactor protein; HRF, homologous restriction factor; CR, complement receptor; PNH, paroxysmal nocturnal hemoglobinuria; LAD, leukocyte adhesion deficiency.

[a]DAF and CD59 can be deleted due to GPI-anchoring defect, which is associated with PNH.

160 to 250 kd) have been identified, and numerical expression of erythrocyte CR1 is subject to considerable polymorphic variability. [196] [197] Additionally, there is evidence for acquired reduction of CR1 owing to proteolysis of the receptor in vivo. In several conditions associated with immune diseases, a reduction of erythrocyte CR1 is observed, and in certain cases this has been shown to be accompanied by increased plasma levels of the receptor, implying removal from the membrane by surface cleavage.[205] [210] Decreased cell-surface CR1 can alter the capacity of these cells to subsequently bind immune complexes and impair processing of C3b by factor I.[211] Both CR1 and CR2 have been implicated as receptors modulating the immune response of B cells. Although it is unclear how a deficiency of these receptors in man affects the overall immune response, genetically engineered mice lacking CR1 and CR2 showed markedly impaired immune responses, particularly to T-cell-dependent antigens. [212]

CR3/CR4

Genetic deficiency of CR3 (CD11a/CD18), CR4 (CD11b/CD18), and LFA-1 (CD11c/CD18) gives rise to the syndrome of leukocyte adhesion defect (LAD). [181] The genes coding for the -chains of these receptors are each located on chromosome 16, while their common -chain (CD18) is coded by a gene on chromosome 21. LAD is caused by defective -chain synthesis, which affects cell-surface assembly of these three heterodimeric integrin receptors. Many of the clinical manifestations of LAD, including recurrent pyogenic infections and defective wound healing, can be related to dysfunction of the adhesive and opsonic functions of CR3 and CR4.

DAF

The gene for DAF is contained within the RCA group on chromosome 1.[15] Allotypic variants of DAF give rise to the blood group antigens contained in the Cromer blood group.[83] Genetic deficiency of DAF is associated with the Inab erythrocyte phenotype. [213] These cells lack the common antigens of the Cromer blood group (see Chap. 132). This isolated deficiency of DAF is not associated with a clinical disorder, suggesting that other complement regulatory proteins are sufficient to protect these cells.[213] [214]

MCP (CD46)

Four isoforms of MCP have been identified, the result of alternative splicing of a single gene. [215] These isoforms have been shown to differ in their activity in regulating complement activation, which raises the possibility of tissue-specific and individual variability in the activity of this important complement regulatory protein.

CD59

The gene for CD59 has been localized to the short arm of chromosome 11. Isolated genetic deficiency of CD59 has been described in a single individual, and evidence for autosomal recessive inheritance was presented. [216] The individual was reported to experience episodic intravascular hemolysis with a clinical course similar to that observed in PNH. PNH is an acquired stem cell disorder in which somatic mutation in a hematopoietic progenitor cell gives rise to defective biosynthesis of the GPI anchor by which DAF, CD59, and several other cell-surface proteins are normally anchored to the plasma membrane (see Chap. 20). The blood cells produced in this disorder can have several different phenotypes, depending on the extent to which individual GPI-anchored proteins are missing from the cell surface. Often the affected proteins can be detected in plasma and urine. The intravascular hemolysis that is characteristic of this disorder appears to be most directly attributable to those cohorts of erythrocytes that are missing CD59, and therefore cannot regulate the cytolytic activity of the C5b9 complex.

Contribution of Complement to Accelerated Destruction of Blood Cells

The complement system mediates the accelerated destruction of blood cells that can arise in several hematologic disorders (see Chap. 34).

Autoimmune Hemolytic Anemia

Antibody-initiated activation of the complement system can result in increased deposition of C3b, C4b, and potentially C5b9 on the red cell surface. [217] Most commonly, the shortened survival rate of these cells reflects accelerated hepatosplenic clearance as a consequence of endocytic uptake initiated when red cell-associated IgG and C3b (or C4b) interact with Fc and CR1 receptors on phagocytic mononuclear cells of the reticuloendothelial system. The rate and organ site of red cell sequestration and removal appear to depend on whether endocytic recognition is principally mediated through Fc receptor interaction with IgG or through CR1 interaction with C3b and C4b. Sequestration of IgG-coated red cells (generally associated with warm antibody hemolytic anemia) occurs primarily in the spleen rather than liver, except when there is a very high density of cell-surface IgG. The ability of non-complement-fixing IgG antibody (e.g., anti-Rh $_0$ D) to shorten red cell survival suggests that in the case of IgG antibodies against red cell antigens, splenic sequestration and clearance can be directly initiated by Fc receptors on phagocytic cells. Studies in complement-deficient animals and humans nevertheless suggest that complement activation does serve to accelerate the rate of clearance of these IgG-coated cells and to shift the site of clearance to the liver. It has also been suggested that in the case of non-complement-fixing IgG antibodies, the small amounts of C3b (or C3d or C3dg) and C4b (or C4d) that are normally found on the red cell surface may be sufficient to initiate endocytic clearance by splenic macrophages, when presented concurrently with IgG.

In the case of IgM antibodies against erythrocyte antigens (e.g., as found in chronic cold agglutinin disease), activation of the complement system appears to be required for red cell survival to be affected. When complement activation does occur, most of the affected cells (bearing IgM and C3b or iC3b) are initially sequestered in the liver. The sequestration of these cells is presumably mediated by the interaction of CR1 on hepatic Kupffer cells with red cell C3b and C4b (or iC3b). A portion of the sequestered red cells are subsequently returned to the circulation and remain coated with IgM and proteolytically degraded fragments of C3b (mainly C3dg). Sequestered red cells that escape endocytic clearance and return to the circulation survive normally, reflecting the general absence of receptors for IgM on phagocytic cells and the specificity of CR1 receptors for intact C3b (Table 37-2).

In addition to mediating extravascular clearance, complement activation on the red cell surface can lead to intravascular hemolysis. Nevertheless, for both IgG- and IgM-mediated immune hemolytic anemias, clinically significant intravascular hemolysis is rarely observed, even when complement-fixing antibodies are documented. Exceptions include circumstances in which massive complement activation at the erythrocyte membrane occurs because of the nature of the antibody (e.g., alloimmune hemolysis of ABO-mismatched red cells, or for the antibody of paroxysmal cold hemoglobinuria) and in PNH, where a decrease in cell-surface CD59 compromises the normal regulatory control of the terminal complement proteins.

Neutropenia and Thrombocytopenia

The potential role of C5a (and $C5a_{desarg}$) in the neutropenia and vascular leukostasis associated with cardiopulmonary bypass procedures, hemodialysis, blood transfusion, and sepsis has been described. [218] [219] [220] [221] [222] There are also data suggesting that complement activation contributes to shortened platelet survival in cases of immune thrombocytopenia and in circumstances of alloimmune platelet transfusion. In most instances, shortened platelet survival is thought to reflect hepatosplenic sequestration and removal through the reticuloendothelial system, and not intravascular platelet lysis per se. Since deposition of the C5b9 proteins promotes exposure of membrane-binding sites for coagulation factors responsible for thrombin formation, activation of these complement proteins may underlie the increased risk of thrombosis observed in PNH, immune thrombocytopenic purpura, and other immune and inflammatory states associated with intravascular complement activation.

Acquired Immunodeficiency Syndrome

Several reports suggest that interaction of HIV-1 with components of the complement system may contribute to the pathogenesis of AIDS. [223] [224] [225] [226] Activation of the classical pathway of complement by HIV-1 has been shown to occur through both antibody-dependent and antibody-independent mechanisms, including direct binding and activation of C1 by the GP120/GP41 viral membrane glycoprotein complex. The membrane envelope of HIV-1 incorporates the GPI-anchored complement regulatory proteins CD55 (DAF) and CD59 from the host cell plasma membrane, and viral GP120 promotes binding of factor H to the membrane surface. Collectively these various complement regulatory proteins may confer selective resistance of the HIV-1 viral particle to lysis by complement. [225] On the other hand, complement-dependent enhancement of HIV-1 infection of numerous lymphocytic cells has also been demonstrated in vitro, with viral entry facilitated through C3dg interaction with cell-surface CR2 (CD21), either alone or in concert with the attachment of HIV-1 GP120 to cell-surface CD4. [167] [168] [227] The possibility that complement contributes to the depletion of CD4+ lymphocytes expressing HIV-1-derived surface antigens has also been suggested. [228] A decrease in the surface expression of

CD55 and CD59 has also been described for T lymphocytes of HIV-infected individuals, raising the possibility of increased susceptibility of these cells to lysis by complement.[229] Whether complement activation in vivo ultimately ameliorates or exacerbates the cellular and clinical manifestations of this disorder remains to be clarified.

Interactions Between Complement and Coagulation Systems

Interactions among certain components of the complement, kinin, coagulation, and fibrinolytic systems are known to occur, although their physiologic significance is poorly understood.[5] [46] [119] Complement activation has been shown to affect plasma clotting, clot retraction, and clot lysis. Additionally, complement activation can result in platelet activation and increased expression of platelet procoagulant activity. Activated complement also induces the clot-promoting properties of the endothelial surface by mediating release of cell-surface glycosylaminoglycans, [230] by inducing expression of tissue factor,[231] and by causing the cell-surface exposure of phosphatidylserine and other procoagulant phospholipids. [46] Cell-surface exposure of phosphatidylserine and other aminophospholipids by the C5b9 complex may contribute to the pathophysiology associated with lupus anticoagulant antibody and other antiphospholipid syndromes, as these autoantibodies have the potential to activate complement and generally recognize epitopes that are induced when plasma proteins bind to those phospholipids that are known to be exposed when C5b9 deposits on the plasma membrane.[232] [233] In gram-negative bacteremia, episodes of disseminated intravascular coagulation can be temporarily associated with prominent intravascular complement activation, and unregulated complement activation at the platelet surface has been implicated in the recurrent deep venous thrombosis that occurs in patients with PNH.[234] In recent years, there has also been increased awareness of the potential role of the terminal complement proteins in initiating the changes in vascular endothelium that can result in the thrombotic occlusion of blood vessels during episodes of tissue ischemia and reperfusion and hyperacute rejection of transplanted organs. [45] [235] [236]

FUTURE DIRECTIONS

Research conducted during the past decade has yielded new insights into the structural, functional, and genetic elements that compose the complement system and has enhanced understanding of the molecular and cellular mechanisms by which complement contributes to human health and disease. Despite widespread appreciation of the role of activated complement in a variety of immune and inflammatory disorders, the development of therapeutic agents that can directly intercede to control the complement system remains a challenge for the future. Recent insight into the molecular specificity of the various regulatory elements that normally control production of the biologically active products of the complement reaction cascades, combined with knowledge of the structure and function of the complement receptors that mediate the myriad of cellular responses to activated complement, enables design of inhibitors that are targeted toward individual complement proteins or selected complement receptors. In this regard, recombinant proteins with complement-inhibitory function in vitro have proved effective in ameliorating complement-mediated inflammatory responses in animal models and are now being tested for safety and efficacy in clinical trials. [48] [50] [220] [237] [238] [239] [240] [241] [242] Complement-related disorders for which a single gene defect can be identified (for example, PNH and LAD) may also be future targets for gene therapy. Finally, the production of genetically altered animals that express one or more human complement inhibitors on cells of the vascular tissue may provide a mechanism to suppress hyperacute rejection following xenotransplantation of nonprimate organs into man. Chapter 38 - Normal Neutrophil Structure and Function

Robert L. Baehner

The neutrophil is the predominant blood granulocyte participating in phagocytic killing of bacteria and certain fungi as well as in acute inflammatory reactions throughout the body. The cell is referred to as polymorphonuclear or segmented due to its lobulated nucleus. It is energized by anaerobic glycolysis, which provides adenosine triphosphate (ATP) from glycogen stored in the cytosol. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) generated in the pentose shunt provides the substrate for phagocytic oxidase (phox), a unique electron transport chain catalytically reducing oxygen to superoxide anion (O_2), resulting in the production of hydroxyl radical (OH:), hydrogen peroxide (H_2O_2), hypochlorous acid (HOCl) and long-acting chloramines. The fine granularity of the cytosol is neutral, staining with Wright-Giemsa stain, but cine studies spotlight the granules churning within the polymorphonuclear neutrophil (PMN). The granules are membrane-bound organelles made up of discrete subsets of vesicles, each with its own distinct protein profile. The PMN is equipped with >50 distinct granular proteins. These proteins reside either in the granule membrane or in the matrix and can be differentially mobilized when PMNs are stimulated by inflammatory mediators. Depending on the nature of the mediator or secretogogue, one or more of the four granule subsets is translocated to phagolysosomes, or to the cell surface and released from the PMN. PMNs circulate throughout the entire vascular bed without compromising the integrity of the microvasculature; however, at sites of incipient inflammation, the cell must be able to adhere to endothelium, diapedese between endothelial cells, and then migrate from the microvasculature into tissues. Precise signal transduction pathways provide the trigger for PMNs to respond appropriately to a gradient of chemokines generated at the site of infection or inflammation.

PMN are terminally differentiated cells that leave the peripheral blood with a half-life of 6.7 hours, but the process may vary from 4 to 10 hours depending on need. PMN movement slows in response to very high concentrations of chemokines. Finally, PMNs bind the opsonised microbes and ingest and kill them. When microbes are not the stimulation for chemokine generation, PMNs accumulate and remain at the site of tissue injury. Thereafter, PMNs undergo programmed cell death (apoptosis) in tissues over the next 48 hours. Delay of apoptosis may facilitate PMN-mediated organ or tissue damage by extending PMN integrity at sites of inflammation. In contrast, molecules promoting apoptosis may reduce inflammation.

This chapter describes the normal development of the PMN from myeloblast stage, including granulocyte kinetics, morphology, composition, and metabolism. The bimodal functions of PMN as phagocytes and as acute inflammatory cells are considered. Cellular and molecular perturbations occurring during PMN activation, including signal transduction mechanisms required for chemotaxis, ingestion of opsonized microbes, granule mobilization and secretion, the respiratory burst, oxidative and nonoxidative microbicidal killing, and apoptosis of PMN are described in the following sections.

MORPHOLOGY OF DEVELOPING POLYMORPHONUCLEAR NEUTROPHILS

The morphologic features seen by light microscopy of developing myeloid cells that are used to identify six stages of PMN development are relative size, nuclear volume, chromatin density, prominence of nucleoli, granule number, and cytoplasmic staining. The ultrastructure of granulocytes is of biologic importance but contributes little to identifying the stages of development based on morphologic criteria using the Wright-Giemsa polychrome-stained bone marrow smear. In general, cell maturation is accompanied by reduction in cell size, diminished volume and increased chromatin condensation of the nucleus, loss of nucleoli, appearance of granules, and cytoplasm that is less basophilic and more abundant relative to nuclear size (Fig. 38-1).

Myeloblast Stage

The myeloblast is the youngest myeloid precursor recognizable in the bone marrow. Size is medium (1520 microns in diameter); the nucleus is large and round, with finely granular chromatin and one or two pale-blue nucleoli; granules are absent; and the cytoplasm is scanty. Ultrastructurally, myeloblasts show numerous round or oval mitochondria (<1 micron in diameter), Golgi apparatus with a centriole, vesicles and sacs, many free cytoplasmic ribosomes, and free polyribosomes but no granules.

Promyelocyte Stage

The promyelocyte is larger than the myeloblast and myelocyte (>20 microns). The nucleus and nuclear chromatin and nucleoli

Figure 38-1 A schematic view of PMN development in human bone marrow as seen under high-magnification light microscopy. Myeloblasts are the youngest recognizable myeloid cell in the marrow. They originate from stem cells programmed for neutrophil development called CFU-G. Nuclear chromatin is fine granular (depicted as white) with one or two nucleoli (depicted as black bodies). Cytoplasm is free of granules. Myeloblasts divide into two larger daughter promyelocytes that contain azurophil (primary) granules (depicted as large black granules) identified by myeloperoxidase stain. The nucleus resembles myeloblast nucleus but may be obscured by azurophilic granules as they continue to assemble only at this stage of myeloid development. Promyelocytes give rise to myelocytes, which proliferate several times, during which time specific or secondary granules (depicted as smaller white granules) are produced. Lactoferrin immunohistochemistry is used to identify specific granules. Myelocytes become smaller with each cell division and nucleoli are lost when the cell is no longer able to divide. Metamyelocytes are smaller than myelocytes and are characterized by a bean-shaped nucleus with dark clumped chromatin. Band cells and PMNs represent the final stages of myeloid development. The addition of a third granule subset, identified by gelatinase assay, and the secretory vesicles, identified by alkaline phosphatase stain, complete the granule profile of PMN. See text for more details. (*From Bainton DF et al: The development of neutrophilic PMN leukocytes in human bone marrow. Origin and content of azurophil and specific granules. J Exp Med 134:907, 1971. © The Rockefeller University Press.*)

resemble myeloblast, but the cardinal feature is the presence of many violet granules with either a dense or coarse pattern, often obscuring other cell landmarks. These so-called azurophilic or primary granules, measuring 0.8 microns, are homogeneous, dense, and round to ovoid and are bounded by a unit membrane. Azurophilic granules are made solely by promyelocytes and contain a variety of bactericidal cationic proteins, proteolytic enzymes, and myeloperoxidase. Electron microscopic studies show that the prototypic protein myeloperoxidase is synthesized and packaged into storage granules by the pathway defined for other secretory proteins (i.e., from endoplasmic reticulum to Golgi complex via vesicles to granules).

Myelocyte

The myelocyte is the last myeloid precursor capable of mitosis. Three cell divisions take place in the myelocyte pool, and as expected with each division the cells change in size, shape, and color. Myelocyte progeny are progressively smaller, being reduced in diameter from >20 microns to 14 microns. During this period, specific secondary granules are synthesized, while primary azurophilic granules are shuffled and diluted throughout the myelocyte pool. Secondary granules of neutrophilic origin are barely visible but become more numerous, filling the cytosol with proteins that stain pale pink or lilac. Specific granules are smaller (0.5 microns) and less dense than primary granules, but like primary granules they have a limiting membrane. They are difficult to see on light microscopy. They contain a variety of adhesive proteins, including -2 integrin (CD11/CD18), cytochrome b (a component of NADPH oxidase), a binding protein for cobalamin, lactoferrin, and unique PMN marker antigens. As the myelocyte divides and matures, the nucleus becomes smaller and irregularly round, the nuclear chromatin becomes coarse and clumped, and nucleoli become sparse to absent. A pink puff is evident on the flattened side of the nucleus of smaller, more mature myelocytes. The nuclear to cytoplasmic ratio is reduced.

Metamyelocyte

The metamyelocyte is slightly smaller than the myelocyte. During this stage, the cytoplasm resembles that of the mature PMN and band forms. The background cytoplasm is uniformly pink. Granules are small and fine, blue-black or gray, and are dispersed homogeneously throughout the cytoplasm. The nucleus is indented like a bean, and the nuclear chromatin is coarse, clumped, and condensed peripherally. The metamyelocyte has lost the ability to divide, and further maturation consists predominantly of nuclear elongation and segmentation. The cell lacks nucleoli, polyribosomes, or endoplasmic reticulum necessary for ongoing protein synthesis.

Band Form

This cell is also called the stab or juvenile form because the nucleus is nonsegmented but is elongated into a sausage or horseshoe shape. No nuclear lobulations are evident, although constrictions may be visible. Nuclear chromatin is aggregated into evenly arranged clumps. The cytoplasm is like the mature PMN, with pink staining and fine azure granules. The proportion of azurophilic primary to specific secondary granules based on cytohistochemistry is about one to two. [1] Band forms are considered fully functional phagocytes and make up 35% of the differential count. They should be included when calculating the absolute neutrophil count (ANC).

Polymorphonuclear Neutrophil

The polymorphonuclear neutrophil or segmented neutrophil is the end stage of maturation. The mature neutrophil is of uniform size (13 microns in diameter), with pink cytoplasm and fine azure granules. The predominant specific secondary granules are so finely dispersed that the cytoplasm may stain only faintly pink. Granular detail normally is not seen at the level of definition by light microscopy. The nucleus is segmented into two to five (mean of three) lobes connected by thin chromatin strands. Five to ten percent of PMNs contain nuclear irregularities such as nicks, appendices, fibrillar bodies, and bridges. Three percent of PMNs from normal females display a drumstick oval mass of dense chromatin 1.5 microns in size attached to one of the lobes by a slender filament. [2] The nuclear chromatin is coarse

and clumped and stains deep purple with Wright-Giemsa. Ultrastructurally, PMN granules show considerable heterogeneity in size and density. A submembranous meshwork of microfilaments poses a barrier for them. Peroxidase staining reveals cytoplasm filled with smaller peroxidase-negative granules (secondary specific granules) and larger, dense peroxidase-positive granules (primary granules). The Golgi region is small compared to the promyelocyte and myelocyte, and the rough endoplasmic reticulum and mitochondria are scant.

Figure 38-2 Transmission electron photomicrograph of a peripheral blood PMN. The nucleus is multilobed. The peripheral distribution of heterochromatin is interrupted by channels of euchromatin where it is in continuity with nuclear pores (arrows). Note the heterogeneity of the granules and the fact that the primary granules (more electron dense) represent a minority population compared to the specific and gelatinase granules (less electron dense). There are few mitochondria, ribosomes, and no rough endoplasmic reticulum. The Golgi zone (labeled Go) is very small. The black dots in the cytoplasm represent glycogen particles. The leading edge or pseudopod is always devoid of granules and rich in actin and actin-associated proteins. (× 17,500) (*From Zucker-Franklin D, Greaves MF, Grossi CE, Marmont AM [eds]: Atlas of Blood Cells, Function and Pathology, 2nd ed. Lea and Febiger, New York 1988, with permission.*)

PMNs contain an abundance of glycogen since the cell depends on anaerobic glycolysis for the generation of ATP (Fig. 38-2).

CONTENT OF POLYMORPHONUCLEAR NEUTROPHIL GRANULES

Polymorphonuclear neutrophils contain four subsets of granules or vesicles identified by marker enzymes or other proteins present in the granule matrix or membranes of granules and secretory vesicles (Table 38-1).

Cytochemical stains of blood and bone marrow smears identify myeloperoxidase-positive azurophil granules in promyelocytes and in all further differentiated stages of PMNs. The matrix of azurophil granules contains microbicidal proteins and acid hydrolases involved in oxidative and nonoxidative killing of bacteria and fungi (see sections on PMN respiratory burst, nitric oxide pathway and nonoxidative microbicidal killing). Azurophil granule membranes contain receptors and proteins for signal transduction (see section on signal transduction). Lactoferrin is localized to specific granules and serves as a convenient marker of that granule subset. [3] Specific granule matrix contains hydrolases distinct from azurophil granules and vitamin B_{12} binding protein, among others. Specific granule membranes contain chemotactic, opsonic, and adhesion protein receptors and the cytochrome b component of the phagocytic NADPH oxidase. Alkaline phosphatase initially was thought to mark secondary specific granules since myelocytes and all further stages of differentiated PMNs stain positive. [4] [5] It is now known that alkaline phosphatase is contained in secretory vesicles scattered throughout the cytoplasm and plasma membrane of myelocytes, metamyelocytes, band forms, and PMNs.[6] Secretory membranes also are a source for cytochrome b and receptors for serum opsonins. Plasminogen activator receptor is also in the vesicular membranes of PMNs. In addition to secretory vesicles, azurophil granules, and specific granules, another subset of granules more recently has been identified by subcellular fractionation techniques combined with double-labeling immunoelectron microscopy. These granules are rich in gelatinase but low in lactoferrin and negative for peroxidase. [7] Gelatinase granules more readily secrete their contents in response to secretogogues compared to specific or azurophil granules. [8] Table 38-1 lists the contents of PMN granules and secretory vesicles based on their function and subcellular localization.

GRANULOCYTE KINETICS

Polymorphonuclear neutrophils are distributed within the bone marrow, the circulating blood, and in various tissues throughout the body, depending on specific need. The largest compartment of PMNs is within the bone marrow and contains $2.26^{9} \times 10$ cells per kg body weight.[9] The blood compartment is approximately one third the size of the bone marrow compartment (0.7×10^{9} cells/kg), and only half are in the bloodstream, while the other half are tumbling on or loosely adhering to the endothelium of the microvasculature.[10] These two compartments are referred to as the circulating granulocyte pool (CGP) and the marginating granulocyte pool (MGP), respectively, and the two pools are in a constant state of dynamic equilibrium.[11] [12] The size of the extravascular tissue compartment has not been quantified, but it varies depending on the attraction for PMNs at sites of infection or inflammation (Fig. 38-3 (Figure Not Available)).[13]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BONE MARROW COMPARTMENTS

The bone marrow compartments of developing myeloid precursors are the stem cell compartment; the mitotic compartment, containing replicating myeloblasts, promyelocytes, and myelocytes; and the maturation-storage compartment, containing nonreplicating metamyelocytes, band forms, and PMNs. The size of the stem cell compartment has not been quantified, but it is very small compared to the mitotic compartment (2.11×10^9 cells/kg) and to the almost threefold larger maturation-storage compartment (5.59×10^9 cells/kg).[14] The transit times of developing myeloid cells are derived from ^{3}H-Tdr (tritiated thymidine) studies.[14] [15] These studies provide data on the hours and days that myeloblasts and all subsequent myeloid precursors spend during the process of replication and maturation to PMNs. Under normal conditions, the entire process requires approximately 10 days. The myeloblast stage is 15 hours, the promyelocyte stage 24 hours, and the myelocyte stage 104 hours, during which the myelocyte replicates up to three times. Thus, the replicating phase of myeloid development is about 6 days. Maturation of metamyelocyte to band form and PMN requires an additional 4.5 days. The PMN may spend another 3 or 4 days in the storage compartment before emerging into the circulation.[16] [17] A model of the production and kinetics of PMNs proposed by Athens is provided in Figure 38-3 (Figure Not Available) .

BLOOD COMPARTMENT

The mechanisms controlling the release of PMNs from the bone marrow are only partially understood. Endotoxin affects the relationship between marrow sinus endothelial cells and the stromal macrophages covering nonluminal sinusoidal surfaces. Endotoxin induces the retraction of macrophages away from the endothelium and facilitates contact between PMNs and endothelial cells. [18] [19] Endotoxin, androgens, glucocorticoids, and a leukocyte mobilizing factor derived from the third component of complement (C3e) induce the release of bone marrow PMNs into the circulation. [20] [21] [22] [23] The cell must be able to deform and migrate to the luminal side of the endothelial sinusoidal surface. In vitro, PMNs and bands readily pass through millipore filters

TABLE 38-1 -- Content of Human PMN Granule Subsets

with pore sizes of 1 micron in response to chemoattractants. Metamyelocytes and late myelocytes are impaired in this response, whereas early myelocytes, promyelocytes, and myeloblasts cannot move or deform.[24] [25] In rabbits, infusion of C5a and tumor necrosis factor- induce leukocytosis, which still occurs when the principal adherence proteins of PMN, -2 integrin, and L-selectin are blocked by specific antibodies. [26]

In most normal persons, the half-life of blood PMNs, as determined by DFP[32] (di-isopropyl fluorophosphate), is about 7 hours. [12] [27] [28] The disappearance of DFP[32] -labeled PMNs from the blood follows a single exponential curve, implying that PMNs are destroyed or leave the blood randomly rather than according to their age (senescence), as is true for erythrocytes. PMNs do not return to the circulation after they leave it. The granulocyte turnover rate is calculated from the total blood pool of PMNs (27128 PMNs × 10^7 /kg) and the half-life of PMNs (410 hours), and is 62400 PMNs × 10^7 /kg/day. [16]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

EXTRAVASCULAR TISSUE COMPARTMENT

Under normal conditions, PMN losses occur on mucosal surfaces throughout the body. For example, isotopically labeled blood PMNs appear in saliva and urine and increase markedly with gingivitis and pyelonephritis, respectively. [29] [30] The size of the extravascular tissue compartment can only be estimated, but current investigations focus on how PMNs die or delay dying on mucosal surfaces or at sites of infection or inflammation. Although PMNs exit the circulation randomly, they age and die at inflammatory sites over the next 72 hours by undergoing selective intracellular programmed cell death or apoptosis.

Figure 38-3 (Figure Not Available) Model of the production and kinetics of human PMNs. The marrow and blood compartments are drawn to show their relative sizes. In the lower third of the figure, the compartment transit times as derived from DFP [32] studies[12] and tritiated thymidine (H^3 -Tdr) studies[14] [15] are compared. (*From Lee GR, Bithell TC, Foester J et al [eds]: Wintrobes Clinical Hematology, 9th ed. Lea and Febiger, New York 1993, with permission.*)

PMN APOPTOSIS

This process results in characteristic morphologic changes in PMN volume and nuclear chromatin condensation, with the formation of pyknotic nuclei. Endogenous endonuclease activation results in a time-dependent increase in low-molecular-weight DNA cleavage products identified by DNA electrophoresis. The apoptotic PMN remains intact morphologically but loses cytoskeletal functions of attachment, spreading, shape change, and random migration. L-selectin expression decreases and Fc RIIIb is shed, but expression of CD11/CD18 increases.[31] Apoptotic PMNs are no longer capable of phagocytosis, degranulation, or respiratory burst activity. The cell has been effectively isolated from its further role in phagocytic killing of microbes or as a participant in the inflammatory response. The apoptotic PMN likely represents a modulating event in the control of inflammation, marking the PMN for disposal and harnessing its ability to generate and release noxious cytotoxic products that could induce further damage to inflamed tissues.[32] [33] The apoptotic PMN becomes the phagocytic target of tissue macrophages, is recognized via adhesive proteins such as thrombospondin, and is ingested intact by the macrophage.[34] The precise molecular genetic site(s) for initiation of apoptosis in PMNs is not known at present, but sodium butyrate, which directly affects chromatin structure, delays PMN apoptosis.[35] Bcl-2, a proto-oncogene rearranged and deregulated in B-cell follicular lymphoma, resulting in delayed apoptosis, is expressed in early myeloid differentiation but not in PMNs. PMNs from transgenic mice expressing Bcl-2 in PMN in vitro show delayed apoptosis but are still recognized and phagocytized by macrophages.[36] One candidate for a molecular trigger of apoptosis in PMNs is the *Fas* gene. *Fas* protein is expressed on PMN plasma membrane, and *Fas* ligand induces apoptosis in PMNs.[37] *Fas*-mediated PMN apoptosis is suppressed in vitro by biologic molecules and drugs known to delay apoptosis in PMNs. Also, PMNs constitutively release *Fas* ligand, thus providing a paracrine pathway for the PMN to mediate its own programmed cell death.[37] Molecules known to delay the onset of PMN apoptosis include granulocyte colony-stimulating factor (G-CSF), granulocyte macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3, IL-6, and IL-15. Glucocorticoids and G-CSF exert a protective effect on PMN survival in vitro at concentrations that occur at pharmacologic doses of dexamethasone and G-CSF achievable in vivo.[38] [39] Mediators of inflammation such as endotoxic lipopolysaccharide (LPS), human recombinant C5a, TNF- and interferon (IFN)- also inhibit PMN apoptosis in a concentration-dependent fashion in vitro.[40] [41] [42] Lyn kinase, an src family tyrosine kinase, couples to the GM-CSF receptor and is required for the delayed apoptosis induced by GM-CSF. PMNs from respiratory burst-deficient persons and normal PMNs display similar degrees of delayed apoptosis under anaerobic conditions. However, the phagocytic event itself, as well as proteolytic granule enzymes, including elastase, accelerate PMN apoptosis, supporting the notion that PMN activation is a suicidal process.

CIRCULATING POLYMORPHONUCLEAR NEUTROPHIL INTERACTIONS WITH ENDOTHELIAL CELLS

Polymorphonuclear neutrophils are subjected to strong shear forces as blood flows through the arterial circulatory system at velocities of 3001000 micron/sec. [27] When viewing the microcirculation with the cine microscope, the vast majority of cells, including red cells, appear as a indistinguishable blur. But within this rapid flow, a subset of PMNs is noted to tumble along the periphery of the blood vessel at a velocity about two orders of magnitude slower than the main flow. Loose PMN interaction with endothelium results in tumbling or rolling and reflects early inflammatory responses of PMN and endothelial cells, preceding firm adhesion of PMNs. [43] Adhesion molecules play a major role in mediating the recruitment of circulating PMNs to sites of inflammation. PMN recruitment involves a dynamic series of events between PMNs and endothelial cells orchestrated by several different families of adhesion molecules and their ligands. PMNs and endothelial cells are transformed from a basal state to an activated state by a variety of inflammatory mediators. The process can be divided into four phases:

1. The inactivated or quiescent state of PMNs and endothelium before release of inflammatory mediators

2. The activated state of endothelium, which mediates PMN rolling
3. The activated or priming state, reflected by alterations in the expression of adhesive molecules, rendering PMNs sticky to endothelium
4. The transmigration phase, when PMNs tread between adjacent endothelial cells supported by adhesive molecules expressed on the lateral surfaces of endothelium (Fig. 38-4).

Figure 38-4 Circulating PMN interactions with vascular endothelial cells during recruitment of PMNs to sites of infection or inflammation. At left, PMNs and endothelial cells are represented in their basal states prior to exposure of either cell type to inflammatory mediators. Constitutive ICAM-2 is expressed on endothelial cells and does not affect free-flowing PMNs, which constitutively express L-selectin and its ligand SLeX. The adjacent right section illustrates PMNs rolling onto endothelial cells that express E-selectin after activation by IL-1, TNF-, or endotoxin. E-selectin induces loose attachment of PMNs to endothelial cells mediated by the L-selectin ligand SLeX. Endothelial cells release IL-8, GM-CSF, and PAF, while other chemoattractants may also be sensed by rolling PMNs. One or more of these molecules induce PMNs to express -2 integrin Mac1 (and LFA-1, not shown), which mediates firm adherence of PMNs to ICAM-1 expressed by activated endothelial cells. At right, PMN is illustrated crawling along endothelial cells and squeezing between them, aided by endothelial cell PECAM-1, which binds PMN Mac1. The subendothelial basement membrane is eroded, presumably by secretion of PMN gelatinase B and elastase. See text for details.

Adhesive molecules involved in PMN-endothelial interactions are selectins and their ligands, including sialylated Lewis X blood group glycoprotein, intercellular adhesion molecules (ICAMs), and the CD18 (-2) family of leukocyte integrins.

SELECTINS AND THEIR LIGANDS

Selectins are found on all leukocytes (L-selectin), on postcapillary venule endothelial surfaces (E-selectin), and in platelet granules and endothelial cell Weibel-Palade bodies (P-selectin). PMNs constitutively express L-selectin, also called Leu-8/TQ-1, DREG, LAM-1, LECAM-1, or gp 90 MEL, since it is expressed also on monocytes, eosinophils, and lymphocytes. E-selectin, also called ELAM-1 or LECAM-2, is not expressed constitutively on endothelial cells, but is transcriptionally induced by inflammatory mediators IL-1, TNF-, and LPS within several hours after exposure. As a result of activated platelet and endothelial release in response to thrombin, substance P or histamine, P-selectin is expressed during acute inflammation or hypercoagulable states resulting in thrombosis. P-selectin, also called LECAM-3, GMP-140, PADGEM, or CD62, mediates PMN, eosinophil, and monocyte adhesion during inflammation associated with allergy or thrombosis. [44] All three members of the selectin family share a structural motif: an N-terminal C-type lectin domain, an epidermal growth factor (EGF)-homologous domain, a variable number of short consensus repeats (SCARS) as found in complement regulatory proteins, and a transmembrane and a C-terminal cytoplasmic domain. They play a major role in PMN adherence to endothelial cells mediated by binding either to ligands on the PMN (E and P) or endothelial cell (L) at their N-terminal site, including lectin and EGF domains. The ligands of selectins share a similar biochemical structure. They contain carbohydrate groups, which are typically found as terminal structures of glycoproteins and glycolipids. One major selectin ligand is a sialylated and fucosylated tetrasaccharide related to the sialylated Lewis X blood group (SleX, CD15). [45] SleX is heavily expressed on inactivated or quiescent PMNs and monocytes. Both the sialic acid and the fucose linkages are critical for binding. [45] [46] Leukosialin (CD43), the predominant sialoprotein expressed by circulating human PMN, has been implicated as an anti-adhesive molecule shed from the plasma membrane after PMN activation.[47]

Intercellular Adhesion Molecules

Three ICAMS share similar structures to immunoglobulin (Ig) supergene family and other Ig-like adhesion molecules such as VCAM-1, and serve as ligands for the -2 integrins. ICAM-1 is a ligand for CD11b/CD18 (Mac1) and LFA-1 present on PMNs and other leukocytes. [48] LFA-1 binds to ICAM-1 domains 1 and 2, while Mac1 binds ICAM-1 domain 3.[49] The distribution and regulation of the three ICAMS are distinct. ICAM-1 is expressed at very low levels on endothelial cells, but expression is markedly increased by inflammatory cytokines such as IL-1, TNF-, LPS, and IFN-. [50] This increased ICAM-1 expression requires 46 hours for mRNA transcription and new protein synthesis. The increased expression of endothelial ICAM-1 lasts several days. [51] ICAM-2 is constitutively expressed on endothelial cells but does not respond to inflammatory cytokines.[52] [53] ICAM-3 is the only ICAM molecule expressed by PMNs[54] and is otherwise restricted to monocytes and lymphocytes. ICAM-1 is chiefly responsible for maintaining firm adhesion between PMN CD11b/CD18 (Mac1) and vascular endothelium. Another member of the endothelial Ig superfamily, PECAM-1 (CD31), serves an important role in mediating transmigration of PMNs from the vascular space into mucosal or other body tissue. CD31 is constitutively expressed and localized to the lateral junctions of endothelial cells, whereas ICAM-1 is expressed over the entire surface area of endothelium. [55] Anti-PECAM-1 monoclonal antibody (Mab) blocks PMN migration across cytokine-activated endothelial monolayers. [55] [56]

Beta-2 Integrins (CD18)

The CD18 -2 integrins were among the first adhesion molecules described on PMNs and other leukocytes. [42] This family of adhesive proteins comprises three membrane glycoproteins with a common subunit, designated -2 (CD18), and three unique subunits, designated CD11a, CD11b, and CD11c. They form three structurally related / heterodimersCD11a/CD18 (LFA-1), CD11b/CD18 (Mac1), and CD11c/CD18. [42] [57] Both the and subunits have a relatively small cytoplasmic domain, which includes regions capable of binding cytoskeletal structures. [58] The extracellular domain is much larger, and the amino terminal portion of the subunit contains the ligand binding region. Both subunits are required for expression of the intact dimer. [59] Mac1 serves as a receptor for the C3bi fragment of complement.[60] [61] The important role played by CD18 integrins for PMN adhesion to vascular endothelium became apparent when the molecular basis of leukocyte adhesion deficiency (LAD) type 1 disease was found to be due to a genetic deficiency in the expression of all three CD18 integrins. [62] [63] LAD type 1 PMNs bind poorly to IL-1-stimulated endothelial cells and cannot

undergo transendothelial migration. [64] [65] Normal PMNs treated with anti-CD18 Mabs show similar effects to LAD type 1 PMNs.[66] PMN -2 integrins are up-regulated by a variety of chemoattractants, including F-Met-Leu-Phe (FMLP), C5a, LTB4, IL-8, and platelet activating factor (PAF). [63] These chemotactic triggers result in a rapid inverse expression of L-selection (decrease) and Mac1 (increase) on PMNs, or a transition from L-selectin-dependent adhesion to Mac1-dependent adhesion. L-selectin is required for PMNs to localize loosely to activated endothelium adjacent to the inflamed tissue, while -2 integrins mediate the movement of PMNs across the vascular endothelium and into tissue. [67] [68] [69] [70] [71]

MOLECULAR INTERACTIONS BETWEEN ENDOTHELIUM AND POLYMORPHONUCLEAR NEUTROPHILS

Polymorphonuclear neutrophils freely flow over endothelial surfaces when neither cell is activated. Inflammatory cytokines IL-1, TNF-, or IFN- activate endothelial cells to express E-selectin and to release IL-8, GM-CSF, and PAF. [72] PMNs roll onto activated endothelium mediated by loose binding of SLeX and L-selectin on PMN surfaces to E-selectin expressed on the surface of activated endothelium. Endothelial inflammatory cytokines or extravascularly derived chemoattractants at minimal concentrations of 1×10^{9} M bind to selective PMN chemotactic receptors, which in turn induce the expression of CD18 -2 integrins Mac1 and LFA-1 and reduce the expression of L-selectin and SLeX. At this stage PMNs are firmly attached by their -2 integrins to activated endothelial cell ICAM-1 ligand. In addition to becoming more adhesive to endothelium, PMNs exposed to chemotactic factors also adhere to each other. Aggregates of PMN slow blood flow and permit even more PMNs to be recruited. PMN aggregation is a Mac1-dependent event. In contrast to inflammatory cytokines, the attachment of PMN to endothelium stimulated by thrombin involves expression of PAF on the endothelial surface. [74] PMNs have receptors for TNF-, but they are deactivated and down-regulated by PAF, endotoxin, FMLP, LTB4, and C5a and play no direct role in PMN adhesion. [75] Supported by the -2 integrins, Mac1, and LFA-1-ICAM attachment, PMNs move laterally on endothelium and squeeze between endothelial cells by adhering to PECAM-1. PECAM-1 is constitutively concentrated at endothelial cell margins and is expressed on PMNs. PMNs isolated from CD18-deficient patients adhere to IL-1-stimulated endothelium but fail to transmigrate, thus underscoring the essential role of Mac1 and LFA-1 in PMN transendothelial migration. [76] [77] [78] PMN migration across subendothelial basement membranes is thought to be dependent on the degradation of membrane constituents by PMN granule proteinases. [79] Inhibition of gelatinase B, a metalloproteinase capable of degrading type IV collagen, inhibits PMN trans-basement membrane migration without affecting chemotaxis or degranulation. PMN elastase activates a precursor form of gelatinase B released into supernatant fluid by PMNs in vitro, and inhibition of PMN elastase also blocks trans-basement membrane migration, presumably by inhibition of gelatinase B activation. [80] Transepithelial migration of PMNs is a defining characteristic of mucosal surface inflammation and requires the continued expression of CD11b/CD18 as well as the integral membrane glycoprotein CD47 on PMN and epithelial surfaces. This 60 kDa glycoprotein has homology to the immunoglobulin superfamily and is up-regulated on epithelial surfaces by IFN-. [81] Sustained activation of PMN requires continued engagement of chemoreceptors with specific chemoattractants. Also, the type of subendothelial collagen supporting PMN movement affects activation. Type I collagen activates PMN, whereas the -3 region of type IV collagen down-regulates PMN activation. [82] Some of these events are illustrated in Figure 38-4 .

MOVEMENT OF POLYMORPHONUCLEAR NEUTROPHILS

Polymorphonuclear neutrophils change their shape and crawl in response to chemoattractants by alternating the extrusion and retraction of a broad frontal lamellipodia that determines the direction of locomotion. They move directly up the gradient of chemoattractant by a tractor-like motion as the lamellapodia fills with soluble proteins and then, contracts as the membrane adheres briefly to the substrate, providing the frictional force for movement. The PMN cell body extends and elongates in the axis defined by the lamellar protrusion, creating a tapered cell with a knobby tail. [83] Orientation accuracy is sensitively regulated by specific chemotactic receptor occupancy along the cell membrane. As little as a 2% change in chemoattractant concentration is detected by the PMN. [84] [85] PMNs move at speeds up to 30 micrometers per minute, qualifying them as the fastest cell in the body. [86] Their cell velocity oscillates between 10 and 30 micrometers per minute, with a periodicity of 5055 seconds. [86]

The molecular underpinnings of PMN crawling have been detailed in a model by Stossel. [86] PMN activation induces contraction of the actin filamentous network in the cortical gel, presumably by inducing the phosphorylation of myosin through a transient increase in cytosolic calcium. Mechanical stress studies suggest that the PMN cortex is a weakly cross-linked structure. [87] The hydrostatic force imposed by network contraction forces the membrane bilayer outwards at a region where it becomes detached from the underlying protein network. Simultaneously at the site of membrane expansion, actin filaments assemble from monomeric subunits into relatively short (1 micrometer) linear filaments. These filaments are cross-linked by actin binding protein, fimbrin, villin, fascin, and actinin into a three-dimensional uniform network. Loss of actin binding protein expression results in an immobile cell that responds feebly to chemoattractants by forming temporary blowouts or blebs over the entire cell surface. This dynamic, cohesive network of actin filaments modulates the flow of sol, provides strength to the forming protrusion, and serves as the anchor for adhesion molecules, welding the protrusion to the underlying substrate. In addition, the cross-linking of initially freely diffusing actin filaments into an immobilized state imparts contractility on the solvent included within the gel, and the squeezing action on the solvent can provide additional force to protrude membrane forward at the leading edge, driving the cell forward (Fig. 38-5).

Thereafter, actin filaments must be disassembled rapidly so that the cycle can be repeated. Gelsolin severs actin filaments rapidly and is activated at micromolar calcium concentrations. Gelsolin blocks actin reassembly by capping actin barbed ends. The barbed end of actin filaments serves as the nidus onto which actin subunits are added. Another highly conserved capping protein, CapZ, [88] may also cap barbed ends, thereby preventing actin filament elongation. Another filamentous actin binding protein, leufactin, was found to be overexpressed in the PMNs of a child with PMN actin dysfunction, resulting in immobile cells and serious infections. [89] The next cycle of assembly and disassembly cannot be initiated until these actin filaments are uncapped. Dissociation and uncapping of the gelsolin-actin and profilin-actin complexes is mediated by polyphosphoinositides generated during signal transduction involved in PMN activation. [90] [91] This information provides a unifying picture linking PMN membrane activation to actin assembly and disassembly. [86] During cell stimulation, signal transduction cascades lead to membrane breakdown or synthesis of polyphosphoinositides, the former generating phosphoinositol and release of intracellular calcium and protons promoting actin disassembly, and the latter providing clusters of polyphosphoinositides promoting actin assembly. The actin cytoskeleton and specific actin binding and bundling proteins seem essential

Figure 38-5 Actin-based mechanism for PMN crawling depicted in three phases: vectorial actin assembly in the left panel, leading to a wave of contraction, gelation in the center panel, and early assembly of actin subunits in the right panel. Vectorial direction is indicated by the arrow. See text for details. (*From Stossel TP: The machinery of blood cell movements. Blood 84:367, 1994, with permission.*)

in selective receptor-mediated responses. [92] [93] [94] The myristoylated MARCKS is a major specific substrate of protein kinase C that is phosphorylated during receptor-mediated activation. MARCKS is thought to regulate the cross-bridge between actin and the plasma membrane. [95]

CHEMOTACTIC RECEPTORS

Polymorphonuclear neutrophils sense chemoattractant signals by either up-regulating specific receptors or using specific receptors constitutively expressed on their cell surface. The first receptors demonstrated on PMNs were the N-formyl-methionyl tripeptide receptors, the most active being f-Met-Leu-Phe. [96] These synthetic peptide products are similar to naturally occurring bacterial-derived factors. [97] Similar for all specific receptors, each demonstrates time-dependent saturable binding kinetics and a high-affinity dissociation constant (Kd) for the specific chemoattractant. [98] Studies using intact human PMNs reveal approximately 50,000 f-Met-Leu-Phe receptors per cell with a Kd of 20 nM.[96] [99] The molecular cloning of the f-Met-Leu-Phe receptor from PMNs occurred in 1980. [100] [101] Thrombospondin is an extracellular matrix protein that has chemotactic activity and binds to PMNs via specific receptors linked to Gi2 proteins, a subpopulation of which is also associated with FMLP receptors.[102] The thrombospondin receptor and the Gi2 protein subunit are stored in azurophil granules, and FMLP receptors are stored in specific granules and vesicles of PMNs.

Polymorphonuclear neutrophils display specific receptors for the chemotactic cleavage product from the fifth component of complement, C5a. [103] Binding of radiolabeled C5a indicates 50,000100,000 receptors per PMN with a Kd of 2 nM. The C5a receptor has been cloned. Oocytes injected with C5a mRNA transcripts [104] [105] obtained from differentiated HL 60 cells result in oocytes with fully responsive transmembrane currents and calcium fluxes inhibitable by pertussis toxin, indicating close coupling to G protein.[106]

Tissue-derived cytokines with potent chemotactic activity for PMNs are called chemokines. Chemokines are small proteins of 7080 amino acids with four conserved cysteines forming two essential disulfide bonds: a short -terminal and a relatively long carboxyl-terminal domain. Chemokines specific for PMNs are distinguished by having their first two cysteines always separated by one amino acid (CXC chemokines). Their genes are clustered on chromosome 4. In contrast, CC chemokines have the first two cysteines adjacent and are inactive on PMNs but stimulate monocytes, basophils, eosinophils, and T lymphocytes. CXC chemokines are produced by many different cell types, including endothelial cells, platelets, PMNs, T lymphocytes, and monocytes. They include (IL-8) (previously known as neutrophil activating peptide 1 [NAP-1]), neutrophil activating peptide 2 (NAP-2), and GRO-. [107] [108] [109] [110] [111] [112]

Polymorphonuclear neutrophils express high numbers of IL-8 receptors of two types, one highly specific for IL-8 (IL-8R1) and the other with high affinity for all CXC chemokines (IL-8R2).[113] [114] There are approximately 20,000 IL-8-specific receptors per PMN, with a Kd of 0.8 nM. [115] GRO-- and NAP-2-specific receptors number 60,00090,000 per PMN, of which 3045% are high affinity, with a mean Kd of 0.3 nM for GRO- and 0.7 nM for NAP-2. The low-affinity receptors of GRO- and NAP-2 display a Kd of 30 nM.[116] cDNA cloning of the two receptors for IL-8 indicates that their transmembrane architecture is similar to all other PMN chemotactic receptors (i.e., seven hydrophobic transmembrane domains).[117] [118] The seven transmembrane domain receptor family includes receptors involved in signal transduction for vision, olfaction, hormone action, cell proliferation, and neurotransmission. In PMNs, the receptors consist of seven hydrophobic transmembrane helices of 2025 amino acids separated by three hydrophilic loops exposed at the cystosolic and the extracellular face of the plasma membrane. A conserved disulfide bridge stabilizes the first and second extracellular loops (Fig. 38-6). The transmembrane domains have several conserved amino acids, which form the agonist-binding pocket. The conserved amino acids in the intracellular domains confer a common conformation to all receptors, ensuring their interaction with Gi2 proteins. The diversity of amino acid structure of the extracellular and transmembrane domains confers ligand specificity. [120] All CXC chemokines require the amino terminal sequence Glu4-Leu5-Arg6 (ELR) for receptor recognition and signaling. [121] A two-site model for receptor activation and for selectivity between CXC and CC chemokines has been proposed, with the initial receptor contact provided by the main body of the chemokine and the activation provided by the amino terminal regions. [122] However, the C5a receptor activation site is located in the C-terminal region, whereas the N-terminal region is involved in receptor binding. [123] [124]

Figure 38-6 Schematic arrangement of the chemotactic seven transmembrane domain receptor employed by all PMN chemotaxins and chemokines. The receptor is stabilized by a conserved disulfide bridge (S-S) linking the first and second extracellular loops. See text for details. (*From Thelen M, Dewald B, Baggiolini M: Neutrophil signal transduction and activation of the respiratory burst. Physiol Rev 73:797, 1993, with permission from the American Physiological Society.*)

TABLE 38-2 -- Properties of PMN Chemotactic Receptors: Seven Transmembrane Domain Family

Specific Receptor	Type	Receptor/PMN	High-affinity kDa (nM)	Low-affinity kDa (nM)
FMLP	Bacterial product	50,000	20	
C5a	Complement fragment	50,000100,000	2	
IL 8R1	CXC chemokine peptide	20,000	0.8	
GRO	CXC chemokine peptide	60,00090,000	0.3 (3045%)	30 (5570%)
NAP-2	CXC chemokine peptide	60,00090,000	0.7 (3045%)	30 (5570%)
PAF	CXC chemokine phospholipid	1,000	0.2	
		270,000		500
LTB4	CXC chemokine phospholipid	4,500	0.4	
		270,000		75

Polymorphonuclear neutrophils display a second group of CXC receptors to secreted products of phospholipid oxidation and oxygenation released from endothelial cells, macrophages, and PMNs, as well as from bacterial toxins and oxidants. PAF is 1-0-alkyl-2-acetyl-sn-glycero-3-phosphocholine, formed in endothelial cells in response to stimulation of specific receptors for thrombin, bradykinin, histamine, ATP, and angiotensin II. [125] Binding of radiolabeled PAF reveals 1,000 high-affinity and 270,000 low-affinity sites per PMN with Kd of 0.2 nM and 500 nM, respectively. PAF receptor is a CXC receptor with seven membrane spanning domains and belongs to the family of Gi2 protein-coupled receptors. [126] [127] [128] [129] The receptor is activated by short sn-2 residues present in PAF and other diacylphosphatidycholines containing sn-2 polyunsaturated fatty acyl residues susceptible to oxidative fragmentation. [130] Among the chemoattractants, PAF is unique in inducing lipid-rich cytoplasmic inclusions in the PMN, which primes the PMN for enhanced leukotriene B4 (LTB4) release. [131] (See section on PMN priming.)

Leukotriene B4 is formed from arachidonic acid in the lipoxygenase-catalyzed reaction by oxygenation at C-5, followed by further transformation to leukotriene A4.

This unstable epoxide intermediate is converted to LTB4 by hydrolysis. The newly defined eicosatetraenoates (ETEs), 5-oxoETE and 5-oxo-15(oh)-ETE, share structural motifs, synthetic origins, and bioactions with LTB4. [132] [133] Binding of radiolabeled LTB4 reveals 4,500 high-affinity and 270,000 low-affinity sites per PMN with Kd of 0.4 nM and 75 nM, respectively. [134] The LTB4 receptor in PMNs also appears to be a Gi2 protein-coupled receptor with interconvertible high- and low-affinity states modulated by GTP and has a molecular mass of 5361 kDa. [135] [136] [137] Table 38-2 lists the properties of PMN chemotactic receptors.

SIGNAL TRANSDUCTION

All inflammatory mediators stimulate PMN in a dose-dependent manner by binding to specific receptors of the Gi2 family proteins. These proteins share the ability to bind guanine nucleotides and possess inherent GTPase activity. Gi2 proteins are arranged in a heterotrimeric structure (, , and subunits). The subunit confers specificity for each receptor, binds guanine nucleotide, and serves as the potential substrate for pertussis toxin-catalyzed ADP ribosylation. Each chemoattractant or chemokine binds to its own distinct set of the seven transmembrane domain receptors on the PMN surface. The receptors use this novel pertussis toxin-sensitive Gi2 protein to transduce a cascade of metabolic reactions, which in turn initiate a diverse set of cellular reactions, including PMN shape changes, increased adherence, chemokinesis and chemotaxis, phagocytic ingestion, initiation of the respiratory burst, and granule secretion. Different concentrations of pertussis toxin are required for inhibition of selected metabolic and cellular responses. For example, inhibition of actin polymerization and the rise in intracellular free calcium (Ca2i) requires higher concentrations of pertussis toxin compared with the dose required to inhibit the respiratory burst. [138] Specific binding of any PMN CXC receptor by the appropriate ligand activates a phosphoinositide-specific phospholipase C that generates two second messengers: inositol 1,4,5 triphosphate (IP3) and 1,2 diacylglycerol (DAG) from hydrolysis of phosphoinositide diphosphate (PIP2). [139] [140] [141] IP3 induces the release of calcium from intracellular storage organelles (calciosomes), leading to a transient rise in cytosolic free calcium (Ca2i). [142] Ca2i potentiates PMN degranulation and superoxide anion generation, whereas total sustained intracellular calcium levels are required for receptor expression. [143] Diacylglycerol remains associated with the membrane and participates in the activation of protein kinase C. [144]

Activation of phospholipase D follows activation of phospholipase C. [145] [146] Phospholipase D acts on phosphotidylcholine (PC) to generate phosphatidic acid, which gives rise to diradylglycerides. Diradylglycerol plays an important role in degranulation and activation of the respiratory burst in adherent PMN. PMNs adherent to fibrinogen exhibit a delay in the onset of the respiratory burst that coincides with the later activation of phospholipase D and the generation of high concentrations of diradylglycerol, release of hydrogen peroxide, and secretion of specific granule marker protein lactoferrin from PMNs. [147]

A third phospholipase, phospholipase A2, is activated in PMNs and provides the source for generation of arachidonic acid and lysophosphatidic acid from phosphatidic acid. Arachidonate and lysophosphatidic acid are subsequently lipoxygenated and acylated to LTB4 and PAF, respectively. [148] These reactions are summarized in Figure 38-7 .

Protein kinase C translocates from cytosol to membrane on activation by Ca2i, which leads to phosphorylation of a variety of proteins on their serine and threonine residues. Protein phosphorylation markedly changes the charge and conformation of the proteins, leading to altered enzyme activity, protein binding, and intracellular distribution of proteins and organelles associated with PMN activation. The protein phosphorylation patterns in PMNs stimulated with various chemotactic agonists are similar. [148] [149] [150] Several of the phosphorylated proteins have been identified, including the p47 phox component of the NADPH oxidase and the MARCKS protein involved in PMN motile responses. [151] [152]

Tyrosine phosphorylation of proteins, including tyrosine kinases themselves, occurs in PMN adherent to endothelium or other surfaces and subsequently activated by chemotactic agonists. [153] [154] [155] Thus, the activation of tyrosine kinases involves PMN

Figure 38-7 Phospholipase-mediated signal transduction reactions during activation of PMNs. In PMN suspensions, activation of phospholipase C (PLC) rapidly generates inositol triphosphate (IP-3) and diacylglycerol (DAG) from phosphoinositol 4,5-bisphosphate (PIP_2). Phosphatidic acid (PA) is generated either from DAG kinase or by the slower action of phospholipase D (PLD) from phosphatidylcholine (PC) in adherent PMN. Diradylglycerols form from PA by activation of PA phosphohydrolase. Tyrosine kinases are activated in adherent PMN. Activation of phospholipase A2 (PLA_2) generates lysophosphatidic acid (LYSO-PA) and arachidonic acid (AA) from PA. See text for details.

-2 integrins CD18 for adherence, [156] [157] as well as the chemotactic CXC seven domain transmembrane receptors, or the nonchemotactic inflammatory mediator receptors present on PMNs. [158] [159] [160] [161]

Adenosine and adrenergic agonists attenuate PMN activation by binding to specific adenosine A2 and -adrenergic receptors, which uncouples chemotactic receptors from Gi2 proteins. [162] The signal for this response proceeds via a novel pathway, independent of cAMP but involving a serine/threonine protein phosphatase in the plasma membrane. [163] Adenosine nucleotides, including extracellular ATP, bind to specific binding sites on PMNs and activate signal transduction in PMNs independent of ATP hydrolysis. [164]

OPSONIC RECEPTOR-MEDIATED PHAGOCYTOSIS

The motile response of PMNs to microbial infection includes emigration out of the vasculature and movement directed toward the source of the inflammatory chemoattractant, culminating in the phagocytic ingestion of opsonized microbes. Engulfment occurs through the advancing broad flat pseudopod as the PMN moves to surround the microbe. The embracing arms of the pseudopod fuse their distal membranes, sealing the microbe into a membrane-lined phagocytic vacuole. The pseudopods are rich in actin, and the dynamic action of the actin machinery is required. Also, signals from the cytoplasm arising from specific ligand receptors seem to direct actin filaments directly beneath the zone of contact of the opsonized microbe. [165] The advancing pseudopods receptors engage a continuous number of specific opsonic ligands coating the microbes, ensuring their solitary confinement in the phagocytic vacuole. [166] The classical opsonins are IgG and C3, corresponding to the heat-stable and heat-labile opsonins. Opsonins bind to bacteria, enhancing their phagocytic uptake by leukocytes. [167] The antigen binding sites (Fab) of IgG bind to the bacteria, exposing the Fc binding site, which in turn is recognized by three classes of receptors, FcRI, FcRII, and FcRIII. FcRIII is constitutively expressed in PMNs with 100,000300,000 copies per PMN and identified by CD16. FcRIII binds IgG subclasses 1 and 3 with intermediate and low affinity, respectively (1,100 nM and 4,700 nM).[168] FcRIIIA and FcRIIIB represent the two genetic isoforms that are structurally similar in their extracellular domains but differ in their transmembrane and cytoplasmic domains. FcRIIIA has the conventional transmembrane and cytoplasmic domain but is not expressed on PMNs. [169] FcIIIB is expressed on PMNs but lacks both transmembrane and cytoplasmic domains and is anchored to the PMN by a glycosyl-phosphatidylinositol (GPI) protein of 5080 kDa. Despite the lack of a cytoplasmic and transmembrane domain, FcRIIIB is capable of triggering a signal transduction cascade leading to granule release but no associated respiratory burst.[170] [171] FcRIIIB and CR3 act synergistically to activate the respiratory burst, but this synergy is dependent on FcRII. Ligand binding of CR3 leads to FcRII association with the actin cytoskeleton on the adherent PMN surface. Coligation of FcRIIIB leads to tyrosine phosphorylation of FcRII, which serves to initiate activation of a signal transduction pathway leading to activation of the respiratory burst. [172] Also, anti-FcRII Fab-coated erythrocytes following cross-linking of FcRIIIB are phagocytized.[173] FcRIIIB has two allotype forms, NA1 and NA2, whereas FcRIIIA is not polymorphic and always types as NA2.[174] A new alloantigen SH has been identified on FcRIII that is independent of NA1 and NA2 and capable of stimulating alloantibodies to it. [175]

FcRII, identified as CD32, is a constitutive low-affinity receptor with a molecular mass of 40 kDa and does not bind monomeric IgG. The expression of IgGRII is low (1,0004,000 copies per cell) and the binding requires dimeric IgG. IgG Ka values are lacking for PMN, but it is considered a low-affinity receptor with the following subclass affinities: IgG1 = IgG3 >> IgG2 = IgG4. [176] FcRII-mediated signaling requires the activation of tyrosine kinases of both Src family kinases and Syk, resulting in tyrosine phosphorylation of Shc, activation of phospholipase C, and an increase in intracellular calcium. [177] Also, FcRII engagement leads to mitogen-activated protein (MAP) kinase phosphorylation and activation, a prerequisite for phagocytosis.

FcRI is not expressed on quiescent or basal state PMNs, but is expressed to a level of 15,00025,000 copies per PMN after exposure to IFN-. Other cytokines, such as G-CSF and GM-CSF, do not induce expression of FcRI in PMNs, although other inflammatory mediators may have the potential. [119] The receptor is a single transmembrane protein receptor identified by CD64 and binds IgG1 and IgG3 with high affinity (50 nM) and promotes phagocytosis of particles or bacteria opsonized with IgG.[119]

Polymeric IgA antibody can function as an opsonin and is recognized by a specific IgA receptor on PMNs (Fc R). [178] Fc R is a 60 kDa protein composed of two Ig-like domains that share homology with FcR. It recognizes monoclonal IgM Ab My43 and is identified as CD89. Fc R mediates signal transduction via G protein-linked phospholipase C activation, leading to phagocytosis and stimulation of the respiratory burst. [179] [180] [181]

Opsonic phagocytosis also involves complement components.

C3 is bound covalently on microbes either by prior-bound IgG or IgM activation of the classical pathway or by antibody-independent activation of the alternative pathway.[182] C3 is proteolytically converted to C3b, which remains covalently bound to the microbe and is recognized by the complement receptor type 1 (CR1) present on PMNs.[183] CR1 binds dimeric C3b with an affinity of 0.5 nM. Although the binding affinity is low, PMNs effectively phagocytize microbes or particles opsonized with C3b because they are coated with such a high density of C3b molecules. The CR1 receptor is a glycosylated protein with a molecular weight of 160250 kDa and can be identified as CD35. CR1 has four allelic forms with molecular weights of 160, 190, 220, and 250 kDa. [184] [185] [186] The alleles are expressed codominantly, accounting for the heterogeneity of molecular weights. To date there is no apparent relationship between the four alleles and functional activity of CR1. The gene for CR1 has been cloned and sequenced.[187] The predicted protein has a single membrane spanning domain and a short cytoplasmic domain, but a very large extracellular domain comprising at least 30 small consensus repeats. [188] CR1 functions as a cofactor in the breakdown of its ligand C3b to inert C3dg, preventing the accumulation of C3bi.[189] [190] When C3b is generated by IgG or IgM, it is labile and is converted to the more stable ligand C3bi, whereas C3b is more stable as a opsonin when its generation occurs via the alternative pathway. [191] In contrast to IgG, the arrangement of C3b and C3bi is clustered on the microbe or particle, coinciding with the observation that the receptor for C3bi (CR3) is also clustered on the surface of PMNs. [192] [193] CR3 recognizes C3bi but not C3b, and the binding requires multimers of C3bi. In contrast to the other opsonic receptors (CR1, FcRI, FcRII, FcRIII), CR3 requires high but physiologic concentrations of divalent cation (about 0.5 mM calcium and magnesium) for effective ligand binding. [194] CR3 is a -2 integrin family member and is designated CD11b/CD18. It is composed of two polypeptide chains, an subunit of 185 kDa and a subunit of 95 kDa. Both chains have been cloned and sequenced. Binding of CR3 to C3bi is enhanced 100-fold by an amphipathic anion lipid called integrin-modulating factor (IMF-1), [73] or by phosphorylation or aggregation of CR3. [188] [193] [195] [196] [197] Although CR3 ligation does not directly trigger the respiratory burst, [198] [199] CR3 plays a critical role in adherence-dependent potentiation of the repiratory burst and secretory responses of PMNs.[200] [201] PMN adhesion-dependent functions are inhibited by neutrophil inhibiting factor (NIF), a glycoprotein produced by the hookworm *Ancylostoma caninum.*[202] C1q, the recognition subunit of the classical complement pathway, interacts with specific PMN surface molecules via C1q collagen-like region (C1q-CLR) to trigger the respiratory burst.[203] Properties of the PMN opsonic receptors are listed in Table 38-3 .

DEGRANULATION OF POLYMORPHONUCLEAR NEUTROPHILS (SECRETION)

Degranulation of the PMN starts with the onset of phagocytosis. The granules translocate and ultimately fuse their membranes with the newly created phagocytic vacuoles formed from invaginations of the plasma membrane.[204] [205] [206] Specific granules discharge their contents more rapidly than do primary granules, [207] [208] and more of their contents are secreted extracellularly, perhaps through incompletely formed phagosomes. [209] [210] [211] Primary azurophilic granules are most analogous to lysosomes since they contain all the acid hydrolases found in PMNs. [212] Moreover, the acidic environment of the phagolysosome creates a pH optimal for these enzymes, and the acid milieu is essential for further degranulation. [213] [214] Blockade of anion channels impairs ion fluxes of Na^+ and H^+ and prevents degranulation in PMNs, [215] whereas alkalization of granules promotes their secretion. [216] Although microbial killing and digestion takes place within phagolysosomes, [217] [218] PMNs function as a double-edged sword because granule contents secreted extracellularly inflict tissue injury. [219] Degranulation also occurs when PMNs adhere to tissue surfaces and then bind immune complexes, aggregated immunoglobulin, complement components, or certain cytokines. [220] [221] [222] [223] [224] [225] Under these conditions, granule content release occurs by a process of reverse endocytosis [226] or frustrated phagocytosis. [222]

TABLE 38-3 -- Properties of PMN Opsonic Receptors

Specific Receptor	Marker	Type/Mol. Mass	Opsonic Ligand	Binding Affinity (Ka)	Functions
FcRI; expression requires IFN-	CD64	Single transmembrane protein 72 kDa	IgG1	High 50 nM	Activation Phagocytosis
FcRIIa(a,b not expressed); expression is constitutive	CD32	Single transmembrane glycoprotein 40 kDa	IgG1	Low	Activation Phagocytosis
FcRIIIB; Expression is constitutive A isoform not expressed	CD 16	GPI-anchored glycoprotein 5080 kDa	IgG1 complexes	Low 110 nM	Activation
	NA 1 & NA 2 allelle-antigen SH antigen		IgG3 complexes	Low 470 nM	Immune-binding
					Phagocytosis requires CR1 or FcR2
FcR	CD89	Single transmembrane glycoprotein 60 kDa	IgA1, IgA2		Activation
	My43 IgM		Secretory IgA1, IgA2		Phagocytosis
CR1	CD35 4 allelles	Single transmembrane glycoprotein 160, 190, 220, 250 kDa	C3b & C4b dimers	High 0.5 nM	Phagocytosis
CR3	CD11b/	Heterodimeric transmembrane protein	C3bi	High 0.5 nM	Activation
	CD18			Ca+2, Mg+2	Phagocytosis
	Mac1			IMF-1	

Granules fuse with the plasma membrane, discharging their contents directly to the outside of the PMN.

Cytoskeletal proteins are essential for degranulation. These proteins facilitate granule translocation to either the phagolysosome or the plasma membrane. Both microtubules and microfilaments are involved in this process. Thirty seconds after PMNs are activated, their granules bind to polymerized microtubules [227] and inhibition of microtubule polymerization blocks degranulation in PMNs. [215] [228] Actin polymers act like a barrier between the plasma membrane and granules by inhibiting granule secretion. [229] The fungicidal metabolite cytochalasin B greatly facilitates granule secretion by disrupting subplasmalemal cytoplasmic actin microfilaments, enabling fusion between granule membranes and plasma membranes to take place when PMNs encounter either a particulate or soluble stimulus. [230] [231] [232] [233] [234] [235] The precise cause of membrane fusion is unknown but likely involves activation of several calcium-sensitive PMN phospholipases, resulting in altered lipid composition of granule-phagosome or granule-plasma membrane contact points. Phospholipase A_2 promotes fusion of complex liposomes similar in composition to PMN plasma membrane by lowering the calcium requirement to achieve fusion. [236] Phospholipase A_2 is found in granule membranes of quiescent PMNs and a secretory form of PLA2 translocates to phagolysosomes.[237] [236] Specific granules and secretory vesicles fuse more readily at very low calcium concentrations with artificial liposomes containing a phosphatidic acid/phosphatidylethanolamine ratio of 1:3 (500 M) than do primary azurophilic granules. The latter fail to fuse at concentrations of calcium as high as 12 mM. [239] Cholesterol added to either the liposomes or granule preparations enhances fusion. [240] The concentration of free cytosolic calcium(Ca+2i) required for exocytosis of PMN primary, specific, tertiary, and secretory vesicles varies. Secretory vesicles are exceptionally sensitive to very small increments in cytosolic Ca+2i, whereas primary granules require the highest concentration. [241] This hierarchy in mobilization among PMN granules is also observed during exudation of PMNs into skin chambers. Exudates of PMNs demonstrate complete mobilization of secretory vesicles, a 38% release of gelatinase granules, a 22% release of lactoferrin from specific granules, but only a 7% release of myeloperoxidase from primary azurophil granules. [242] In permeabilized PMNs, Ca+2i concentrations of 1 uM (in vivo physiologic range) result in up-regulation of the specific granule marker CD67, whereas for primary azurophilic granules marked by CD63, GTP-S and 1 uM Ca+2i is required. [243] PMN primary granules contain two GTP binding proteins (25 and 26 kDa), whereas specific granules and plasma membranes contain a set of three GTP binding proteins ranging between 20 and 23 kDa. [244] Also, Mg-ATP and other trinucleotides at 0.31.0 mM concentrations stimulate degranulation in permeabilized PMNs, supporting the notion of a shared trinucleotide receptor regulating degranulation in PMNs.[245] [246] Two adenosine receptors are present on PMNs, and adenosine is known to block degranulation as well as the respiratory burst. [247] [248] [249]

Phospholipase D activation in stimulated PMNs converts phosphotidylcholine to phosphatidic acid (Fig. 38-7). This change in membrane composition promotes degranulation by replacing a nonfusogenic phospholipid with a fusogenic one. Phospholipase D lowers the Ca+2i concentration requirement for the fusogenic action of annexin I to promote fusion of PMN granules with artificial liposomes containing phosphatidic acid and phosphoethanolamine. Annexin I and II are two of several proteins that promote fusion between phospholipid vesicles and the cytoplasmic surface of PMN membranes. Intact PMN or PMN membrane preparations treated with trypsin do not bind to liposomes enriched with fusogenic lipids. This indicates a role for cytoplasmic plasma membrane proteins including annexin I in PMN degranulation.[250] [251] Two isoforms of another fusogenic protein, synaptosomal-associated protein of 25 kDa size (SNAP-25), are present in PMNs. SNAP is essential for exocytosis at nerve terminals.[252] Other proteins functioning in the docking and fusion of synaptic vesicles at the plasma membrane and identified in PMN are

secretory vesicle-associated membrane protein-2 (VAMP-2), syntaxin 4, and SCAMP. The latter protein is also found in gelatinase, specific and azurophilic granules, and the secretory vesicles of PMNs.[253]

Secretogogues are soluble molecules that activate PMNs and provoke release of granule contents to the outside of the cell. Complete secretogogues induce the release of both primary and specific granules and elicit a transient rise in Ca+2i and cAMP. Incomplete secretogues cause a rise in Ca+2i and induce release of specific granules without altering cAMP levels.[254] Most chemotactic factors, including C5a, fMLP, PAF, LTB4, and the calcium ionophore A23187, are complete secretogogues, whereas the incomplete secretagogues include phorbol myristate acetate (PMA) and the cell surface reactive lectin concanavalin A (ConA). Several nonchemotactic interleukins, cytokines, and bone marrow growth factors act as either complete or incomplete secretagogues. The inflammatory mediators TNF-, IL-1, and IL6 each induce release of primary and secondary granules in cytochalasin B-treated PMNs,[255] [256] [257] [258] whereas IL4 and chemotactic IL8 effect release of specific granules.[259] [260] [261] GM-CSF causes a release of specific granules from PMN and acts as a complete secretagogue with cytochalasin B-treated PMNs.[262] [263] A single dose of GM-CSF (7.5 g/kg) to human normal volunteers increases expression of the -2 integrin CD11b found in all PMN granule subsets except primary granules. GM-CSF induces the release of chemotactic IL8 but not IL6 or TNF-.[263] A single dose of G-CSF (300 g) also up-regulates CD11b as well as FcRIII, and results in elevation of plasma lactoferrin and elastase. Continued daily administration of G-CSF raises the absolute neutrophil count and markedly elevates TNF- levels without increasing IL8 or GM-CSF plasma levels.

It is possible to deplete PMN totally of gelatinase tertiary granules while leaving intact 50% of lactoferrin-containing specific granules and 90% of myeloperoxidase-containing primary granules within the partially stimulated PMN. This low level of PMN activation in which tertiary granule gelatinase is selectively released is associated with PMN priming.[263] [264]

PRIMING OF POLYMORPHONUCLEAR NEUTROPHILS

Polymorphonuclear neutrophils exist in one of three states: quiescent, activated, or primed. Primed PMNs are poised to display an exaggerated respiratory burst or secretory response when specific receptors are triggered by their appropriate agonists. Agonists capable of priming PMN are of three main types:

1. The inflammatory mediators that are chemotactic and bind to the seven transmembrane domain family of receptors (Table 38-2)
2. The serum immunoglobulin and complement opsonins, which bind to the single transmembrane receptors that require cross-linking for their full activation (Table 38-3)
3. The inflammatory cytokines and growth factors that bind to their specific single transmembrane receptors (e.g., TNF-, LPS, GM-CSF, G-CSF, substance P, orthovanidate, IL1).

These molecules prime at dose levels that do not elicit a rise of cytosolic free calcium, but do lead to intracellular protein phosphorylation of tyrosine residues in PMNs.[265] [266] Activation of any of the three classes of receptors prime the PMN for the subsequent exaggerated respiratory burst or secretory response. However, only the chemotactic and opsonic phagocytic receptors can trigger the exaggerated response when engaged by the higher level of the appropriate agonist. PMNs can be primed by one agonist and then triggered into the exaggerated response by a second agonist. [267] Priming can occur through either high- or low-affinity receptors of the same receptor class. Depending on the nature of the stimulus, priming may be achieved rapidly

Figure 38-8 Reactions of the respiratory burst pathway. The enzymes responsible for reactions 1 to 9 are as follows: (1) The respiratory burst oxidase (NADPH oxidase); (2) superoxide dismutase or spontaneous; (3) nonenzymatic, Fe^{2} +-catalyzed; (4) myeloperoxidase; (5) spontaneous; (6) glutathione peroxidase; (7) glutathione reductase; (8) glucose-6-phosphate dehydrogenase; (9) glutathione synthetase. (*Adapted from Curnutte JT, Orkin SH, Dinauer MC: Genetic disorders of phagocyte function. In Stamatoyannopoulous G (ed): The Molecular Basis of Blood Diseases, 2nd ed. Saunders, Philadelphia, 1994, p. 505, with permission.*)

over a few minutes, or more slowly over 30 minutes. The primed state may last several hours.[265] [268]

Priming results from the intracellular crosstalk between the calcium signaling system acting via serine/threonine kinases such as a protein kinase C, phospholipase A_2,[269] or calmodulin-dependent kinases, and the calcium-independent tyrosine kinase signaling system acting via tyrosine kinases such as Fgr, Lyn, Fyn, and Syk. [265] The end intracellular result is complete phosphorylation of those proteins involved in achieving an exaggerated respiratory burst and degranulation response of the PMN.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

RESPIRATORY BURST

Activation of PMNs leads within seconds to a dramatic increase in oxygen consumption that is unaffected by mitochondrial inhibitors. [270] This burst of respiration results from activation of a latent enzyme system referred to as NADPH oxidase or the respiratory burst oxidase. [271] [272] [273] The products of the respiratory burst are generated by single electron transfer from NADPH to molecular oxygen (O_2) forming superoxide anion (O2). Superoxide rapidly dismutates either spontaneously or catalyzed by superoxide dismutase (SOD) to hydrogen peroxide (H_2O_2). H_2O_2 reacts with superoxide anion, forming the highly reactive hydroxyl radical (OH) and with chloride ion (Cl), forming hypochlorous acid (HOCl). Superoxide anion is only weakly bactericidal, but hydroxyl radical kills microbes and injures surrounding tissue. Hypochlorous acid forms longer-lasting chloramines that contribute to oxidative killing of microbes. These oxidative products also inactivate antiproteinases and activate metaloproteinases such as elastase and collagenase during PMN degranulation or secretion. This contributes to surrounding tissue injury. [274] Low concentrations of H_2O_2 react with reduced glutathione (GSH), catalyzed by glutathione peroxidase to form water and oxidized glutathione (GSSG). PMNs are also equipped with other antioxidants, including ascorbic acid, membrane -tocopherol, and soluble catalase. The source of reducing equivalents for the respiratory burst oxidase and the glutathione regeneration is NADPH, which is replenished from $NADP^+$ by glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase in the hexose monophosphate shunt (HMPS) (Fig. 38-8).

The NADPH oxidase is a multicomponent enzyme system composed of at least seven distinct proteins located in various regions of the quiescent PMN. The properties of these proteins are listed in Table 38-4 (Table Not Available) . Some of these proteins translocate to the cortical cytoskeleton and membrane of the phagolysosome or plasma membrane during opsonic phagocytosis or secretagogue activation of the PMN. In the quiescent PMN, p47 phox protein resides in the cytosol along with p67 phox protein, complexed to p40 phox protein. [275] [276] [277] [278] Activation of the NADPH oxidase results from protein kinase C-mediated phosphorylation of p47 phox protein [279] and the subsequent translocation and binding of p47 phox phosphoprotein and the p67 phox-p40 phox complex to the membrane flavocytochrome b558, a heterodimer comprising a 22 kDa -subunit (p22 phox) and a glycosylated 91 kDa -subunit (gp 91 phox). [280] [281] [282] Initiation of phosphorylation of p47 phox is essential for the translocation and assembly of cytoskeletal and membrane-associated NADPH oxidase components from the cytosol. [283] [284] The binding of the three cytosolic components takes place in the cortical cytoskeleton of the PMN, where p47 phox phosphorylation is completed (Fig. 38-9). [285] Eighty percent of the cytochrome b558 is located in the specific granules, gelatinase granules, and secretory vesicles of the PMN and translocates to the cortical cytoskeleton and plasma membrane on PMN activation. [286] [287]

Low-molecular-weight GTP-binding protein Rap1A is tightly associated with the flavocytochrome b558 and may be required for complete function of the NADPH oxidase. [288] [289] Rap1A is found both in the plasma membrane and in the specific granule membrane and is translocated with the cytochrome b558 to the cortical cytoskeleton or to the phagolysosomal membrane during opsonic phagocytosis of microbes. [290] The binding of Rap1A to cytochrome b558 is lost when Rap1A is phosphorylated (Fig. 38-9). [291] Activation of Rap1 occurs independently of the respiratory burst and is normally activated in PMN from patients with chronic granulomatous disease. [292]

A cytoplasmic GTP-binding protein, Rac2, is also transferred

Figure 38-9 Assembly of the seven components of the NADPH phagocytic oxidase during activation of PMNs. Depicted is the docking of the cytoplasmic components, p47 phox phosphorylated and bound to submembrane actin cytoskeleton, p67 phox complexed to p40 phox, and Rac2-GDP after activation and release from Rho-GDI. Rac2 shuttles the cytoplasmic components, which dock with membrane cytochrome b558 dimer composed of gp-91 phox and p22 phox. Rap1A remains bound to cytochrome b558 unless phosphorylated. Also depicted is the transfer of electrons from cytoplasmic NADPH to the flavoprotein to the cytochrome b558. P67 phox facilitates electron flow from NADPH to the flavoprotein and p47 phox is required for electron transfer beyond the flavoprotein to the heme groups of gp-91 phox and p22 phox of cytochrome b558. Electrons flow from cytochrome to oxygen, which reduces oxygen (O_2) to superoxide anion (O_2). The flow of protons is also depicted, indicating the resultant acidification of phagolysosomes or extracellularly to adjacent sites. See text for further details.

with p47 phox and p67 phox-p40 phox complex to the cortical cytoskeleton on PMN activation. Rac1 and Rac2 are normally inactive by being complexed with the GDP dissociation inhibitor Rho-GDI. [293] [294] [295] Both Rap1A and Rac2 appear to regulate oxidase activity by utilizing their preferred substrate GTP, but not GDP. [296] On PMN activation, biologically active lipids such as arachidonic acid, phosphatidic acid, and phosphatidylinositols are generated. These lipids disrupt the binding of Rap1A from cytochrome b558 and Rac2 from Rho-GDI. Rac2 is active in PMNs and is required for translocation of p47 phox and p67 phox-p40 phox complex. It is likely that rac proteins function as shuttle proteins carrying phox proteins to the cytoskeleton in their GTP-bound state and dissociate in their GDP-bound state while returning to the cytosol. [285] During PMN activation, p47 phox becomes heavily phosphorylated on its serine residues. [297] [298] However, only Ser379 at the C-terminus domain of p47 phox is essential for oxidase activity and for p47 phox binding to the cytoskeleton. [299] In a cell-free system, Rac protein is also required for complete activity of p47 phox and p67 phox (Fig. 38-9). [300]

The cytochrome b558 is the terminal component of the microbicidal superoxide generating system. Both - and -subunits contain a heme group and probably share a third heme group. These heme-containing regions of the cytochrome b558 lie within the PMN membrane lipid bilayer. This structure provides an efficient transfer of electrons from cytoplasmic NADPH to the flavoprotein to cytochrome b558 across the plasma membrane to the surface of the phagolysosome or to the extracellular surface, where oxygen is reduced to superoxide anion. [301] The volt potential is from 330 mV for NADPH to 256 mV for flavoprotein to 245 mV for cytochrome b to 160 mV for O_2 to O2 (Fig. 38-9). These midpoint potentials are considered low compared to mitochondrial cellular cytochromes. [272] P67 phox facilitates electron flow from NADPH to the flavoprotein, and p47 phox is required for electron transfer to proceed beyond the flavoprotein to the heme groups in the cytochrome b558 and then on to superoxide and oxygen. [302] [303] Two moles of oxygen are reduced to superoxide anion and one mole of reduced nicotinamide adenine dinucleotide is oxidized: $2O_2$ + NADPH 2O2 + $NADP^+$ + H^+ . The assembly process of the seven components of the phagocytic oxidase and the associated electron shuttle as NADPH is oxidized and oxygen is reduced to superoxide anion during the PMN respiratory burst is illustrated in Figure 38-9 .

Nitric Oxide Pathway

Another microbicidal pathway, independent of PMN phagocytic oxidase, is the nitric oxide synthetase (NOS) generation of reactive nitrogen intermediates. [304] Nitric

oxide (NO) or other labile NO intermediates, derived from L-arginine, are induced in PMNs exposed to mediators of inflammation.[305] [306] Also, superoxide dismutase enhances the inhibition of thrombin-induced platelet aggregation by release of nitrite anions (NO_2) (NO_3) and peroxynitrite from PMNs. Constitutive NOS purified from quiescent human PMNs is a 130 kDa protein whose activity requires L-arginine and NADPH, tetrahydro biopterin, and flavin adenine dinucleotide (FAD) for maximal activity.[307]

Circulating PMNs display very low NOS activity due in part to an endogenous inhibitor to constitutive NOS. [308] Although NOS colocalizes to the primary granule of PMNs, release of nitric oxide intermediates from PMNs is not associated with either degranulation or the respiratory burst. [309] [310] Three isoforms of NOS occur in blood cells: NOS I in PMNs, NOS II in eosinophils, and NOS III in platelets and megakaryocytes. NOS II isoform is inducible in PMNs to almost 50-fold by gram-negative bacterial endotoxins[311] [312] and likely plays the major role in PMN NO-related inflammatory responses.

NONOXIDATIVE MICROBICIDAL KILLING

Polymorphonuclear neutrophils can kill bacteria using antimicrobial proteins present in primary azurophilic granules and in gelatinase and specific granules (Table 38-1). The most important antimicrobial proteins of PMNs are defensins; serprocidins, including cathepsin G and azurocidin (GAP 37), and bacterial permeability-increasing protein (BPI).[313] Defensins constitute as much as 50% of PMN granule protein content.[314] They are viricidal, fungicidal, and bactericidal to many microbes and are highly cationic. They exert their cidal activity by inserting into hydrophobic channels, forming voltage-dependent ion channels in lipid bilayers.[315] Cathepsin G is a serine protease that kills both gram-positive and gram-negative bacteria. It exerts its bactericidal action by binding to penicillin-binding proteins of bacteria such as *Staphylococcus aureus* and interferes with the synthesis of peptidoglycans.[316] Azurocidin is another serine proteinase that kills *Escherichia coli, Streptococcus faecalis,* and *Candida albicans* at acid pH, achievable in phagolysosomes of PMNs.[317] BPI protein kills gram-negative bacteria by binding to their LPS capsule and altering their bacterial membrane permeability to extracellular solutes. A mutant strain of *Salmonella typhimurium* resistant to BPI protein was also found to be resistant to PMN bactericidal activity under strict anaerobic conditions, pointing to the clinical importance of BPI protein in nonoxidative killing by PMNs.[318] The specific granule marker lactoferrin is bactericidal to some gram-negative bacteria by generating free radicals from iron bound to it. Lysozyme, present in azurophil, specific, and gelatinase granules, likely aids in the digestion of killed bacteria after they have had their capsule altered by both oxidative and nonoxidative mechanisms within phagolysosomes of PMNs.[319]

Chapter 39 - Monocyte and Macrophage Development and Function

Douglas V. Faller
Steven J. Mentzer

INTRODUCTION

The functional macrophage was first described approximately 130 years ago, when large cells with unsegmented nuclei were observed in acutely damaged tissues and areas of inflammation. In areas of chronic inflammation, these cells were more frequent and appeared larger, suggesting that the cells were capable of ingesting demolished cells and inflammatory debris. Because these cells appeared to be capable of ingesting large particles, they were termed macrophages. This scavenger function was long thought to be their principal role. It was not until 1882 that Robert Koch noted that these inflammatory phagocytic cells could engulf tubercle bacilli. Metchnikoff concluded that the epithelioid-like cells making up tuberculous granulomas were actually derived from monocytoid cells of the blood. The monocyte was established as a distinct cell type by 1913. Even then, many pathologists were convinced that monocytes and macrophages were cells of different ontogeny. Much later, cells were identified that represented intermediate forms between typical monocytes in the circulating blood and tissue macrophages, and the connection between these two cell types was established.

In the 1960s, the critical role played by monocytes and macrophage in the eradication of certain intracellular microorganisms was discovered. The macrophages in the skin, lung, and gut appeared to provide a first line of defense against microbial infections and parasitic infections. [1] [2] [3] [4] Exposure to environmental pathogens caused macrophages to enlarge, increase their number of lysosomes, and become more phagocytic. Furthermore, macrophages developed strong resistance to these microorganisms with repeated challenge. This altered state was termed activation.

An additional observation was that even after the acute macrophage-mediated inflammation subsided, rechallenge with the same exogenous microorganisms would result in rapid reaccumulation and activation of macrophages. This reactivation appeared to be an antigen-specific event, triggered by memory lymphocytes. These results indicated an important interaction between lymphocytes and macrophages. More recently, the reciprocal interaction, in which macrophages regulate lymphocyte function, has been the focus of intensive study. Current models of the immune system implicate macrophages in all steps of the hosts encounter with microbial pathogens: from the initial processing of exogenous antigens, to their presentation to lymphocytes, to their own subsequent activation by these lymphocytes, and, in turn, their regulation of these lymphocytes. Macrophages thus play an active role in regulating both the afferent and the efferent arms of the immune system. This phylogenetically older, nonspecific defense system has evolved to interact with, and regulate, the newer and more specific cellular and humoral immune defense systems. Even the term resident or sessile macrophage is being challenged because it becomes clear that this cell can circulate, trafficking into and through normal tissues, and into lymphatics as far as the lymph node. [5] Finally, the role of monocytes and macrophage in the host response to tumors, in tissue maintenance, and in disease states such as atherosclerosis are active areas of research that are only now being elucidated.

The activities of monocytes and macrophage can be divided into 3 broad categories (Table 39-1), described in the following sections.

Tissue Maintenance

Tissue maintenance is an activity that comprises the functions of tissue repair and remodeling activities. Examples include the osteoclast remodeling of bone after injury and the osteoclast

mobilization of bone in calcium homeostasis.[6] [7] [8] [9] Another example is the splenic macrophage, which mediates phagocytosis of senescent red blood cells. [10] Langerhans cells control keratinization of the skin epidermis, [11] and Kupffer cells in the liver manage gut-absorbed endotoxin as well as red blood cell phagocytosis in the neonatal liver,[12] [13] and macrophages in the central nervous system may participate in neuroendocrine control. [14]

Immune Regulation

Monocytes and macrophages play a central role in immune regulation by coordinating the interaction of T and B cells during antigen presentation. [15] [16] [17] The macrophage, especially in its specialized forms, the Langerhans cell and the lymphoid dendritic cell, not only processes antigens, but releases an array of cytokines that modulate lymphocyte function.[18] Immune regulatory function also includes monocyte or macrophage-mediated suppressor activities such as suppression of lymphocyte proliferation[19] [20] and inhibition of lymphokine production. [21]

Pathogen Control

The antimicrobial properties of monocytes and macrophage include antibacterial, [22] [23] antiparasitic,[24] antifungal,[25] and antiviral[26] properties. Monocytes and macrophage may play multiple roles in a single area of inflammation. For example, macrophages may infiltrate an area of damaged tissue, debride the wound, direct fibroblast and connective tissue regrowth, participate in angiogenesis, and destroy invading pathogens. [27] [28] [29] [30] [31] [32] The versatile role that migratory monocytes and tissue macrophages play in areas of inflammation demands that they have the capacity to express a wide range of morphologic, functional, and biochemical phenotypes. Furthermore, the interaction of monocytes and macrophages with immune, hematopoietic, endothelial, or connective tissue cells appears to require cellular communication mediated both by cell-cell contact as well as the elaboration of cytokines, growth factors, and small molecules such as nitric oxide (NO), reactive oxygen intermediates, and prostaglandins (Table 39-2).

ORIGINS OF MONOCYTES AND MACROPHAGES

In fetal life, primitive macrophages develop and differentiate into fetal macrophages before the appearance of fetal monocytes. [33] Monocytes appear in the fetal circulation at approximately the fifth month of gestation and increase in number during the third trimester. [34] The monocyte count reaches a peak at approximately 12 hours of age and remains high during the first 2 weeks of life. Monocytes develop from a pluripotential stem cells in the bone marrow, [35] now designated as colony-forming unitgranulocyte, erythrocyte, monocyte, megakaryocyte (CFU-GEMM) and the more committed colony-forming unitgranulocyte, macrophage (CFU-GM; Fig. 39-1). This pluripotent stem cell can commit along both granulocytic and monocytic lineages. Some of the signals necessary for the commitment to the monocytic lineage are known. M-CSF (monocyte colony-stimulating factor, also called colony-stimulating factor-1 [CSF-1]) is the most important of the CSFs in the development of monocytes/macrophages. M-CSF enhances production of the monocyte precursors, stimulates the chemotactic activity or monocytes/macrophages, induces differentiation of monocytes into macrophages, induces proliferation of some monocyte/macrophage subtypes, and is necessary, but not sufficient for activation of monocytes/macrophages.[36] Genetic knockouts or naturally occurring mutants lacking M-CSF in mice result in osteopetrosis (because of impaired osteoclast development),[37] and a severe deficiency but not complete absence of monocytes/macrophages, demonstrating the existence of an M-CSF-independent monocyte/macrophage subpopulation (Kupffer cells,

Langerhans cells and microglia). Interleukin-3 (IL-3) and granulocyte-macrophage CSF (GM-CSF) have been shown to mediate differentiation of monocytic cells both in vitro and in vivo.[38] [39] GM-CSF is produced by T cells, endothelial cells, and fibroblasts; M-CSF is produced by monocytes, endothelial cells, and fibroblasts. [40] Bone marrow precursors exposed to GM-CSF produce mixed granulocyte-monocyte/macrophage colonies (CFU-GM); M-CSF produces colonies that are primarily monocytic (CFU-M). Knockout of the GM-CSF gene in mice produces accumulation of surfactant lipids and proteins in the alveolar space, secondary to defective alveolar macrophage differentiation and inadequate macrophage processing of surfactant. [41]

The development of the monocyte lineage demonstrates the close relationship between the origins of monocytes and granulocytes. Once the pluripotential stem cell has committed to the monocyte lineage (CFU-M), the cell develops through morphologically distinct monoblast and promonocyte stages. The mature monocyte, in the G_1 phase of the cell cycle, is released within 24 hours from the bone marrow to the peripheral circulation. Peripheral blood monocytes rapidly partition between the marginating and circulating pools in the peripheral circulation. Although the marginating pool is approximately 3.5 times greater than the circulating pool, [42] the factors regulating monocyte margination are unclear. The monocyte remains in the peripheral circulation for 871 hours (half-life of 17.4 hours) before migrating into peripheral tissues.[42] [43]

Circulating blood monocytes are 1215 m in diameter with a highly convoluted surface and a lobulated (kidney-shaped or folded), foamy nucleus. A Wright-stained smear of peripheral blood monocytes typically demonstrates indistinct nucleoli as well as gray and variably vacuolated cytoplasm. [44] Monocytes contain a single type of granule with staining characteristics suggestive of lysosomes. Monocytes may be further characterized by the presence of a fluoride-sensitive, nonspecific esterase. After the monocyte has migrated into the extravascular tissues, the cell becomes larger and acquires the cytologic appearance of a tissue macrophage. The cell nucleus appears oval and euchromatic with more prominent nucleoli. The cytoplasm stains blue, reflecting high concentrations of RNA. Compared with the circulating cell, in the macrophage there is an appearance of more ribosomes, lysosomes, mitochondria, endoplasmic reticulum, open vesicles, and electron-dense inclusions of varying sizes and shapes. Increased levels of pinocytic as well as phagocytic activity are also a property of some mature macrophages, although the activities and morphologies of tissue macrophages vary widely according to their location and purpose.

TRANSITION OF MONOCYTES TO MACROPHAGES

The number of monocytes produced, circulating, and extravasating is controlled at a number of levels. Active inflammation can affect the generation and circulating time of peripheral blood monocytes. The production of monocytes from promonocytes can increase up to fourfold within 12 hours of an inflammatory stimulus. [45] In this setting, the average circulation time of monocytes in the peripheral blood may fall to as little as 30 minutes. [42] The young monocyte is capable of producing growth factors, including M-CSF and GM-CSF, which can act in a paracrine or autocrine manner to stimulate monocytopoiesis. [46] [47] [48] Monocytes contain lysosomal hydrolases and the intracellular enzymes elastase and cathepsin, but have little capacity for production of metalloproteases. They express receptors for glycoproteins, apolipoprotein-E, and transferrin. As monocytes differentiate into macrophages, they begin to produce predominantly metalloproteases and metalloprotease inhibitors, lose expression of hydolases and certain cell surface receptors, and express macrophage-specific genes and products such as inducible NO synthase (NOS), interferon (IFN)-, and the complement

component Bf.[49] The movement of the peripheral blood monocyte into the extravascular tissue produces a tissue-specific macrophage. [50] [51] [52] Tissue-resident macrophages are long-lived and (in some cases) slowly self-proliferating [53] and self-sustaining cells.

Tissue macrophages are a heterogeneous population with very different morphologic and functional properties depending on the tissue where they reside. [54] [55] Even within certain tissues, like the spleen, there is distinct, region-specific microheterogeneity of macrophage populations. [36] This tissue heterogeneity is the result of three interacting forces: (1) a lineage- or origin-dependent effect (i.e., whether the macrophage is bone marrow derived or the result of local proliferation); (2) the subpopulation of the marrow-derived macrophages, which is determined by the types of CSFs in the marrow environment and the developmental stage of the monocyte/macrophage; and (3) adaptive influences, in response to the conditions and stimuli in which the macrophage is residing (Fig. 39-2).[56] For example, the presence of M-CSF and expression of c-*fos* can drive monocytes to differentiate into osteoclasts, whereas exposure to GM-CSF and IL-4 facilitates differentiation toward Langerhans and dendritic cells.

Alveolar macrophages, Kupffer cells, osteoclasts, peritoneal macrophages, and synovial type A cells all belong to the resident mononuclear phagocyte system (or reticuloendothelial system). Macrophages of the reticuloendothelial system are found not only at portals of entry, such as pulmonary alveoli and the gastrointestinal tract, but in generally sterile areas of the body, such as the brain, bone, and bone marrow. These mature resident macrophages have a relatively long life, ranging from 14 days to 1 year. Some of these cells perform primarily homeostatic function, whereas others exert survey or acute antipathogen activities. Tissue macrophages retain some propensity for chemotaxis, and have full capacity for phagocytosis and oxygen-dependent microbicidal activity.

In inflammatory infiltrates, mononuclear phagocytes also comprise a heterogeneous group. They consist of macrophages already residing in the tissue before the onset of inflammation (*resident macrophages*), as well as mononuclear phagocytes recruited from the circulation (*exudate macrophages*). The differentiation from circulating monocyte into resident macrophage may include a transitional form called the *exudate-resident macrophage*. Once extravasation has occurred, it is likely that the microenvironment plays a critical role in determining the cells

Figure 39-2 Terminal differentiation pathways of monocytes. GM (M)-CSF, granulocyte-macrophage (monocyte) colony-stimulating factor; IL-4, interleukin-4. *(Adapted with permission from Gordon S, Clarke S, Greaves D et al: Molecular immunobiology of macrophages: recent progress. Curr Opin Immunol 7:24, 1995 [Current Biology, Ltd.].)*

maturation. The tissue-specific levels of lymphokines, monokines, hormones, and toxins can act as microenvironmental mediators of maturation. Macrophages achieve a spectrum of functional phenotypes depending on these microenvironmental signals. IFN--treated macrophages are more bactericidal and tumorcidal, express increased levels of major histocompatibility complex (MHC) class II for antigen presentation to lymphocytes, and are primed for the release of cytokines, such as tumor necrosis factor (TNF)-, in response to bacterial toxins. [57] [58] [59] [60] Alternatively, T-cell-derived cytokines such as IL-4, IL-10, IL-13, and transforming growth factor (TGF)- may inhibit the effects of the activating cytokines, creating a counter-balance to IFN- and GM-CSF. [61] [62] Tissue microenvironments may also regulate reversible changes in macrophage phenotype and function. For example, the heterogeneity in Fc-receptor expression in pulmonary alveolar macrophage can be reversed by in vitro culture.[63] The glycolytic metabolism of the peritoneal macrophage is high, whereas that of the pulmonary macrophage is low. This metabolic state can be reversed when alveolar macrophages are transferred to an oxygen-poor environment. [64] [65] [66] Thus, differentiation in macrophages is not permanent or terminal, but rather exhibits an adaptive or plastic potential. [56]

MONOCYTE/MACROPHAGE BIOLOGY

Metabolism

Monocytes and macrophages are facultative anaerobes, with the exception of pulmonary macrophages, which appear to be uniquely dependent on aerobic metabolism.[66] [67] Phagocytosis and the phagocytosis-related oxygen burst through NADPH oxidase and the hexose monophosphate shunt are cyanide insensitive, and the energy for these phenomena depends primarily on glycolysis. [68] [69] Only pulmonary macrophages, their energy metabolism more dependent on oxygen and oxidative metabolism, show little postphagocytic respiratory burst beyond their high resting level. [70]

Monocyte/Macrophage Activation

As our appreciation of the wide spectrum of monocyte/macrophage functions grows, it becomes less useful to speak of macrophage activation as the acquisition of a single class of properties. Unlike T cells, macrophage function does not seem to be defined by unique pathways of differentiation, but rather by the balance of cytokines and factors to which the cells are exposed in their environment. [71] It is more accurate to think of macrophage activation in terms of the acquisition of competence to complete specific complex functions,[59] correlating with patterns of specific gene expression, rather than conversion of macrophage to a single activated state. Different macrophage activation states would include the phagocytic/cytocidal state, the immune/antigen-presenting cell (APC) state, and differentiation-specific states, such as that of the activated osteoclast.

Monocytes and macrophages can readily achieve the complex metabolic state that characterizes macrophage-mediated microbicidal and tumorcidal (cytocidal) activities. [59] [72] Agents that can trigger macrophage activation can be divided into two main classes: physiologic factors produced by the host, such as cytokines and metabolites; and environmental factors derived from viruses, bacteria, or chemical synthesis. Although both classes of activators can stimulate the macrophage, combinations of such stimuli are synergistic in activating macrophages, and are required for some effector functions. Furthermore, the activation process in vivo is likely to be a multistep, multipathway process involving a defined sequence of events. A plausible sequence for macrophage activation in situ may include the priming of the macrophage with one agent (e.g., a physiologic macrophage-activating factor), with synergistic cellular activation on exposure to a second factor. [73] [74] This sequence provides an explanation for the combination of physiologic (e.g., IFN-) and environmental (e.g., LPS [lipopolysaccharide] or phorbol ester [e.g., PMA (phorbol myristate acetate)]) signals required to activate macrophage tumorcidal activity. It is likely that different combinations of the stimuli are responsible for the multiple activation phenotypes, and correlated patterns of macrophage-specific gene regulation, that can be observed.

A soluble factor produced by T lymphocytes was the first cytokine identified as a stimulus of the macrophage cytocidal activation process. This activity was termed macrophage-activating factor (MAF)[59] [72] [75] and was later identified as IFN-.[76] [77] [78] Additional, non-IFN forms of MAF activity have been identified, including T-cell products such as IL-2, IL-4, and macrophage migration inhibitory factor, hematopoietic growth factors such as M-CSF and GM-CSF, and a variety of other products. [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] However, many of these factors may work indirectly, through IFN-, because studies of the consequences of deletion IFN- or IFN- receptor genes demonstrate that IFN- is required for many aspects of macrophage function. [90] [91] M-CSF, although not activating in the classic sense, does stimulate monocyte/macrophage proliferation, increases adhesive properties by inducing glycoprotein receptor expression, and facilitates pathogen clearance by stimulating endocytic pathways and the production of proteolytic agents such as urokinase.

The different external stimuli that result in monocyte/macrophage cytocidal-type activation appear to use a variety of signal transduction pathways to produce intracellular superoxide and microbicidal activity. Lectins are thought to trigger production of superoxide through a rise in intracellular calcium, [92] whereas prostaglandin E_2 appears to effect signaling through adenyl cyclase with the generation of cyclic adenosine monophosphate. LPS, binding to the macrophage by the surface receptor CD14,[93] activates an inositol and diacylglycerol messenger system as well as calcium mobilization. Guanine nucleotide binding proteins (G-proteins) may also play a role in some activation pathways.[92] [94]

Oxidative burst stimulation of phagocytes leads to an increase

in oxygen consumption, activation of the hexose monophosphate shunt, and an increase in glucose uptake. This respiratory burst results in the production of toxic oxygen species (reactive oxygen intermediates)[95] [96] that are generated from oxygen through a membrane-bound hemo-flavoprotein, NADPH oxidase. A B-type cytochrome is related to this oxidase, probably as part of a chain of electron carriers. The NADPH oxidase system catalyzes the one-electron reduction of O_2 to superoxide (O_2) through oxidation and reduction steps. O_2 is converted to several other toxic oxygen species such as hydrogen peroxide, hydroxyl radicals, and singlet oxygen. Ferric iron may react with hydrogen peroxide and superoxide to produce hydroxyl radicals with strong oxidant (i.e., microbicidal) properties over relatively short distances, as in a phagosome. In combination with an enzyme from the azurophilic granules (myeloperoxidase, or an equivalent), H_2O_2 plus a halide form a powerful oxidation system resulting in the generation of oxidized halogens, such as hypochlorous acid. A substantial portion reacts with amines, particularly taurine, to yield chloramines. Cytokines such as TNF- and colony-stimulating factors are able to prime monocytes to respond to a second stimulus, with resulting increases in production of oxygen radicals, release of lysosomal enzymes, increases in phagocytic and cytotoxic capacity, and increased adherence at sites of inflammation.[97]

Mononuclear phagocyte cytocidal-type activation results in certain quantitative and qualitative changes in the macromolecular composition of the macrophage cell membrane. These changes include the increased expression of Fc receptors, class II MHC antigens, IL-2 receptors, and membrane-associated TNF. In contrast, macrophage activation results in decreased expression of other receptors such as transferrin, mannose-fucose, and C3bi (CR3).

Whereas the production of IFN- by the T-helper 1 (Th1) lymphocyte population results in a cytocidal state of macrophage activation, the cytokines produced by the Th2 population, specifically IL-4 and IL-13, stimulate the APC type of activation state (sometimes called an alternative activation state). These T-lymphocyte-derived cytokines in turn enhance macrophage stimulation of T cells by inducing class II MHC antigen and B7 co-stimulatory molecule expression, [98] and antigen uptake and expression. Once activated, monocytes/macrophages in turn can produce cytokines that stimulate both types of helper T-cell subsets. IL-12 production in response to IFN-, especially in combination with B7 expression, is a determining factor in the Th1 lymphocyte-mediated immune response, [99] [100] and TNF- also stimulates this helper subset.

There are a number of routes to macrophage deactivation, including the products of lymphocytes and macrophages themselves. The major macrophage inhibitory cytokines include IL-4, IL-10, IL-13, and TGF-, with each one inhibiting some, but not all, macrophage functions, depending on the activation state of the macrophage.[101] [102] All four inhibit NO production by the macrophage. IL-10, in addition, suppresses T-cell responses to monocytes/macrophages by inhibiting the

expression of the B7 co-stimulatory molecule and lymphocyte-activating cytokine production. As noted previously, IL-4 and IL-13 stimulate the APC type of activation state, while simultaneously inhibiting the cytocidal type of activation state. Other monocyte/macrophage inhibitors include prostaglandin E_2.[59] [72] [75] [103] The synthesis and release of prostaglandin E_2 by macrophages is likely to provide a negative feedback loop for the modulation of the immune response. Corticosteroids are also well known anti-inflammatory agents that suppress the induction of activation-associated gene products in macrophages.

Monocyte/Macrophage Surface Molecules

In keeping with their broad range of activities, monocytes/macrophages express a variety of receptors on their surfaces with which they interact with their environment. These receptors can be artificially divided into those that mediate uptake of microorganisms and particles, and those that mediate cell-cell contact, but many of these receptors are in fact able to serve multiple roles.

Receptors Mediating Uptake of Microorganisms and Particles

There are at least five major classes of receptors on the surface of monocytes and macrophages that mediate attachment and entry of microorganisms or other materials into the cell:

1. Macrophage scavenger receptors (MSRs) bind and endocytose low-density lipoproteins (LDL), [104] especially after their oxidation from contact with vascular wall components. MSRs are further subdivided into MSRs-1, -2, and -3, and include MARCO [105] and CD36 (platelet glycoprotein IV), which differ in expression in macrophage subtypes, and some of which can bind extracellular matrix proteins and bacterial wall proteins such as lipoteichoic acid, LPS, and others. [106]
2. The immunoglobulin Fc-receptors (FcR) mediate uptake of immunoglobulin-opsonized particles and immune complexes, [107] [108] and include those with high specificity for monomeric IgG (FcRI, CD64), complexed IgG (FcRII or III, CD32 or CD16), or for IgE (CD23). The FcRI is expressed only on mononuclear phagocytes, in contrast to the other FcR, which are expressed on both neutrophils and mononuclear phagocytes. Ligand binding to the FcR induces the release of numerous products from the macrophage, including TNF and tissue plasminogen activator, and triggers the respiratory burst. [109]
3. Receptors that recognize the third component of complement (CRs) include CR1 (CD35), binding C3b/C4b, and the 2-integrins CR3 (CD11b/CD18) and CR4 (CD11c/CD18), binding iC3b.[110] The CRs are activated or their expression is induced with monocyte/macrophage activation. Complement fragments may not only identify potential pathogens, but may facilitate their phagocytosis. Because the CR endocytotic pathway can bypass the oxidative burst, this path is often used for uptake by intracellular parasites such as *Mycobacteria*, *Legionella*, and *Leishmania* species.
4. Receptors recognizing mannose/fucose-*N*-acetylglucosamine-terminated glycoproteins are termed macrophage mannose receptors (MMRs). The MMR is found on mature, nonactivated macrophages and mediates endocytosis, phagocytosis, and cytotoxicity by reactive oxygen intermediates, during the ingestion of yeast wall particles (such as zymosan) and *Pneumocystis carinii*.[111] [112] [113] These receptors are composed of repeating domains of calcium-dependent or C-type lectin domains. The receptors described so far include receptors composed of eight [114] and ten contiguous (DEC205) [115] C-type lectin domains.
5. CD14 binds LPS and microorganisms bearing polyanionic molecules.

Monocytes and macrophages also express receptors for coagulation factors VII and VIIA, [116] [117] -endorphin, [75] [118] LDL, and very-low-density lipoprotein (VLDL). [119] [120] [121] [122]

Cell-Cell Adhesion Receptors

Macrophages possess abundant cell-cell adhesion receptors and ligands, which can mediate their recruitment into inflamed tissue or their interactions with other immune cells.[123] These can be grouped into three families: (1) integrins, (2) immunoglobulin superfamily, and (3) selectins. The major integrins on monocytes/macrophages are of the 1 and 2 subfamilies, as classified according to their common chain. The 1 family (VLA molecules) mediate binding of monocytes/macrophages

to the extracellular matrix, and include thrombospondin, fibronectin, and laminin. The 2 family consists of the three leukocyte-restricted integrins, LFA-1 (CD11a/CD18), CR-3 (MAC-1, CD11b/CD18), and p150/95 (CD11c/CD18). The immunoglobulin superfamily members include intercellular adhesion molecule (ICAM)-1 (CD54), -2 (CD102), and -3 (CD50), as well as LFA-3 (CD50) and PECAM (CD31). LFA-3 binds to CD2 on lymphocytes. PECAM is required for diapedesis of monocytes.[124] The selectins (lectin-binding molecules) include L-selectin (CD62L), which is the only selectin on macrophages, but also include E-selectin (CD62E) and P-selectin (CD62P), which recognize oligosaccharide ligands on monocytes/macrophages such as CD15 and CD15s. These lectin receptors likely also serve a role in recognition of microorganisms by macrophages. LFA-1 (CD11a/CD18) and one of its many ligands, ICAM-1, [125] are both present on monocytes and mediate homotypic cell interactions[126] [127] as well as the attachment of monocytes to endothelial cells and to lymphocytes bearing the corresponding receptor/ligand, thus facilitating antigen presentation. [125] [126] [127] [128] MAC-1 (CD11b/CD18) appears to have a major role in the attachment and possibly extravasation of monocytes through endothelium that has been activated by stimuli.[129] Inflammatory cytokines and bacterial products can induce and activate pre-existing integrins. Inflammatory cytokines such as TNF and IL-1 induce the expression of ICAM-1, VCAM-1, and ELAM-1 on endothelial cells. [130] VLA-4 and other ligands on monocyte plasma membranes mediate binding to endothelial VCAM-1 and ELAM-1, facilitating monocyte recruitment to inflammatory sites. [131] The integrin adhesion molecules also have a transmembrane signaling function.[132] Cellular activation appears to be triggered by macrophage binding to the extracellular matrix proteins type IV collagen and fibronectin.[133]

Other adhesion molecules include CD44, which binds hylauronin, and CD36, which binds thrombospondin. Sialoadhesin (CD22) is a sialic acid-binding lectin expressed by stromal macrophages that mediates macrophage binding to bone marrow hematopoietic cells, allowing critical cell contact without activation of phagocytosis.[134]

Movement/Extravasation

Under normal conditions, monocytes constitute 16% of nucleated blood cells. Resident tissue macrophages derived from monocytes are recruited in the absence of inflammation at a basal level by unknown mechanisms. Inflammation induces the rapid egress of monocytes from the circulation. Monocyte movement from the blood to the tissue can be divided into somewhat discrete phases mechanistically (i.e., attachment, diapedesis, dissolution of vessel basement membrane, and migration along gradient of inflammatory mediator or chemoattractant), but the stimuli provoking extravasation of monocytes often act on more than one component simultaneously. Chemoattractant factors responsible for inflammatory cell recruitment include *N*-formyl-methionyl-capped bacterial proteins, complement products such as C5a, fibrinopeptides, leukotriene B4, platelet-activating factor (PAF), and a large number of growth factors and cytokines, such as TGF-, platelet-derived growth factor (PDGF), IL-1, TNF, and IL-2.[135] Many of these factors appear to act by stimulation of phospholipase C with subsequent activation of protein kinase C. Proinflammatory factors selectively chemotactic for monocytes or granulocytes, designated chemokines, have recently been characterized. [136] They fall into two families, c-x-c and c-c, based on their structure. The c-x-c family, which is more chemotactically active for granulocytes than monocytes, includes IL-8, neutrophil activating peptide-2, and melanoma growth-stimulating activity (MGSA). The c-c family members, which recruit monocytes more actively than granulocytes, include monocyte chemoattractant proteins (MCP)-1, -2, and -3, macrophage inflammatory proteins (MIP)-1, -1, and -2, and RANTES. [137] [138] [139] [140] The chemokines act through calcium-dependent activation of protein kinase C, but also activate inhibitory cyclic adenosine monophosphate-dependent kinases that may autoregulate their activity. The monocyte specificity of some of these factors may provide an explanation for the macrophage predominance in chronic inflammatory lesions such as tuberculous granulomas. Monocytes/macrophages express two types of chemokine receptors, the MCP-1 receptor and the cc-chemokine receptor-1, the latter of which binds RANTES and MIP-1 and -1.

A number of agents appear to facilitate monocyte extravascular transmigration by inducing endothelial cell adhesivity to circulating monocytes. [141] These factors include IL-1, TNF-, LPS, IFN-, thrombin, and viral infections, including herpes simplex type I and cytomegalovirus. [142] Conversely, stimulation of monocytes with the cytokines IL-3 or GM-CSF, with complement chemotactic factors, with phorbol esters, or with the formylated bacterial products f-met-leu-phe increases adhesion of monocytes to the endothelium through monocyte activation.[128] [129] [142] Monocytes selectively transmigrate through endothelial junctions during inflammatory states. [143] Monocyte migration into the subendothelial space may also occur in response to chemoattractants present in the intima or media of the vessel wall. [144]

Pinocytosis/Phagocytosis

Cells, microorganisms, and proteins can bind to the monocyte or macrophage cell surface without eliciting any active response. Macrophage activation, however,

results in increased membrane adhesiveness and the simultaneous invagination of membrane and extension of pseudopodia that cause the formation of endocytic vacuoles. Small or soluble molecules are taken up by the process known as pinocytosis. Pinocytosis may be bulk, in which the molecules are in solution around the cell and are taken up into pinocytic vesicles, or may be adsorptive, in which the molecules adhere to the monocyte plasmalemma and enter the vesicles attached to it. If the attachment of these molecules is to a specific receptor, the internalization process is termed receptor-mediated endocytosis.

The uptake of larger objects is termed phagocytosis,[145] and is strongly enhanced by activating stimuli, including engagement of macrophage receptors recognizing Arg-Gly-Asp residues. Most pathogens bind by the complement receptors or MMR, or by Fc receptors if antibody-bound. Once a particle is bound to the macrophage surface, the plasma membrane expands along the particle and engulfs it using actin microfilaments lying just under the cell membrane, creating the phagosome. So called zipper phagocytosis, with circumferential, sequential interactions between the ligands on the particle and the receptor on the macrophage, appears to be the most common mechanism of phagocytosis, although coiling phagocytosis and phagocytosis into spacious vacuoles, resembling pinocytosis, have also been described.[146] [147] Cytoplasmic granules and Golgi-derived vesicles fuse with the phagosome. The subsequent phagolysosome (secondary lysosome) plays an important role in the digestion of internalized particles. Macrophage phagocytosis is important to host defenses against many potential pathogens such as *Mycobacteria*, *Leishmania*, and *Salmonella* species. Some of these organisms may survive by preventing phagosome-lysosome fusion and are able to grow within the resident alveolar macrophages without inducing macrophage activation. Intracellular infection with certain *Mycobacteria* or *Leishmania* species actually causes down-regulation of MHC class II antigen and co-stimulator B7 expression, blunting subsequent immune responses and resulting in the energy associated with chronic infections. Cytoplasmic granules and Golgi-derived vesicles fuse with the plasmalemma of the phagosome at the site of microorganism binding and subsequently discharge their granular contents across the membrane barrier, into the extracellular fluids, in a process called degranulation.

Synthesis and Secretion of Cytokines, Growth Factors, and Effector Molecules

Macrophages are capable of secreting over 100 well defined molecules, which fall into a broad number of categories (see Table 39-2).[75] [135] These categories include cytokines (lymphokines, chemokines, and monokines), growth and differentiation factors, vascular permeability factors, eicosanoids, enzymes and enzyme inhibitors, clotting factors and complement components, plasma binding proteins, and low-molecular-weight reactive oxygen and nitrogen products.

Macrophage-derived cytokines (monokines) can be grouped into several classes based on similarities in structure or biologic activities. TNF-, IL-1, and IL-1, although structurally quite distinct, have broadly overlapping activity profiles.[60] [148] [149] Monocytes and macrophages can produce, as well as respond to, a number of the chemokines, including IL-8, MGSA, IP-10, MCP-1, and MIP-1, -2, and -3.[150] [151] [152] [153] [154] [155] Although some of these factors have been reported to exhibit growth or chemoattractant activity, the precise function for each family member is still being defined. One example of the varied activity of these factors is provided by the chemokines MIP-1 and MIP-2. These cytokines are chemotactic for neutrophils in vitro and also elicit a marked inflammatory response when injected in vivo.[156]

Additional cytokines are elaborated during the inflammatory stimulation of mononuclear phagocytes. These include growth factors (PDGF, fibroblast growth factors, TGF, GM-CSF and M-CSF), the IFNs (and), and IL-6.[75] [157] [158] [159] [160] [161] All of these cytokines are produced early after stimulation, are expressed only transiently, and do not appear to depend on the synthesis of any other gene products for their expression. Many of these factors are made in response to the lipid A component of LPS[162] or to cytokines made by other cells.[163] The process is calcium dependent[164] and is generally the result of the synthesis or increased stability of specific mRNA. Of these secreted proteins, only IL-1 is not made with a signal peptide.[165] [166] Some of the TNF produced is attached to the monocyte membrane,[167] but most is secreted into the medium.[168] These factors contribute to the inflammatory and hematopoietic effects of macrophages, but also play a role in effecting and regulating macrophage cytotoxic activity itself.[72] [75] [89] [103] For example, TNF- induces the expression of IL-1 and IL-6 by macrophages.[88] [169] Conversely, IL-1 stimulates the synthesis of TNF-, IL-6, CSF-1, GM-CSF, and IL-1 itself.[88] [170] [171] The IFNs are potent inducers of a number of monokines. IFN- stimulates the release of IL-12, contributing to natural killer cell and T-lymphocyte activation. IL-10, produced by phagocytosing macrophages (and Th2 lymphocytes), feeds back on the macrophage to decrease the production of inflammatory monokines. Combinations of cytokines can thus have additive, synergistic, or antagonistic regulatory effects on monokine production by macrophages.

Monokines may have interrelated functions that affect specific cells involved in inflammation as well as the general processes of host metabolism. For example, monokines can alter endothelial cell function.[172] IL-1 and TNF can cause fever,[165] [173] [174] muscle breakdown,[174] and changes in liver metabolism.[175] IL-1 and TNF both appear to be involved in the cachexia associated with chronic infection and malignancy.[176] TNF may play a role in the anemia of chronic disease.[177] IL-1 indirectly results in the synthesis of acute-phase reactants, through stimulation of IL-6 synthesis and secretion. These acute-phase reactants are secreted into the circulation; they include C-reactive protein, fibrinogen, $_1$ -antitrypsin, haptoglobin, and serum amyloid A. In addition, IL-6 causes a decrease in the synthesis of albumin, fibronectin, and transferrin.[178] The latter effect is responsible for the decrease in total iron-binding capacity associated with inflammation. The CSFs synthesized and secreted by monocytes and macrophages stimulate the appropriate progenitor cells in the bone marrow to make neutrophils and monocytes in response to infection. The interactions of these factors appear to play an important role in the regulation of cell growth, protein synthesis, cell movement, and cell-cell interactions. Activated monocytes/macrophages are potent producers of eicosanoids synthesized from arachidonic acid. The products of the cyclo-oxygenase pathway include thromboxanes and prostaglandins, and the lipoxygenase pathway produces secreted leukotriene B4 (LTB4) and 5-hydroxyeicosatetraenoic acid (5-HETE).

PATHOGEN CONTROL

Macrophage have been shown to be critical for arresting the proliferation of, or killing, the facultative and obligate intracellular bacteria, protozoa, and fungi. After activation, macrophages synthesize an array of proteins that regulate and catalyze the production of toxic oxygen intermediates. [179] [180] Toxic oxygen intermediates appear in the phagolysosome and kill microorganisms, primarily those that produce pyogenic infections. Intracellular killing in macrophages, as in granulocytes, is mediated by an oxygen-dependent system that uses hydrogen peroxide, a halide such as chloride, iodide, or a bromide, and a myeloperoxidase-like enzyme. [181] Macrophages, in contrast to monocytes, lack the myeloperoxidase enzyme but may have a similar analogous enzyme; alternatively, their cytocidal activity may be related to the direct activity of reactive oxygen species. [182] [183] Highly reactive oxygen radicals, including superoxide, hydrogen peroxide, singlet oxygen, and the hydroxyl radical, are produced by a membrane-associated NADPH oxidase and associated reactions, and these reactive oxygen species are available for the microbicidal process. Ferric ion may react with hydrogen peroxide and superoxide to produce hydroxyl radicals with strong oxidant properties over relatively short distances, as in a phagosome. Superoxide may be released into surrounding tissue or into phagocytic vacuoles. Superoxide leads to alkalinization of the phagolysosome, activating the neutral and cationic proteases to kill ingested organisms. Lysozyme activity has not conclusively been shown directly to kill ingested bacteria, and may be limited to degrading dead organisms.

Oxygen-independent bactericidal mechanisms also exist, as evidenced by bacterial killing under anaerobic conditions or in the absence of an oxidative burst, and antimicrobial activity by phagocytes with impaired oxidated metabolism (e.g., chronic granulomatous disease). [184] Oxygen-independent mechanisms include granule-associated proteins with microbicidal activity (neutral proteases, lysosomal hydrolases, perforin or perforin-like activities), [185] as well as cationic proteins that may kill bacteria and fungi through their action on the microbial plasma membrane. [186] Numerous bactericidal secretory products, such as lysosomal enzymes, lysozyme, and other factors from macrophages, have also been described. [187] Most of the antimicrobial cationic proteins belong to one of two families, the defensins and the serprocidins. [188] [189] The defensins are basic peptides of 2943 amino acids, and are active against a variety of bacteria. The serprocidins include elastase, cathepsin G, proteinase 3, azurocidin, and BPI. The latter two appear specific for gram-negative bacteria by virtue of their interaction with LPS. Oxygen-independent cytocidal mechanisms may be more selective in their expression than oxygen-dependent mechanisms. [181] Although there is in vitro evidence for cytocidal activity against bacteria, fungi, and some viruses, [190] and resistance to defensins has been suggested a mechanism used by organisms like *Salmonella* to survive in phagolysosomes, there are no comprehensive studies of human monocyte and macrophage oxygen-independent cytocidal mechanisms. The biologic importance of oxygen-independent cytocidal mechanisms thus remains unclear.

In addition to microbicidal capacity, macrophages possess microbiostatic activity for a variety of intercellular organisms. [187] [191] [192] [193] [194] The capacity for macrophages to inhibit the growth of intracellular microorganisms depends on previous exposure to the activating agent and, in some cases, to chemical signals originating from the microbe itself. [193] [195] An important contribution to microbiostasis appears to be the synthesis of small, diffusible molecules by the macrophage. The production of NO has recently been recognized as a major mechanism of monocyte and macrophage toxicity toward microorganisms and tumor cells. [196] [197] The inducible, calmodulin-bound isoform of NOS is monocyte/macrophage specific and generates large amounts of NO for long periods of time, in contrast to other isoforms. A cytocidal type of monocyte/macrophage activation program is required for inducible NOS expression, with priming by IFN- followed by a second signal, such as IL-2, TNF-, LPS, or other bacterial polyanions. [198] NO produced by activated macrophages is cytostatic or cytotoxic for a variety of invading microorganisms. The effector functions of NO appear to involve iron-dependent reactions, the inhibition of enzymes, and perhaps formation of perioxinitride. [199] Killing of *Leishmania* amastigotes by IFN--activated macrophages and macrophage fungistasis are both mediated by NO. [200] [201]

The originally identified macrophage-activating factor, IFN-, enhances macrophage killing of intracellular pathogens, including *Candida* species, *Toxoplasma gondii*, and mycobacteria. [202] Therapeutic activation of the circulating blood monocyte has been achieved after intravenous, intradermal, intramuscular, and subcutaneous administration of IFN- in patients with cancer, lepromatous leprosy, acquired immunodeficiency syndrome, and chronic granulomatous disease. Activation of the alveolar macrophage has also been induced in a compartmentalized fashion by aerosolized IFN-. [203]

Monocytes and macrophages express the CD4 membrane molecule and can serve as a reservoir for the human immunodeficiency virus (HIV), and may be responsible, in part, for the persistence of HIV infections. The predominant infected cell found in cerebrospinal fluid from patients with HIV meningoencephalitis is a macrophage. The brain macrophage, the microglia cell, and macrophage-derived multinucleate giant cells have been found to be infected by HIV. [204] [205] [206] [207] HIV can also be found in pulmonary macrophages, epidermal Langerhans cells, and lymph node macrophages. Not all macrophages, however, appear susceptible to HIV infection. Kupffer cells, for example, have not been shown to be infectable by HIV. Cytokines may play a significant role in HIV-macrophage interactions. Whereas proinflammatory cytokines like TNF- can enhance virus production from infected macrophages, the Th1-type cytokines (IFN-) and the Th2-type cytokines (IL-4, IL-10, and IL-13) inhibit HIV in macrophages. [208]

IMMUNOLOGIC FUNCTIONS

Antigen Presentation

The monocyte lineage gives rise to a variety of cells (APCs) involved in the processing of antigen, which is required for the development of an immune response. Langerhans cells of the skin, interdigitating cells of the thymus, reticular cells of the spleen, and dendritic cells of lymph nodes are all active in the processing of exogenous antigen. The process of presentation of exogenous antigens to T cells requires the antigenic peptides to be recognized in association with MHC class II molecules on the macrophage cell surface. This molecular association occurs within lysosomes, as newly synthesized class II MHC molecules enter the endosomic pathway, are processed, bind noncovalently to the peptide products of degraded antigens previously endocytosed, and are then transported as a complex to the cell surface. Most antigens presented in the context of class I MHC molecules are normal cellular (endogenous) proteins. These are degraded by an adenosine triphosphate-dependent, large proteolytic complex (proteosome). These peptides are then transported to the endoplasmic reticulum, where they bind to class I molecules before movement to the cell surface. T-lymphocyte interaction with antigen presented by mononuclear cells in the context of MHC molecules involves direct cell-cell contact, and this process is further regulated by interaction with co-stimulatory molecules on the macrophage, such as B7, which engages CD28 on the lymphocyte. The activation of the T lymphocyte may be enhanced by the elaboration of monokines such as IL-1, IL-12, and TNF-. Subsequent T- and B-lymphocyte collaboration results in immunoglobulin production. APCs in certain tissues, such as lung, are not phagocytic and may internalize antigen by pinocytosis [209] ; nonetheless, these cells retain Fc and C3b receptors on their surface for interaction with T lymphocytes and antigen. Macrophages can also present processed antigen to B cells to elicit a humoral response. [210] [211]

Dendritic Cells

Steinman and Cohn originally described the dendritic cell in 1973 as a rare cell with a distinctive appearance. [212] The so-called dendritic cell is distinctive because of its long cytoplasmic processes and intracellular endosomes. Dendritic cells are found in virtually all organs except the brain.

The lineage of dendritic cells was originally postulated to be unique from that of macrophages. Dendritic cells express high levels of MHC class II molecules, but also unique membrane molecules such as CD1, CD83, p55, and s100b.[213] Despite their distinctive membrane phenotypes, more recent experimental evidence using cytokines (such as GM-CSF and TNF-) to stimulate the growth of bone marrow progenitors suggests that granulocytes, macrophages, and dendritic cells all share a common lineage.[214] [215] [216]

The in vivo function of dendritic cells is suggested by their ability to stimulate naive T lymphocytes to proliferate in vitro. In a mixed lymphocyte reaction, dendritic cells stimulate a 100-fold stronger proliferative response than unfractionated leukocytes. [217] Dendritic cells appear to be particularly potent at stimulating a primary T-cell immune response. Once T cells are stimulated, they are relatively more responsive to other APCs such as monocytes or B cells. Dendritic cells may be the only cells capable of stimulating a naive T lymphocyte and initiating a primary immune response.

The tissue distribution and antigen-presenting function of dendritic cells have led to the suggestion that dendritic cells initiate the immune response by processing antigen, migrating through tissues, and stimulating naive T lymphocytes. In the periphery of the body, dendritic cells pick up antigen and deliver it to lymphoid organs by selectively migrating through tissues. In the skin, the Langerhans cells appear to provide the dendritic cell function. Langerhans cells are less differentiated than dendritic cells in lymphoid organs. Langerhans cells can, however, mature into dendritic cells with the same immunostimulatory function. Maturation of the Langerhans cell appears to depend on cytokines such as IL-1 and GM-CSF. [218]

Dendritic cells are capable of remarkably efficient processing of extracellular antigen. In most cases, the peptide antigen is taken up and loaded onto MHC class II molecules. In some conditions, dendritic cells appear to be capable of loading peptide antigens onto MHC class I molecules as well. Dendritic cells, particularly immature dendritic cells, are capable of several types of antigen processing. Dendritic cells can pick up soluble antigens by constitutive macropinocytosis. [114] Macropinocytosis is a specialized type of actin-dependent, fluid-phase endocytosis. Using this type of processing, dendritic cells can internalize

---

half of their own volume in 1 hour.[114] Dendritic cells are also capable of receptor-mediated endocytosis, which is a more efficient process because it permits the effective uptake of antigen at a 100-fold lower concentration of antigen. An example of receptor-mediated antigen uptake is the interaction of antigen-IgG complexes that are internalized after binding FcRII (CD32). [114] Dendritic cells express FcRI for the internalization of antigen-IgE complexes. [219] Dendritic cells also appear to be capable of a form of receptor-mediated antigen uptake intermediate between nonspecific fluid uptake and antigen-specific immune complex binding. This process is mediated by so-called pattern recognition receptors. The recently described recycling MMRs appear to be responsible for mediating this type of recognition. MMRs allow dendritic cells efficiently to internalize mannosylated proteins. [220] These receptors are functionally useful as pattern recognition receptors because mannosylated proteins are present on the surface of many microbes.

Dendritic cells process the internalized antigen in endosomal/lysomal compartments. The internalized proteins are processed and loaded onto newly synthesized MHC class II molecules.[221] The MHC-peptide complexes are expressed on the cell surface and retained on the membrane for several days. Once on the cell surface, the MHC-peptide complexes are available for ligand binding with antigen-specific T lymphocytes.

When dendritic cells migrate from the periphery into lymphoid organs, they localize in discrete compartments in peripheral lymphoid organs. Dendritic cells appear to home to specific T-cell areas of lymph nodes and the spleen. [213] In these specialized areas, dendritic cells present antigen to T lymphocytes. A second type of dendritic cell appears to be located in B-cell areas of lymphoid organs. These dendritic cells are specialized for the presentation of native antigen as immune complexes to B cells and are found in germinal centers. Because of their unique location and specialized function, these dendritic cells are called follicular dendritic cells.

The clinical implications of a central regulatory role for dendritic cells have centered on the use of dendritic cells as adjuvants to immunotherapy. The ability reliably to isolate and grow dendritic cells ex vivo could provide an opportunity to load dendritic cells with antigen and reinfuse the cells into the body. [222] Such an approach would have implications for the generation of both tumor- and virus-specific immune responses. [217]

Dendritic cells may also play a role in immune deficiency states and provide a potential target for HIV therapy. HIV-1 has recently been shown readily to enter immature dendritic cells. The presence of intracellular HIV-1 becomes important with the formation of dendritic cell-T-cell conjugates. [223] HIV-1 causes dendritic cells

and memory T cells to fuse. The resulting heterokaryons or syncytia are sites of viral replication and cell death. [224]

Cellular Cytotoxicity

Macrophages have been proposed as the first line of defense against neoplastic diseases by virtue of the selective cytotoxicity gained by macrophages against transformed cells, but not normal cells.[225] Toxicity by monocytes and macrophages to tumor cells can be divided into two types.

Antibody-Dependent Cellular Cytotoxicity

Antibody-coated target cells are recognized by the Fc receptor on monocytes. This recognition enables the monocyte to kill selected target cells with efficiencies determined by the immunoglobulin class and the density of immunoglobulin bound to the target cell and by the Fc receptor type involved on the effector cell. This process is termed antibody-dependent cell-mediated cytotoxicity (ADCC), and this tumorcidal activity has been demonstrated on a number of tumor cell lines in culture.[226] [227] [228] Monocyte tumorcidal activity may be induced by a variety of agents, including LPS, IFN-, interleukins, TNF, phorbol esters, [125] and GM-CSF. This antitumor activity appears to be markedly enhanced by M-CSF.[226] [227] [229] In vivo, the importance of tumor-associated macrophages in tumor rejection remains unclear. Tumor-associated macrophages have the potential to inhibit tumor growth and destroy neoplastic cells. [230] [231] [232] Conversely, macrophages can produce growth factors and promote angiogenesis, resulting in possible paracrine stimulation of neoplastic cells. The clinical importance of ADCC is suggested by regression of neuroblastoma and melanoma in culture when murine monoclonal antibodies are added. [233] [234] Studies of human cells engrafted into nude mice also indicate that ADCC may be an important mechanism for tumorcidal activity.[226]

Antibody-Independent Cellular Cytotoxicity

Recognition of specific target cell structures alone by monocytes and macrophages is a possible stimulus for spontaneous cellular cytotoxicity. The ability of monocytes that have not been previously activated to kill tumor target cells remains controversial. [175] Induction of non-receptor-mediated cytotoxicity can be achieved in monocytes using various soluble and particulate mediators. Phorbol esters, zymosan-activated serum, and aggregated IgG [125] [235] are capable of stimulating monocyte-mediated target cell lysis and the oxidative burst. The maturation of monocytes to macrophage in long-term culture enhances tumorcidal activity. [236]

Mechanisms of Cellular Cytotoxicity

The mechanism of tumor cell lysis appears to involve cell contact [237] and the secretion of a variety of cytotoxic mediators. [238] [239] The cytocidal mechanisms for macrophages may differ from those of their monocyte progenitors because myeloperoxidase is absent [240] and the energy needed for killing may depend more heavily on the respiratory chain [241] than on glycolysis. Arginine-derived NO, synthesized by the inducible isoform of NOS, is also a major mediator of tumor cytostasis by activated macrophages.[197] [242] [243] Potential cellular targets of NO in tumor cells include the oxidoreductases in the electron transport chain, the Krebs cycle enzyme aconitase, and ribonucleotide reductase. [242] [243] [244] [245] NO-independent mechanisms that facilitate tumor cell destruction by activated macrophages also exist, and may include TNF and perforin production.[246] The production of TNF by activated monocytes appears to play an important role in some cytotoxicity, [228] [229] although TNF may not be essential in all systems.[226]

TISSUE MAINTENANCE

Tissue-resident macrophages are capable of playing a wide variety of roles because of their ability to develop specialized functions on extravasation into certain tissues.

Waste Management

Littoral Macrophages

Resident tissue macrophages were formerly referred to as histiocytes. In organs that act as filters for blood and lymph, such as the spleen, liver, lungs, and lymph nodes, the macrophages (littoral macrophages) are situated to facilitate the clearance of pathogenic organisms and senescent cells. This filtering role of the littoral mononuclear phagocyte system led to the older designation of reticuloendothelial system. The recognition of the monocyte/macrophage lineage as well as the phagocytic function of these cells has led to the newer mononuclear phagocyte system nomenclature.

Spleen

Macrophages are found in all parts of the spleen. Microheterogeneous populations of macrophages in the marginal zones serve specific scavenger and pathogen control functions, whereas those in the white pulp, in close association with lymphocytes and germinal centers, regulate B-cell differentiation and antigen presentation.[247] Macrophages in the red pulp and sinuses, where intimate contact occurs between red blood cells and macrophages during the sluggish percolation of blood through this circulation, cull senescent, deformed, and parasitized erythrocytes from the circulation.

Liver

The portal circulation of the liver flows through the spaces of Disse before entering the hepatic venous system. These spaces are lined with liver macrophages, also known as Kupffer cells, allowing intimate contact of the elements of blood with these phagocytic cells. The Kupffer cells may also play a role in clearing ingested and bacterial toxins from the portal circulation.

Lymph Nodes

Macrophages exist in all areas of the lymph nodes and are especially abundant in the medullary zones, adjacent to efferent lymphatic and blood capillaries. Antigen presentation by macrophages to T lymphocytes occurs in these areas.[248]

Bone Marrow

Macrophages are found throughout the bone marrow, in hematopoietic islands and on the walls of the marrow sinuses, where they play a clearance function, especially in states of ineffective hematopoiesis.[249] In lysosomal storage diseases such as Gauchers disease, large inclusions build up within marrow macrophages (as well as hepatic and splenic macrophages) because of the inability of the cells to break down their lysosomal contents.[54]

Lung

In the lung, macrophages reside both in the interstitium of alveolar sacs and freely in the spaces. At least four types of pulmonary macrophages have been identified, including alveolar, interstitial, intravascular, and dendritic or Langerhans cells.[250] The alveolar macrophages lie within the surfactant film, exposed to air, and represent a first line of defense in the lung. These cells have a role in the clearance of inhaled microorganisms and particulate matter,[251] as well as in the removal of endogenous materials like surfactant proteins. Inhaled foreign material such as asbestos or particulates from smoking is found in these alveolar macrophages. Hemosiderin-laden alveolar macrophages may be diagnostic of recurrent pulmonary hemorrhage in idiopathic hemosiderosis or Goodpastures syndrome, in which iron is sequestered in lung tissue.

Other Tissues

Mononuclear phagocytes are also found throughout the alimentary tracts, particularly in the submucosal tissues and villi of the small intestine. They are present in the central nervous system, especially after injury. Mammary gland macrophages appear in the milk during lactation and have been implicated as a potential source of postnatal transmission of the HIV virus.[252]

Lipid Metabolism and Atherosclerosis

Monocytes take up denatured or oxidized LDL and native VLDL by receptor-mediated endocytosis [119] [120] [121] [122] through the MSR. The LDL enters the lysosomal compartments and free cholesterol is liberated and esterified in the cytoplasm. The cholesterol-laden foam cell, which defines the earliest stage in atherosclerosis, is of monocytic origin.[253] [254] Monocytes and macrophages in culture exposed to sufficient quantities of denatured LDL can acquire the appearance of foam cells after engorgement of the lipid.[119] Plasma LDL that has undergone minor chemical oxidative modification can potently stimulate MCP-1 expression in cultured vascular cells, potentially mediating recruitment of circulating monocytes.[255] Lipoproteins in circulating blood may also facilitate adhesion of circulating monocytes to endothelium. The monocyte-derived macrophage plays a significant role in all stages of atherosclerotic plaque formation. From the initial events in atherogenesis (increased vascular permeability and increased monocyte adherence and intimal recruitment) to the advanced disease (monocyte/macrophage-derived foam cells, cell necrosis, and formation of a necrotic plaque), atherosclerotic pathogenesis appears to involve a strong monocyte/macrophage inflammatory component. [256] [257] [258] Proliferation of macrophages in atherosclerotic lesions has been observed.[259] Experimental knockout of the MSR genes have demonstrated the contribution of these receptors to the atherosclerotic process.[256] The primal role of the MSRs was facilitation of the uptake and clearance of microorganisms and senescent cells, but this useful function is suborned in the presence of circulating oxidized lipids to render the monocyte the inciting agent of atherosclerosis.

Clearance of Senescent or Damaged Cells

Senescent or defective red blood cells (such as those formed in hereditary spherocytosis) may be sequestered in the spleen and removed from the circulation by splenic macrophages, with subsequent degradation of cellular material and return of iron to the iron pool. The presence of antibody or complement components on red blood cells enhances macrophage erythrophagocytosis in the spleen and the bone marrow and plays a central role in the pathophysiology of immune-mediated hemolytic anemias.

Macrophages have the ability to recognize circulating proteins or cell-associated proteins that have been modified by nonenzymatic reactions with extracellular glucose over time. These glycated proteins are taken up through a specific cell surface receptor designated the advanced glycation end-product receptor. [260] Binding to this receptor results in activation of the macrophage with release of cytokines. Macrophages are able to recognize certain sugar residues on tumor cells by specific cell surface lectin receptors. An *N*-acetyl galactosamine/galactose-specific receptor on liver macrophages mediates the attachment of desialylated cells to liver macrophages.[261]

Tissue Growth and Repair

Wound Healing and Angiogenesis

Macrophages are required for angiogenesis and wound healing. [31] [262] Monocytes enter a wound within the first or second day (inflammatory phase of wound repair), where they differentiate, and these macrophages become the predominant immune cell in the tissue by days 35 (proliferative phase). [263] The recruitment of the monocytes is determined by a chemoattractant gradient of MIP-1 and -2, MCP-1, and MGSA. Macrophage depletion studies [31] have shown that macrophages are required for clearance of senescent cells and debris in the wound, for deposition of new fibrous tissue (collagen synthesis and fibroblast proliferation, and for stimulation of angiogenesis).[264] Activation of the recruited macrophages can occur by products released from platelets (TGF- and PAF), thus linking the hemostatic and inflammatory phases of wound repair, and also as the result of exposure to, and phagocytosis of, microorganisms in the wound. Macrophages can also be activated by the low PO_2 and high lactate concentrations in inflamed or wounded tissue.

Activated macrophages in wounds secrete large amounts of

fibroblast and epithelial cell growth factors such as TGF-, fibroblast growth factors, epidermal growth factors, PDGFs, and insulin-like growth factors. Many of these growth factors have overlapping angiogenic activities. Wound macrophages also release the inflammatory mediators IL-1, IL-6, and TNF-, which have mixed activities on cell growth and angiogenesis. In addition, macrophages secrete several complement inhibitors such as $_2$ -macroglobulin, $_1$ -protease inhibitor, and C3 inhibitor, and a wide range of proteases as well as neutral or metalloprotease inhibitors that facilitate reduction of inflammation and tissue remodeling, respectively. [135] Macrophages directly and indirectly result in the production of extracellular matrix components necessary for wound repair, including fibronectin, proteoglycans, and thrombospondin-1. Macrophages are able to induce neovascularization, angiogenesis, and endothelial cell mitogenesis. [265]

Hematopoiesis

In the adult bone marrow and fetal liver, resident tissue macrophages express cell surface receptors (sialoadhesin) that bind developing myeloid and erythroid cells without causing phagocytosis.[266] [267] Immature blood cells, especially erythroblasts, are found clustered around a central macrophage that performs a critical but not well characterized nurse function in hematopoiesis. Monocytes and macrophage are capable of secreting a number of hematopoietic growth factors, including GM-CSF, G-CSF, erythropoietin, IL-1, and M-CSF. [135]

Bone and Calcium Metabolism

The multinucleate osteoclast, which is responsible for bone resorption, remodeling, and calcium homeostasis is derived from a monocyte precursor. The earliest studies demonstrating the hematopoietic origin of osteoclasts used a parabiotic union of osteopetrotic mice. [268] Culture of circulating monocytes with bone stroma is sufficient to induce osteoclastic differentiation, and this process is stimulated by parathyroid hormone (PTH) and vitamin D_3, and inhibited by calcitonin. [198] The differentiation process depends on M-CSF and the product of the c-*fos* gene,[269] whereas osteoclast activity depends on the function of the c-*src* gene product, which may mediate PTH signal transduction.[270] Mature osteoclasts express tartrate-resistant acid phosphatase, PTH, and calcitonin receptors. Bone resorption activity by the osteoclast is stimulated by PTH and vitamin D_3, and also by some of the products of monocytes themselves, including IL-1, TNF-, TGF-, M-CSF, and reactive oxygen intermediates. TGF-, estrogens, IL-4, and IFN- inhibit osteoclast activity. Osteoclasts themselves can secrete IL-6, IL-1, and TGF-2.

Nervous System

Monocytes are uniquely privileged to cross the blood-brain barrier, initially in response to programmed neuronal cell death during development, or later through recruitment in inflammatory or degenerative states. Over a period of 46 days, the surrounding neural tissue induces a profound differentiation of these monocytes, resulting in the formation of microglia, with fine-branching processes extending throughout the neural net. [5] In the pituitary, microglia remove fragments from viable neuroendocrine cells, perhaps processing or regulating the release of neuropeptides. [14] Macrophages also appear to play a critical role in nerve regeneration. In addition to the path clearing achieved by removal of axonal and myelin debris, macrophages also appear to have a direct effect on regrowth of neurites and Schwann cells, resulting in the production of nerve growth factor and insulin-like growth factor. [271]

Monocytes and Macrophages as Therapeutic Agents

Because of their unique characteristics, macrophages have long been identified as potential vehicles for the targeting of genes or other therapeutics to the site of disease. Their relatively long life span and their residence in tissue have made them attractive targets for gene therapy in the treatment of storage diseases and enzyme- or hormone-deficiency diseases. Similarly, their ability to travel through the blood to sites of inflammation or malignancy and selectively intercalate into the diseased tissue has suggested a possible role for monocytes and macrophages in the delivery of cytokines, antineoplastic proteins, or toxins specifically to the tumor. The early and critical role of monocytes in atherosclerosis may again facilitate targeting of genes or other products to the nascent atherosclerotic plaque. The technical difficulties, however, of achieving stable, efficient transfection of this very-slow-growing blood cell have hindered the development of such indirect monocyte/macrophage therapies to date.[272]

Monocytes and macrophages may also have potential for manipulation as direct effectors of an anticancer response. The selective cytotoxicity of activated macrophages against transformed cells while sparing normal cells [225] has suggested their use in adoptive transfer immunotherapy protocols. In these instances, monocytes are activated in vivo or in vitro using a combination of cytokines and sometimes exposure to tumor antigens. Such activated monocytes and macrophages have been shown to home preferentially to tumor and to enhance tumor destruction. The use of these unique cells to deliver therapeutics or directly to effect therapy themselves has great potential.[273]

Chapter 40 - Eosinophilia, Eosinophil-Associated Diseases, and the Hypereosinophilic Syndrome

Steven J. Ackerman
Joseph H. Butterfield

HISTORICAL BACKGROUND, ETIOLOGY, AND PATHOPHYSIOLOGY OF HYPEREOSINOPHILIA

Following the initial identification of the eosinophilic granulocyte by Paul Ehrlich in 1879, an extensive cataloguing occurred over the next 100 years of diseases and conditions characterized by blood and/or tissue eosinophilia (Table 40-1). However, the specific functional roles of eosinophils in host defense, allergic reactions and other inflammatory responses, tissue injury, and fibrosis have only begun to be fully delineated and understood during the past 25 years. [1] Recent research has now served to characterize the unique cellular characteristics of activated tissue and peripheral blood eosinophils, their preformed granule protein constituents and inducible lipid, oxidative, and cytokine products, focusing on the eosinophils pro-inflammatory and cytotoxic potential in the pathogenesis of allergic, parasitic, neoplastic, and a variety of other idiopathic disease processes. [2] Recognition of the eosinophil as a proinflammatory effector cell in bronchial asthma has in part fueled the surge in interest in this granulocyte in asthma and other respiratory diseases, [3] and the recent epidemic of eosinophil myalgia syndrome related to ingestion of tainted L-tryptophan [4] served to markedly increased public interest and awareness of the eosinophil.

Studies of the biochemistry, biologic activities, and in particular, the localization in tissues of the distinctive enzymatic and non-enzymatic cationic protein constituents of the eosinophils secondary or specific granule provided the first convincing evidence for the role of this granulocyte in the pathogenesis of inflammation and tissue damage in eosinophil-associated diseases. [2] In addition, identification of eosinophil-specific granule constituents in tissues by a variety of sensitive and specific immunochemical methods provided additional evidence for the participation of this leukocyte in diseases not normally associated with tissue or blood eosinophilia, e.g., certain skin diseases. [5] Investigations over the past 1015 years of the biochemistry, functions, and localization in tissues of these unique enzymatic and non-enzymatic cationic proteins have now provided compelling evidence supporting a pathologic effector role for the eosinophil in directly inducing tissue damage. [6] These distinctive cationic granule protein constituents include the major basic protein (MBP), the eosinophil peroxidase (EPO), and the ribonucleases eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN). Eosinophils have also been shown to have the capacity to express a variety of toxic oxidative intermediates, [7] eicosanoid and other lipid mediators of inflammation [8] and most recently, inflammatory and hematopoietic cytokines that are integral to the normal and pathologic role of this granulocyte in health and disease. [9] This chapter provides an overview of current understanding of the inflammatory and pathologic activities of this granulocyte in human disease, focusing principally on the consequences of hypereosinophilia in the idiopathic hypereosinophilic syndrome (HES).

Patients presenting with hypereosinophilia provide an often daunting diagnostic challenge to physicians who must navigate multiple medical subspecialties in order to wade through the long and diverse list of potential causes (Table 40-1). This process, an often frustrating experience for both physician and patient, may result in an indeterminate diagnosis of hypereosinophilia of unknown etiology. The hypereosinophilic syndrome (HES) comprises a group of myeloproliferative disorders of unknown etiology that are marked by sustained overproduction of eosinophils and tissue infiltration. In addition to the striking and sometimes profound eosinophilia associated with the syndrome, idiopathic HES is characterized by a predilection for end organ damage most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related cardiac pathologies. However, because heart disease can also develop with eosinophilias of known etiologies, e.g., tropical eosinophilia and certain cancers, [10] [11] the cardiac manifestations of idiopathic HES are not unique to this syndrome. The currently defined criteria for HES as originally presented by Chusid and colleagues, [12] and which serve to distinguish HES patients from those with identifiable (reactive) causes for their eosinophilia include: (1) persistent eosinophilia of >1,500 eosinophils/mm ^{3} for more than 6 months, (2) exclusion of other potential etiologies for the eosinophilia including parasitic, allergic, or other causes, and (3) presumptive signs and symptoms of organ system dysfunction or involvement which appears related to the eosinophilia or is of unknown cause in the clinical presentation. The recent identification of subgroups of patients with profound idiopathic eosinophilia characteristic of HES, but who do not go on to develop end organ damage characteristic of HES (e.g., patients with episodic angioedema with eosinophilia [13] [14]), complicates the diagnosis, treatment, and management of patients with profound eosinophilia of unknown etiology. This chapter reviews the distinguishing as well as more variable hematologic and clinical features of HES that should assist the physician in separating this syndrome from more common (reactive) eosinophilias of known etiology. This will include a discussion of the current understanding of HES etiology and pathogenesis, as well as therapeutic approaches and strategies for managing this complex syndrome.

EOSINOPHIL MORPHOLOGY

The eosinophil is similar morphologically to a mature or band neutrophil except for a two-lobed nucleus and the presence of numerous bright orange spherical cytoplasmic granules (Plate 40-1). Eosinophils contain three distinct membrane-bound granule populations that are produced during their differentiation from hematopoietic progenitors in the bone marrow (Fig. 40-1). These include round, uniformly electron dense primary granules present mainly at the eosinophilic promyelocyte/myelocyte stages, specific or secondary granules containing an electron dense crystalloid core surrounded by a less dense granular matrix (>95% of granules in mature eosinophils and the

TABLE 40-1 -- Diseases, Syndromes, and Conditions Commonly Associated with Peripheral Blood Eosinophilia and/or Tissue Eosinophils[a]

Infectious Agents	**Reactions to Cytokine Therapies**
Parasitic	IL-2 and IL-2 plus lymphokine activated killer (LAK) cells
Tropical Eosinophilia	GM-CSF for chemotherapy-induced neutropenia
Visceral Larval Migrans (VLM, Toxocariasis)	
Helminth Infections	**Cutaneous Disorders**
Filariasis (Wuchereria bancrofti, Brugia malayi)	Atopic dermatitis
Onchocerciasis	Immunologic skin diseases
Schistosomiasis	Scabies
Fascioliasis	Eosinophilic cellulitis (Wells syndrome)
Paragonimiasis	Episodic angioedema with eosinophilia
Strongyloidiasis	Chronic idiopathic urticaria
Trichinosis	Bullous pemphigoid
Hookworm	Herpes gestationis
Ascariasis	Recurrent granulomatous dermatitis
Echinococcus/hydatid disease	
Nonparasitic	**Immunodeficiency Syndromes**
Coccidiomycosis	Wiskott-Aldrich
Chlamydial pneumonia of infancy	Selective IgA deficiency with atopy
Scarlet fever and pneumococcal pneumonia (convalescent phase)	Hyper-IgE recurrent infection syndrome (Job syndrome)
Cat scratch disease	Swiss-type and sex-linked combined immunodeficiency
Cryptococcus (CSF eosinophilia) HIV	Nezelofs syndrome
	Graft-versus-host disease
Allergic Diseases	**Connective Tissue Diseases**
Asthma (atopic and intrinsic, nasal polyps, aspirin intolerance syndromes)	Vasculitis/collagen vascular disorders
Bronchopulmonary aspergillosis	Hypersensitivity vasculitis
Allergic rhinitis	Allergic granulomatosis with angiitis (Churg-Strauss syndrome)
Urticarias (acute allergic and chronic idiopathic)	Serum sickness
Atopic dermatitis	Eosinophilic fasciitis
Acute drug (hypersensitivity) reactions (interstitial nephritis, cholestatic hepatitis, exfoliative dermatitis)	Sjögren syndrome
	Rheumatoid arthritis (severe)
Respiratory Tract Disorders	**Neoplastic and Myeloproliferative Diseases and Syndromes**
Hypersensitivity pneumonitis	Neoplastic
Allergic bronchopulmonary aspergillosis	Eosinophil leukemia
Eosinophilic pneumonia	Lymphomas (T cell, Hodgkins disease)
Transient pulmonary infiltrates (Löefflers syndrome)	Chronic myelogenous leukemia
Prolonged pulmonary infiltrates with eosinophilia (PIE syndromes)	T-cell lymphocytic leukemia
Tropical pulmonary eosinophilia (TPE)	Myelomonocytic leukemia with bone marrow
Bronchiectasis	Eosinophilia (M4Eo, inversion 16)
Cystic fibrosis	Solid tumors (mucin secreting, epithelial cell origin, ovarian)

Endocrinologic Disorders	Idiopathic hypereosinophilic syndrome (HES)
	Angioimmunoblastic lymphadenopathy
Addisons disease	Angioblastic lymphoid hyperplasia (Kimuras disease)
	Systemic mastocytosis
Gastrointestinal Diseases	
Inflammatory bowel disease (IBD)	**Rare Causes**
Eosinophilic gastroenteritis	Chronic active hepatitis
Allergic gastroenteritis (young children)	Chronic dialysis
Celiac disease (usually tissues)	Acute pancreatitis
	Postirradiation
Toxic Reactions to Injected Agents	Hypopituitarism
Eosinophil myalgia syndrome (L-tryptophan)	
Toxic oil syndrome

morphologic trademark of this granulocyte), and less well characterized small granules, which are sites for hydrolytic enzymes such as acid phosphatase and arylsulfatase, may contain catalase, and may be functionally analogous to lysosomes and peroxisomes of other cells. The large specific granule is the major repository for the eosinophils cytotoxic and pro-inflammatory cationic proteins (Fig. 40-1) which also confer the unique and characteristic tinctorial (eosinophilic) properties of this cell as originally identified by Paul Erlich in 1879. Eosinophils also contain lipid bodies, non-membrane-bound and lipid-rich organelles often confused with granules and present in many types of leukocytes and other cells. [8] Normal blood eosinophils contain greater numbers of lipid bodies than neutrophils and the numbers of lipid bodies increase during eosinophil activation in vitro and engagement in inflammatory reactions in vivo. [15] Although the functions of lipid bodies are incompletely understood, they incorporate fatty acids such as arachidonate and likely serve as intracellular depots for its storage and metabolism,

Figure 40-1 Schematic structure of the mature human eosinophil. Primary (1) and secondary (2) granules, small granules (SG) and non-membrane-bound lipid bodies (LB), are shown, as are the major cell surface cytokine, immunoglobulin and complement receptors. The subcellular localizations of the eosinophil granule cationic proteins, MBP, EPO, ECP, and EDN in the secondary granule and the Charcot-Leyden crystal (CLC) protein (galectin-10) in the coreless primary granule, nucleus, and cytosolic space beneath the plasma membrane are also indicated. as suggested recently by the localization of all the principal eosinophil eicosanoid-forming enzymes including 5-lipoxygenase, leukotriene C4 synthase, and cyclooxygenase in lipid bodies. [16] As reviewed in detail elsewhere, [17] these four organelles, along with vesiculotubular structures and small vesicles involved in transport and secretion in the activated cell, serve as the major subcellular sites for the eosinophils armamentarium of preformed cytotoxic and inflammatory mediators.

EOSINOPHIL DEVELOPMENT, RECRUITMENT AND ACTIVATION

Eosinophilopoiesis

Eosinophils differentiate in the bone marrow from stem cell-derived, CD34+ multipotential myeloid progenitors in response to a number of T-cell-derived eosinophilopoietic cytokines and growth factors including IL-3, GM-CSF, and IL-5. These cytokines affect the eosinophil lineage at three different levels including (1) commitment, proliferation, and differentiation of hematopoietic progenitors in the bone marrow, (2) priming and activation in the blood and tissues for enhanced functional activities, and (3) recruitment and tissue localization (see discussion later in this chapter). Although activated T cells are likely the primary source for IL-3, IL-5 and GM-CSF pertinent to eosinophil differentiation and the development of reactive eosinophilia in disease, other cell types including mast cells, macrophages, natural killer cells, endothelial cells, and stromal cells such as fibroblasts are also producers of GM-CSF. IL-5, produced primarily by activated Th2 type helper T cells[18] and mast cells,[9] [19] stimulates the proliferation and differentiation of murine activated B cells and regulates the production of eosinophils in vitro and in vivo. [20] [21] [22] Both IL-3 and GM-CSF have activities on other hematopoietic lineages, whereas IL-5 is more eosinophil-specific and plays a crucial role in regulating the terminal differentiation and post-mitotic activation of eosinophils. [23] IL-5 is therefore a late-acting cytokine that demonstrates maximum activity on an eosinophil progenitor pool that is first expanded by the earlier-acting, multipotential cytokines such as IL-3 or GM-CSF. [23] Although IL-3 and GM-CSF participate in the proliferation and commitment of progenitors to the eosinophil lineage, IL-5 is both necessary and sufficient for eosinophil development to proceed in vivo. [23] [24] In humans, IL-5 does not appear to have any effect on B cells or other lymphoid lineages, and its activity, high affinity receptor, and functions are restricted to eosinophils and hematopoietically related basophils. [23] The expression of the high-affinity receptor for IL-5 is an important prerequisite and very early lineage-specific event in the hematopoietic program for these granuloctyes. Overexpression of IL-5 is observed in many eosinophil-associated diseases [25] [26] [27] and IL-5 transgenic mice develop profound eosinophilia[28] [29] indicating that IL-5 plays important roles in promoting the production and function of eosinophils in vivo. These general observations have recently been confirmed and expanded in studies of IL-5 deficient (gene knockout) mice, [30] [31] which produce basal levels of normal eosinophils in the bone marrow, but do not develop blood and tissue eosinophilia, airway hyperreactivity or lung damage in the murine ovalbumin allergic asthma model, [31] nor eosinophilic responses to helminth parasites. [30] For these reasons, IL-5 and its receptor may be excellent targets for therapeutic intervention in eosinophil-associated inflammatory diseases.

Mobilization and Migration of Eosinophils to Sites of Inflammation

In the normal individual, eosinophils produced in the bone marrow reside only briefly in the peripheral circulation in transit to extravascular sites. They tend to localize preferentially in certain tissues and organs exposed to the external environment, principally in the submucous membrane and loose connective tissue of skin, gastrointestinal tract, genital tracts and the lungs. [32] In contrast, the acute and chronic inflammatory recruitment of eosinophils into tissues occurs primarily in response to the early- and late-phase components of immediate hypersensitivity reactions, but also in association with a number of other immunologically mediated reactions, diseases and idiopathic syndromes to be outlined or discussed in detail later in this chapter. In addition, diurnal variations in the eosinophil intravascular compartment are well documented, with minimum

numbers of blood eosinophils early in the morning and highest numbers late at night, mirroring circadian rhythms in circulating adrenal corticosteriods. Likewise, diurnal variations have also been documented to occur in the mobilization, recruitment, and activation state of eosinophils in tissues, e.g., in diseases such as nocturnal asthma.[33] [34]

Although eosinophils may represent only part of an inflammatory infiltrate comprised of neutrophils, monocytes, and/or lymphocytes, the mechanisms by which they are selectively recruited in large numbers in certain reactions are currently under investigation. [35] The mobilization of eosinophils, as for other leukocytes, from the vasculature involves their rolling and adherence to vascular endothelium via L-selectin, followed by interactions with intercellular adhesion molecule-1 (ICAM-1) through a CD18/CD11a,b-dependent mechanisms, and migration in response to specific cytokines or chemoattractants. Adherence via CD18-independent mechanisms involves binding to cytokine-activated endothelial cells utilizing either E-selectin, also known as endothelial leukocyte adhesion molecule-1 (ELAM) or vascular cell adhesion molecule-1 (VCAM). Selective recruitment of eosinophils likely involves adhesion to VCAM via the $_1$ integrin very late activation antigen-4 (VLA-4), which is expressed by eosinophils but not neutrophils. [36] Because no single chemotactic agent identified thus far is uniquely specific for eosinophils, selective eosinophil recruitment likely involves the complex interaction of multiple adhesion pathways and chemotactic gradients. The inflammatory mediators identified to function as potent eosinophil chemoattractants include the complement fragment C5a and platelet activating factor (PAF), along with a number of the eosinophil-active cytokines including IL-3, IL-5, and GM-CSF, which also prime eosinophils for enhanced migratory responses to agents such as PAF, fMLP, LTB $_4$, and IL-8. The most potent eosinophil chemoattractants identified thus far are active in the 10^{-12} to 10^{-11} M range, are 1,000-fold more active than PAF and C5a, and include IL-2, the CD8+ T-cell-derived lymphocyte chemoattractant factor (LCF) that utilizes CD4 expressed on the activated eosinophil as its receptor, and the chemokine eotaxin.[37] The chemokine RANTES, which is chemotactic for certain T-cell subsets and monocytes, but not for neutrophils, is likewise a potent stimulus for eosinophil migration;[38] its production by the CD4+ T-cell component of cutaneous and pulmonary allergen-induced late-phase reactions may contribute to the eosinophil infiltration characteristic of these responses.

Eosinophil-Activation in Disease: Eosinophil Heterogeneity

Eosinophils secrete both their preformed granule constituents and newly synthesized lipid, cytokine, and peptide mediators of inflammation upon stimulation (Fig. 40-2). It has become increasingly clear that both peripheral blood eosinophils from patients with eosinophilia and eosinophils from the inflammatory tissue microenvironment are heterogeneous with regard to their capacity for stimulation and secretion of the previously described mediators. Eosinophils from blood and tissues of patients with eosinophilia differ from their normal counterparts by a variety of morphologic, biochemical, and functional characteristics, [39] some of which appear to be linked to a significant decrease in cell density as measured by separation over density gradients. Thus, a distinction is now made between the populations of normodense (normal density) and hypodense (light density) eosinophil phenotypes isolated from the peripheral blood and tissues. The blood of normal individuals contains <10% of eosinophils with densities less than 1.082 g/ml, whereas patients with eosinophilia can have markedly increased numbers of the hypodense cells.[26] [40] [41] Hypodense eosinophils possess a variety of properties consistent with their being primed and/or activated in vivo, by analogy with classical macrophage activation. Morphologically, activated hypodense eosinophils show increased vacuolization, decreased granule size (and content of granule cationic proteins such as MBP[41]), and increased numbers of cytoplasmic lipid bodies. [16] The numbers of surface receptors for a variety of eosinophil-active agonists including complement cleavage fragments of C3 (CR1 and CR3), immunoglobulins (IgE, IgA), cytokines, and PAF are increased on hypodense eosinophils from eosinophilic patients, as are a variety of membrane surface antigens such as CD4. [37] Functionally, hypodense eosinophils show increased metabolic activity, oxygen consumption, and generation of superoxide anion, as well as an increased capacity for the synthesis and secretion of LTC $_4$ and certain cytokines, enhanced chemotaxis, and augmented cytotoxicity for antibody-coated targets.

Figure 40-2 Eosinophil degranulating stimuli and eosinophil-derived inflammatory mediators. The listed factors have been shown to stimulate the release of inflammatory mediators from the eosinophil. These mediators may be either pre-formed, such as the eosinophil granule-derived cationic proteins, or newly generated mediators, such as oxidative products, lipid mediators (e.g., LTC_4), and inflammatory or hematopoietic cytokines. (*Reproduced with permission from Furuta et al.*[232])

The mechanism by which eosinophils develop the morphologic, biochemical, and functional characteristics of activated cells in vivo has been largely defined through the in vitro analysis of factors capable of prolonging eosinophil survival and inducing the development of the hypodense phenotype. Culture of normal peripheral blood eosinophils with growth factors (GM-CSF), hematopoietic cytokines (IL-3, IL-5), and interferons (IFN and) either alone or in co-culture with endothelial cells or fibroblasts, induces the development of the hypodense activated phenotype characteristic of eosinophils isolated from patients with hypereosinophilic disorders. In addition, the eosinophilopoietic cytokines (IL-3, IL-5, and GM-CSF) also prolong the survival of mature normodense and hypodense eosinophils in vitro (and possibly in vivo in the tissue microenvironment), likely through the prevention of programmed cell death (apoptosis). [42] [43] Of interest, culture of eosinophils with the previously noted factors in vitro does not precisely recapitulate all the functional characteristics of the in vivo activated, tissue-derived cell, suggesting a requirement for additional as yet undefined factors that may include interaction of adhesion receptors with their ligands during eosinophil recruitment and migration into the tissue or stromal cell-derived factors.

The diagnostic and therapeutic significance of eosinophil heterogeneity has not been fully evaluated. Although the percentage of hypodense eosinophils in the blood may correlate with the degree of peripheral blood eosinophilia, [40] precise relationships between the percentage of hypodense eosinophils and the clinical status of an eosinophilic disorder have not been easily defined. Rough correlations have been reported between disease severity and numbers of hypodense eosinophils in circulation for certain hypersensitivity disorders such as allergic asthma and allergic rhinitis. However, there is a significant overlap in the percentage of hypodense peripheral blood eosinophils in hypereosinophilic disorders of greatly varying severity such as bronchial asthma, the hypereosinophilic syndrome, and certain helminth infections. Because eosinophils reside primarily in the tissue microenvironment for the majority of their lifespan, it is not surprising that their heterogeneity in the peripheral circulation is at best a crude reflection of disease severity. In vitro models of eosinophil heterogeneity suggest a number of pathways for the development of eosinophil subpopulations, including acute exposure to mediators generated in immediate-type hypersensitivity reactions (e.g., PAF, eosinophil-active cytokines such as GM-CSF, IL-3, IL-5, IFN, or TNF), or more chronic exposure to eosinophil active cytokines in combination with as yet undefined factors in the tissue microenvironment as discussed previously. Regardless of the specific mechanisms or mediators involved in eosinophil priming and/or activation, the development of eosinophil heterogeneity as a reflection of the functional, pro-inflammatory capacity of the cell in vivo, suggests the possibility that these processes could be manipulated in a therapeutic manner. For example, in disorders such as HES where excessive levels of IL-5 have been occasionally demonstrated in the peripheral circulation (see discussion later in this chapter), [25] therapies aimed at modulating IL-5 levels in order to both normalize eosinophil phenotype and attenuate the eosinophilia may be appropriate. One such example has been the use of cyclosporin A to produce a clinical remission in a patient with steroid-resistant HES. Cyclosporin A has been shown in vitro to inhibit IL-5 production from T-cell clones derived from the patient. [44] In contrast, since eosinophil infiltration of certain types of malignancies including colon cancers or lung adenocarcinomas may be associated with improved prognosis, [45] [46] it may be advantageous to induce the development of tissue eosinophilia and enhanced cytotoxicity as demonstrated in response to local production of IL-4. [47]

EOSINOPHILIA AND EOSINOPHIL-ASSOCIATED DISEASES, SYNDROMES, AND INFLAMMATORY REACTIONS

Identification and Quantitation

Eosinophils, so named for their unique granular staining with acidic fluorone dyes such as eosin, were first identified by Paul Ehrlich in 1879. Subsequently, histochemical staining with eosin-based stains became the standard for eosinophil identification in both blood and tissues (haematoxylin and eosin), although other more specific histochemical dyes such as chromotrope 2R are more definitive in tissues, and Fast Green or Luxol Fast Blue can be utilized to specifically distinguish the mature eosinophil from other polymorphonuclear leukocytes in blood smears or cytocentrifuge slides, i.e., neutrophils and basophils, for which the granules do not stain. The chemical characteristics of the fluid medium or tissue in which the eosinophil is analyzed, and most importantly the eosinophils degree of maturity, activation, secretion, and/or degranulation can all induce significant variability in histochemical characteristics for the Romanovsky-type metachromatic stains used most widely for detection of eosinophils in blood and bone marrow specimens. For example, eosinophils in urine, as found in eosinophilic cystitis or interstitial nephritis, are best detected by Hansels stain.[48] As a result, it is now understood that the definitive identification of the eosinophils participation in a particular inflammatory response or disease may require immunochemical localization using specific monoclonal or polyclonal antibodies to eosinophil-specific granule proteins such as major basic protein (MBP), eosinophil peroxidase (EPO), or eosinophil cationic protein (ECP), all of which have been used to identify eosinophil infiltration and secretion/degranulation in tissues where they have been missed by more classical histochemical techniques. [5] [49] For peripheral blood, absolute eosinophil counts done manually or utilizing automated counting systems provide a much more reliable estimation of eosinophil numbers than does microscopic differential counting of blood smears combined with total leukocyte counts, especially when there is an absolute leukocytosis or leukopenia for another lymphoid or myeloid lineage. Circulating eosinophils are generally present in low numbers in normal healthy individuals with consensus absolute counts ranging from 35 to 350 eosinophils/mm^3 (mean 125 for adults; 225 for children under 12 years). The broad range of variability in normal blood eosinophil levels reflects the multiple sources of both subtle and more obvious physiologic effects due to diurnal variation in endogenous glucocorticoid levels (see previous discussion), degree of atopy in the general population, and other factors that can include exercise, emotional stress, and hormonal influences of the menstrual cycle.

Clinical Assessment of Eosinophilia: Peripheral Blood versus Tissue Eosinophils

The low numbers of eosinophils in the blood compared to neutrophils and lymphocytes, coupled with their principal localization in tissues, makes accurate quantitation and interpretation of blood eosinophil counts more difficult than that of other cellular elements. As noted earlier in this chapter, 100200 cell differential counts are fraught with the problems inherent in sampling error when eosinophils constitute <35% of total peripheral blood leukocytes. Further, the use of automated cell counters that may not accurately enumerate eosinophils unless they are present in sufficiently high numbers, and that can miss eosinophil peroxidase deficient cells, may nevertheless require a manual differential or absolute count to be performed if modest to moderate eosinophilia is suspected in the clinical evaluation of a patient. The number of circulating eosinophils in the blood reflects a complex interplay of factors including rates of

development and transit from the bone marrow, margination, and subsequent emigration into tissues through postcapillary venules. Because the eosinophil is primarily a tissue-dwelling cell, is present in extravascular sites at levels several hundred-fold more than in peripheral blood in the rat, and blood levels may vary significantly as noted earlier in this chapter, circulating cells reflect only those in traffic between the marrow and their final functional destination. In humans, the marrow to blood ratio for eosinophils is 57:1. Normal adult bone marrow contains 35% eosinophils, with 40% mature cells, and migration of eosinophils from the marrow into the blood takes 3.5 days. The half-life of the eosinophil in the peripheral circulation of normal individuals is 18 hours, with an average blood transit time of 26 hours, similar to that of neutrophils. Daily mean turnover is 0.2×10^9 /kg and the bone marrow has a post-mitotic reserve of 0.1×10^9 eosinophils/kg. Under ideal steady-state conditions, one would anticipate that peripheral blood eosinophil levels are proportional to levels in normal tissue compartments. In contrast, under the dynamic conditions of certain acute inflammatory or immune responses, temporal lags have been observed to occur between infiltration into reactive tissue sites and the induction of eosinophil development and emigration from the marrow, resulting in the development of eosinopenia and/or delayed blood eosinophilia. [50] [51] [52] Moreover, in the pathology of more chronic eosinophil-associated inflammatory conditions, tissue eosinophilia may be prominent in the absence of minimal or any peripheral blood eosinophilia, e.g., in certain skin diseases. [5] Thus, the clinical assessment of peripheral blood eosinophilia, although diagnostically important, must be interpreted with these caveats in mind.

The list of diseases, syndromes, and inflammatory processes associated with peripheral blood and/or tissue eosinophilia is quite extensive (Table 40-1). Of course, the most common associations are infections with parasitic helminths and allergic diseases and their related inflammatory reactions. Effective clinical assessment of patients with eosinophilia requires a careful and detailed history including travel information, where the patient has lived, drug use including intravenous drugs, L-tryptophan and vitamin supplements, and other over-the-counter nonprescription medications, diet, and allergic symptomology. In addition, the systemic nature of many of the nonallergic/noninfectious conditions involving eosinophilia dictates that a careful history of fever, weight loss, myalgias, arthralgias, rashes, lymphadenopathy, etc. should be obtained as well. Symptomatic or asymptomatic eosinophilia in patients taking drugs associated with known eosinophil responses and eosinophil-related drug reactions strongly dictates that their use be discontinued and that follow-up evaluation confirm that the eosinophilia and related symptoms have resolved. Patients with eosinophilia who have resided in or visited areas endemic for helminths or other parasites should be examined for intestinal and bloodborne infections, with additional serologic evaluation as necessary to identify the causative agent. Once the more common and obvious causes of eosinophilia have been excluded, i.e., drug reactions, parasitic infections, and various allergic conditions, the differential diagnosis of eosinophilia becomes more difficult due to the complexity and number of potential organ systems and conditions involved (Table 40-1).

Monitoring of Eosinophil Activity

An understanding of the importance of both numbers of tissue eosinophils and their functional status, as well as differences in functional status between circulating eosinophils and those that have been recruited into and exposed to cytokines and other factors in the tissue microenvironment, has resulted in the development and more routine use of methods to monitor eosinophil activity in situ. Tissue biopsies have become more routinely employed for both the clinical and experimental evaluation of eosinophil function in diseases involving the skin, [5] [50] [53] lung, [34] [54] [55] lymph nodes,[56] heart,[57] and other tissues, greatly contributing to the current understanding of the eosinophils pro-inflammatory role in disease pathogenesis. The difficulties, tediousness, and sampling errors inherent in accurately quantitating the numbers of eosinophils, let alone their functional status in tissue biopsy specimens, even using antibodies that recognize specific cell surface activation markers or secretion products and modern morphometric techniques, makes routine clinical evaluation of tissue eosinophils by these methods somewhat impractical. Alternatives, such as analysis of tissue secretions from affected organs, e.g., bronchoalveolar lavage (BAL) of the lung, have been utilized with great success in the clinical and experimental evaluation of eosinophil function in diseases such as asthma. [33] [58] [59] In addition to the more routine histochemical identification and enumeration of eosinophils, and immunochemical localization of secreted eosinophil granule cationic proteins in tissue biopsies, two additional methods have been extensively used to monitor eosinophil activation, secretion, and involvement in disease pathogenesis. These include the identification of activated eosinophils by staining with a monoclonal anti-ECP antibody EG2 that recognizes a secreted, deglycosylated form of the protein, [60] [61] [62] [63] and measurement of the eosinophil

granule cationic proteins such as MBP, ECP, and eosinophil-derived neurotoxin (EDN) by radioimmunoassay [63] [64] [65] in various body fluids including serum, plasma, urine, sputum, nasal lavage, cerebro-spinal fluid, and BAL fluid. [66] Under controlled sampling conditions, measurements of these eosinophil granule products have served as excellent indicators of eosinophil secretory activity in vivo and eosinophil involvement in a variety of allergic, parasitic, and certain inflammatory and skin diseases not normally associated with blood or tissue eosinophilia. Examples include assays of MBP and ECP in bronchoalveolar lavage [67] and nasal lavage[68] in asthma and allergic rhinitis, [66] in serum and plasma in lymphatic filariasis, [50] [69] and in skin diseases such as chronic idiopathic urticaria. [70] Such measurements likely reflect both in vivo secretion in tissues and/or secretory activity of eosinophils in the fluid sampled [66] and have provided compelling evidence for relationships between eosinophil secretory activity and disease severity. [67] [71] [72]

IDIOPATHIC HYPEREOSINOPHILIC SYNDROME

The hypereosinophilic syndrome (HES) comprises a group of myeloproliferative disorders of unknown etiology that are marked by a sustained overproduction of eosinophils. In addition to the striking and sometimes profound eosinophilia associated with the syndrome, HES is characterized by a predilection for end organ damage, most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related valvular pathologies. The currently defined criteria for HES as originally presented by Chusid et al. [12] include: (1) persistent eosinophilia of >1,500 eosinophils/mm ^{3} for more than 6 months, (2) exclusion of other potential etiologies for the eosinophilia including parasitic, allergic, or other causes, and (3) signs and symptoms of organ system dysfunction or involvement that appears related to the eosinophilia or is of unknown cause in the clinical presentation. Total leukocyte counts are often less than 25,000/mm ^{3} with 3070% eosinophils. However, extremely high leukocyte counts of (>90,000/mm^3) may be associated with a poor prognosis in some patients. These three primary features of the syndrome, including sustained eosinophilia of unkown etiology or disease association, along with evidence of organ involvement (Table 40-2) comprise the defining characteristics of HES. The clinical features of patients diagnosed with HES as summarized by Spry [73] and most recently reviewed by Weller and Bubley, [74] Brito-Babapulle, [75] and one of

TABLE 40-2 -- Major Organ Involvement and Prominent Clinical Features in Patients with the Hypereosinophilic Syndrome[a]

Primary Organ Involvement[b]	Clinical Manifestations[c]	
Hematologic (100)[d]	Eosinophilic endomyocardial disease	Psychiatric disturbance
Cardiovascular (58)	Skin lesions, e.g., angioedema, urticaria	Myalgia
Cutaneous (56)	Anorexia and weight loss	Arrhythmias
Neurologic (54)	Thromboembolic disease	Renal impairment
Pulmonary (49)	Lymph node and/or spleen enlargement	Splenic infarction
Splenic (43)	Ophthalmologic complications	Diarrhea alone
Hepatic (30)	Fever, excessive sweating	Arthralgia
Ocular (23)	Gastrointestinal involvement, including diarrhea	Pericarditis
Gastrointestinal (23)	Central nervous system disease	
	Pulmonary involvement

us[76] are shown in Table 40-2 in their frequency of presentation. The most commonly encountered feature in 5075% of patients studied in detail to date [77] [78] [79] include the cardiovascular manifestations, especially endomyocardial disease to be discussed later in this chapter, and its associated thromboembolic complications, the major causes of morbidity (and mortality) in the HES.

DIFFERENTIAL DIAGNOSIS OF HES

As shown in Table 40-1 , a large number of diseases have been identified that are associated with reactive, secondary eosinophilia, and hypereosinophilia. Their clinical presentations vary significantly and must be clearly distinguished from HES. In particular, there are a number of eosinophilic diseases and syndromes of questionable or unknown etiology that must be differentiated from HES based on both clinical and pathological parameters. The pathology of a number of these eosinophilic syndromes is generally restricted to specific organs, e.g., eosinophilic gastroenteritis and eosinophilic pneumonia; these syndromes lack the multiplicity of end organ damage generally seen in HES, and for this reason they can usually be distinguished from HES. For reasons that remain unclear, these syndromes lack the propensity to evolve toward secondary eosinophil-mediated cardiac disease. Because some patients with HES exhibit evidence of vasculitic disease, and the major eosinophil-associated vasculitis is the Churg-Strauss syndrome, this syndrome likewise needs to be ruled out. The Churg-Strauss syndrome is characterized by a history of blood eosinophilia >10%, asthma, pulmonary infiltrates (non-fixed), abnormalities in the paranasal sinuses, mono- or poly-neuropathy, and extravascular eosinophilic infiltrates in biopsied blood vessels. [80] Necrotizing vasculitis of small arteries and veins and extravascular granulomas are characteristic findings in biopsies from most, but not all Churg-Strauss patients, [81] [82] and asthma, peak eosinophil counts of >1,500/mm^3 , and systemic vasculitis involving two or more extrapulmonary organs generally identify these patients. [82] Although neurologic, pulmonary, and possibly paranasal findings may accompany HES, [77] asthma is characteristically absent. [83] Nevertheless, it may be difficult in some patients to make a clear distinction between HES and Churg-Strauss syndrome, especially since responses to high dose corticosteroids would be identical for both at the outset.

Eosinophilic syndromes with cutaneous involvement can generally be distinguished from HES by the histopathology of biopsied skin lesions. These syndromes include Kimuras disease (angiolymphoid hyperplasia with eosinophilia), Wells syndrome (eosinophilic cellulitis), eosinophilic fasciitis, and eosinophilic pustular folliculitis. The more recently described syndrome of episodic angioedema with eosinophilia, characterized by periodic recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia, is generally not associated with end organ cardiac damage, and has thus been distinguished from HES. [13] [14] Finally, the eosinophil myalgia syndrome, induced by ingestion of tainted L-tryptophan, should also be excluded.

A differential diagnosis of HES requires the exclusion of all identifiable eosinophilias of reactive, secondary etiologies (Table 40-3 and box, Treatment Approach: Diagnosis and Therapy of HES). These especially include eosinophilias due to parasitic infections caused predominantly by helminthic parasites, but also by two enteric protozoans, *Dientamoeba fragilis* and *Isospora belli*. In adults, filarial infections and strongyloidiasis are most likely to elicit pronounced and prolonged eosinophilias, in contrast to *Trichinella spiralis* infections which cause an acute eosinophilia that does not persist without reinfection. [84] Infections with *Strongyloides stercoralis*, which have the capacity to induce marked hypereosinophilia that mimics HES, [77] [85] are particularly important to exclude, especially since HES has been misdiagnosed in patients with unsuspected strongyloidiasis, and treatment of these patients with immunosuppressive glucocorticoids can lead to disseminated, often fatal disease. [86] Serial stool examinations, and in particular serologic enzyme-linked immunosorbent assays (ELISA) for strongyloides infection should be performed. Parasitic helminth infections not amenable to or detectable by routine stool examinations, including tissue- or blood-dwelling helminths causing filariasis, trichinosis or visceral larval migrans [87] (*Toxocara canis* infections in children), should be evaluated by diagnostic examinations of blood, tissue

TABLE 40-3 -- Diagnosis of the Idiopathic Hypereosinophilic Syndromea [a]

Eosinophils >1,500/mm^3 for at least 6 months duration
Reactive causes of eosinophilia excluded
Known eosinophilic disease entities excluded
Evidence of eosinophilic end organ damage
Clonal eosinophilic disorders excluded
Factors favoring a diagnosis of HES
Elevated serum immunoglobulins
Elevated levels of tumor necrosis factor, interleukins (IL-5) and/or IFN-, -, or -
Elevated serum IgE levels
Good therapeutic response to corticosteroids

TREATMENT APPROACH: DIAGNOSIS AND THERAPY OF HES[196]

Patients presenting with eosinophilia of unknown etiology should undergo a thorough clinical and laboratory evaluation consisting of the following:

Complete/detailed history and physical examination

Complete blood count with total eosinophil count and review of peripheral blood smear

Hepatic and renal function tests, urine analysis, erythrocyte sedimentation rate, rheumatoid factor, human immunodeficiency virus (HIV) assay and others as indicated

Quantitation of total IgE level

Stool for ova, parasites × 3, duodenal aspirate

Serologic assays for strongyloides, trichinella, toxocara, and others as clinically indicated

Bone marrow aspirate and biopsy (with cytogenetics)

Chest radiograph, computed tomograph scan of chest, abdomen, and pelvis

Electrocardiogram and echocardiogram

Molecular analysis of immunoglobulin and T-cell receptor gene rearrangement status

Patients meeting the diagnostic criteria for HES:

1. persistent eosinophilia of >1,500 eosinophils/mm^3 for more than 6 months
2. exclusion of other potential etiologies for the eosinophilia including parasitic, allergic, or other causes
3. presumptive signs and symptoms of organ system dysfunction or involvement which appears related to the eosinophilia or is of unknown cause in the clinical presentation.

These patients should be managed according to the strategy defined in the following algorithm for HES (
adapted from Schooley et al.,[195] *with permission*). Patients without any overt evidence of organ dysfunction or severe symptoms should be observed periodically without treatment. Periodic reinvestigation of the etiology of the eosinophilia is appropriate and recommended every 3 months to reconfirm the diagnosis of HES.

Treatment of hypereosinophilia secondary to a defined etiology should be directed at the underlying cause. For patients failing to respond to these measures, a trial of corticosteroids is warranted to halt progressive organ dysfunction secondary to the eosinophilia.

Treatment Strategy

Algorithm adapted from Schooley RT, Flaum MA, Gralnick HR, Fauci AS: A clinicopathologic correlation of the idiopathic hypereosinophilic syndrome. II. Clinical manifestations. Blood 58:1021, 1981, with permission.

biopsies, or specific serological tests (ELISAs or reverse transcription polymerase chain reaction [RT-PCR] assays) that are now available.

CLINICAL MANIFESTATIONS OF HES

Hematologic Findings

The definitive hematologic manifestation of HES is sustained eosinophilia of 3070%, with total leukocyte counts ranging from 10,000 to 30,000/mm ^{3} . However, extremely high leukocyte counts of greater than 90,000/mm^3 are not uncommon in some patients with HES, but are often associated with a poorer prognosis. [88] Blood smears generally show more or less normal, mature eosinophil morphology including typical bilobed nuclei and granule-rich cytoplasm. However, eosinophilic myeloid precursors may also be noted, though less commonly, and eosinophils may also exhibit morphologic abnormalities including nuclear hypersegmentation, decreased size and/or numbers of secondary granules and cytoplasmic vacuolization when

viewed at the light microscope level.[12] [89] The presence of myeloblasts and/or dysplastic findings in the peripheral blood may suggest an alternative, clonal etiology such as AML or a myelodysplastic syndrome (Table 40-4).[75] Ultrastructurally, HES eosinophils may show a selective loss of secondary granule components (crystalloid MBP-containing core and/or granular matrix), decreased numbers and/or size of granules, and increased numbers of cytoplasmic lipid bodies and tubulovesicular structures of unknown function.[15] [41] [90] [91]

In addition to their hypereosinophilia, patients with HES may also present with an absolute neutrophilia, further contributing to their overall increased leukocyte counts. This may include bands, less mature precursors, as well as alterations in neutrophil nuclear segmentation and cytoplasmic granules. [92] Basophilia, when seen in some HES patients, is usually minimal. Levels of leukocyte alkaline phosphatase may be abnormally elevated or decreased in HES patients, [12] and vitamin B_{12} and B_{12} -binding proteins in serum can be normal or elevated. [93] [94] In the NIH series, platelet counts were found to be decreased or increased in 31% and 16% of patients, respectively.[92] Approximately 50% of HES patients may be anemic, with abnormal and nucleated erythrocytes in circulation. The hypercellular bone marrow in these patients shows significant increases in the percentage of eosinophils (generally from 25 to 75% of marrow elements), with a clear left shift in eosinophil maturation.[92] Myeloblasts are generally normal in number, and myelofibrosis is rare, being observed in only a minority of patients in the NIH series. [92] Splenomegaly has been reported in 43% of HES patients (Table 40-2), and hypersplenism in these individuals may contribute to both thrombocytopenia, anemia, spleen infarction, and splenic pain induced by capsular distention or infarction is a frequent complication of splenic involvement in these individuals. [95] The progressive leukocytosis with hypereosinophilia in these patients, along with the hypercellular bone marrow and lack of increased numbers of myeloblasts, can make it difficult to distinguish HES from other myeloproliferative syndromes.

Cardiovascular Findings

The cardiac manifestations of HES can be frequent and considerable (5060% of patients; Table 40-2). Prior to the advent of early diagnosis, improved management and newer therapies, cardiac disease was the leading cause of both morbidity and mortality in HES patients. The cardiac and thromboembolic manifestations of HES are likely eosinophil-mediated. However, the risks of developing cardiac disease are not necessarily related to the extent or duration of the eosinophilia, [96] [97] since patients that ultimately develop cardiac involvement are more likely to be males with an HLA-Bw44 phenotype, develop splenomegaly and thrombocytopenia, have elevated vitamin B_{12} levels, and have abnormal hypogranular and vacuolated blood eosinophils and circulating early myeloid progenitors. [96] In contrast, HES patients who do not develop heart disease tend to be females with angioedema, hypergammaglobulinemia, and increased serum IgE levels and immune complexes.[96] The cardiac damage seen in HES, progressing from early necrotic changes through thrombosis and fibrosis, is identical to that seen in patients with hypereosinophilias of diverse etiologies. These include tropical eosinophilias due to loiasis or other filarial infections and parasitic infections such as trichinosis and visceral larval migrans,[98] drug reactions or administration of GM-CSF,[99] and eosinophilias of neoplastic origin including eosinophil leukemia, various carcinomas [100] and Hodgkins or non-Hodgkins lymphomas.[101] Because identical forms of cardiac pathology can develop in patients with hypereosinophilias of diverse etiologies, and some patients never go on to develop cardiac involvement, the pathogenesis of eosinophil-associated cardiac disease likely involves both eosinophils and as yet undefined factors required for the recruitment, activation, and secretion of these granulocytes in the heart and associated cardiovascular tissues.

Eosinophilic endomyocardial fibrosis, as first described by Löffler, [102] is pathologically similar to that of tropical endomyocardial fibrosis, [103] [104] save for the frequent absence of eosinophilia in the latter disorder. [102] However, the general absence of hypereosinophilia in patients with tropical endomyocardial fibrosis is thought to be a function of the late stage of helminthic disease in which the heart disease develops. The histopathology of cardiac involvement in HES is well characterized and can evolve through three sequentially defined stages for which eosinophils and secretion of eosinophil-derived mediators may be directly involved in the pathogenesis. These include: (1) an initial acute necrotic stage of short duration (average of 5 weeks) involving active endomyocarditis, (2) a later thrombotic stage (during an average 10 months of eosinophilia) with mural thrombus formation over endocardial lesions, and (3) a late fibrotic stage (after 2 years of illness) with development of endomyocardial fibrosis.[105] The early necrotic stage with damage to endocardium, involves marked eosinophil and lymphocyte infiltration of the myocardium with myocardial necrosis, formation of eosinophilic microabscesses, and eosinophil degranulation. Unfortunately, this early necrotic stage of cardiac disease is usually not

recognized clinically. Echocardiography and angiography may fail to detect abnormalities in this early stage of the disease since ventricular thickening has not yet occurred, and endomyocardial biopsies, generally from the right ventricle, are required to make the diagnosis of cardiac involvement. [78] Treatment of HES patients with corticosteroids during this acute necrotic stage may avert or control the subsequent development of myocardial fibrosis. However, patients often present at the later stages of the cardiac involvement. In the second stage, thrombi form over the damaged endocardium in either of the ventricles or the atrium, generally with sparing of the aortic and pulmonary valves. [106] Although electrocardiographic changes in these patients are common, they are not specific to HES. Progressive scarring at sites of mural thrombus formation ultimately lead to the late fibrotic stage, with endomyocardial fibrosis resulting in a restrictive cardiomyopathy and mitral and/or tricuspid valve regurgitation. The more common clinical manifestations in the later progressive stages of endomyocardial fibrosis include dyspnea, chest pain, signs of left and/or right ventricular congestive heart failure, the murmurs of mitral valve regurgitation, cardiomegaly, and T-wave inversions. [106] Most patients who progress to this stage of HES cardiomyopathy will benefit from standard medical therapies for congestive heart failure, or mitral valve replacement where hemodynamically indicated. Two-dimensional echocardiography is the most sensitive method for detecting cardiac abnormalities in these patients, including visualization of mural thrombi and the various manifestations of fibrosis, including thickening of the mitral valve and its supporting structures. Approximately 80% of HES patients in the NIH series had echocardiographic abnormalities, with thickening of the left ventricular free wall the most common finding (68% of patients). [106] Cardiac catheterization may

also be useful for demonstrating elevated right and left ventricular end diastolic pressures and angiography may be used to visualize valvular incompetence.

Histopathologic evaluation of the heart of HES patients generally shows four dominant features: (1) endocardial fibrosis and thickening, including involvement of mitral valve and supporting structures, (2) mural thrombus and granulation tissue on the endocardium with extensive infiltration by eosinophils, (3) thrombotic and fibrotic involvement of small intramural coronary vessels, including inflammatory cells and eosinophils, and (4) eosinophilic infiltration of the endocardium, and myocardium (in some cases). In a multicenter study of biopsy and postmortem specimens of cardiac tissue from HES patients at various stages of eosinophilic endomyocardial disease, we identified activated eosinophils (identified by staining with the EG2 anti-ECP monoclonal antibody) and marked intracardiac extracellular deposition of eosinophil granule cationic proteins including MBP, ECP, and EDN/eosinophil protein (EP)X in the early necrotic and later thrombotic lesions, mainly in areas of acute tissue damage on and beneath the endocardium, myocardial necrosis, and in the walls of small vessels. [57] The presence of activated eosinophils and toxic granule proteins in the early lesions of this disease suggests an active role for eosinophils and their products in inducing endocardial damage and myofibrillar injury, although the mechanisms involved in eosinophil recruitment into the heart have yet to be identified. In vitro studies have shown that secretion products of activated eosinophils can damage rat heart cell plasma membranes. [107] In addition, EPO in the presence of hydrogen peroxide and bromide or thiocyanate ion can induce damage to the endothelium of the working isolated rat heart [108] and eosinophil granule proteins can impair thrombomodulin activity, [109] findings supporting a role for these eosinophil products in the development of endocardial injury and subsequent thrombotic events in the HES. [110] The in vitro findings that eosinophil secretion products such as EDN can induce fibroblast proliferation, [111] that ECP alters fibroblast proteoglycan synthesis, [112] and that MBP can augment IL-1 or TGF- induced production of inflammatory cytokines (IL-6 and IL-11) by fibroblasts, [113] further implicates the eosinophil in the development of endocardial fibrosis in later stages of the disease.

OTHER MAJOR CLINICAL MANIFESTATIONS OF HES

Pulmonary Findings

The overall pulmonary involvement reported for HES patients is approximately 50% (Table 40-2), with the most common respiratory problem being a chronic and persistent, usually nonproductive cough. Although the physiologic basis for pulmonary involvement in HES is not known, it may be secondary to aspects of congestive heart failure, or a number of other factors including infiltration and sequestration of eosinophils in lung tissues or pulmonary emboli originating from ventricular thrombi. Although bronchospasm has been noted in some series of patients, [114] asthma is apparently quite rare in HES.[115] Transudative pleural effusions are the commonest abnormality in patients with frank congestive heart failure. [12] In contrast to chronic eosinophilic pneumonia, [116] the pulmonary infiltrates seen in 1428% of HES patients[12] [114] were either diffuse or focal, without any preference for particular regions of the lung. Pulmonary infiltrates in HES may or may not clear with prednisone treatment, and pulmonary fibrosis can develop in patients with endomyocardial fibrosis. [77]

Neurologic Manifestations

As noted in Table 40-2 , neurologic involvement is quite frequent in HES (50% of patients), encompassing three different complications. [117] The first type of neurologic involvement is caused by thromboemboli, which may originate from intracardiac thrombi in the left ventrical. These thromboembolic episodes may occur even before overt cardiac disease is visible by echocardiography. Patients with thrombotic complications may experience embolic strokes or transient ischemic episodes which may be multiple and recurrent, and these episodes may occur even though the patient is adequately anticoagulated with coumadin and antiplatelet agents. [78] [117] The second type of neurologic manifestation involves primary diffuse CNS dysfunction of unkown etiology. HES patients may variably exhibit changes in behavior, confusion, ataxia, and loss of memory.[117] The third neurologic dysfunction noted in HES is the development of peripheral neuropathies, which can occur in 50% of HES patients exhibiting neurologic involvement.[117] These include symmetric or asymmetric sensory polyneuropathies, including sensory deficits, painful paresthesias, or mixed sensory and motor defects.[117] [118] [119] These neuropathies may improve with steroid administration or other treatments, may be stable or continue to progress despite therapy, or may improve or resolve with time. The histopathology of the involved nerves usually shows varying degrees of axonal loss, without evidence of vasculitis or direct or peripheral eosinophil infiltration. [117] [118] [119] The presence in eosinophils of two granule cationic proteins, eosinophil-derived neurotoxin (EDN) [120] and eosinophil cationic protein (ECP), [121] both equally potent in inducing a neurotoxic and paralytic syndrome known as the Gordon Phenomenon [120] [122] when injected experimentally (intrathecally) into rabbits, [123] has led to speculation that these proteins might be responsible for inducing the various neuropathies commonly seen in HES. The histopathology of the cerebellar dysfunction in the brains of experimental rabbits undergoing the Gordon Phenomenon includes a spongiform degeneration of white matter and loss of Purkinje cells,[122] changes not comparable to the peripheral axonal nerve damage seen in HES. Both EDN and ECP, related 16 kD cationic proteins with 70% amino acid sequence homology, [124] [125] are members of the ribonuclease gene family and possess potent ribonuclease activity and cellular toxicities in vitro.[126] However, there is no direct evidence that these ribonucleases and cellular toxins have the capacity to mediate the types of neurologic damage seen in HES, nor have these proteins been visualized by immunochemical means at sites of HES neuropathology. Thus, the pathogenesis of the encephelopathic, CNS, and peripheral manifestations of HES-associated neuropathy remain speculative.

Cutaneous Manifestations

For reasons that remain unclear, the skin is frequently involved in HES pathology, with cutaneous manifestations present in >50% of patients in most series (Table 40-2).[12] [77] [127] The skin lesions associated with HES most commonly fall into three categories, (1) angioedematous and urticarial, (2) erythematous, pruritic papules and nodules and (3) mucosal ulcerations. As noted earlier, patients with angioedema and urticaria are more likely to have a benign disease course that is responsive to corticosteroids, without the development of cardiac or neuropathic complications. [77] [95] A subgroup of HES patients with cyclic angioedema and eosinophilia are now considered to have a syndrome (episodic angioedema with eosinophilia) that is distinct from classical HES. [14] These patients have a disorder with recurrent attacks of angioedema, urticaria, fever, and bodyweight gain that can be quite pronounced. These clinical manifestations are associated with marked leukocytosis and eosinophilia during the episodes. In HES patients that develop papular or nodular lesions, these usually improve concomitant with positive responses to systemic therapy.[127] Dermal biopsies in these patients generally show mixed cellular infiltrates including eosinophils, without signs of vasculitis. [127] Perivascular eosinophilic infiltrates are also found in these lesions. [127] The aquagenic erythematous

pruritic eruptions and indurated papules and nodules in some HES patients have been found to respond to psoralen and ultraviolet light therapy (PUVA), [128] [129] and in some patients, this treatment has interestingly been accompanied by a return of eosinophil counts to normal. [129] PUVA therapy may also be effective for the cutaneous manifestations of HES associated with HIV infection (exfoliative erythroderma and linear flagellate plaques). [130] HES-associated pruritis and nodular lesions have also been controlled with the addition of dapsone (75150 mgday) to prednisone. [131] Oral sodium cromoglycate (cromolyn sodium) given before meals has also been reported to be efficacious,[132] though neither of these agents had any effect on peripheral eosinophilia. Severe and sometimes incapacitating mucocutaneous ulcerations may be a prodrome to HES and indicate a subset of HES patients with a poor prognosis. [133] [134] They can occur at multiple sites including the mouth, nose, pharynx, penis, esophagus, stomach, and anus,[133] [134] and lesions can flare up independently of other clinical manifestations of HES. Biopsies of the ulcerative lesions usually show mixed cellular infiltrates, without a predominance of eosinophils or any evidence of vasculitis or microthrombi. [133] These ulcers have generally been resistant to treatment with topical or systemic corticosteroids, colchicine, and hydroxyurea, but have recently been shown to respond remarkably well to IFN- with complete and durable remissions.[135] [136]

Eosinophils are present in many skin diseases and in certain conditions may constitute part of the diagnostic histology of the lesion. [137] Although eosinophils in general may not appear prominent in many cutaneous diseases, there is now ample evidence to suggest that they may nevertheless participate in the pathogenesis of cutaneous inflammation[5] [138] and contribute to edematous reactions in atopic dermatitis, [53] syndromes associated with acute[139] [140] and chronic urticarias, [70] IgE-mediated late-phase reactions,[141] chronic dermatitis associated with parasitic infections such as onchocerciasis, [50] episodic angioedema with eosinophilia, [14] eosinophilic cellulitis, [142] and skin lesions associated with rIL-2 administration for advanced malignancies. [143] Indirect evidence includes the ability of the eosinophil to elaborate its granule cationic proteins, some of which are capable of inducing release of vasoactive amines from basophils and mast cells and inducing cutaneous wheal-and-flare reactions following direct injection into human skin, [138] and production of lipid mediators such as leukotriene (LT)C_4 and platelet activating factor (PAF), both potent inducers of vasopermeability in vivo. In addition, levels of eosinophil-active IL-5 are elevated in the syndromes of episodic angioedema with eosinophilia, [13] eosinophil-associated toxicity due to IL-2 administration, [143] and in the acute inflammatory response (Mazzotti reaction) in human onchocerciasis patients treated with diethylcarbamazine.[144]

By far, the most direct evidence to date for eosinophil participation in the etiology of the skin diseases listed in the previous paragraph has been the immunochemical detection, generally by immunofluorescent staining of skin biopsies, of prominent extracellular deposits of eosinophil granule cationic proteins such as MBP, ECP, or EDN, but not neutrophil products (neutrophil elastase) in affected but not unaffected skin, and in the absence of prominent numbers of intact eosinophils in lesional

infiltrates. One exception is the IgE-mediated late-phase reaction that follows the wheal-and-flare response characteristic of type I, IgE-mediated hypersensitivity. This classical late-phase reaction characterized clinically by erythema, edema, pruritis and tenderness peaking 612 hours after intradermal antigen or anti-IgE challenge, involves infiltration by mononuclear cells, neutrophils, basophils, and eosinophils presumably in response to mast cell degranulation, along with extensive extracellular deposition of both eosinophil (MBP) and neutrophil (elastase) granule products. [141] The secretion and extracellular deposition of eosinophil-granule constituents shown to possess potent cytotoxic and pro-inflammatory activities in edematous and eczematous lesions clearly suggest that eosinophils may contribute to the pathogenesis of both acute and chronic skin diseases, including the cutaneous lesions associated with HES. [145] However, studies elucidating the mechanisms that regulate eosinophil recruitment, activation, and secretion in the skin are needed to more clearly understand the dynamics of eosinophil participation in these cutaneous disorders and to identify potential therapeutic approaches to selectively blocking their influx and function.

ETIOLOGY OF HES

HES Versus Eosinophil Leukemia

The hypereosinophilic syndrome has historically been confused with eosinophil leukemia, especially since distinguishing between malignant and nonmalignant causes of hypereosinophilia can be quite difficult (Table 40-4, Table 40-5, Table 40-6).[75] Truly malignant acute eosinophil leukemias have a number of distinguishing characteristics such as a marked increase in the numbers of immature blood and/or bone marrow eosinophils, >10% blast forms in the bone marrow and tissue infiltration with immature eosinophilic cells, and a clinical course and findings that tend to resemble other acute leukemias, including anemia, thrombocytopenia, and increased susceptibility to infections (Table 40-5).[49] Because the cardiac and neurologic manifestations of HES can also develop in eosinophil leukemia, they cannot be used as distinguishing clinical features. In contrast, CNS infiltration by eosinophils and the tendency to produce bone myeloblastomas are features more frequently associated with acute eosinophil leukemia.[49] Chromosomal abnormalities may occur with both HES and eosinophil leukemia, but eosinophil leukemia is more frequently associated with chromosomal anomalies characteristic of other acute nonlymphocytic leukemias including 8:21 and 10p+11q-translocations, and trisomy-1. In addition, eosinophil leukemia has been reported as a variant of the M4Eo phenotype of acute myelomonocytic leukemia with eosinophilia, now linked to inversion 16 chromosomal abnormalities.[146] [147] [148] Chronic forms of eosinophilic leukemias have also been described.

TABLE 40-5 -- Major Factors Supporting a Diagnosis of Clonal Disorder Resulting in Hypereosinophiliaa[a]

Major Factors Supporting a Diagnosis of a Clonal Disorder
Cytogenetic abnormalities
FISH in eosinophils
G6PD alloenzymes in heterozygote females
Cultured eosinophil colonies with abnormal cytogenetics
Grade III bone marrow fibrosis
Trilineage blood or bone marrow myelodysplasia
Abnormal localization of immature precursors (ALIP)
Activating mutations in the K ras oncogene
Abnormal nucleotide content of eosinophils
Clonal T-cell proliferation or T-cell receptor gene rearrangement
Minor Factors Supporting a Diagnosis of Clonality
Elevated B_{12} binding
Hepatomegaly/splenomegaly
Normal levels of interleukins and immunoglobulins
Low neutrophil alkaline phosphatase
Markedly abnormal eosinophil morphology
Anemia or thrombocytopenia
Poor therapeutic response to steroid
Factors of Uncertain Significance
Apoptosis on blood film examination
Thrombotic events
Eosinophilic end organ damage

Lymphomas and Hypereosinophilia

A number of lymphomas may be associated with the development of eosinophilia including Hodgkins lymphoma,[149] T-cell lymphoblastic lymphoma,[150] and adult T-cell leukemia/lymphoma,[151] but the eosinophilia is generally much more modest than that seen in HES. In contrast, there are a number of reports of patients presenting with classical clinical and hematologic features of HES who have gone on to develop acute lymphoblastic leukemias [152] [153] [154] [155] or T-cell lymphomas.[156] [157] [158] [159] In a number of T-cell lymphoma cases, the accompanying eosinophilias were shown to be associated with the production of eosinophilopoietic cytokines (GM-CSF, IL-3, or IL-5) by the lymphomas themselves.[160] [161]

PATHOGENESIS OF EOSINOPHIL-ASSOCIATED END ORGAN DAMAGE IN HES

Based on current understanding of eosinophil function and hypereosinophilic conditions, sustained eosinophilia due to any cause, regardless of whether it is of reactive, clonal, or idiopathic origin, has the capacity to lead to end organ damage. The multiple manifestations of such eosinophil-associated end organ damage are considerable as presented in Table 40-7 , and their identification and management have been discussed in many reports and reviews. [49] [74] [76] [84] [115] [162] However, not all cases of sustained hypereosinophilia necessarily lead to end organ damage. For example, patients with syndromes such as eosinophilic pneumonia and episodic angioedema with eosinophilia [14] characteristically fail to develop the cardiac damage characteristic of HES patients. Experimentally, IL-5 transgenic mice, which develop extremely high numbers of peripheral blood eosinophils, do not develop significant end organ damage, suggesting that other factors in addition to IL-5 are likely to be necessary for eosinophil recruitment to the tissue, eosinophil activation, and tissue damage. [27] [28] Other factors may be necessary to induce eosinophilic end organ damage, such as secretion of eosinophil-active inflammatory or hematopoietic cytokines (e.g., GM-CSF), genetic predisposition, clonal T-cell dysfunction, development of a Th2 instead of Th1 T-cell profile, or in situ production of cytokines that block eosinophil apoptosis and enhance eosinophil survival and activation. It is not currently known whether true myeloproliferative eosinophilic disorders of clonal origin have the capacity to lead to end organ damage. It is notable that, HES patients in the National Institutes of Health (NIH) series who ultimately developed cardiac disease, exhibited features suggestive of a diagnosis of myeloproliferative disease, including splenomegaly, thrombocytopenia, anemia, elevated B_{12} levels, cytogenetic abnormalities, and circulating myeloid precursors and myeloid dysplasia. [74] [77] As noted earlier, the eosinophil expresses a number of granule cationic protein mediators capable of inducing thrombotic events, [163] endothelial and endocardial damage, [57] and neurotoxicity (the ribonucleases, eosinophil-derived neurotoxin [EDN] and eosinophil cationic protein [ECP]). [124] [125] Eosinophil granule major basic protein (MBP) and eosinophil cationic protein are both potent cellular toxins capable of damaging normal host cells and tissues in a manner reminiscent of end organ damage associated with tissue eosinophilia. [2] [164] In addition, the eosinophil has the capacity to undergo a potent respiratory burst upon activation, generating

reactive oxidative species that can directly, or in association with eosinophil peroxidase, induce oxidant-mediated tissue damage. [108] [110] [165] However, the mechanisms by which eosinophils induce thrombosis and the thromboembolic events associated with hypereosinophilic diseases such as idiopathic HES remain unclear, especially since most investigators have failed to identify consistent systemic alterations in coagulation and fibrinolytic pathways in these patients. [77] [78] However, recent studies by Slungaard and colleagues suggest that eosinophil granule cationic proteins have the capacity to alter thrombomodulin activity, suggesting one possible mechanism for thromboembolism in hypereosinophilic heart disease. [109]

THERAPY AND PROGNOSIS FOR HES

The earlier literature on HES is filled with reports of poor to dismal patient prognosis. For example, a 1975 review by Chusid

and colleagues of 57 published cases indicated an average survival time of 9 months, with a 3-year survival of only 12%. [12] The high morbidity and mortality reported in these reviews of prior decades likely reflects the fact that most HES patients tended to present late with more advanced disease, in particular significant cardiovascular problems. Deaths in these patients were generally the result of congestive heart failure and secondary complications of endomyocardial disease including bacterial endocarditis, progressive valvular incompetence, and the thromboembolic sequelae of the syndrome. [49] [115] However, earlier diagnosis of HES, along with improved clinical and echocardiographic methods for monitoring, and use of cardiac medications and cardiothoracic surgical procedures not previously available, has resulted in more successful prevention and management of cardiac disease in these patients, considerably improving clinical outcome and survival. A report in 1989 of 40 HES patients in France reported an 80% survival after 5 years and 42% survival at 10 and 15 years. [114] Thus for many patients, prevention and management of HES end organ damage, in particular the cardiac sequelae, results in prolonged survival over decades. [74] [115] Current, previously unavailable supportive therapies for managing the cardiovascular complications of HES, along with therapies aimed at controlling the eosinophilia to prevent end organ damage in the first place, are the mainstay of HES treatment regimens (Table 40-8). [74] Treatment should focus on controlling end organ damage, not just on suppressing or eradicating the eosinophilia, especially since the severity of cardiovascular complications of HES do not necessarily correlate with the duration or level of eosinophilia. [96] [97] Although more aggressive treatment (e.g., cytotoxic chemotherapy or bone marrow transplant) may be indicated and necessary in selected patients, the current goal is chronic maintenance therapy. In a 1992 review of HES, Spry [115] points out that overaggressive cytotoxic therapy for some HES patients may be more deleterious than the HES itself, with the risk of marrow aplasia. [12] Current therapeutic options for treatment and management of HES are listed in Table 40-8 and described in greater detail later in this chapter. Recent experience with the use of biologic response modifiers, in particular interferon-, hold considerable promise for durable remissions of eosinophilia and clinical signs and symptoms, particularly in patients with resistant disease, but also in HES patients in general as a first-line therapeutic option. [76]

Initial Therapeutic Options

The indication for aggressive initial treatment is evidence of progressive organ involvement and/or symptoms. In asymptomatic eosinophilic patients who lack evidence of end organ involvement, specific therapy need not be administered immediately. However, careful and frequent (36 month interval) clinical and echocardiographic follow-ups should be done to evaluate such patients for the onset of cardiac involvement, which may develop insidiously. It may be valuable in such patients to evaluate the effect of a short course of prednisone (60 mg/kg/day or 1 mg/kg/d) to determine whether the eosinophilia will be responsive to corticosteroid suppression, should organ involvement ultimately develop. Several prognostic

TABLE 40-8 -- Therapies for the Hypereosinophilic Syndrome[a]

Therapy	Indications
None	If no evidence of organ involvement, i.e., those patients with eosinophilia, but without any defining features of HES
Corticosteroids	First-line agent for those with organ involvement; if effective in suppressing peripheral blood eosinophilia, dose may be tapered or changed to every other day; response to corticosteroids associated with a better patient prognosis
Hydroxyurea	Used in those patients with organ involvement and eosinophilia unresponsive to corticosteroids; anemia and/or thrombocytopenia common with chronic therapy
Vincristine	Especially useful for acute reductions when eosinophil counts become excessive (50,00075,000/l); can be administered episodically to control HES, often with amelioration of thrombocytopenia
Alkylating agents	Chlorambucil and others; may be administered in 4-day pulse doses repeated as dictated by the magnitude of blood eosinophilia
Biologic response modifiers and immunosuppressive agents	-Interferon; cyclosporin A. Experience with these agents is somewhat limited, but they have been used with some apparent successes, especially -interferon
Cardiac surgery	Indicated for serious mitral regurgitation with bioprosthetic mitral valve replacement; less commonly, thrombectomy or endomyocardectomy
Other treatments with poorly defined therapeutic or management roles:	
Pheresis	Plasma- and leukapheresis have no defined role in long-term management of HES; use is usually restricted to emergency situations for patients developing profoundly high eosinophil counts; cell counts rebound to prepheresis levels within 1 day
Antiplatelet agents/anticoagulation	Thrombotic/thromboembolic events are a frequent serious HES complication; anticoagulation is administered where thrombo-emboli or intraventricular thrombi have been identified; effectiveness in HES has not been established
Splenectomy	No established role in routine management of HES; may ameliorate platelet sequestration from hypersplenism; relieve pain from splenic distention and infarctions common to those HES patients with splenomegaly
Radiation therapy	Effective for chloromas of eosinophilic leukemias
Bone marrow transplantation	Clinical experience still very limited; risks do not appear to be justified unless patients have an extremely aggressive disease course that is refractory to other preferred modalities listed above

[a] *Modified from Weller and Bubley,[74] with permission.*

features mentioned earlier may predict a good response to corticosteroid therapy including the presence of angioedema and urticaria, elevated serum IgE levels, and a rapid drop in eosinophil counts in response to the initiation of corticosteroids. Initial therapy in patients presenting with evidence of end organ involvement is with prednisone (1 mg/kg/day or 60mg/d in adults). If an adequate suppression of blood eosinophil counts is obtained, then doses may be slowly tapered and ultimately switched to alternate day therapy (1 mg/kg/day). In the NIH series, 38% of patients responded well and 31% partially to prednisone treatment. [92] [95] [106] Patients less likely to respond favorably to prednisone include those with the poor prognostic signs of splenomegaly, cardiac dysfunction, and neurologic symptoms at the time of presentation. The mechanisms of steroid refractory eosinophilia in HES have not been clearly defined; however, Prin and colleagues have reported decreased eosinophil glucocorticoid receptor expression in HES patients and that absence of receptor correlates with steroid resistance. [166]

Chemotherapeutic Agents

In patients with evidence of end organ involvement and steroid-resistant eosinophilia, the decision may be made to use more aggressive cytotoxic chemotherapy. Hydroxyurea (12 grams/day) has demonstrated efficacy in steroid-nonresponsive patients and is given with the goal of reducing total leukocyte counts to a normal range of <10,000/mm^3 . Eosinophil counts begin to diminish after 714 days of treatment, reflecting the kinetics of eosinophil development and turnover in these patients. Hydroxyurea interferes with DNA synthesis, thereby inhibiting the development of all marrow-derived cells, in addition to eosinophils. The development of anemia and thrombocytopenia as a consequence of hydroxyurea may necessitate red cell transfusions and decreased doses or cessation of therapy. Weekly leukocyte counts may be necessary to monitor idiosyncratic fluctuations in red blood cell or platelet counts, and for consequent adjustment of hydroxyurea dosage. [74] Vinca alkaloids are also effective in HES, and vincristine (1.01.5 mg/m^2 at biweekly intervals), which produces a permanent mitotic arrest by disrupting spindle microtubules, has been shown to be beneficial in some patients. [73] [167] [168] [169] However, use of vincristine, which generally spares marrow toxicity for platelets, may become limited by neurologic complications that may be indistinguishable from the peripheral neuropathies associated with HES in some patients. Because vincristine decreases blood eosinophil counts in 13 days, it may be particularly efficacious for acute treatment of patients with marked hypereosinophilia (>100,000 eosinophils/mm^3) (Table 40-8). Other chemotherapeutic agents that have been used with some success in a limited number of patients include etoposide (VP-16) and alkylating agents such as chlorambucil. Etoposide, a podophyllotoxin derivative and topoisomerase II inhibitor that induces DNA damage, has been used successfully in a number of patients to date. Oral followed by parenteral etoposide, administered in one patient after cessation of hydroxyurea treatment, was effective in controlling symptoms and eosinophil counts for a period of 18 months, but was ultimately withdrawn due to marrow suppression. [170] Two additional patients reported by Bourrat et al.[171] responded to etoposide with prolonged and durable remissions, despite discontinuance of the etoposide treatment. In these cases, doses of 300 mg/m^2 were given IV over a 2-day course or 200 mg/m^2 for 7 or 10 days. Use of oral pulses of chlorambucil have been reported by Weller and Bubley [74] at doses ranging from 410mg/m^2 daily for 4 consecutive days approximately every second month for 2 years with some efficacy in patients refractory to steroids and intolerant to hydroxyurea.

Biologic Response Modifiers

A number of biologic response modifiers and immunosuppressive agents have been used more or less successfully in HES patients with a poor response to corticosteroids and hydroxyurea, including interferon- and cyclosporin A. In fact, the most important recent advance in treating resistant HES has been the use of interferon-. [75] Interferon- has been used successfully to treat a number of leukemias including CML, multiple myeloma, and hairy cell leukemia. Experience by one of us with a series of six HES patients treated with interferon- at the Mayo Clinic suggests that interferon may be a valuable agent for HES patients who are unresponsive to or intolerant of conventional corticosteroid or hydroxyurea therapies, and for patients with this syndrome who develop incapacitating mucosal ulcers.[135] [136] In this series, IFN-$_{2b}$ was administered daily in single subcutaneous injections ranging from 1.0 to 6.25 × 10^6 U/day (MU/day) individualized for each patient. Doses from 1.5 MU/day to 8 MU/day were successful in decreasing eosinophil counts to <1,000/mm^3 in five of six patients and all patients were able to taper and discontinue prednisone and hydroxyurea. [135] [136] Two patients in this series with incapacitating mucosal ulcerations had resolution and no recurrence of their lesions. A number of additional reports indicate variable success in suppressing eosinophilia and hepatosplenomegaly, in clinical parameters and echocardiographic improvements in HES patients treated with interferon- as well as sustained disease remissions. [172] [173] [174] [175] [176] [177] Thus, there is a growing body of evidence in the literature that IFN- has a major place in the long-term treatment of HES, particularly in cases that are unresponsive to more conventional therapies, those with intractable mucosal ulcerations, those with cytogenetic abnormalities, and those presenting as myeloproliferative variants of HES. [178] Cyclosporin-A, an immunosuppressant that interferes with multiple aspects of immunocompetent T-lymphocyte function, has been reported to be effective in a series of four HES patients.[44] [179] [180] The rationale for use of cyclosporin-A is the inhibition of production of eosinophilopoietic cytokines (i.e., IL-5) from putative T-cell clones thought to drive the eosinophilia in these patients. [44] [75] [179] Of interest, T-cell clones have been established and characterized from the peripheral blood of a number of patients with HES,[44] providing the rationale for its use. Cyclosporin-A has been used in conjunction with low-dose corticosteroids, although the reported duration of therapy has been limited (10 months) and longer-term efficacy or side effects in HES have not been determined. Indeed, Zabel and Schlaak [180] demonstrated corticosteroid-sparing effects and durable control of eosinophilia using 4 mg/kg cyclosporin-A in a series of three HES patients.

Pheresis

As noted in Table 40-8 , plasma and leukapheresis have no defined role in the long-term management of HES. The use of leukapheresis, or more specifically eosinopheresis, has generally been restricted to emergency situations for patients developing profoundly high eosinophil counts. However, cell counts rebound rapidly to prepheresis levels within 1 day of the procedure. [181] [182] Even multiple repeated sessions of leukapheresis are usually not sufficient to induce more than a transient decrease in blood eosinophil levels. [181] [182] [183] Five repeated plasma- and leukapheresis sessions over a period of two weeks for a single patient was reported to significantly decrease blood eosinophilia, however continued sessions in this patient were ineffective by themselves to lower blood eosinophil counts to acceptable levels.[183] The mechanism by which pheresis transiently decreases eosinophil levels is not known, but has been suggested to involve a temporary removal or decrease in the levels of circulating eosinophilopoietic factors. [181] [183]

Anticoagulation and Antiplatelet Agents

Because thrombotic and thromboembolic events are frequently serious complications of HES, anticoagulants have often been used, especially in those patients with clear evidence of thromboemboli, neurologic symptoms, and cardiac involvement. Commonly used agents include warfarin, antiplatelet agents, or heparin. However, the efficacy of anticoagulation or antiplatelet agents has not been clearly established in HES disease, and a number of patients treated with these agents have continued to have thrombotic events, despite their adequate use. [78] [115]

Splenectomy

As noted earlier in this chapter, splenomegaly has been reported in 43% of HES patients, and hypersplenism in these individuals may contribute to both thrombocytopenia, anemia, and spleen infarction. Splenic pain induced by capsular distention or infarction is a frequent complication of splenic involvement in these individuals.[95] In HES, splenectomy has the capacity to ameliorate platelet sequestration from hypersplenism and to relieve the pain associated with splenic distention and infarctions. However, splenectomy has no established role in the routine management of HES patients.

Bone Marrow Transplantation

There is still very limited experience reported for bone marrow transplantation as a modality for the treatment of HES. [184] [185] [186] [187] [188] However, a number of the recent reports of bone marrow transplantation for refractory HES include two successes with patients apparently in complete remission [186] [188] and a third that was a success except for the development of graft-versus-host disease (GVHD) requiring management with cyclosporin-A. [184] In a fourth report, a relapse occurred 40 months after transplantation with the patient surviving at least through 44 months. [187] In a much earlier case reported in 1988, an HES patient given an allogeneic transplant recovered hematologically, but subsequently died within three months from a diffuse cytomegalovirus (CMV) infection, thus preventing adequate evaluation of the procedure.[185] Only in HES cases with an extremely aggressive course unresponsive to standard therapies, or in young patients with refractory disease and clinical features suggestive of a myeloproliferative disorder (e.g., chromosomal abnormalities), should allogeneic bone marrow transplantation be considered a treatment option at this time. Without greater understanding of the underlying mechanisms responsible for the overproduction of eosinophils and the aggressive development of end organ damage in some of these patients, the risks associated with bone marrow transplantation may outweigh its more routine use in treatment of this syndrome.

Cardiac Surgery

Treatment of the cardiovascular sequelae of HES continues to be one of the major therapeutic challenges of this syndrome. However, the use of cardiac surgery is one of the major advances since the 1970s in treating the varied cardiac complications of HES. [49] Surgical intervention in eosinophilic heart disease does not appear to carry any risk of disease recurrence at the operative sites. For patients who develop significant compromise of valvular function, endomyocardial thrombosis, or fibrosis, cardiac surgery has the capacity to provide substantial clinical and quality of life improvements. [49] Mitral valve[189] or tricuspid valve (or both) repairs or replacements[190] have been reported for >50 eosinophilic patients.[49] Endomyocardectomy and thrombectomy, as performed for advanced stage Löefflers endomyocardial fibrosis, has also been used effectively in some HES patients [78] [191] and ventricular decortication may be performed in combination with valve replacement. For mitral valve replacements, mechanical valves have proven problematic in terms of recurring thrombotic episodes despite adequate anticoagulation,[191] [192] [193] suggesting the deliberate use of porcine bioprostheses whenever possible. [74] [194] HES patients who have received valve replacements have generally experienced long-term improvement in cardiac function and well-being, making it a useful procedure for the long-term care of HES with cardiac involvement.[74]

Ineffective Agents in HES

A number of agents have proven either less useful or totally ineffective for the treatment of HES. These include antihistamines, anabolic steroids, methotrexate and busulfan (alone or combined), azathioprine, and cyclophosphamide.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

SUMMARY AND CONCLUSIONS

The hypereosinophilic syndrome comprises a rather heterogeneous collection of relatively rare disorders distinguished by end organ damage. It shares many clinical features with a variety of eosinophilic syndromes related to vasculitis, myeloproliferative disorders, and certain parasitic infections. The heterogeneity of HES, ranging from patients with clear myelodysplastic features including cytogenetic abnormalities, to patients with more benign clinical courses such as episodic angioedema with eosinophilia, suggest that multiple disease mechanisms are likely involved. Current research aimed at defining the etiology of HES and mechanisms regulating the development of eosinophil-mediated end organ damage in eosinophil-associated diseases in general, should ultimately lead to more selective and improved therapies. The therapeutic targets for these efforts are likely to include IL-5 and its high-affinity receptor, underlying T-cell clones (either immunocompetent or occult T-lymphoid malignancies) that elaborate eosinophilopoietins such as IL-5 or GM-CSF, tissue or organ-specific dysfunctional elaboration of eosinophil-active chemoattractant factors such as eosinophil-selective chemokines (eotaxins) or vascular endothelial adhesion molecules (VCAM/VLA-4), or as yet undefined mechanisms that induce the overproduction of eosinophils and/or serve to recruit and activate eosinophils selectively in certain tissues and organs. The essential absence of end organ damage in some syndromes of hypereosinophilia contrasts starkly with the morbidity (and mortality) associated with the development of endomyocardial fibrosis in HES and certain other eosinophilias. Because HES patients are clearly a heterogenous group, clinical management based on current knowledge must be specifically tailored to the individual, [76] with the overall goal of controlling the eosinophilia, and in particular, the eosinophil-mediated end organ damage. The past 25 years have seen an evolution in clinical and surgical management of patients with hypereosinophilia and HES. Current treatment options are numerous, such that both eosinophilia and end organ damage can be controlled or even eradicated in the majority of HES patients. For patients with resistant forms of HES, IFN- and bone marrow transplantation hold great promise for durable disease remissions in these patients. It is important to note that treatment with IFN- should now be considered as an initial option for the management of HES, either alone or in combination with existing therapies. [76]

Chapter 41 - Disorders of Phagocyte Function and Number

John T. Curnutte
Thomas D. Coates

Disorders of Phagocyte Function

INTRODUCTION

The defense of the host against pathogenic microbes is the critical responsibility of the immune system. Unfortunately for the host, these microbes are diverse in nature mdash; they may be viruses, bacteria, fungi, or uni- or multicellular parasites and many have evolved an impressive array of mechanisms to penetrate the host, evade immune surveillance, and even neutralize the antimicrobial poisons generated by the host defense systems. In light of this diversity and the evolutionary cat and mouse game played between pathogens and the immune system, it is not surprising that the immune system has evolved into a complex defense network comprising a variety of cell types and humoral mediators. The innate host defense system is responsible for the first line of protection against invading bacteria, fungi, and parasites and is composed of phagocytes (especially neutrophils), natural killer lymphocytes, complement, and other plasma proteins. As reviewed in Chapters 38 and 39 , phagocytes perform their critical functions either as resident cells in a variety of tissues or as circulating marauders in the bloodstream capable of traveling into any infected tissue. Members of the former category include such well-studied cells as the alveolar, hepatic, peritoneal, and splenic macrophages. The circulating phagocytes, on the other hand, are dominated by neutrophils but also include monocytes and eosinophils.

A complex series of cellular regulatory phenomena are involved in the phagocytes role as a primary defender of the host. These are most acute in the case of the circulating neutrophils, which must be able to sense exceedingly weak chemotactic signals from infected tissues, transduce this information rapidly into purposeful movement toward the source of the signals, engulf

the target microbes on arrival at the infected tissue, and then destroy the pathogens with extremely potent and effective agents while sparing surrounding normal tissues. Microbial killing is accomplished by two types of mechanisms: (1) de novo synthesis of highly toxic, and often unstable, derivatives of molecular oxygen by an enzyme known as the respiratory burst oxidase; and (2) delivery into the phagocytic vacuoles containing the ingested microbes of preformed polypeptide antibiotics and proteases stored within several types of lysosomal granules. [1] [2] [3]

Congenital and acquired disorders of each of the steps in phagocyte function have been described. As would be predicted, these disorders are manifested clinically by recurrent bacterial and fungal infections. Interestingly, the converse of this is only rarely observed. Most patients with recurrent infections do not have any identifiable abnormality in their phagocytes. There are at least two explanations for the clinical rarity of phagocyte disorders. First, given their critical role in host defense, nature may be quite intolerant of major abnormalities in phagocytes. Prior to the modern antibiotic era, patients afflicted with severe disorders probably did not survive into their childbearing years. Second, there is a remarkable redundancy in the antimicrobial machinery of the phagocytes that permits one system to compensate for a defect in another. For example, the host does not rely on a single chemotactic signal or neutrophil membrane receptor to ensure that phagocytes accumulate at sites of infection. Instead, multiple chemotactic signals and receptors are used.

This chapter reviews the major functional and quantitative disorders of phagocytes and is divided into two sections. The first focuses on the qualitative abnormalities and is organized according to the cellular functions outlined: disorders of the respiratory burst microbicidal pathway, abnormalities of phagocyte adhesion and chemotaxis, and defects in the structure and function of lysosomal granules. The second section outlines the quantitative abnormalitiesleukocytosis and leukopeniawith a particular emphasis on neutropenia. The chapter is not meant to be an encyclopedic review of the many papers published on phagocyte abnormalities. This chapter focuses on those disorders for which correlations do exist, with particular emphasis on those that are best understood at the molecular level. Many comprehensive reviews are available to the reader who is interested in the less well characterized phagocyte disorders. [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18]

DISORDERS OF THE RESPIRATORY BURST PATHWAY

The unstimulated human neutrophil consumes relatively little oxygen and relies primarily on glycolysis for energy. [19] [20] Within seconds after contact with suitably opsonized microorganisms or a variety of soluble stimuli, the rate of oxygen consumption abruptly increases, usually by a factor of >100, a metabolic event known as the respiratory burst.[21] This oxygen is consumed in a nonmitochondrial reaction in which it is reduced with a gain of one electron to form superoxide (as the O_2 ion) by a plasma membrane-bound nicotinamide adenine dinucleotide phosphate (NADPH) oxidase referred to as the respiratory burst oxidase (Fig. 41-1 , reaction 1).[22] [23] [24] NADPH is the preferred substrate for this enzyme, and O_2 appears to be the sole metabolite of the oxygen in most instances.[20] [21] [22] NADPH oxidase, along with those enzymes and reactions that are directly involved in the production or metabolism of reactive oxygen species, constitute the respiratory burst pathway [20] as depicted in Figure 41-1 . Five clinically significant defects have been identified in this pathway involving the following enzymes: NADPH oxidase [25] [26] (reaction 1), leukocyte glucose-6-phosphate dehydrogenase (G6PD) [27] (reaction 8), myeloperoxidase [13] [28] (reaction 4), glutathione reductase [7] [29] (reaction 7), and glutathione synthetase

Figure 41-1 Reactions of the respiratory burst pathway. The enzymes responsible for reactions 1 to 9 are as follows: (1) respiratory burst oxidase (NADPH oxidase); (2) superoxide dismutase (SOD) or spontaneous; (3) nonenzymatic; Fe^{2} +-catalyzed; (4) myeloperoxidase; (5) spontaneous; (6) glutathione peroxidase; (7) glutathione reductase; (8) glucose-6-phosphate dehydrogenase; (9) glutathione synthetase.

[7] (reaction 9). These reactions are involved in the production of O_2 (reactions 8 and 1), in the conversion of O_2 and hydrogen peroxide to other toxic derivatives (reaction 4), or in the detoxification of excess hydrogen peroxide needed to protect the phagocyte during the respiratory burst (reactions 6, 7, and 9).

Chronic Granulomatous Disease

Biology

Chronic granulomatous disease (CGD) comprises a heterogeneous group of defects that share in common the failure of neutrophils, monocytes, macrophages, and eosinophils to undergo a respiratory burst and generate O_2.[11] [25] [30] [31] [32] [33] The disorder is relatively rare, with a prevalence of approximately 1/500,000 individuals based on unpublished estimates from large urban populations. Data from the United States CGD Registry encompassing 368 registered patients indicates a rate of 1200,000 live births for the period 19801990. Because of the central role of superoxide and other respiratory burst products in microbial killing, patients with CGD suffer from recurrent severe bacterial and fungal infections. [34] [35] The disease was first described in 1957 in two independent reports, [36] [37] both of which describe severe recurrent infections associated with visceral granulomas containing pigmented histiocytes. The disease was termed fatal granulomatous disease owing to this distinguishing histologic feature and the grim clinical course in most patients. [36] [38] [39] [40] It was not until the late 1960s and early 1970s that the defect in oxygen consumption and O_2 production was identified and a convenient diagnostic assay, the nitroblue tetrazolium (NBT) test, was developed. [41] [42] [43] [44] [45] It was also during that time that it became apparent that CGD is a heterogeneous disorder. Although most patients were male and had inherited the disease in an X-linked manner, [46] a few female patients with CGD were discovered in whom the mode of inheritance appeared to be autosomal recessive. [31] [47] [48] [49] By 1975 it was clear that most, if not all, instances of CGD were caused by defects in the activity (or activation) of NADPH oxidase [50] (reaction 1, Fig. 41-1).

Our current understanding of CGD was reached with the aid of two major findings. The first was that a unique, low-potential (245 mV) cytochrome b was undetectable in nearly all patients with X-linked disease. [51] [52] The second was the discovery of a method by which NADPH oxidase could be activated in a cell-free system in the presence of negatively charged lipids such as arachidonic acid. [53] [54] [55] [56] These studies disclosed that both

TABLE 41-1 -- Cell-Free Activation of NADPH Oxidase in Two Genetic Forms of CGD

Source of Subcellular Fraction		Superoxide Generation[a] [b]	
Cytosol	**Membrane**	**Experiment 1**	**Experiment 2**
Normal	Normal	73.2	58.5
Patient	Patient	0.1	0.3
Normal	Patient	0.1	50.1
Patient	Normal	68.7	40.1
50% patient/50% normal	Normal	65.3	24.4

[a]Numerical data represent nmoles O_2 per minute per 10^7 cell-equivalents of membrane.

[b]The rate of superoxide generation was used to measure the extent of activation of dormant NADPH oxidase in a cell-free activation system using arachidonic acid (82 M) as the stimulus. Experiment 1 was performed with membranes and cytosol from a normal individual and a patient with X-linked cytochrome b-negative CGD, the most common type of CGD. Experiment 2 was performed with a different normal donor and a patient with autosomal recessive, cytochrome b-positive CGD lacking the p47-phox cytosol oxidase component, the second most common type of CGD. Oxidase activation was performed as described in Curnutte et al.[57]

cytosolic and membrane proteins were required for oxidase activation and that all patients had defects involving either the membranes or the cytosol. [53] [57] [58] Table 41-1 demonstrates this point. If cytosol and membranes from a normal individual are combined in the cell-free system and activated with arachidonic acid, large quantities of O_2 are generated. In experiment 1 in the table, cytosol and membranes from a patient with X-linked CGD (who was missing cytochrome b) were combined, and virtually no O_2 was produced following arachidonate stimulation. The cross-mixing experiment indicated that the patients membranes, but not cytosol, were defective. In experiment 2, a female patient with autosomal recessive CGD associated with a normal level of cytochrome b was studied. In contrast to the patient with X-linked CGD, her cytosol was severely defective while her membranes were normal.

It is now appreciated that NADPH oxidase is a complex enzyme consisting of multiple catalytic and regulatory subunits and that the activity of the oxidase is regulated, at least in part, by controlling the assembly of these components. [23] [24] [59] [60] [61] [62] [63] [64] [65] [66] [67] Perhaps as a fail-safe mechanism to prevent inadvertent activation, some of these components are localized in the membrane in the unstimulated neutrophil, whereas others are present in the cytosol (left side of Fig. 41-2). The membrane contains cytochrome b that functions as the catalytic and redox center of the oxidase, and this cytochrome consists of two closely interacting subunits present in a 1:1 stoichiometrygp91-*phox* (glycoprotein 91 kd of the phagocyte oxidase) and p22-*phox*. [68] [69] [70] [71] [72] [73] [74] Each cytochrome b contains one flavin adenine dinucleotide (FAD) group and two hemes. [75] [76] [77] [78] A low-molecular-weight G protein, rap1A, is also closely associated with cytochrome b, but it is not known whether it is a functional part of the oxidase. [79] [80] [81] The four remaining known oxidase components reside in the cytosol in unstimulated neutrophils: p47-*phox*, p67-*phox*, p40-*phox*, and another low-molecular-weight guanosine triphosphate (GTP)-binding protein, rac2 (or rac1 in guinea pig macrophages) (Fig. 41-2).[63] [82] [83] [84] [85] [86] [87] [88] [89] [90] [91] [92] [93] [94] [95] Prior to stimulation of the neutrophil, three of the cytosolic components (p47- *phox*, p67-*phox*, and p40-*phox*) appear to exist in a 260-kd complex that is stabilized by multiple protein-protein interactions between SH3 (src homology region 3) and proline-rich domains within the proteins (Fig. 41-2). [24] [58] [67] [96]

Figure 41-2 Model of NADPH oxidase activation. Current knowledge of the oxidase suggests that in its dormant state (left side of figure) it is composed of both membrane-bound and cytosolic components. The former include gp91-*phox* and p22-*phox,* which together form the cytochrome b heterodimer that also contains the redox centers of the enzyme: FAD and two heme groups (Fe). Rap1A, a low-molecular-weight GTP-binding protein, is also present in the membrane and may functionally associate with the cytochrome. The cytosolic components include p40- *phox,* p47-*phox,* and p67-*phox,* which exist in a complex of 260 kd. A pool of free, monomeric p47- *phox* is also present in the cytosol prepared from resting neutrophils. In its inactive GDP-bound state, the small GTP-binding protein Rac (Rac2 in human neutrophils) is also cytosolic and is bound to RhoGDP-dissociation inhibitor (GDI). On stimulation (right side of figure), p47- *phox,* p67-*phox,* and p40-*phox* become associated with the plasma membrane primarily through interactions between p47-*phox* and the subunits of the cytochrome. This translocation process is accompanied by, and perhaps requires (1) the release of Rac from RhoGDI, its conversion to an active (GTP-bound) state, and its association with the plasma membrane, and (2) the multisite phosphorylation of p47- *phox*. By a mechanism that is not fully understood, binding of the cytosolic components activates the flavocytochrome to catalyze the transfer of electrons from NADPH to oxygen via the FAD and heme redox centers. The compartment labeled inside is the cytoplasmic space; outside refers either to the extracellular or phagosomal space. *(From Heyworth et al.,[24] with permission.)*

TABLE 41-2 -- Classification of CGD

Component Affected	Gene Locus	Inheritance	Subtype Designation[a]	NBT Score (% positive)	O_2 Production (% normal)	Cytochrome b Spectrum (% normal)	Defect in Cell-Free System	Families Evaluated		Frequency (% of cases)
								Scripps[b]	Europe[c]

			$A22^+$	0	0	100	Membrane	1	0	<1
p47-*phox*	7q11.23	AR	$A47^0$	0	01	100	Cytosol	31	13	17
p67-*phox*	1q25	AR	$A67^0$	0	0	100	Cytosol	9	3	5

Abbreviations: X, X-linked inheritance; AR (or A), autosomal recessive inheritance; NBT, nitroblue tetrazolium.

Modified from Curnutte,[104] with permission.

[a]In this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]), and the number indicates the phox component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (^{0}), diminished (), or normal (+) as measured by immunoblot analysis.
[b]This group represents 212 kindreds evaluated at the Scripps Research Institute/Stanford University CGD Clinic.
[c]Cooperative study reported in 1992[105] represents 57 kindreds and 63 patients.

On neutrophil activation, p47-*phox* becomes partially phosphorylated and translocates to the membrane along with the other cytosol components in a process that requires GTP, rac2, and docking sites on p22-*phox* and gp91-*phox* [59] [60] [63] [67] [97] [98] [99] [100] [101] [102] (right side of Fig. 41-2). All CGD cases thus far analyzed at the molecular level are caused by mutations involving one of the four components gp91-*phox*, p22-*phox*, p47-*phox*, and p67-*phox*.

The molecular heterogeneity of CGD can be organized into a modern classification scheme based on the oxidase component affected [103] [104] [105] (Table 41-2). Nomenclature has also been adopted for an abbreviated designation for each subtype of CGD, as outlined in the legend for Table 41-2 . Defects in gp91-*phox* are all inherited in an X-linked fashion and account for approximately 74% of all CGD cases. [105] [106] In most X-linked CGD, gp91-*phox* is completely absent, and there is no measurable cytochrome b, NBT reduction, or intact cell superoxide production (the $X91^0$ subtype). In about 10% of X-linked cases, gp91-*phox* can be present at normal levels, but is nonfunctional ($X91^+$), partially deficient (X91), or mutated in such a way that the Michaelis constant (Km) for NADPH is abnormal (X91). [52] [107] [108] [109] [110] [111] [112] [113] [114] Mutations involving p22-*phox* occur in approximately 4% of patients with CGD and usually result in the complete absence of cytochrome b ($A22^0$).[115] [116] [117] [118] [119] This defect is inherited in an autosomal recessive manner. Because the full expression of cytochrome b in the membrane requires the production of both subunits, a primary deficiency of either component leads to a secondary loss of the other. [69] [120] Thus, neither subunit can be detected on immunoblot analysis in either $X91^0$ or $A22^0$ CGD. The second most common form of CGD is caused by a severe deficiency in the cytosol of p47-*phox* ($A47^0$) and is seen in 17% of all patients. [57] [83] [85] [86] [121] (Table 41-2). In the remaining 5% of patients, CGD is caused by the absence of p67-*phox* ($A67^0$).[57] [83] [85] [86] [121] Both cytosol defects are inherited in an autosomal recessive manner and are characterized by a severe deficiency of cytosol activity in the cell-free system. [57] Membrane function is intact in the cell-free system in these two types of CGD, and cytochrome b levels are normal. [57]

Despite the fact that more than 90% of patients with CGD have respiratory burst defects that result in undetectable levels of O_2 production, there is a surprising heterogeneity in the clinical manifestations of the disease. [31] [34] [104] [122] [123] At one end of the spectrum are the patients who suffer from severe bacterial and fungal infections starting in infancy, and who seldom have more than 612 months between serious infections. At the other end of the spectrum are patients who are well for many years and then unexpectedly develop a highly unusual infection such as a staphylococcal hepatic abscess or *Aspergillus* pneumonia. After their first major infection, some of these patients may be relatively healthy again for another 310 years before the next severe infection occurs. Based on experience with over 150 CGD patients, those with $X91^0$ and $A22^0$ CGD tend to have a more severe clinical course, whereas patients with $A47^0$ CGD often enjoy the milder clinical phenotype despite the equal severity of their respiratory burst defect. [123] Individuals with $A67^0$ CGD or partial respiratory burst activity <10% of normal (most X91 patients) tend to have disease of intermediate severity. Because of this heterogeneity, the diagnosis of CGD should be considered, not only in young children with recurrent severe infections, but also in adolescents and young adults who experience exceptionally severe or unusual infections.

Molecular Genetics of CGD

All of the subtypes of X-linked CGD are caused by mutations in the gene encoding the gp91-*phox* subunit of cytochrome b (Table 41-3).[33] [68] [69] [71] [106] [124] [125] [126] [127] [128] This gene, termed CYBB (MIM 306400), contains 13 exons and spans approximately 30 kb in the Xp21.1 region of the X chromosome. [129] [130] [131] [132] [133] [134] Based on the analysis of 261 X-linked CGD kindreds described in a multicenter international database, there is a striking heterogeneity in the mutations seen, with most being family specific.[125] Deletions, missense mutations, and nonsense mutations occur with comparable frequencies, each accounting for approximately 25% of all the mutations (Table 41-3). Splice-site mutations (16%) and insertions (10%) comprise most of the remaining mutations. Two putative regulatory mutations have also been identified to date. [133] [134] Distribution of the mutations within the CYBB gene

TABLE 41-3 -- Summary of Mutations in the CYBB Gene Encoding gp91-*phox* in 261 Kindreds with X-linked CGD

Type of Mutation	Number of Kindreds	Frequency (%)	Phenotype
Deletions	63	24.2	$X91^0$
Insertions	27	10.3	$X91^0$
Splice-site mutations	42	16.1	$X91^0$
Missense mutations	59	22.6	$X91^0$, X91 , $X91^+$
Nonsense mutations	70	26.8	$X91^0$

Data are from a multicenter database.[125]

appears to be more or less random with no apparent mutational hot spots.[106] Based on these large series of X-linked patients, it is clear that most instances of X-linked CGD arise from mutations in the coding and splice regions of CYBB and not from defects in the regulation of the gene. [106] [125] [126] Most of these mutations affect either the stability of the mRNA or the protein (or both), usually to the extent that no measurable cytochrome b is expressed in the phagocytes (Table 41-2).

The diversity of the mutations in gp91-*phox* parallels the clinical heterogeneity seen in X-linked CGD and, in many cases, provides at least a partial explanation for the phenotype observed. For example, large interstitial deletions in the Xp21.1 region can affect not only CYBB, but also a number of flanking genes. Distal to CYBB are the genes that encode a Kell blood group precursor Kx (gene locus XK) and dystrophin (DMD), defects which cause McLeod hemolytic anemia and Duchenne muscular dystrophy; centromeric to CYBB are the genes for ornithine transcarbamylase and retinitis pigmentosa-3. [130] [135] [136] One patient has been reported who suffered from CGD, Duchenne muscular dystrophy, McLeod hemolytic anemia, and retinitis pigmentosa,[130] whereas several others have been identified who have a similar constellation of defects without retinitis pigmentosa. [68] [106] [137] Because the XK locus that is responsible for the McLeod phenotype is closer to CYBB than the DMD locus,[139] it is more common to see McLeod hemolytic anemia in conjunction with CGD.[68] [106] [137] [138] [139] The variant forms of X-linked CGD (X91) in which some residual cytochrome b and respiratory burst activity are retained can also be explained at the molecular genetic level. For example, an in-frame nucleotide triplet deletion leading to the loss of a single amino acid in an extracellular domain of gp91-*phox* (K315) leads to only a 75% deficiency of cytochrome b and O_2 production and an exceedingly mild phenotype.[106] Similarly, two brothers with mild CGD have been identified who have a missense mutation (K161 R) that still allows their neutrophils to express low levels of a functional cytochrome b and generate O_2 at a rate 3% of normal.[106] In other instances, missense mutations predicting less conservative changes result in either absent (G20 R) or nonfunctional (P415 H) cytochrome b and a more severe clinical picture. [106] The severe phenotype is also more frequently seen in those patients with either nonsense or frameshift mutations because these lead to stop codons at either the site of mutation or slightly downstream (in the case of a frameshift). Truncated forms of gp91-*phox* are apparently highly unstable because patients with premature stop codons, even near the end of the gene, all have undetectable levels of cytochrome b and respiratory burst activity. [106] [126]

Mutations in the regulatory regions of the gp91-*phox* gene are uncommon and seen in <1% of X-linked CGD cases. The two that have been described are from unrelated kindreds that involve point mutations 55 and 57 bp upstream (5) of exon 1. [133] [134] Interestingly, the three patients from these two kindreds exhibited the same, highly unusual biochemical and functional phenotype. By both NBT testing and flow cytometric analysis of H_2O_2 production (using the dichlorofluorescin

assay[140]), 5% of each patients neutrophils had full respiratory burst activity while the remaining 95% were devoid of activity. The total amount of cytochrome b was also 5% of normal, presumably due to normal expression levels in the small clone of cells with full respiratory burst activity. It appears that these putative regulatory mutations adversely affect cytochrome b expression in the majority, but not all, of the circulating neutrophils and that this reflects some type of underlying heterogeneity in the way certain subpopulations regulate gp91- *phox* expression.

Mutations in the gene for p22-*phox* subunit of cytochrome b cause one of the three forms of autosomal recessive CGD and account for about 5% of all CGD cases (Table 41-2). The p22-*phox* gene, termed CYBA (MIM 233690), resides at chromosome 16q24 and contains six exons that span 8.5 kb.[116] As with X-linked CGD, the mutations identified in the nine kindreds studied (seven females and four males) are heterogeneous and family specific (Table 41-4).[44] [47] [116] [118] [119] In all but two of the cases listed in Table 41-4 (cases 2 and 9), the patients are homozygous for the mutant allele due to consanguinity of the parents. The mutations in general predict either major defects in p22-*phox* (e.g., case 1) or nonconservative amino acid substitutions. Not surprisingly, these patients fail to express p22- *phox*, are devoid of cytochrome b, cannot generate O_2 , and have clinically more severe disease. The one exception to this is case 6, who has a nonfunctional, yet spectrally normal cytochrome b that is expressed at normal levels. There is a predicted structural defect in the intracytoplasmic C-terminal domain due to the substitution of a Gln for Pro at residue 156.[119] Analogous to the $X91^+$ patients described above, this mutant nonfunctional cytochrome b is unable to support a respiratory burst and results in severe disease.

The gene for p47-*phox*, termed NCF1 (MIM 233700), resides

TABLE 41-4 -- Summary of Mutations in the CYBA Gene Encoding p22-*phox* in Nine Kindreds with Autosomal Recessive CGD

[c] In these cases, homozygosity of the mutant allele was due to consanguinity in the parents.

on chromosome 7 at q11.23[141] and contains eleven exons spanning 15 kb.[33] Mutations at this locus cause autosomal recessive CGD and account for about 17% of all CGD cases (Table 41-2). In contrast to the diversity of mutations seen in patients with cytochrome b defects, only two different mutations have been reported thus far in the thirty-five unrelated patients studied.[33] [142] [143] In 31 of these 35 cases, the patients are homozygous for a mutant allele with a GT deleted at the beginning of exon 2 that predicts a premature stop codon later in that same exon.[143] The other four patients are apparently compound heterozygotes with one allele containing the GT deletion in exon 2 and the other a distinct second mutation. In one of these four patients, the other mutation has been identified as a deletion of a single nucleotide (G502).[143A] The predominance of the mutant allele containing the GT deletion in the $A47^0$ CGD patient population appears to be caused by the presence of at least one highly homologous NCF1 pseudogene that contains this GT deletion. [143B] Both the NCF1 wild type and pseudogene(s) colocalize to chromosome 7q11.23 and this close association, coupled with the presence of multiple recombination hot spots within each gene, suggest that the high frequency of the GT deletion mutation in $A47^0$ CGD is caused by recombination events between these two genes.[143B]

Mutations in the gene for p67-*phox* account for the remaining 5% of CGD patients (Table 41-2). This gene, referred to as NCF2 (MIM 233710), is located on the long arm of chromosome 1 at position q25[141] and contains 16 exons that span 40 kb.[144] As shown in Table 41-5 , mutations in the p67-*phox* gene have been reported in twelve kindreds with this type of autosomal recessive CGD.[33] [145]

Clinical Manifestations

In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life with the onset of recurrent, purulent bacterial or fungal infections. Table 41-6 summarizes the types of infections and infecting organisms most frequently encountered in CGD.[34] [146] [147] [148] [149] [150] [151] [152] The most common types of infections involve sites in contact with the outside worldconsistent with the role of neutrophils as the first line of defense against infection. *Staphylococcus aureus*, enteric gram-negative organisms, *Serratia marcescens, Burkholderia cepacia* (formerly known as *Pseudomonas cepacia*), and *Aspergillus* species represent the most frequently encountered pathogens. Most CGD pathogens share the property of being catalase negative and as such, inadvertently lend H_2O_2 secreted from the pathogen to the peroxide-starved CGD phagocyte, which in turn uses it (once converted to HOCl by myeloperoxidase; see Fig. 41-1) to kill the microbe.[153] It also appears that at least some of the CGD pathogens are resistant to the nonoxidative killing mechanisms of the phagocyte, [154] and thus can proliferate relatively unchecked. It is somewhat surprising how often one fails to identify the infecting organism in CGD, perhaps greater than half the time despite aggressive culturing. In this situation, one treats empirically with the antibiotic that should work and if this fails, one then aggressively pursues more invasive diagnostic procedures looking for one (or more) of the less commonly seen microbes such as *Nocardia* species, *Candida*, and a host of other bacteria and fungi (Table 41-6).[152] [155] [156] [157] [158] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168] [169] [170] [171] [172] [173] [174]

Pneumonia is the most common type of infection seen in CGD with *S. aureus, Aspergillus* species, *B. cepacia*, and enteric gram-negative organisms as the major pathogens. It is noteworthy that *B. cepacia* has emerged as one of the most lethal pneumonias in the past 12 years, having been responsible for a number of deaths.[175] [176] [177] [178] [179] It often is not covered with the first line of antibiotics used for *S. aureus* and most gram-negative organisms and can quietly proliferate (with persistent fevers) to the point of quick, explosive collapse due to endotoxic shock. Intravenous trimethoprim-sulfamethoxazole has been most effective in treating patients if given before widespread dissemination of the

TABLE 41-5 -- Summary of p67-*phox* Mutations in 12 Kindreds with CGD

TABLE 41-6 -- Infections in CGD

Infections	% of Infections	Infecting Organisms
Pneumonia	7080	*Aspergillus, Staphylococcus, B. cepacia, Pseudomonas, Nocardia, Mycobacterium* (including atypical), *Serratia, Candida, Klebsiella, Paecilomyces*
Lymphadenitis	5060	*Staphylococcus, Serratia, Candida, Klebsiella, Nocardia*
Cutaneous infections/impetigo	5060	*Staphylococcus, Serratia, Aspergillus, Klebsiella, Candida*
Hepatic/perihepatic abscesses	2030	*Staphylococcus, Serratia, Streptococcus viridans, Nocardia, Aspergillus*
Osteomyelitis	2030	*Serratia, Aspergillus, Paecilomyces, Staphylococcus, B. cepacia, Pseudomonas, Nocardia*
Perirectal abscesses/fistulae	1530	Enteric gram-negative organisms, *Staphylococcus*
Septicemia	1020	*B. cepacia, Pseudomonas, Salmonella, Staphylococcus, Serratia, Klebsiella*
Urinary tract infections/pyelonephritis	15	Enteric gram-negative organisms
Brain abscesses	<5	*Aspergillus, Staphylococcus*
Meningitis	<5	*Candida lusitaniae, Hemophilus influenzae, B. cepacia*

The relative frequencies of different types of infections in CGD are estimated from data pooled from several large series of patients in the United States, Europe, and Japan.[34] [147] [148] [149] [150] [151] [152] These series encompass approximately 550 patients with CGD after accounting for overlap between reports. Unpublished data from the United States CGD Registry encompassing 368 patients was also used to estimate the relative frequencies of infections and the responsible organisms. The infecting organisms are arranged in approximate order of frequency for each type of infection. Note: *Burkholderia cepacia* (*B. cepacia*) was previously classified as *Pseudomonas cepacia*.

infection. An open lung biopsy is often needed to establish the diagnosis. *Aspergillus* pneumonia is also difficult to treat, but usually responds to 36 months of daily (then thrice weekly) amphotericin B therapy (with interferon-). Surgery has generally not been needed, except for biopsy or resection of large cavitary lesions.

Lymphadenitis is the second most common infection and is usually caused by *S. aureus* or *S. marcescens*. Incision and drainage should not be delayed if the lesion fails to respond to parenteral antibiotics. Cutaneous abscesses should be similarly managed. Recurrent perinatal impetigo is almost a signature infection in CGD and often requires months of therapy (mostly oral antibiotics) to clear. Hepatic (and perihepatic) abscesses are also common in CGD and are usually, but not always, caused by *S. aureus*. [180] [181] Most lesions require drainage (needle or surgical) to permit efficient healing to occur. Bone infections are particularly problematic in CGD and arise from either hematogenous or contiguous spread (as often is the case with *Aspergillus* infections in the lung invading ribs, vertebral bodies, or the diaphragm).[182] [183] [184] [185] Perirectal abscesses are difficult to treat, even with months of therapy, and can lead to fistula formation. [180]

Many of the more problematic complications of CGD result from imperfectly controlled infections in which stalemates develop between the pathogen and the leukocytes. These lesions become granulomas as the host uses lymphocytes and histiocytes to aid the failing neutrophils in containing the pathogens. As a result of this chronic inflammatory stimulation, patients with CGD can suffer from a variety of more chronic complications (Table 41-7). Lymphadenopathy, hepatosplenomegaly, eczematoid dermatitis,[186] and anemia of chronic disease (hemoglobin levels usually 810 g/dl) are common manifestations of this process and are most prominent in the first 510 years of life in CGD. A chronic ileocolitis resembling Crohns disease is seen in 10% of patients and can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy. [187] [188] [189] [190] Throughout the body, granuloma formation can lead to dysfunction and obstruction in the esophagus, [191] stomach,[180] [192] [193] intestine,[194] and urinary bladder and kidneys. [195] [196] [197] [198] [199] [200] [201] [202] [203] In the stomach, the gastric antral narrowing can be severe enough in infants and children to resemble pyloric stenosis. Granulomatous lesions and inflammatory cell infiltrates in the urinary system can lead to chronic cystitis, dysuria, and hydronephrosis. Other types of chronic inflammation include gingivitis, [204] chorioretinitis, [205] destructive white matter lesions in the brain,[206] [207] and glomerulonephritis[197] [208] In rare circumstances, patients may develop either discoid or systemic lupus erythematosus by a mechanism that is unknown.[209] [210] [211] [212]

Carriers of CGD, whether the X-linked form or any one of the autosomal recessive forms, are usually asymptomatic with two important exceptions. First, X-linked carriers are at risk of developing mild to moderately severe discoid lupus erythematosus characterized by discoid skin lesions and photosensitivity [211] [213] [214] A few will also suffer from arthralgias, polyarthritis, and Raynauds phenomenon. About one-fourth of women are symptomatic, with discoid lupus, with onset usually in the second decade of life. The disease does not progress to systemic lupus nor does one find serologic evidence of even subclinical disease. Severe discoid lupus can be treated with Plaquenil.

TABLE 41-7 -- Chronic Conditions Associated with CGD

Condition	Relative Frequency (%)

Lymphadenopathy	98
Hypergammaglobulinemia	6090
Hepatomegaly	5090
Splenomegaly	6080
Anemia of chronic disease	Common*
Underweight	70
Chronic diarrhea	2060
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	1025
Granulomatous ileocolitis	1015
Gastric antral narrowing	1015
Ulcerative stomatitis	515
Granulomatous cystitis	510*
Pulmonary fibrosis	<10*
Esophagitis	<10*
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

The relative frequencies of the chronic conditions associated with CGD were estimated from the series of reports listed in Table 41-6 . In some instances (asterisks), the incidence is estimated from the 50 cases of CGD followed at the Scripps Research Institute and Stanford University (unpublished data).

The second important complication of the CGD carrier state is infection in those X-linked carriers who have an unusually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that <10% of the cells function, then the carrier has an increased risk of infections that fortunately are usually mild. [215] [216] [217] [218]

Diagnosis

The diagnosis of CGD is usually suggested by the unusual clinical histories outlined above or by a family history of CGD. The diagnosis is most easily confirmed using the NBT slide test.[44] A typical result is shown in Figure 41-3 . Figure 41-3A shows the normal positive staining of a group of seven neutrophils and one monocyte. Figure 41-3B shows the complete absence of NBT staining in a patient with $X91^0$ CGD, the classic X-linked form of the disease. Figure 41-3C shows the mixed population of NBT-positive

Figure 41-3 Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate. **(A)** Normal neutrophils and monocytes, all of which are NBT-positive. **(B)** Neutrophils and monocytes from an X-linked CGD patient, which are all NBT-negative. **(C)** A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in panel B.

and NBT-negative cells observed in that patients mother. Because of random X-chromosome inactivation, some of the female carriers cells are NBT positive and others negative.[216] [217] [219] Because in this test nearly 100% of the normal cells are positive, we are able to reliably detect the carrier state in X-linked CGD, when as few as 5% of the cells are NBT negative. This test also permits detection of diffuse populations of weakly positive cells such as those seen in X91 CGD, which are characterized by a partial deficiency of cytochrome b. Because X-linked CGD can arise by new mutations in the germ lines of the parents, one does not always see NBT-negative cells in the mother. [2C] [106] [22C]

The diagnosis of CGD can also be established by directly measuring respiratory burst activity as oxygen consumption, O_2 production, or H_2O_2 production. The subtyping of CGD also requires measurement of the cytochrome b content in the patients (and parents) neutrophils, usually by a spectrophotometric assay.

Also required in many instances is the measurement of the activity of the patients neutrophil membranes and cytosol in the cell-free oxidase activation system, as depicted in Table 41-1 . Once a cytosol defect is suspected, the determination of which component is defective can be made by either immunoblot analysis [121] or complementation studies in the cell-free system using known cytosols deficient in either p47- *phox* or p67-*phox*. These latter tests are best performed by laboratories specializing in neutrophil biochemistry.

Molecular genetic analysis of either myeloid cell cDNA [112] or genomic DNA [106] [220] [221] can be used to confirm the genetic subtype and define further the molecular properties of the mutant oxidase. Moreover, the molecular genetic data can be used for genetic counseling in identifying carriers and (if genomic sequencing can be used) for prenatal diagnosis using fetal DNA from the chorionic villus or amniocytes. [221] [222] Alternatively, potentially informative polymorphisms exist in the genes for gp91-*phox* and p67-*phox* that can be used for fetal DNA analysis.[33] [144] [221] [223] [224] [225] In the absence of a molecular genetic approach, prenatal diagnosis can be performed using the NBT test and a small sample of fetal blood obtained by percutaneous umbilical sampling. [226] [227] [228] [229] [230] [231]

Therapy

The four cornerstones of therapy in CGD are (1) prevention and early treatment of infections; (2) aggressive use of parenteral antibiotics for most infections; (3) use of prophylactic trimethoprim-sulfamethoxazole (5 mg/kg/day of trimethoprim) or dicloxacillin (2550 mg/kg/day) for patients allergic to sulfa; and (4) use of prophylactic recombinant human interferon- (rIFN-). Several approaches can be used to prevent infections. Patients with CGD should receive all their routine immunizations on schedule, with influenza vaccine administered each year as well. Cuts and skin abrasions should be cleansed promptly with soap and water and a topical antiseptic applied (2% hydrogen peroxide or Betadine ointment or both). Frequent brushing, flossing, and professional cleaning of teeth can help prevent gingivitis. Constipation should be avoided because it can lead to rectal/anal fissures and abscesses. Early anal infections can be treated with soaking in soapy water (with or without Betadine). The frequency of pulmonary infections can be reduced by not using commercially available bedside humidifiers, by avoiding smoking (cigarettes and marijuana), and refraining from handling decaying plant materials, which often contain numerous *Aspergillus* spores (e.g., hay, mulch, rotting sawdust).[232] Use of corticosteroids should generally be avoided, including extensive topical use, except in cases of severe asthma, esophageal strictures, gastric antral narrowing, granulomatous cystitis, or inflammatory bowel disease. Evidence indicates that corticosteroids are beneficial in these clinical

settings because the steroids induce rapid regression of obstructive symptoms at relatively low oral doses (e.g., 1 mg/kg/day of prednisone). [233] [234] [235] In these situations, the physician and patient should be aware of the risks of the additional immunosuppression caused by the corticosteroids. Finally, rare patients with X91 ^{0} CGD have genomic deletions that span the gp91-*phox* gene and the Xk gene, which encodes a 37-kd red blood cell membrane protein necessary for expression of the Kell genes. [236] [237] Absence of the Xk gene product results in the McLeod syndrome, in which red blood cells have acanthocytosis and weak Kell antigens. [236] Treatment of patients with McLeod syndrome by transfusion poses a serious problem because they can develop alloantibodies of wide specificity that can preclude any further transfusions except with McLeod blood products.

Good evidence now indicates that chronic prophylactic trimethoprim-sulfamethoxazole can decrease the number of bacterial infections in CGD patients by more than half, without a concomitant increased risk of fungal infection. [149] [238] Antibiotic prophylaxis of fungal infections has been less successful because ketoconazole has not been found to provide any protection against *Aspergillus* infections. [149] Itraconazole may, however, be effective in this context and a study is currently underway to test this possibility.

One of the most frequent errors in the management of CGD patients is the failure to treat potentially serious infections promptly and aggressively with appropriate parenteral antibiotics. Even the best antibiotics can be rendered ineffective if given too late in the course of an infection in CGD. Therefore, early intervention is advisable. Although many of the minor infections and low-grade fevers in CGD patients can be managed on an outpatient basis, episodes of consistently high fever over a 24-hour period or clearly established infections (such as pneumonia or lymphadenitis) should be treated with parenteral antibiotics that cover, at least initially, *S. aureus* and enteric gram-negative organisms. Reasonable attempts to define the source of the infection and the responsible microbe should also begin promptly. If the infection fails to respond, then more aggressive diagnostic procedures should be instituted (computed tomography, bone and gallium scans; open biopsies if indicated) and empiric changes in the antibiotics used to broaden coverage to *B. cepacia*. If fungus is identified or strongly suspected, amphotericin B is the drug of choice. Even when appropriate antibiotics are being used, certain types of infections respond slowly and may require months of therapy, particularly *Aspergillus* infections. In this instance, 46 months of amphotericin B (given first daily for 23 months and then thrice weekly) followed by a 13-year course of daily oral itraconazole has been effective in clearing most infections and preventing their recurrence. It is important to note that surgical drainage or resection can sometimes play a key role in accelerating healing of certain types of infection such as lymphadenitis, osteomyelitis, and abscesses of visceral organs such as the liver. Finally, granulocyte transfusions may be of benefit in the treatment of stubborn or extremely serious infections. [151] [239] [240] [241] [242]

In a multicenter trial, patients were randomized in a double-blind fashion to receive either placebo or rIFN- (0.05 mg/m ^{2} three times per week). [243] The results from this study, summarized in Table 41-8 , show a substantial decrease in the number of serious infections in the interferon arma 70% reduction in risk when compared with the placebo. Side effects were observed in some of the patients, but these were minimal (mild headaches and low-grade fevers). The highly significant clinical improvements were not accompanied by improvements in phagocyte function, as measured by O_2 production or in vitro *S. aureus* killing. A few patients with rare variant forms of X91 CGD have shown modest to dramatic increases in O_2 production. [244] [245] [246] It now appears that interferon- augments host defense in the vast majority of patients by means other than reversing the respiratory burst defect. [247] [248] This interpretation is consistent with the observation that rIFN- was comparably effective in both X-linked and autosomal recessive types of CGD across a broad range of mutations that would preclude the synthesis of a functional oxidase (see previous discussion). Over 30 CGD patients have been treated with rIFN- for 810 years without interruption of their thrice weekly regimen. No additional adverse reactions have been noted, and the patients continue to have a substantial benefit with approximately five-fold fewer serious infections compared to the placebo group in the phase III multicenter study (Table 41-8). On average, this group of patients is averaging one serious infection per patient every 45 years.

Neutrophil G6PD Deficiency

The primary substrate for the respiratory burst oxidase, NADPH, is generated by the first two reactions of the hexose monophosphate shunt pathway, for which the responsible enzymes are G6PD (Fig. 41-1 , reaction 8) and 6-phosphogluconate dehydrogenase. [20] [27] [249] As would be expected, a severe deficiency of G6PD in neutrophils results in a greatly attenuated respiratory burst and a clinical picture that can resemble CGD. [20] [250] [251] [252] [253] [254] [255] The key features of this extremely rare X-linked disorder are summarized in Table 41-9 . In light of the relatively high frequency of G6PD mutations in the American black and Mediterranean populations, [27] [249] as well as the fact that leukocyte and erythrocyte G6PD are encoded by the same gene, [249] it might be expected that clinically significant neutrophil G6PD deficiency would occur more often than it does. One of the reasons it does not is the short life span of the neutrophil. Because most G6PD mutations cause the enzyme to decay over a period of days and weeks, levels in the short-lived neutrophil usually do not become critically low, even in some of the most unstable G6PD variants. It appears that only those rare and poorly understood mutations that cause congenital nonspherocytic hemolytic anemia (CNSHA) are associated with extremely low (<5% of normal)

TABLE 41-8 -- Efficacy of IFN-in Preventing Serious Infections in CGD

Variable	Clinical Study			
	Phase III Placebo[a]	Phase III IFN-[a]	Phase IV (U.S.) IFN-[b]	Phase IV (Europe) IFN-[c]

TABLE 41-9 -- Summary of Neutrophil G6PD Deficiency

Incidence	Extremely rare
Inheritance	X-linked
Molecular defect	Poorly characterized family of mutations that cause congenital nonspherocytic hemolytic anemia (CNSHA) in erythrocytes and functional failure of G6PD in neutrophils (possibly kinetic mutants); other rare mutants may also be responsible
Pathogenesis	Severe functional failure of neutrophil G6PD (<5% of normal), leading to an extremely low steady-state concentration of NADPH, which serves as the substrate for NADPH oxidase
Clinical manifestations	CNSHA (hemolytic anemia that occurs even in the absence of redox stress) CGD-like syndrome with recurrent bacterial infections
Laboratory evaluation	Neutrophil G6PD activity <5% of normal Severely diminished respiratory burst and abnormal NBT test Associated CNSHA and diminished erythrocyte G6PD activity
Differential diagnosis	CGD Glutathione reductase or synthetase deficiency
Therapy	Prophylactic trimethoprim-sulfamethoxazole Aggressive use of parenteral antibiotics Transfusion support for severe anemia

Prognosis	Not clear because data on too few patients have been reported May be as severe as CGD if neutrophil G6PD levels are extremely low

levels of G6PD in the neutrophil. [250] [251] [252] [253] [254] [255] Thus, a CGD-like syndrome due to neutrophil G6PD deficiency has only been observed in patients who also have CNHSA (hemolysis that occurs in the absence of redox stress). This unique clinical association, coupled with the laboratory demonstration of extremely low G6PD levels in neutrophils and erythrocytes, distinguishes this disease from CGD. [250] The treatment for neutrophil G6PD deficiency is the same as for CGD except that the efficacy of rIFN- has not been demonstrated in the former. The chronic hemolytic anemia is treated by supportive means, including transfusions. [249]

Disorders of Glutathione Metabolism

As depicted in Figure 41-1 (reaction 6), glutathione peroxidase serves to protect the neutrophil from the deleterious effects of hydrogen peroxide on NADPH oxidase and other neutrophil proteins such as those found in microtubules. [256] [257] The effectiveness of glutathione peroxidase depends on having adequate amounts of reduced glutathione (GSH). Adequate intracellular levels of GSH are maintained by recycling oxidized glutathione (GSSG) to GSH by glutathione reductase (Fig. 41-1 , reaction 7) as well as by de novo synthesis of glutathione by glutathione synthetase (Fig. 41-1 , reaction 9). Severe deficiencies in either of these enzymes have been observed to cause mild phagocytic defects.[256] [257] [258] The key features of these disorders are outlined in Table 41-10 . Both are extremely rare and appear to be inherited in an autosomal recessive manner. The precise mutations for the individual disorders have not been established. In glutathione reductase deficiency, the respiratory burst terminates prematurely, presumably owing to the toxic effects of accumulating hydrogen peroxide on NADPH oxidase. [29] This brief burst of O_2 , however, appears to be sufficient for adequate microbial killing, because the few patients reported have not had problems with recurrent infections. [258] They do have a congenital hemolytic anemia due to diminished levels of glutathione reductase in erythrocytes, which becomes clinically evident during periods of oxidant stress. [256]

In glutathione synthetase deficiency the respiratory burst proceeds normally. [257] The patients have some problems with recurrent infections and have a severe metabolic acidosis due to elevated levels of 5-oxoproline. This metabolite is the product of the first step in glutathione synthesis and is present in increased levels because of a lack of feedback of GSH on the synthetic pathway. Patients with glutathione synthetase deficiency also have intermittent neutropenia [259] (perhaps caused by the acidosis) as well as oxidant-induced hemolysis. [257] Therapy with vitamin E (400 IU/day) has been beneficial in patients with severe glutathione synthetase deficiency suffering from hemolysis and infections. [259] Patients with less severe deficiencies usually do not require therapy.

Myeloperoxidase Deficiency

Myeloperoxidase (MPO) deficiency is the most common inherited disorder of phagocytes. [260] Complete deficiency is seen in 1/4,000 individuals, and partial deficiency is even more common (1/2,000 persons).[28] [261] The key features of MPO deficiency

TABLE 41-10 -- Disorders of Glutathione Metabolism

Disease Aspect	Glutathione Reductase Deficiency	Glutathione Synthetase Deficiency
Incidence	One family: three siblings	Several reported cases
Inheritance	Autosomal recessive	Autosomal recessive
Molecular defect	Diminished glutathione reductase levels in neutrophils (1015% of normal) and erythrocytes; mutation not known	Severe deficiency of glutathione synthetase activity (510% normal); mutation(s) not known
Pathogenesis	Brief respiratory burst truncated by toxic accumulation of $H_2 O_2$ in neutrophil caused by diminished catabolism of $H_2 O_2$ by glutathione	Same as with glutathione reductase deficiency; elevated 5-oxoproline due to lack of feedback inhibition by glutathione
Clinical manifestations	No history of repeated infection	Metabolic acidosis due to elevated 5-oxoproline
	Hemolysis with oxidant stress	Otitis media
		Intermittent neutropenia
		Hemolysis with oxidant stress
Laboratory evaluation	Glutathione reductase level diminished	Severe decrease in glutathione synthetase level
	Premature cessation of O_2 production by neutrophils	Normal respiratory burst
Differential diagnosis	CGD	Glutathione reductase deficiency
	G6PD deficiency	
Therapy	None required	Vitamin E for hemolysis and infections
		Treatment of metabolic acidosis
Prognosis	Benign disorder	Relatively benign disorder

are summarized in Table 41-11 . The disorder is inherited in an autosomal recessive [262] [263] [264] [265] [266] manner, although variable expression of the defect has been observed.[267] Acquired forms of MPO deficiency are also seen. The gene that encodes for MPO is located on chromosome 17 at q22q23 near the breakpoint for the 1517 translocation of promyelocytic leukemia. [268] [269] [270] [271] Subpopulations of MPO-deficient cells can be seen not only in the M3 (promyelocytic) form of acute myeloid leukemia but also in the M2 and M4 forms. [28] MPO-deficient cells are also seen in 25% of patients with chronic myeloid leukemia and myelodysplastic syndromes.[272] [273] [274]

A growing understanding of the molecular basis of congenital MPO deficiency has been made possible by the isolation of both cDNA and genomic clones for MPO [13] [28] [275] [276] [277] [278] [279] [280] and gives insights on how MPO gene expression is regulated. [281] [282] In the few patients thus far studied, several different types of genetic lesions have been observed. [283] [284] These generally appear to affect the post-translational processing of a precursor polypeptide for MPO (apoproMPO). [28] [260] [285] [286] One particularly common missense mutation has been identified in MPO deficient patients (Arg 569 Trp) that interferes with the post-translational incorporation of heme into the apoproMPO and results in an enzymatically inactive MPO precursor protein. [13] Other MPO mutations have not yet been reported. Although the levels of MPO are severely deficient in neutrophils and monocytes as a result of these mutations, the level of eosinophil peroxidase is normal in MPO-deficient patients because it is encoded for by a separate gene. [287] (A series of 21 individuals with eosinophil peroxidase deficiency has been reported. [288] As with MPO deficiency, these individuals were asymptomatic.)

One of the most curious features of MPO deficiency is the remarkable lack of clinical symptoms in affected persons. As

TABLE 41-11 -- Summary of MPO Deficiency

Incidence	1/2,000 (partial deficiency) 1/4,000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; MPO gene on chromosome 17 at q22-q23
Molecular defect	Defective post-translational processing of an abnormal MPO precursor polypeptide; eosinophil peroxidase encoded by different gene and levels normal

Pathogenesis	Partial or complete MPO deficiency leads to diminished production of HOCl and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially *Candida*) but not absolutely required
Clinical manifes-tations	Usually clinically silent Disseminated candidiasis/fungal disease (rare; usually in conjunction with diabetes mellitus) Acquired deficiency in M2, M3, and M4 acute myeloid leukemias (AML) and myelodysplasia
Laboratory evaluation	Deficiency of neutrophil/monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal, killing of bacteria in vitro Failure to kill *Candida albicans* and hyphal forms of *Aspergillus fumigatus* in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in M2, M3, and M4 AML, myelodysplastic syndromes, and Batten disease
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetics
Prognosis	Usually excellent

shown in Figure 41-1 (reaction 4), MPO catalyzes a key reactionthe production of a potent antimicrobial agent, hypochlorous acid. [20] [289] HOCl in turn reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic. Moreover, HOCl is capable of activating latent metalloproteinases (e.g., collagenase) and inactivating antiproteinases. [20] [28] [260] Thus, one might predict that severe MPO deficiency would cripple important antimicrobial reactions catalyzed by HOCl. In vitro, an impressive defect in killing *C. albicans* and hyphal forms of *A. fumigatus* is observed.[260] [261] [265] Bacterial killing in vitro is also abnormal in being somewhat slower than normal, but eventually it is complete. [261] [262] [263] [264] [265] [267] [291] These in vitro abnormalities, however, are rarely manifested in patients, except for rare individuals who also suffer from diabetes mellitus. [261] [262] [265] In these individuals disseminated fungal infections (usually candidiasis) are seen.

The discrepancy between the in vitro and in vivo manifestations of MPO deficiency in most patients can be explained in several ways. First, the respiratory burst in MPO-deficient neutrophils is substantially augmented in terms of velocity and duration, presumably owing to the absence of the toxic effects of HOCl on NADPH oxidase.[260] Second, other products of the respiratory burst besides HOCl, together with the oxygen-independent antibacterial proteins, appear to have sufficient potency to compensate for the loss of MPO-dependent reactions. [28] Finally, residual amounts of MPO coupled with the normal levels of eosinophil peroxidase may provide at least some degree of peroxidative activity at the sites of infection.

Treatment is usually not required for MPO deficiency except in those individuals suffering from fungal infections. In these patients aggressive use of antifungal antibiotics is indicated. The prognosis is excellent in the majority of patients with MPO deficiency.

DISORDERS OF PHAGOCYTE ADHESION AND CHEMOTAXIS

Since 1970, numerous investigators have found in vitro chemotactic abnormalities in neutrophils from patients suffering from a wide variety of clinical disorders associated with increased susceptibility to bacterial and fungal infections. [6] [8] [292] In most circumstances the chemotactic abnormality identified was only marginal and not always clearly related to the clinical status of the patient. In other instances, however, clear and major defects were identified in vitro that correlated with the in vivo propensity for infection. Extensive classification systems have been devised to categorize the numerous acquired defects in chemotaxis, [6] and several reviews are available on this subject. [6] [292] [293] [294] The problem in many of these reports is that it is unclear whether the infections were caused by the in vitro chemotactic abnormality or by the multiple medical complications of the underlying disorder (e.g., acidosis, malnutrition, or exposure to nosocomial infections). A further complicating factor is that the in vitro chemotaxis assays have inherent limitations. Abnormal migration of purified neutrophils through filter disks in response to in vitro-generated chemotactic gradients is difficult to quantify and is subject to laboratory artifacts. Furthermore, the extent to which these in vitro chemotactic assay systems faithfully reflect prevailing in vivo conditions is not known. Understanding of chemotactic disorders has been hampered by the limitations of these assays, just as the elucidation of respiratory burst defects was obscured when the major available assay was in vitro bacterial killing. In this section the most important and best characterized of the chemotactic disorders, leukocyte adhesion deficiency, is discussed in detail. A brief discussion of several other clinically significant chemotactic disorders is also provided.

Leukocyte Adhesion Deficiency

Biology

Leukocyte adhesion deficiency (LAD) is a relatively rare disorder of leukocyte adhesion and chemotaxis, which results in severe and sometimes fatal bacterial infections. [292] [295] [296] [297] Approximately 20 patients were described in the literature in the 1970s who, in retrospect, probably had LAD and shared the clinical phenotype of recurrent infections, decreased neutrophil motility, and abnormal particle-stimulated respiratory burst activity. [295] Many also had persistent leukocytosis and delayed umbilical cord separation.

The molecular basis for LAD was first suggested by the finding that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein. [298] The molecular weight was originally thought to be 110,000 but was subsequently found to be 180,000. The variability was likely due to the highly variable electrophoretic mobility of glycoproteins. The patients neutrophils could not be made to adhere to plastic surfaces or to respond to serum-opsonized particles in terms of ingestion and respiratory burst activity. [298] It was hypothesized that the missing glycoprotein was responsible for cell-surface adhesion and for cell-particle interactions. Several other reports followed that described other patients in whom a similar glycoprotein was missing. [299] [300] It was later found that the missing glycoprotein was actually a group of closely related glycoproteins with molecular weights ranging from 95 kd (the $_2$ subunit) to 150180 kd (three distinct subunits) that form three types of - heterodimers. The dominant heterodimer in phagocytes was designated Mo1, [301] [302] which functions as the C3bi receptor (CR3) of human neutrophils and monocytes. [302] [303] [304] [305] [306]

The molecular basis of LAD has now been proven to involve this group of three leukocyte glycoproteins, which are part of the integrin superfamily of adhesion molecules. [302] [305] [306] [307] [308] [309] [310] [311] [312] [313] Integrins are noncovalently linked heterodimeric glycoproteins consisting of an and a subunit. [296] Within each of the eight known integrin subfamilies the subunit is identical (and defines the subfamily), whereas the subunit varies and confers the functional specificity on the integrin. [296] [308] [309] A total of 22 distinct integrin subunits have been defined (14 and 8 chains) that give rise to 20 different integrins that function as mediators of adhesion (cell-cell and cell-extracellular matrix) and receptors for C3bi and a group of coagulation factors (factor X, fibrinogen, and von Willebrand factor). The molecular defect in LAD involves all three members of the $_2$ integrin subfamily: $_{L\,2}$ (CD11a/CD18), $_{m\,2}$ (CD11b/CD18), and $_{x\,2}$ (CD11c/CD18). [296] [302] [305] [306] The molecular weights of these subunits are $_L$ 180,000; $_m$ 170,000; $_x$ 150,000; and $_2$, 95,000. CD11a/CD18 is often referred to as LFA-1 while CD11b/CD18 is called Mo1 or Mac-1. In the dozens of patients with LAD who have been studied thus far at the molecular level, an absent, diminished, or structurally abnormal $_2$ subunit (CD18) has been identified. In the absence of a normal subunit, the three types of chains in the $_2$ integrin subfamily cannot assemble into normal - heterodimers. Thus, all three $_2$ integrins are moderately to severely deficient on all leukocytes in LAD. The $_2$ integrins serve as receptors for the opsonic complement fragment C3bi, the intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2), and fibrinogen. [296]

In all of the patients with LAD reported to date who have been analyzed at the molecular level, mutations have been identified in the gene encoding the $_2$ (CD18) subunit. Mutations in the subunits have not been found thus far in patients with LAD. The gene encoding CD18 is located on the long arm of chromosome 21 at position q22.3 (the genes for $_2$ integrin subunits are clustered on chromosome 16p11.1p13). [314] [315] [316] [317] [318] [319] [320] [321] CD18 is synthesized as a 747 amino acid polypeptide with a 22 amino acid signal sequence that is subsequently cleaved. The glycoprotein has a single transmembrane domain with a 46 residue cytoplasmic tail. Near the N-terminus of the large extracellular domain is a stretch of 250 conserved amino acids, and it is in this region that the majority of LAD mutations are found. [296] [314] [322] [323] [324] [325] [326] [327] [328] [329] Table 41-12 summarizes the CD18 mutations found in LAD. As with X-linked CGD, LAD mutations are heterogeneous in nature, family specific, and can lead to either undetectable or low (920% of normal) levels of - dimer expression that correlates with the clinical severity of the disease. Among the 12 different mutant alleles identified, there are 8 missense mutations, 2 splice defects, 1 interstitial deletion of 230 bp (patient 19), and 1 frameshift due to

a single bp deletion (patient 18) (Table 41-12).

An example of a mutation leading to low levels of CD18 expression and a moderate clinical phenotype is patient 14. Two different missense mutations are present, one in the conserved region of the domain (Lys 196Thr) and the other in an extracellular cysteine-rich area (Arg 593Cys). [327] It is not clear which allele permits the expression of 1020% normal levels of the $_2$ integrins (or whether both do). A similar moderate phenotype is seen in the three related patients 811 in Table 41-12 . These patients have a third-position mutation in a 5 splice site (gtgagtca) that results in aberrant splicing in 97% of the mRNA with the in-frame loss of 90 nucleotides. [323] [324] [325] The $_2$ subunit precursor translated from this defective mRNA was abnormally small and apparently unable to associate normally with the subunit precursors. Roughly 3% of the CD18 mRNA, however, was found to be normally spliced and was probably responsible for the low level of - dimer expression in the patients leukocytes and moderate phenotype. Severe LAD, with undetectable $_2$ integrins, is seen in patient 18. The one mutant allele identified has a frameshift due to a single nucleotide deletion that predicts a premature stop codon and the loss of the last 56 amino acids that encompass the entire cytoplasmic domain and part of the transmembrane region. [328] This mutation fails to permit the synthesis of - dimers. The other mutant allele must also have a severe mutation.

The diminished or absent expression of all three $_2$ integrins in LAD leukocytes results in the failure of phagocytes to emigrate from the bloodstream to sites of infection. [311] The early stages of phagocyte-endothelial cell interactions, termed rolling, is mediated by selectins [330] and occurs normally in LAD. [311] It is the tight adherence of neutrophils and monocytes to cytokine-activated endothelium that is severely defective in LAD because these interactions are mediated by the $_2$ integrins. Transendothelial migration is also impaired. The other major functional defect in LAD is the failure of phagocytes to bind C3bi opsonized microbes. Because CD11b/CD18 is the predominant C3bi receptor for the neutrophil, those phagocytic functions dependent on this opsonin receptor (i.e., C3bi-mediated ingestion, degranulation, and respiratory burst activity) are severely affected in LAD. [295] [296] [297] Thus, LAD neutrophils are not able to efficiently ingest and kill microbes opsonized with C3bi, a defect that contributes to the propensity of these patients to become infected. Despite the absence of CD11a/CD18, patients with LAD rarely have clinical manifestations of impaired lymphocyte function. [292] [296] It is now possible that the role CD11a/CD18 plays in lymphoid cell function can be compensated, at least in part, by other adhesion proteins (CD2, CD4, CD8, etc.) and costimulatory molecules. [296]

Clinical Features

The key features of LAD are summarized in Table 41-13 . Approximately 60 patients have been described in the literature to date. [296] The mode of inheritance is autosomal recessive, consistent with the location of the CD18 gene on chromosome 21. [296] [297] The clinical presentation of LAD is heterogeneous and is related to the severity of the deficiency of the $_2$ integrins. The severe

TABLE 41-12 -- $_2$ Subunit (CD18) Mutations in LAD

[b] Predicated from nucleotide change.

clinical phenotype is associated with <0.3% of the normal amount of these glycoproteins on the leukocyte surface, while the moderate phenotype has 2.56% of normal levels. [292] [297] In both the severe and moderate forms of the disease, persistent granulocytosis (neutrophil count of 12,000100,000/mm ^{3}) is a constant finding, as are recurrent cutaneous abscesses and periodontal infections or gingivitis. [292] [295] [296] [297] Additional clinical features seen more often in the severe clinical phenotype include delayed umbilical cord separation, perirectal cellulitis, severe ulcerative stomatitis, and bacterial sepsis. Because neutrophils are unable to emigrate to tissues, abscesses and other sites of infections are devoid of pus despite the marked neutrophilia.

Diagnosis

The diagnosis of LAD is made by flow cytometric measurement of surface CD11b (or CD18) in unstimulated and stimulated neutrophils using monoclonal antibodies

directed against CD11b.[292] [295] Neutrophils contain an intracellular pool of CD11b/ CD18 in their secondary (specific) and tertiary granules that can be mobilized to the cell surface during stimulation.[296] [331] [332] Therefore, the deficiency of CD11b can be more dramatically demonstrated by using stimulated neutrophils. Carriers of LAD can be identified by this method because they have been found to express 50% of normal levels of CD11b on the surface of their stimulated neutrophils. [297] [331]

Therapy

Treatment for LAD depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, cutaneous and oral infections can be managed as they occur. The use of prophylactic antibiotics such as trimethoprim-sulfamethoxazole appears to be beneficial, as does aggressive prophylactic

TABLE 41-13 -- Summary of LAD

Incidence	60 patients described in literature
Inheritance	Autosomal recessive
Molecular defect	An absent, diminished, or structurally abnormal subunit (CD18) caused by one of several types of mutations in the gene; in the absence of a normal subunit, the three types of chains in the $_2$ integrin subfamily (CD11a, b, c) cannot assemble into normal - heterodimers
Pathogenesis	All three $_2$ integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18) are deficient on all leukocytes causing multiple abnormalities in cell function: adherence, chemotaxis, and C3bi-mediated ingestion/degranulation/ respiratory burst
Clinical manifestation	Persistent granulocytosis (neutrophil count of 12,000100,000/mm^3) Severe or moderate phenotypes depending on severity of deficiency Recurrent pyogenic infections with absent neutrophil infiltration Delayed umbilical cord separation Severe gingivitis/periodontitis
Laboratory evaluation	Flow cytometric measurement of surface CD11b in stimulated neutrophils with monoclonal anti-CD11b
Differential diagnosis	CGD May be associated with severe neutrophil actin dysfunction
Therapy	Bone marrow transplant in clinically severe patients (CD11b < 0.3% of normal) Aggressive use of parenteral antibiotics Possible benefit of prophylactic trimethoprim/sulfamethoxazole
Prognosis	Severe: high incidence of death before 2 years Moderate: can survive into twenties and thirties but with recurrent infections

treatment of periodontal disease. It is important to note that even patients with the moderate phenotype can die of overwhelming infection, as evidenced in several recent reviews, and by the absence of any known patients over the age of 40.[292] [295] [296] [297] In patients with severe LAD, aggressive management is indicated because of the high incidence of death before the age of 2 years.[292] [295] [296] At present, bone marrow transplantation is recommended for these patients and has been reported to be successful in several cases.[295] [323] [333] [334] In theory, LAD should be amenable to gene replacement therapy. The technical feasibility of this approach has now been demonstrated by several groups using Epstein-Barr virus (EBV)-transformed lymphocyte lines from LAD patients.[335] [336]

Actin Polymerization Defect Associated with LAD

A subset of patients with severe LAD may suffer from an additional biochemical abnormality characterized by defective neutrophil actin polymerization. [337] An infant boy who suffered from extremely severe infections associated with profound defects in neutrophil chemotaxis/ingestion was described in 1974. [338] The underlying defect appeared to reside in the neutrophil actin because it failed to polymerize normally in vitro in response to 0.6 M KCl. This index patient was subsequently diagnosed as having LAD on the basis of intermediate levels of CD11b found in neutrophils from surviving family members. LAD is not generally associated with defective actin filament assembly.[337] In rare patients with LAD, however, actin polymerization is abnormal and presumably reflects a functional link between the cell surface integrins and the cytoskeleton. Evidence indicates that the cytoplasmic domains of the integrin and chains associate with cytoskeletal proteins such as talin, vinculin, and -actinin.[309] [339] [340] Given the heterogeneity of the mutations in LAD (Table 41-12), it is possible that only certain types of mutations lead to an associated defect in actin function.

LAD Caused by a Deficiency in Sialyl-Lewis X (LADII)

A clinical syndrome closely related to LAD, but caused by a defect in selectin-mediated adhesion events, has been reported in two unrelated boys of Moslem Arab origin and has been termed LADII.[341] The disease appears to be inherited in an autosomal recessive manner because both patients were products of consanguinous matings. The patients had marked neutrophilia, recurrent bacterial infections, and periodontitis like LAD patients, yet their neutrophils expressed normal levels of CD18. A clue as to the molecular cause of LADII came from the observation that the patients had the rare Bombay (hh) erythrocyte phenotype and were negative for the Lewis antigen as well. These antigenic defects share in common the failure to form certain fucose carbohydrate linkages, raising the possibility that the patients had a generalized defect in fucose metabolism leading to not only the erythrocyte defects, but also a failure to synthesize critical Sialyl-Lewis X moieties on E-selectin and P-selectin counterreceptors on neutrophils. As predicted, neutrophils from both boys were devoid of immunoreactive Sialyl-Lewis X structures and were unable to adhere to human umbilical cord endothelial cells activated with interleukin (IL)-1 to induce E-selectin expression. The precise defect in fucose metabolism is still under investigation.

Hyperimmunoglobulin E Syndrome

Biology

The hyperimmunoglobulin E (hyper-IgE) syndrome is a complex disorder characterized by markedly elevated serum IgE levels, serious recurrent infections, and chronic dermatitis.[342] [343] [344] [345] [346] [347] Although technically not a phagocyte defect, neutrophils from patients with this syndrome exhibit a variable and at times profound chemotactic defect.[342] [343] [344] [348] [349] [350] The hyper-IgE syndrome was first described in 1966 and was called Jobs syndrome, in reference to the biblical description of Job as being afflicted with sore boils from the soles of his feet unto his crown. [343] The skin abscesses in patients with hyper-IgE syndrome lack the erythema that is typical of such lesions and are referred to as cold abscesses. The key features of the hyper-IgE syndrome are described in Table 41-14 .

The disease is extremely rare and its mode of inheritance has not been firmly established, although familial occurrence has been noted. [342] [344] [346] Both males and females have been affected, which suggests autosomal inheritance. The molecular basis for the syndrome is not known. The extremely high serum IgE level is believed to reflect a T-lymphocyte imbalance, leading to abnormal regulation of IgE production, as well as decreased production of IFN- and tumor necrosis factor. [342] [347] [351] [352] [353] Further evidence for a more broad-based immune disorder is the finding that patients with hyper-IgE mount abnormal antibody responses to vaccines.[354] The recurrent bacterial infections are thought to arise by two mechanisms: (1) excessive production of IgE directed against *S. aureus* that occurs at the expense of protective antistaphylococcal IgG,[355] and (2) a variable neutrophil chemotactic defect that occurs independently of fluctuations in the serum IgE level. [342] [356] [357] The underlying T-cell defect may be responsible for this chemotactic defect because it may

TABLE 41-14 -- Summary of Hyper-IgE Syndrome

Incidence	Approximately 50 cases have been reviewed in the literature; single institution series of 6, 13, and 23 cases have been described
Inheritance	Autosomal (? dominant) with incomplete penetrance
Molecular defect	Unknown; putative T-lymphocyte defect, in part manifested by diminished production of interferon-, which affects regulation of IgE production as well as other immune functions
Pathogenesis	The following may contribute to the increased risk of infection: high levels of antistaphylococcal IgE and low levels of antistaphylococcal IgG; fluctuating neutrophil chemotactic defect possibly due to an inhibitor from mononuclear cells; poor antibody response in some patients
Clinical manifestations	Staphylococcal pneumonia Pneumatoceles Fungal superinfection of lung cysts Cold cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Coarse facies, growth retardation, osteopenia Sinusitis, keratoconjunctivitis
Laboratory evaluation	Serum IgE >2,500 IU/ml Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis Wiskott-Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic anti-*S. aureus* antibiotics Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Plasmapheresis in severe cases (experimental) IFN- (experimental)
Prognosis	Generally good if managed aggressively Some patients develop lymphoid malignancies

cause the release of chemotactic inhibitors from mononuclear cells. [342]

Clinical Manifestations

The onset of clinical manifestations in patients with the hyper-IgE syndrome is generally in the first 2 months of life and is manifested by chronic dermatitis. [342] By 5 years of age, patients have a history of recurrent skin abscesses, pneumonias, chronic otitis media, and sinusitis. As patients grow older, recurrent staphylococcal pneumonia is a common problem and can be complicated by the formation of pneumatoceles. [358] [359] Septic arthritis, cellulitis, and osteomyelitis are also observed, with the offending microbe usually being *S. aureus*, although other bacterial pathogens have also been found. Patients can have chronic mucocutaneous candidiasis and occasionally exhibit keratoconjunctivitis, sometimes complicated by corneal scarring. Osteopenia of unknown etiology is observed in most patients and results in increased risk of fractures to the long bones and vertebral bodies. [346] One feature noted in the majority of patients is the presence of coarse facial features (broad nasal bridge, prominent nose).

Diagnosis

The diagnosis of hyper-IgE syndrome should be entertained in any child or young adult who has the above-described clinical picture or simply a history of recurrent infections. The hallmark laboratory finding is a marked elevation of serum IgE, almost always >2,500 IU/ml. [342] Levels can be as high as 150,000 IU/ml. [342] Despite the impressive elevations in serum IgE seen in the syndrome, this laboratory finding alone is not diagnostic because comparably high serum levels of IgE can be seen in patients with atopic dermatitis. [342] Because many patients with this latter disorder are also afflicted with eczema and superficial skin infections, atopic dermatitis must be considered in the differential diagnosis of hyper-IgE syndrome. The two can be distinguished because of the severe and recurrent nature of the staphylococcal furuncles and pneumonias seen in hyperIgE syndrome. Patients with other primary immunodeficiency syndromes may also manifest elevated IgE levels [342] (Table 41-14).

Therapy

The therapy for hyper-IgE syndrome is largely supportive because there is no known curative treatment. Prophylactic antibiotics (e.g., dicloxacillin or trimethoprim-sulfamethoxazole) can be effective in preventing *S. aureus* infections. [342] Dermatitis can be treated with topical steroids. Intravenous antibiotics are used for deep-seated infections or for resistant cutaneous infections. Surgical resection of persistent pneumatoceles is sometimes indicated to prevent superinfection by fungal and gram-negative organisms. Plasmapheresis has been reported to be effective in treating patients who have not responded to the above-mentioned therapies. [342]

Treatment of hyper-IgE syndrome with recombinant human IFN- has been investigated based on the observations that this cytokine can suppress the synthesis of IgE [360] [361] and that IFN- production in this disease is diminished. [351] [352] In uncontrolled studies, patients treated with rIFN- (50 g/m^2 subcutaneously thrice weekly) report that they feel better; moreover, their neutrophils exhibit improved in vitro chemotaxis [362] [363] and occasionally their serum IgE levels decrease. [364] In light of the results observed with rIFN- in CGD discussed above, there may be a role for IFN- in preventing infections in hyper-IgE syndrome.

Miscellaneous Chemotactic Disorders

One of the most consistently observed chemotactic abnormalities is seen in neonatal neutrophils. [292] [293] [363] [365] [366] [367] [368] [369] These cells exhibit impaired chemotaxis in vitro in response to a wide variety of chemotactic factors. [292] It appears as though this abnormality is due, at least in part, to defects in cellular adhesion as a result of diminished mobilization of intracellular adhesion-promoting molecules to the cell surface. [6] [365] [370] Defective neutrophil chemotaxis can be seen in normal neonates between birth and 5 days of age. [292] In severely ill infants, the defect may persist for a longer time. As with hyper-IgE syndrome, rIFN- may be helpful because this cytokine has been found to increase the chemotactic activity of neonate neutrophils in vitro. [363] [367]

Localized juvenile periodontitis (LJP) is a heterogeneous disorder of unknown etiology characterized by chronic and recurrent periodontal infections and severe alveolar bone loss with onset at the time of puberty. Nearly 75% of patients with LJP have been reported to have defective neutrophil chemotaxis in vitro. [292] [371] [372] [373] [374] [375] [376] [377] [378] [379] The molecular basis for the chemotactic defect is poorly understood. A number of reports suggest that cellular products derived from certain periodontal bacteria can alter leukocyte function and may be responsible for the diminished chemotactic activity. [380] [381] These inhibitors cannot entirely explain the disorder, however, because neutrophils from patients with LJP exhibit abnormal chemotaxis in vitro even in the presence

of normal serum. [292] [372] [373] [375] [376] At present it appears that LJP is an acquired disorder in some patients and a genetic disorder in others. It may also be a combination of both in certain patients because they may inherit an unusual sensitivity to the chemotactic inhibitors released by certain periodontal microorganisms. The diagnosis of the disorder is made on the basis of severe periodontal disease and destructive alveolar bone loss involving the first molars and incisors developing during adolescence. It is important to note that many qualitative and quantitative neutrophil disorders are also associated with severe periodontal disease. [292] [382] Therefore, the differential diagnosis should include neutropenia (both chronic and cyclic), LAD, CGD, and Chediak-Higashi syndrome (CHS).

DEFECTS IN THE STRUCTURE AND FUNCTION OF LYSOSOMAL GRANULES

Two major disorders of neutrophil granules have been described: Chediak-Higashi syndrome and specific granule deficiency (SGD). A great deal has been learned about the structural and functional abnormalities of neutrophils from patients with these conditions. Both disorders are exceedingly rare but are obligatory components in the differential diagnosis for any patient with recurrent bacterial or fungal infections.

CHS

Biology

Chediak-Higashi syndrome is a rare autosomal recessive, multisystem disease characterized by partial oculocutaneous albinism, frequent (and sometimes fatal) bacterial infections, giant lysosomes in leukocytes, a mild bleeding diathesis, progressive peripheral neuropathies, and cranial nerve abnormalities associated with defects at the optic chiasm.[6] [383] [384] [385] [386] [387] [388] [389] [390] Over 85% of those who survive the recurrent infections develop an accelerated phase of the diseasea progressive lymphoproliferative syndrome that usually occurs during the first two decades of life and is eventually fatal due to a profound pancytopenia that develops.[6] [385] Those patients who survive into their teenage years also suffer from the worsening of their peripheral neuropathies. The abnormal granules in neutrophils, monocytes, and macrophages compromise the function of these leukocytes, thereby leading to the consideration of CHS as a phagocyte disorder.

The diffuse symptoms of CHS are due in large part to the widespread presence of abnormal granules in numerous cell types in the CHS patient. In addition to the lysosomal defects seen in the phagocytes, giant granules are seen in melanocytes, Schwann cells, platelets, and certain cells in the liver, kidney, spleen, pancreas, and adrenal gland.[387] [388] The oculocutaneous albinism with light sensitivity characteristic of CHS is caused by grossly abnormal pigment distribution in melanocytes due to the giant melanosomes.[385] The melanocyte defect is also reponsible for the grayish silver sheen and lighter than expected color in the hair of CHS patients as the abnormal melanosomes poorly transfer their pigment to hair follicle keratinocytes. [388] Platelets in this disorder have a storage pool deficiency of adenine diphosphate and serotonin, presumably due to the abnormal granule morphogenesis in the megakaryocytes, leading to a defect in platelet aggregation that manifests itself as easy bruising and epistaxis. [391] [392] [393] [394]

Some of the most dramatic structural and functional lysosomal defects are seen in the phagocytes and contribute substantially to the increased susceptibility of patients with CHS to bacterial infections. Neutrophils contain a highly inhomogeneous population of giant granules that appear to be derived from the coalescence of both azurophilic and specific granules. [395] [396] [397] [398] [399] The giant granules are often more prominent in the bone marrow than in the peripheral blood because many of the abnormal myeloid precursors are apparently destroyed before they leave the marrow, resulting in moderate neutropenia with absolute neutrophil counts ranging between 500 and 2,000 cell/mm^3 . [385] [400] This neutropenia contributes to the propensity of patients with CHS to develop infections, particularly during the accelerated phase. Making matters worse, the neutrophil granules are markedly deficient in the antimicrobial protein, cathepsin G, as well as elastase. [146] Inhibitors of cathepsin G and elastase are present in mature CHS neutrophils (but not normal neutrophils) and may play a role in this deficiency. [401] Phagocyte function is also impaired. Not surprisingly, degranulation is delayed and incomplete in CHS neutrophils, resulting in diminished rates of bacterial killing. [402] [403] [404] [405] Chemotaxis is also defective, perhaps owing to the presence of the giant granules that interfere with the ability of the phagocyte to travel through narrow passages (e.g., between endothelial cells).[384] [406] Monocytes and macrophages exhibit similar giant cytoplasmic granules, [396] with resultant abnormalities in their phagocytic functions. [383]

Other key cells in the immune system are also affected in CHS. Giant granules are seen in lymphocytes and are associated with diminished antibody-dependent cell-mediated cytolysis of tumor cells.[407] [408] [409] More recent studies reveal a marked defect in the ability of CHS CD8+ cytotoxic T lymphocytes to destroy target cells recognized via the T-cell receptor. [410] The CHS cells contain normal levels of the lytic proteins granzyme A, granzyme B, and perforin properly compartmentalized within the appropriate, though abnormally large, lytic granules. The killing defect is due to the failure of the T cells to secrete these cytotoxic proteins onto the target cells.[410] Natural killer cell function is also profoundly abnormal in CHS and may contribute to the development of the accelerated phase of the disease. [407] [411] [412] [413] Epidermal Langerhans cells in a CHS patient have also been reported to have giant cytoplasmic granules; it is not known whether antigen presentation is adversely affected.[414] Eosinophils contain enlarged crystalloid granules, although the functional significance of this defect is not known. [415]

Molecular Genetics

The presence of dysmorphic granules in multiple tissues suggests an underlying global defect in granule morphogenesis. [292] [385] [386] [387] [398] [399] [416] [417] [418] [419] [420] The search for the molecular defect in CHS has been confounded by the rarity of the syndrome in humans (only several hundred cases identified) but has been greatly aided by the presence of a homologous disorder in a broad range of animals (Aleutian mink, blue foxes, killer whales, cats, Hereford cattle, beige rats, and beige mice).[386] [390] [419] [421] It appears that the same gene product is defective in at least humans, beige mice, and mink because fibroblast complementation studies have revealed that normal fibroblasts from any of these three species can restore normal lysosome size and distribution when fused with any of the three types of Chediak fibroblasts; complementation was not observed in any of the cross-species Chediak-Chediak fusion pairs. [422] The gene locus for the granule defect in beige mice has been mapped to the proximal end of mouse chromosome 13.[423] Through the use of yeast artificial chromosome complementation techniques, the gene responsible for the murine beige phenotype, termed Lyst, has been cloned and has been found to encode a lysomal trafficking regulator protein. [424] [425] The distal region of mouse chromosome 13 containing Lyst is highly homologous to the human chromosome 1q42q44. [426] [427] With the aid of this information, the gene responsible for human CHS (termed CHS1) was cloned and mapped to this region, consistent with the observed autosomal recessive inheritance of this disorder. [425] [428] [429] The human CHS protein is highly homologous to the mouse lysosomal trafficking regulation protein: it is a 3801 amino acid polypeptide encoded by a 13.5 kb mRNA. [430] [431] An alternatively spliced mRNA

TABLE 41-15 -- Summary of CHS1 Mutations in Eight Kindreds with CHS

Kindred; Sex	Type of Mutation	Nucleotide Change[a]	Predicted Amino Acid Change	Comments	References
1. M	Deletion	Delete G1467	Premature stop at codon 566	Homozygous	[428]
2. M	Nonsense	C3310 T	R1104 Stop	Homozygous; survived into adulthood	[428]
3. F	Insertion	G inserted after G117	Premature stop at codon 63	Compound heterozygote; mutation on second allele not known	[425] [428]
4. M	Insertion	A inserted in cluster of six adenines (18971902)	Premature stop at codon 638	Homozygous; parents consanguineous and of Kuwaiti Bedouin origin	[431]
5. M	Deletion	A9590 deleted	Premature stop at codon 3258	Homozygous; parents consanguineous and of Turkish origin	[431]
6.	Nonsense	C148 T	R50 Stop	Compound heterozygote; mutation on second allele not known	[432]
7.	Nonsense	C3085 T	Q1029 Stop	Compound heterozygote; mutation on second allele not known	[432]
8.	Deletion	A3073 and A3074 deleted	Premature stop codon	Compound heterozygote; mutation on second allele not known	[432]

[a]Nucleotide residues are numbered from the ATG initiation codon with A defined as +1.

isoform of 5.8 kb has also been identified, the biologic significance of which is still under investigation. [432]

The molecular genetic defects in several patients with CHS have been identified (Table 41-15). One patient was found to be homozygous for a frameshift mutation caused by the deletion of A9590.[431] Similarly, another was found to have a single-base insertional mutation at the other end of the gene leading to a frameshift and premature stop codon after amino acid 62.[425] A third patient in another report had a dinucleotide deletion (nucleotides 3073 and 3074) leading to a frameshift defect.[432] In the same report, two patients with nonsense mutations were also characterized: each had a C T transition leading to R50 stop in one patient and Q1029 stop in the other.

Clinical Manifestations

The key features of CHS are summarized in Table 41-16 . The disease is usually manifested in infancy or early childhood, with infections involving the lungs, skin, and mucous membranes being most commonly encountered.[385] The most frequent offending organism is *S. aureus*.[383] Gram-negative bacteria, *Aspergillus* species, and *Candida* species also are responsible for many

CLINICAL APPROACH TO PATIENTS WITH DISORDERS OF PHAGOCYTE FUNCTION

All the disorders of granulocyte function discussed in this chapter present with recurrent bacterial and fungal infections. The major diagnostic problem faced by the clinician is that patients with recurrent bacterial and fungal infections seldom have an identifiable granulocyte or monocyte defect. Given this low yield and the relative unavailability of laboratories capable of evaluating phagocyte defects, the physician is faced with the difficult question of deciding which patients with recurrent infections merit a complete evaluation. An excellent discussion of this problem has been published by Johnston [9] and by Holland and Gallin.[16] Guidelines are not well defined, and the following comments should be viewed as suggestions.

Our approach is to consider four aspects of each patients infection history: frequency, severity, location, and responsible pathogen. When considering frequency, the patients age and associated medical conditions must be taken into account. For example, recurrent otitis media in a 2-year-old is far less worrisome than a similar history in a 40-year-old. Another recommendation is that the more unusual the infection, the less frequently it has to occur before a phagocyte evaluation is indicated. Similarly, as few as two or three infections of unusual severity might warrant an evaluation. Infections in unexpected anatomic locations should also alert the clinician to a possible underlying immune disorder. Hepatic, pulmonary, and rectal abscesses, as well as disseminated candidal infections, may be indicative of an underlying phagocyte defect. Finally, the identification of certain pathogens (e.g., *S. marcescens, Aspergillus* species, *Nocardia* species, and *P. cepacia*) in children and young adults can provide the strongest indications for pursuing further studies. Certain unusual clinical findings can also be helpful in determining which patients warrant further testing. For example, an infant with a history of delayed separation of the umbilical cord who has also had several bouts of pneumonia should be evaluated for leukocyte adhesion deficiency (LAD), and a child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for CHS.

Once the physician has decided that a phagocyte evaluation is warranted, what is the appropriate sequence of tests to perform? The following algorithm is useful for approaching patients with recurrent infections regardless of the immune defect responsible. The algorithm should be used in conjunction with the published literature relevant to these disorders, and each laboratory finding must always be interpreted in the clinical context of the patient under examination.*

TABLE 41-16 -- Summary of CHS

Incidence	200 cases described
Inheritance	Autosomal recessive
Molecular defect	A defect in granule morphogenesis in multiple tissues resulting from mutations in the CHS1 gene encoding a lysomal trafficking regulator protein
Pathogenesis	Giant coalesced azurophil/specific granules in neutrophils resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually *S. aureus*) Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss) Hepatosplenomegaly and complications of pancytopenia in the accelerated phase
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in bone marrow myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Differential diagnosis	Other genetic forms of partial albinism Giant granules can be seen in acute and chronic myelogenous leukemias
Therapy	Prophylactic trimethoprim/sulfamethoxazole Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) Bone marrow transplant at beginning of accelerated phase
Prognosis	Most patients die from infection or complications of the accelerated phase during the first or second decade of life. A few patients have survived into their thirties.

infections. Patients who survive into their teenage years and beyond must contend with progressive peripheral neuropathies that can lead to a bed-ridden state. Approximately 85% of CHS patients will develop an accelerated phase of the disease in which lymphohistiocytic proliferation occurs in the liver, spleen, lymph nodes, and bone marrow.[416] This phase of the disease is often seen in the second decade of life but can be seen much earlier. Occasionally children with CHS present in the accelerated phase. The cellular infiltration is not neoplastic by histopathologic criteria, although the prognosis is dismal all patients dying unless curative therapy is administered as discussed below. The accelerated phase resembles the virus-associated hemophagocytic syndrome because the invading histiocytes often exhibit hemophagocytosis.[416] The bone marrow infiltration and progressive hepatosplenomegaly eventually lead to pancytopenia and death due to infection and bleeding. The accelerated phase may be precipitated by EBV infection. [433] [434]

Diagnosis

The diagnosis of CHS is made on the basis of the giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes or in bone marrow myeloid cells. This morphologic approach can also be used to diagnose CHS prenatally. [435] [436] The accelerated phase of the disease is characterized by diffuse infiltrates of lymphohistiocytic cells seen on biopsy and by pancytopenia. [416] Occasionally, giant granules that resemble those of CHS can be seen in both acute and chronic

myelogenous leukemias.[437] [438] [439]

Therapy

The treatment for the stable phase of CHS is similar to that for other neutrophil disorders. Prophylactic antibiotics such as trimethoprim-sulfamethoxazole appear to be beneficial. Parenteral antibiotics are indicated for acute infections. Treatment with high-dose ascorbic acid (200 mg/day for infants, 6 g/day for adults) has improved the clinical status of some patients in the stable phase.[440] [441] Although there is some controversy regarding the efficacy of ascorbic acid,[442] given the safety of this medication it seems prudent to administer it to all patients.

The treatment of the accelerated phase is extremely difficult. The lymphohistiocytic infiltrates respond poorly, if at all, to vincristine and corticosteroids.[385] [408] [409] [410] [411] [412] [413] [414] [415] [416] The only curative therapy appears to be bone marrow transplantation,[383] [443] [444] [445] [446] [447] which is ideally performed before or at the beginning of the accelerated phase. A total of six patients with CHS have been reported to have received bone marrow transplants from human leukocyte antigen (HLA)-compatible donors, of whom five were still alive at the time of the reports.[383] There is a possibility that the accelerated phase could be prevented or delayed by vaccines against EBV.[383] The onset of the accelerated phase may be related to the inability of patients with CHS to contain and control this virus.[416] [433] Intravenous -globulin has been used in an attempt to delay the development of the accelerated phase, presumably by protecting the patient from infection with EBV.

SGD

Neutrophil SGD is a rare congenital disorder characterized by recurrent bacterial and fungal infections, primarily involving the skin and lungs.[292] [383] [448] The key features of this disorder are summarized in Table 41-17 . SGD is quite rare, but the six cases that have been reported[448] [449] [450] [451] suggest that it is inherited in an autosomal recessive manner. The precise molecular defect responsible

TABLE 41-17 -- Summary of Neutrophil SGD

Incidence	Six cases reported
Inheritance	Autosomal recessive
Molecular defect	Deficiencies in lysosomal proteins in both azurophil granules (defensins) and specific granules (lactoferrin, vitamin B_{12} -binding protein) suggest a common defect in the regulation of the production of these proteins. The precise defect is unknown.
Pathogenesis	Recurrent infections result from the combined effect of deficiencies in microbicidal granule proteins, such as defensins and lactoferrin, and abnormal chemotaxis, perhaps due to a failure to up-regulate surface $_2$ integrins from specific granule stores
Laboratory evaluation	Absent or empty specific granules in neutrophils by light or electron microscopy Bilobed nuclei in neutrophils frequently seen Severe deficiency of neutrophil lactoferrin, vitamin B_{12} -binding protein, and defensins
Differential diagnosis	Acquired specific granule deficiency (e.g., thermal burns or myeloproliferative syndromes)
Therapy	Prophylactic antibiotics Granulocyte transfusions Parenteral antibiotics for acute infections Surgical drainage of refractory infections
Prognosis	With appropriate medical management, patients can survive into their adult years.

for the disorder has not been identified, but growing evidence suggests that there is an abnormality in the transcriptional regulation of a closely related group of myeloid lysosomal proteins.[383] [452] [453] Neutrophils from patients with this disorder have multiple deficiencies in lysosomal proteins present in both azurophilic granules (defensins)[146] [451] and specific granules (e.g., lactoferrin, vitamin B_{12} -binding protein, neutrophil procollagenase).[451] [452] Not only are the protein levels of these granule constituents deficient, but so are the levels of the corresponding mRNAs, supporting the hypothesis of a transcriptional regulatory defect in the neutrophils.[452] Further supporting this explanation is the observation that lactoferrin secretion was normal in the glandular epithelia of patients with SGD despite its severe deficiency in the neutrophils.[454] Because there is only a single lactoferrin gene that encodes for protein in both myeloid and secretory cells, this finding suggests that there is a myeloid-specific regulatory defect. Interestingly, granule formation also appears to be abnormal in eosinophils from patients with SGD as these cells are deficient in three eosinophil-specific proteinsmajor basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin.[453] Unlike the neutrophil and its precursors, however, the eosinophil contains mRNA transcripts for these granule proteins.

The recurrent skin and pulmonary infections characteristic of SGD appear to be caused by two fundamental defects in the neutrophils. One is the marked deficiency of at least two important microbicidal granule proteins, lactoferrin[450] and defensins.[146] [451] The other defect is a relatively severe chemotactic abnormality presumably caused by the absence of the intracellular pool of leukocyte adhesion molecules that normally reside in the specific granules.[449] [455] [456] [457] As discussed above, these $_2$ integrins play a key role in phagocyte chemotaxis.

The diagnosis of SGD can be readily made by microscopic examination. Wright-stained neutrophils are devoid of specific granules but contain normal numbers of azurophilic granules.[383] Electron microscopy reveals small peroxidase-negative vesicles, which presumably represent empty specific granules.[383] [458] Thus, the ultrastructural findings are consistent with the putative defect in regulation of protein synthesis discussed above. The diagnosis of SGD can also be established by directly demonstrating a severe deficiency in either lactoferrin or vitamin B_{12} -binding protein. An acquired form of SGD can be seen in burn patients[383] or in individuals with various myeloproliferative disorders.[459] The treatment for SGD is similar to that for other neutrophil disorders. If medical management is aggressive, the prognosis appears quite good, with patients surviving into their adult years.

Leukocytosis and Leukopenia

INTRODUCTION

Changes in the number of circulating leukocytes can represent a primary disorder of leukocyte production or a secondary response to some disease process or toxin. Leukocytosis or leukopenia should be defined based on age- and population-based means of neutrophils, lymphocytes, monocytes, or eosinophils. The distribution of leukocytes, or differential, undergoes specific developmental changes and genetic differences as well as changes that reflect disease states. In the neonate, there is a predominance of neutrophils, which persists until the second or third week of life when lymphocytes begin to predominate. At about 5 years of age the neutrophil again becomes the predominant leukocyte. This section focuses on abnormal elevation or depression of mature neutrophils. Abnormalities in lymphocytes and eosinophils are considered elsewhere in this text.

Definitions of Leukocytosis and Neutropenia

Leukocytosis refers to white blood cell (WBC) count elevation >2 standard deviations above the mean of circulating WBCs. Neutrophilia refers specifically to elevation of the absolute neutrophil count (ANC). The latter is calculated by multiplying the percentage of neutrophilic granulocytes by the total WBC count (see equation). The usual explanation for leukocytosis is neutrophilia.

Neutrophil counts show considerable variability during the neonatal period with a mean of 11,000/mm ^{3} and a range of 6,00026,000/mm^3 . Total WBC counts may be as high as 38,000/mm^3 at 12 hours of age.[460] The WBC count drops after 12 hours of age, reaching a mean neutrophil count of 5,500/mm ^{3} (1,50010,000) at 1 week. The differential in the first week of life resembles that of the adult with approximately 60% neutrophils. From 1 week until 56 years, however, there is a predominance of lymphocytes. Thereafter neutrophils increase to about 60%. The mean adult total leukocyte count is 7,500/mm ^{3} (4,50011,000) and the mean neutrophil count is 4,400/mm^3 (1,8007,700).[460] Total leukocyte counts of premature infants are about 30% lower than those of term infants. The sequential changes noted after birth also occur in premature infants but with wider variability. [461]

Neutropenia is defined as a neutrophilic granulocyte count of <1,500/mm ^{3} . This definition can be used for all ages, although separate standards should be used for certain groups. Certain populations of blacks and Yemenite Jews normally have lower granulocyte counts. [462] [463]

The ANC is calculated by multiplying the total WBC count by the percentage of bands and mature neutrophils:

Absolute neutrophil count =WBC × (% bands + % mature neutrophils) × 0.01.

Regulation of Granulocyte Counts

The peripheral neutrophil count reflects the equilibrium of several compartments. In the bone marrow, there is a mitotic pool, a maturation pool, and a storage pool. Outside the marrow, there is a circulating pool, a marginated pool of neutrophils adherent to vascular endothelium, and a tissue pool. The clinical assay of the number of neutrophils, the WBC count and differential, only monitors neutrophils in the circulating pool during a brief 36-hour period of transit from marrow to tissue. There is a complex interplay of factors that regulates the production of granulocytes and their movement from one pool to another, but the movement is always from marrow to blood to tissue.[464]

Granulocytes are derived from a common progenitor that also gives rise to erythrocytes, megakaryocytes, eosinophils, basophils, and monocytes. The biology of hematopoeisis is complex and is regulated by a number of cytokines with overlapping activities. The hematopoietic stem cells normally reside in the bone marrow in a state of quiescence/dormancy. Cytokines that lead to proliferation (or exit from dormancy) of the early progenitor/stem cells are stem cell factor, thrombopoietin, FLT3 ligand, IL-11, granulocyte colony-stimulating factor (G-CSF), and IL-6. IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF) act on the later progenitor cells, while cytokines that support differentiation along specific lineages are G-CSF, monocyte colony stimulating factor (M-CSF), and erythropoietin, leading to granulocytic, monocytic, and erythroid differentiation, respectively. [465] [466] [467] [468] [469] [470] Some of these cytokines along with components of complement[471] [472] [473] [474] release granulocytes from the marrow storage pool. This can result in

a two- to threefold increase in the granulocyte count within 45 hours. [471] [475] More than half of the granulocytes in the peripheral circulation at a given time are attached to the vascular endothelium.[476] These marginated neutrophils can be released almost immediately at times of stress. Epinephrine in part mediates this effect.[477] There is now clear evidence that margination is mediated by specific receptors. L-selectin is constitutively expressed on the neutrophil surface and tethers the cell to the vessel probably by binding to sulfated glycoconjugates on the endothelium. E-selectin and P-selectin may also be involved in this process. [464] Some experimental evidence suggests a feedback inhibition loop in the regulation of neutrophil production. Lactoferrin, which is contained in neutrophil-specific granules, suppresses production of colony-stimulating factors by monocytes, thus shutting off neutrophil production when granulocyte counts rise. Acidic isoferritins may also participate in this regulation. [478] [479]

Of the 1.2×10^9 granulocytes per kilogram, 20% are in the myeloid precursor pool, 75% in the marrow storage pool, 3% in the marginated pool, and 2% in the circulating blood.[476] [480] Normally, 1.5×10^9 granulocytes/kg body weight are produced per day. Production can be increased in the presence of an inflammatory stimulus. Granulocytes spend about 9 days in marrow, 36 hours in blood, and 14 days in the tissues. [476] Thus, the total granulocyte count as measured from peripheral blood represents a sample of a population that comprises only 5% of the total pool sampled during a fleeting 2% of the total transit time.

One must consider movement of neutrophils from one compartment to another as well as changes in production in assessment of neutrophilia and neutropenia. Thus, neutrophilia can be due to increased production, as in infection or myeloproliferative disorders, or inhibition of egress from the blood, as in certain chemotactic disorders or steroid therapy. [475] Neutropenia may be due to decreased production, increased margination and egress (as in systemic complement activation or burns),[481] [482] or destruction (as in immune neutropenia).

Unfortunately, evaluation of these processes is limited to examination of the peripheral blood and the bone marrow. Although sophisticated radiotracer techniques exist, they are not of much clinical use. Similarly, clinical tests such as hydrocortisone challenge or epinephrine stimulation, which reflect a releasable marrow storage

pool or marginated pool, have limited differentiating power.

CAUSES OF NEUTROPHILIA

Neutrophilia is classified as primary or secondary, as listed in Table 41-18 .

Secondary Causes of Neutrophilia

Leukemoid Reaction

Leukocytosis >50,000/mm^3 is referred to as leukemoid reaction [483] and is characterized by a significant increase in early neutrophil precursors in the peripheral blood. The differential count has a marked left shift evidenced by the presence of myelocyte, metamyelocyte, and band forms. Promyelocytes and myeloblasts may be observed in severe reactions. In contrast to acute leukemia, proliferation and orderly maturation of all normal myeloid elements is observed in the bone marrow. The morphology of the myeloid elements is normal. Chronic myeloid leukemia may be distinguished from a leukemoid reaction by the finding of a low leukocyte alkaline phosphatase score and the presence of the Philadelphia chromosome on karyotypic analysis of the bone marrow. Leukemoid reactions to infections may be accompanied by toxic granulation, Doehle bodies, and cytoplasmic vacuoles in the neutrophils. [483]

TABLE 41-18 -- Classification of Neutrophilia

Primary (no other evident associated disease)
Hereditary neutrophilia
Chronic idiopathic neutrophilia
Chronic myelogenous leukemia (CML) and other myeloproliferative diseases
Familial myeloproliferative disease
Congenital anomalies and leukemoid reaction
Leukocyte adhesion deficiency (LAD)
Familial cold urticaria and leukocytosis
Secondary
Infection
Stress neutrophilia
Chronic inflammation
Drug induced
Nonhematologic malignancy
Generalized marrow stimulation as in hemolysis
Asplenia and hyposplenism

Newborns have unique responses to stress and infection. The relative number of band forms and less mature granulocyte precursors in the differential of newborn infants has been correlated with sepsis and with depletion of the marrow neutrophil storage pool. [484] [485] In the normal infant, the band/neutrophil ratio is <0.14:0.11 in the first 48 hours irrespective of birth weight or gestational age. [486] An immature/total neutrophil ratio >0.8 in the peripheral blood indicates that marrow reserves are depleted and the risk for death in septic infants is significantly increased. [484] Some infants have extreme responses to stress. Extreme leukocytosis >200,000/mm^3 has been seen in a 26-week infant whose mother received steroids. [487] Transient leukemoid reactions have also been seen in phenotypically normal infants who had trisomy 21 limited to their hematopoietic cells. [488] [489]

When the marrow is directly invaded by tumor, or in cases of marrow fibrosis, or granuloma reactions, neutrophilia associated with immature granulocytes, nucleated red blood cells and teardrop-shaped erythrocytes may be seen accompanied by thrombocytosis. This is called a leukoerythroblastic response. A bone marrow aspirate and biopsy should be performed in these cases to look for granuloma, tumor, or marrow fibrosis. Cultures of the marrow for fungus and tuberculosis [490] should be obtained. Leukoerythroblastic reaction may also be seen with recovery from marrow suppression after chemotherapy. Leukoerythroblastosis can also be seen during recovery from severe myelosuppression. Interestingly, transient erythroblastopenia of childhood, which was thought to be related to parvovirus infection, has been reported to present with leukoerythroblastosis. [491]

Pelger-Huët Anomaly

Although technically not leukocytosis, the Pelger-Huët anomaly can raise the question of serious infection because of an apparent high band count. The Pelger-Huët anomaly is a benign dominantly inherited defect of terminal neutrophil differentiation found with a frequency of 1:6,000 live births. Most of these neutrophils have bilobate nuclei and excessively coarse clumping of nuclear chromatin. The two lobes are joined by a thin, hair-like bridge that is much thinner than that seen in a normal band. This gives the characteristic pince nez or spectacle appearance to the nucleus. The function of these cells is normal. [492] Interestingly, Pelger-Huët cells can develop multiple lobes during states of vitamin B_{12} or folate deficiency but return to their bilobate state when the vitamin deficiency is corrected. [493] Colchicine, sulfonamides, ibuprofen, taxoids, and valproate reversibly induce the anomaly. [494] [495] [496] [497] [498] This so-called pseudo Pelger cell has also been reported transiently during certain acute infections, in acute myelogenous leukemia, and in myelofibrosis. In

particular, the defect has been associated with cytogenetic abnormalities of chromosome 17 in leukemias. [499] The homozygous state results in neutrophils that contain a single round eccentric nucleus with clumped chromatin. Eosinophils and basophils may be involved as well. An unusual case of Pelger-Huët anomaly has been reported in four generations of one family with late-onset progressive proximal muscular dystrophy. [500]

Neutrophilia and a left shift can be indicative of disease or may be totally benign. An outline of the major primary and acquired causes of neutrophilia is presented in Table 41-18 . The causes of neutrophilia are divided into two groups, those that seem to be due to intrinsic problems with the neutrophil or regulation of neutrophil production, and those that are secondary to some other disease process.

Chronic Myelogenous Leukemia

The major differential diagnosis of leukemoid reaction is chronic myelocytic leukemia (CML). This topic is considered in detail in Chapter 62 . Leukemoid reactions and CML can be difficult to distinguish. The classical differentiating features are the presence of a low leukocyte alkaline phosphatase (LAP) score and presence of the Philadelphia chromosome in CML. The LAP score is also low in familial myeloproliferative disease [501] and paroxysmal nocturnal hemoglobinuria. [502] Juvenile CML can be distinguished from the usual adult form by the ability of circulating stem cells to form monocyte colonies in vitro [503] and the absence of the Philadelphia chromosome. Leukocyte counts in CML can be extremely high, occasionally >500,000/mm^3 . Patients with granulocyte counts >200,000/ mm^3 require emergent intervention to prevent the vaso-occlusive complications of hyperviscosity related to the markedly elevated WBC counts.

Acute Infection

Modest leukocytosis with a left shift is commonly seen in association with many acute bacterial infections. Certain bacterial agents such as pneumococcus or staphylococcus may cause particularly high leukocyte counts. Leukocytosis is seen in association with acute otitis media with 9% of patients having >20,000 WBC/mm^3 , whereas 27% of culture-proven positive acute otitis media cases have WBC counts below the mean for age. [504] The predictive value of leukocytosis and increased band forms (WBC >15 × 10^9 /L immature/total >0 2) in detecting bacterial disease was increased from 32% to 71% when associated with depressed fibronectin levels (1 SD < mean for age). This is of particular interest in view of the role of fibronectin in promoting phagocytosis by polymorphonuclear cells and monocytes.[505] The risk of positive blood cultures in children between 3 and 36 months of age with fever >39.5°C is directly related to WBC count. If the temperature is >39.5°C and the WBC is >15,000/mm^3 , 16% have a positive culture, whereas 43% of cultures from similar children with a WBC >30,000/mm^3 are positive. In contrast, only 3.7% of children with counts <15,000/mm^3 , and none with counts <10,000/mm^3 had positive blood cultures.[506] Neutrophilic leukocytosis can also be associated with severe viral disease. Patients with Hantavirus infection, for example, have WBC counts as high as 65,000/mm^3 (median 26,000/mm^3) with 67% bands (median 27%).[507]

Chronic Inflammation

Acute changes in the neutrophil count are due to release from the marrow storage pool and the marginated pool. In cases of overwhelming infection, marrow depletion can occur resulting in neutropenia rather than neutrophilia. Chronic inflammatory processes result in stimulation of granulocyte production and are usually more modest in degree and may be associated with increase in monocytes.

Stress Neutrophilia

Modest elevation in the neutrophil count has been associated with many types of stress. Neutrophilia can occur within minutes of exercise [508] or stress[509] or epinephrine injection[477] and is presumed to be related to movement of neutrophils from the marginated pool into the circulating pool. The neutrophilia secondary to catecholamine injection has been related to reduced neutrophil adherence. The neutrophilia as well as the adherence inhibiting ability of plasma can be blocked by pretreatment of the subject with propranolol or in vitro treatment of the adherence assay system with antibody to cyclic adenosine monophosphate. [477]

Studies of exercise-induced neutrophilia failed to show blockade by propranolol, despite measurable increases in plasma epinephrine. [510] The neutrophilia was directly related to the work load and cardiac output, suggesting a larger role for mechanical and flow-related effects on dislodgment of the leukocytes sequestered in the lung, than possible direct effects of catecholamines on the neutrophils. Other studies show no effect of exercise on circulating colony-forming unit granulocyte/macrophage (CFU-GM) or colony-forming unit granulocyte, erythrocyte, monocyte, macrophage (CFU-GEMM) [508] although it has been suggested that the delayed leukocytosis (up to 235% increase at 5 hours after exercise) may be related to marrow release of leukocytes. [511]

Mild neutrophilia and lymphopenia have been associated with unipolar depression but may be related to the use of antidepressant medications. [512]

Neutrophilia is also seen in the postoperative period. There is a doubling of the leukocyte count 3 hours after surgery. This does not seem to be related to the type of anesthesia.[513] [514]

Leukocytosis in the 12,00020,000/mm^3 range has been reported in the postictal state. This can be associated with fever or pulmonary edema and resolves in a few hours to days.[515]

There is an interesting association between leukocyte count and myocardial infarction. Subjects with a leukocyte count >9,000 had a 4.5-fold higher incidence of myocardial infarction than those with a leukocyte count <6,000. [516] It is also not clear whether the WBC count is a risk factor or merely an indicator of stress. [517] However, the WBC count has been shown to be an independent indicator of atherosclerotic cardiovascular disease. [518]

Drug-Induced Neutrophilia

Leukocytosis has been seen in association with a number of drugs and drug reactions. Steroids are known to induce release of neutrophils from the bone marrow [475] and result in a chronic low-grade neutrophilia. Leukocytosis as high as 200,000/mm^3 in neonates has been associated with maternal steroid administration as well. [487] [519] -Agonists produce an acute neutrophilia by releasing neutrophils from the marginated pool. [520] Lithium is known to produce leukocytosis by increasing production of CSF and has been used with varying success to treat several neutropenic states. [521] Tetracycline has also been associated with leukemoid reaction with WBC counts >80,000/mm^3 .[522] G-CSF is now in common clinical use and can cause significant neutrophilia if use is not closely monitored.

Nonhematologic Malignancy

Leukocytosis is frequently seen in large-cell lung cancer. [523] Usually the leukocytosis seen with solid tumors is modest in the 12,00030,000/mm^3 range[523] [524] [525] [526] [527] although it can be as high as 106,000/mm^3 even in the absence of marrow metastasis.[528] Leukemoid

reactions have been seen in patients with marrow involvement with tumor from lung, stomach, and breast, or with neuroblastoma in children. [528] In some instances, solid tumors of lung, tongue, and kidney have been shown to secrete colony-stimulating activity. [529] [530] [531]

Heat Stroke

Leukocyte counts up to 30,000/mm^3 have been seen in heat stroke. Up to 50% of the neutrophils may have botryoid nuclei with nuclear segments smaller than usual, resembling a clustering of grapes around a central stem.[532] [533]

Marrow Stimulation

Significant leukocytosis can be seen in states of chronic stimulation of the bone marrow such as hemolytic anemia or immune thrombocytopenia. [534] Patients with sickle cell anemia commonly have leukocyte counts in the 12,00015,000/mm^3 range and have an exaggerated elevation in WBC counts with infection. This response may be further augmented by functional asplenia. Likewise, significant rebound leukocytosis can occur in the recovery phase of marrow suppression. [535] [536] These reactions can last several weeks. In one instance there were 90% myeloblasts in the marrow and as many as 20% myeloblasts in the peripheral blood. [537]

Asplenia and Hyposplenism

Moderate neutrophilia can be associated with congenital disease-related asplenia (such as in sickle cell anemia) or surgical asplenia. Usually the neutrophilia is mild.[538] [539]

Primary Causes of Neutrophilia

Hereditary Neutrophilia

A family of four was described in 1974[540] with leukocyte counts that were chronically in the 20,00070,000/mm^3 range, splenomegaly, and widened diploe of the skull. There was no apparent propensity to bacterial infection. The defect seemed to be dominantly inherited. The LAP scores were high in the affected subjects. To date, none of the family members have had any serious medical problems other than a bleeding diathesis related to platelet dysfunction. [540] We have studied one of the

members of this family and find normal neutrophil function and normal expression of surface CD18/CD11b so this is not a variant of leukocyte adhesion deficiency (W. Herring, T.D. Coates, unpublished data). We have seen a second family with this syndrome (D. Powars, personal communication). In this case, the father had marked leukocytosis and spenomegaly and eventually had his spleen removed. His son had similar problems with neutrophil counts at times in 100,000/mm ^{3} range and massive splenomegaly. The neutrophil function and CD18/CD11b expression in the affected father and son are also normal (D. Powars and T.D. Coates, unpublished data).

Chronic Idiopathic Neutrophilia

Chronic leukocytosis can occur in patients who are otherwise well. A series of 34 patients with leukocyte counts between 11,000 and 40,000/mm ^{3} were followed for up to 20 years without associated clinical problems. Bone marrow aspirations were generally normal and LAP scores were normal. The remainder of the blood counts were normal, except for occasional thrombocytosis.[541] These data point out that certain normal subjects fall outside of the 95th percentile with respect to WBC counts and should be considered normal, thus sparing them frequent and extensive evaluations.

Familial Myeloproliferative Disease

A syndrome of growth retardation, hepatosplenomegaly, anemia, and leukocytosis has been described. [50C] Some of these children died in early life, whereas others remained stable or improved. All of the affected subjects had low LAP scores. Furthermore, several other members in four generations of the family had low LAP scores but no other findings. Chromosomal analysis showed no significant consistent abnormalities and no subject had a Philadelphia chromosome. Other families have been reported with familial occurrence of polycythemia vera, CML, and myelofibrosis. [542] [543] Furthermore, there is evidence that myeloproliferative syndromes associated with monosomy 7 may have familial features.[544] [545]

Congenital Anomalies and Leukemoid Reaction

Leukemoid reactions have been associated with amegakaryocytic thrombocytopenia and congenital abnormalities such as tetralogy of Fallot, dextrocardia and absent radii, and rudimentary little toes. [546] [547]

Down Syndrome

Infants with Down syndrome may have a transient leukemoid reaction that resembles congenital leukemia. [548] These children can also have an exaggerated leukemoid response to stress.[549] A transient leukemoid reaction has been seen in a phenotypically normal child who expressed trisomy 21 mosaicism in myeloid cells but not in skin fibroblasts. The chromosomal abnormality disappeared after the leukemoid reaction resolved. [489] [550]

LAD

Since the 1970s, several patients have been described with persistent leukocytosis, delayed separation of the umbilical cord, recurrent infections, and a stimulus-dependent activation defect of the neutrophil. The laboratory hallmark of these disorders is leukocytosis. WBC counts may be only mildly elevated but often are in the 18,00030,000/mm^3 range and may be as high as 150,000/mm^3 during infection.[551] [552] There are no specific morphologic abnormalities seen in the granulocytes. The diagnosis is established by demonstration of absence or marked reduction (<10% of control) in the CR3 receptor on granulocytes. These patients have severe functional defects as well and are described in detail earlier in this chapter.

Familial Cold Urticaria and Leukocytosis

An interesting syndrome of leukocytosis, fever, urticaria, rash, and muscle and skin tenderness on exposure to cold has been reported. This syndrome appears to be dominantly inherited. The onset of symptoms is in infancy and symptoms have been provoked by exposure to cold in the delivery room. Urticaria, followed by fever, starts 7 hours after cold exposure. Leukocytosis, sometimes up to 34,000/mm^3 , starts 10 hours after cold exposure and begins to subside 1214 hours later. [553] [554] In contrast to other causes of urticaria, the skin rash in these patients is characterized histologically by a marked infiltration by neutrophils. The leukocytosis and urticaria were blocked when the patients were infused with endotoxin before cold exposure. This has been related to cold activation of clotting system as it is associated with a transient decrease in levels of C1 esterase inhibitor. [555] [556]

APPROACH TO THE EVALUATION OF NEUTROPHILIA

Laboratory error must always be included in the differential diagnosis of unexplained isolated neutrophilia or neutropenia.

With current technology, much of the human error has been removed [557] although some clinicians continue to believe that manual counts are more accurate. Blood counts that do not make sense in the context of the clinical findings should be repeated before extensive evaluation is undertaken. [558]

Factitious leukocytosis can be seen due to blood sampling problems or certain primary disease states. Inadequate anticoagulation of the specimen can result in platelet clumps being counted as leukocytes by automated cell counters. The WBC count is rarely increased >10% and is usually associated with spurious thrombocytopenia.[559] [560] In cryoglobulinemia, a temperature-dependent increase in leukocyte and platelet counts occurs at about 30°C and can result in WBC counts as high as 50,000/mm^3 and a doubling of the platelet count, presumably due to various sizes of precipitated cryoglobulin particles. [561] This effect is increased if the sample is allowed to cool to lower temperatures.

The general approach to the evaluation of the patient with neutrophilia will depend on the degree of neutrophilia and the signs and symptoms of the associated diseases. Neutrophilia is most commonly seen secondarily to acute or chronic inflammatory processes, and the diagnosis and treatment are dictated by the nature of the primary illness. In the absence of clear history or physical examination findings, the sedimentation rate may be very helpful. An elevated sedimention rate suggests a more extensive evaluation for collagen vascular or other occult inflammatory disease is warranted, whereas a normal value suggests watchful waiting may be the best course. Examination of the bone marrow is of little help in mild leukocytosis. In leukemoid reactions or leukoerythroblastosis, direct invasion of the marrow and myelodysplasia must be excluded. Bone marrow biopsy, marrow cytogenetics, and fungal and tuberculosis evaluation should be included. The biopsy may reveal granulomata, which may intensify the search for fungus, or may reveal metastatic tumor that is missed in marrow aspirate. Marrow cytogenetics may reveal mosaic trisomy 21,[488] [489] monosomy 7,[544] Philadelphia chromosome, or other signs of dysplastic states. The LAP score, which is high in infection and low in CML, is also of help. It must be kept in mind, however, that the LAP score can be normal in CML, particularly juvenile CML, making this diagnosis difficult at times.

Many factors contribute to the wide variability in granulocyte counts in normal populations. Particularly in the asymptomatic patient with persistent mild neutrophilia, one must remember that, by definition, the WBC count in 2.5% of the normal population must be >2 standard deviations above the mean. Because regulation of granulocyte production is genetically controlled, [462] [463] [541] [562] examination of the parents or siblings blood counts may be of help in these few cases.

LEUKOPENIA

There are fewer causes of neutropenia than of neutrophilia. Because most clinicians are looking for increased WBC counts, the diagnosis of neutropenia is often overlooked.

Relation of ANC to Propensity to Infection

Propensity to infection in patients whose neutropenia is due to decreased production is related to the ANC (Table 41-19). In contrast, patients with peripheral destruction or margination of neutrophils, such as seen in immune neutropenias, demonstrate no direct correlation between degree of neutropenia and propensity to

infection.

Patients with neutropenia secondary to chemotherapy, marrow failure, or marrow exhaustion are at great risk for overwhelming bacterial infection. [484] [485] [563] In contrast, children with chronic benign neutropenia of infancy and childhood may have neutrophil counts <200/mm ^{3} for months or years and have no

TABLE 41-19 -- Clinically Significant Neutrophil Counts

ANC	Clinical Significance
>1,500/mm^3	Normal
1,000>1,500	No significant propensity to infection. Fevers can be managed on an outpatient basis.
5001,000	Some propensity to infection. Occasionally fever can be managed on an outpatient basis.
<500	Significant propensity to infection. Always should be managed as inpatient with parenteral antibiotics. Few clinical signs of infection.

These rules apply strictly for neutropenia with hypoplastic marrow, early myeloid arrest, and decreased granulocyte reserve pools. There is more latitude for clinical judgment in neutropenias with normocellular marrow. The only regular exception to these rules is documented chronic benign neutropenia of childhood.

serious infectious problems.[563] Similarly, some adults with immune neutropenia may have severe depression of their neutrophil counts and suffer no serious episodes of infection.[564] Both of these entities are characterized by neutropenia and a cellular marrow. The marrow differential usually shows normal early granulocyte precursors but may have a late myeloid arrest.

Many patients with chronic neutropenia have normal or increased monocytes. These cells are functioning phagocytes and may account for the lack of correlation of neutrophil count with propensity to infection in certain patients. [565] [566] Tissue delivery of neutrophils in chronic immune-mediated neutropenia has been shown to be greater than that in chemotherapy-induced neutropenia of equal degree suggesting that the peripheral blood count may not accurately reflect neutrophil availability.[567] It seems that adequacy of the marrow reserve pool of granulocytes may be the most important determinant of propensity to infection in neutropenic patients.

The types of infections encountered in neutropenic patients depend on the degree and chronicity of the neutropenia as well as the nature of the associated diseases. Patients in good clinical condition with severe neutropenia secondary to decreased production can go many weeks without serious infection although infection is inevitable. If the patient is debilitated or receiving suppressive chemotherapy, the frequency of infection is greater. *S. aureus, Pseudomonas aeruginosa, Escherichia coli*, and *Klebsiella* species are common causes of infection in these patients.[565] [566] [568] Patients with less severe chronic neutropenias (ANC >300) may have recurrent sinusitis, stomatitis, perirectal infection, and gingivitis, [565] [566] [569] but they usually do not become septic.

CLASSIFICATION OF NEUTROPENIA

Neutropenia can be due to decreased production of granulocytes, shift of granulocytes from the circulating pool to marginated or tissue pools, peripheral destruction, or a combination of these causes.[566] [570] The mechanisms have been determined using leukokinetic measurements and bone marrow cultures. These assays are not routinely available and do not significantly alter clinical management. Thus, from a practical standpoint, the simple classification in Table 41-20 is preferred. This classification also generally corresponds to marrow cellularity and propensity to infection.

The classification of some of the neutropenias depends on the clinical course. Because the laboratory characteristics of many of the neutropenias overlap, the differential diagnosis can be difficult. If there is no family history of neutropenia and the bone marrow is normocellular or hypercellular, there is no certain way to differentiate the various neutropenias other than to follow the patient clinically. In fact, the syndromes called chronic benign neutropenia, chronic idiopathic neutropenia, chronic benign neutropenia of infancy, and

TABLE 41-20 -- Classification of Neutropenia

Acquired neutropenia
Postinfectious
Drug induced
Benign familial neutropenia
Chronic benign neutropenia of childhood
Chronic idiopathic neutropenia
Autoimmune neutropenia
Isoimmune neutropenia
Neutropenia associated with immunologic abnormalities
Neutropenia associated with metabolic diseases
Neutropenia due to increased margination
Nutritional deficiency
Intrinsic defects
Kostmann syndrome (severe infantile agranulocytosis)
Myelokathexis/neutropenia with tetraploid nuclei
Cyclic neutropenia
Shwachman-Diamond-Oski syndrome
Chediak-Higashi syndrome
Reticular dysgenesis
Dyskeratosis congenita

autoimmune neutropenia are all very similar, differing only in age of onset or association with recognizable immune disease. Differentiating these syndromes is probably not important. It may be better to lump them into a category of neutropenia with adequate marrow neutrophil reserve because this better predicts the clinical behavior.

Acquired Neutropenia

Many acquired neutropenias have decreased survival of neutrophils in the peripheral circulation. Bone marrow examination reveals normal or increased cellularity with a late maturation arrest, usually at the metamyelocyte or band stage. Elevation of serum lysozyme or lactoferrin reflects destruction of neutrophils. These measurements help demonstrate destruction of neutrophils but do not help with clinical management. [481] [571]

Postinfectious Neutropenia

Neutropenia can be commonly seen after viral infections, particularly in children. [572] The neutropenia can start within a few days of the onset of infection and last several weeks. Granulocyte counts usually return to normal as the viremia resolves. Viral diseases that have been implicated include varicella, measles, rubella, hepatitis A and B, infectious mononucleosis, influenza, cytomegalovirus, [573] [574] [575] and Kawasaki disease. The mechanism of the neutropenia can involve decreased production, redistribution, and destruction of neutrophils. [570] [576] [577] [578] In addition, virus-induced antibody can result in protracted immune neutropenia. Parvovirus B19 is commonly associated with transient neutropenia and can cause protracted leukopenia in immunosuppressed patients. [579] Leukopenia is seen in >70% of patients with acquired immunodeficiency syndrome (AIDS) and can be associated with hypersplenism and with the presence of antineutrophil antibodies. [580] [581] [582] [583]

Infection with *S. aureus*, brucellosis, tularemia, rickettsia, and *Mycobacterium tuberculosis*[570] can cause moderate neutropenia. Marked neutropenia can occur in any patient with overwhelming sepsis. This is more likely in debilitated adults or in newborns. The mechanism is probably due to exhaustion of the marrow reserve pool and is particularly well documented in sepsis in newborns. [484] [485] [584] Furthermore, systemic activation of complement during sepsis with production of C5a, a neutrophil activator, can result in increased adherence of neutrophils to the vascular endothelium and neutropenia due to margination of activated cells. [585]

Drug-Induced Neutropenia

Many therapeutic agents cause neutropenia. [586] The mechanism can involve direct bone marrow suppression as seen with many antineoplastic agents, antibody and complement-mediated damage to precursor cells,[587] [588] or peripheral destruction and clearance of neutrophils. [508] [564] [589] [590] The most common presenting symptoms are fever, sore throat, pharyngitis, sepsis, stomatitis, and pneumonia. [591] Mortality rates as high as 1225% have been reported, although full recovery can be expected in >80% of patients.[591] An overall annual risk of agranulocytosis is 3.4 per million population in an ambulatory population from Israel, Europe, and northeast United States. Approximately 72% of all cases of agranulocytosis in the United States are attributed to medications with procainamide, antithyroid drugs, and sulphasalazine being the most commonly implicated.[592] Most drug-related neutropenias are due to dose-dependent marrow suppression. Phenothiazines, semisynthetic penicillins, nonsteroidal anti-inflammatory agents, aminopyrine derivatives, benzodiazepines, barbiturates, gold compounds, sulfonamides, and antithyroid medications are the most common causes.[592] [593] The cardiac drugs propranolol (relative risk 2.5), dipyridamole (3.8), digoxin (2.5), and acetyldigoxin (9.9) are significantly associated with agranulocytosis. The excess risk from these drugs ranges from 1 to 3 cases/10 million persons exposed for up to 1 week. [594] A more extensive list can be seen in Table 4121 . [591] Usually the neutropenia becomes evident within 12 weeks of exposure to drug. [593] Recovery usually starts within a few days of stopping the drug and is preceded by the appearance of monocytes and immature neutrophils in the peripheral blood. [589] Early recovery occurs more frequently in patients with normal or increased marrow cellularity. In patients with pancytopenia, the median leukocyte recovery time was 14 days for patients with marrow hypoplasia and 10 days for those without marrow hypoplasia.[596] Rebound leukocytosis with marrow and peripheral blasts have been reported, simulating a leukemic state. [546] [547]

Although it is always best to stop the drug if neutropenia occurs, often clinical circumstances make it difficult to do this. With certain medications, such as sulfamethoxizole, the neutropenia depends on the dose and duration of therapy. It is often possible to continue the medication with careful observation. Neutropenia secondary to anticonvulsants often places the clinician in the difficult situation of having to balance the risk of neutropenia with stopping the medication and losing control of the seizures. As long as the ANC remains >500700 cells/mm^3 and there are no infections, it may be safe to continue the medication. A bone marrow aspiration can be helpful under these circumstances. A cellular, late-arrested marrow indicates the neutropenia is immune mediated. In this instance, the neutropenia is less likely to be clinically significant.

Chronic Benign Neutropenia

Chronic benign neutropenia is a syndrome occurring in older children and adults. Onset can occur from childhood to late adulthood. The clinical findings and presentation are quite variable. [565] [566] Neutrophil counts are commonly between 200 and 500/mm^3 , and bone marrow examination usually reveals normal to increased numbers of myeloid precursors with an arrest at a late stage of maturation. Often peripheral monocytosis is present. Some of these patients may have moderately hypocellular marrows.[566] Hepatosplenomegaly is not seen, and there is no other infectious, inflammatory, or malignant disease to which the neutropenia can be attributed. Frequently these patients have a benign course despite the degree of neutropenia. This may be due to the fact that they have some marrow reserve, as demonstrated by the response of their neutrophil count to a hydrocortisone stimulation test. [566] They are also able to mobilize more neutrophils to the tissue than patients with acute

TABLE 41-21 -- Causes of Agranulocytosis/Neutropenia

206 patients (more than one cause per patient possible). [591]

Agranulocytosis: nadir of neutrophil count 0.5 × 10^9 /L. Neutropenia: nadir of neutrophil count >0.5 × 10^9 /L but 1.5 × 10^9 /L.

A, causal relation certain or probable: drug taken within 10 days of onset of neutropenia, recovery when drug stopped, no other likely cause of the agranulocytosis or neutropenia; B, causal relationship possible: same as A, but more than one possible cause of neutropenia present.

[a]Isolated agranulocytosis or neutropenia: marrow results and complete blood count information available.
[b]Agranulocytosis or neutropenia present but results of hemoglobin, platelet count, or bone marrow aspiration not available.
[c]Procainamide (2), ajmaline (1), tocainide (1), aprindine (5), and amiodarone (1).
[d]Amoxycillin (1), azlocillin (1), benzylpenicillin (3), phenethicillin (1), cloxacillin and penicillin (2).
[e]Methylthiouracil (1), and propylthiouracil (7).
[f]Captopril (5) and enalapril (1).
[g]Cephalexin (1), cephazolin (1), cefuroxime (1), cefitaxime (1), and cephradine (1).
[h]Glibenclamide (1) and tolbutamide (3).
[i]Phenytoin (2), chlorthalidone (2), sulphamethizole (2), norfloxacin (2), naproxen (2), clomipramine (2), trazodone (2), omeprazole (2), alimemazine (2), pirenzepine, ticlopidine, ibopamine, hydralazine, nifedipine, spironocatone, nalidixic acid, doxycycline, clindamycin, gentamicin, fusidic acid, dapsone, azapropazone, combination preparations with aminophenazone, respectively, propyphenazone, sulindac, piroxicam, pirprofen, niflumic acid, allopurinol, glafenine, valproate, levodopa with carbidopa, chlorpromazine, haloperidol, zuclopenthixol, zopiclone, cinnarizine, metronidazole, combination preparations with pyrimethamine, and theophylline.

drug-induced suppression of equal degree. [567] Antineutrophil antibodies, as well as other immunologic abnormalities, have been seen in some patients though these studies are usually normal. [566] [596] [597] [598] The lack of strong evidence for antineutrophil antibodies in these patients does not preclude the possibility that antibodies against myeloid precursors are present. Antibodies against the promyelocytic leukemic line, HL-60, were detected in sera from three patients with idiopathic neutropenia with no detectable antibody to mature neutrophils. [598] Bone marrow cytogenetic studies are normal as is G-CSF concentration. [566] [599]

Corticosteroids, splenectomy, and cytotoxic agents have been successful in increasing neutrophil counts. [566] Recently, human G-CSF has been used successfully to treat a patient with idiopathic neutropenia. [600] This patients course was benign for several years until his marrow became hypocellular. G-CSF has been shown to decrease the rate of infection in patients with chronic idiopathic neutropenia. [601] Because the clinical course of

this disease may be benign, treatment intended to increase the neutrophil count should be reserved for patients with significant recurrent infectious complications.

Chronic Benign Neutropenia of Infancy and Childhood

This interesting childhood syndrome highlights the relationship between marrow reserve pool and propensity to infection. It probably should be considered as a subset of chronic benign neutropenia. Even though these patients have severe neutropenia, they have no significant propensity to infection. Chronic benign neutropenia of infancy and childhood [602] [603] is a chronic state of mature neutrophil depletion with a compensatory increase in immature granulocytes in the bone marrow. [603] The median age of detection is 8 months. Although it can present any time in the first 3 years of life, 90% of patients are detected before 14 months of age There is a slight female predominance (3:2) and no correlation with birth order. Neutrophil counts are usually very low at presentation, although these counts are normal at birth. There is no family history of neutropenia. [563] [602] [603] [604] Antineutrophil antibodies have been detected in 98% of patients when both immunofluorescent and agglutination assays are used. [563] [605] Although the exact mechanism of the neutropenia is unclear, the facts that antineutrophil antibodies are frequently no longer detectable late in the course of the disease [563] and that antiimmune therapy is effective [563] [606] [607] suggest an immune mechanism. [563]

Many children with benign neutropenia have purulent otitis despite a neutrophil count <200/mm^3, emphasizing the fact that neutrophils can go to sites of infection even when they are not seen in the peripheral blood. It is common for these patients to go several months with neutrophil counts <200/mm^3 and have no febrile episodes. Some of these patients have measurable defects in neutrophil movement and have been described as having the so-called lazy leukocyte syndrome. [608]

Autoimmune Neutropenia

Autoimmune neutropenia has been seen as an isolated phenomenon, [564] [609] secondary to other known autoimmune diseases, [564] [609] [610] related to infections, [576] and related to administration of drugs. [564] Furthermore, with increasing sophistication of immunologic evaluations, immunologic mechanisms are being seen in instances of neutropenia that have classified as idiopathic. [563] [564] [598] [601] [610] Immune neutropenia can be seen in association with idiopathic thrombocytopenic purpura and immune hemolytic anemia as well. [564] In the neutropenia associated with Rh hemolytic disease, however, there is evidence of down-regulation of neutrophil production associated with an increase in erythropoiesis. [611]

Patients with autoimmune neutropenia have moderate to severe neutropenia, usually accompanied by monocytosis. Marrow cellularity is increased with a late maturation arrest. The propensity to infection is related to the degree of neutropenia although the correlation is not good. [564] [610] [612] Hepatosplenomegaly has been seen in about half the patients. The age of presentation is wide, ranging from early childhood to old age.

Neutrophil-specific antibodies to the neutrophil antigens NA1, NA2, ND1, ND2, NB1, as well as to antigens shared by erythrocytes and to HLA antigens have been detected. [605] They are detected by a variety of assays including leukoagglutination, [605] [613] opsonization, [520] [610] immunochemical assays, [564] direct antibody binding, [609] complement activation, [564] [614] and various modifications of these techniques. [615] The antibodies are usually of IgG or IgM type. Due to a lack of a good, readily available panel of known neutrophil antigens, most assays detect only the presence of neutrophil-associated antibody. Antibodies to CD13 have been detected in some neutropenic patients with cytomegalovirus. [616] Detection of antineutrophil antibodies is helpful in establishing the diagnosis of immune neutropenia, although a negative assay does not exclude the diagnosis. [564] [605] This may be due to antibody specificity for neutrophil progenitors rather than mature neutrophils. [587] [588] [598] The degree of neutropenia is related to the specificity of the antibody as well as the titer. This probably accounts for the variability of success in correlating the amount of antibody with severity of disease. [564] [605] [610] In addition to neutrophil-associated antibodies, circulating immune complexes have been detected in about one-third of

patients with immune neutropenia[610] and in patients with chronic idiopathic neutropenia. [617] Although immune complexes can cause a positive indirect immunofluorescent test, patients with immune complexes and negative immunofluorescence antineutrophil antibody tests have been reported. [610]

Antineutrophil antibodies of the IgG type have been reported in systemic lupus erythematosus. These antibodies have been seen both before and after correction of neutropenia by therapy. [564] [618] Approximately 50% of patients with lupus are neutropenic, although few have severe enough neutropenia to result in increased in susceptibility to infection. [617] Neutropenia in lupus may also be related to decreased myelopoiesis. [618] Immune neutropenia can also occur in conjunction with autoimmune hemolytic anemia and thrombocytopenia.[601]

The neutropenia of Felty syndrome (rheumatoid arthritis, splenomegaly, and neutropenia) has also been related to the presence of antineutrophil antibodies. In this complex autoimmune disorder, decreased granulocyte survival as well as decreased production have been reported. [619] [620] [621] Infection is the major cause of death in Felty syndrome. Although neutropenia contributes to the predisposition to infection, neutrophil functional defects have also been found. [622] Immune complexes have also been associated with this disorder. [620] [621] More recently, suppressor T cells have been implicated in mediation of the neutropenia. [601] [623] [624] Improvement in neutropenia and decrease in antineutrophil antibody levels with methotrexate treatment provides further evidence that an immune mechanism may play a role in the etiology of this neutropenia. [625] Splenectomy produces resolution of the neutropenia and improvement in symptoms in 80% of cases. Treatment with G-CSF (510 g/kg/day) has been reported to be successful in management of complications of neutropenia due to Felty syndrome. [626] Despite the possible serious nature of this syndrome, about half the patients do not experience any infections. [626]

Treatment of autoimmune neutropenia depends on the severity of the neutropenia-related symptoms and the nature of the underlying disease. Because many of these patients have a benign course, therapy solely to increase the neutrophil count is not indicated. If the patient has significant neutropenia (ANC <500/mm ^{3}) and recurrent or severe infections, high-dose intravenous IgG [606] [607] [627] or steroids may be used. Splenectomy provides only transient correction of the neutropenia and results in a subsequent propensity to infection. Other cytotoxic therapy may be considered, particularly in lupus or rheumatoid arthritis. [618] [625]

Use of G-CSF has been successful in patients with immune neutropenia and should be considered if the patient is having problems with infection. [601] A low-dose regimen has been used in such cases at reduced cost. [628]

Isoimmune Neonatal Neutropenia

Moderate to severe neutropenia can occur in newborn infants secondary to IgG antibodies transferred from mother to infant. The pathogenesis of this disorder is identical to that of Rh hemolytic disease, with prenatal sensitization to neutrophil antigens resulting in production of antibodies that cross the placenta. [590] [605] [629] The incidence has been estimated at 2/1,000 live births. [629] If the infant is septic, or if subsequent episodes of bacterial infection occur, then marrow aspiration should be

performed. If there is early arrest or storage pool depletion, treatment with granulocyte transfusions or G-CSF should be considered.

Neutropenia in Infants of Hypertensive Mothers

Granulocyte counts as low as 500/mm^3 have been reported in infants of hypertensive mothers. [630] Forty-nine percent of infants of hypertensive mothers had neutropenia that lasted from 1 hour to 30 days. [631] Neutropenia was more common in infants who had growth retardation or whose mothers had severe hypertension. Thrombocytopenia to 90,000/mm^3 was also seen. [631] The neutropenia seems to be due to marrow suppression and may be associated with a slightly increased incidence of infection. [630] [631] [632]

Pure White Cell Aplasia

Pure white cell aplasia (PWCA) is a rare syndrome characterized by severe pyogenic infections and neutropenia. Many (70%) of these patients have an associated thymoma. In some patients, PWCA occurred years after thymoma removal. Bone marrow examination shows almost complete absence of myeloid precursors, with normal erythroid precursors and megakaryocytes. This is in contrast to T- neutropenia or Kostmann syndrome where only early myeloid precursors are seen. Marrow inhibitory activity is seen in both IgG and IgM fractions of patients serum and disappears as the marrow recovers. [587] [588] [633] [634] [635] [636] In some instances, the inhibitory activity is in lymphocyte fractions and not in the plasma. PWCA has been seen with ibuprofen therapy. In vitro serum inhibitory activity required the presence of the drug and of complement. The clinical syndrome resolved when ibuprofen was discontinued. [588] It has also been associated with chlorpropamide [637] and certain natural remedies. [638] In PWCA associated with thymomas, removal of the mass is indicated but may not be sufficient. Cytoxan, steroids, as well as cyclosporin A have been effective in treatment of PWCA, as has intravenous IgG. [639]

Neutropenia Associated with Immunologic Abnormalities

Neutropenia has been found in association with a number of immunologic abnormalities. The patients usually present in childhood with frequent bacterial infections, hepatosplenomegaly, and failure to thrive. Some of these children die in the first few years of life. Hypergammaglobulinemia or hypogammaglobulinemia, [640] [641] [642] [643] T-cell defects, [644] [645] natural killer cell abnormalities, [596] and autoimmune phenomena [646] [647] have been reported. Many of the patients had a positive family history of neutropenia. [640] [641] [642] Neutropenia is found in 26% of patients with X-linked agammaglobulinemia and 4050% of patients with X-linked hyper-IgM syndrome and has been associated with decreased marrow production of neutrophils. [643] [647] Chronic diarrhea, skin rashes, and recurrent viral infections may also be seen in these children. The treatment of these disorders depends on the constellation of immunologic abnormalities present. Some of these patients have been treated with bone marrow transplantation. [644]

It is important to distinguish these patients from the much more common syndrome of idiopathic benign neutropenia. In contrast to benign neutropenia, children with global immune defects associated with neutropenia have manifestations of recurrent or unusual infections. If the child has failure to thrive, frequent hospitalizations for pneumonia or sepsis, a full immunologic evaluation is indicated. Furthermore, live-virus vaccines must be withheld, and any blood products irradiated, until a T-cell defect has been carefully ruled out.

The majority of patients with AIDS have neutropenia as well as anemia. About 30% have thrombocytopenia. [648] Neutropenia has been seen in up to 8% of asymptomatic carriers of human immunodeficiency virus (HIV). The bone marrow is usually hypercellular and has lymphoid aggregates and plasmacytosis. There is commonly dysplastic change in the granulocytes. The neutropenia is felt to be due to ineffective hematopoiesis. The immunoglobulin fraction of HIV-positive serum inhibits CFU-GM and burst-forming unit erythroid in vitro and thus may contain antibodies to progenitors.

T- Lymphocytosis and Neutropenia

Approximately 80% of patients with T- lymphocytosis present with neutropenia during the course of evaluation for recurrent infections. [649] The median age of onset is 5565 years, although it has been seen in children. There may also be a history of rheumatoid arthritis. Splenomegaly occurs in many of the patients, although enlargement of liver or lymphandenopathy is not common. The peripheral blood shows lymphocytosis, although rarely >20,000. Most of the lymphocytes are large granular lymphocytes. The bone marrow in these disorders is normocellular, with an arrest at the myelocyte stage and an increase in lymphocytes. The lymphocytes may contain CD2, CD3, Fc, HNK-1 but lack CD5. [650] They may also show the myeloid marker M1. Natural killer cells are a subpopulation of these cells, making this syndrome of particular interest. Most patients follow a benign course for many years. The longest survival is 20 years. Patients die of progressive lymphoproliferation or of sepsis related to neutropenia. [645] [646] [650] Although the course may be relatively protracted and benign, the lymphocytosis does represent a clonal proliferation and is felt by some to be malignant. [646] [651] [652] A decrease in suppressor cell and natural killer cell activity concomitant with improvement in neutropenia after treatment with intravenous IgG [607] [627] provides support to laboratory data [479] [624] suggesting that these cells play a role in the regulation of myelopoiesis and the pathophysiology of neutropenia. Cyclosporin A has also been effective in some patients. [653]

Neutropenia Associated with Metabolic Diseases

Neutropenia can be associated with ketoacidosis in patients with hyperglycemia, hyperglycinuria, orotic aciduria, and methylmalonic aciduria. [654] [655] [656] [657]

Neutropenia is also seen commonly in association with glycogen storage disease type Ib but not with glycogen storage disease type Ia. Recurrent infections are a major source of morbidity in these patients. The degree of neutropenia is variable but commonly counts may be <500 /mm ^{3} . The bone marrow is normocellular or hypercellular. Variable functional defects have been seen in the neutrophils from these patients. [658] [659] [660] [661] Patients with glycogen storage disease Ib have been treated with G-CSF and GM-CSF.[662] Two patients with severe Crohns disease-like symptoms were greatly helped by treatment with GM-CSF.[662] [663] Interestingly, both of these patients had hypercellular marrows with no evidence of arrest. GM-CSF was required twice daily to maintain granulocyte counts, suggesting its role in promoting release of granulocytes from the marrow storage pool.

Neutropenia Due to Increased Margination

Both acute and chronic neutropenia can occur because of complement activation.[571] [572] [585] [664] [665] [666] The mechanism was first recognized in patients undergoing hemodialysis and is associated with pulmonary dysfunction.[665] [666] Generation of C5a activates neutrophils, resulting in increased adherence and aggregation, and subsequent entrapment in the pulmonary vasculature.[572] [585] Similar activation of complement and neutropenia has been found with the use of membrane oxygenators.[667] Complement-mediated neutropenia due to shifts in the neutrophil pools has also been seen with burns [481] and transfusion reactions.[571] Because

lung dysfunction and pulmonary infiltrates have been seen in some of these processes, the neutrophil has been implicated in the pathophysiology of adult respiratory distress syndrome.[481] [571] [572] However, the occurrence of this syndrome and severe neutropenia, with no neutrophilic infiltration of the lungs, suggests that mechanisms other than direct damage by neutrophils are possible.[668] Neutropenia may be related to complement-mediated destruction of neutrophils as seen in paroxysmal nocturnal hemoglobinuria[669] [670] or due to destruction of granulocyte precursors. [587] [588] [614]

Neutropenia Associated with Hypersplenism

Neutropenia can be seen in association with hypersplenism. Usually the neutropenia is not severe enough to cause symptoms, unless there is antibody present. Anemia and thrombocytopenia are usually also present. Improvement in the hypersplenism induced leukopenia in a patient with AIDS was obtained by splenic embolization.[671]

Neutropenia Associated with Nutritional Deficiency

Neutropenia has been seen in association with anemia in nutritional deficiency of vitamin B_{12} , folate, and copper.[672] [673] [674] All of these neutropenias are characterized by ineffective myelopoiesis and megaloblastic changes in the bone marrow. Similar findings have been seen in the inherited deficiency of transcobalamin II.[675] Neutropenia and megaloblastosis has also been seen in association with sideroblastic anemia in the DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, deafness). The hematologic abnormalities were responsive to thiamine. [675]

Primary Causes of Neutropenia

Ethnic or Benign Familial Neutropenia

Neutropenia has been seen in several ethnic groups and has been referred to as ethnic, pseudo, or benign familial neutropenia. The level of neutropenia is usually mild and is not associated with any increased propensity to serious infection. Benign familial leukopenia is characterized by neutrophil counts in the 2,1002,600/mm ^{3} range and no propensity to infection. The disorder has dominant inheritance and is not associated with any propensity to infection. The bone marrow is normocellular.[676] [677] Ethnic neutropenia has been seen in American blacks,[462] South African blacks,[462] [678] Yemenite Jews,[463] [678] black Bedouin, and Falasah Jews.[678] While this entity is generally benign, [679] [680] there have been reports of periodontal problems in some of these patients. [681] [682] [683]

Kostmann Syndrome (Infantile Agranulocytosis)

Severe infantile agranulocytosis was described by Kostmann in 1956. [684] This is one of several similar disorders that present in early infancy with severe, recurrent infections and neutropenia. This entity has been reported as demonstrating autosomal dominant or autosomal recessive [622] [668] types of inheritance. Bone marrow examination usually reveals myeloid hypoplasia with an arrest at the promyelocyte stage. Ultrastructural examination shows abnormalities in granule production in some patients.[668] Bone marrow culture studies generally show colony growth[599] [685] that is dependent on exogenous colony-stimulating factors. More than 95% of patients with this previously fatal disorder respond well to G-CSF. [15] [686] [687] Patients may need doses of G-CSF of 1020 g/kg/day with some requiring up to 100 g/kg/day.[15] Bone marrow transplantation should be considered in these patients, particularly if response to cytokine therapy is poor.

Myelokathexis/Neutropenia with Tetraploid Nuclei

Several patients have been described with severe recurrent infection, neutropenia, and dysmyelopoieic features. Many of these patients display neutrophil mobility abnormalities as well. [668] [688] [689] [690] Although they have been reported as separate diseases, there is considerable overlap in many of the infantile neutropenia syndromes.[668] [684] [688] [689] Although these syndromes usually present in childhood, a patient with myelokathexis presented at 34 years of age. [691]

One patient had neutrophil counts in the 100450/mm ^{3} range with biploid- and tetraploid-nucleated neutrophils, bands, and metamyelocytes in the bone marrow. All mature neutrophils, 64% of the bands, and 42% of the metamyelocytes were binucleate. In contrast, early precursors were normal, and only rare abnormal neutrophils were found in the peripheral blood. The cellularity and structure of the marrow was normal, except for the binucleate cells. This child had a history of severe recurrent infections. Chemotaxis of neutrophils obtained from the marrow was markedly decreased compared to adult control. [689]

Similar abnormalities have been found in patients with myelokathexis. One of the first reported patients had abnormal chemotaxis as assessed by the Rebuck skin window.[688] Some of these patients have nuclear abnormalities in peripheral blood neutrophils as well. Abnormalities in phagocytosis, chemotaxis, and the respiratory burst were found in another patient with multiple congenital anomalies, neutropenia, and abnormally hypersegmented neutrophil nuclei. [690] These patients have been helped by treatment with G-CSF.[15]

Cyclic Neutropenia

Cyclic neutropenia is a rare dominantly inherited disorder with variable expression characterized by neutropenia that recurs every 1535 days. The patients have associated recurrent fever, pharyngitis, stomatitis, and other bacterial infections. The severity of the infections parallels the severity of the neutropenia and can be variable from patient to patient. Although the disease tends to be benign, several patients have died of infection. [692] Most of the patients present in childhood, but there is an adult-onset form. The disorder can persist for many years but tends to decrease in severity with time. The bone marrow during times of neutropenia is usually hypoplastic with a myelocyte arrest. [692] [693] [694]

Cyclic neutropenia is felt to represent a stem cell regulatory defect. It can be cured by bone marrow transplantation in an animal model [692] and has been transferred from affected human donor to recipient during bone marrow transplantation. [695]

The disorder must be differentiated from cyclic fevers without neutropenia [696] and from other causes of neutropenia. The diagnosis is established by documentation of periodic neutropenia. This requires monitoring of the neutrophil count at least twice and preferably three times a week for 8 weeks. The nadir of the neutropenia usually lasts 35 days and can be missed if the patient is monitored less frequently than two to three times per week. To establish the diagnosis, there must be regular cyclic fluctuations in neutrophil counts with a nadir of <200/mm ^{3} with a periodicity of 1521 days. Interestingly, patients may report an increased sense of well-being as their counts recover to >500/mm^3 . [593] It is not uncommon to see patients whose neutrophil counts cycle with nadirs in the 5001,000/mm ^{3} range. These patients

usually do not have symptoms nor do they have the signs of chronic gingival infection characteristic of patients with chronic severe neutropenia. It is best to reserve the diagnosis of cyclic neutropenia for those patients with granulocyte counts that periodically fall below 200 to 300/mm ^{3} .

Patients with cyclic neutropenia as defined above almost always have, or will soon develop, severe dental, gingival, and

mucosal infection and therefore should be treated with G-CSF. Treatment should include regular and aggressive dental care. The antibacterial mouthwash, Peridex, is useful in decreasing gingivitis. [15] [593] [697] Shwachman-Diamond-Oski syndrome and T- lymphocytosis can also present with cyclic neutropenia.

Shwachman-Diamond-Oski Syndrome

The combination of neutropenia, metaphyseal dysplasia, and pancreatic insufficiency is known as Shwachman-Diamond-Oski syndrome. [698] [699] These patients present in the first 10 years of life with steatorrhea and infections. Severe or fatal infections occur in over half the patients, although many have relatively few problems with infection despite the neutropenia. Although pancreatic insufficiency is detectable by fecal fat determination or trypsin or lipase measurement, some patients have minimal problems with steatorrhea. Half the patients show moderate improvement in fat malabsorption by 58 years of age. [699] Thus, absence of a clear history of bowel problems does not rule out this diagnosis. Physical examination reveals short stature and a variety of other physical anomalies including strabismus, cleft palate, syndactyly, and microcephaly. Twenty-five percent of patients have metaphyseal dysplasia. Magnetic resonance imaging of the pancreas shows it to be normal or enlarged and has signal characteristics of fat. [700]

The neutrophil counts are usually <500/mm ^{3} . Thrombocytopenia may be present in 70% of the patients, and a mildly macrocytic, prednisone-responsive anemia is seen in 10% of patients. [698] In addition to neutropenia, a neutrophil capping and chemotactic defect is present. A partial chemotactic defect may be seen in the parents, [479] consistent with the presumed recessive inheritance. The reported functional defects have been corrected by injection with thiamine in some patients. [701] [702] The mechanism for this response is unknown. The bone marrow is usually hypoplastic, although it can be normal. Sweat chloride determination is normal.

The steatorrhea responds to pancreatic enzyme replacement and resolves by 5 or 10 years of age, although the pancreatic insufficiency remains. Treatment consists of management of infections and bleeding episodes and supplementation with pancreatic enzymes. The anemia may respond to treatment with prednisone. The neutropenia has responded to G-CSF. Because all patients do not have problems with infection, it is not necessary to treat all patients with G-CSF. However, if the patient develops any serious infection related to the neutropenia, G-CSF should be started. The overall expected survival is 50%. As with other constitutional marrow failure syndromes, there is an increased incidence of malignancy. Both lymphocytic and nonlymphocytic leukemias have been reported, [703] [704] accounting for some of the mortality seen with this syndrome.

CHS

As discussed previously, CHS is a rare inherited disorder characterized by oculocutaneous albinism, progressive neurologic impairment, and giant granules in many cells including neutrophils. The patients also develop severe neutropenia, felt to be due to ineffective granulopoiesis. [705]

Reticular Dysgenesis

A syndrome of agranulocytosis, lymphoid hypoplasia, and thymic dysplasia with normal megakaryocyte and erythroid precursors has been called reticular dysgenesis. [706] [707] These patients have low IgM and IgA, and abnormal T cells. [707] The marrow is hypoplastic with very few neutrophilic or lymphocytic precursors. The few early myeloid cells present have decreased granule formation. [707] These patients die in infancy. Early bone marrow transplantation should be considered.

Dyskeratosis Congenita

Dyskeratosis congenita is an X-linked disorder involving abnormalities of integument and usually mild neutropenia, [708] although some patients have pancytopenia. [709] [710] The marrow can be hypocellular. Some studies suggest an immunologic mechanism for the neutropenia. [709]

Other Causes of Neutropenia

Isolated neutropenia can be part of the presentation of other marrow failure syndromes such as myelodysplasia, preleukemia, Fanconi anemia, and aplastic anemia. Usually there are other characteristic features that are associated with the neutropenia.

DIAGNOSTIC APPROACH TO NEUTROPENIA

The approach to the diagnostic evaluation of a patient with neutropenia can be largely guided by the clinical history and physical examination and does not always require an extensive laboratory evaluation from the onset. If the patient is asymptomatic and has no significant history or physical findings to warrant immediate further evaluation, clinical observation is the best approach. The presence of recurrent oropharangeal infection or significant periodontal infection in the face of an ANC <500/mm^3 suggests that the neutropenia is more significant and that marrow examination should be performed. To the contrary, a patient with normal gingiva and no history of recurrent mucosal infection is less likely to have serious long-standing chronic neutropenia, regardless of the ANC. Isolated neutropenia is an unusual presentation of malignancy, so there is usually time to follow the course of the neutropenia before proceeding with an extensive evaluation. This is particularly true in young children where the most common neutropenias are benign. If the ANC is >7501,000/mm ^{3} , it is unlikely that anything will be gained by bone marrow aspiration for isolated neutropenia. If anemia, particularly normocytic or macrocytic anemia, or thrombocytopenia is present, bone marrow aspiration should be performed. If there is a recent history of a viral infection, or if the patient is on a medication known to be associated with neutropenia, several weeks of observation and discontinuation of the medication may reveal resolution of the neutropenia and avoid a bone marrow aspiration. If the neutropenia is persistent, bone marrow aspiration with biopsy, immunologic evaluation, marrow chromosomes, collagen vascular work-up and other tests may be useful in determining the cause of the neutropenia. Bone marrow culture, epinephrine stimulation test, and hydrocortisone stimulation tests are often discussed on rounds, but are of little discriminatory value, and do not alter the approach to treatment.

Based on the history plus marrow cellularity and morphology, the patient can usually be classified as having a secondary neutropenia or a primary marrow defect, and management can be determined.

In summary, asymptomatic patients with isolated neutropenia can be observed clinically for several weeks. Patients with infections attributable to their neutropenia or other clinical manifestations of serious diseases associated with neutropenia should be evaluated completely.

MANAGEMENT OF NEUTROPENIA

The clinical management of neutropenic states depends on the cause and degree of the neutropenia and on associated disease states. The major problem is management of infectious complications.

Patients with severe neutropenia and little marrow reserve tend to have acute severe infection, whereas patients with hypercellular marrows tend to have chronic infection or no infection problems at all.

Table 41-19 gives the relationship of the ANC to propensity to infection. These guidelines should be used in patients with chemotherapy-induced neutropenia and in neutropenia associated with granulocyte hypoplasia such as aplastic anemia, Kostmann syndrome, or familial severe neutropenia. These patients have no marrow

reserve and tend to have decreased marrow cellularity with an early myeloid arrest. Because these patients cannot respond to infection, many of the inflammatory signs of infection may be absent. For example, radiographs may not reveal pneumonias or there may be no abdominal tenderness with an early ruptured viscus. The organisms that cause infection come from the gastrointestinal tract or skin and can result in overwhelming sepsis very quickly. Thus, febrile patients with neutropenia related to marrow suppression should be treated immediately with broad-spectrum parenteral antibiotics. Antibiotics should be continued for several days past the end of fever. If fever and neutropenia persist more than a week, consideration should be given to the empiric use of amphotericin B. Granulocyte transfusions are effective in certain instances of culture-proven gram-negative infections. They should be used in patients with severe neutropenia with culture-proven gram-negative sepsis who have not shown a clinical response to antibiotics within 2448 hours. Enthusiasm for the use of granulocyte transfusion has waned in recent years, in part due to difficulties in procurement and in part due to better antibiotics, although there is some recent increase in interest with the availability to increase yields with G-CSF. [711] [712] Routine reverse isolation procedures are of no benefit, [713] [714] and serve to decrease contact with medical personnel. Although empiric antibiotics are clearly indicated in patients with fever, prophylactic antibiotics should not be routinely used.

Patients with late marrow arrest and normocellular marrow may be able to handle infections reasonably well. Children in whom the diagnosis of chronic benign neutropenia of infancy has been confirmed can be treated like normal children. In older patients with evidence of marrow reserve and a several month history of severe neutropenia without serious infections, less aggressive therapy may be reasonable as well. When these patients are first encountered, however, they should be treated like other patients with more severe forms of neutropenia.

All patients with chronic neutropenia should receive regular dental care. Chronic gingivitis and recurrent stomatitis can be major sources of morbidity. Antibiotic mouthwash, such as Peridex, can be very helpful in preventing gingivitis.

Until recently, therapy to increase neutrophil counts has had only variable success. Corticosteroids have been effective in some instances of immune-mediated neutropenia[566] [571] [590] as has intravenous IgG. Recombinant G-CSF has been effective in correcting neutropenia in cyclic neutropenia and severe infantile agranulocytosis and should be considered in individuals with symptoms referable to their neutropenia. [15] [601] [686] [687] [697] Bone marrow transplantation has been used successfully in certain patients with severe neutropenia and should be considered if an appropriate donor is available.

MONOCYTOPENIA AND MONOCYTOSIS

Alterations in the number of circulating monocytes are seen in a number of clinical situations (Table 41-22), although generally the disorders are less well defined than those of granulocytes. Production of monocytes is regulated by IL-3 and GM-CSF produced by T lymphocytes and M-CSF produced by endothelial cells and by monocytes themselves. IL-3 and GM-CSF selectively induce M-CSF production by monocytes, suggesting one

TABLE 41-22 -- Disorders Associated with Monocytosis

mechanism for production of the monocytosis in patients with certain chronic infections associated with enhanced T-lymphocyte activity. [715] Monocytes comprise 19% of peripheral leukocytes though the total monocyte count is higher during the first two weeks of life. [716] [717]

The blood monocyte and tissue monocyte-macrophages undoubtedly play an important role in defense against bacteria and fungal invasion; however, there is no clear association between circulating numbers of monocytes and propensity to infection as there is with granulocytes. Decreases in the number of monocytes has been seen with endotoxemia and with glucocorticoid administration. [718] Noncirculating monocytes seem to be relatively resistant to radiation and cytotoxic chemotherapy.[719]

Monocytosis is generally seen in association with chronic inflammatory processes, whether infectious or immune in nature. Monocytosis has been seen with tuberculosis,[720] subacute bacterial endocarditis, syphilis, and fever of unknown origin. [720] [721] Collagen vascular diseases such as rheumatoid arthritis, systemic lupus erythematosus, myositis, periarteritis, and temporal arteritis have been associated with monocytosis, as well as granulomatous diseases such as sarcoid, regional enteritis, and ulcerative colitis. [720] [722]

Monocytosis has been seen with several primary neutropenic syndromes including cyclic neutropenia, chronic idiopathic neutropenia, and Kostmann syndrome. [603] [676] [684] [692] An increase in monocytes usually heralds recovery from agranulocytosis.

Monocytosis is commonly seen in a number of primary hematologic malignancies. Increased promonocytes and monocytes are seen in patients with chronic and acute nonlymphocytic leukemias as well as in preleukemic states. [723] [724] [725] In many of these patients, the monocytes may be malignant but are indistinguishable from normal by light microscopy.[725] In addition to leukemia, monocytosis has been seen in both Hodgkin and non-Hodgkin lymphomas, [9] histiocytoses, as well as nonhematologic malignancies.[726] [727] [728] Monocytic leukemoid reactions have been seen in association with corticosteroids in patients with myelodysplastic syndrome.[729]

Chapter 42 - Disorders of Lymphocyte Function

Richard A. Insel
Emmanuel A. Quaidoo

INTRODUCTION

Disorders of lymphocyte function may be categorized as either primary defects or secondary to, or associated with, some underlying disorder. This chapter emphasizes primary lymphocyte defects[1] [2] [3] [4] [5] (Table 42-1) and only briefly summarizes secondary disorders,[6] many of which are detailed in other chapters of this text. The secondary immunodeficiency diseases, which include malnutrition and acquired immune deficiency syndrome (AIDS) (Chaps. 75 and 154), are far more numerous both in the United States and worldwide. Immunodeficiency secondary to Epstein-Barr virus (e.g., X-linked lymphoproliferative syndrome [XLP]) is discussed in Chapter 45 , malignancy in Part

TABLE 42-1 -- Primary Immunodeficiencies

Disorder	Inheritance	Locus	Gene Defect/Pathogenesis	Associated Features
Predominantly antibody deficiencies				
X-linked agammaglobulinemia	XL	Xq21.3-22	Defective pre-B-cell maturation 2° to abnormality of *Btk,* a B-cell-lineage cytoplasm tyrosine kinase	
Non-X-linked hyper-lgM syndrome	AR,?		Defective B-cell activation 2° to abnormal CD40 expression, function, or signaling	Autoimmune hematologic diseases (neutropenia, thrombocytopenia, hemolytic anemia)
Common variable immunodeficiency (predominant antibody deficiency, predominant cell-mediated immunity defect)	AR,AD,?	?6p21.3	Defect of B-cell maturation/differentiation with intrinsic B-cell defect, decreased B-cell numbers, defective T-helper cell function, antibodies to B cells, or augmented suppressor function	Autoimmunity, malignancy
Ig heavy chain deletion	AR	14q32.3	Chromosomal deletion at Ig heavy chain gene locus	
heavy chain deficiency (autosomal recessive agammaglobulinemia)	AR	14q32.3	Defective pre-B-cell maturation 2° to failure of heavy chain expression	
chain deficiency	AR	2p11	Point mutation at light chain gene locus	
Selective deficiency of IgG subclasses with or without IgA deficiency	?	?	Defects of isotype differentiation	
IgA deficiency	XL,AR,?	?6p21.3	Failure of deletional isotype switching to and terminal differentiaion of IgA-secreting B cells	Autoimmunity, allergy
Antibody deficiency with normal Ig	?	?	?	
Combined immunodeficiencies				
Severe combined immunodeficiency (SCID)				
T B + SCID				
X-linked ($_c$ deficiency)	XL	Xq13.1-13.3	Defect of T lymphocyte and NK cell development 2° to mutation of common chain ($_c$) of IL-2,4,7,9, and 15 receptors.	
JAK3 deficiency	AR	19p13.1	Mutations in Janus associated kinase 3 (JAK3), signaling molecule for $_c$, phenotype identical to X-SCID	
T B SCID				
RAG1/RAG2 deficiency	AR	11p12-13	Maturation defect of both T- and B-cell development 2° to absence of antigen receptor gene recombination from mutations of RAG1 and/or RAG2 recombinase proteins	
Adenosine deaminase (ADA) deficiency	AR	20q13-ter	Defect of T- and B-cell development 2° to toxic metabolites due to ADA deficiency	Cartilage abnormalities in some
Autosomal-SCID variants	AR	?	Maturation defect of both T- and B-cell development, etiology unknown	
Reticular dysgenesis	AR	?	Stem cell defect affecting maturation of lymphoid and myeloid cells	Pancytopenia
MHC class II deficiency	AR	16p13.1-13.2, 1q21,13q,?	Mutation of transcription factors [CIITA (group A), RFX5 (group C), RFXAP (group D), RFX? (group B)] for MHC class II molecules	Diarrhea, severe viral infections
Purine nucleoside phosphorylase (PNP) deficiency	AR	14q13.1	Defect of T-cell development and function 2° to toxic metabolites due to deficiency of PNP	Anemia, neurologic symptoms

X-linked hyper-IgM syndrome	XL	Xq26-27	Defective B-cell activation and T-cell function due to abnormal CD40 ligand expression on activated T cells	Autoimmune hematologic diseases (neutropenia, thrombocytopenia, hemolytic anemia)
T-cell activation defects				
CD3 or CD3epsilon deficiency	AR		Defective CD3 or CD3epsilon transcription	
Defective response to cytokines or expression of cytokine receptors	?		Defect of IL-2, IL-2 receptor, IL-2 signaling	
ZAP-70 deficiency (CD8 T-cell deficiency)	AR	2q12	Mutations in ZAP-70 kinase gene required for TCR signaling	
TAP2 deficiency	AR	6p21.3	Mutation in TAP2 translocator gene affects MHC class I expression	
Other immunodeficiencies				
Wiskott-Aldrich syndrome	XL	Xp11.22-11.3	Defect of cytoskeletal expressed WASP gene	Thrombocytopenia, small platelets, eczema, malignancies, autoimmunity
Ataxia-telangiectasia	AR	11q23.1	Disorder of cell cycle checkpoint pathway and cellular responses to DNA damage 2° to mutation of *ATM* gene	Ataxia-telangiectasia, malignancies, radiation sensitivity
3rd and 4th pharyngeal pouch/arch syndrome (DiGeorge anomaly)	AR,?	22q11.21-11.23	Embryopathy with thymic hypoplasia or aplasia 2° to deletion or unbalanced translocation of chromosome 22	Hypoparathyroidism, abnormalities of cardiac outflow tract, and abnormal facies (CATCH22)

Figure 42-1 Immunodeficiency diseases associated with maturation of T and B lymphocytes.

IV, Hematologic Malignancies, bone marrow transplantation in Part VII, and the autoimmune lymphoproliferative syndrome secondary to defects in Fas-mediated apoptosis in lymphocytes in Chapter 66 .

The primary defects arise from abnormalities in development, maturation, or function of cells of the immune system, and can be divided into those giving rise to immunodeficiency diseases primarily involving antibody production and those that have combined defects in both antibody production and T-lymphocyte function (Table 42-1). Excluding immunoglobulin (Ig) A deficiency, primary immunodeficiency disorders have a prevalence of approximately 1/10,000 and most commonly present in the first 6 years of life. The immunodeficiency diseases are characterized by an increased frequency or severity of infections or infections with unusual, relatively avirulent opportunistic organisms. Antibody deficiency diseases, which are more common than T-cell disorders, are most frequently characterized by recurrent pyogenic infections. T-cell deficiency is associated with difficulty in handling opportunistic infections and intracellular pathogensviral, fungal, or parasitic infectionson the basis of abnormal T-cell function, as well as pyogenic bacteria, because of impaired production of antibody by lymphocytes due to the T-cell deficiency. Diarrhea and malabsorption, autoimmune disorders, and malignancies frequently occur in primary immunodeficiency diseases. The majority of malignancies are observed in patients with ataxia-telangiectasia, Wiskott-Aldrich syndrome, common variable immunodeficiency, and the hyper-IgM syndrome. [7] [8] [9]

The immunodeficiency diseases reflect defects of lymphocyte development along a maturational pathway, detailed in Chapters 8 and 9 and shown in Figure 42-1 , or in the function and cooperative interaction of mature lymphoid cells, as described in Chapter 10 and shown in Figure 42-2 . Primary defects of lymphocyte function are usually inherited, and the molecular basis for many of these disorders has been described.

ANTIBODY DEFICIENCIES

X-Linked Agammaglobulinemia

Etiology and Pathophysiology

The defect in X-linked agammaglobulinemia (XLA) is characterized by the failure of mature B cells to develop from precursor B cells or so-called pre-B cells. Mature B cells are absent or markedly decreased in the peripheral blood, plasma cells are absent in lymphoid tissues, and functional antibody is not produced. [10] [11] [12] Pre-B cells, CD34-CD19+ cells that express intracytoplasmic IgM heavy chain (C) but not light chain or surface

Figure 42-2 Receptorligand interactions of T and B lymphocytes.

immunoglobulin (sIg), are in low-normal numbers or absent in the bone marrow.[13] When pre-B cells are present in XLA, a smaller proportion are proliferating than from healthy subjects. In contrast, pro-B cells (C , TdT+, CD19+, CD10+) are present in normal numbers, suggesting a block at the C+ pre-B-cell stage of B-cell development (Fig. 42-2). Rare B cells can be detected in the circulation of patients and, when present, have an immature surface phenotype with a high ratio of surface IgM to IgD and low levels of human leukocyte antigen (HLA) class II gene products. [14] Occasionally, circulating mature B cells and serum IgG levels higher than observed in typical XLA are detected in patients, but deficiency of antibody production usually persists. [15]

The gene defect in XLA is intrinsic to the B cell, maps to Xq21.3-q22, and affects gene expression of the B-cell specific, 77 kDa, cytoplasmic protein Bruton tyrosine kinase (*Btk*), named after the discoverer of human agammaglobulinemia.[10] [11] [12] [16] [17] This Tec-family tyrosine kinase is involved in signal transduction from sIg and other B-cell receptors (e.g., interleukin [IL]-5, IL-10). At least 175 unique genetic events involving all five domains of *Btk* have been shown to give rise to XLA.[18] The most common mutation is a missense mutation at CpG dinucleotides, and the most common domain targeted for mutation is the kinase domain of *Btk.* A direct correlation between clinical phenotype and specific *Btk* mutations does not exist, and phenotypic differences can be observed even among males in a single kindred. The role of *Btk* in signal transduction from a pre-B-cell receptor (IgM heavy chain with surrogate light chain) or other receptors, the substrates phosphorylated by *Btk,* and the mechanism(s) of inhibition of pre-B-cell maturation with *Btk* gene defects are being defined. In female carriers of XLA, only the normal X chromosome and not the XLA-affected X chromosome encoding the defective *Btk* is used as the active X chromosome in B cells. This is believed to be secondary to decreased proliferation or survival of cells expressing the XLA gene. [15] [19]

Non-X-Linked Agammaglobulinemia

Rare disorders of absent B cells and panhypogammaglobulinemia that resemble XLA but are autosomal recessively inherited have been described. [20] Patients with one form express a structural defect in the m heavy chain gene (C deficiency) that inhibits production and expression of membrane m heavy chain and leads to failure of B-cell development[20] (Fig. 42-2). Another gene defect that gives rise to a similar clinical picture is deficiency of human 5/14.1, [21] a component of the pre-B-cell receptor complex that consists of a rearranged m heavy chain, a surrogate light chain composed of 5/14.1 and V pre-B, and the Ig association signal transducing chains Ig and Ig. These patients illustrate the essential requirement for expression of B-cell surface Ig or a pre-B-cell receptor for early B-cell-differentiation beyond the pre-B-cell stage to the stage of mature B cells.

Another non-X-linked or autosomal recessive form of agammaglobulinemia of unknown etiology is characterized by an arrest of B-cell development at the CD34+CD10+ pre-B-cell compartment, with complete absence of pre-B cells in the bone marrow and mature B cells in the periphery. [22]

Clinical Manifestations

Affected boys with XLA have the onset of recurrent pyogenic infections during the latter half of the first year of life as maternal antibody titers wane. The clinical presentation includes chronic or recurrent otitis media, sinusitis, conjunctivitis, pneumonia, or pyoderma. [23] Infections occur at more than one anatomic site, and are usually caused by pyogenic bacteria such as *Streptococcus pneumoniae, Streptococcus pyogenes,* and *Hemophilus influenzae.* On physical examination, patients with XLA are found to have a paucity of tonsils, adenoids, and peripheral lymph nodes. Mono- or oligoarticular arthritis of large joints with sterile effusions caused by infections with an enterovirus or a nonpathogenic commensal *Mycoplasma* strain such as *Urea-plasma urealyticum* may be the presenting problem.[24] Diarrhea from infection with such organisms as *Giardia lamblia* or rotavirus commonly occurs. Vaccine-associated poliomyelitis is a potential complication caused by the persistence and mutation of the attenuated live poliovirus vaccine strain into a virulent neurotropic form. [25] Before institution of therapy with Ig replacement therapy, neutropenia often occurs during infection. Leukemia and lymphoma occur with increased frequency. There may be a family history of death from infection at an early age in maternal male relatives.

Infectious diseases can cause significant morbidity. Chronic infections of the upper and lower respiratory tract with otitis media, pneumonitis, and sinusitis may occur in spite of Ig replacement therapy. In the past, chronic pulmonary disease has been described in almost half of XLA patients and hearing loss, as a result of chronic otitis media or meningoencephalitis, in about one third of patients. [23] Chronic, disseminated enteroviral infection, usually from echovirus, is a potentially fatal complication and may be associated with meningoencephalitis, hepatitis, pneumonitis, or vasculitis, as well as with a dermatomyositis-like syndrome with rash, brawny edema of the subcutaneous tissues, and muscle weakness.[26] [27] These complications, as well as other serious infections, have accounted for a mortality rate of about 15% by the age of 20 years in the past.[23] In recent times, however, earlier diagnosis and more effective Ig replacement therapy, by the intravenous rather than the intramuscular route, has decreased the morbidity and mortality rate.

Laboratory Evaluation

Absent antibody responses after immunization or natural antigenic exposure, low levels of serum Ig, and absence or very low levels of peripheral blood B lymphocytes are characteristic of the disease. The IgG level is usually <100 mg/dl, but exceptions occur. The other Ig isotypes are usually low or absent. Rarely, some patients have a milder form of disease with some antibody production and a low number of B cells. T-lymphocyte

numbers and function are intact. Neutropenia, secondary to infection and release of endotoxin, accompanied by a maturation arrest in the bone marrow, frequently occurs as a presenting feature.[28] Lymph nodes show an absence of plasma cells, lymphoid follicles, and germinal centers. Definitive diagnosis, prenatal diagnosis, and diagnosis of the carrier state can be performed by genetic analysis.

Therapy

Immunoglobulin replacement therapy is the mainstay of treatment and should be started once the diagnosis is made, preferably

THE EVALUATION OF SUSPECTED IMMUNODEFICIENCY

Laboratory studies should be used to confirm a diagnosis of an immunodeficiency disease after performing a thorough history and physical examination to exclude a localized anatomic or physiologic defect that may be predisposing to recurrent infections. An immunodeficiency should be suspected with the occurrence of infections of unusual frequency, type, or severity. Recurrent infections may occur at multiple sites, and infection may be caused by unusual or opportunistic organisms such as *Pneumocystis carinii, Candida, Mycobacterium avium, Pseudomonas, Serratia,* and cytomegalovirus. There is often a lack of history of exposure, excessive severity or complications of infections, and poor response to treatment. With immunodeficiency diseases, organisms may disseminate more widely, multiply to greater numbers, or remain alive in phagocytes. Patients with immunodeficiency diseases often fail to recover to normal health between individual infections, and may have weight loss or poor weight gain. Autoimmune diseases may accompany antibody deficiency states.

Recurrent pyogenic infections such as otitis media, sinusitis, pneumonia, meningitis, arthritis, osteomyelitis from encapsulated bacteria (e.g., *Streptococcus pneumoniae, Hemophilus influenzae* b, *Neisseria meningitidis, Staphylococcus aureus*) suggest a deficiency of antibody or, less commonly, an abnormality of white blood cells or serum complement. Low numbers or poor function of polymorphonuclear white blood cells is also commonly associated with abscesses and infections with nonencapsulated, nonpathogenic bacteria that reside at the skin or mucosal surfaces. Recurrent infections from viruses, fungi, or intracellular bacteria suggest a deficiency of T-cell function. Infection with *P. carinii* suggests T-cell deficiency. Combined deficiency of T- and B-cell function is characterized by infections with bacteria or viruses. Recurrent systemic *Neisseria* infections suggest deficiency of a terminal complement component. Antibody deficiency in the young child does not predispose to infections until the latter half of the first year of life due to the passive protection provided by maternal antibody. T-cell immunity, however, is not present at birth.

Laboratory evaluation should initially be directed to the type of deficiency suspected on the basis of the history and physical examination. Studies should begin with less expensive and more readily available tests. Results must be compared to age-related normal values. Examination of the complete blood count and peripheral blood smear may suggest the diagnosis. Live viral immunization should be withheld, and blood products should be irradiated before administration, to prevent graft-versus-host disease in patients with suspected T-cell deficiency.

before repetitive infections have caused irreversible pulmonary damage. [29] [30] [31] Intravenous Ig should be employed to provide high doses of Ig replacement. The higher levels of IgG provided by intravenous Ig can prevent chronic pulmonary disease and chronic enteroviral meningoencephalitis, but the latter has been described even with intravenous therapy. Pyogenic infections should be treated vigorously with antibiotics to prevent organ damage. Chronic or recurrent infection of the upper and lower respiratory tracts may require continuous prophylactic antibiotic therapy.

Patients with persistent enteroviral infections have been treated successfully with Ig preparations containing high titers of antibody specific for the infecting enterovirus.[26] [32] For the treatment of enteroviral meningoencephalitis, high titer antibodies specific for the infecting virus may need to be administered directly into the ventricles of the brain to obtain sufficiently high levels at that site, [33] but even with this therapeutic approach, infections have not always been cleared. [27] Novel antiviral therapies for enteroviral infections are in development and should be considered for this complication.

Common Variable Immunodeficiency

Etiology and Pathophysiology

Common variable immunodeficiency (CVI), the most common symptomatic primary antibody deficiency syndrome, includes a group of heterogeneous disorders associated with recurrent infections, poor antibody responses, and hypogammaglobulinemia. [34] [35] [36] [37] CVI includes both congenital and acquired defects with variable ages of onset, clinical symptoms, immunologic defects, and underlying basic defects. Both sexes are affected, with the usual age of presentation in either the first 5 years or the second or third decade of life.

Occasionally, the disorder is familial, with or without a clear-cut pattern of inheritance. Offspring and first-degree relatives may have selective IgA deficiency or autoimmune diseases such as systemic lupus erythematosus (SLE), hemolytic anemia, or idiopathic thrombocytopenic purpura (ITP). [38] [39] In some families, CVI is observed in the parent and IgA deficiency in the children with suggestion of dominant transmission without linkage to the major histocompatibility complex (MHC). [40] A CVI susceptibility gene has been proposed to lie within, or near, the MHC class III region on chromosome 6. This is based on common expression of particular extended haplotypes with deletions in the complement C_4 locus in patients with either CVI or IgA deficiency, suggesting a common genetic predisposition underlying both disorders.[41] [42] [43] Viral infections, including congenital rubella and EBV, have been incriminated in the etiology of some instances of CVI. In contrast, human immunodeficiency virus (HIV) and hepatitis virus infections have been reported to restore IgG and antibody production in some patients with CVI. [44] [45] [46]

Although the exact nature of the defect(s) that give rise to CVI are unknown, a number of immunologic abnormalities have been described. [37] [47] [48] [49] Most patients with CVI have normal numbers of mature B cells that fail to differentiate into antibody-secreting cells. Failure of in vivo B-cell maturation and differentiation is usually thought to be primarily due to defective interactions between T and B cells. Both intrinsic B-cell defects and T-cell abnormalities have been described, but the current thinking is that the abnormal interaction between T and B cells is usually caused by a T-cell defect.

The B cells in CVI may express an immature surface phenotype, with surface IgG-bearing cells in CVI more commonly coexpressing surface IgM than B cells from normal controls.[50] [51] Intrinsic B-cell defects include failure to proliferate or secrete one or more immunoglobulin isotypes, most often IgG or IgA, with appropriate

stimuli. CVI has been classified into subgroups

based on defects of CVI B cells in secreting IgM, IgG, or IgA on stimulation with various polyclonal activators (anti-IgM with IL-2, Epstein-Barr virus [EBV], anti-CD40 with IL-4 or IL-10).[47] [52] [53] [54] [55] [56] In part, these in vitro defects reflect defective in vivo deletional isotype switching to the respective Ig heavy chains.

Defects of CD4 T lymphocytes have been incriminated as the primary defect in CVI. The majority of patients have normal numbers of T-cell subsets, but a subgroup of CVI patients have increased CD8+ T cells and decreased CD4+ T cells. Some patients show a functional T-cell defect with abnormal signal transduction after activation through the T-cell receptor (TCR)CD3 complex with decreased production or expression of second messengers, [57] intracellular protein tyrosine kinases, [58] cytokines IL-2, IL-4, IL-5, -interferon (IFN), [37] [48] [59] [60] and cell surface CD40 ligand.[61] [62] These defects obviously may contribute to defective interactions between T and B cells. An in vivo correlate of these in vitro findings is the presence, in CVI patients, of a profound decrease in the number of antigen-specific T cells that are induced in vivo after immunization.[63] Rarely, circulating antilymphocyte antibodies, inhibitors or cytokines, or suppressor lymphocytes that block in vivo B-cell activation and differentiation have been demonstrated in CVI patients. [64]

Clinical Manifestations

Common variable immunodeficiency occurs in both sexes, with a variable clinical spectrum and an age of onset varying from childhood to late adulthood. Recurrent pyogenic infections with otitis media, sinusitis, bronchitis, and pneumonia, often from pneumococci, staphylococci, *H. influenzae*, or *Mycoplasma pneumoniae*, occur.[34] [35] [36] [37] [65] [66] [67] Bronchiectasis is a frequent complication and may even be the presenting abnormality. Cor pulmonale and respiratory failure on the basis of chronic lung disease are common causes of death. In contrast to XLA, lymphoid tissue is normal or enlarged as a result of B-cell proliferation and prominent germinal center formation. Splenomegaly, secondary to reactive follicular hyperplasia, occurs in approximately 25% of patients and may be associated with neutropenia and thrombocytopenia from hypersplenism. Noncaseating granulomas, resembling sarcoidosis, in the spleen, liver, or lung may be found. Arthritis and arthralgia are common. Gastrointestinal abnormalities with chronic gastritis and achlorhydria, diarrhea, a spruelike syndrome with malabsorption, lactose deficiency, or protein-losing enteropathy may complicate the clinical course. [68] [69] *G. lamblia* or *Campylobacter* infection of the gastrointestinal tract may contribute to these symptoms. Pernicious anemia develops in some patients because of atrophic gastritis and absence of intrinsic factor. Hepatitis may develop. Reactivation of varicella zoster and recurrent herpes simplex infection occur commonly. Autoimmune diseases, including autoimmune hemolytic anemia, thrombocytopenia or neutropenia, rheumatoid arthritis, SLE, chronic active hepatitis, or thyroiditis, are seen frequently.

There is overall a 5-fold increase in the incidence of cancer, with a 47-fold increase in gastric cancer and a 30-fold increase in lymphoma. [7] [8] [9] [70] [71] This increased incidence of gastric cancer may be related to the high frequency of achlorhydria and atrophic gastritis in CVI. [72] A nonmalignant lymphoproliferation with follicular hyperplasia of lymph nodes or nodular lymphoid hyperplasia of the intestine and splenomegaly may also occur and must be distinguished from a malignancy. [73]

Laboratory Evaluation

Serum immunoglobulins, especially IgG and IgA, are decreased and antibody responses are impaired. The peripheral blood B-cell number is normal in about 75% of patients, but the surface phenotype may be immature, and the cells of some patients fail to differentiate to antibody-secreting cells after appropriate stimuli. If a low number of B cells are detected in a male with a presumed diagnosis of CVI, atypical XLA must be excluded. T-cell numbers may be decreased and a reversal of the helper/suppressor (CD4/CD8) T-cell ratio may be present, usually secondary to an increase in CD8+ T cells. Some patients have an expanded number of activated CD8+CD57+CD25+HLA-DR+ circulating T cells.[48] [74] Depressed T-cell function and absent delayed hypersensitivity skin test reactivity may be found, especially in older patients and patients with lymphopenia. As described above, CD40 ligand expression of T cells activated in vitro may be abnormal.

Therapy

Immunoglobulin replacement and aggressive antibiotic therapy are indicated. [29] [30] [31] After Ig replacement therapy is instituted, pulmonary radiographic and functional changes may stabilize. Serial pulmonary function tests need to be performed. Acute infections, however, may still occur with Ig replacement therapy and necessitate the prolonged use of antibiotics to prevent deterioration of lung function. In the face of chronic lung disease and bronchitis, some patients require doses of Ig replacement higher (600 mg/kg or higher) than commonly used to prevent acute lung exacerbations. [75] Parenteral therapy with vitamin B_{12} is required for pernicious anemia. Therapy with IL-2 has been used experimentally in a limited number of patients, with some improvement of in vitro lymphocyte function. [76]

Selective IgA Deficiency

Etiology and Pathogenesis

Deficiency of serum IgA, defined as a serum IgA concentration <5 mg/dl, is found in approximately 1 in 600 individuals of northern European ancestry. [77] [78] Most of these individuals are asymptomatic, but some patients suffer recurrent sinopulmonary infections, autoimmunity, or allergies. [79] [80] [81] [82] The latter two symptoms may occur in some patients on the basis of either absorption of environmental and dietary antigens into the systemic circulation due to the lack of secretary IgA at mucosal surfaces, or an underlying broader immunologic defect with poor regulation of autoantibody production due to common susceptibility genes in IgA deficiency and autoimmunity.

IgA deficiency may be primary or secondary and can occur in a sporadic form or with an autosomal dominant or recessive pattern of inheritance. [77] [78] [83] IgA deficiency or CVI may be found in extended families with evidence of linkage or nonlinkage to the MHC locus. [39] [40] [41] [42] As described under CVI, an autosomal dominant inheritance pattern has been observed in families. [40] An increased frequency of particular fixed MHC haplotypes, so-called supratypes reflecting conserved ancestral haplotypes, has been associated with IgA deficiency. An important locus for regulation of IgA production may exist in the MHC class III gene cluster, [41] [42] an 1,100 kb region of DNA located between the class I and II gene clusters that encodes heat shock proteins, tumor necrosis factor (TNF)-, lymphotoxin and , complement proteins C2, C4, and factor B, and the 21-hydroxylase steroid-biosynthesis gene. An MHC class II susceptibility gene for IgA deficiency has also been suggested.[84] These putative MHC gene(s) may be necessary, but not sufficient, for the development of the immunodeficiency, and may also increase susceptibility to the autoimmune diseases observed in IgA deficiency.

Congenital infections with rubella, cytomegalovirus, or *Toxoplasma gondii* and acquired EBV infection have been associated with IgA deficiency. IgA deficiency may also occur after use of drugs such as penicillamine, phenytoins, sodium aurothiomalate, captopril, sulfasalazine, or antimalarial agents. [77] [78] IgA deficiency can be transitory in children, especially when the serum

IgA is only moderately decreased, but in adults the deficiency is usually permanent. [85] [86]

Most patients lack both serum and secretory IgA and have a deficiency of both the IgA1 and IgA2 subclasses. Patients with IgA deficiency who lack serum IgA but express IgA2 secretory plasma cells in the gastrointestinal tract have been described. Rarely, IgA deficiency is associated with a deficiency of the secretory component, the protein that is required for secretion of IgA into the mucosa. The susceptibility to infection in IgA deficiency may be secondary, not to IgA deficiency per se, but to a concomitant deficiency of IgG2 and IgG4 subclass immunoglobulins. [81] [87] [88] [89] Thus, IgA deficiency, in some patients, may represent a manifestation of a more widely based immunologic defect with similarities to CVI, which also is an arrest in B-cell differentiation. As noted previously, CVI also occurs in family members and shares MHC haplotypes with IgA deficiency. IgA deficiency may in fact evolve into CVI, and is also frequently found in ataxia-telangiectasia, which is also associated with T-cell abnormalities and IgG subclass deficiency.

IgA deficiency is usually associated with intact structural IgA immunoglobulin heavy chain genes. Surface IgA-bearing B cells are present in normal or reduced numbers, and the cells may display an immature phenotype with coexpression of surface IgM in some patients. [90] The primary defect appears to be failure of B cells to differentiate to mature isotype-switched surface IgA-positive B cells and IgA-secreting plasma cells with appropriate stimuli. [77] [78] [91] The basis for the defect is not

known. B cells from patients with IgA deficiency activated via CD40 and IL-10 are capable of synthesizing and secreting IgA. [92] Defective in vitro T-helper cells and excessive suppressor T-cell activity for IgA production are rarely present. The possibility that cytokines that favor isotype switching to IgA are abnormal has been explored. Normal levels of transforming growth factor (TGF)-1 in RNA were detected in mononuclear cells, [93] although decreased serum levels of TGF-1 were observed in some patients.[94]

Clinical Manifestations

The majority of individuals with IgA deficiency are healthy, but many have variable clinical symptoms, and IgA deficiency patients, asymptomatic when young, may develop symptoms in later life.[77] [78] [79] [80] [81] [82] An increased frequency of upper and lower respiratory tract infections occurs. Infections occur more commonly when low levels of IgA occur with a deficiency in IgG subclasses and with decreased levels of antipneumococcal polysaccharide antibodies. [87] [88] [89] Some patients have recurrent bacterial infections with recurrent sinusitis, otitis media, bronchitis, and even bronchiectasis. There is an increased incidence of autoimmune diseases, especially rheumatoid arthritis and SLE.[95] Other autoimmune diseases may be observed, and autoantibodies may be present without symptoms. Allergic diseases, including rhinitis, urticaria, eczema, and asthma, occur with increased frequency. Gastrointestinal and hepatic complications associated with IgA deficiency include malabsorption, celiac disease, giardiasis, nodular lymphoid hyperplasia, pernicious anemia, atrophic gastritis, primary biliary cirrhosis, and chronic active hepatitis. Gastric and colon carcinoma are found with increased frequency. Production of antibodies to food antigens, such as cows milk, may cause immune complexes that may be pathogenic.

Laboratory Evaluation

The serum concentration of IgA is <5mg/dl, and the levels of IgG and IgM are normal. Secretory IgA is also decreased. Approximately 25% of patients have decreased levels of IgE. Some patients, especially those with recurrent sinopulmonary infections, have a concomitant deficiency of IgG2 and IgG4 subclasses or defective antibody responses to polysaccharides. IgA and IgG levels should be repeated after a period of time to determine whether the deficiency of IgA is persistent, or whether the immunologic disorder has become more extensive and has begun to resemble CVI. An increased incidence of autoantibodies directed against nuclear proteins; immunoglobulins; thyroglobulin; or adrenal, parietal, smooth muscle, or pancreatic cells; or antibodies to food antigens, such as cows milk protein, is found. Serum antibodies to IgA occur in >20% of patients with IgA deficiency, especially those with severe IgA deficiency, but are not predictive of adverse reactions to blood products containing IgA. Exposure to blood products with IgA may, however, induce IgE anti-IgA antibodies that can cause anaphylactic reactions. [96]

Therapy

Treatment should be directed at the associated infections and allergic, autoimmune, and gastrointestinal diseases. Precipitating drugs should be discontinued. Antibiotic therapy is indicated for bacterial infections. If infections are severe or cause significant sequelae, prophylactic antibiotics should be considered. Ig replacement therapy is not usually indicated for IgA deficiency. Severe or fatal anaphylactic reactions can occur with the intravenous administration of IgA-containing blood products to IgA-deficient patients. [96] This may be caused by anti-IgA antibody of the IgE isotype, which may increase after Ig replacement therapy. Some patients with anaphylactic reactions to IgA and with severe, recurrent infections and concomitant deficiency of IgG subclasses and antibody production, however, benefit clinically from treatment with intravenous replacement therapy with Ig preparations containing low levels of IgA. [97] Blood products should be washed prior to transfusing IgA-deficient individuals or obtained from IgA-deficient donors, including the recipient, prior to surgery. Plasma for transfusion should be collected from IgA-deficient individuals. Oral administration of gamma globulin has improved chronic diarrhea in some patients.

Selective Deficiency of Immunoglobulin Isotypes

Selective deficiency of an immunoglobulin isotype is not usually associated with structural gene abnormalities. Rarely, deletions of the Ig constant region genes have been described and may involve several or single constant region gene segments. [98] Most of the patients with these partial deletions, however, are usually healthy.

Selective IgM deficiency is a rare immunodeficiency disorder characterized by a low level of serum IgM and severe or life-threatening, recurrent infections. [99] Pneumococcal and meningococcal sepsis or meningitis may occur. IgM antibodies are not produced and IgG antibody responses are usually decreased, although the IgG level is normal. Defects of T-cell helper and excessive suppressor T-cell activity have been described. Some of these patients subsequently develop CVI.

Absence of either or light chains associated with hypogammaglobulinemia or IgA deficiency and recurrent respiratory tract infections, pernicious anemia, diarrhea, or malabsorption have rarely been reported. In one patient with light chain deficiency, there was a point mutation in the Ck gene involving amino acid residues that are required for the formation of intrachain disulfide bonds and protein folding. [100]

IgG Subclass Deficiency and Selective Antibody Deficiency with Normal Immunoglobulins

Recurrent upper and lower respiratory tract bacterial infections, sinusitis, and otitis media may occur in patients with low levels of an IgG subclass. [101] The most common symptomatic IgG subclass

IMMUNOGLOBULIN REPLACEMENT THERAPY

Replacement therapy with gammaglobulins or immunoglobulins is indicated for patients with recurrent infections who have defects in antibody production. It can be life-saving, and prevent recurrent infections and progressive lung damage. The cost of immunoglobulin replacement therapy is high, however, so it should not be used indiscriminately. Ideally, antibody titers before and after immunization with protein and polysaccharide antigens should be evaluated to assess the need for replacement therapy (see Table 42-1). Usual indications include X-linked agammaglobulinemia, common variable immunodeficiency, severe combined immunodeficiency disease, hyper-IgM syndrome, and the Wiskott-Aldrich syndrome. Replacement therapy should not be given to patients with IgG subclass deficiency unless they have been shown to have a deficiency of antibody production and have failed antibiotic prophylaxis. IgG replacement therapy is not usually indicated for isolated IgA deficiency, but some patients with IgA deficiency with concomitant deficiency of IgG antibody production and severe, recurrent infections have benefitted from replacement therapy. Patients with IgA deficiency may develop anti-IgA antibodies of the IgE isotype that can cause severe or fatal anaphylactic reactions with the intravenous administration of IgA-containing blood products. Immunoglobulin replacement therapy with immunoglobulin preparations containing low levels of IgA that are administered by the intravenous or subcutaneous route have been used successfully in these patients.

Development of safe intravenous gammaglobulin formulations allows high doses to be given without the pain, side effects, and tissue loss experienced with intramuscular gammaglobulin replacement. There are multiple intravenous immunoglobulin (IVIG) preparations approved by the Food and Drug Administration (FDA). All preparations are safe, contain predominantly IgG1 and IgG2, have roughly comparable and consistent IgG antibody titers, and are generally therapeutically equivalent. The FDA-licensed immunoglobulin preparations do not carry a risk of transmitting the human immunodeficiency virus. Patients vary in their half-life of administered IgG. The optimal amount and frequency of infusion of immunoglobulin and the serum level of IgG to be achieved need to be individualized to render the patient asymptomatic from recurrent infections, but it is recommended that a trough serum level be attained before the next injection at least 200400 mg/dl higher than the pretherapy level or >500 mg/dl. An initial IgG dose of 400 mg/kg is usually given, followed by administration of a similar dose 37 days later, and then monthly. Trough levels should be checked bimonthly for the first 8 months, and then every 6 months. This dose will result in a steady-state level after 48 months with trough levels >500 mg/dl. In general, a dose of 100 mg/kg of IVIG will increase the IgG peak by 200300 mg/dl and trough levels by 100 mg/dl (28 days postinfusion). Higher doses (600 mg/kg or greater) of IVIG may be required to prevent infections in some patients, and may prove better at preventing acute infections or exacerbations in patients with chronic pulmonary disease. If patients complain of fatigue, upper respiratory infections, or conjunctivitis during the week before the next infusion, or if intercurrent infections occur, the frequency of infusion or the dose should be increased to raise the trough serum level to >500 mg/dl. During intercurrent infections, extra infusions are required because of increases in the catabolic rate of the passively provided immunoglobulin. Home infusion therapy is now being practiced widely. Subcutaneous infusion of immunoglobulins is an alternative to intravenous infusions, with a low frequency of systemic adverse reactions.

Intramuscular gammaglobulin (16% solution of Cohn fraction II) may still be useful in small infants in whom chronic complications of infections have not occurred, and there is difficulty with access to a center where IVIG can be administered. Contraindications to intramuscular gammaglobulin include thrombocytopenia, inadequate muscle mass, and poor control of infections. A dose of 100 mg/kg/month is given after loading the patient with the same dose administered three times over a 1- to 2-week period. Intramuscular preparations can never be administered intravenously.

Adverse reactions to IVIG administration include flushing, chest tightness, flank or abdominal pain, nausea and vomiting, chills, fever, headache, myalgias, dyspnea, diaphoresis, or hypotension. These reactions can usually be controlled by decreasing the infusion rate. In general, reactions are more common with the first infused dose, and in the presence of an intercurrent infection. In these situations, infusions should be slower. Repeated, severe reactions not responding to a decrease in the rate or volume of the infusion may, in some individuals, be averted by pretreatment 1 hour before IVIG with aspirin or acetaminophen, antihistamines, or steroids. Rarely, anaphylactic reactions may occur. Anaphylactic reactions require stopping the infusion and immediate administration of epinephrine, steroids, and antihistamines, together with respiratory and circulatory support. Anaphylactic reactions are rarely caused by production of IgE antibodies to IgA in patients with IgA deficiency or those with common variable immunodeficiency with absent IgA. Anti-IgA antibodies should be quantitated following an anaphylactic reaction and, if present, IVIG preparations with low levels of IgA should be used and the subcutaneous route considered.

deficiency in childhood is IgG2 subclass deficiency, a subclass that represents approximately 2025% of the total IgG. IgG2 subclass deficiency may occur alone or with concomitant IgG4 subclass or IgA deficiency[101] [102] and can be associated with the inability to generate antibodies to polysaccharides. [88] [89] [103] The clinical picture of IgG2 subclass deficiency, IgA deficiency, and poor antibody responses reflects an underlying broad immunoregulatory defect in these patients, and it should not be thought that the IgG2 deficiency represents the primary etiology for the poor antibody responses to polysaccharide antigens. Recurrent infections with decreased antibody responses to polysaccharide antigens may, in fact, occur with either normal or low IgG subclass levels. [104] The poor antibody responses to polysaccharide antigens may contribute, however, to a low IgG2 subclass level, which contributes disproportionately to antibody responses to polysaccharides. In most patients, the structural IgG heavy chain genes on chromosome 14 are normal. Antibody deficiency, and not isolated IgG subclass deficiency per se, is therefore the cause of recurrent infections. The etiology of IgG subclass deficiency or poor antibody responses to polysaccharides is not known. Patients who lack one or more IgG subclasses on the basis of a homozygous deletion of heavy chain IgG constant region genes have been described, [98] but such patients are usually asymptomatic. A defect in production of IFN- by

LABORATORY EVALUATION FOR SUSPECTED IMMUNODEFICIENCY

GENERAL

Complete blood cell count

Chest radiograph

Serology, culture, and polymerase chain reaction or antigen detection for human immunodeficiency virus

ANTIBODY DEFICIENCY
Initial

Quantitative immunoglobulins

Antibody titers before and after immunization: tetanus toxoid, diphtheria toxoid, *Hemophilus influenzae* b or pneumococcal capsular polysaccharides

Isohemagglutinin titer

Later

Quantitation of B cells

IgG subclasses

In vitro Ig isotype switching and synthesis

Btk gene mutation

T-cell CD40 ligand expression

T-LYMPHOCYTE DEFICIENCY
Initial

Absolute lymphocyte count

Quantitation of T cells and T-cell subsets

Delayed-type hypersensitivity skin tests

CD11/CD18 expression

Spleen scan

mononuclear cells of patients with IgG2 subclass deficiency, with restoration of IgG2 production by addition of IFN- to in vitro cultured cells has been observed. [105] Isolated IgG subclass deficiency may be associated with IgA deficiency, as noted previously, or with ataxia-telangiectasia. Although IgG2 subclass deficiency predominates in children, symptomatic isolated IgG3 deficiency more commonly is detected in adults. [101]

Interpretation of IgG subclass values must be approached with attention to the wide range of normal age-related values. A low IgG subclass level should be followed by quantifying the antibody response to a polysaccharide vaccine, such as the *H. influenzae* b or pneumococcal capsular polysaccharide vaccine. [106] In children with recurrent sinopulmonary infections, quantitation of antibody responses to protein and polysaccharide antigens is preferable to quantitating IgG subclass levels. Immunization with polysaccharide-protein conjugate vaccines can overcome the unresponsiveness to polysaccharide antigens in IgG2 subclass deficiency [107] and may be of therapeutic value. If the frequency of infections in patients with symptomatic IgG subclass deficiency is not decreased with prophylactic antibiotics, Ig replacement therapy may be used, but caution must be exercised if there is concomitant IgA deficiency. In some children, the IgG subclass deficiency disappears spontaneously in later childhood.

COMBINED IMMUNODEFICIENCIES

Etiology and Pathophysiology

Severe combined immunodeficiency (SCID) is a heterogeneous disorder characterized by profound T- and B-lymphocyte deficiency that may be autosomal recessive or X-linked inherited.[108] [109] [110] About 80% of affected patients are boys, and only about one third of SCID patients have a positive family history. In SCID, there is a defect in T- or T- and B-cell development. SCID with preservation of B-lymphocyte numbers (T B + SCID) occurs in X-linked SCID (X-SCID) and autosomal recessive Janus-associated kinase (JAK)3 deficiency. The other autosomal forms of SCID are usually associated with decreased numbers of both T and B lymphocytes (T B SCID). Because bone marrow transplantation can completely correct the defect, a primary thymic defect is not the underlying basis of the disease, although the thymus is secondarily affected, with defective epithelial cell differentiation and absence of lymphoid cells and Hassalls corpuscles.

T B + Severe Combined Immunodeficiency

X-Linked Severe Combined Immunodeficiency

X-linked SCID, thought to be the most common form of SCID with estimates ranging from 2842% of cases, occurs in an estimated 1 per 50,000 births. [108] [109] [110] X-SCID maps to Xq13.113.3 and is characterized by absence of mature T cells in the presence of B cells. The molecular basis of X-SCID is a mutation in the $_{c}$ chain that is common to and indispensable for signaling through the high- and intermediate-affinity interleukin-2 (IL-2) receptors, and the receptors for IL-4, IL-7, IL-9, and IL-15 (Fig. 42-3). [5] [111] [112] [113] [114] [115] Mutation of this common cytokine receptor chain interferes with T-cell development in the thymus through lack of IL-7 signaling, and with signal transduction through lack of IL-2 signaling. B cells are present in the periphery, but the late stage of B-cell differentiation is impaired through decreased IL-2 and possibly IL-4 and IL-15 signaling. Although the number of B cells in X-SCID may be normal, the B cells have an immature phenotype, are not functional, fail to differentiate or produce IgG after in vitro stimulation, and are defective in IL-2 and IL-4 signaling. Natural killer (NK) cells are absent because of their impaired development from abnormal IL-15 signaling. In female carriers of X-SCID, there is nonrandom lyonization of

the X chromosome bearing the X-SCID mutation in T cells, mature differentiated B cells, and NK cells. Milder forms of the disease have been described in which $_{c}$ is present but fails to associate with its downstream signaling molecule, the tyrosine kinase JAK3. Up to one third of cases arise spontaneously and, therefore, lack a family history.

JAK3 Deficiency

Another form of B-cell-positive SCID, one that is phenotypically indistinguishable from X-SCID, is autosomal recessive inherited

Figure 42-3 IL-2 receptor activation. IL-2 binds to the multimeric IL-2 receptor (IL-2R) composed of three transmembrane proteins IL-2R, which regulates receptor complex affinity for IL-2, and the intracellular signaling proteins IL-2R and $_c$ that heterodimerize after binding IL-2. IL-2R is constitutively associated with JAK1 and $_c$ binds JAK3. With IL-2 binding, JAK1 and JAK3 are activated, and in turn lead to tyrosine phosphorylation of various signal transducers and activation factors of transcriptionSTAT1, STAT3, STAT5. Phosphorylation of STATs leads to their dimerization through reciprocal phosphotyrosineSH_2 domain interactions and subsequent translocation to the nucleus, where they mediate transcriptional activation. SCID arises from mutation of the $_c$ chain (X-SCID) or the JAK3 gene (autosomal recessive SCID). Immunodeficiency also occurs with mutations of IL-2R.

and arises from mutations in the Janus family protein tyrosine kinase JAK3, which is essential for signaling through the $_c$ common cytokine receptor chain.[116] [117] After cytokine binding, the cytoplasmic tail of the cytokine receptor dimerizes and brings JAKs into close proximity, promoting their tyrosine phosphorylation. JAK3 phosphorylation leads to the phosphorylation of cytokine receptor chains and the creation of docking sites for *Src* homology (SH_2)-containing signal transducer and activator of transcripts (STAT) proteins (Fig. 42-3). STAT proteins become phosphorylated, dimerize, and translocate to the nucleus to activate gene transcription. Activation of JAKs also leads to recruitment and activation of the SHC-Grb2-SOS-Ras-Raf1-MAPK signaling pathway, which leads to transcription of early-immediate genes (*c-fos, c-jun*) and of phosphatidylinositol 3-kinase, a signal for cell growth. The phenotypic picture of low T-cell numbers, absence of NK cells, and defective B-cell signaling in JAK3 deficiency is identical to X-SCID.

T B Severe Combined Immunodeficiency

Adenosine Deaminase Deficiency

Approximately 15% of patients with SCID and 3040% of patients with autosomal recessive inherited SCID have deficiencies of the enzyme adenosine deaminase (ADA), an enzyme of the purine salvage pathway that deaminates adenosine and deoxyadenosine

to inosine and deoxyinosine.[118] [119] [120] [121] Although ADA is expressed by all cell types, ADA deficiency affects preferentially the lymphoid system and interferes with lymphoid development in the thymus, which contains the highest level of ADA activity in the body. In ADA deficiency, there is accumulation of the toxic metabolites of purine metabolism, deoxyadenosine triphosphate (dATP) and 2-deoxyadenosine. Deoxyadenosine is generated in high amounts in the thymus from the extensive lymphocyte death that occurs with lymphoid development at that site. Deoxyadenosine is freely transported out of cells but is converted intracellularly by deoxyadenosine kinase into dATP that is trapped in the cell. These metabolites preferentially accumulate in lymphocytes because of the high expression of deoxyadenosine kinase. dATP inhibits T-cell proliferation by affecting DNA synthesis through inhibition of ribonucleotide reductase. Also contributing to the lymphocyte defect is the accumulation of *S*-adenosylhomocysteine, which occurs from inactivation of the enzyme *S*-adenosylhomocysteine hydrolase by 2-deoxyadenosine. The accumulation of these metabolites may also block endogenous DNA repair, leading to chromosomal breaks.

ADA deficiency, which may be complete or partial, is usually due to point mutations of the ADA gene, located on the long arm of chromosome 20, giving rise to a nonfunctional protein because of alteration in enzyme activity, stability, or structure. Splicing defects and chromosomal deletions of the ADA gene have also been described. The immunodeficiency is progressive and variable in age of presentation, depending on the amount of residual normal ADA activity, and may even present in adulthood. In contrast to other forms of SCID, ADA deficiency may be associated with thymus development and production of Hassalls corpuscles.

Lymphocyte Receptor Gene Rearrangement Defects

In another autosomal recessive form of the disease, ADA activity is normal, with failure of maturation of T and B lymphocytes resulting in lymphopenia. NK cells are present and functional. The possibility that this form of SCID is due to defective DNA repair, which is required during the normal rearrangement of immunoglobulin and T-cell receptor (TCR) genes, was suggested by the finding of aberrant D-J $_H$ joining in bone marrow pre-B cells from patients with SCID.[122] This suggestion was confirmed with the demonstration that in almost half of autosomal recessive B, ADA+ SCID patients, nonsense, missense, or deletional mutations in RAG1 and/or RAG2 occur with loss of functional V(D)J recombinase activity that results in an inability to generate antigen receptors in both T and B lymphocytes. [123] [124] Other patients with ADA+ autosomal recessive SCID have normal RAG1 and RAG2 activity but show increased radiosensitivity of granulocyte-macrophage colony-forming units and skin fibroblasts, suggesting a DNA repair defect. [125] [126] The possibility is under investigation that the defects in those autosomal recessive SCID patients with normal RAG1 and RAG2 arise from mutations in the enzyme DNA-dependent protein kinase p350, or associated proteins (e.g., KU70 and KU80, XRCC-4) that mediate DNA double strand break repair and are required for Ig and TCR gene rearrangements.

Omenn Syndrome

Omenn syndrome is an autosomal recessive combined immunodeficiency with scaly erythroderma, generalized lymphadenopathy, hepatosplenomegaly, failure to thrive, eosinophilia, and increased IgE levels. [127] The syndrome clinically resembles graft-versus-host disease, (GVHD), but the T cells infiltrating the skin and organs are autologous, activated (HLA-DR+ CD45R0+CD29+CD30+) self-reactive cells with restricted heterogeneity and spontaneously produce high levels of IL-4 and IL-5, thereby explaining the eosinophilia and increased IgE levels. [128] [129] [130] [131] Families in which one offspring had Omenn syndrome and another had typical lymphopenic SCID have been described, and cells from patients with Omenn syndrome also have displayed increased radiosensitivity, as described above. Both findings suggest that Omenn syndrome may be a leaky type of autosomal recessive SCID. Treatment with either cyclosporin [128] or IFN-[132] has improved the clinical condition and even the eosinophilia, but bone marrow transplantation is required to correct the syndrome permanently. [133]

Reticular Dysgenesis

Another rare autosomal recessive form of SCID, reticular dysgenesis, is characterized by the absence of both B and T lymphocytes and granulocytes in the peripheral blood and bone marrow.[134] [135] [136] [137] There is defective maturation of both lymphoid and myeloid lineage cells in the bone marrow. The molecular basis of this defect is unknown. Overwhelming infections ensue unless the defect is corrected by bone marrow transplantation. [137]

OTHER COMBINED IMMUNODEFICIENCIES

Major Histocompatibility Complex Class II Deficiency

Major histocompatibility complex class II deficiency, or bare lymphocyte syndrome, is an autosomal recessive disorder characterized by failure of expression of MHC or HLA class II surface molecules on B lymphocytes, monocytes, activated T lymphocytes, dendritic cells, Langerhans cells in the skin, and epithelial cells in the thymus and intestine.[138] [139] [140] [141] The immunodeficiency arises from mutations of regulatory factors essential for MHC class II gene transcription that are not linked to the MHC locus. MHC class II recognition is required for positive selection of T cells in the thymus and for interaction and activation of T cells by antigen presented to the T-cell receptor as a peptideMHC complex on the surface of antigen-presenting cells. There is heterogeneity in the gene defects in MHC class II deficiency, with four distinct genetic defects of transactivating factors that regulate MHC class II gene expression. [140] [141] In most patients, there are mutations of the multimeric protein transactivating regulatory factor X (RFX) complex, including RFX5 (complementation group C) and RFXAP (complementation group D), that cause failure of transcription factor activity or binding to the X box in the 5 promoter common to HLA class II molecules and prevent transcription of HLA class II molecules. In another form of the disease (complementation group A), there is a defect of the MHC class II transactivator (CIITA), a master switch that regulates constitutive expression of MHC class II genes, as well as genes involved in antigen processing and presentation (e.g., invariant chain and DM molecules) and induction of transcription by IFN-. CIITA is thought to be a non-DNA-binding coactivator that binds to RFX and other transcription factors after their binding to the upstream promoter.

In MHC class II deficiency, there is inconsistent reduction of HLA class I expression in fresh cells of some patients, which is not well understood since CIITA and RFX do not regulate class I expression. MHC class II deficiency differs from another subtype of the bare lymphocyte syndrome (termed type 1), which is characterized by inconstant and incomplete expression of HLA class I antigens. [142] HLA class I deficiency may arise from mutations of the TAP2 gene that encodes the TAP2 peptide transporter, which is required for transport of peptides into the endoplasmic reticulum for binding to MHC class I molecules. [142] HLA class I molecules remain peptide-free and fail to reach the cell surface. TAP2 deficiency is associated with chronic bacterial lung inflammation, decreased CD8 T-cell counts, but without

severe viral infections. The latter may be due to TAP-independent HLA class I restricted viral antigen recognition and preserved NK cell activity.

Normal numbers of T and B lymphocytes are found in MHC class II deficiency, but CD4+ T lymphocytes are commonly decreased and CD8+ T lymphocytes increased.[138] [139] It is unclear why CD4+ T cells are detected in these patients in the absence of MHC class II expression, which is required for their selection and development in the thymus. One possible explanation is the presence of residual MHC class II expression in the thymus. Lymphocyte function is abnormal in MHC class II deficiency, with absent in vitro and in vivo T-cell responses to specific antigens. Mitogen and allogeneic in vitro responses may be preserved, although class II molecules are not expressed after T-cell activation. Macrophages fail to present antigens to normal T cells. Although immunoglobulin levels may be normal, antibody responses after immunization are usually absent. Diagnosis is made by demonstrating absence of MHC class II expression on B lymphocytes, monocytes, or activated T cells.

T-Cell Activation Defects

T-cell defects that impair T-cell activation through the TCR and CD3 complex may lead to SCID in the presence of normal numbers of T lymphocytes. [143] [144] [145] Clinically, an increased incidence of infections, autoimmune hemolytic anemia, neutropenia or thrombocytopenia, allergies, cancer, and chronic diarrhea are observed. Different defects can lead to impairment of early events in T-cell signaling and signal transduction. In some of these defects, the TCR/CD3 complex is poorly expressed on T cells because of mutations in the genes encoding one of the protein constituents of the CD3 receptor. Mutations in the genes encoding the CD3- or epsilon chains may lead to defective expression of and signaling through the TCRT-cell complex. [146] [147] Rare cases have been associated with abnormal transmembrane calcium influxes after anti-CD3 antibody binding. Calcium entry is required for calcineurin activation and nuclear translocation of cytoplasmic nuclear factor of activated T cells (NF-AT),[148] [149] a T-cell-specific transactivating factor that binds to a response element in the regulatory region of the IL-2 gene.

Occasional instances of combined immunodeficiency with a normal number of T cells have been attributed to defective production of IL-2 or from failure of IL-2 gene transcription after T-cell activation. [150] [151] [152] The defects causing IL-2 deficiency may be heterogeneous. In vitro proliferative responses to mitogens are augmented by exogenous IL-2. In defects associated with defective in vitro production of IL-2, in vivo trials with IL-2 or polyethylene glycol-modified IL-2 have been attempted. [150] [153] IL-2 deficiency may be accompanied by deficiency of other cytokines (IL-4, IL-5, and IFN-). [151] In some patients, there is a defect in activation or binding activity of the T lymphocyte NF-AT.[149] [154] Abnormal responses to IL-1 and IL-2 have also been associated with combined immunodeficiency. Mutation of the chain of the IL-2 receptor gene can give rise to a form of SCID with decreased numbers of circulating T cells and abnormal T-cell infiltration of tissues secondary to failure of down-regulation of the antiapoptotic protein bcl-2 during thymocyte development. [155] [156]

ZAP-70 Deficiency (CD8 Deficiency)

This rare immunodeficiency is characterized by decreased CD8+ T lymphocytes with normal to increased numbers of CD4+ T cells, which fail to function. [157] [158] [159] The disorder arises from mutations of the ZAP-70 chain, a zeta (TCR component) associated protein kinase gene, that encodes a 70 kDa, non- *Src* protein tyrosine kinase of the Syk family. ZAP-70 kinase associates with the TCR after T-cell activation to transduce signals from the TCR (Fig. 42-4 (Figure Not Available)). [160] Cross-linking of the TCRCD3 complex with antigen leads to recruitment of CD4 or CD8, which is associated with the *Src* protein tyrosine kinase Lck. The recruited *Lck* or protein tyrosine kinase Fyn phosphorylates the various immunoreceptor tyrosine-based activation motifs (ITAMs) of the TCRCD3 complex, providing binding sites with SH2 domains that are capable of binding phosphotyrosines in the proper context. ZAP-70, a protein tyrosine kinase with tandem SH2 domains, binds to the phosphotyrosines of individual ITAMs and is phosphorylated by Lck or Fyn to induce its activation. Subsequently, other signaling and adaptor molecules (e.g., phospholipase C1, Vav, Cbl, SLP-76, pp36) are recruited to the activated TCR and ZAP-70, and in turn are activated to form a multicomponent complex that signals downstream activation events. In the absence of a functional ZAP-70, TCR-mediated signaling is lost.

Figure 42-4 (Figure Not Available) T-cell signal transduction pathway. The TCR is associated with CD3 and , CD4 or CD8, CD28, and CD45 on the plasma membrane. Immediately after antigen binds to the TCR, cytoplasmic protein tyrosine kinases (PTK) (Lck, Fyn, ZAP-70, and Syk) associated with the TCR become activated. PTK activation results in the phosphorylation of PLC1 and the activation of other kinases. Distal signaling events, including PKC activation and calcium mobilization, result in the transcription of genes encoding IL-2 and other molecules required for T-cell activation and proliferation. ZAP-70 deficiency prevents TCR signaling. *(From Elder ME: Investigation of signal transduction defects. In Rose NR, Conway de Macario E, Folds JD et al [eds]: Manual of Clinical Laboratory Immunology, ASM Press, Washington, DC, 1997, p. 830.)*

The paucity of CD8+ T cells is due to the failure of maturation and selection in the thymus. [157] Although there is an accumulation of double-positive thymocytes in the cortex in the thymus medulla in this disorder, only single-positive CD4+ T cells and not CD8+ T cells are observed, and only mature single-positive CD4+ T cells egress to the periphery. The CD4+ T cells fail to proliferate, however, when incubated in vitro with phytohemagglutinin, concanavalin A, or antigens that activate through the TCR, but are normally activated by stimulation with phorbol esters and calcium ionophore, which bypass the requirements of TCR-associated protein tyrosine kinases. NK cells are normal in number and function.

Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase deficiency is a rare, autosomal recessive disease of the purine metabolic pathway. [161] The immunodeficiency is progressive, and symptoms, which are variable, begin commonly in early infancy with enhanced susceptibility to opportunistic viral and fungal infections and failure to thrive. Death may result from an overwhelming viral infection from herpes zoster, measles, or cytomegalovirus. The immunodeficiency is thought to be due to failure of conversion of deoxyguanosine to guanine and its consequent phosphorylation to deoxyguanylic acid (dGMP) in lymphoid tissue. The toxic metabolite deoxyguanosine triphosphate (dGTP) accumulates in cells and inhibits ribonucleotide reductase, required for DNA synthesis and proliferation of thymocytes. T-cell numbers are markedly decreased. In vitro T-cell responses are abnormal, with absent delayed-type cutaneous hypersensitivity. There is an attrition in T-cell function over time. In contrast, antibody and Ig production in some patients is preserved, and at times the antibody response is exaggerated. Autoantibodies, including rheumatoid factors, antinuclear antibodies, and antibodies to blood cells, may be produced, and autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, and systemic lupus erythematosus may ensue. The reasons for preferential toxicity for T cells and the clinical and laboratory differences from ADA deficiency have not been completely elucidated. Megaloblastic anemia, neurologic abnormalities with spastic paresis of the trunk and extremities, developmental delay, or mental retardation may be observed. Diagnosis is made by quantitating purine nucleoside phosphorylase activity in erythrocytes, lymphocytes, or fibroblasts and levels of deoxyguanosine and dGTP in blood. A low serum uric acid level is a useful screening assay for this enzyme deficiency. Prenatal diagnosis is possible. Attempts at enzyme replacement therapy have not altered the clinical course, and bone marrow transplantation is the preferred form of therapy. Gene therapy will probably be tried in the future to correct the enzymatic abnormality.

Clinical Manifestations

The different forms of SCID are generally clinically indistinguishable. [108] [109] [110] SCID usually presents in early infancy with recurrent severe infections, or persistent infections with low-virulence, opportunistic organisms, such as *Candida albicans* or *Pneumocystis carinii*, giving rise to chronic thrush or interstitial pneumonitis, respectively. Chronic diarrhea and failure to thrive usually occur. Recurrent otitis media, skin infections, and chronic severe viral infections are frequently present. The diagnosis of SCID should be considered a pediatric emergency, because correction of the defect becomes more difficult if serious infection ensues before bone marrow transplantation.

In contrast to other forms of SCID, patients with partial ADA deficiency may have symptoms delayed until the latter half of the first or second year of life, or even at older ages (38 years). [118] [119] [120] With partial ADA deficiency, there is slower progression of the deterioration of immunity because of the time required to accumulate the toxic metabolites. About half of the children with ADA deficiency have radiologic anomalies of the rib cage, with flared costochondral junctions, scapula, and skeleton, but these abnormalities are not specific for ADA deficiency. Neurologic and hepatic abnormalities have been observed with ADA deficiency.

Patients with MHC class II deficiency clinically present in the first year of life with a picture typical of SCID with recurrent, severe bacterial, viral, or fungal infections causing recurrent bronchopulmonary disease, chronic protracted diarrhea, malabsorption, liver disease, or failure to thrive. [138] [139] Death is often caused by severe viral infections that occur in the first years of life.

Graft-versus-host disease may arise from transfusion of nonirradiated blood products or from maternal/fetal transfer of lymphocytes in utero or at delivery. It may be associated with fever, eczematoid rash, diarrhea, hepatosplenomegaly, and eosinophilia. [162] Although engraftment with maternal lymphocytes occurs in up to 4050% of cases of SCID, symptomatic GVHD often does not ensue, probably because the maternal lymphocyte cells are immature, represent a limited repertoire, and have suboptimal responses to activation. [163] [164]

Laboratory Evaluation

The diagnosis of SCID should be established at the earliest age possible so that optimal therapy can be offered. The total lymphocyte count is almost invariably low in SCID, but normal lymphocyte counts do not exclude the diagnosis. The lymphocyte counts must be compared to age-matched healthy controls. T-cell numbers, especially CD4+ T cells, are usually markedly decreased, and those present may display an immature phenotype. If substantial numbers of T cells are present, they may be derived from engraftment of maternal lymphocytes, or reflect the presence of a T-cell activation defect or MHC class II deficiency. With the latter, an increase in CD8+ T cells masks a decrease in CD4+ T cells. ZAP-70 deficiency is associated with a normal number of dysfunctional CD4+ T cells with a paucity of CD8+ T cells. In X-SCID and JAK3 deficiency, the B cells are normal or increased in number but fail to mature and function. ADA deficiency and deficiency of RAG1 or RAG2 are associated with a decrease in both T and B lymphocytes.

In vitro T-cell responses to mitogens and allogeneic cells are absent or very poor, and responses to antigens are absent in SCID. Cutaneous delayed-type hypersensitivity reactions are absent. Immunoglobulin levels are usually decreased, and antibody responses are usually absent, except in some patients with partial ADA deficiency. NK cells are decreased in $_{c}$ -deficient, JAK3-deficient, and ADA-deficient SCID, although in ADA-deficient SCID, NK cell function may be preserved in the face of low numbers of NK cells. The thymus in SCID is small, weighing <1 g, and lacks thymocytes, Hassalls corpuscles, and a corticomedullary junction.

Special studies that may be necessary include assays for the $_{c}$ chain, JAK3, ADA enzyme activity, dATP, and deoxyadenosine, purine nucleoside phosphorylase activity, dGTP and deoxyguanosine, ZAP-70 kinase, signal transduction in T cells, class I and class II MHC surface expression, and skin biopsy of rashes to establish a diagnosis of GVHD.

For many of these diseases, prenatal diagnoses by genetic analysis or immunologic evaluation of fetal blood can be performed. ADA-deficient SCID, X-SCID, and JAK3 deficiency can be diagnosed prenatally and the carrier stage can be identified. The prenatal diagnosis of ADA deficiency is performed by assaying ADA activity or dATP levels in cultured amniotic cells, fetal blood obtained by fetoscopy, or chorionic villi samples. However, some children have small amounts of residual ADA activity, which may make diagnosis difficult. The prenatal diagnosis of SCID can be performed by molecular approaches

once the $_{c}$ or JAK3 gene defect in family members has been identified.

Therapy

If the immunodeficiency is not corrected, SCID is invariably fatal. Transplantation of bone marrow cells from HLA genotypically identical family donors completely restores the immunologic function of patients with different forms (X-linked, JAK3 deficiency, autosomal recessive ADA/+, reticular dysgenesis) of SCID, and is successful in correcting MHC class II deficiency, purine nucleoside phosphorylase deficiency, Wiskott-Aldrich syndrome, and X-linked hyper IgM. [165] [166] Pretransplant preparative cytoablation is not required for haploidentical transplants. The success rate of HLA-identical bone marrow transplantation now approaches 100%, with engraftment of both donor T and B lymphocytes. Lymphoid and hematopoietic stem cell engraftment is required to correct SCID from reticular dysgenesis, MHC class II deficiency, and IL-1 deficiency. In the absence of matched related donors, T-cell-depleted haploidentical parental, [165] [166] [167] [168] matched unrelated donor bone marrow transplantation, [169] and umbilical cord blood stem cell transplantation [170] have been successful with relatively low frequencies of GVHD. Mature T cells are depleted from the bone marrow by physical or immunologic approaches to prevent GVHD from transferred mature donor T cells. Donor stem cells develop into T cells that undergo clonal deletion and anergy in the host thymus to establish a state of tolerance in the host. Although T cells can engraft in the absence of GVHD with these purged bone marrows, immunologic reconstitution is slower than that observed after HLA-identical bone marrow transplantation. This is probably because T cells are developing solely from donor lymphoid stem cells with recapitulation of immunologic ontogeny. B-cell engraftment may be extremely delayed or fail to occur

with failure of cooperation between donor haploidentical T-helper cells and host B cells. The success rate of haploidentical bone marrow transplants now exceeds 70% and is approaching the success rate of genotypically identical bone marrow transplants. The presence of pre-existing infection or GVHD hinders the success rate of transplantation. In utero transplantation of parenteral CD34+ hematopoietic progenitor cells has corrected X-SCID diagnosed in the fetus. [171] [172]

All blood products should be irradiated before transfusion of patients with SCID to prevent GVHD. Ig replacement therapy, nutritional support, and prophylaxis against *P. carinii* infection are usually required prior to bone marrow transplantation. Family members should be immunized with killed poliovirus vaccine to prevent infection in patients.

In the absence of an HLA-identical bone marrow donor for correction of ADA-deficient SCID, and as an alternative to HLA-haploidentical bone marrow transplantation, patients may be treated with ADA enzyme replacement therapy by intramuscular injection of polyethylene glycol (PEG) modified bovine ADA. [173] Modification of ADA with PEG prolongs the circulating half-life of the enzyme and decreases its immunogenicity. PEG-ADA can improve the immunologic and clinical status of patients with ADA deficiency. The exogenous ADA lowers the level of the toxic metabolites in ADA-deficient lymphocytes by deaminating adenosine and 2-deoxyadenosine. HLA-haploidentical bone marrow transplantation is an alternative to ADA replacement therapy favored by some for treatment of ADA-SCID in the absence of an HLA-identical donor. Use of PEG-ADA before bone marrow transplantation, however, may restore host immunologic function and predispose to graft rejection. Similarly, ADA activity in the transplanted marrow may stimulate immunologic function of the recipients residual T cells and prevent engraftment, which can be avoided by the use of pretransplant cytotoxic agents.

Gene replacement therapy to correct ADA deficiency permanently is under investigation. [174] [175] [176] [177] Older children have been treated with autologous IL-2 activated peripheral blood T cells and neonates with autologous CD34+ pluripotent umbilical cord blood stem cells that were transduced with retroviral vectors containing the gene encoding human ADA. The long-term success of somatic ADA gene therapy is not defined at this time.

IMMUNOGLOBULIN DEFICIENCY WITH NORMAL OR INCREASED IgM (HYPER-IgM SYNDROME)

Etiology and Pathophysiology

Immunoglobulin deficiency with normal or increased IgM is associated with recurrent infections and normal or increased serum levels of polyclonal IgM and, at times, IgD, with low levels of other immunoglobulin isotypes.[12] [178] [179] Both pyogenic and opportunistic infections, such as *P. carinii, Candida, Crytosporidium, Cytomegalovirus,* and *Mycobacteria,* occur. Although B cells are normal in number, the only isotypes expressed on their surface are usually IgM and IgD. When B cells are stimulated in vitro or immortalized with EBV, they secrete only IgM. Plasmacytoid cells spontaneously secreting IgM may be present in the circulation and in lymphoid tissues. Rarely, cells expressing surface IgM and IgG can be detected, but this may result from alternative splicing of a long germline encoded C_H region sequence RNA transcript that has not undergone isotype switch recombination.

The disease may be inherited in an X-linked (X-HIM) or autosomal recessive manner. X-HIM, which maps to Xq26, is due to failure of activated T cells to express a functional CD40 ligand, a type II transmembrane glycoprotein that binds CD40 on B cells to signal the B cell to proliferate, undergo deletional isotype switching, and develop into memory B cells.[5] [12] [180] [181] CD40 ligandCD40 interactions are required for induction of germinal center formation in lymphoid follicles and generation of memory B cells, which occurs in germinal centers.[181] CD40 ligandCD40 interactions induce the expression or up-regulation of costimulatory molecules (e.g., B7.1 and B7.2) on B cells that are required for effective T cellB cell interactions. Defective CD40 ligand expression may therefore lead to decreased full activation of responding T cells from the poor expression of costimulatory molecules and cytokine production. The opportunistic infections observed in X-HIM may reflect this T-cell defect as well as decreased activation of CD40-expressing macrophages. Missense and nonsense mutations and deletions in the CD40 ligand gene have been described.[180] Cross-linking of CD40 on B cells from patients with X-HIM with antibody or functional CD40 ligand and stimulation with the appropriate cytokines can bypass the defect and activate normal isotype switching and immunoglobulin secretion.

A disease similar to X-HIM is autosomal recessive inherited and arises from defective CD40 expression or signal transduction in B cells.[182] In some of these patients, no mutations have been detected in CD40 or CD40 binding proteins, and the syndrome arises secondary to a defect in the CD40-triggered signaling cascade. An acquired form of this syndrome has been described associated with congenital rubella infection or anticonvulsant (phenytoin) therapy, but usually the etiology of the acquired form is unknown.

Clinical Manifestations

Pyogenic bacterial infections begin during the first or second year of life, as observed in XLA, with recurrent otitis media, upper respiratory tract infections, and pneumonia.[178] [179] In contrast to other primary humoral immunodeficiencies, the hyper IgM syndrome is associated with an unusual susceptibility to *P. carinii* pneumonia, *Candida, Cryptosporidium, Cytomegalovirus,* and *Mycobacteria.* In fact, *P. carinii* pneumonia is a common form

of presentation in the first year of life.[179] This susceptibility may be explained by failure of CD40 ligand on activated T cells to activate CD40-expressing macrophages or dendritic cells to secrete IL-12, which is required for T_H 1-type immune responses. Thus, there is failure to develop the ability to kill microbes or form complete T-cell activation due to lack of costimulation or cytokine activation. Diarrhea and sclerosing cholangitis occur secondary to *Cryptosporidium* infection. Lymphoid hyperplasia with lymphadenopathy, tonsillar enlargement, and hepatosplenomegaly occur. Chronic neutropenia occurs in about half of the patients and arises from defective myeloid differentiation at the promyelocyte or myelocyte stage. The neutropenia may be cyclic or episodic, where it is associated with infection. Stomatitis and chronic recurrent oral or rectal ulcers occur as a complication of the neutropenia. Autoimmune manifestations include arthritis or arthralgia, nephritis, and hemolytic anemia. Surface IgM-positive non-Hodgkins and Hodgkins lymphoma with gastrointestinal tract, liver, or gallbladder involvement may also be observed.

Laboratory Evaluation

Serum levels of IgM and, at times, IgD are markedly elevated, and the other isotypes are low or absent. At an early age, however, the IgM level may be normal. In a recent study, only half the patients with X-HIM had increased serum IgM levels at the time of diagnosis, and one third of patients failed to develop increased levels of IgM with follow-up.[179] The IgM is polyclonal, and antibody responses, when they occur, are restricted to the IgM isotype. In addition to the normally occurring 19S IgM molecules, a 7S IgM fraction may be produced. Peripheral blood B cells are normal in number and express IgM and IgD, but cells with surface IgG or IgA usually, but not invariably, are absent. In vitro stimulation of peripheral blood B lymphocytes with anti-CD40 in the presence of IL-10 or IL-4 will activate isotype switching and secretion of IgG or IgE, respectively, in X-HIM. Definitive diagnosis of X-HIM is made by demonstrating the lack of binding of soluble forms of CD40 to CD40 ligand on activated T cells. Some patients generate a defective CD40 ligand protein that binds anti-CD40 ligand antibody but fails to bind CD40. In vitro lymphocyte proliferative responses to soluble antigens may be decreased. Lymph nodes lack secondary follicles with germinal centers, and show a severe depletion of follicular dendritic cells. Female carriers of X-HIM can be diagnosed by demonstrating expression of functional CD40 ligand on only half of their activated T cells.

Therapy

Bone marrow transplantation should be considered because of the high morbidity and mortality of the syndrome. Ig replacement therapy is indicated. With Ig replacement therapy, increased IgM levels decrease in about half of the patients,[179] presumably on the basis of feedback inhibition and prevention of infection. Lymphoid hyperplasia and neutropenia may also be reversed with Ig replacement therapy. The neutropenia may also respond to therapy with granulocyte colony-stimulating factor. Prophylaxis to prevent *P. carinii* pneumonia is required. Identification of the genetic basis of X-HIM has improved diagnosis, prenatal detection, and counseling, and will lead to gene therapy for this disease.

WISKOTT-ALDRICH SYNDROME

Etiology and Pathophysiology

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive syndrome characterized by the triad of eczema, thrombocytopenia, and immunodeficiency. [183] [184] The cell lineages affected by the defect include both lymphoid and hematopoietic lines. The Wiskott-Aldrich gene maps to position Xp11.22-p11.3 on the X chromosome and encodes a 502 amino acid protein termed WASP (Wiskott-Aldrich syndrome protein). [185] [186] WASP localizes in the cytoplasm with polymerized actin, where it is thought to link the actin cytoskeleton to signaling from surface receptors. [187] There is a GTPase binding site on WASP that binds to GTP carrying Cdc42, a member of the Rho family of GTPases. This results in remodeling of the actin cytoskeleton to alter cell shape and motility. Actin remodeling leads to formation of filopodia, finger-like projections on the cell surface that aid cell movement in response to external stimuli; filopodia are critical for polarization and orientation of T cells toward antigen-presenting cells. [188] An additional site where WASP acts is in signal transduction pathways by binding to *Src* homology 3 (SH3)-containing proteins, such as Nck, and nonreceptor tyrosine kinases, such as Fyn and Itk.

The exact contributions of the WASP defect to the hematologic and immunologic abnormalities in WAS are under investigation. [189] An increased percentage of peripheral blood lymphocytes or T-cell lines with decreased surface microvilli, giving a bald appearance, are observed by scanning electron microscopy. The T cells in WAS display an unusual morphology, with disorganized submembranous actin cytoskeleton cells and decreased surface microvilli, that have actin at their core. The cell surface glycoprotein CD43, termed leukosialin or sialophorin, a major component of the plasma membrane that contributes heavily to the surface charge on lymphocytes and colocalizes with the cell surface microvilli, has been reported to be absent, decreased, or structurally altered in lymphocytes of patients with WAS. [190] The defect in polarization and orientation of T cells toward antigen-presenting cells described above may explain the poor antigen-specific T-cell responses in WAS.

The etiology of the thrombocytopenia, which is the most consistent finding of the triad, has not been completely explained. [189] [191] Abnormal thrombocytopoiesis makes a major contribution to the thrombocytopenia, which may be explained by a tyrosine kinase signaling pathway that signals through WASP and controls assembly of actin, and has been shown to be essential for megakaryocyte differentiation. [192] Increased platelet destruction due to an intrinsic platelet defect also contributes to the thrombocytopenia. The mean platelet volume is reduced, but there is a broad overlap with the normal range. The platelets in WAS express decreased surface glycoprotein IIb, IIIa, and IV and display defective thrombin-induced expression of CD62P and CD63 and decreased actin. After splenectomy, the platelet count usually increases, and the mean distribution of the platelet volume returns to normal, indicating that platelet circulation through the splenic microarchitecture leads to reduced platelet size. [193] [194] Platelet-associated IgG is frequently present; it disappears after splenectomy. Relapse of thrombocytopenia after splenectomy may be accompanied by autoimmune thrombocytopenia and redevelopment of platelet-associated IgG. With relapse, the platelet volume does not decrease to the presplenectomy size, but fails to increase to the size observed in immune-mediated platelet destruction.

Hereditary X-linked thrombocytopenia is characterized by thrombocytopenia and small platelets, similar to WAS, without the immunodeficiency or eczema. [195] This disorder is an allelic variant of WAS arising from mutations of the WASP gene that are usually point or missense mutations instead of the frameshifts, splice, or nonsense mutations that may be observed in WAS. [196] [197]

Carrier females are asymptomatic because of selection against cells that have the X chromosome carrying the mutant Wiskott-Aldrich gene as their active X chromosome. Nonrandom X chromosome inactivation patterns are observed in obligate carriers in T and B lymphocytes, monocytes, polymorphonuclear leukocytes, and platelets, but not in fibroblasts. [5]

Clinical Manifestations

The initial symptoms are usually petechiae or bleeding in the skin, mouth, nose, the gastrointestinal or urinary tract, or from the umbilical cord, beginning in the first several months of life. Thrombocytopenia is present at birth. [198] [199] A life-threatening bleed (gastrointestinal, intracranial, or severe oral) is observed in up to one third of patients before a diagnosis is made. Early in life, an eczematoid rash appears, most prominent in the antecubital and popliteal fossae; it tends to become petechial. At the time of diagnosis, only about 25% of patients with WAS have the classic triad of thrombocytopenia, eczema, and recurrent otitis media. [199] Infections with bacteria, fungi, or viruses cause recurrent otitis media with chronic purulent drainage and perforated tympanic membranes, recurrent pneumonia and sinusitis, and recurrent herpes infections. The thrombocytopenia and bleeding tendency are often worsened with infection. Chronic or recurrent herpes simplex or disseminated varicella may occur. Autoimmune disorders develop in up to 40% of patients with arthritis, vasculitis, uveitis, inflammatory bowel disease, or autoimmune hemolytic anemia.

The median survival in WAS patients is 6.5 years, with the cause of death being infection, usually from pneumonia or sepsis, in 59%, bleeding in 27%, and malignancy in 5% of patients. The risk of malignancy in WAS is 100-fold higher than in normals. A high incidence of lymphoreticular tumors that initially present at extranodal sites, especially non-Hodgkins lymphomas with B-cell-immunoblastic sarcomas, is observed in those who survive to later childhood. [7] [8] [9]

Laboratory Evaluation

The serum IgM level is decreased in older children and adults with WAS but may be normal early in life. IgA and IgE levels are often increased. IgG paraproteins may be present. Poor to virtually absent antibody responses to polysaccharide antigens, and defective low titer with antibody responses to protein antigens, lack of immunologic memory, and isotype switching occur. Titers of isohemagglutinins to the blood group polysaccharide antigens are usually low. T-cell responses to nonspecific mitogens are normal to decreased, but are usually absent to anti-CD3 antibody and antigens. Delayed-type hypersensitivity skin reactions are also usually absent. Lymphocyte counts are usually normal at diagnosis, and then decrease with age as a result of a progressive decline in T-cell numbers, especially CD8+ T cells. Peripheral lymphoid tissues gradually become depleted of T cells. Eosinophilia may be present. The lymphocytes have a characteristic bald appearance on scanning electron microscopy. The platelet count is decreased, ranging from 10,000 to 100,000/mm ^{3} , and the platelet size is characteristically small, a feature relatively specific for WAS or X-linked thrombocytopenia. The platelet count may vary considerably in a patient, with a decrease occurring with viral infections. The number and morphology of megakaryocytes in the bone marrow are normal. The bleeding time is more prolonged than would be predicted from the platelet count. The carrier state can be diagnosed by demonstrating nonrandom X-chromosome inactivation patterns in T cells, B cells, or polymorphonuclear leukocytes. Prenatal diagnosis can be made by detecting polymorphisms flanking the WASP gene or WASP mutations and by decreased fetal platelet count and size.

Therapy

Bone marrow transplantation can correct all of the defects of this otherwise fatal disorder, including the susceptibility to malignancy. [200] Successful engraftment requires preparative ablation or cytoreduction of the recipients bone marrow. While the success rate with HLA-identical marrow is high, the success rate of haploidentical parental bone marrow transplantation has been disappointing, complicated by severe viral infections, lymphomas, EBV-induced B-cell lymphoproliferative disease, or chronic GVH in the post-transplantation period. Matched unrelated donor bone marrow transplantation for WAS has met with some success, especially when performed at an early age. [169]

Splenectomy combined with regularly administered prophylactic antibiotics has been used to manage some patients with severe bleeding problems who could not undergo transplantation. [193] [194] Splenectomy increases the platelet count and decreases the bleeding tendency, but it may increase susceptibility to overwhelming sepsis, even with the use of prophylactic antibiotics. The majority of splenectomized patients have a sustained increase of platelet counts by at least 20,000/mm ^{3}, and in over half of patients by at least 100,000/mm ^{3}. Recurrences of thrombocytopenia with an acute ITP-like episode, however, can occur after splenectomy. Corticosteroids and intravenous Ig have been used to treat such patients. Intravenous Ig replacement therapy is indicated to decrease the risk of infections but is not invariably efficacious in decreasing the frequency of infections.

ATAXIA-TELANGIECTASIA

Etiology and Pathophysiology

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder characterized by progressive cerebellar ataxia, telangiectasia, recurrent sinopulmonary infections, combined immunodeficiency, an increased incidence of malignancies, and premature aging. [201] Although the frequency of A-T is estimated to be only 1 per 40100,000 live births, the carrier state is relatively frequent (1%) in the population, and heterozygotes, as well as homozygotes, appear to be at increased risk for malignancy. [202] The underlying defect in A-T is due to mutations of the ATM (A-T mutated) gene that encodes a 350 kDa protein kinase with a phosphatidylinositol (PI) 3-kinase domain involved in multiple signaling pathways of cellular responses to DNA damage, and in control of the cell cycle and DNA replication, recombination, and repair.[203] [204] [205] [206] A-T cells display chromosomal instability and hypersensitivity to agents that cause DNA strand breaks, including -rays and x-rays, ionizing radiation, and radiomimetic chemicals such as bleomycin. [201] [202] [203] [204] Cells of heterozygous carriers of A-T show a sensitivity intermediate between those of normal individuals and homozygotes. A-T cells have an increased number of spontaneous and radiation-induced chromosome breaks, which are not rejoined as efficiently as normal cells.

Cells in A-T do not reduce their rate of DNA synthesis after irradiation as do normal cells because of dysfunction or absence of the ATM protein. In normal cells, irradiation-induced double-strand breaks in DNA lead to an arrest at the G_1-S transition, S, or G_2-M transition phases of the cell cycle. These cell cycle checkpoints ensure that damaged DNA is not replicated and cell division does not occur until DNA strand breaks have been repaired. The A-T gene product functions in several irradiation-induced signal transduction pathways (which operate through p53, p21, and cyclinE-cyclin-dependent kinase [cdk] complexes or through the *abl* proto-oncogene, or *Chk1,* Cdc25, and Cdc2, cyclin B) that recognize DNA damage and transduce a signal from damaged DNA to arrest the cell cycle and repair damaged DNA.[205] [206]

A high spontaneous rate of intrachromosomal recombination is observed in A-T, and there is a high frequency of lymphocytes with chromosome translocations and aberrant interlocus TCR gene rearrangements.[207] [208] The defective checkpoint response to DNA strand breaks may lead to an accumulation of aberrant recombinations of immunoglobulin and T-cell receptor genes, and result in the high frequency of lymphoid tumors observed in A-T. Chromosomal breaks, inversions, and translocations cluster at bands 7p13-p14, 7q32-q35, 14q11, and 14q32 in

510% of peripheral T lymphocytes in A-T. [209] [210] It is at these sites that the T-cell and immunoglobulin receptor genes normally undergo DNA rearrangement to generate a functional gene. This may account for the T- and B-cell abnormalities and low number of / compared to / bearing TCR in A-T. [211] In approximately 10% of A-T patients, expanded clonal populations of nonmalignant T cells with translocations involving chromosomes 7 or 14 at 14q32.1, centromeric to the immunoglobulin heavy chain locus, and possibly the site of a putative oncogene, appear in the blood. [209] [210] These clonal cells have a proliferative advantage, and may increase in a quiescent fashion in the blood over a period of years. In some instances, they evolve into a T-cell leukemia. It is possible that the nonrandom translocation confers a preactivated, premalignant state that progresses to malignant transformation after a second genetic event.

In A-T there are also defects in tissue differentiation, with failure of organ maturation. The immunologic defect is characterized by absence of or production of only a small thymus that has an embryonic histologic appearance, with lack of Hassalls corpuscles and sparse population with lymphoid cells. [201] Other evidence for tissue immaturity includes the presence of elevated levels of serum -fetoprotein and carcinoembryonic antigen, produced normally by fetal organs, ovarian agenesis, and hypogonadism. In the absence of cell cycle arrest with ATM gene dysfunction, even low levels of DNA damage in A-T cells may activate an apoptotic cell death, which in normal cells would be activated only by irreparable DNA damage. This increased apoptosis may explain the thymic and other organ atrophy in A-T.

Clinical Manifestations

The most common initial presentation of A-T is a progressive cerebellar ataxia that is observed in the second year of life. [212] Other neurologic symptoms occurring later are choreoathetosis, nystagmus, strabismus, dysarthric speech, and decreased deep tendon reflexes. Telangiectasias appear later in childhood, and are most prominent on the bulbar conjunctivae, exposed areas of the skin, external ear, eyelids, face, flexor folds of the neck, extremities, and dorsa of hands and feet. Recurrent sinopulmonary infections occur in the majority of patients and may become chronic, resulting in bronchiectasis and respiratory insufficiency. The overall risk of cancer is 60180 times the normal rate, with up to 10% of patients developing malignancies. [7] [8] [9] [202] [206] [213] Black patients with A-T have even higher risks of malignancy, especially lymphomas and leukemia. The majority of neoplasms occur before age 15. Non-Hodgkins lymphomas with histologic subtypes that are observed with chromosome 14 translocations, and Hodgkins lymphoma, mostly of the lymphocytic depletion type, T-cell leukemia, and epithelial carcinomas predominate. Heterozygotes for the A-T gene have an approximately threefold to fourfold increased risk of malignancy. It is suggested that heterozygous females, who have an approximately fivefold increased risk of breast cancer, account for up to 8% of all cases of breast cancer in the United States. Caution must be exercised in the treatment of neoplasms because of the increased sensitivity of patients with A-T to radiation therapy. Endocrinologic abnormalities occur commonly, including delayed somatic growth, insulin resistance, delayed development of secondary sexual characteristics in females (secondary to absent or hypoplastic ovaries), hirsutism in females, and hypogonadism in males. Premature aging of the skin and diffuse graying of the hair usually occur.

Laboratory Evaluation

Absence or deficiency of serum IgA, secretory IgA, and IgE are found in about 75% of patients. Low levels of IgG2 and IgG4 and decreased antibody responses to immunization are also found. Anergy to delayed-type hypersensitivity skin testing, decreased T-cell numbers, and abnormal in vitro lymphocyte proliferative responses commonly occur. Serum levels of -fetoprotein are increased in over 95% of patients, and levels of carcinoembryonic antigen may be elevated. Nonrandom chromosomal breaks and chromosome 14 translocations are frequently detected.

Therapy

No therapy can halt the disease, and treatment is symptomatic. Antibiotics are indicated for recurrent pulmonary infections, and Ig replacement therapy may be indicated. Exposure to excessive sunlight should be minimized to prevent skin changes. Malignancies in A-T patients may require the use of lower doses of radiotherapy and chemotherapy.

DIGEORGE/VELOCARDIOFACIAL ANOMALY (THIRD AND FOURTH PHARYNGEAL POUCH SYNDROME)

Etiology and Pathophysiology

The DiGeorge or velocardiofacial syndrome arises from either monosomy of 22q11.2, which occurs from a deletion, most frequently of maternal origin, or an unbalanced translocation of the chromosome.[214] [215] [216] Up to 25% of cases are inherited as a 22q11.2 deletion. This genetic defect results in an abnormality of, or an insult to development of, the third and fourth pharyngeal pouches, occurring during the fourth to seventh week of fetal development. This contributes to the abnormal development of the thymus, parathyroid glands, conotruncal components of the heart, ear, and facial structures. [214] [217] The acronym CATCH22*c*ardiac abnormalities, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemiahas been applied to the syndrome to designate the involved organs. The genetic basis by which the 22q11 deletion gives rise to the DiGeorge anomaly is not known, and will require identification of the minimal critical genetic region. It is suggested that the embryologic reactive unit affected is the cephalic neural-crest mesenchymal population of cells. [217] The failure of the neural crest to contribute to the mesenchymal derivatives of the pharyngeal pouches may explain the heart lesions typically found in the syndromeinterrupted aortic arch type B and truncus arteriosus. The anomaly may arise from an environmental insult and has been associated with maternal alcoholism and diabetes or exposure to retinoids. [214] [218]

Development of the thymus, which is formed from the endodermal epithelium of the third and fourth pharyngeal pouches, is interrupted. [214] The thymus may be completely absent in the most severe form of this developmental field defect, but more frequently it is small and hypoplastic and ectopic in location, because of lack of descent into the mediastinum. This variability in thymic development produces variable T-cell deficiency. Most patients have a partial T-cell deficiency with decreased T-cell number and function at birth that corrects itself with time. More rarely, complete thymic aplasia (complete DiGeorge anomaly) is present with profound deficiency of T-cell number and function. When present, it is associated with a marked susceptibility to viral and fungal infections. Parathyroid aplasia is present at birth and produces hypocalcemia.

Clinical Manifestations

A broad and variable spectrum of malformations may occur.[214] [219] [220] Affected infants usually present with hypocalcemic tetany in the newborn period. Cardiac malformations include interrupted, right-sided, or double aortic arch, truncus arteriosus

, patent ductus arteriosus, or ventricular septal defect, and give rise to cyanosis or cardiac murmurs. Type B interrupted aortic arch or truncus arteriosus occurs frequently and is suggestive of the diagnosis. Facial dysmorphic features include hypertelorism, antimongoloid slant of the eyes, midline facial clefts, micrognathia, shortened philtrum of the lip, cleft palate, choanal atresia, low-set posteriorly rotated ears, and notched ear pinnae. If the T-cell deficiency is severe, which occurs in less than 25% of patients,[214] [221] [222] the infant may develop chronic or recurrent rhinitis, pneumonia, candidal infections, diarrhea, and failure to thrive. Moderate to severe mental retardation and developmental delay are common, and hearing loss may be present.

Laboratory Evaluation

Total T cells are low, and B-cell numbers and total lymphocyte counts are usually normal. At times, B-cell numbers are increased. In vitro T-cell responses to nonspecific mitogens or allogeneic lymphocytes may be normal or absent. Unless there is a severe T-cell defect, immunoglobulin levels of IgG, IgA, and IgM are usually normal, or at times increased. Patients with CD4+ T-cell counts of <400/l and decreased in vitro T-cell responses to mitogens may have increased susceptibility to infection and a persistent immunodeficiency. [221] Profound T-cell deficiency results in defective antibody responses. Decreased serum calcium, increased phosphorus, and decreased parathyroid hormone levels are present. Cytogenetics with fluorescence in situ hybridization should be used to identify chromosome 22q11.2 abnormalities in the patient and parents.

Therapy

Hypocalcemia should be treated with intravenous calcium replacement; it may prove difficult to control. Long-term treatment with oral calcium replacement, vitamin D, and a low-phosphate formula is usually required. The cardiac abnormalities, which may be severe, must be evaluated completely. Therapy is not usually required for partial T-cell deficiency, since there is spontaneous improvement in T-cell function with increasing age. In patients with severe, persistent T-cell deficiency with marked susceptibility to infections and failure to thrive, transplantation of fetal thymus, postnatal thymus, or bone marrow may be indicated, but the efficacy of thymic transplantation for complete DiGeorge anomaly has not been critically evaluated. [214] [223] Blood products should be used from cytomegalovirus-negative donors and be irradiated before administration to prevent GVHD, a potential complication with severe T-cell deficiency. Antibiotic prophylaxis to prevent *P. carinii* pneumonia is also indicated in the face of T-cell deficiency. Prenatal diagnosis is possible, and may be indicated if molecular evaluation is informative in a parent of an affected child.

Chapter 43 - Histiocytic Disorders

Jeffrey M. Lipton

INTRODUCTION

The histiocytic disorders comprise a broad grouping of hematologic diseases united only by the observation that a dendritic cell or monocyte/macrophage appears to be the principal pathologic protagonist. The ubiquitous nature of these histiocytes, their extraordinary metabolic capabilities, their role as regulators of hematopoiesis, and their prominence in the immune and inflammatory response (as well as uncertainty regarding dendritic cell and monocyte/macrophage ontogeny) all have contributed to the persistent confusion regarding the nosology of these disorders. To help clarify the nomenclature, Favara et al. refer to histiocytes as a group of immune cells that include[s] macrophages and dendritic cells. [1] Thus, the term histiocyte is analogous to lymphocyte in that both denote groups of immune cells that are phenotypically and functionally diverse. Based on this definition, a nosology derived from new information regarding cell lineage and biologic behavior has been developed,[1] replacing the previous classification system. [2] In doing so the World Health Organizations Committee on Histiocytic/Reticulum Cell Proliferations and the Reclassification Working Group of the Histiocyte Society have

TABLE 43-1 -- A Contemporary Classification of Histiocytic Disorders

(Not Available)

From Favara BE, Feller AC, Pauli M et al: Contemporary classification of histiocytic disorders. Med Pediatr Oncol 29:157, 1997. Copyright 1997. Reprinted by permission of Wiley-Liss, a division of John Wiley & Sons, Inc.

created a paradigm for the continued reassessment of the classification of these disorders as new laboratory and clinical science comes to light.

Currently, two broad categories of disease, disorders of varied biological behavior and malignant disorders, are each subdivided into dendritic (antigen-presenting) cell- or macrophage/monocyte (antigen processing cell)-related disorders. Other disorders in which histiocytes are implicated such as storage diseases, hyperlipidemic xanthomas, well-defined chronic infections such as tuberculosis and leprosy and granulomatous reactions to foreign materials are excluded. [1]

The clinical syndromes making up the major dendritic cell-related disorders of varied biologic behavior termed Langerhans cell histiocytosis, [3] [4] previously known as histiocytosis X, are the main focus of this chapter. The macrophage-related histiocytoses, also covered, include familial primary hematophagocytic lymphohistiocytosis, still referred to as familial hematophagocytic lymphohistiocytosis (FHL) or previously as familial erythrophagocytic lymphohistiocytosis (FEL), sporadic primary hematophagocytic lymphohistiocytosis, and sinus histiocytosis with massive lymphadenopathy. The malignant histiocytic disorders, which include the malignant proliferations of the monocyte/macrophage lineage, acute monocytic leukemia (FAB-M5), acute myelomonocytic leukemia (FAB-M4), chronic myelomonocytic leukemia, macrophage-related histiocytic sarcoma, and the more recently described dendritic cell-related neoplasms, are discussed in other chapters. Table 43-1 (Table Not Available) presents the currently accepted classification of the histiocytic syndromes.

EPIDEMIOLOGY

The syndromes constituting Langerhans cell histiocytosis (LCH) were originally considered by many to be malignant neoplasms. That they have been treated with aggressive chemotherapy and radiation therapy, and more recently that they have been found to be clonally derived, have not resolved the difficulties in properly categorizing this class of disorders. Still, there are clear differences between the clinical behavior observed in most instances of LCH and true malignant disease. These differences suggest conservative management for many patients.

The clinical course of malignant neoplasia is generally relentlessly progressive, with virtually no survival in untreated patients (stage IVS neuroblastoma being the notable exception). In LCH, however, even with multiple site involvement, spontaneous remissions have been described. [5] In addition, varying morbidity and mortality have been reported in untreated patients with LCH, depending on the extent of disease. Pathologically, the lesions of LCH appear as reactive infiltrates, the hallmark being immature Langerhans cells that have little of the cellular atypically and homogeneity characteristic of most malignancies. Using flow cytometry, most investigators have found no evidence of DNA aneuploidy. [6] [7] [8] Although the cause of these phenomena is unknown, LCH is thought by some, as previously proposed, [3] [9] [10] to represent a reactive immune disorder triggered by unknown stimuli. There is no evidence

implicating viruses in this process, either directly or as immune triggers. [11]

Using X-chromosome-linked DNA probes to detect clonal X-chromosome inactivation, it was found that LCH is characterized by a clonal proliferation of CD1a+ cells.[12] All tissues derived from either localized or disseminated LCH were found to be clonally derived. [13] However, the identification of clonality does not necessarily indicate malignancy. More information on the biology of dendritic cell differentiation and activation is needed to interpret these data, and ultimately to develop new therapeutic strategies.[14]

Historically, the classic LCH syndromes are (1) monostotic or solitary eosinophilic granuloma (SEG) or multifocal eosinophilic granuloma (MEG)localized lesion(s) confined to bone;[15] [16] (2) Hand-Schüller-Christian diseaseprotracted multiple-site involvement with the classic but rare triad of skull defects, diabetes insipidus, and exophthalmos;[17] [18] [19] [20] and (3) Letterer-Siwe diseasedeeper visceral lesions involving skin, liver, lungs, bone marrow, lymph nodes, spleen, and other organs. [21] [22] The prevalence of these syndromes is estimated to be 1:50,000, with an incidence of 1.08 per 200,000 per year in children <15 years old. [23] The syndromes predominantly affect infants and young children, although disease in adults, even the elderly, [24] is well described. A male predominance has been widely reported. [25] [26] [27] [28] [29] [30] Since disease occurs on a continuum and frequently does not fit these rigid and arbitrary designations, a prognostic grouping system has been developed. Classification is best accomplished according to the criteria originally developed by Lahey [31] and refined by Komp and co-workers[32] and Osband et al. [10] Although the Histiocytosis Society has simplified its prognostic groups for the stratification of systemic treatment protocols into a low-risk group (patients >2 years old with no involvement of the hematopoietic system, liver, lungs, or spleen) and an at-risk group (patients <2 years old with involvement of these organs), the system described in Table

[a] Dysfunction includes the following:

1. Hepatic dysfunction: one or more of the followinghypoproteinemia (total protein <5.5 mg/dl or albumin <2.5 mg/dl), hyperbilirubinemia (>1.5 mg/dl), edmerna, ascites.
2. Pulmonary dysfunction: one or more of the followingtachpnea, dyspnea, cyanosis, cough, pneumothrorax, pleural effusion.
3. Hematopoietic dysfunction: one or more of the followinganemia in the absence of iron deficiency or significant infection (<10 g/dl hemoglobin), leukopenia (<4,000/ml), thrombocytopenia (<100,000/ml).

[b] By arbitrarily assigning either 0 or 1 point for the absence or presence of one of the three important prognostic variables, a number of total points is obtained and a patient is assigned a group.

43-2 may be helpful in defining prognosis and treatment options over a broad spectrum of patient types.

Patients in groups 0 to I and some in group II (Table 43-2), particularly those with any single system disease, do well, with some morbidity but virtually no disease-related mortality. They frequently need little or no systemic therapy. Other patients in group II and most in group III need systemic therapy and generally do well, while patients in group IV have significant morbidity and mortality regardless of therapy. [10]

The yet to be determined optimal management for the patient with LCH would be one that balances therapeutic intervention structured to minimize both short- and long-term disease-related morbidity with appropriate systemic therapy designed to reduce treatment-associated morbidity. Although recurrences are common, almost all patients who respond to therapy will be able to discontinue treatment completely. This philosophy applies to those patients (generally in groups IIII) with relatively favorable prognoses. Another goal thus remains to find effective therapy for those patients whose disease does not respond to therapy (predominantly group IV patients).[2] These patients should have HLA typing performed at diagnosis and should be considered for bone marrow transplantation or other experimental therapies.[2]

BIOLOGIC ASPECTS

In order to understand the histiocytic disorders, in particular Langerhans cell histiocytosis, it is important to review monocyte/macrophage and dendritic cell differentiation, characterized by the developmental sequence shown in Figure 43-1 .[33] [34] [35] [36] [37] [38] [39]

In the bone marrow this process begins with the pluripotent hematopoietic stem cell, which may give rise either to a lymphoid progenitor capable of T- or B-lymphocyte lineage commitment or to a multipotent myeloid progenitor capable of differentiation to either erythroid, megakaryocytic, eosinophil, basophil/mast cell, or granulocyte/macrophage cell lines. The granulocyte and the macrophage share a common progenitor, the granulocyte/macrophage colony-forming unit (GM-CFU). The GM-CFU, capable of granulocyte or monocyte differentiation, gives rise to the monocyte/macrophage progenitor (M-CFU). M-CFU gives rise to the monoblast, then to the bone marrow promonocyte (the first morphologically identifiable macrophage precursor), and finally to the monocyte, a process that takes approximately 6 days.[34] The promonocyte ranges from 1018 m in diameter and has a well-developed Golgi apparatus as well as peroxidase-positive granules. The typical monocyte has a folded nucleus, lightly basophilic cytoplasm, and faintly azurophilic granules. [36]

Bone marrow monocytes enter the circulation and migrate, apparently in a random fashion, into tissues, where they transform into tissue-specific macrophages under the influence of the local environment and become the cells of the mononuclear phagocyte system (MPS). [34] Dendritic cells likewise have their origin in the bone marrow[37] and can be cultured from progenitors residing in both the bone marrow and peripheral blood. [38] A CD34+ progenitor can, in single cell culture, give rise to either dendritic cells, via the dendritic Langerhans cell colony-forming unit (DL-CFU), or macrophages confirming that dendritic cells and macrophages share a common progenitor. Proliferative precursors of the dendritic cell enter the circulation from the bone marrow in a fashion somewhat analogous to the monocyte. They then enter the tissues,[39] where proliferation and differentiation to functional, antigen-presenting dendritic cells ensue. The morphology of the dendritic cell may vary depending on its functional (veiled versus dendritic) state. It is a large cell with multiple cytoplasmic extensions that is essentially devoid of phagolysosomes and other cytoplasmic organelles. The cytoplasm of this mobile cell is rich in mitochondria. [40] [41] The nucleus

Figure 43-1 Development of cells of the monocyte/macrophage lineage. CFU-GM, colony-forming unitgranulocyte/macrophage; CFU-M, colony-forming unitmacrophage; CFU-DL, colony-forming unitdendritic Langerhans cell.

is eccentric with small nucleoli.[41] Langerhans cells are characterized by Birbeck granules, [42] which appear ultrastructurally as tennis-racquet shaped pentalaminar structures.[33]

Functionally the MPS, also known as the reticuloendothelial system, consists of a multitude of ordinary tissue histiocytes (fixed macrophages) that act to provide host defense by disposing of senescent or damaged blood cells, ingesting invading organisms, processing antigens for the immune system, and stimulating the inflammatory process through the production of a number of cytokines.[34] [35] [42] [43] The most important of these cytokines are interleukin-1 (IL-1) and tumor necrosis factor (TNF), which activate T lymphocytes as well as other macrophages.

The MPS system is a component of many organs. These cells include splenic sinusoidal macrophages, hepatic Kupffer cells, [44] pulmonary alveolar macrophages,[45] bone osteoclasts, [46] pleural, peritoneal, and synovial macrophages, and microglial cells of the brain. [47] [48]

As phagocytic cells, the ordinary tissue histiocytes have IgG Fc receptors, whereas tissue-based dendritic cells, which make up the dendritic cell system (DCS), lack phagocytic capacity, peroxidase or esterase expression, or Fc receptors and are predominantly antigen-presenting cells. [33] [49] Found in virtually all tissues except the brain,[33] the Langerhans cell is the major immunologic cellular component of the integument and mucosa. Normal Langerhans cells reside within the epidermis and regional lymph nodes as well as the thymic epithelium and bronchial mucosa.[50] Functionally, cells of the DCS interact with and process antigen, then migrate (most likely as veiled cells) to lymphoid organs, where they participate as effector cells with T cells in generating a cellular and, indirectly, a humoral immune response. [33] The types of dendritic cells are summarized in Table 43-3 . As with the cells of the MPS, dendritic cells are capable of elaborating a wide array of cytokines, including IL-1 and TNF.[51]

Hematopoietic differentiation is regulated by a family of glycoproteins termed colony-stimulating factors and interleukins. A large family of these growth factors has been purified, cloned, and functionally characterized. GM-CSF, IL-3 or multi-CSF, M-CSF, and G-CSF [52] [53] [54] [55] exert a major influence on monocyte/macrophage differentiation.[52] [56] [57] [58] GM-CSF and IL-3 have a broader range of activity, influencing differentiation of primitive as well as committed progenitors. [56] [58] In addition, GM-CSF increases the functional activity of mature granulocytes, eosinophils, and monocytes. [59] [60] [61] M-CSF and G-CSF, restricted in their activity, influence the discrete monocyte/macrophage and granulocyte pathways, respectively, and enhance granulocyte and monocyte/macrophage function. [62] [63] Early work implicated T cells as a source of stimulating activity. [64] Since then, the monocyte/macrophage, the fibroblast, and other cells have also been shown to be involved in factor production.[65] [66] In addition, the production of these factors by cells outside the bone marrow supports the finding that some factors have the dual functions of stimulating marrow progenitor differentiation and proliferation and of enhancing the function of mature myeloid cells. [67]

Dendritic cells can be generated from progenitors in vitro using GM-CSF plus IL-4 or TNF [39] as well as other cytokines. GM-CSF appears to serve as a survival rather than a differentiation factor, while TNF induces maturation of these cells. [68] Thus, there exists a complex regulatory network, activated by a wide variety of stimuli, that controls the proliferation and function of the MPS and the DCS as well as associated myeloid cells, whose presence characterizes the lesions of the histiocytic syndromes. The complexity of activation/inhibition, cellular transformation, proliferation, and phagocytosis, and the multitude of factors that modulate the DCS and MPS, contribute to the difficulty in understanding the histiocytic disorders described in this chapter. The ability of dendritic cells and macrophages to produce cytokines and activate T lymphocytes and other inflammatory cells also contributes to the varied, sometimes

TABLE 43-3 -- Types of Dendritic Cells

Cell Type	Location	Function
Peripheral blood dendritic cell	Peripheral blood	Migratory

Langerhans cell[a]	Skin, epidermis, cervix, vagina, stomach, esophagus	Antigen uptake and processing(?), transport to lymph nodes
Veiled cells[a]	Afferent lymphatics	Antigen transfer
Interdigitating dendritic cell	Lymph node, paracortex (T area), periarteriolar lymphatic sheath of the spleen	Antigen presentation for the T cells
Thymic dendritic cell[a]	Thymic medulla	Induction of immune tolerance
Interstitial dendritic cell	Parenchymal organs (excluding brain and central cornea)	Antigen uptake and processing(?)
Indeterminate cells of the skin (dermal dendrocytes)	Dermis	Unknown
Follicular dendritic cell[b]	Germinal center of lymph nodes	Antigen presentation in B cells and maintenance of long-term immunologic memory

protean clinical manifestations of the histiocytic disorders. In particular, since Nezelof et al. [69] first concluded that histiocytosis X was characterized by the proliferation of Langerhans cells, hematopoietic cell culture, immunopathology, electron microscopy, and immunophenotyping have led to a greater (yet still incomplete) understanding of the pathobiology of LCH in the context of the developmental scheme described in Figure 43-1 .

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

CLINICAL MANIFESTATIONS

The signs and symptoms of LCH vary considerably, depending on which organs are infiltrated by the Langerhans and accompanying immunoreactive cells. Bone, skin, teeth, gingival tissue, ear, endocrine organs, lung, liver, spleen, lymph nodes, and bone marrow can all become involved, and exhibit dysfunction secondary to cellular infiltration. [70] Although patients rarely have disease that falls into the discrete classic categories of eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease, this nomenclature remains valuable, if only to catalogue the clinical manifestations of LCH. In addition, these eponyms preserve an important historical perspective on this enigmatic group of disorders.

The difficulty in diagnosis and the historically complex nomenclature have made the true prevalence and incidence of these disorders difficult to ascertain. [71] Malones review reveals that most cases do occur between 1 and 15 years of age. [72] A 1993 study reported from Denmark placed the prevalence at 150,000 and the incidence at 1.08/200,000 per year in children <15 years old. [23]

Solitary or multifocal eosinophilic granuloma (SEG or MEG) is found predominantly in older children as well as in young adults, usually within the first three decades of life. The incidence peaks between the ages of 5 and 10 years. [73] SEG and MEG account for 6080% of all instances of LCH. [73] Patients with systemic involvement frequently have similar bony lesions in addition to other manifestations of disease. [70] There is often an inability to bear weight and a tender (sometimes warm) swelling that is due to tissue infiltrates overlying the bony lesions. [70] [74] Radiographically, the lesions are sharply marginated, round, or oval, with a beveled edge that gives the appearance of depth. [70] [75]

Hand-Schüller-Christian disease is described in younger children aged 25 years and represents 1540% of cases of LCH. [73] Signs and symptoms include bony defects with exophthalmos due to a tumor mass in the orbital cavity. This usually occurs because of involvement of the roof and lateral wall of the orbital bones (although bony involvement is not necessary). [76] In addition, teeth are often lost consequent on gum infiltration and mandibular involvement. The most frequent sites of bony involvement are the flat bones of the skull, ribs, pelvis, and scapula. [70] There may be extensive involvement of the skull with irregularly shaped lucent lesions, giving rise to the so-called geographic skull. [77] Somewhat less frequently, long bones and lumbosacral vertebrae (usually the anterior portion of the vertebral body) are involved. In one recent series the majority of children with vertebral involvement had involvement of only a single vertebra, with nine of the 15 having other skeletal lesions. [78] In long bones, growth of lesions in the medullary cavity leads to pressure that may result in erosion through the cortex, stimulating the formation of periosteal new bone, accompanied by soft tissue involvement. [79] A differential diagnosis that includes Ewing sarcoma and osteogenic sarcoma or osteomyelitis must be considered in these instances. Only rarely are the wrists, hands, knees, feet, or cervical vertebrae involved. [70] Orbital involvement may result in loss of vision or strabismus as a result of optic nerve or orbital muscle involvement, respectively. Oral involvement may begin in the gums or in the periapical regions of the teeth. Erosion of the lamina dura gives rise to the characteristic floating tooth seen on dental radiographs. [75] The entire mandible may be involved, with loss of bone leading to diminished height of the mandibular rami. Erosion of gingival tissue causes premature eruption, decay, and tooth loss. [80] Parents of affected children, particularly infants, frequently report precocious eruption of teeth when in fact the gums are receding to expose immature dentition. Chronic otitis media due to involvement of the mastoid and petrous portion of the temporal bone and otitis externa are not uncommon.

Diabetes insipidus (DI) affects 550% of patients with LCH. [81] Most instances of DI occur in children, who present with systemic disease and involvement of the orbit and skull. [81] Less than one-third of children who ultimately develop DI have polydypsia and polyuria as presenting symptoms of LCH. [81] In most children DI develops within 4 years of diagnosis. DI is due to infiltration by Langerhans cells of the hypothalamus, with or without involvement of the posterior pituitary gland. [82] Local tissue

damage may be a consequence of IL-1 and prostaglandin E_2 production. [81] Polydypsia and polyuria may be present at presentation or may develop during active disease (even when there is improvement in other areas) or after therapy is discontinued and there is no other apparent active disease.

Short stature has been found in up to 40% of children with systemic LCH. [82] [83] Chronic illness and steroid therapy play an important role in this phenomenon. Short stature may also be a consequence of anterior pituitary involvement and growth hormone deficiency. [83] Other endocrine manifestations include hyperprolactinemia and hypogonadism due to hypothalamic infiltration. [84] Pancreatic and thyroid involvement have also been reported. [84] [85]

Gastrointestinal tract disease has been identified. [86] [87] In one retrospective series only 2% of 348 children had biopsy-proved gastrointestinal involvement, [88] but in a prospective trial, 13% of 78 patients had digestive tract symptoms. [89]

The rarest (10% of cases) and most severe form of LCH is Letterer-Siwe disease. [73] Typically, an infant <2 years old presents with a scaly seborrheic, eczematoid, sometimes purpuric rash involving the scalp, ear canals, abdomen, and intertriginous areas of the neck and face. The rash may be maculopapular or nodulopapular. Ulceration may result, especially in intertriginous areas. Ulcerated and denuded skin may serve as a portal of entry for microorganisms, leading to sepsis. Draining ears, lymphadenopathy, hepatosplenomegaly, and, in severe cases, hepatic dysfunction with hypoproteinemia and diminished synthesis of clotting factors can occur. Anorexia, irritability, failure to thrive, and significant pulmonary symptoms such as cough, tachypnea, or pneumothorax may occur as well. One of the most clinically important areas of involvement is the hematopoietic system, where involvement manifests as anemia or thrombocytopenia. The pathophysiology of hematopoietic dysfunction is not well understood, since direct bone marrow involvement is only occasionally noted and significant marrow infiltrates are rare. Thrombocytopenia most frequently portends a fatal outcome. [25] Because of their physical appearance, these patients are frequently diagnosed as victims of abuse or neglect.

A relatively recently described and severe manifestation of LCH is non-hypothalamic-pituitary involvement of the central nervous system (CNS). [90] The majority of patients with CNS involvement had associated skull, orbit, or mastoid disease. Magnetic resonance imaging (MRI) with contrast agent enhancement is the best way to identify lesions of the CNS. As expected, the hypothalamic-pituitary region, characterized by DI, was the most common site of involvement, followed by the cerebellum, pons, and cerebral hemispheres. Lesions of the basal ganglia, spinal cord, and optic nerves were also seen. Involvement of the CNS was frequently observed years after the initial diagnosis. Extraxial lesions of the dura, meninges, or choroid plexus usually responded well to treatment. However, lesions of the cerebellum or pons frequently resulted in severe, even fatal sequelae. Pathologically, CNS lesions, other than for those of the hypothalamic-pituitary axis, almost uniformly were not CD1a, Birbeck granule-positive. The etiology and pathophysiology of this gliotic and demyelinating process, [91] which often leads to fatal degeneration of the CNS, are poorly understood.

Three other so-called presentations are described. A nodal presentation (not to be confused with sinus histiocytosis with massive lymphadenopathy) is characterized by significant enlargement of multiple lymph node groups, with little or no other signs of disease. In the pulmonary syndrome there is almost exclusive involvement of the lungs. This condition is usually seen in men in their third or fourth decade (and occasionally in adolescents) and may follow an indolent, severe, and chronic debilitating course, or may manifest acutely with a pneumothorax. [92] Cigarette smoking has been strongly implicated. [92] In contrast, the pulmonary involvement in younger patients with systemic disease is frequently mild, although fulminant pulmonary disease may occur in this age group. [93] [94] The chest radiograph may vary

from a diffuse infiltrate consistent with bilateral interstitial pneumonia, to a honeycomb lung appearance due to pulmonary fibrosis. [94] [95] Finally, pure cutaneous disease with no evidence of dissemination has been described in children and adults. [96] Rarely, patients present with deep subcutaneous skin nodules only (formerly described as Hashimoto-Pritzker syndrome). [71]

With such a vast spectrum of disease manifestations, adherence to strict labels such as eosinophilic granuloma, Hand-Schüller-Christian disease, or Letterer-Siwe disease, Hashimoto-Pritzker syndrome, and other syndromes or presentations cannot adequately describe a particular patient, and the development of a classification scheme predictive of prognosis becomes necessary (Table 43-2).

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

NATURAL HISTORY AND PROGNOSIS

As originally proposed by Lahey, [31] the prognosis for patients with LCH depends on three factors: age at onset, number of organs involved, and degree of dysfunction of specific organs. An adolescent or adult who presents with solitary bone eosinophilic granuloma has the best prognosis, [97] whereas an infant with multiple affected organs has the worst.[25] [26] [27] [28] [31] [32] A prognosis-based classification (Table 43-2) allows one to discard the labels of eosinophilic granuloma, Hand-Schüller-Christian disease, Letterer-Siwe disease, and other syndromes (or presentations) and to group patients according to age at onset, localization, and severity of disease. Specifically, age 2 years is associated with a good prognosis, whereas age <2 years is associated with a worse prognosis (Table 43-4 (Table Not Available)). When LCH develops in individuals >65 years old, regardless of site and extent of disease, the prognosis is usually poor. [72] Involvement of fewer than four organ systems is a relatively good prognostic sign, whereas involvement of four or more organ systems predicts a less favorable outcome (Table 43-5), and dysfunction of three specific organ systems (hepatic, pulmonary, and hematopoietic) is an extremely important adverse predictor of outcome (Table 43-4 (Table Not Available)). In a review covering a 25-year experience at a single institution, [96] 7 of 28 patients with multisystem disease died, 5 of 14 had single disease recurrences, and 9 of 14 had multiple disease recurrences. Of interest, the recurrence rate in those patients with polyostotic bone involvement was higher (8 of 12) than in those with multisystem disease. However, there were no deaths in this group.

Organ dysfunction, as described in Table 43-2 , must be distinguished from involvement (e.g., hypoproteinemia or hyperbilirubinemia versus hepatomegaly), since involvement alone is not as adverse a prognostic sign as dysfunction. By arbitrarily assigning either 0 or 1 point for absence or presence of one of the three important prognostic variables, the grouping system described in Table 43-2 is defined. This classification is a reliable prognostic tool and also indicates which patients need systemic therapy. A review of 62 patients ages 0 (birth) to 14 years [30] confirms these observations, stressing the importance of two factorsage and localized disease. All but one of the 15 patients who died were <2 years old at diagnosis. With regard to local involvement, the presence of bony involvement was a good prognostic sign, and skin involvement that was localized to the scalp was associated with a considerably better outcome than generalized cutaneous involvement.

HISTOLOGIC DIAGNOSIS

The typical histologic appearance of LCH varies with the age of the lesion examined. The Langerhans cell is the prominent diagnostic feature in the histology of Langerhans cell histiocytosis.[99] Early lesions are cellular and locally destructive, with a proliferation of essentially normal Langerhans cells. [72] LCH cells, however, differ somewhat from normal Langerhans cells in that they are functionally defective, are frequently found in tissues where Langerhans cells do not normally reside, and are arrested at an early stage of cell activation. [50] Mitoses are usually not present in great numbers, but when found are of no prognostic significance. [100] Multinucleated histiocytes are often present. Other inflammatory cells, such as granulocytes, eosinophils, macrophages, and occasionally lymphocytes and plasma cells, are present as well. The histiocytes and macrophages may be phagocytic, but Langerhans cells are not. [100] With time these cells may accumulate cholesterol. Occasionally there is necrosis present, with only rare Langerhans cells. In addition, as lesions mature, there are fewer Langerhans cells. Pathologically, a presumptive diagnosis of LCH is made on the basis of a biopsy specimen demonstrating the characteristic histopathology. [72] [95] [100] [101] [102] The Langerhans cell is 1525 m in diameter, with a central to slightly eccentric ovoid to uniform-shaped nucleus with a delicate chromatin network and inconspicuous nucleoli. An indentation or groove across the face of the nucleus is a feature of many cells.[101] Additional diagnostic criteria beyond standard histopathology, immunochemical staining with ATPase, S-100 protein, -mannosidase, peanut lectin, vimentin, and other markers [100] [103] [104] are necessary to establish the diagnosis. An extensive immunophenotype of normal and LCH Langerhans cells (Table 43-6) has been recently reviewed.[33] However, the definitive diagnosis of LCH relies most specifically on the immunohistochemical identification of the presence of Langerhans cells by cell-surface CD1a or of Birbeck granules [42] [65] by electron microscopy. Thus, pathologic criteria for the diagnosis of LCH have been established, [72] [100] [103] and in 1987 the Histiocyte Society formalized these criteria (Table 43-7).[2] Favara et al. now suggest that with the availability of new antibodies to CD1a for use in routinely processed paraffin-embedded specimens, the category of diagnosis can be omitted as redundant.[1] Clinicians

must keep in mind that standard histology still permits only a presumptive diagnosis and must insist, in all cases, on a definitive immunohistochemical or ultrastructural diagnosis.

The differential diagnosis of LCH is limited and depends on the clinical presentation. It includes immunodeficiency syndromes with graft-versus-host disease, viral infections, infiltrative diseases such as leukemia or lymphoma, reticuloendothelial storage diseases, congenital infections, benign and malignant bone tumors and cysts, and papular xanthomas.

A careful evaluation of biopsy material will generally result in a diagnosis. However, one of the historic dilemmas in the evaluation of LCH is that the histopathology of lesions from patients with single-site eosinophilic granuloma (group 0) is similar, if not identical, to that of classic Letterer-Siwe disease (group III or IV). [70] [102] Indeed, this is consistent with the recent finding that tissue in lesions from patients with localized or systemic disease cannot be distinguished on the basis of clonality. [12] [13] As expected on the basis of these observations, efforts to distinguish favorable from unfavorable histologic types [105] have been shown not to be of any value.[106] Although patients are grouped in large part based on the extent of disease, untreated patients generally do not progress to a higher stage, as occurs with lymphoma patients. In fact, progression from a limited syndrome to diffuse systemic disease is extremely rare. [70] Within a few months after presentation it will become apparent that the bony lesions seen initially are limited to the skeleton or were the heralding lesion(s) of diffuse systemic involvement. [97]

TABLE 43-7 -- Criteria of the Writing Group of the Histiocyte Society (1987) for the Diagnosis of Langerhans Cell Histiocytosis (Formerly Histiocytosis X)

I. Presumptive diagnosis: study of conventionally stained biopsy material with findings that are consistent with those defined in the literature.
II. Diagnosis: an increased degree of diagnostic confidence with presumptive diagnosis plus presence of two or more features: positive stain for ATPase, S-100 protein, -mannosidase, or peanut lectin.
III. Definitive diagnosis: requires the demonstration of Birbeck granules by electron microscopy or CD1 antigenic determinants (T6 positivity) on cryostat sections in the context of presumptive diagnosis or diagnosis.

From Hall et al.,[103] with permission from Blackwell Science, Ltd.

When cutaneous involvement is the only obvious presenting sign, 612 months may be required to determine the ultimate extent of disease. [7C]

These observations strengthen the need for a complete clinical and laboratory evaluation with proper imaging studies once a definitive diagnosis of LCH is made. In general, the baseline evaluation of a newly diagnosed patient requires a reasonable search for all sites of disease. The laboratory and imaging evaluation must be guided by a complete history and thorough physical examination, including a dental examination. All patients should be evaluated with a complete blood cell count, liver function tests and liver enzyme assays, a coagulation workup, urine osmolality, chest radiography, and a skeletal survey, including views of the skull. In a recent series of children with LCH in whom both radiographic and radionucleotide skeletal evaluations were performed, the radiologic evaluation detected virtually all significant skeletal lesions.[107] Other tests such as panoramic dental radiography, pulmonary function tests, MRI of the brain and middle ear, and bone marrow aspirates/biopsies and other tissue biopsies should be done based on findings on the initial evaluation.

THERAPY

The philosophy for treatment of LCH is to use an appropriate amount of the least toxic therapy to treat the disease. In patients with potentially morbid or life-threatening disease at presentation, or in those in whom morbid or life-threatening disease develops during the course of treatment, more aggressive therapy should be implemented. This approach emphasizes the need for treatment protocols based on careful prognosis-based risk stratification. Whether more intense front-line therapy in lower-risk patients with systemic disease can reduce disease sequelae such as DI, CNS degeneration, sclerosing cholangitis, or disease recurrence, and whether a reduction in these problems outweighs the risk of more intense therapy, are under evaluation.

The primary specialist should coordinate the care of these patients. Subspecialty consultation should be sought from dentists, dermatologists, endocrinologists, gastroenterologists, neurologists, orthopedic surgeons, otolaryngologists, and others experienced in managing LCH. The goal of therapy for the majority of patients with localized or limited systemic disease must be to minimize loss of function and prevent cosmetic deformity.

Severely ill patients are hospitalized and given antibiotic, ventilatory, nutritional (including hyperalimentation), blood product, skin care, physical therapy, medical, and nursing support as required in addition to definitive treatment. Scrupulous hygiene is quite effective in limiting auditory canal, cutaneous, and dental lesions. Debridement, and even resection of severely affected gingival tissue, is done to limit oral involvement. The seborrhea-like dermatitis of the scalp may improve with the use of a selenium-based shampoo twice a week. Topical steroids are occasionally effective but should be used sparingly, and only for short-term control of small areas.

Surgery and Radiation Therapy

After complete evaluation, those patients with disease involving a single bone, and some patients with disease involving multiple lesions and multiple bones, are managed with local therapy. This involves surgical curettage for patients whose lesions are in easily accessible, noncritical locations. Complete cancer operation resections are not necessary. Surgical restraint must be exercised to avoid drastic cosmetic and orthopedic deformities and loss of function. Local soft tissue disease (e.g., of the scalp, thymus, or lymph nodes) generally recurs despite surgery; thus, systemic treatment or low-dose radiation in emergency situations is recommended for these types of lesions. Localized radiation therapy (usually 600900 cGy, with 450 cGy for small lesions and 1,500 cGy for large lesions) in 200-cGy fractions, utilizing only megavoltage equipment, is currently employed. Older patients may need slightly higher doses (2,000 cGy for large lesions). If possible, structures such as the lens of the eye and the thyroid gland should be spared. Patients at risk for skeletal deformity, visual loss secondary to exophthalmos, pathologic fractures, vertebral collapse, or spinal cord injury should receive radiation therapy. Patients with severe pain, symptomatic adenopathy, or multiple lesions may also warrant low-dose radiation therapy to affected areas if systemic therapy is not rapidly effective. Lesions in poorly accessible sites, such as the orbit, or lesions recurring after curettage should also be irradiated.[108] [109] DI may occur at any time during the course of LCH. Patients should be instructed to report signs of DI as soon as they develop, since dehydration and electrolyte imbalance may be quite serious. The results of hypothalamic and pituitary radiation therapy, even instituted early in the course of DI, have been poor, and the use of this modality is not recommended. [109] [110] [111]

A review of 40 patients receiving radiation therapy between 1970 and 1984 indicates that patients with unifocal disease have a higher rate of response for individual lesions than patients with multifocal disease (two or more soft tissue sites). Thus, patients who appear to have an isolated lesion that does not respond to appropriate radiation therapy should be carefully re-evaluated for additional sites of disease. In this review, the complete plus partial response rate for solitary bone lesions was 100% (35 of 35), with 24 complete responses. Soft tissue lesions adjacent to involved bone healed better than isolated soft tissue lesions. There was no response to irradiation for liver, spleen, or lung lesions, and none of eight patients with DI responded. [110]

Chemotherapy

Historically, drugs used in the therapy of classic malignant diseases have been used systemically for LCH. Nitrogen mustard, vincristine, vinblastine, cyclophosphamide, procarbazine, chlorambucil, etoposide, methotrexate, corticosteroids, and 6-mercaptopurine (6-MP) have been used, singly or in combination, with variable success. Response to chemotherapy varies from 25% to 90%. An early study did show that treatment improves survival in patients <2 years old (Table 43-8).[25] Table 43-9 summarizes selected best-designed early chemotherapeutic trials utilizing well-characterized patients. [112] [113] [114] [115] [116] [117] [118] [119] [120] [121] [122] A reasonable therapeutic approach to systemic therapy is to observe patients in group I (some in group II) who respond to local (i.e., surgery, radiation therapy) or nonsystemic (i.e., topical steroids) therapy and look for signs of continuing disease resolution. If there are symptomatic lesions or signs of failure to thrive, systemic treatment should be pursued. The erythrocyte sedimentation rate is sometimes a useful indicator of disease activity. Patients in groups II and III will benefit dramatically from chemotherapy, while there are poor responses and death in many group IV patients. Because of the rarity of LCH and the large number of therapeutic questions for which answers must be sought, all patients with disseminated disease should be enrolled in well-designed collaborative studies. Based on data from several small studies demonstrating the efficacy of etoposide in previously untreated patients [121] [123] and those with resistant disease,[124] the Histiocyte Society in April 1991 sponsored its first international randomized study, LCH-I, for patients <18 years old with disseminated disease. This study compared the efficacy of vinblastine with that of etoposide for previously untreated disseminated LCH. [125] Treatment in each arm consisted of a single pulse of high-dose methylprednisolone for induction, followed by weekly vinblastine (6 mg/m^2 by intravenous bolus) versus 3-consecutive-day courses of etoposide (150 mg/m^2 by intravenous infusion over 2 hours) every 3 weeks. Each treatment continued for 24 weeks. An interim

TABLE 43-8 -- Treatment versus No Treatment[a]

No. of Patients	Treatment	No. Dead	No. Alive	Mean Age (mo)
27	No	27	0	10.5
64	Yes	40	24	15.0

Data from Lahey.[25]

[a] Treatment consisted of variable chemotherapy (steroids, antimetabolites, and alkylating agents); no treatment entailed supportive care.

evaluation of LCH-I showed that the rapidity of the initial response seemed to correlate with prognosis and that those patients with a poor initial response in either arm did not do well in a crossover to the alternative arm. [125] [126] With no difference in survival between the two arms, combined with the potential risk of leukemogenesis

with etoposide, the study has given rise to LCH-II. LCH-II uses the framework of the DAL HX-83 study, [126] in which all patients receive a 6-week induction with prednisone, vinblastine, and etoposide, followed by 1 year of therapy with only oral 6-MP, vinblastine, and prednisone (a), or 6-MP, vinblastine, and prednisone plus either etoposide (b) or etoposide and methotrexate (c) for patients with multifocal bone involvement (a), soft tissue involvement without organ dysfunction (b), and organ dysfunction (c), respectively. [126] In LCH-II, patients are stratified into low risk (patients >2 years old with no involvement of the hematopoietic system, liver, lungs, or spleen) and at risk (patients <2 years old with involvement of these organs). Patients with multisystem disease in the low-risk group receive initial treatment with a 6-week course of prednisone and weekly vinblastine, followed by continuation treatment with oral 6-MP, prednisone pulses, and weekly vinblastine for 24 weeks. Patients in the at-risk group are randomized to the low-risk arm treatment versus that treatment with the addition of etoposide to both initial and continuation treatment. [126] Low-risk patients whose disease does not respond are switched to the etoposide arm. Those patients whose disease does not respond to conventional chemotherapy containing etoposide should be evaluated for salvage therapy.

A variety of experimental modalities, such as hemibody irradiation, [127] thymic hormone therapy, [10] [128] and IFN-, [129] have been explored at some centers for advanced or refractory disease, but these approaches have been largely abandoned. A number of chemotherapeutic approaches have had limited success, and need to be evaluated in prospective studies. [130] [131] [132] The relatively good results reported to date with bone marrow transplantation [133] [134] [135] for high-risk patients or those with refractory disease warrant further evaluation of this modality in a controlled clinical trial.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

LONG-TERM FOLLOW-UP

A careful retrospective analysis of 71 patients from a single institution who were followed up for a median of 8.1 years from diagnosis revealed significant late sequelae in 64% of patients followed up for more than 3 years, despite a relatively good survival rate of 88%, 88%, and 77% at 5, 15, and 20 years, respectively. [98] Skeletal defects were found in 42%, dental problems in 30%, DI in 25%, growth failure in 20%, sex hormone deficiency in 16%, hypothyroidism in 14%, hearing loss in 16%, and CNS dysfunction in 14%. Indeed, these data emphasize the importance of appropriate therapeutic choices, as sequelae such as bony malformations and scoliosis seemed to be a consequence of treatment with radiation. Although previous studies [89] [126] found a lower incidence of DI and fewer recurrences when aggressive initial chemotherapy that included etoposide was used in patients with multifocal bone and disseminated disease, the study discussed above included 28 patients with multisystem disease, many of whom received aggressive chemotherapy and still had recurrences and late sequelae. [98] These contradictory results emphasize the importance of a controlled clinical study (LCH-II) to determine the effect of more aggressive chemotherapy on the outcome and toxic effects in patients with LCH. In addition, three of 51 patients followed up for more than 3 years developed a malignancy. All three were <3 years old at diagnosis. Two tumors were in a radiation field, but one was a leukemia in a patient treated with an etoposide-containing chemotherapy regimen.

TABLE 43-9 -- Comparison of Selected Chemotherapy Trials for Langerhans Cell Histiocytosis

Drug(s)[a]	Study Group		No. of Patients	Response (CR + PR)[b]
Single agents				
Vincristine (VCR)	SWCCG	1972	6	50
Vinblastine (VBL)	SWCCG	1972	20	55%
VBL	CCSG	1975	18	56%
VBL	Mayo	1980	18	77%
Cyclophosphamide (CTX)	SWCCG	1972	22	63%
Procarbazine (PCB)	SWOG	1974	10	50%
Chlorambucil (CMB)	SWOG	1980	32	56%
CMB	CCSG	1980	26	27%
Etoposide (VP-16)	Italy	1988	18	83%
VP-16	AIEOP (Italy)	1993	27	70%

THERAPY FOR LANGERHANS CELL HISTIOCYTOSIS PHILOSOPHY

PHILOSOPHY

The optimal management, yet to be determined, for the patient with LCH would be one that balances therapeutic intervention structured to minimize both short- and long-term disease-related morbidity with appropriate systemic therapy designed to reduce treatment-associated morbidity. Currently almost all patients who respond to therapy will be able to discontinue treatment completely, although recurrences are common. This philosophy applies to those patients (generally in groups IIII) with relatively favorable prognoses. Another goal thus remains, to find effective therapy for those patients whose disease does not respond to therapy (predominantly group IV). These patients should have HLA typing performed at diagnosis and should be considered for bone marrow transplantation or other experimental therapies.

PROGNOSTIC GROUPING

When patients are grouped according to three prognostic variablesage, extent of disease, and presence of organ dysfunctionthe prognosis and the need for and extent of treatment can be evaluated. By assigning either 0 to 1 point for the absence or presence of one of the three important prognostic variables, a patient may have from 0 points (group I) to 3 points (group IV) (Table 43-2). Patients in groups 0 to I and some in group II, particularly those with any single system disease, do well, with some morbidity but virtually no disease-related mortality. They frequently need little or no systemic therapy. Other patients in group II and most in group III need systemic therapy and generally do well, while patients in group IV experience significant morbidity and mortality regardless of therapy. All patients should be considered for well-designed collaborative trials. Group IV patients as well as those with disease refractory to chemotherapy should undergo HLA typing and be considered for bone marrow transplantation, if a suitable donor exists. If not, these patients should be considered for experimental therapy at an appropriate center.

SUPPORTIVE CARE

Severely ill patients are hospitalized and given antibiotic, ventilatory, nutritional (including hyperalimentation), blood product, skin care, physical therapy, medical, and nursing support as required, in addition to definitive treatment. Scrupulous hygiene is quite effective in limiting auditory canal, cutaneous, and dental lesions. Debridement, and even resection of severely affected gingival tissue, is done to limit oral involvement. The seborrhea-like dermatitis of the scalp may improve with the use of a selenium-based shampoo twice a week. Topical steroids are occasionally effective but should be used sparingly, and only for short-term control of small areas. Diabetes insipidus may occur at any time during the course of LCH. Patients should be instructed to report signs of DI as soon as they develop, since dehydration and electrolyte imbalance may be quite serious. The results of hypothalamic and pituitary radiation therapy instituted early in the course of DI have been poor, and this modality is not recommended.

LOCAL THERAPY (SURGERY AND RADIATION THERAPY)

After complete evaluation, patients with disease involving a single bone and some patients with disease involving multiple lesions and multiple bones are managed with local therapy. This entails surgical curettage for patients whose lesions are in easily accessible noncritical locations. Complete cancer operation resections are not necessary. Surgi- cal restraint must be exercised to avoid drastic cosmetic and orthopedic deformities and loss of function. Local soft tissue disease (e.g., of the scalp, thymus, or lymph nodes) generally recurs despite surgery; thus, systemic treatment or low-dose radiation in emergency situations is recommended for these types of lesions. Localized radiation therapy (usually 600900 cGy, with 450 cGy for small lesions and 1,500 cGy for large lesions) in 200-cGy fractions, utilizing only megavoltage equipment, is currently employed. Older patients may need slightly higher doses (2,000 cGy for large lesions). Since individual lesions in patients with unifocal disease have a higher rate of response than those in patients with multifocal disease, patients who appear to have an isolated lesion and who fail to respond to appropriate radiation therapy should be carefully re-evaluated for additional sites of disease. Structures such as the lens of the eye and the thyroid gland should be spared if at all possible. Patients at risk of skeletal deformity, visual loss secondary to exophthalmos, pathologic fractures, vertebral collapse, and spinal cord injury should receive radiation therapy. Patients with severe pain, symptomatic adenopathy, or multiple lesions may also warrant low-dose radiation therapy to affected areas if systemic therapy is not rapidly effective. Lesions in poorly accessible sites, such as the orbit or lesions, that recur after curettage should also be irradiated.

CHEMOTHERAPY

Patients in group I and some in group II can be observed for signs of spontaneous improvement. If symptomatic lesions or failure to thrive are evident, treatment should be pursued. Patients in groups II and III will benefit dramatically from chemotherapy, while those in group IV will usually die despite chemotherapy. Experimental modalities such as bone marrow transplantation are being pursued at specialized centers for group IV patients whose disease is nonresponsive to conventional chemotherapy.

The philosophy for treatment of LCH is to use an appropriate amount of the least toxic therapy to treat the disease. In patients with potentially morbid or life-threatening disease at presentation, or in those in whom morbid or life-threatening disease develops during the course of treatment, more aggressive therapy should be implemented. This approach emphasizes the need for treatment protocols based upon careful prognosis-based risk stratification. Whether more intense front-line therapy in lower-risk patients with systemic disease can reduce disease sequelae such as DI, CNS degeneration, sclerosing cholangitis, or disease recurrence and whether a reduction in these problems outweighs the risk of more intense therapy are under evaluation. Patients with this rare disease are best served by treatment according to collaborative protocols such as those of the Histiocytosis Society. Bactrim prophylaxis in patients for whom long-term immunosuppressive therapy is anticipated should be instituted.

LONG-TERM FOLLOW-UP

All patients with LCH must receive long-term follow-up. In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic and functional orthopedic and cutaneous deformities that may lead to loss of function and severe emotional disorders, loss of permanent dentition, endocrine disorders and growth failure, hearing impairment, CNS abnormalities, and sclerosing cholangitis with biliary cirrhosis, as well as pulmonary fibrosis and cor pulmonale. Patients with chronic disabilities as sequelae of LCH should be followed up with the help of appropriate subspecialists.

TABLE 43-10 -- Late Malignancy Following Treatment of Langerhans Cell Histiocytosis

Patient	Treatment	Malignancy	Interval Between Histiocytosis and Malignancy (yr)
1	CMB	Hepatocellular carcinoma	14
2	CMB + RT	Thyroid carcinoma	16
3	CMB (CT) + RT	Acute leukemia	2
4	CMB, NM (CT) + RT	Acute leukemia	6.5
5	CMB, NM (CT) + RT	Acute leukemia	5
6	RT	Thyroid carcinoma	28

Abbreviations: CMB, chlorambucil; RT, radiation therapy; CT, combination therapy; NM, nitrogen mustard.

Data from Greenberger et al.[28]

This risk of malignancy in patients with LCH undergoing radiation and chemotherapy is well documented. Of 127 patients with LCH, [28] 84 received chemotherapy, and

six of these developed late malignancies. Two patients who received radiation therapy developed an in-field tumor, and one of these received no chemotherapy. Table 43-10 briefly describes those patients. Late malignancy developed in five of 54 patients who received chlorambucil as a single agent or in combination chemotherapy and in two of 29 patients given nitrogen mustard as part of combination therapy that included chlorambucil, vincristine, procarbazine, and prednisone. Thus, the judicious application of radiation therapy using modern techniques, avoidance of potentially carcinogenic chemotherapeutic agents, and good supportive care are highly recommended as a treatment philosophy. Although patients with LCH could have an inherently increased risk of malignancy, [136] the experience cited suggests an excess of malignancy associated with chlorambucil use. Also, the relatively poor outcome with this drug (Table 43-9) has argued effectively against its use in this disease. The issue of etoposide use is more difficult, since this is a very active agent in LCH (Table 43-9). Early reports of leukemia in LCH patients treated with etoposide as a single agent [122] [137] and in combination with other agents [98] [138] [139] have appeared. Depending on the true incidence of leukemia, [126] [140] to be determined in LCH-II, the use of this drug as a front-line agent in LCH may be modified.

Another serious sequela of LCH, sclerosing cholangitis, has been reported. [141] This complication may lead to secondary biliary cirrhosis and liver failure. The only successful treatment has been liver transplantation. [141] Sclerosing cholangitis joins severe CNS dysfunction as the most devastating sequelae of LCH. Thus, all patients with LCH must receive long-term follow-up. In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic and functional orthopedic and cutaneous deformities that may lead to loss of function and severe emotional disorders, loss of permanent dentition, endocrinologic disorders and growth failure, hearing impairment, CNS abnormalities, and sclerosing cholangitis with biliary cirrhosis, as well as pulmonary fibrosis and cor pulmonale. The hope is that newer approaches to treatment that reduce the incidence of these sequelae will become available as a consequence of a better understanding of the pathophysiology of LCH.

HEMATOPHAGOCYTIC SYNDROMES

Primary Hematophagocytic Lymphohistiocytosis (Familial and Sporadic)

Familial hematophagocytic lymphohistiocytosis, or FHL (formerly known as familial erythrophagocytic lymphohistiocytosis, or FEL), is a rapidly fatal, inherited disorder characterized by peripheral pancytopenia with bone marrow hyperplasia, systemic lymphadenopathy, intermittent fevers, and severe liver dysfunction accompanied by hepatosplenomegaly and increased liver enzyme levels.[142] [143] Patients have a characteristic severe hypofibrinogenemia not attributable to disseminated intravascular coagulation, since plasma levels of all other clotting factors are normal and no evidence of fibrinolysis is observed. [144] Hypertriglyceridemia is characteristic. Most affected children are infants (ages 2 weeks to 7 years), and two-thirds of them present within the first 3 months of life. [145] Patients usually present with pallor, irritability, anorexia, diarrhea, and failure to thrive. Occasionally there is a nonspecific, sometimes sunburned-appearing or maculopapular skin rash. [142] [145] Pulmonary effusions are present in one-third of patients. The Histiocyte Societys diagnostic criteria consist of fever of unknown etiology, splenomegaly, hematopoietic cytopenias, hypofibrinogenemia or hypertriglyceridemia, and hematophagocytosis in the bone marrow, spleen, lymph node, or other tissue. [146] The clinical course is usually progressive, lasting only an average of 6 weeks. [145] Most patients die as a consequence of sepsis, bleeding, or a lymphocytic meningitis accompanied by refractory seizures. Approximately 75% of patients have CNS involvement at diagnosis. [145] Disease essentially confined to the CNS, leading to seizures, has been reported.[147] There is no sex predilection, [145] and the presence of the disorder in siblings and cousins [145] and parental consanguinity[144] support an autosomal recessive mode of inheritance.

There are no specific biologic markers of FHL, but laboratory evaluation consistently demonstrates hypofibrinogenemia, hyperlipidemia, [148] pancytopenia, hyperbilirubinemia, and increased liver enzyme levels. [142]

Pathologic study of the liver shows focal fatty changes, necrosis, and infiltration by lymphocytes and histiocytes. The infiltrate is periportal but extends into adjacent lobules. Erythrophagocytosis and hematophagocytosis are prominent, and essential to the diagnosis. The spleen demonstrates similar focal necrosis and foci of lymphocytes and histiocytes with erythrophagocytosis. Involvement of the thymus and lymph nodes is similar, but later in the course of disease, lymph nodes show significant lymphocytic depletion. Hematophagocytosis is also present. The lungs are infiltrated with lymphocytes and histiocytes, again with some erythrophagocytosis. The bone marrow is hyperplastic, with increased numbers of hematophagocytic histiocytes. [142] [145] [149] The cellular infiltrate lacks features of malignant cells. The characteristic pathologic findings and clinical presentation clearly distinguish FHL from LCH and other histiocytic disorders.

As there are no diagnostic tests and a gene defect has not been identified, FHL may be difficult to distinguish from sporadic or secondary hematophagocytic lymphohistiocytosis, formally called infection-associated hemophagocytic syndrome (IAHS), which was originally described in immunocompromised hosts as a consequence of underlying viral infections [150] as well as bacterial and protozoal infections. [151] [152] In addition, the syndrome is now known to be associated with T-cell

lymphomas, Chédiak-Higashi disease, and, rarely, rheumatoid arthritis or even LCH. [1] The clinical course of secondary hematophagocytic lymphohistiocytosis is variable, but a 40% mortality has been reported, [150] and some patients may benefit from systemic treatment.[1] In addition, treatment of the underlying disorder is essential.

Although the etiology remains obscure, immunodeficiency is a consistent finding in FHL. Evidence strongly suggests that the disease is mediated by hypercytokinemia with elevated levels of IFN-, TNF, and in some instances IL-6 as a consequence of the uncontrolled activation of macrophages and perhaps T cells. [153] [154] [155] The authors propose a genetic defect in cytokine regulation. There is depressed antigen-induced lymphocyte proliferation and decreased monocyte antibody-dependent cytotoxicity.[156] Removal of plasma by plasma exchange transiently corrects these abnormalities but does not improve the prognosis. [156] Whether the disorder is due to a primary immunodeficiency or the immune abnormalities are secondary to another underlying defect is unknown.

Steroids and cytotoxic agents have generally been ineffective in the treatment of FHL. Etoposide has induced clinical remissions accompanied by resolution of the characteristic hyperlipidemia.[157] Although virtually all patients experience relapse, this agent, usually given in combination with prednisone and intrathecal methotrexate,[145] has resulted in complete to very good responses in patients with FHL and has been used prior to more definitive therapy with bone marrow transplantation in this otherwise lethal disorder. [145] [158] [159]

Sinus Histiocytosis with Massive Lymphadenopathy

First described in 1969 and more recently reviewed in 1990, [160] [161] sinus histiocytosis with massive lymphadenopathy (SHML), or Rosai-Dorfman disease, is characterized clinically as a benign, frequently chronic, painless massive lymphadenopathy that usually involves the cervical lymph nodes and, less frequently, the axillary, hilar, peritracheal, and inguinal nodes. [162] Extranodal disease is present in 28% of patients. [163] The upper respiratory mucosa is involved in 20%, [160] bone in 25%,[164] [165] and the orbit or eyelid in 10% of patients. [166] [167] Occasionally there is skin involvement [168] as well as CNS, lung, liver, and kidney involvement. [161]

Although SHML is a benign and polyclonal disorder, [169] as opposed to LCH, significant morbidity and even death have been associated with massive tissue invasion of the liver, kidney, lung, and other critical structures. [161] [170] In these instances, the disease has a rapid downhill course. Respiratory distress due to tracheal obstruction[171] and paraplegia secondary to epidural involvement have been described. [172] Death in SHML has also occurred as a consequence of severe hemolytic anemia.[170]

Eighty percent of patients are diagnosed in their first or second decade, [173] [174] [175] but the disorder can also affect the elderly. [173] [175] Typically, patients are of African descent. [173] [174] Males and females are equally affected. Worldwide, the incidence of SHML is highest in Africa and the West Indies. [174]

Laboratory evaluation frequently reveals an elevated erythrocyte sedimentation rate, moderate polyclonal and (rarely) benign monoclonal hypergammaglobulinemia, anemia, and granulocytosis.[168] [171]

Involved lymph nodes show marked sinusoidal dilation and follicular hyperplasia with proliferation of foamy histiocytes and multinucleated giant cells within the sinuses. There are no eosinophils, and abundant plasma cells are present. [160] [162] [163] [164] Lymphocytes are often found in the cytoplasm of histiocyte-like cells. This characteristic finding is referred to as emperipolesis. [171] The proliferating histiocytes share properties of macrophages and interdigitating cells. These large pale cells are S-100 positive[176] but are morphologically distinguished from Langerhans cells found in the lymph nodes of patients with classic LCH by the absence of Birbeck

granules[164] as well as by the surface phenotype, determined by monoclonal antibodies, [168] [177] and by the presence of $_1$ -antichymotrypsin.[171]

As with LCH, the etiology of this disorder is unknown, and as in LCH, disordered immune regulation has been proposed. [168] It was originally thought that SHML represented an unusual response to a *Klebsiella* antigen or Epstein-Barr virus,[175] but this has not been confirmed.[168] Although patients are frequently febrile, infectious agents have not been implicated, and the fever is presumed to be a manifestation of systemic disease.

Treatment is usually both unnecessary and ineffective. Disease manifestations usually subside over several months to years. Of 215 cases in a patient registry, 21% had complete resolution of disease. However, 14 patients died. Five died from immunologic causes, such as severe hemolysis, three died from infections, and six probably died as a direct consequence of disease infiltration. [178] As the disease resolves, extranodal disease regresses prior to nodal disease. Radiation, corticosteroids, vinblastine, and low-dose cyclophosphamide are sometimes effective; however, the results with these agents have been inconsistent. [163] [172] [179] [180] Attempts at treatment should be reserved for special circumstances, such as tracheal or epidural compression or invasion of other vital structures. Local excision may also be useful in selected patients. [164]

Chapter 44 - Lysosomal Storage Diseases: Perspective and Principles

Gregory A. Grabowski
Nancy Leslie

THE CONCEPT OF THE LYSOSOME

The lysosome was first described by deDuve as an acid phosphatase-containing unit membrane-bounded organelle within the cytoplasm of eukaryotic cells. [1] As the name implies, lysosomes participate in the lysis or breakdown of cellular material, that is, the digestive tracts of cells or of suicide packages. The containment of hydrolytic enzymes within these organelles prevents autodigestion of cellular contents. Since this description, the concept of the lysosome has expanded to a dynamic heterogeneous subcellular organelle with tissue and cellular-specific differentiated functions and contents. Several tissues have specialized lysosomal mechanisms that extrude hydrolytic enzymes into the extracellular microenvironment. Such cells and their lysosomal enzymes are critical to host defense, wound healing, and bone remodeling (e.g., neutrophils and osteoclasts). Implicit in DeDuves description was the need for systems to sort and specifically localize proteins to lysosomes and the potential of replacing deficient enzymes. [1]

The concepts of lysosomes as hydrolytic sacs and the need for specific targeting of enzymes to the lysosome have provided a fertile milieu for research during the past three decades. Hers was the first to delineate engorged lysosomes in patients with -glucosidase deficiency [2] and other lysosomal storage diseases.[3] This description led to a pathophysiologic view that related the malfunction of these organelles or cells principally to the resultant architectural distortion produced by stored materials in the lysosome. Recently, this passive process has been enhanced by postulating a more active role for toxic degradative products (e.g., lysosphingolipids) in altering normal cellular function. [4] Goldstein et al., [5] Neufeld,[6] and others, developed the concept of receptor-mediated endocytosis and emphasized directed targeting and sorting of proteins from the extracellular space. This culminated in the Brown and Goldstein model of receptormediated endocytosis for the low-density lipoprotein (LDL) particle [5] and its general implications for the uptake and targeting of proteins to cells. Neufeld described the phenomena of cross-correction during coculture of skin fibroblasts from patients with two different types of mucopolysaccharidoses (MPS). [7] The subsequent loss of accumulated cellular deposits in each cell type suggested the presence of specific corrective factors that were secreted by one MPS cell type and internalized by the other cell type.[7] These factors were later identified as enzymes. Cross-correction required the secretion of a functional enzyme that contained a signal for receptor-mediated endocytosis by other cells. Because only one lysosomal hydrolase is usually defective in MPS variants, all other secretable lysosomal hydrolases are normal and, potentially, would be able to correct a specific deficiency in other cells. These investigations culminated in the characterization of the mannose-6-phosphate receptor system by the groups of Sly,[8] Kornfeld,[9] [10] von Figura,[11] and others. This ligand-mediated targeting system is central to selective sorting of most soluble lysosomal proteins within many cells, [10] their uptake into cells, and delivery to the lysosome. In comparison, membrane-bound lysosomal proteins use different, incompletely defined, amino acid-based, targeting systems. [12] These concepts of storage, cross-correction, and targeting have provided the foundation for the development of therapeutic interventions for lysosomal storage diseases including enzyme reconstitution by transplanted tissue or enzyme replacement. Both approaches may stabilize or reverse the pathophysiologic process in selected lysosomal storage diseases. These findings implied a dynamic and interactive communication of the lysosome with intra- and extracellular compartments. Comprehensive reviews of individual lysosomal diseases are available (Table 44-1).

TABLE 44-1 -- Selected Lysosomal Storage Diseases

Disease (Major Review)	Common Name	Enzyme Defect	Major Organs InvolvedPhenotype Variation	Stored Substrate
Mucopolysaccharidoses (MPS)[124]				
MPS IH	Hurler	-L-Iduronidase	Liver, spleen, brain, heart, cornea, bonesmild and severe variants	Dermatan and heparan sulfate
MPS II	Hunter	Iduronidate sulfatase	Liver, spleen, brain, heart, bones	Dermatan and heparan sulfate
MPS III	Sanfilippo A	Heparan *N*-sulfatase	Brain, liver, spleen, heart, bones	Heparan sulfate
	Sanfilippo B	*N*-Acetyl-glucosaminidase	Brain, liver, spleen, heart, bones	Heparan sulfate
MPS IV	Morquio A	*N*-Acetyl-galactosamine 6-sulfatase	Bone, cornea	Keratan sulfate, chondroitin-6-sulfate
	Morquio B	-Galactosidase	Bone, cornea	Keratan sulfate
MPS VI	Maroteaux-Lamy	*N*-Acetyl-galactosamine 4-sulfatase	Bone, cornea, liver, spleen, heartmoderate and severe variants	Dermatan sulfate
MPS VII	Sly	-Glucuronidase	Brain, liver, spleen, bone, coronary arteries	Dermatan sulfate, heparan sulfate, chondroitin-4 and -6 sulfate
Glycoproteinoses[125]				
Mannosidosis		Lysosomal -mannosidase	Brain, liver, spleen, boneseveral variants	-Mannose-rich oligosaccharides

Fucosidosis		Glycoprotein -fucosidase	Brain, liver, spleen, heart, skinseveral variants	Fucose-containing oligosaccharides
Aspartylglucosaminuria		Aspartyl-glucosaminidase	Brain, liver, spleen, bone, heart	Aspartylglucosamine-containing peptides
Sialidosis		Glycoprotein -neuraminidase	Brain, liver, spleen, bone, retinaseveral variants	Sialylated glycopeptides
Galactosialidosis		Protector proteincombined -neuraminidase/-galactosidase deficiency	Brain, liver, spleen, boneseveral variants	G_{M1} -Ganglioside and sialyated glycopeptides
Mucolipidosis II[126]	I-Cell disease	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bones, connective tissue	Glycoproteins, glycolipids
Mucolipidosis III	Pseudohurler polydystrophy	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bones, connective tissue	Glycoproteins, glycolipids
Sphingolipidoses				
Gaucher disease[53]	Gaucher disease type 1 (non-neuronopathic)	Acid -glucosidase; glucocerebrosidase	Liver, spleen, bone, bone marrowhighly variable phenotype	Glucosylceramide
	Gaucher disease type 2 (acute neuronopathic)	Acid -glucosidase; glucocerebrosidase	Brain, brainstem, liver, spleen, bone marrow, lungs	Glucosylceramide; glucosyl-sphingosine
	Gaucher disease type 3 (subacute neuronopathic)	Acid -glucosidase; glucocerebrosidase	Brain, liver, spleen, bone marrow, lungsvariable phenotype	Glucosylceramide; glucosyl-sphingosine
Metachromatic leukodystrophy (MLD)[127]	Infantile MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
	Juvenile MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
	Adult MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
		Saposin B deficiency	Brain, peripheral nerves	Sulfatide
	Pseudodeficiency	Partial arylsulfatase A	Normal	None
Multiple sulfatase deficiency[127]		Cysteine modification enzyme	Brain, liver, spleen, bones	Sulfatide, dermatan, and heparan sulfate
Gangliosidoses				
G_{M2} -Gangliosidoses[65]	Infantile Tay-Sachs (TSD)	-Hexosaminidase A (-chain)	Brain	G_{M2} -Ganglioside
	Juvenile TSD	-Hexosaminidase A (-chain)	Brain	G_{M2} -Ganglioside
	Adult TSD	-Hexosaminidase A (-chain)	Brain	G_{M2} -Ganglioside
	Activator deficiency	G_{M2} -Activator	Brain	G_{M2} -Ganglioside
	Sandhoff disease	-Hexosaminidase B and A (chain)	Brain, liver, spleen, bone	G_{M2} -Ganglioside, globoside
G_{M1} -Gangliosidoses[55]	Landing disease	-Galactosidase	Brain, liver, spleen, bone	G_{M1} -Ganglioside, keratan sulfate
Neutral Sphingolipidoses				
Fabry disease[39]		-Galactosidase A	Kidney, vascular endothelial system, heart, central nervous system vessels	Globotriaosylceramide
Schindler disease[39]		-*N*-Acetyl-galactosamidase	Brainprobable several variants	*N*-Acetylgalactose-linked oligosaccharides and ?
Krabbe disease[128]		Galactocerebrosidase	Brain	Galactocerebroside
Niemann-Pick[129]	Niemann-Pick A (infantile)	Sphingomyelinase	Brain, liver, spleen, lungs	Sphingomyelin
	Niemann-Pick B (late onset)	Sphingomyelinase	Liver, spleen, lungs	Sphingomyelin
Neutral Lipid Storage Diseases				
Wolman disease[40]		Lysosomal acid lipase	Liver, spleen, adrenal glands, bone marrow	Cholesteryl esters, triglycerides
Cholesterol ester storage disease[40]	CESD	Lysosomal acid lipase	Liver, spleen, blood vessels	Cholesteryl esters
Farber disease[130]		Ceramide	Brain, joints, tendons, skin, liver	Ceramide

PHYSIOLOGY OF LYSOSOMES

Unlike mitochondria, lysosomes do not contain DNA and, therefore, cannot self-replicate. Consequently, lysosomal biogenesis is a continuous process that requires synthesis of lysosomal hydrolases, membrane constitutive proteins, and membrane. This process includes the fusion of vesicles from the *trans*-Golgi network (TGN) with late endosomes (multivesicular bodies)[13] [14] (Fig. 44-1). The TGN vesicles contain lysosomal hydrolases. The maturation of TGN vesicular bodies to lysosomes and of endosomes from early to late compartments accompanies a progressive internal vesicular acidification. A gradient is established so that early endosomes have an internal pH 6.06.2, whereas late endosomes and lysosomes have a pH of 5.56.0 and 5, respectively. This acidification is needed for the pH-dependent dissociation of receptors and ligands (e.g., the mannose-6-phosphate receptor and mannose-6-phosphate-containing

Figure 44-1 Schematic diagram of lysosomal development from the endoplasmic reticulum (ER), through the Golgi apparatus (Golgi), and the endosomal compartments (EN). EN develop from the plasma membrane (PM)-coated pits. The EN and TGN pathways converge in vesicles containing material from newly synthesized lysosomal proteins, and ER or multivesicular body (MVB) contents. Between the MVB, PL-EN, and return to the PM exists the CURL, a virtual compartment for the uncoupling of receptors and ligands. The various EN and lysosomal compartments are distinguished by the progressive acidification of the vesicles from early to late endosomes and the loss of the mannose-6-phosphate receptors in the CURL. The MVB is an ultrastructural compartment that contains internal small vesicles derived from the PM. Vesicles that bud from the TGN fuse with late EN or MVB to form the lysosomal compartment. Mannose-6-phosphate receptors are recycled to the PM and to the mid-Golgi. Secretion indicates a direct route from the TGN to EN for delivery outside of the cell. Auto and Phago refer to autophagy and phagocytosis, respectively, by which internal and external materials are delivered to preexisting lysosomes. Larger arrows indicate a major common pathway through the mature lysosomes. The double-headed arrows depict a necessary interaction between various types of lysosomes to account for the major similarities of lysosomes in cells. Lysosomes are inherently heterogeneous. This indicates a dynamic compartment that communicates, probably bidirectionally, with other components of the endosomal/lysosomal system. In addition to what is shown, vesicular transport is needed between the ER and Golgi.

oligosaccharides) and the optimal functioning of lysosomal hydrolases. [15] Dissociation occurs in a virtual compartment termed CURL (compartment of uncoupling of receptors and ligands). Formation and segregation of lysosomes with their constitutive integral and associated membrane proteins are less well understood. [16] These proteins are essential for lysosomal integrity and function. In particular, the lysosomal membrane contains a proton pump needed for developing and maintaining the acidic internal environment required for lysosomal hydrolase function. The signals for the fusion of TGN vesicles with endosomal vesicles requires the interaction of several membrane components, the sorting of proteins destined for the lysosome, the loss of the mannose-6-phosphate receptors, the recycling of these receptors to the mid-Golgi bodies and plasma membrane,[15] and segregation of endosomal membrane and contents. Consequently, the view of the lysosome as an end-stage compartment has been replaced by one of a dynamic communicating organelle with continuously changing contents, that, at least in part, exchanges material with other lysosomes in the cell. This leads to a lysosomal compartment that is composed of heterogeneous populations of similar organelles whose individual contents differ significantly in time and space.

Post-translational modifications of lysosomal hydrolases are important for specific sorting and targeting of enzymes and for their enzymatic activity. Lysosomal enzymes are glycoproteins that are synthesized on ribosomes of the rough endoplasmic reticulum (RER). As with all secretory proteins, lysosomal hydrolases are synthesized with an N-terminal hydrophobic leader or signal peptide that is required for penetration through the ER membrane and into the lumen of the ER. During penetration through the ER membrane, the lysosomal proteins are co-translationally glycosylated on selected N-glycosylation consensus sequences (asparagine-X-serine or threonine). This occurs by the en bloc transfer of antennerary mannosyl oligosaccharide chains from a dolicholphosphate (Fig. 44-2). It is unclear how N-glycosylation sequences are selected for occupancy [17] except that asparagine-proline-serine or threonine sites are not used and the surrounding protein sequences appear important for transfer of the dolicholphosphate-oligosaccharide. Following complete synthesis and glycosylation, the lysosomal enzymes may undergo additional proteolytic processing or assembly and are incorporated into transport vesicles for further processing in the *cis*-Golgi apparatus. At this stage all proteins destined for the lysosomes contain only branched mannosyl chains that terminate with short chain -glucosyl moieties. Most enzymes destined for the lysosome acquire complex oligosaccharide modifications during transport through the Golgi apparatus (Fig. 44-2). A series of glycosyl hydrolases and glycosyltransferases within specific regions of the *cis*-, mid-, or *trans*-Golgi participate in these sequential modifications. In the *cis*-Golgi network, -glucosidases and -mannosidases remove terminal glucose and mannose residues to produce mannose-terminated core oligosaccharides. For each branch point of the mannosyl chain there are specific -mannosidases for cleavage. Following mannosyl trimming, additional sugars including - *N*-acetylglucosamine and -galactoside are added to the short mannosyl core by the mid-Golgi system. The addition of terminal sialic acid residues occurs in the *trans*-Golgi. Each of these sugars is added by glycosyl transferases that have been retained in their respective Golgi compartment by specific signals. Thus, the carbohydrate composition of the lysosomal proteins is indicative of its passage through regions of the Golgi during the synthetic process. Prior to, or coincident with, ER or *cis*-Golgi modifications, is the attachment of an *N*-acetylglucosamine-1-phosphate to the sixth position on mannosyl residues of the mannosyl core oligosaccharide. This modification can be uni- or multivalent and is selective for various branches of the oligosaccharides on a specific lysosomal protein. An *N*-acetylglucosylaminyl-1-phosphotransferase [9] [11]

Figure 44-2 Compartmentalized *N*-linked oligosaccharide modifications of lysosomal proteins. Attachment of the core mannosyl-glucose to selected Asn-X-Ser/Thr consensus sequences occurs co-translationally in the ER lumen via en bloc transfer of the shown core oligosaccharide structure from a dolichophosphate. Initial removal of terminal glucosyl residues and a mannosyl residue are removed prior to exit from the ER to the Golgi. Additional -mannosyl residues are removed by specific mannosidases in the cis-Golgi to a pentamannosyl core. *N*-acetyl-glucosamine-1-phosphate is transferred by glucoaminylphosphotransferases for the creation of a mannose-6-phosphate. In the mid- and *trans*-Golgi -galactosyl and sialyl (NeuNAc) residues are added by transferases localized to those compartments. The final oligosaccharide structures can contain mostly mannose (high mannose), short mannose cores, *N*-acetyl-glucosamines, -galactosyl and sialyl residues on the core structure (complex), or several combinations of the above on different branches of the structure.

is essential for this process, and its deficiency leads to a severe condition, I-cell disease, in which many soluble lysosomal enzymes are lost by default secretion out of the cell.[9] Shortly after the attachment of the phosphosugar group, a specific hydrolase cleaves the protecting *N*-acetylglucosamine from the phosphate to expose the mannose-6-phosphate residue, the targeting signal for soluble lysosomal proteins. These modification processes culminate in most lysosomal enzymes having several oligosaccharide chains with nonidentical antennerary modifications. As a result, the lysosomal enzymes can have portions of the attached oligosaccharide tree having only mannose residues (high mannose modification), mannose residues, *N*-acetylglucosylaminyl, -galactosyl- and sialyl-containing oligosaccharides (mixed type modification), or only terminal sialyl acid residues (complex type modification). [18] [19] Importantly, many soluble enzymes use ill-defined M-6-P independent intracellular trafficking signals alone or in combination with the mannose-6-phosphate system.

Defective mannose-6-phosphate targeting of soluble lysosomal proteins, as occurs in I-cell disease, has no effect on the integrity of the lysosome per se or its membrane. Lysosomal integral or associated membrane proteins (LIMPS or LAMPS) are sorted to the lysosomal membrane or to the interior of the lysosome via mannose-6-phosphate-independent trafficking systems. Signals for such trafficking have been identified as strategically located tyrosine residues near the carboxyl terminal end of some LIMPS and LAMPS.[12] It is apparent that additional signals will be required for targeting of other lysosomal membrane components. Importantly, for theoretical diseases involving LIMPS and LAMPS, cross-correction of cocultured cells would not occur; this has significance for therapeutic strategies of such

diseases.

In addition to glycosylation, some lysosomal proteins require proteolytic clipping, phosphorylation, or macromolecular assembly for the development of full function within the lysosomal environment. Proteolytic processing can occur at the NH_2 or carboxyl termini or by clipping of single peptide precursors into mature subunits or active peptides. For example, prosaposin is cleaved into four biologically active saposins A, B, C, and D that are functional in the lysosomal compartment [20] [21] [22] [23] [24] (Fig. 44-3). A protector protein precursor is involved in galactosialidosis and is clipped from its zymogen form into two, disulfide-linked, subunits within the Golgi apparatus prior to its achieving proteolytic activity. [25] [26] Some proteins also may acquire phosphorylation of serines or threonines or sulfation of tyrosines. Macromolecular assembly is required for several heteromeric lysosomal proteins. The association of the -hexosaminidase - and -chains in the mid-Golgi is necessary for synthesis of active hexosaminidase A (- and -heteromers) or hexosaminidase B (-homomers). Macroassembly of the -ga- lactosidase/neuraminidase/protector protein complex probably occurs within the Golgi apparatus coincident with other processing required for the assembly of the active catalytic complex. [25]

Although the control of tissue expression of many lysosomal proteins has not been characterized, tissue- and cell-specific expressions have been described for prosaposin and lysosomal acid lipase [27] [28] and probably exist for other lysosomal proteins. These expression patterns may have import for the variability of the phenotype of lysosomal diseases. Most tissues contain similar lysosomal hydrolases for degradation of macromolecules (e.g., mucopolysaccharides, glycoproteins, and glycosphingolipids) because these are essential to cell function. Thus, lysosomal storage disease involvement is apparent in most tissues at the histologic or biochemical levels. However, concordant levels of lysosomal hydrolase activities are not found in all tissues. Lysosomes of neutrophils contain myeloperoxidases that are not found in fibroblast lysosomes. [29] Also, -L-iduronidase, prosaposin, and other lysosomal proteins are at similarly high levels in seminal fluid, but not in plasma or cerebrospinal fluid. -L-iduronidase activity is easily detected in amniocytes and placental tissue but is nearly absent in early chorionic villi. [30] Acid -glucosidase (deficient in Gaucher disease) is present at nearly 10-fold lower levels in myeloid-derived cells compared to fibroblastic cells. [31]

Such differential expression allows for extension of the Conzelmann and Sandhoff threshold hypothesis for the development

Figure 44-3 Diagram of the processing of prosaposin from the chromosomal gene to mRNA to mature saposin proteins that interact with lysosomal enzymes. The chromosomal gene is over 30 kb in length, the first intron is >20 kb, and is located on chromosome 10p. Introns are shown as the white rectangles and exons are filled and matched to the domains for each saposin. The mRNA contains four highly homologous, but not identical, domains that code for the saposins A, B, C, and D. The mature mRNA encodes the saposins and intersaposin peptide links in the same reading frame. The intersaposin peptides are removed by proteolysis. The individual saposins are produced by proteolytic cleavage mostly within the lysosomes where they interact with their respective lysosomal hydrolases.

of manifestations of specific lysosomal hydrolase deficiency diseases. [32] [33] This working hypothesis implies that a set level of residual enzymatic activity, or substrate flux, is necessary to prevent lysosomal disease manifestations. Below this threshold, disease manifestations (in tissues or specific cell type) will be expressed, whereas above this threshold there will be no phenotype. In the most simple form, this formalizes the notion that less enzyme activity leads to more severe disease and more enzyme activity results in less severe or delayed disease manifestations. This formalism is conceptually important because it incorporates the potential for regional and cell-type localization of disease manifestations. The hypothesis also implies that particular levels of enzyme activity will be necessary to normalize tissues and that each tissue or cellular type may require specific levels of activity. The implications for therapeutic strategies are clear because only about 110% of normal lysosomal enzyme levels may be sufficient to correct metabolism in many tissues and prevent, reverse, or significantly delay localized disease manifestations. Also, very small incremental changes in enzyme activity or substrate flux could have profound effects on disease development and severity. Expansion of this hypothesis incorporates the potential need for threshold levels of enzymatic activity at critical times during development. If adequate levels of activity are not present at these developmental stages, disease manifestations or irreversible damage may occur and may not be amenable to later therapeutic interventions. For example, after a progression to a pathologic stage, dysostosis multiplex of bones, cardiac valvular involvement, or neurodegeneration in the MPS may not be reversed by bone marrow transplantation (BMT) or enzyme replacement therapies.

This threshold hypothesis then leads directly to a model for the pathogenesis of lysosomal disease phenotypes, that is, necessary and sufficient conditions can be identified for the occurrence of the disease state. The presence of deleterious mutations that lead to the deficiency of specific proteins is a necessary prelude to the phenotype. However, the relationships of the residual mutant activity to the level of substrate flux through the lysosome, to the temporal and spatial metabolic needs of a particular tissue, and to the phenotype are poorly understood. Conzelmann and Sandhoff studied G_{M2} -ganglioside and sulfatide degradation in fibroblasts from patients with Tay-Sachs disease (TSD) and metachromatic leukodystrophy (MLD) respectively. These data support the contention that the age of onset (and therefore disease severity) of a lysosomal disease phenotype correlates with a threshold level of residual activity within lysosomes of cells. [33] However, additional factors can dramatically affect substrate flux and must be defined to provide a larger conceptual background as a model for pathogenesis.

As shown in Equation 1 and the accompanying box, the total body turnover of a particular substrate represents the total rate of change of substrate concentrations, $(v_T) = S_T/t$, in a variety of cell types. The flux of substrate in individual cells or organs, $v_i(t) = S_i/t$, varies substantially throughout the body and potentially with developmental stage. For our purposes, the subscript i incorporates the organ- or cell-specific property at different development stages. Thus, the sum of all $[v_i(t)]$s would represent the total body substrate flux. v_T also may depend on developmental stage and the level of substrate in the cell, that is, $v(S_i)$. Four major factors impinge on S_i attained in each cell at each developmental stage (scheme 2) including: S_{exo}, S_{end}, L_{ex}, and L_{en}. These represent, respectively, the exogenous (exo) and endogenous (end) source(s) of substrate(s) that alter intracellular concentration (S_i). Also included are the pathways that lead to decreases in substrate levels (L) through excretion/secretion (ex) and enzymatic degradation (en) to end products within the lysosome. L_{en} represents decreases in substrate concentration due to the residual activity. Although such an equation is a heuristic device, it provides a framework to qualitatively, and eventually quantitatively, examine each of the factors that influence intracellular substrate concentration. This could provide an overall conceptual frame for the dissection of the various phenotypes in lysosomal storage disease and potential targets for therapeutic intervention that may have the greatest impact on the phenotype.

Equation representing flux (v_T) of substrate (S_i) through various cell types (i). The sum of various rates of substrate change in n tissues (S_i/t) equals the total flux of substrate (S_T/t) through the body of an affected individual. $v(S_i)$ represents the developmental stage-specific

rate of substrateconcentration changes in a particular cell type and its potential dependence on the concentration of substrate (S_i) in that tissue. The subscripts of v represent substrates from various sources (i.e., x_i = exogenous, phagocytosis, n_i = endogenous sources from catabolism of more complex macromolecules, L_i = losses due to excretion/secretion, en_i = decreases due to enzymatic degradation).

As shown in scheme 3, the level of S_{exo} is influenced by several factors including: (1) genetic factors, that is, genetic determinants of cellular turnover or substrate delivery; (2) exogenous (environmental) agents that lead to increased substrate availability; and (3) the developmental stage that could include increased cellular and substrate turnover. This last aspect may be of importance for changes in the progression of various lysosomal diseases with age. Thus, different developmental stage-specific genes and substrate turnovers could affect an age-dependent threshold for the balance of v_{in} v_{out}. It is implicit in this discussion that disease progression is likely to be nonuniform, and there could be exacerbations and remissions of symptoms depending on exogenous and other genetic factors. Also, the balance of v_{Sex} and $v_{Ser.}$ between cells and organs may differ substantially. This will depend greatly on the pathophysiology of various organs. Gaucher disease is a prime example. In many

Scheme representing major factors influencing flux of substrate through the cells. S_i indicates the different substrate concentrations within various cell types. Each of the parameters indicated can vary with developmental stage and tissue type; exo, end, exi, and eni refer to exogenous (phagocytosis), endogenous (degradation from other glycosphingolipids), excretion/secretion out of the cell, and enzymatic degradation of the substrate, respectively. The other terms are defined in equation 1.

Factors influencing the substrate concentration (S) in phagocytic (S_{exc}) and nonphagocytic (S_{end}) cells. These reflect the major, but not exclusive, dependence of S on these pathways in these different cell types.

visceral tissues (hepatocytes, skin cells, lymphoid cells), v_{Sex} for glucosylceramide is much less than v_{Sen} . v_{Ser} is probably very low because, even in the most severe variants, storage of glucosylceramide cannot be detected ultrastructurally in such cells. In comparison, in phagocytic cells of the viscera, v_{Sex} v_{Sen} . This implies that phagocytic cells will have a much greater variation in degree of involvement because of the inherent greater dependence on the exogenous supply of substrate, that is, greater variation in S_{ex} and v_{xi} (scheme 1). In contrast, involved central nervous system (CNS) cells are primarily dependent on the S_{en} for glucosylceramide and other substrates that accumulate in the brain. The contribution of S_{ex} is small. Detailed histology of the brains from Gaucher disease type 2 consistently show significant regional variation in neuronal loss, neuronophagia, and gliosis. There is a rostral-caudal gradient of involvement with greatest severity in the basal ganglia and the dentate nucleus. [34] [35] Thus, in Gaucher disease, not only are the pathophysiologies in the viscera and the brain fundamentally different, but within the CNS regional variation exists. The greater dependence of the visceral pathology on S_{ex} implies a potentially greater number of steps that could be altered to influence the rate and degree of disease progression.

This discussion indicates that a necessary condition for the development of disease is the *relative* enzymatic deficiency, that is, is there sufficient hydrolytic power to cleave the substrate presented at any given time? The enzyme deficiency reduces the ability of cells, and, therefore, the individual, to adapt to changes in v_T . Thus, the variation in v_T , either endogenous or exogenous, determines, to a great extent, the eventual phenotypic severity. Because v_T can vary, the progression of the specific disease manifestations may be variable at different stages of the disease. The most maladaptive mutations, such as a homozygous null mutation, frequently may be associated with the most severe phenotypes, but modifier factors (genes) could lessen disease severity. The converse also applies. Currently, little is understood about the essential factors that influence substrate flux in the tissues of patients with lysosomal storage diseases.

Definition of these thresholds of activity also may provide clues to dose-response relationships for treatment of various storage diseases and the evaluation of exogenous enzyme replacement therapy. Once delivered to the tissue and cellular sites of pathology, exogenous enzymes will have finite life spans. Assuming appropriate stoichiometric relationships for components required for intracellular activity, the initial, high hydrolytic rates will decrease to background levels over several half-lives of the supplied enzyme. Thus, large amounts of enzyme, potentially several-fold above threshold levels, may be needed to eliminate the extreme excess tissue burden of substrate. Normal metabolism could then be maintained with pulses or intermittent dosing of lesser amounts of enzyme, presumably at levels slightly above the disease threshold, because only catabolism of new substrate would be required. [33] This pulse model of enzyme therapy assumes that small amounts of reaccumulating substrates are not irreversibly toxic. Otherwise, a continuous supply of enzyme would be required to avoid such toxic effects. This model also assumes metabolic interaction between lysosomal compartments in cells and that the exogenous enzyme is delivered to the cells that are causal to the disease manifestations.

PATHOPHYSIOLOGY OF LYSOSOMAL STORAGE DISEASES

The majority of lysosomal enzyme deficiencies result from point mutations or genetic rearrangements at a locus encoding a single protein required for the activity of the lysosomal hydrolase (Tables 44-1 and 44-2). Some mutations at a locus can result in the deficiencies of several lysosomal hydrolases due to abnormalities in macromolecular association or trafficking. The final

common pathway for lysosomal storage diseases is the accumulation of macromolecules within tissues and cells that synthesize or ingest particular substrates or toxic metabolites in substantial amounts. For many lysosomal diseases, the clinical manifestations derive from the accumulation of substrates that are synthesized endogenously within particular tissue sites of pathology. The degree of involvement of any particular organ or organ system reflects the rate of endogenous synthesis or degradation of those specific compounds in particular tissues. The stored substrates are macromoleculesmucopolysaccharides, glycoproteins, or glycosphingolipidsthat require degradation through a pathway with the sequential removal of single components of the substrate molecules at each step in a catabolic cascade (Fig. 44-4). Most of the enzymes are exohydrolases. Table 44-1 lists selected lysosomal storage diseases categorized according to substrate groups and indicates some of the tissues involved by the various diseases. Specific organ systems are involved by particular diseases to a greater or lesser extent and reflect the balance of endogenous and exogenous substrate presentation. For example, in Hurler disease (MPS IH), dermatan and heparan sulphate accumulate in connective tissue leading to joint contractures and abnormal skin consistency. Tissue-specific pathology also is present in several other diseases. Galactocerebroside is found in

greatest concentration within the myelin sheaths of the central and peripheral nervous systems. Although the deficiency of galactocerebrosidase in Krabbe disease occurs in all tissues, the synthesis of galactocerebroside is much greater in the central and peripheral nervous systems. [36] [37] Consequently, the manifestations of the disease are localized to the nervous system. Similarly, in TSD or Sandhoff disease, the deficiency of -hexosaminidase A or -hexosaminidase A and B, respectively, results in either primarily CNS disease or in combined CNS and visceral diseases due to the different accumulated substrates. [38] -Hexosaminidase A cleaves the specific substrate, G_{M2} -ganglioside, whereas -hexosaminidase B cleaves primarily sialylgangliosides and globosides. G_{M2} -ganglioside is synthesized in large amounts only in brain or other nervous system tissues, and globoside is synthesized primarily in visceral tissues.

Additional mechanisms, other than endogenous substrate synthesis, must be involved in pathologic substrate deposition in Fabry disease, Gaucher disease, and cholesterol ester storage disease (CESD). Fabry disease (-galactosidase-A deficiency [39]) and CESD[40] (lysosomal acid lipase deficiency) result from an inability to catabolize globotriaosylceramide and cholesterol esters, respectively. Both of these compounds are found in plasma associated with LDL particles. These LDL particles are internalized via receptor-mediated endocytosis and presented to the lysosome for degradation. In these two disorders, the major pathophysiology, endothelial cell involvement, is due to the LDL uptake of these substrates and the inability to degrade them within the lysosomes. Endogenous synthesis of globotriaosylceramide as well as cholesterol esters is relatively low within most tissues. The vast majority of accumulated substrate is derived from distant sources (i.e., hepatocytes). In comparison, the visceral manifestations of Gaucher disease (acid - glucosidase deficiency) derive from the storage of glucosylceramide primarily in cells of monocyte/macrophage origin[41] (Fig.44-5).

Figure 44-4 Pathway of glycosphingolipid degradation and the diseases that result from specific enzyme deficiencies. The numbers refer to the following lysosomal hydrolases: (1) -galactosidase. (2) -hexosaminidase A, (3) ganglioside neuraminidase, (4) -hexosaminidase B, (5) -galactosidase A, (6) -galactosidase for lactosylceramide, (7) acid -glucosidase (glucocerebrosidase), (8) sphingomyelinase, (9) arylsulfatase A, (10) -galactocerebrosidase, (11) ceramidase. The deficiency of each of the respective enzymes leads to the accumulations of the substrate preceding the hydrolytic step. Diseases have yet to be described due to the deficiencies of either enzyme 3 or 6.

The vast majority of the viscerally stored substrate probably derives from leukocyte and erythrocyte membrane turnover via phagocytosis of aging blood cells. [42] The inability to degrade all the glucosylceramide from the membranes of these cells results in storage in macrophage lysosomes. Thus, the major pathophysiology of the visceral disease involves imported glycosphingolipid substrate, rather than endogenously synthesized substrate within cells of the monocyte/macrophage system. In comparison, Gaucher disease type 2 is a severe neurodegenerative disorder of infancy. The massive visceromegaly, particularly of the spleen and liver, and bone marrow infiltration by Gaucher cells in this disease result from the phagocytic pathway. However, the severe neurodegenerative disease appears related to the presence of toxic by-products derived from degradation of endogenously synthesized glucosylceramide within CNS neurons of affected patients. These endogenous toxic metabolites, and the importation into the brain of glucosylceramide from peripheral sources, jointly contribute to the severe neurodegenerative disease. The contribution of transported and imported substrates to the pathophysiology of other diseasesMLD, MPS, and the glycoproteinosesare not fully understood and certainly would have an impact on therapeutic approaches to these diseases. Thus, several mechanismsthresholds of enzyme activity, tissue or developmental specificity, substrate localization, and substrate importationplay roles in the pathophysiology of lysosomal storage diseases. The relative importance of each process varies among diseases and may explain differential organ involvement within a specific disease category.

The direct distortion of the lysosomal architecture (i.e., engorgement of lysosomes) probably has significant pathologic

Figure 44-5 Diagram of the cellular pathophysiology of Gaucher disease. Monocytes are produced in the bone marrow and mature to macrophages in the marrow or in specific sites of distribution as liver Kupffer cells, bone osteoclasts, and lung and tissue macrophages. Once resident, they accumulate glucosylceramide by phagocytosis and become end-stage Gaucher cells. The resultant tissue fibrosis, ischemia, osteoporosis, and other pathologic features have not been adequately explained.

consequences, but the pharmacologic effects of the accumulated substrates or by-products are increasingly recognized as major components of the disease pathophysiology.[4] [43] [44] In the glycosphingolipidoses, the toxic metabolites of these complex lipids derive from their incomplete or improper degradation in the lysosome. The deacylated analogs of glycosphingolipids are known as sphingoid bases. These compounds are potent inhibitors of a variety of cellular enzymes including protein kinase C isozymes and other membrane proteins. [44] [45] Sphingoid bases (lyso-glycosphingolipids) accumulate in TSD, Sandhoff disease, [46] Krabbe disease,[47] and Gaucher disease types 2 and 3.[48] The toxicity of sphingoid bases is most evident in Krabbe disease and Gaucher disease type 2. The excessive accumulation of galactosylsphingosine and glucosylsphingosine in these diseases, respectively, leads to the destruction of neurons within the brains of affected individuals. Consequently, the CNS disease manifestations likely are the result of neuronal loss and death rather than the storage of galactosyl- or glucosyl-ceramide per se. In Gaucher disease type 1, small amounts of glucosylsphingosine accumulate in visceral organs and may be related directly or indirectly via cytokines [49] [50] to the fibrosis in the liver, spleen, and bone marrow of affected patients. [51] This would provide a unifying pathophysiologic basis (i.e., cell death and scarring) for the manifestations of Gaucher disease. In TSD G_{M2} -ganglioside and lyso-G_{M2} -ganglioside accumulate.[46] The formation of meganeurites in TSD indicates that at least one of these stored substrates may alter the growth and development of neurons, as well as accumulating in lysosomes. [52] Additional toxic products would be expected in visceral tissues and in a variety of the lysosomal storage diseases, but direct evidence is lacking. In some categories of lysosomal diseases characteristic pathologic patterns are present. In MPS I, II, IV, and VII, dysostosis multiplex is the pattern of bony abnormalities. These bony manifestations must result from an as yet unknown common pathophysiology of stored mucopolysaccharides that lead to similar altered pathways in bony development.

MOLECULAR GENETIC MECHANISMS OF LYSOSOMAL STORAGE DISEASES

The molecular mechanisms that result in the lysosomal storage diseases are as varied as the diseases. The mechanistic abnormalities include:

1. Deficiency of a single hydrolase, predisposing to multiple phenotypes
2. Deficiencies of multiple lysosomal proteins mediated by a single gene defect
3. Specific in vivo substrate accumulation with intact in vitro hydrolase activity
4. Absence of functional lysosomal hydrolysis with intact hydrolase activities

Single Gene, Multiple Phenotypes

The vast majority of the lysosomal storage diseases result from mutations at single loci that involve a single gene product and are either point mutations or deletions or insertions in genes encoding subunits of a particular protein. Missense or nonsense mutations result in the production of proteins with abnormal catalytic function, stability, or processing. For many of these mutations an abnormal protein with low enzymatic activity is synthesized. For example, >100 mutations have been described in Gaucher disease or TSD at the respective loci. These mutations have differential effects on enzyme stability, catalytic activity, or effector interactions. [53] Because these two diseases are found at high frequencies in the Ashkenazi Jewish population, a few common mutations would be expected, due to either founder effect or selective pressures. The phenotypic variation in these two diseases represents a continuum of degrees of involvement or age at onset of symptoms. For Gaucher disease, this continuum extends to the asymptomatic population. The majority of affected Ashkenazi Jews with the N370S/N370S genotype are asymptomatic and never come to medical attention. [54]

In comparison, two completely different disease phenotypes appear to result from the same enzymatic deficiency due to mutations at the -galactosidase locus: the G_{M1} -gangliosidoses and Morquio type B (MPS IVB). In the former, G_{M1} -ganglioside accumulates preferentially in the CNS and mucopolysaccharide metabolites in the visceral organs. [55] In Morquio type B disease, keratan sulphate accumulates in visceral organs leading to skeletal dysplasia and abnormal connective tissue properties (e.g., hypermobility). The CNS is not directly involved. These very different phenotypes result from mutations in the structural locus for -galactosidase affecting different protein domains of -galactosidase. [55] [56] Thus, mutations in single lysosomal polypeptides can result in multiple disease variants, but their molecular etiologies differ. The severe infantile variant (G_{M2} , gangliosidosis) can be associated with a protein that poorly interacts with its protector protein and is rapidly degraded. The later onset variant has a protein peptide that can be improperly targeted with little enzyme routed to the lysosome. The MPS IVB protein binds to protector protein and is properly routed to the lysosome, but exhibits little catalytic activity toward keratan sulfate. [57]

Several lysosomal hydrolases are multimeric or occur as multienzyme complexes. A mutation in a common subunit or a component of the multienzyme structure could result in selective deficiencies of individual enzyme components or in all the components of the complex. TSD and Sandhoff disease are typical examples of heteromeric proteins in which distinct phenotypes result from mutations in different subunits. -Hexosaminidase A is composed of - and -chains, whereas -hexosaminidase B is composed of only -chains. Mutations at the -chain locus result in TSD (-hexosaminidase A deficiency), whereas those in the -chain result in Sandhoff disease (-hexosaminidase A and B deficiency). [58] The substrates for -hexosaminidase B occur in the viscera and those for -hexosaminidase A, G_{M2} -ganglioside, occur predominantly in the CNS. Therefore, Sandhoff disease has manifestations in the CNS and in the viscera.

The -galactosidase/neuraminidase/protector protein complex is more complicated. Isolated deficiencies of each of these enzymatic components have been described. [55] Neuraminidase deficiency results in sialidosis, a glycoprotein storage disease, and protector protein defects result in deficiencies of both -galactosidase and neuraminidase. The protector protein is a protease that attaches to the neuraminidase/-galactosidase complex sometime during synthesis and protects this complex from inactivation or degradation. [25] Thus, point mutations in the protector protein can lead to galactosialidosis, a triple enzymatic deficiency producing variable phenotypic effects. [26]

A unique and important example of a mutation in a nonlysosomal enzyme causing multiple enzyme deficiencies is multiple sulfatase deficiency (MSD). In this disease, hydrolysis of sulfated mucopolysaccharides and glycolipids is impaired and a phenotype is produced that resembles a composite of MLD (arylsulfatase A deficiency), MPS II (iduronate sulfatase deficiency), and ichthyosis (microsomal steroid sulfatase deficiency). Because the structural genes for the sulfatases are not involved, a co- or post-translational modification defect common to cellular sulfatases was suspected. By direct analyses of cellular sulfatases, it was shown that active sulfatases require a specific post-translational modification of a conserved cysteine. An enzyme is required to modify this cysteine to 2-amino-3-oxo-propionic acid that acts as a carrier of the sulfite group

at the active site of most (maybe all) sulfatases. MSD cells are deficient in this post-translational process. [59]

Normal In Vitro, Deficient In Vivo, Substrate Cleavage

Mutations in protein activators or cofactors necessary for the catalytic activity of a variety of glycosphingolipid hydrolases result in diseases that are phenocopies of particular enzyme deficiencies. For glycosphingolipid hydrolysis, five such protein activators have been described. Four of these, termed saposins A, B, C, and D, are encoded by a single locus on chromosome 10 (Fig. 44-3). The G_{M2} -activator required for catabolism of G_{M2} -ganglioside by -hexosaminidase A is encoded by a locus on chromosome 5. [60] The hallmark of the saposin deficiencies is the accumulation of specific lipid substrates for a suspected deficient enzyme activity, with normal in vitro activity of the associated enzyme. Gaucher-like diseases have been described due to the deficiency of saposin C and prosaposin. [61] [62] Metachromatic leukodystrophy-like diseases result from saposin B deficiency, [63] [64] and Tay Sachs-like diseases are due to G_{M2} -activator deficiencies. [65] Of these saposin deficiencies, the defects in the prosaposin locus are particularly interesting. Each of the saposins, A, B, C, and D, participates in the hydrolysis of a variety of glycosphingolipids (Fig. 44-3). These saposins are thought to participate in specific interactions with the cognate enzyme in glycosphingolipid catalysis, [66] in ganglioside transport, [67] and in substrate presentation. As expected, the deficiency of prosaposin leads to a complex disorder mimicking the deficiency of several glycosphingolipid hydrolases. [68] Importantly, the in vitro activities of the corresponding enzymes are nearly normal in tissues from patients with the saposin defects. It is anticipated that several other activator or cofactor molecules, required for the assistance in hydrolysis of complex macromolecules, will be discovered in the future.

Intracellular Deficiencies/Extracellular Excess

I-cell disease exemplifies the impact on lysosomal enzymes of mutations at loci for nonlysosomal proteins. The enzyme, *N*-acetylglucosamine-1-phosphotransferase is required for the attachment to many lysosomal proteins of the mannose-6-phosphate ligand sorting signal. [9] [11] Mutations at the loci for subunits encoding this

enzyme result in the absence of the mannose-6-phosphate ligand and the secretion into the media of most soluble lysosomal enzyme proteins. The lysosomes are nearly devoid of mannose-6-phosphate receptor targeted enzymes. Consequently, the phenotypes resemble a mixture of various mucopolysaccharide, glycoprotein, and glycosphingolipid degradation defects, due to the loss of many enzymes and proteins involved in the respective catabolic pathways. Because some of the membrane-bound proteins of the lysosome are targeted via mannose-6-phosphate independent pathways, they are retained within the lysosomes. However, their catalytic activity may be affected by the loss of activator proteins and other lysosomal components that require mannose-6-phosphate receptor-mediated sorting.

Mucopolysaccharidoses II is associated with multiple de novo micro- and macro-deletions in the iduronate sulfatase gene. [69] A pseudogene adjacent to the iduronate sulfatase gene promotes unequal homologous recombination events as a major cause of new mutations in this condition. [70] At least one case of contiguous gene deletion including both iduronate sulfatase and the fragile X gene has been reported related to the proximity of these loci. [71] In comparison, the gene for -L-iduronidase (MPS I) overlaps with a gene for a sulfate transporter. This latter gene is encoded on the opposite strand within the structural gene for - L-iduronidase.[72] This raises the possibility that mutations could affect both genes and lead to phenotypic variation in MPS IH. Several new mutational mechanisms have been found and may be important in phenotypic variation of lysosomal storage diseases.

GENOTYPE/PHENOTYPE CORRELATIONS

Implicit in the threshold hypothesis is a relationship between the level of enzymatic activity in cells and the phenotype expressed in the patients tissues. Consequently, for lysosomal storage diseases, and other inherited defects, investigators have attempted to relate genetic mutations to phenotypic manifestations. For three lysosomal storage diseases good, albeit imperfect, correlations have been obtained: MLD, TSD, and Gaucher disease. In each of these disorders, major variants include rapidly to slowly progressive onset types. In MLD combinations of two mutant arylsulfatase A alleles account for the majority of infantile-, juvenile-, and adult-onset variants of this disease.[73] [74] [75] The presence of two copies of a null allele (splicing defect in intron 2) results in a severe infantile disease. In comparison, homozygotes for a P426L substitution develop an adult-onset disease. The combination of a null and P426L mutant alleles can lead to a juvenile-onset variant. These results correlate well with the measured in situ lysosomal cleavage of exogenously supplied sulfatide substrate. [33] It is noteworthy that a very common pseudodeficiency allele at the arylsulfatase A locus results in deficient activity toward artificial substrates as measured in vitro, whereas the in vivo cleavage of sulfatide is low-normal in these cells. This mutant allele contains an altered polyadenylation signal in the 3 untranslated region, leading to inefficient polyadenylation and a decrease in available mRNA for protein synthesis. In combination with the glycosylation or null alleles for MLD, individuals with a pseudodeficient allele appear to be deficient for arylsulfatase A activity and would be expected to develop MLD symptoms. However, these individuals are asymptomatic. Because this pseudoallele is present in 1015% of the population, it is important to exclude its presence in suspected MLD families, particularly before the institution of therapies. [74] Disease-causing mutations can occur on the background of the pseudodeficient allele. Thus, the detection of the pseudodeficient mutation does not exclude a disease mutation on the same allele. In situ measurement of sulfatide cleavage is required to ensure proper diagnosis, and interpretation can be difficult. [76] The pseudodeficient alleles for -hexosaminidase A [77] and -L-iduronidase [78] raise similar concerns.

In TSD, various combinations of null and missense mutations produce different onset forms of -hexosaminidase A deficiency. The most common allele in the Ashkenazi Jewish population is a four-base pair insertion that results in the production of a nonfunctional mRNA, [58] [79] that is, a null allele resulting in the total lack of -chains for -hexosaminidase A synthesis. In comparison, the missense mutation leading to a glycine to serine (G269S) substitution produces residual -hexosaminidase A activity and a more slowly progressive disease. The onset of neurodegeneration and dementia occurs in adolescence to adulthood. [80] Similar to MLD, the combinations of null mutations with those that lead to partially functional enzymes lead to the different ages of disease onset. In these disease variants, neuropathic manifestations are progressive, and the rate of deterioration correlates inversely with the in situ level of enzyme activity from 05% of normal. In comparison, nearly all Gaucher disease types are associated with residual enzymatic activity within cells. Although good correlations have not been obtained between the level of in vitro enzymatic activity of acid -glucosidase and the disease phenotype, [81] improved correlations have been found when in situ lysosomal glucosylceramide cleavage is estimated.[82] Within this more physiologic environment, lower levels of residual activity were found in the more severe types 2 and 3 variants as compared to the type 1 non-neuronopathic variants. Unlike the TSD and MLD variants, the

genotype/phenotype correlations in Gaucher disease relate to the presence or absence of neuronopathic disease, not the delayed onset of CNS involvement (for a review see reference [53]).

Gaucher disease is the prototype for lysosomal storage diseases where several thresholds of substrate flux are apparent. The first threshold is for the preservation of normal glucosylceramide metabolism. This threshold (50% of normal) is apparent in carriers because they do not develop disease manifestations or have Gaucher cells in their tissues. The next level is that in affected homozygotes who are enzyme deficient (<20% normal) and are relatively mild to asymptomatic. These patients have enzyme deficiency and Gaucher cells in their bone marrow but minimal to no disease involvement. The next threshold is for children, adolescents, or young adults with significant to severe visceral manifestations and shortened life span. Within this group of type 1 individuals, the presence of the N370S and other disease alleles modifies the disease expression. Although the degree of involvement is highly variable, homozygotes for N370S are less severely involved by the disease, and some are asymptomatic. Indeed, about 6070% of N370S homozygotes in the Ashkenazi Jewish population are minimally symptomatic to asymptomatic.[54] In comparison, the N370S/null allele genotype usually leads to a very severe, but non-neuronopathic, course of disease. The next threshold is for the development of neuronopathic disease. Within this group are patients with types 2 and 3 disease. Type 3 patients have later onset of neuronopathic manifestations. Among type 3 variants there is significant heterogeneity with two different subtypes of neuronopathic disease, designated 3a and 3b. [83] From studies of in situ glucosylceramide metabolism, as well as genotype analysis among homozygotes for the L444P mutation, the type 3 patients appear to have significantly greater flux of glucosylceramide through their fibroblasts than do type 2 patients. The most severe type 2 patients may have one L444P mutation and an additional allele, which is null. These thresholds are relative because even in genetically normal individuals, the massive substrate load presented by the turnover of cells in diseases such as acute myelogenous leukemia, leads to the presence in bone marrow of Gaucher-like cells in patients with completely normal enzymatic activity. Thus, not unexpectedly, other factors or genes can modify the disease expression in patients with the same genotype. These factors or genes have yet to be identified, and the role of ethnic or racial background on disease expression requires definition.

From a practical view, the level of residual enzymatic activity could determine the eventual need for enzyme or gene therapy. In patients with substantial amounts of residual enzymatic activity (e.g., symptomatic N370S homozygotes), less total enzyme may be needed than in patients who have the genotype N370S/null or other severely compromised alleles. The former patients can supply significant amounts of endogenous enzymatic activity for the cleavage of glucosylceramide and may have decreased need for exogenous enzyme. For other lysosomal diseases, calculations based on in situ activity of enzymes indicate that very small differences in the quantity of enzyme in cells have major impacts on the phenotype.[33] Exogenously supplied enzyme might also influence the onset of specific organ, tissue, or cellular disease manifestations. The findings in TSD, MLD, and Gaucher disease variants anticipate similar findings in other lysosomal storage diseases. Clearly, mutation analysis in the defective gene alone will not provide for accurate prognostication. Considerable intrafamilial variation exists between affected members with these diseases. This makes it difficult to counsel and prognosticate from historical family data alone. [84]

THERAPEUTIC APPROACHES AND IMPLICATIONS

The threshold hypothesis implies that small amounts of enzymatic activity may be sufficient for prevention of various disease manifestations in the lysosomal diseases. During the past two decades, two major approaches have been exploited to overcome these thresholds and correct the underlying metabolic defects: (1) direct enzyme therapy by delivering a specific, pure, lysosomal enzyme that is missing and (2) supplying the missing enzyme by transplantation of normal organs or cells. For the transplantation strategy, bone marrow, liver, spleen, or skin cells could act as metabolic or enzyme pumps for delivery of enzyme to the plasma for uptake at distant sites to contiguous host cells or direct replacement and correction of specific cell types. Both of these approaches require receptor-mediated endocytosis through specific recognition in the target sites of pathology. This implies the need to correct only specific cell types, for example, those using the specific receptor system or being derived from bone marrow precursor cells. The normal enzyme could be supplied to deficient cells via partially corrected cell populations (chimerism) or by the administered enzyme. This applies to enzymes that are soluble or those that can be solubilized in plasma or interstitial spaces. For membrane-bound proteins, cell-cell contact (i.e., metabolic cooperation) may be required for the direct transfer of the enzyme with subsequent targeting to the lysosome. This mechanism may constrain delivery of the enzyme only to those cells in direct proximity to the normal cell and could lead to nonuniform correction. In diseases where the target sites of pathology may be distant from the sites of synthesis of a membrane-bound protein, delivery of enzymes via a secretory pathway will not work, and alternative strategies are required for delivery of enzyme. Thus, the approach with enzyme therapy or cellular transplantation strategies is disease dependent, based on knowledge of enzyme distribution and intra- and intercellular transport.

Substantial amounts of accumulated substrates in various tissues may be of exogenous origin, that is, transported from distant sites and deposited in lysosomes within particular sites of pathology. Consequently, depletion of the plasma pool of these accumulating substrates may lead to a re-equilibration of previously stored material from tissue sources into the plasma. Although this is hypothetical for most diseases, in Fabry disease previously stored substrate can be mobilized from tissue storage sites.[85] Such a depletion mechanism has obvious therapeutic implications and implies an interaction of several organs and cell types in phenotypic development. In the neuronopathic Gaucher phenotypes, some accumulating substrate in adventitial layers of CNS blood vessels is derived from visceral sources. [86] Depletion of substrate from these visceral sources might lead to a modified progression of the phenotype, depending on the impact of this pathology on CNS function. This depletion approach has not been exploited in many of the lysosomal storage diseases because little is known about glycosphingolipid, mucopolysaccharide, and glycopeptide systemic trafficking. If such depletion and re-equilibration can occur, the delivery of particular enzymes for specific diseases to the target sites of pathology may not be essential, and transport of soluble disease metabolites from tissues might prove efficacious alone or in combination with enzyme reconstitution.

The implications for genetic therapeutic approaches to the treatment of lysosomal storage diseases are clear. If the deficient enzyme must be delivered directly to the target site of pathology, transplantation of the appropriate stem cell containing the appropriate genes is obtainable in selected visceral tissues. The macrophage/monocytes of liver, spleen, bone marrow, lungs, and other reticuloendothelial tissues can be replaced by BMT with normal cells. Thus, irrespective of the complex practical and theoretical issues surrounding gene therapy approaches, gene transfer into bone marrow progenitor stem cells of the affected individuals should prove efficacious. However, metabolites might not re-equilibrate out of brain rapidly enough to prevent the manifestations of the disease in the CNS. If so, the enzyme or cells would need to be delivered to the CNS cell

types or areas that are pathologically involved. The delivery of macromolecules, cells, and recombinant viruses to the brain has proven too difficult to date, and continues as a significant barrier to the development of gene delivery for neurologic diseases, as it has been for their enzyme therapy.

Animal models of human lysosomal storage diseases are essential to the continuing development of therapies and pathophysiology studies. Although numerous naturally occurring models have been identified in mice, rats, dogs, cats, cattle, and other species, targeted gene disruption techniques provide for the generation of null and missense mutations in any desired gene, particularly in mice. Although critical to applied and basic advances, caution is needed in extrapolating data from such mice directly to humans. There are several examples of knock-out mice that have either no or lethal phenotypes and do not correspond to the human phenotypes. For the lysosomal storage diseases, the generated phenotypes have been similar to those in humans when similar mutations are compared (e.g., Gaucher disease, TSD, Niemann-Pick A). However, the presence or absence of alternative metabolic pathways in different species can have major impact on the phenotype or the efficacy of a therapeutic intervention. For example, *N*-butyl-deoxynojirimycin inhibits the synthesis of G_{M2} -ganglioside. When given to mice homozygous for null mutations for -hexosaminidase A, dramatic reductions in storage in G_{M2} -ganglioside storage were observed, suggesting a major therapeutic effect.[87] However, the observed effects rely on an alternative pathway for G_{M2} -ganglioside degradation in mice; G_{M2} -ganglioside asialo G_{M2} -ganglioside degradative products, in which the last step is not dependent on -hexosaminidase A. This provides an alternative disposal of limited quantities of G_{M2} -ganglioside. This pathway is not present in humans and similar dramatic effects might not be anticipated.

RESULTS AND LESSONS FROM THERAPY

The principal objective of cellular transplantation and enzyme therapy approaches has been to supply enzyme to various organs in the body, either via cells or by direct enzyme administration. The results and interpretations of these experiences are critically important to the development of future gene-based strategies for the lysosomal storage diseases. Based on the pluripotency of bone marrow stem cells, most transplantation studies have focused on these cells. The isolation and characterization of stem cells from other organs, including neuronal stem cells, have been encouraging and may provide pluripotent sources of enzyme in the future.[88] [89] As indicated in Table 44-1 , various lysosomal storage diseases have preferential sites of pathology. However, all cells in the body are involved with the enzyme deficiency, and most tissues can manifest symptoms and signs of these diseases. For BMT or other organ transplantations to be effective, the cells containing enzymes must be able to catabolize supplied substrate. This ultimately depends on the mass of cells transplanted because each cell can synthesize only limited amounts of enzyme for supply to the body. Such considerations are particularly relevant for organs like kidneys and liver where donor cells do not migrate from the organ.

Transplantation Approaches

Animal and human studies identified a critical limitation to transplantation strategies for lysosomal storage diseases: the inability to get enzyme or sufficient bone marrow-derived cells into brain substance. The delivery of the enzyme directly into the brain may not be necessary for CNS removal of cytotoxic substrates. However, it is theoretically desirable to deliver the enzyme to the involved cells and organs. Currently, insufficient data are available from autopsy or clinical material of transplanted humans to conclusively show the extent of biochemical or clinical improvements in the CNS of patients with most of the lysosomal storage diseases, making data obtained from animal models important in design of therapies.

The MPS I dog results from a point mutation in the -L-iduronidase gene leading to a truncated protein. [90] The visceral phenotype is similar to the moderately severe MPS I HS in humans, although the CNS storage resembles the more severe MPS IH. BMT from unaffected litter mates leads to functional and pathologic improvements in bony deformities, cardiac abnormalities, corneal clouding, and hepatosplenomegaly of affected dogs. [91] The host hepatocytes were cleared of storage material, consistent with uptake of -L-iduronidase from donor Kupffer cells. Vertebral and joint pathology continue to progress, although at a slower rate than in untransplanted affected dogs. The CNS effects were difficult to evaluate functionally, but lysosomal distention was decreased in glial cells, and there were varying improvements in neurons.

The efficacy of BMT, enzyme infusions, and gene therapy [92] [93] [94] [95] have been compared in MPS VII mice. A single base pair deletion in exon 10 of the *gus* gene (e.g., -glucuronidase) causes the disease. BMT from syngenetic unaffected mice into irradiated MPS VII affected mice increased life span and cleared storage material from liver, spleen, kidney, and cornea. Early BMT resulted in greater improvements in the skeleton and in auditory function, but neurologic and behavioral improvements were not noted. The pre-BMT irradiation regimen was shown to directly affect CNS development in young mice, producing a CNS dysplasia. [92] In comparison, infusion of recombinant -glucuronidase had no effect on the cornea and limited ability to slow the skeletal disease when initiated at 6 weeks of age. Combination of neonatal enzyme infusions, followed by later BMT, showed the synergistic effects even though brain enzyme levels were restored to only 0.75% of normal, compared to 20% in spleen, in treated mice. Poor entry of enzyme into the brain, either by infusion or BMT, is a barrier, but it is possible that very low levels of reconstitution may be sufficient to prevent severe disease. This was shown in the Twitcher mouse (a model for Krabbe disease) rescued by a -galactocerebrosidase transgene driven by a myelin basic protein promoter (K. Suzuki, personal communication). Expression was detectable only by reverse transcriptase-polymerase chain reaction, but substantial improvement in the phenotype was shown. These results indicate that reconstitution toward normal substrate flux may require very small amounts of enzyme, but the threshold amount will be disease, and probably, tissue dependent.

Continued efforts to evaluate BMT in affected animals are important because conclusive outcomes in human lysosomal storage diseases accrue only over many years. Also, the relatively small numbers of affected patients affect study design and appropriate controls. Although mouse analogs can supplement the human data on potential effects, the neurologic issues can only be addressed in humans. The greatest experience with human BMT has been in MPS IH. For this disease, early transplantation improves the clinical course and longevity in matched related and unrelated donors. The skeletal disease continues to be a major progressive clinical problem. Also, the risks of death, graft-versus-host disease (GVHD), and graft failure are substantial in those receiving matched unrelated donor marrow. The effects on developmental and neurologic function are less clear. In a study of 40 unrelated donor BMT with MPS IH, the developmental outcome was evaluable in only 11 patients. Although the trajectory of development was said to improve in unrelated donor BMT patients with initial mean developmental index (MDI) >70, the absolute MDI values decreased in 50%,[96] and if the initial MDI was <70, the results were poor. Very poor CNS results have been obtained in MPS II and III, where severe behavioral disorders appear to progress even in those patients stably engrafted. [97] In MPS III, GVHD may play a role in the

poor outcome. The older age of patients undergoing BMT for MPS II and III is thought to influence the poor outcome. But even young MPS III patients do poorly. [97] In MLD and Krabbe disease, the experience has been less extensive and varied. In both disorders, better CNS outcomes were obtained in later-onset phenotypes.

The effects of cytoreductive therapy and GVHD, and their interaction with the underlying disease, make the analysis of effectiveness even more complicated in humans where controlled trials are difficult. Also, the therapeutic goals should be carefully delineated. In humans, the natural evolution of tissue lesions in many of the lysosomal storage diseases and, particularly in the brain, are poorly documented. However, with time, these lesions probably become irreversible in a tissue-dependent manner, and a window of opportunity may exist for achieving reversal of disease manifestations in each disease. Once this disease-specific developmental threshold is passed, the damage to the brain or other organs may progress despite therapy. Progressive CNS involvement in Krabbe disease (human and murine) and Sanfilippo syndrome, and the worsening skeletal disease of MPS IH following BMT, support this notion. In addition, the varying levels of reconstitution of metabolic flux in each tissue may lead to differing results in patients. For example, variable reconstitution in the CNS following BMT may convert infantile to juvenile MLD, that is, from an earlier-onset, severe abnormality to a later-onset progressive disease. BMT will have its greatest potential beneficial effects in diseases that are pathophysiologically derived from a single cell line that can be replaced by BMT. Gaucher disease is the prime example where BMT cures the visceral lesions if instituted before irreversible damage in liver, spleen, lung, or bone marrow. [98] [99] [100] [101] The visceral components of this disease derive from monocyte/macrophage-lineage cells. The effects of BMT on the resolution or progression of signs and symptoms have been disease variant and stage specific. BMT is probably not warranted in patients with severe irreversible pathology. Careful baseline evaluation, selection, and follow-up of patients will be required to assess the therapeutic impact of BMT in the individual lysosomal storage diseases.

The results of transplantation of other organs, such as liver, kidney, and spleen, in these diseases have been limited. In diseases that result from soluble enzyme defects, hepatic, splenic, or other solid organ transplantation may be beneficial if sufficient amounts of enzyme can be synthesized and secreted for delivery to distant sites. In comparison, in diseases such as Gaucher disease, where the enzyme is not normally secreted, transplantation of liver has resulted in the accumulation of Gaucher cells and development of pathology in transplanted livers. [102] These results indicate that hepatic transplantation alone is insufficient for preventing

redevelopment of symptoms in such severely involved patients. Blood chimerism may develop following hepatic transplantation because the donor liver may supply small amounts of enzyme and bone morrow cells to recipient organs. [103] Patients receiving hepatic transplantation and small amounts of donor bone marrow may become chimeric and develop two populations of bone marrow-derived cells in their bodythose that are normal and those that are not. At a low level of chimerism, the storage cells would be expected to accumulate in tissues and in the absence of cross-correction eventually result in recurrence of disease manifestations. Greater degrees of monoctye/macrophage chimerism could lead to improvement if the normal cells can prevent accumulation of end-stage Gaucher cells in tissues. [104]

Enzyme Therapy Approaches

Enzyme therapy has been evaluated in several MPS animal models and in human Gaucher disease. The results in MPS animals were similar to the human diseases, with histologic improvements in hepatocytes, Kupffer cells, myocardium, heart valves, cartilage, and cornea. These results vary with the disease, but in general, few improvements are observed in the brain. [105] [106] [107] The skeletal disease slows but is not reversed. These results also vary somewhat depending on the source of the enzyme, that is, type of recombinant cell type, and, therefore, oligosaccharide modification.

A significant concern for the use of enzyme therapy is the development of antibodies to exogenous protein. This has been assessed in only a few studies. MPS I dogs given recombinant canine or human -L-iduronidase developed antibodies. Similarly in dogs implanted with retrovirally transduced myoblasts expressing canine -L-iduronidase, anti-iduronidase antibodies were induced, with eventual loss of the transduced cells in these animals. [108] The molecular lesion in the MPS I dog leads to premature termination of translation after the first exon, that is, these animals are null for - L-iduronidase protein. Mutations causing premature termination of -L-iduronidase are frequent in human patients with MPS IH, and similar problems might be anticipated. MPS VI cats had repeated episodes of anaphylaxis during enzyme infusions, but the IgG antibodies were not directed against the recombinant human enzyme itself. These difficulties cannot be ascribed only to the presence or absence of endogenous enzyme protein because 15% of treated Gaucher disease patients develop antibodies to the administered enzyme, and all have residual enzyme activity.

Unlike many other therapeutic modalities, enzyme therapy has been studied extensively only in human Gaucher disease. Enzyme therapy in this disease exploits the receptor for -mannosyl-terminated oligosaccharides on the surface of cells of monocyte/macrophage origin. The membrane-associated human acid -glucosidase is extracted from placental tissue or from over-expressing Chinese hamster ovary cells, purified to near homogeneity, treated with exoglycosidases to expose -mannosyl groups, and intravenously administered to affected patients. Several studies have demonstrated the utility of this approach, and many patients have excellent responses. [109] [110] [111] [112] [113] [114] [115] The population of reported patients is varied, and insight can be gained into responses for individual patients during treatment. There is substantial variation in the response to therapy, but after 1 year of enzyme therapy responses can include: (1) 2030% decrease in liver volume if the liver is initially enlarged, (2) 3050% decrease in splenic volume, (3) a 1.5 gm% hemoglobin increase if initially anemic with 3350% of such patients achieving normal hemoglobin levels, and (4) an increase in platelet counts. In many patients with massive or heavily scarred spleens, thrombocytopenia may persist for several years. Patients on higher doses have somewhat better responses in splenic volume than those on smaller doses, but the dose-response relationships are highly variable. Patients with massive splenic enlargement have poor hematologic responses until the spleen decreases by 5070%. This suggests that there may be a threshold size of spleen for adequate hematologic response, secondary to intrasplenic hemolysis and platelet consumption. There is a large variation in response to enzyme therapy among patients and at different times during therapy in one patient. Consequently, patients continue to require follow-up and monitoring to evaluate responses and to initiate treatment changes.

Hepatic and splenic changes are more rapid than those in bones or lungs. One cannot exclude the potential for each tissue having a different dose-response threshold. This is a particular concern in light of the inability to discern bony or pulmonary changes during a period of rapid dose reduction while maintaining hematologic, hepatic, and splenic improvement rates. However, little data are available on the tissue, cellular, and subcellular distribution or the half-lives of the administered enzyme. Data in mice suggest that the enzyme has relatively low uptake by monocyte/macrophage cells [116] and very different uptake and survival patterns in bone marrow, liver, and lung. [110] [117]

In addition, the cellular distribution of exogenous enzyme in affected patients is unknown, but the slowness of response to enzyme suggests that the pre-Gaucher cell compartment may be the major target for enzyme uptake. These corrected cells would then ingest Gaucher cells and degrade the contained glucosylceramide.

In view of the high cost of enzyme therapy, the timing of the initiation of therapy must be carefully evaluated. Highly symptomatic patients should begin therapy immediately. In addition, other patients with major hematologic and visceral organ involvement should receive high priority for therapy. Although bone disease appears to be the slowest to respond, [118] patients with substantial bone involvement are candidates for treatment to recover bone integrity and to prevent irreversibility of some bony damage. More difficult questions are posed by presymptomatic patients whose susceptibility to major disease manifestations can be anticipated by genotype analysis. [54] Clearly, the issue of the timing and use of an apparently universally effective therapy must be carefully considered and evaluated as a potential preventive intervention.

Using Gaucher disease as a prototype, several difficult scientific issues need to be resolved to promote optimal use of therapeutic strategies in other lysosomal storage diseases. There is extensive interpatient variability in dose response. What are the determinants of this variability? Will the effects of more easily accessed tissues be preferentially evaluated rather than those in more difficult, potentially more relevant, tissues? Is there a diminution in the need for intense therapy for continued improvement as the tissues are healed? Most importantly, what is the window of opportunity for effective therapy? Is it more efficacious to prevent the disease manifestations than to attempt to return a sick individual, with potentially irreversible tissue damage, to health? This is particularly relevant for those disorders which involve the CNS.

Gene Transfer

Lysosomal diseases, which can be treated successfully by BMT, should be amenable to permanent correction by gene therapy using hematopoietic stem cells carrying a copy of the normal gene. Following autologous transplantation with these corrected cells, somatic genetic reconstitution could be achieved by the repopulation of tissues with monocyte/macrophage derived cells. For diseases due to defects of soluble enzymes, only a portion of stem cells would need to be corrected because the corrected cells could supply enzyme to other tissues. For diseases that result from membrane-associated enzymes (e.g., Gaucher disease), all or most of the cells would need to be corrected because the enzyme cannot cross-correct other cells, and tissue macrophage chimerism could have pathophysiologic effects. For either of these types of enzyme defects, the amount of enzyme supplied to tissues directly or via cellular replacement would be mass dependent, and insufficient amounts of enzyme or cells would lead to the redevelopment or just delay of onset of symptoms and signs. Stem cells that produce active lysosomal enzymes do not have any obvious proliferative advantage over those that do not. Thus, therapeutic effects would be expected only if the patients untransformed cells were ablated by chemotherapy or irradiation. Rational strategy for the treatment of these diseases might include marrow ablation followed by autologous transplantation with transformed hematopoietic stem cells. [94] Considerable effort has been expended to develop the required efficient gene transfer technology and hematopoietic stem cell culture systems. Significant long-term expression of transgene has been accomplished with several of these enzymes. [119] [120] [121] [122] Protocols for somatic gene therapy of lysosomal diseases will likely be evaluated during the next several years.

Gene therapy studies in animal analogs have attempted to exploit targeted enzyme delivery and cell transplantation strategies. The objective of the former is to implant a continuous source of enzyme for delivery to distant sites. The latter approach attempts to replace the primary cells of pathologic involvement with gene-corrected cells. The major motivation for cellular replacement approaches to gene therapy is to avoid the real and potential immunologic barriers to tissue transplantation by using autologous transplants of corrected cells. Overexpression of -glucuronidase or - L-iduronidase from retrovirally transduced fibroblasts, implanted as neo-organs, results in secretion of sufficient enzyme for detection in distant organs. The levels achieved in these enzyme-deficient organs are modest, up to 2% of control in liver. This can be compared to those levels achieved by enzyme infusion or BMT 518%. [123] Immunohistochemical studies show detection of the secreted enzyme only in periadventitial macrophages in the brain and not in brain substance, despite in vitro studies showing enzyme uptake into neuronal and glial cells. The use of neuronal stem cell transplants appears to have promise for neuronopathic diseases. Ideally, these cells would be pluripotent neuronal cells that when transplanted into neonatal or adult mice would migrate to specific brain regions and differentiate into appropriate neurons. These cells, allogenic or immunotolerized, could then replace diseased neurons or supply enzyme to neighboring diseased cells for metabolic correction. Initial animal studies are promising, but clinical trials are in the future.

DIAGNOSIS OF LYSOSOMAL STORAGE DISEASES

The elucidation of the molecular lesions causing the lysosomal storage diseases has provided insight into the great heterogeneity within each of these diseases. In addition, the proliferation of tests for the specific genetic lesions has led many to substitute molecular testing for enzyme-based diagnoses. The great specificity of molecular testing is its downfall, whereas the more generic nature of enzyme testing is a major strength. For any of the disease categories listed in Table 44-1 , the diagnosis is established by detection of the specific enzyme defect. In experienced laboratories many of these activities are accurately determined and will establish the specific diagnosis. Once the diagnosis is established, additional molecular testing can provide supplementary information and, in some cases, prognostic insight. Because of the presence of pseudodeficient alleles in some lysosomal diseases, molecular testing and other adjunct investigations (e.g., sulfatide loading studies) are necessary to fully establish a phenotype and prognosis. Because of the therapeutic and basic import, every effort should be made to thoroughly and completely characterize these patients at the clinical, biochemical, and molecular levels. Detailed neurologic and physical assessments by clinical and imaging examinations should be made longitudinally in all patients, so that the effects of intervention or relationship of specific mutations to phenotype can be evaluated.

Chapter 45 - Infectious Mononucleosis and Other Epstein-Barr Virus-Associated Diseases

John L. Sullivan

INTRODUCTION AND HISTORY

The association of Epstein-Barr virus (EBV) with diseases of lymphoreticular and hematopoietic tissue began in 1964 with the discovery of the virus. [1] Clinically apparent EBV infection was probably first described in 1885 by the Russian pediatrician Filatov as an idiopathic lymphadenopathy in childhood. [2] In 1885, Pfeiffer described glandular fever,[3] and the term *infectious mononucleosis* (IM) was first used in 1923 by Sprunt and Evans.[4] Paul and Bunnell described the appearance of heterophil antibodies during the course of IM, [5] and Davidsohn and Walker devised the differential absorption test, which rendered the heterophil antibody test highly specific for IM.[6]

A major advance in our understanding of EBV infection occurred in 1966, when Gertrude and Werner Henle developed indirect immunofluorescent antibody assays that detected EBV-specific viral antigens. [7] [8]

In 1968, the Henles made a critical observation when they noted that seroconversion to EBV occurred during the course of acute IM in a female laboratory technician.[9] Furthermore, an immortalized EBV-carrying lymphoblastoid cell line was established from a peripheral blood leukocyte culture taken during the acute phase of this womans illness. The Henles followed up this observation with a serologic study of a collection of sera provided by Niederman and McCollum of Yale University. This collection consisted of sera obtained routinely from incoming freshmen, and later from individuals who had had acute IM. This study, as well as others, revealed EBV-specific antibodies in the sera of all students in whom IM developed, thus confirming the etiologic association between EBV and IM. [10] [11]

EPIDEMIOLOGY

Transmission and Persistence of EBV

Epstein-Barr virus was reported in the early 1970s to be transmitted primarily through contact with oropharyngeal secretions. [12] [13] Observations of EBV in the uterine cervix, reported by Sixbey et al. in 1986, suggest a possible sexual mode of transmission as well. [14] Until recently, it was thought that EBV infection was initiated after infection of oropharyngeal epithelial cells with subsequent infection and dissemination by B lymphocytes. Recent studies, however, have demonstrated that B lymphocytes can support lytic EBV replication in vivo, and it now appears that B lymphocytes may initiate, disseminate, and maintain persistent infection with EBV. [15]

Distribution and Prevalence

Seroepidemiologic studies have demonstrated a wide variation in the age at which EBV infection may be acquired. [16] Differences in geographic and socioeconomic factors account for the differences in prevalence of EBV infection. In the New Hebrides,

where large extended family units exist and the custom of mastication of food for infants by family members is practiced, nearly all infants are infected with EBV by the age of 1 year. [17] In the West Nile district in Africa, where Burkitts lymphoma is endemic, prospective studies have demonstrated that primary infection occurs in most infants between the ages of 4 months and 1 year. [18] [19] By 2 years of age, 81% have experienced primary EBV infection. Most of these infections are asymptomatic.

These studies suggest that early widespread seroconversions to EBV and other herpesviruses during infancy are associated with intense interpersonal contact with many different people. EBV infections have been considered to be of low contagiousness, and true epidemics have not occurred. Spread of EBV within families has been studied by Fleisher et al., who demonstrated serologic evidence of transmission in 7 of 35 families. [20] Each year in the college-age population in the United States, approximately 1015% of susceptible students become infected, and 5070% of the infections are associated with a mononucleosis syndrome.

BIOLOGIC AND MOLECULAR ASPECTS OF THE DISORDER

Characteristics of EBV Infection

Epstein-Barr virus is a ubiquitous virus infecting most (>90%) of the worlds population. It is associated with both benign disorders (IM) and malignant diseases (African Burkitts lymphoma and nasopharyngeal carcinoma).[8] [21] [22] EBV is a 172kilobase-pair, guanine-cytosinerich (60%), double-stranded DNA virus. [23] [24] EBV is a member of the herpesvirus family, a family that also includes the human viruses herpes simplex, herpes zoster (varicella), and cytomegalovirus. The herpesvirus family, which contains over 80 members, is clustered into 3 subfamilies, , , and herpesviridae, based on host cell range, site of latent infection, cytopathology, and duration of the replicative cycle.[25] EBV is the prototype of the herpesviridae, a subfamily characterized by tropism for B and T lymphocytes. Other members of the subfamily include Kaposis sarcoma-associated herpesvirus, herpesvirus saimiri, a monkey T-lymphotropic virus, and Mareks disease herpesvirus, a chicken lymphotropic virus.[25]

Structurally, the EBV virion is composed of four elements: (1) a dense central genetic core composed of DNA coiled around protein; (2) a nucleocapsid with 162 capsomeres in an icosahedral shape; (3) a protein integument; and (4) an outer membrane or envelope containing four major virus-encoded proteins, three glycosylated proteins (gp) of size 350, 220, and 85 kd (gp350, gp220, and gp85, respectively), and a nonglycosylated 140-kd protein (p140). [21] [25] These proteins are incorporated into the host plasma membrane during virus assembly, as evidenced by their identification on the plasma membrane of cells replicating virus. [26] [27] These proteins are acquired by the virion as it buds through the host cell membrane.

Virion Infectivity

The receptor for EBV is CD21,[28] the 140-kd complement receptor type 2 (CR2), specific for the C3d/C3dg component of the complement cascade. The gp350 and gp220 components mediate EBV virion absorption by binding CD21.[29]

Epstein-Barr virus is internalized into normal B cells by endocytosis into large, thin-walled vesicles, which are distinct from the clathrin-receptosome-lysomal pathway used by other viruses.[30] These vesicles are distinct from clathrin-coated vesicles both in size (larger) and morphologic appearance (no electron-dense, thickened appearance); they do not contain lysosomal enzymes and are not sensitive to weak bases, such as chloroquine, methylamine, or substituted ammonium chlorides. [30]

The mechanism of release of EBV nucleocapsids from vesicles into the cytoplasm is poorly understood. However, it is presumed to occur through virusvesicle membrane fusion. The major glycoprotein mediating this fusion is believed to be gp85, on the basis of its amino acid sequence being similar to that of the glycoprotein of herpes simplex virus (HSV-1), which is implicated in HSV-1 virusvesicle membrane fusion.[31] Antibodies to gp85 do not inhibit virus adsorption or internalization, but do inhibit virusvesicle fusion and thereby inhibit release of EBV into the cytoplasm. [32]

Host Cell Range of EBV

Epstein-Barr virus has traditionally been thought to have a very narrow host cell range, confined primarily to B lymphocytes and certain epithelial cells. [33] [34] Recent descriptions of EBV infection of T cells in patients with peripheral T-cell lymphoma, [35] [36] Reed-Sternberg cells in patients with Hodgkin disease, [37] [38] and smooth muscle cells in human immunodeficiency virus (HIV)-infected people [39] [40] suggest a broader host cell range for EBV infection.

Expression of CD21 antigen is a specific feature of mature B lymphocytes, and either is not present, or is present at very low density, on pre-B and immature B cells. However, mature B cells circulating in the peripheral blood express significant levels of CD21. [41] Activated B cells but not plasma cells also uniformly express CD21. [41] Although CD21 is necessary for infection, it is not sufficient. When B cells are fractionated by size only, the low-density, or resting B cells are susceptible to infection.[42] These results suggest that prior activation of B cells may render cells refractory to EBV infection. [42] Susceptibility of B cells to EBV apparently depends on a number of factors, including CD21 expression and the physiologic state of the B cell.

It has long been recognized that a strict tropism for B cells is inconsistent with many experimental observations, including (1) the association of EBV with nasopharyngeal carcinoma, an epithelial cell malignancy; (2) a study demonstrating EBV viral genome in epithelial cells from a nasopharyngeal tumor; [43] and (3) a large body of evidence demonstrating the presence of CD21 or a related structure on T lymphocytes. [44] Cytohybridization studies with oropharyngeal epithelial cells, reported in 1977, demonstrated the presence of EBV nucleic acid, [45] and subsequent work demonstrated EBV infection and replication in epithelial cells. [34]

Initial studies focused on the mechanism of infection were unable to detect CD21 on the epithelial cell surface, which led to suggestions that infection resulted from infected lymphocytes.[46] The anti-CD21 monoclonal antibodies HB5 and anti-B2 have been shown to bind a 200-kd epithelial protein, which could be a homologue of CD21 and a receptor for EBV.[47] Epithelial cell expression of the CD21 homologue is concentrated on the microvilli, and a less dense expression of the CD21 homologue is present on epithelial cells compared with lymphoid cells. [47] Studies by Sixbey and Yao have shown that polymeric IgA specific to the EBV membrane glycoprotein gp350 can block immortalization of B lymphocytes while concurrently mediating virus entry into epithelium by the polymeric immunoglobulin receptor (secretory component).[48]

Thymocytes and peripheral T cells express CD21 or CD21-like molecules. T-cell binding of anti-CD21 antibodies differs from that of B cells, suggesting structural differences between T- and B-cell CD21 molecules. Human T-lymphotropic virus type 1transformed T-cell lines also express low levels of the CD21 receptor. [49]

Latent Infection

Epstein-Barr virus is associated with both latent and lytic infections. Infection of primary B lymphocytes is primarily a latent,

non-virus-producing infection, whereas infection of epithelial cells is believed to be primarily a lytic, virus-producing infection. Latent infection of B lymphocytes by EBV causes activation and transformation, as evidenced by establishment of continuously growing B-lymphoblastoid cell lines. [50]

A limited number of viral genes are expressed during latent infection. At present, 10 genes are known to be expressed: (1) six code for EBV nuclear protein, *EBNA-1, EBNA-2, EBNA-3A, -3B, -3C,* and EBNA leader protein (*LP*); (2) two code for latent membrane proteins (LMP), *LMP-1* and *LMP-2*; and (3) two code for small, nonpolyadenylated nuclear RNAs (EB-encoded RNAs, *EBER*s). The *EBER*s are primarily transcribed by cellular RNA polymerase III and the latent genes by cellular

RNA polymerase II.[51] After infection, *EBNA2* and *LP* are expressed the earliest with maximal levels obtained by 24 hours.[52] [53] By 48 hours, the remainder of the genes have reached maximal expression.[52] [53] Expression of at least five of the latency genes is estimated for the transformation process: *EBNA-1, EBNA-2, EBNA-3A, EBNA-3C,* and *LMP-1*.[54]

PATHOGENESIS

Epstein-Barr virus replicates in the lymphoreticular system and provokes an intense immunologic response, resulting in the immunopathology and clinical symptomatology that follows the initial infection. The virus remains latent in the lymphoreticular system after host recovery, and can be reactivated during periods of immunosuppression, which leads to further disease manifestations. EBV is acquired by intimate contact of a susceptible person with a virus-containing secretion from a previously infected person. Saliva appears to be the most common vehicle of viral spread; [43] [55] however, the recent demonstration of cell-free virus in female genital secretions raises the possibility of sexual transmission. [14] Initiation of the life cycle of EBV may occur with the infection of oropharyngeal epithelial cells [56] or intraepithelial B lymphocytes. [57] EBV-infected B lymphocytes are disseminated throughout the lymphoid system, with EBV-infected B cells appearing in the circulation. Persistence of EBV infection in B lymphocytes has been demonstrated for the lifetime of an infected person. The incubation period from initial contact with a virus excreter to the appearance of large numbers of EBV-infected B cells in the circulation is approximately 3050 days. [58]

Infectious mononucleosis is a self-limiting lymphoproliferative disease characterized by lymphadenopathy, splenomegaly, and lymphocytosis. A hallmark of IM is the appearance of atypical lymphocytes in the peripheral blood, which account for 6070% percent of the total white cell count, averaging 12,00018,000/mm ^{3} . The atypical lymphocytes are primarily activated CD8 T lymphocytes and natural killer cells and are believed to be the principal mediators of clinical symptoms during acute IM. This intense immune response to the virus results in a marked reduction in the numbers of latently infected B cells in the peripheral blood, which decrease to approximately 1 in 10^5 10^6 B cells during the subsequent months, and remain at such levels for life. This small pool of latently infected B cells serves as a reservoir for viral persistence or reactivation and, when grown in vitro, these latently infected B cells transform and can be propagated as B-lymphoblastoid cell lines (BLCL). The efficient in vitro expansion of latently infected B cells into BLCL is accomplished by the removal of EBV-specific CD8+ cytotoxic T cells or their inhibition by cyclosporine A. The virus-specific cellular immune response is long-lived, such that EBV-specific cytotoxic T cells persist at a relatively high frequency in the peripheral blood for life, likely a result of continued restimulation by EBV antigen-bearing B cells. [59] [60]

Stimulation of both the humoral and cellular immune responses is evident during acute IM. The humoral response during acute IM is characterized by nonEBV-specific (e.g., heterophil antibody and autoantibody responses) and EBV-specific responses directed against viral capsid antigen (VCA), early antigen (EA), membrane antigen, and Epstein-Barr nuclear antigen (EBNA). [61] [62] In addition to IgM and IgG isotypes, polymeric IgA specific to EBV membrane antigen is transiently present in the serum during acute infection. [48]

The production of irrelevant antibodies is likely the product of polyclonal stimulation of B cells by EBV, a potent B-cell stimulator. [63]

Although there exists a strong humoral response to EBV, as demonstrated by the generation of many EBV-specific antibodies, it is the cellular immune response that is believed to be primarily responsible for controlling and preventing EBV-induced lymphoproliferative disorders. [64]

The specific cellular immune responses responsible for controlling EBV are among the best studied in humans. The in vivo activated T cells originally found during acute IM have recently been shown predominantly to comprise EBV-specific, major histocompatibility complex class I-restricted cytotoxic T lymphocytes that recognize EBV lytic as well as latent gene products. [59] [65]

The pathogenesis of acute EBV infection is summarized in Figure 45-1 . Infection is initiated in the oropharynx after contact with infected secretions. Viral replication occurs first in epithelial cells or B lymphocytes, which disseminate virus throughout the lymphoreticular system. The cellular immune responses that occur after EBV infection are complex, and it is likely that these cellular events result in the immunopathologic process that accompanies acute infection. Although humoral immune responses appear to be important in preventing recurrent infections, current evidence suggests that cellular mechanisms are responsible for the control of acute and reactivation infections with herpesviruses. Perturbations of these cellular immune responses may result in poorly controlled EBV infections or in immunologic disease clinically manifested as a lymphoproliferative disorder.

CLINICAL MANIFESTATIONS

Congenital and Neonatal Infections

Intrauterine infection with EBV appears to be a very rare event. A few case reports suggest that an embryopathy may occasionally occur as a result of congenital EBV infection.[66] Chang and Seto evaluated over 2,000 cord blood samples for evidence of in utero EBV infection and found only 1 to be positive. [67] The EBV-positive infant demonstrated normal growth and development through the first 2 years of life. It is possible that EBV infection during pregnancy is associated with a high frequency of fetal wastage, and this could explain the difficulty in finding infants with congenital EBV infection.

Relatively little is known about the importance of EBV as a cause of perinatal infections. The description of a postnatal cytomegalovirus syndrome associated with blood transfusions in premature infants[68] highlights the importance of conducting similar studies to determine if transfusion-acquired EBV infections pose a risk to the premature infant.

Primary EBV Infection in Infants and Children

Primary EBV infections in infants and children are frequently asymptomatic. When symptoms do occur, a variety of syndromes have been observed, including otitis media, diarrhea, abdominal complaints, upper respiratory infection, and IM. [69] It is now appreciated that these syndromes may occur without the production of heterophil antibodies, and EBV-specific serologic studies are necessary to establish the diagnosis. Several studies have focused on the clinical and serologic findings that are associated with IM in infants and children. Horwitz et al. have reported 32 patients younger than 4 years of age with IM. [69] Their patients were selected from a population of 200 children by review of blood smears. Those children with >50% mononuclear cells and >10% atypical lymphocytes (a total of 34 patients) were evaluated by EBV-specific serology; primary EBV infection was documented in 32 of the 34. Most of the patients had clinical evidence compatible with IM (significant cervical adenopathy and tonsillar pharyngitis). Respiratory symptoms were frequently prominent, especially in young infants. Only 25% of infants 1024 months of age demonstrated heterophil antibody responses, whereas 75% percent of children ages 2428 months were heterophil antibody positive. Only 60% of infants demonstrated VCA-IgM antibodies, compared with 100% of older children and young adults. Peak titers of VCA antibody and the development of antibodies to EA were also decreased in infants compared with older children and young adults.

This study suggests that the IM syndrome is not uncommon among young children. The presence of atypical lymphocytes and lymphadenopathy in the absence of heterophil antibodies further documents the age-related differences in host responses to EBV. Tamaki et al. have demonstrated that young infants can mount an EBV-specific cytotoxic T-lymphocyte response during acute EBV infection. These cytotoxic T-lymphocyte responses in young infants appear to be directed against the same epitopes recognized by young adults.

Infectious Mononucleosis in the Young Adult

The IM syndrome appearing in young adults is characterized by fever, anterior and posterior cervical lymphadenopathy, exudative pharyngitis, and fatigue. The syndrome is self-limited, lasting on the average 23 weeks. It is estimated that 3050% of students entering college in the United States are susceptible (seronegative) to EBV.[71] Approximately 1015% of seronegative people become infected each year, and most of those infected show signs and symptoms of classic IM. [71] Studies conducted at West Point have demonstrated an association of clinically apparent IM with the likelihood of being under stress. [71]

In people experiencing acute IM, morbilliform rashes may develop when they are treated with ampicillin or penicillin during the acute phase of the disease. [71] Hepatosplenomegaly is commonly present and severe, but only rarely results in splenic rupture, after trauma and fulminant hepatitis secondary to periportal necrosis. One of the most common causes of hospitalization during acute IM is severe pharyngitis, with concern for airway obstruction. This complication, which usually resolves in 2472 hours, may be severe enough to warrant empiric treatment with intravenous steroids, although the efficacy of such treatment is not proven. [72]

Chronic Active or Persistent EBV Infection

The use of the terms *chronic mononucleosis*,[73] *active EBV*,[74] and *persistent EBV*[75] has caused confusion and frustration for physicians investigating clinical disorders caused by EBV, as well as for those involved in day-to-day patient care. The major problem with these terms is the complete lack of proven objective criteria for applying them to a patient or group of patients. Their use in describing a syndrome characterized by chronic fatigue, fever, pharyngitis, myalgias, headaches, arthralgias, paresthesias, depression, and cognitive deficits is misleading because many of the people presenting with the syndrome have not had an identified acute EBV infection at the onset of clinical symptoms.[73] [75] These patients have been diagnosed on the basis of certain clinical symptoms associated with EBV-induced IM (i.e., fatigue, fever, pharyngitis) and an unusual or elevated pattern of EBV antibodies (especially those directed against early antigens). [73] [75]

In a study of 500 unselected patients, 1750 years of age, seeking primary care for any reason, 21% were found to be suffering from a chronic fatigue syndrome suggestive of chronic EBV.[76] They had been experiencing severe fatigue, usually cyclic, for a median of 16 months (range, 6458 months), with associated sore throat, myalgias, or headaches. Of these patients, 45% were periodically bedridden, and 2573% reported recurrent low-grade fevers, cervical adenopathy, paresthesia, arthralgias, difficulty in concentrating, and difficulty in sleeping. The patients had no recognized chronic physical illness and were not receiving psychiatric care. Although antibody titers to several EBV-specific antigens were higher in these patients than in age- and sex-matched control subjects, the differences were not significant. The available data do not support a causal role for EBV in the pathogenesis of a chronic fatigue syndrome.

By contrast, there seems little doubt that there are rare patients with extraordinarily high titers of EBV antibodies (VCA-IgG, EA-IgG) who experience clinical symptoms in the face of chronic or persistently active EBV infection. These patients may have pancytopenia, chronic lymphadenopathy, hepatosplenomegaly, interstitial pneumonitis, and chronic liver dysfunction. [76] Preliminary data suggest that an abnormal humoral immune response to EBV-EBNA antigens or infection with a variant EBV strain may be associated with chronic or persistent infection. [77] A relationship between these clinical syndromes and replication of EBV is suggested by apparent clinical responses to acyclovir therapy. [78]

Effects of EBV Infection on Hematopoietic Elements

The effects of EBV infection on the hematopoietic system have been well described. [79] [80] Patients with acute EBV infection present with lymphocytosis and not uncommonly have an associated thrombocytopenia. Infrequently, patients experience more serious hematologic complications that may involve the erythroid, myeloid, or megakaryocytic lineages.

Neutropenia is seen in many cases of IM during the first month of disease; [81] however, severe neutropenia is seen relatively

infrequently. A study by Sumaya and Ench[82] showed that 8% of patients had an absolute neutrophil count of 5001,000 cells/mm ^{3} , and 8% had a neutrophil count <500/mm^3 . In most instances, the neutropenia resolved within 2 weeks. Fatal infections attributed to severe neutropenia have been reported. [83] Examination of the bone marrow may show left-shifted myelopoiesis with a paucity of mature myeloid forms.[83] Neutrophil autoantibodies, which may be seen in a high proportion of patients with acute IM, may contribute to the neutropenia.[84] It has also been shown that T cells from patients with IM may decrease colony-forming unitsgranulocyte-macrophage (CFU-GM), suggesting that these T cells down-regulate myelopoiesis.

Epstein-Barr virus infections in infants may rarely result, at presentation, in a clinical syndrome similar to juvenile chronic myeloid leukemia. [85] These patients present with hepatosplenomegaly, leukocytosis, and thrombocytopenia and have increased levels of fetal hemoglobin. This syndrome may be distinguished from juvenile chronic myeloid leukemia by evidence of acute or recent EBV infection. Clinical symptoms may persist for months or years, but usually resolve spontaneously. Immunoregulatory abnormalities have been described, but whether these are of primary or secondary importance in pathogenesis remains uncertain.

Erythropoiesis

Mild hemolysis is common in patients experiencing acute EBV infection, but clinically significant anemia is uncommon, occurring in 13% of patients. [86] When hemolysis develops, it is usually seen within the first 2 weeks of illness. Patients usually have a positive direct Coombs test. Most frequently the autoantibody has anti-i specificity.[87] Antibodies with anti-N[88] and anti-I specificity, [89] as well as Donath-Landsteiner antibodies, [90] have also been described. In addition, patients with hereditary red cell defects may have an exaggerated rate of red blood cell destruction during acute EBV infection. [91]

Pure red cell aplasia has been described after acute EBV infection, and has been associated with persistently abnormal EBV serology over a 2-year period. [92]

Thrombopoiesis

Mild thrombocytopenia with platelet counts ranging from 50,000 to 150,000/mm ^{3} is commonly seen in patients with acute EBV infection.[93] [94] The thrombocytopenia usually occurs in the first 2 weeks after the onset of clinical symptoms. Severe thrombocytopenia may be seen in 13.5% of patients. The normalization of platelet counts may take up to 2 months.[94] Bone marrow examination shows normal or increased numbers of megakaryocytes, compatible with peripheral platelet destruction. It is thought that anti-platelet antibodies and sequestration with destruction in the spleen are responsible for the thrombocytopenia. Platelet counts usually return to normal within 2 months, and even the more chronic cases tend to resolve spontaneously. [94]

Bone Marrow Progenitors

Acute EBV infection is rarely complicated by pancytopenia and marrow hypoplasia compatible with aplastic anemia. This bone marrow complication is similar to that seen in patients with infection-associated hemophagocytic syndrome (IAHS) with pancytopenia. In a case report and review of the literature, Lazarus and Baehner described six patients with aplastic anemia in whom a bone marrow examination was performed; in four patients, the findings met the criteria for severe aplastic anemia.[95] The mean time from the onset of symptoms of IM to the development of pancytopenia was 21 days, with recovery occurring by the end of the first week of bone marrow aplasia. Several mechanisms have been proposed for EBV-associated marrow aplasia, with experimental data supporting some of them. [96] Suppressor T lymphocytes, which inhibit the growth of colony-forming unitsculture (CFU-C) in vitro, have been described in some patients. A marked increase in T cells bearing the morphologic markers for the T-cytotoxic suppressor cell population occurs during acute EBV infection and could have a role in marrow aplasia. It has also been postulated that cytotoxic cells may lyse hematopoietic stem cells. Autologous lymphocytotoxicity has been reported in patients with aplasia anemia. [96]

FATAL INFECTIOUS MONONUCLEOSIS

Infection-Associated Hemophagocytic Lymphohistiocytosis

The term *lymphohistiocytosis* was adopted by the Histiocyte Society in 1987 to include IAHS as well as other hemophagocytic disorders. [97] Virus-associated hemophagocytic syndrome is a term introduced by Risdall and co-workers in 1979 to describe a disorder characterized by a benign, generalized histiocytic proliferation with marked hemophagocytosis associated with a systemic virus infection. Since this first description, the agents associated with the induction of a hemophagocytic syndrome have expanded beyond viruses to include virtually any infectious agent, carcinomas, and hematologic malignancies. Table 45-1 lists some of the infections associated with hemophagocytic syndromes.

The syndrome is characterized by fever and by generalized constitutional symptoms with myalgias and malaise. Physical examination reveals an enlarged liver and spleen with generalized lymphadenopathy. Laboratory studies commonly demonstrate abnormal liver function tests with a coagulopathy that is more severe than that expected on the basis of the abnormal liver function. The patient is usually pancytopenic and may appear very toxic. This syndrome has been most frequently observed in people with underlying immunosuppression, including allograft recipients, patients with leukemia, and patients

with severe collagen vascular disease receiving high-dose corticosteroids. The mortality rate in patients experiencing infection-associated hemophagocytic lymphohistiocytosis (HLH) has been high; however, it is likely that the use of immunosuppressive agents in patients experiencing infection-associated HLH has contributed to the high mortality rate.

There has been some controversy regarding the pathologic differentiation between secondary HLH and malignant histiocytosis. The pathologic features of secondary HLH vary with the time that biopsies are performed. Early in the disease, the bone marrow may be hypercellular with few infiltrating histiocytes. Erythrophagocytosis is usually best demonstrated in aspirate smears. Later in the disease, the bone marrow is hypocellular and shows varying numbers of infiltrating histiocytes. Lymph nodes early in the disease may exhibit an intense immunoblastic proliferative response with partial effacement of the lymph node architecture. The number of histiocytes early in the disease may be low. Later in the disease, lymphoid depletion supervenes, and there may be a massive sinusoidal infiltration by benign-appearing histiocytes, many of them exhibiting erythrophagocytosis. Liver biopsy reveals large portal infiltrates of lymphocytes, immunoblasts, and histiocytes. Histiocytes, many of which exhibit erythrophagocytosis, are seen in liver sinusoids. Mild fatty metamorphosis may also be present. Immunologic studies have been reported in only a few patients. In most patients studied, EBV was the associated infectious agent. Atypical lymphocytes, which are the hallmark of acute EBV infection, are absent or diminished, reflecting a decrease in activated CD8 T cells normally seen in response to EBV. We have speculated that immunodeficiency or underlying immunosuppression may play a role in the pathogenesis of HLH. Many of the infectious agents associated with HLH are potent stimulators of the immune system and require complex interactions of immunoregulatory cells for host recovery. Underlying immunoregulatory disturbances may allow an inappropriate antiviral

response. As this response progresses, cytokines secreted by activated T lymphocytes may elicit the proliferation and activation of histiocytes.

X-Linked Lymphoproliferative Syndrome

The X-linked lymphoproliferative (XLP) syndrome is characterized by a selective immunodeficiency to EBV manifested by severe or fatal IM and acquired immunodeficiency.[98] Prospective studies in male patients before EBV infection have demonstrated normal cellular and humoral immunity. [99] During acute EBV infection, male patients with XLP demonstrate vigorous cytotoxic cellular responses that predominantly involve polyclonally activated alloreactive cytotoxic T cells, but cytotoxic T cells that recognize EBV-infected autologous B cells have been demonstrated. Fatal EBV infections in male patients with XLP usually result from extensive liver necrosis, and those who survive acute EBV infection demonstrate global cellular immune defects with deficient T-cell, B-cell, and natural killer cell responses. It is hypothesized that uncontrolled alloreactive T-cell responses triggered by EBV-transformed B cells result in the immunopathologic process of XLP. The gene for XLP is localized in the 9q region of the X chromosome,[100] and has recently been identified as the Duncans disease SH2 protein (DSHP). [101] The identification of the XLP gene will enable diagnosis of sporadic cases of XLP, and when DSHP function is understood, new therapeutic interventions during acute EBV infection may be realized.

EBV and Post-transplantation Lymphomas

Allograft recipients are at increased risk for the development of EBV-induced lymphoreticular malignancies. [102] The incidence of post-transplantation lymphomas is in the range of 115%, depending on the allograft and the immunosuppressive regimen. Most of the lymphomas are categorized as diffuse large cell lymphomas, with most having immunoblastic features. Molecular probes specific for EBV have streamlined the diagnosis of EBV-associated post-transplantation lymphoma. Studies using molecular probes to analyze clonality of post-transplantation lymphomas have demonstrated that most patients with lymphomas have monoclonal tumors, but often the disease is multiclonal, with biopsy material from different anatomic sites showing different proliferating clones of tumor cells. A recent study suggests that LMP-1 plays a critical role in the pathogenesis of EBV-induced lymphoproliferative disorders in immunosuppressed patients. [103] The specific immune defect responsible for these lymphoproliferative disorders is unknown, but is thought to be related to the loss of memory cytotoxic T lymphocytes specific for EBV-transformed B lymphocytes.

EBV- and HIV-Associated Non-Hodgkin Lymphoma

The incidence of non-Hodgkin lymphomas is 60100 times that expected in HIV-infected people. [104] The incidence of lymphomas increases with the duration of HIV infection. It has been reported that lymphoma developed in 19% of patients with symptomatic HIV infection receiving antiretroviral therapy and surviving 3 years. [105]

For unknown reasons, most EBV-associated non-Hodgkin lymphomas in HIV-infected patients have presented as primary central nervous system lymphomas. [106] It appears that the combination of chronic B-lymphocyte stimulation in the setting of severe T-cell immunodeficiency in a person with previous EBV infection is a set-up for the development of non-Hodgkin lymphoma.[107]

Peripheral T-Cell Lymphoma and Hodgkin Disease

Recent studies suggest that peripheral T-cell non-Hodgkin lymphomas, which occur in people without global immune defects, are associated with EBV in 1035% of cases.[35] [36] Angioimmunoblastic lymphadenopathy and angiocentric polymorphous lymphoreticular infiltrates known clinically as lethal midline granuloma are T-cell lymphomas frequently associated with EBV. Both the A and B strains of EBV have been associated with EBV-associated T-cell lymphomas.

Epstein-Barr virus is detectable in Reed-Sternberg cells in approximately 4050% of cases of Hodgkin disease, particularly of the mixed cellulosity subtype. [37] [38] [40] EBV is detectable in most cases of Hodgkin disease developing in HIV-infected people. The Reed-Sternberg cell has been shown to contain monoclonal EBV genomes with restricted expression (*LMP-1, EBER-1, EBER-2*) of latent gene products. Recently it was demonstrated that EBV replicates in Reed-Sternberg cells of Hodgkin disease.[38]

Recent studies also suggest mechanisms that may play a role in EBV-induced oncogenesis. [103]

LABORATORY DIAGNOSIS OF IM

Serology

In 9095% of young adults with clinical EBV-induced IM, atypical lymphocytosis and heterophil antibodies are present. [108] However, in infants and children with primary EBV infection (regardless of whether associated with IM), heterophil antibody responses are frequently absent. [69] Primary EBV infection is usually suggested by the presence of atypical lymphocytes, but these may also be absent or present in small numbers. [109] Diagnosis of primary infection in childhood frequently requires EBV-specific serologic tests. Our approach to a patient suspected of having a primary EBV infection is first to perform a rapid slide test for heterophil antibodies; if this is positive (differential absorption

with guinea pig kidney and beef erythrocyte antigens should be performed), EBV-specific serology is unnecessary, but if the rapid slide test is negative, the serum sample should be tested for EBV-specific antibodies.

In people with negative Paul-Bunnell heterophil antibody tests (especially infants and children) and patients with atypical primary EBV infections, specific antibodies for EBV should be determined. Antibodies to three specific EBV antigens have been thoroughly studied and found to be of diagnostic importance: (1) VCA; (2) EAs (both of which may be expressed by certain EBV-infected B-lymphoblastoid cell lines); and (3) EBNAs, which are expressed by all cell lines. [110] These antigens have been detected by the indirect immunofluorescence test in serum samples from patients with EBV-associated diseases. Patients experiencing acute EBV-induced IM and the EBV-associated malignancies (Burkitts lymphoma and nasopharyngeal carcinoma) have been thoroughly studied, as well as normal control subjects, and certain characteristic antibody patterns have been described.

Figure 45-2 shows the characteristic antibody patterns observed in young adults experiencing EBV-induced IM. [110] Before EBV infection, all three antibodies are absent, but during the acute phase of infection, high titers of IgM and IgG antibodies to VCA are seen. IgM antibodies are transient and disappear after a few months. Most people develop transient IgG antibodies against EAs; these antibodies disappear after a few months. In 1985, it was reported that between 12 and 39% of normal people maintain moderate (1:20 to 1:40) antibody titers to EAs for years after primary infection. [111] Antibodies directed against the EBNA proteins are produced early in infection; however, detectable titers by indirect immunofluorescence are not usually found until 12 months after acute infection. This pattern of late appearance is probably a reflection of the insensitivity of the complement-dependent indirect immunofluorescent antibody test, because sensitive enzyme-linked immunosorbent assay-based methods detect antibodies to the EBNAs early after infection. Healthy people who have had past infection with EBV show VCA-IgG antibodies. In infants, VCA-IgM responses may be seen in only 60% and EA responses in approximately 50% of patients during acute EBV infection. [67]

In general, acute or recent primary infection is indicated by the following: (1) the presence of VCA-specific IgM antibodies, (2) high titers of VCA-specific IgG antibodies (1:320 or greater), (3) detection of anti-EA antibodies (1:10 or greater), and (4) the absence of anti-EBNA by the immunofluorescent antibody test. [110] Convalescent serum samples should be obtained to demonstrate the disappearance of VCA-IgM and appearance of EBNA antibodies. EBV antibody titers should not be used to make a diagnosis of chronic IM or other EBV-associated syndromes on the basis of mild to moderate elevation of VCA (1:160 to 1:320) or EA (1:20 to 1:40) antibodies because normal people may show such titers years after uncomplicated infection. [111] Elevated EBV titers are also seen in patients with EBV-associated malignancies and in those with virtually any condition associated with suppression of cellular immune function (e.g., allograft recipients, patients receiving chemotherapy, patients with HIV infection). Past infection is indicated by the presence of VCA-IgG and EBNA-IgG antibodies.

Isolation of EBV

Epstein-Barr virus cannot be cultured by routine virologic culture methods that use standard animal cell cultures; it grows only in primate B lymphocytes. The presence of virus can be demonstrated by inoculating human umbilical cord blood lymphocytes (EBV-nonimmune B lymphocytes) with throat washings or by establishing an EBNA-positive, spontaneous B-lymphoblastoid cell line from the peripheral blood of the infected person. However, both methods detect virus in people with past infection because EBV is a latent virus, and most healthy, previously infected people chronically shed virus in the oropharynx. [55] Because of the difficulties in making a serologic diagnosis in patients with unusual or rare manifestations of EBV infection, molecular diagnostic techniques must be used.

Molecular Diagnostic Techniques

Molecular diagnostic techniques have contributed greatly to the identification of EBV in pathologic materials (see Pagano [112]). In situ hybridization (ISH), Southern blot analysis, and the polymerase

Figure 45-2 Characteristic EBV-specific antibody responses observed in young adults with acute IM. EA, early antigen; EBNA, Epstein-Barr nuclear antigen; VCA, viral capsid antigen. *(Adapted from Henle W, Henle GE, Horwitz CA: Epstein-Barr virus specific diagnostic tests in infectious mononucleosis. Hum Pathol 5:551, 1974, with permission.)*

chain reaction (PCR) are useful techniques used alone and in combination.

Southern blot hybridization of DNA extracted from affected tissue is used when it is not necessary morphologically to identify infected cells or when sufficient cells containing EBV are present in the lesion. Such cases include entities such as HIV-associated lymphoma or Burkitts lymphoma. Southern blots are probed with a Bam W probe, which detects an internal repeat in the EBV genome.

The EBV genome contains terminal repeats that hybridize when the genome is in the circular or episomal form. When a clonal cell population is present, only one form of the genome with a single terminal repeat is present. When a Southern blot is probed with a terminal repeat probe such as Bam NJ, a single band is obtained.[108] Such results are found in Burkitts lymphoma or nasopharyngeal carcinoma. In a polyclonal infection, a heterogeneous collection of bands is found. This technique also discriminates replicating from nonreplicating (latent) EBV infection. [108]

In situ hybridization using oligonucleotide probes complementary to the *EBER* genes has provided an extremely powerful technique for the identification of EBV-infected cells in tissue sections and smears.[113] The advantages of ISH for the detection of *EBER*-encoded RNA is that it is a relatively simple technique, uses cheap, stable probes, can be used on archival material, does not require radioactivity, and provides a permanent morphologic endpoint. Because latently infected cells may express millions of copies of *EBER*-RNA, ISH provides an extremely sensitive technique for the identification of even a few infected cells in a tissue. Not only does this technique provide morphologic information, it is more sensitive than Southern blotting and approaches the sensitivity of PCR. ISH is used when it is important to obtain morphologic information, when only access to paraffin-embedded archival material is possible, when it is desired to obtain information about what portion of cells may be infected, or when high sensitivity is needed. This technique is now widely applied and has been extremely useful in identifying EBV in entities such as Hodgkin disease, T-cell lymphoma, IAHS, and nasopharyngeal carcinoma.

A third modality useful for the detection of EBV is PCR.[114] [115] [116] The advantages of PCR are its ability to detect rare infected cells (on the order of 1 in 1×10^6) and its rapidity. DNA may be extracted from fresh material or from paraffin-embedded archival material. However, PCR is a relatively complex technique, and great care must be taken to ensure that positive signals are true positives. Currently, a technique described by Tamaki et al. that amplifies the *EBNA-3C* region of EBV is commonly used.[117] This technique is useful in screening materials that require high sensitivity, such as in determining whether EBV is present in novel lymph node diseases or carcinomas. Another utility of the PCR technique is its ability to subtype EBV strains. EBV strains are classifiable into two subtypes based on differences in genomic sequences, especially the *EBNA-2* and *EBNA-3* genes. The A subtype is prevalent in Western countries and Japan and has an enhanced ability to transform B lymphocytes in vitro. The B subtype is more prevalent in Africa, although it has been shown that in oropharyngeal fluid obtained from people in the United States, both strains are equally distributed.

THERAPY AND FUTURE DIRECTIONS

The use of corticosteroids in severe cases of EBV infection and IM is recommended in many standard textbooks and review articles. [93] Controlled studies have demonstrated a shortened duration of fever in corticosteroid-treated IM. [72] However, controlled studies have not been made of the efficacy of corticosteroids in the treatment of severe or life-threatening EBV infections, including those associated with severe pharyngeal involvement, neurologic involvement, thrombocytopenia, and myocarditis. Immunologic interactions appear to be so important for normal host recovery that the use of corticosteroids in nonlife-threatening EBV infections should be discouraged. It is possible that steroid-related effects on the hostvirus relationship may take months or years to develop, and long-term epidemiologic studies of steroid-treated patients have not been reported.

Acyclovir has been shown to inhibit EBV replication in vitro. [118] In a placebo-controlled trial of intravenous acyclovir in patients with acute IM who required hospitalization, no significant differences in outcome were observed between the placebo- and acyclovir-treated groups. [119] A placebo-controlled trial of oral acyclovir in ambulatory college students experiencing acute IM also demonstrated no significant effects of acyclovir on clinical outcome. [120]

Various therapeutic agents have been tried unsuccessfully in XLP patients experiencing acute EBV infection. It is clear that high-dose immunosuppressive therapy predisposes these patients to fatal B-cell lymphoproliferative disorders. This effect has been observed with the use of high-dose corticosteroids and antithymocyte globulin. Acyclovir therapy of patients with the XLP syndrome has been reported. [121] In no instance was objective evidence of clinical improvement apparent. Patients have died with disseminated EBV-infected B lymphocytes throughout the lymphoreticular organs despite a 2-week course of acyclovir (1,500 mg/m ^{2} /day). Virologic studies have revealed that the virus in infected B lymphocytes was in a nonreplicating state, and mature virus particles were not being produced. In view of these results, it is likely that acyclovir will prove to be efficacious only in those patients with syndromes associated with replicating EBV infection.

A recent study of acyclovir and ganciclovir prophylaxis in pediatric liver transplant recipients demonstrated no apparent benefit toward the prevention of EBV disease.[122] It is thought that male patients with XLP experiencing primary EBV infection should be treated with broad-spectrum cytotoxic chemotherapy in an effort to eliminate the activated CD8 T lymphocytes and, at the same time, control the proliferation of the EBV-transformed B cells. Such therapy remains unproven but appears worthy of trial.

Correction of XLP by transplantation of bone marrow[123] and cord blood stem cells[124] has been reported. The advent of genetic diagnosis of presymptomatic (EBV-seronegative) XLP male patients now makes it possible to correct the defect by transplantation before primary EBV infection has occurred. In the absence of a marrow or stem cell donor, high-dose (600 mg/kg/month) intravenous gamma globulin containing high titers of EBV antibodies is being used in an attempt to prevent primary infection. It is hoped that the discovery of the XLP gene defect will lead to new therapeutic modalities as well as prevention of EBV-induced immunodeficiencies.

Chapter 46 - The Spleen and Its Disorders

Susan B. Shurin

INTRODUCTION

Galen described the spleen as the organ of mystery, with functions related to mood and good or ill humors. It was not until the 18th century that the spleens relationship to the immune and hematologic systems was appreciated. The complexities of splenic function continue to be the focus of research and observation. The spleen is not necessary to life because its many functions are redundant, overlap with the functions of other organs, and can be assumed by other organs. Nonetheless, the spleen is an important part of many disease processes as well as of normal function of both the immune and hematologic systems. An appreciation for the subtleties of its anatomy and

function is important for the physician evaluating patients with many hematologic, immunologic, and hepatic diseases.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

NORMAL SPLENIC ANATOMY AND FUNCTION

Embryology

The spleen arises from the mesoderm. By the ninth week of gestation, layers of the left dorsal mesogastrium condense, and blood vessels appear. Sheaths are formed around arterioles by reticular cells and fibers. Macrophages are present and phagocytic by the end of the first trimester. Lymphocytes appear during the fourth month. Red and white pulp can be identified by the sixth month. Germinal centers do not develop during fetal life, but primitive inactive follicles are evident at birth. [1] In mice, a homeobox gene, *Hox11*, controls the genesis of the spleen;[2] a human counterpart has yet to be described. The spleen is capable of supporting hematopoiesis both during fetal life and, in a variety of pathologic states, postnatally. The circulation of primitive hematopoietic stem cells in peripheral blood during prenatal life through birth makes it difficult to distinguish between hematopoiesis dependent on tissues in the organs and the incidental presence of hematopoietic cells within the circulation of those organs. [3] [4]

Anatomy

The spleen is covered with a fibrous capsule with blood vessels, lymphatics, and nerves and is coated by peritoneal mesothelium (Fig. 46-1). The splenic artery comes from the celiac axis, enters the capsule at the hilum, and branches into trabecular arteries. The trabecular arteries then branch into central arteries and enter the white pulp. On the cut surface of the normal spleen, white pulp is visible as white nodules 12 mm in diameter. The periarterial lymphoid sheath consists of a cuff of T lymphocytes, plasma cells, and macrophages around the central arteries. As the arteries branch, the sheath narrows. B-lymphocyte clusters appear in follicles along the periarterial lymphoid sheath at arterial branch points. The components of the white pulp are connected by a reticular network and supporting stromal cells. On the cut surface of the normal spleen, white pulp is visible as white nodules 12 mm in diameter. Their size varies with age and antigenic stimulation. Normally developed at birth, the size of the nodules increases in childhood, especially with immunizations and infections, peaks at puberty, and involutes

Figure 46-1 Anatomy of the spleen. *(From Weiss and Tavassoli,[10] with permission.)*

in adulthood. Immunologically normal, uninfected adults normally have no evident germinal centers. A mantle zone of B lymphocytes surrounds the follicle, or secondary germinal center. Antigen trapping and processing take place in the marginal zone of the white pulp.

The red pulp of the spleen consists of vascular sinuses, the cords of Billroth, and the terminal branches of the penicilliary arteries. [5] [6] Vascular sinuses are lined with endothelial cells with long processes and a basement membrane with ring fibers, which attach to macrophage dendritic processes. No tight junctions or interdigitations connect the cytoplasmic processes. Intact leukocytes, erythrocytes, and platelets are able to squeeze through the potential spaces between these cells and between the ring fibers. Processes of the reticular cells of the cords of Billroth are outside the sinus walls. Endothelial cells line the sinuses and pulp veins, but not the cords. Circulation of blood through red pulp lined with endothelium, or closed circulation, is rapid. Circulation into the cords, or open circulation, is slower and permits the macrophages lining the cord to remove damaged or aged cells.

Functions

The functions of the spleen are summarized in Table 46-1 .

Hematopoiesis

Active hematopoiesis can be seen in the fetal spleen throughout the second trimester, and decreasing in the third trimester. [7] Erythropoiesis and megakaryocytopoiesis predominate, with myelopoieis present to a lesser extent. As hematopoiesis moves from the hepatic phase into the bone marrow, it is less evident within the fetal spleen. The spleen is not normally a site of hematopoiesis in postnatal life but may resume that function in a number of pathologic states. [3] [4] Extramedullary hematopoiesis is a significant cause of splenomegaly in bone marrow diseases (e.g., myelofibrosis, osteopetrosis) and chronic hemolytic anemias (e.g., thalassemia). The stromal cells of the spleen appear to be capable of supporting hematopoiesis and may produce c- *kit* ligand,[8] [9] as do marrow stromal cells. When splenic hematopoiesis occurs, the erythrocytes and platelets that circulate tend to be less mature than when hematopoiesis occurs in the bone marrow, which suggests that egress from the spleen is easier than from the marrow.

Removal of Damaged and Aged Formed Elements

As erythrocytes and platelets age, they tolerate the hostile splenic environment less well than when they are healthy with metabolic reserve. [10] The spleen is acidotic (pH 6.87.2), hypoxic (P_{O_2} 54 mm Hg), and hypoglycemic (glucose concentration 60% of that in venous blood). Damage to aged anucleate cells includes changes in their membrane complex carbohydrates, which facilitate recognition by splenic macrophages and removal from the circulation. [11] [12] *Culling* describes the destruction of erythrocytes, either the normal removal of aging cells or the removal of damaged cells in pathologic states. Most platelets and leukocytes are not removed by the spleen as they age but adhere to vessel walls and migrate into tissues, where they die. *Pitting* refers to the removal of inclusions from within erythrocytes, which are then released back into the circulation. Erythrocytes must pass between or through the cordal macrophages, through the fenestrations of the basement membrane of the sinus, and then between the endothelial cells. Poorly deformable cells are unable to enter the sinuses. The erythrocyte membrane is in close apposition to the macrophage membrane, so that aged or damaged glycoproteins, antibody, or complement on the surface of the cell are easily recognized and activate

TABLE 46-1 -- Functions of the Spleen

Category	Function	Effector Cells/Areas
Clearance/filtration	Antibody-mediated clearance	Macrophages
	Culling and pitting	Reticular meshwork
Immune response		

Marginal zone	Interaction of antigens with effector cells	Monocytes, lymphocytes
	Antigen processing	Macrophages
White pulp	Immune recognition	T cells (periarteriolar sheath)
	Immunoregulation, antibody production	B cells (lymphoid follicles)
Red pulp	Antigen processing, preservation	Macrophages
	Phagocytosis	Macrophages, monocytes, neutrophils
Hematologic	Hematopoiesis	Cords and sinuses
	Storage of erythrocytes, platelets, leukocytes	Reticular meshwork, red pulp
	Finishing/polishing of erythrocytes	Reticular meshwork, macrophages
Hemostasis	Production of factor VIII, von Willebrand factor	Endothelial cells

phagocytosis. Particulate matterHowell-Jolly bodies, Heinz bodies, Pappenheimer bodies, and malarial and other parasitescan be removed and the cell returned to the bloodstream. Membrane-containing adsorbed antibody can be removed, and the remainder of the cell released with changes in shape and volume. Internal vesicles near the erythrocyte membrane appear as if they were on the surface of the cell, and are termed *pits* or *pocks*. [13] [14] [15] [16] The spleen also normally removes these, with the polished erythrocyte returned to the circulation. The lack of this polishing function can be used to assess splenic function.

Immunologic Function

The spleen is important in the recognition of antigens, especially when administered intravenously; in the production of antibody; and in the clearance of antibody-coated particles from the bloodstream (Table 46-1).[17] [18] [19] The white pulp of the spleen is the largest mass of lymphoid tissue in the body. Trapping and processing of antigens is a major function of the marginal zone, with its abundant blood supply (2 L/min) and large number of macrophages. Antigens penetrate the germinal center, where T lymphocytes predominate. Processing of carbohydrate antigens is a special function of splenic marginal zone lymphocytes. [20] The B lymphocytes, which ultimately produce antibodies, predominate in the nearby germinal centers and mantle zones. These areas all increase in size and activity with immunization or infection. Splenic macrophages are more sensitive to small amounts of opsonic antibody or complement on the surface of particles than are macrophages in the liver, lung, or bone marrow.[21] In the absence of a spleen, nonimmune individuals may fail to remove bacteria with little opsonic coating. [22] [23] The production of antigen-specific IgM is impaired in the absence of a spleen. [20] [24] Thus, an asplenic individual has defective recognition of carbohydrate antigens, defective production of IgM early in infection, and defective removal of lightly opsonized particlesall crucial components of response to invasive infection with encapsulated organisms.

Storage of Cells

The normal spleen contains 2040 ml of blood in an adult, and does not serve as a reservoir for either blood volume or erythrocytes. This changes in many conditions associated with splenomegaly, especially if portal hypertension is also present. The widening of the pulp cords creates an organ with more storage volume. Vascular pooling of both blood and formed elements occurs, regardless of the underlying cause of the splenomegaly. [25] Platelets and granulocytes, however, are normally stored in the red pulp of the spleen. As much as one-third of the total platelet mass may be stored in the spleen and released when cytokines affecting platelet adhesiveness are released.[26] The lack of musculature in the human splenic capsule prevents the distention and contraction that occur in many animals, such as dogs. After splenectomy, both platelet counts and granulocyte counts rise significantly, then fall. [27] [28] However, the circulating masses of both of these cell pools are chronically increased, which may contribute to an increased incidence of atherosclerosis years after splenectomy. [29] [30]

EXAMINATION OF THE SPLEEN

For adequate examination of the spleen, the examinee must be fully supine, relaxed, with arms adjacent to the trunk, and the examiner must be on the examinees right side.[31] Beginning in the right iliac fossa, the examiners hand gently advances toward the left upper quadrant. This minimizes the likelihood that a grossly enlarged spleen will be unappreciated, and the lower pole and medial border should be easily appreciated. If the spleen cannot be felt with this approach, the left hand of the examiner is placed on the left flank, lifting the lower part of the rib cage to displace the spleen medially toward the examiners right hand. The splenic notch should be felt in the inferior medial border. Rotating the subject into the right lateral position while still recumbent may make it easier to palpate the spleen. The spleen should move with deep inspiration. It is dull to percussion. The degree of enlargement is usually measured in centimeters below the costal margin. It may be difficult to appreciate even significantly enlarged spleens, depending on the position of the spleen within the abdomen. Normal splenic size in an adult is up to 250 g, and up to 13 cm in its long axis. Up to half of spleens weighing 600750 g are not palpable. [32] Greater degrees of splenomegaly are less difficult to appreciate on physical examination.

Up to 15% of normal children and 3% of young adults have palpable spleens, up to 2 cm below the left costal margin, without evidence of illness. [33] The spleen involutes with age, and hence a spleen that is palpable in an older person is less likely to be a normal variant and more likely to be associated with clinical disease.

IMAGING OF THE SPLEEN

Radionuclide scintigraphy assesses both anatomic and functional aspects of the spleen. [34] The most common procedure is a liver-spleen scan in which ^{99m}Tc sulfur colloid is injected intravenously and taken up by hepatic and splenic macrophages.

Thus, it is the phagocytic activity of macrophages, rather than the presence of the spleen itself or any aspects of lymphoid function, which is assessed. A dynamic ^{99m}Tc scan can also assess the distribution of blood within the portal system, and suggest the presence of portal hypertension.

Ultrasonography readily shows the size, shape, and several aspects of splenic anatomy, including the presence of cysts and abscesses. [35] The procedure is noninvasive, painless, low cost, and avoids radiation exposure for patients, and thus is a good screening study when the spleen is thought to be enlarged. Accessory spleens tend not to be well visualized on ultrasonography.

Computed tomography (CT) has the advantage of showing both the anatomy and some aspects of splenic function. [36] [37] [38] Contrast material in the stomach, small bowel, and colon, given enterally, helps delineate splenic tissue when it impinges on these organs. Intravenous contrast material is required to delineate splenic lesions whose density is the same as normal splenic tissue. Abscesses have a rim of contrast agent enhancement. [39]

CT can be used to estimate the volume of the spleen. Accessory spleens have the same attenuation as a normal spleen, which is somewhat less than that of liver. [40] Accessory spleens are usually located in the gastrosplenic ligament near the hilum. Subcapsular and intrasplenic hematomas and splenic lacerations are clearly seen on CT. Leukemias and many inflammatory diseases produce diffuse splenomegaly. Granulomas and infarcted areas eventually calcify. Cysts, abscesses, and some malignancies have inhomogeneous patterns on CT scan. [41] [42] [43]

In addition to imaging the spleen, CT can be used for diagnostic and even therapeutic studies. Abscesses, hematomas, and cysts can be drained. As long as portal hypertension is not present and vascular lesions have been excluded, thin needle aspiration under CT guidance is generally a safe intervention.

Magnetic resonance imaging (MRI) is primarily useful for identifying vascular lesions that would otherwise require angiography. It is more difficult to image the contents of the upper abdomen with MRI than with CT because of respiratory motion. Some of these limitations are likely to be overcome with the newer, more rapid MRI technology.

TESTS OF SPLENIC FUNCTION

The peripheral blood smear may be the most sensitive tool for identification of functional or anatomic hyposplenia. The presence of Howell-Jolly bodies, which are nuclear remnants normally removed by the spleen, is an excellent indicator of hyposplenism. [44] These are rarely seen until the spleen is largely nonfunctional or overwhelmed by other phagocytic functions, such as extravascular hemolysis. Newborn infants commonly have visible Howell-Jolly bodies, and splenic function appears to be at least somewhat impaired in the first week of life. [14] [15] [45] Pappenheimer bodies (siderotic granules normally removed by the spleen) are often seen in hyposplenic states, particularly when a component of hemolysis exists. [46] Erythrocyte morphology reflects the lack of membrane polishing by the spleen, with the presence of acanthocytes and target cells. [11] [13] [27] Both granulocyte and platelet numbers are increased during asplenic states, including splenic infarction and surgical splenectomy. [27] [28]

To confirm suspected hyposplenism, the simplest test is a count of pitted or pocked erythrocytes. Fixation in 0.51.0% glutaraldehyde and examination under interference optics for surface pits reveals endocytic vesicles containing hemoglobin, ferritin, and remnants of mitochondria. [13] These form in mature erythrocytes and are normally removed by the functioning spleen. The number of pitted cells (not the number of pits per cell) is inversely proportional to splenic function, with normal persons having <2% pitted cells.

ASPLENIA AND HYPOSPLENIA

Congenital asplenia may be an isolated lesion or associated with severe cyanotic congenital hearing disease and bilateral right-sidedness. [47] Life-threatening cardiac lesions, including transposition of the great vessels, pulmonary artery atresia or stenosis, septal defects, anomalous venous drainage, and single atrioventricular valve, are components of this condition. The liver is central, and both lungs have three lobes. The peripheral blood smear shows Howell-Jolly bodies and other signs of hyposplenism. Children who survive the cardiac difficulties in the neonatal period have a significant incidence of sepsis due to a variety of organisms. [48]

Polysplenia is associated with bilateral left-sidedness. Dextrocardia, bilateral superior venae cava, septal defects, and anomalous pulmonary venous return are associated cardiac lesions. Both lungs have two lobes, the liver is midline, and bowel malrotation is common. The splenic tissue is divided into two to nine masses. [49] The peripheral blood smear usually does not suggest hyposplenism, and no clear association with an increased risk of infection has been documented.

Asplenia occurring without heart disease is less likely to be detected before an infection develops than when associated cardiac lesions bring the patient to medical attention.[50] [51] Some of these patients also have situs inversus. Isolated cases of asplenia discovered after death of an otherwise healthy adult or child from overwhelming sepsis with encapsulated organisms have been reported. Imaging to determine whether a spleen is present should follow identification of Howell-Jolly bodies on the blood smear of an otherwise healthy person. Immunization with polysaccharide vaccines and early intervention with antibiotics for apparent infection may prove lifesaving for these individuals. [48]

Acquired Hyposplenism

Infarction in Sickle Cell Disease

The course of sickle cell disease is marked by progressive dysfunction of many organs over many years. [52] [53] One of the earliest organs to be affected is the spleen. Serial measurement of pitted erythrocytes in sickle syndromes demonstrates that splenic dysfunction develops progressively over the first few years of life in the major sickle syndromes (Figs. 46-2 (Figure Not Available) and 46-3). The hypoxic, acidotic, hypoglycemic environment of the spleen creates optimal conditions for tactoid formation and for sickling of the poorly deformable erythrocytes, which then block splenic blood vessels and infarct the tissues. The hyposplenism is reversible with transfusion for at least the first few years of life, but becomes irreversible by age 6 in patients with hemoglobin SS disease, with progressive damage to blood vessels.[54] [55] [56]

Splenic sequestration is a manifestation of the infarctive process of sickling in the spleen that extends to involve larger veins. [57] [58] The unimpeded flow of well-oxygenated blood in the splenic arterioles into the distensible splenic tissues results in pooling of a large amount of blood, while the venous drainage is occluded by sickled hypoxic erythrocytes. Unlike the chronic process of smaller vessel infarction, the acute splenic sequestration crisis can be life-threatening because a large amount of blood can collect in the spleen. The tendency to recurrence and the potential for fatal outcome lead to the common recommendation for splenectomy in a patient who has had one severe splenic sequestration crisis, or more than one less severe crisis. Occlusion of venous drainage also occurs in the liver, but the less distensible capsule of the liver and the options for venous drainage through the portal system make this less likely to threaten life.

Figure 46-2 (Figure Not Available) Development of functional asplenia in sickle cell disorders. *(From Pearson HA, Gallagher D et al: Developmental patterns of splenic dysfunction in sickle cell disorders. Pediatrics 76:392, 1985. Reproduced by permission of Pediatrics in Review.)*

Immunologic and Autoimmune Diseases

Poor phagocytic function of the spleen is associated with impaired function of the Fc receptors on splenic macrophages in a wide variety of immunologic, rheumatic, and inflammatory disorders. Among those in which hyposplenism have been clearly defined and associated with a risk of infection are systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis,[59] systemic vasculitis, ulcerative colitis, celiac disease, [60] amyloidosis,[61] chronic graft-versus-host disease, [62] [63] mastocytosis, [64]

Figure 46-3 Pocked erythrocytes in the sickle hemoglobinopathies. *(From Sills and Oski,[995] with permission. Copyright 1979, American Medical Association.)*

and combined immunodeficiency.[65] Both the diseases themselves and the immunosuppressive therapies that are used in their management may contribute to the risk of infection in these conditions. Immunization to polysaccharide antigens and recognition of the risk of bacterial infection are both important to minimizing the risks of splenic hypofunction.[66]

Splenomegaly and the production of autoantibodies (such as to platelets, in idiopathic thrombocytopenic purpura) are features of the acquired immunodeficiency syndrome (AIDS). In the late stages of AIDS, atrophy of lymphoid follicles and depletion of T-cell-dependent areas are common. It is not clear that impairment of phagocytic function is a component of this splenic atrophy in AIDS.

Therapy-Induced Splenic Hypofunction

Radiation therapy affects splenic function, depending on the dose administered. In general, phagocytic cells are little affected by irradiation, but lymphoid cells are extremely sensitive. B-cell function is nearly fully ablated with as little as 500 cGy. T-cell lymphoblastogenesis is eliminated by administration of 3,000 cGy. With doses of 2,000 cGy, splenic hypofunction is usually transient, as the macrophages and splenic stroma are little affected, and circulating B and T lymphocytes can repopulate the splenic follicles. Thus, patients receiving irradiation to the bed of a left Wilms tumor are not hyposplenic. However, permanent splenic hypofunction develops with doses of 4,000 cGy, which are standard doses for Hodgkin disease. [67] The risk of infection is significant after such therapy.

Corticosteroid therapy impairs the affinity of the Fc receptors of splenic macrophages for opsonic IgG, and decreases the adhesiveness of granulocytes and monocytes.[68] [69] This creates a pharmacologic splenectomy acutely with administration of corticosteroids at common therapeutic dosages. The function of the Fc receptors on hepatic, pulmonary, and bone marrow macrophages is far less affected than that of splenic macrophages. The acute rise in platelet count or hemoglobin values seen with corticosteroid therapy in idiopathic thrombocytopenic purpura or autoimmune hemolytic anemia is due to decreased clearance of sensitized cells.

With longer therapy, the production of antibodies by splenic lymphocytes is also affected, and splenic function continues to be impaired.

Intravenous Immune Globulin G appears to decrease the phagocytic function of the spleen by binding to Fc receptors and impeding their recognition of opsonized particles.[70] This is a transient effect, as the Fc receptors are internalized and recycled, and opsonic function returns to normal within 23 weeks. [71] Occupancy and impairment of function of Fc receptors is also seen with administration of anti-D immunoglobulin to Rh-positive patients, which induces a transient hemolytic anemia. Reticuloendothelial blockade, or occupancy of these receptors, refers to the impaired ability of the spleen to recognize and remove other IgG-coated particles, including bacteria, in the presence of these agents. [72]

SPLENOMEGALY AND HYPERSPLENISM

An enlarged spleen is not a disease state in itself but usually indicates some underlying pathology. The processes run the gamut from minor to life-threatening, from congenital disorders to those at the end of life, and few organ systems are not represented in the underlying conditions. It is useful to approach splenomegaly by considering the processes that may cause splenic enlargement, and then focus on the specific diagnoses within those categories.

The spleen may be enlarged as a result of infiltration, hypertrophy of normal elements (macrophages and lymphoid components), extramedullary hematopoiesis, inflammatory/immunologic processes, and systemic or portal congestion. Rarely,

TABLE 46-2 -- Causes of Splenomegaly

Primary Process	Pathogenesis	Examples
Anatomic	Developmental anomalies	Cysts, pseudocysts, hamartomas, peliosis, hemangiomas
Hematologic	Hemolysis	Intrinsic (membrane, enzyme, hemoglobin disorders); extrinsic (immune)
	Extramedullary hematopoiesis	Myeloproliferative diseases/myelodysplasias, myelofibrosis, osteopetrosis
Infectious	Bacteria	Acute and chronic systemic infection, abscesses, SBE
	Mycobacteria	Miliary tuberculosis
	Spirochetes	Syphilis, Lyme disease, leptospirosis
	Viruses	EBV, CMV, HIV, hepatitis A,B,C
	Rickettsia	Rocky Mountain spotted fever, Q fever, typhus
	Fungi	Disseminated candidiasis, histoplasmosis, South American blastomycosis
	Parasites	Malaria, babesiosis, toxoplasmosis, *Toxocara canis/catis*, leishmaniasis, schistosomiasis, trypanosomiasis
Immunologic	Collagen vascular diseases	Felty syndrome, SLE, mixed connective tissue disorder, systemic vasculitis, Sjögrens syndrome, systemic mastocytosis
	Immunodeficiency	Common variable immunodeficiency
	Immune/inflammatory	Graft-versus-host disease, serum sickness, LGL lymphocytosis, Weber Christian histiocytoses
Neoplastic	Primary malignancies	Lymphomas, leukemias
	Metastatic malignancies	Breast, lung, skin, colon
Infiltrative	Storage diseases	Gaucher disease, Niemann-Pick disease, GM-1 gangliosidosis, glycogen storage disease type IV, Tangier disease, Wolman disease, mucopolysaccharidoses, hyperchylomicronemia types I and IV
Congestive	Portal hypertension	Intrahepatic cirrhosis, extrahepatic cirrhosis (Budd-Chiari syndrome)
	Systemic	Congestive heart failure

Abbreviations: SBE, subacute bacterial endocarditis; EBV, Epstein-Barr virus; CMV, cytomegalovirus; HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus; LGL, large granular lymphocyte.

anatomic abnormalities will cause splenomegaly. Splenomegaly is important to investigate because it is frequently the presenting finding of a serious disorder whose earlier recognition and treatment may prevent significant long-term morbidity and mortality. The diseases associated with splenomegaly are detailed in Table 46-2 .

Hypersplenism refers to nonimmune, indiscriminate destruction of the formed elements of the blood by a spleen that is enlarged, affected by portal hypertension, or both. The bone marrow is hyperplastic, and the peripheral blood cell counts are decreased as a consequence of destruction of mature formed elements. Splenectomy corrects the cytopenia. Any of the formed elements of the blooderythrocytes, neutrophils, or plateletscan be affected, alone or in combination. Splenic hypertrophy results in both pooling of formed elements and premature destruction of cells by splenic macrophages. Because a normal function of splenic macrophages is to remove senescent cells, this is an exaggeration of a process that is physiologic for splenic macrophages.

SPLENECTOMY

Indications and Timing

Splenectomy should be performed for clinical indications rather than for specific diagnoses. In many instances, removal of the spleen will improve the condition of patients with hemolytic anemia due to intrinsic disorders of erythrocyte membranes and enzyme disorders, and of those with chronic conditions such as storage diseases and portal hypertension. Specific clinical indices that require intervention should be identified, and parameters that can be used to identify clinical improvement (usually an increase in peripheral blood cell counts, growth, or energy level) determined before the procedure is performed. Thus, for patients with inherited erythrocyte membrane or enzyme disorders such as hereditary spherocytosis or pyruvate kinase deficiency, marked reticulocytosis indicating significant metabolic energy required for erythropoiesis, somatic growth failure, or lack of exercise tolerance would be potential indications for splenectomy. Avoidance of formation of gallstones, formerly often considered an indication for splenectomy when a diagnosis of hereditary spherocytosis was made, is less important today, as minimally invasive surgical procedures have improved the management of cholelithiasis. Patients with storage disorders such as Gaucher disease develop splenomegaly and hypersplenism. Cytopenias requiring intervention should be present before splenectomy is performed. The clinical benefit to be obtained from splenectomy should at least balance, and preferably outweigh, the potential long-term risks of postsplenectomy septicemia, [73] [74] [75] [76] [77] [78] [79] [80] [81] [82] [83] the possibly increased incidence of arteriosclerotic cardiovascular disease, [30] and the shift of storage cells from the spleen to other organs such as bone

marrow, where they may do more harm in the absence of the spleen.[84] [85] [86] [87] Not all patients with hemolytic anemias such as hereditary spherocytosis need splenectomy. If they develop an aplastic crisis, as with parvovirus B-19 infection, while their spleens are intact, they may need transfusion. Many patients with mild chronic hemolysis and well-compensated anemia may be better off with their spleens remaining in situ. Patients with immune thrombocytopenic purpura should undergo surgical splenectomy when the risks of bleeding or of medical therapies (such as long-term corticosteroids) are such that the benefits of splenectomy exceed the risks. These indications for splenectomy are different in adults and in children, and are affected by the presence of underlying disorders such as systemic lupus erythematosus and HIV infection.

The timing of splenectomywhen it is to be performedshould again be chosen to minimize risks and maximize benefits. Immunity to carbohydrate antigens, such as those in the cell walls of encapsulated organisms such as *Streptococcus pneumoniae, Neisseria*, and *Hemophilus influenzae* type b, develops over the first 23 years of life. When splenectomy can be delayed until the patient is at least 2 and preferably >5 years of age, specific immunity and response to administered polysaccharide vaccines will improve host defenses and lessen the risk of postsplenectomy sepsis. [73] [81] When patients have storage diseases such as Gaucher disease, or hemolytic anemia predisposing to iron overload, such as thalassemia, the presence of the spleen as a preferential site for storage of harmful products may protect other organs from damage.[84] [85] [86] [87] Delaying splenectomy until a clear clinical indication is present will balance risks optimally.

Relative Contraindications

Extramedullary hematopoiesis is a relative contraindication; in some conditions, splenomegaly reflects the fact that the bone marrow is not the primary site of hematopoiesis, as intrinsic bone marrow pathology such as myelofibrosis renders the marrow cavity incapable of supporting hematopoiesis. Myeloid metaplasia may reflect the fact that the spleen has become a predominant site of hematopoiesis. Splenectomy under these circumstances may render the patient pancytopenic and produce massive hepatomegaly.[85] The major conditions leading to this circumstance are malignant osteopetrosis in young children and myelofibrosis in adults. It is important to determine before splenectomy that the patient is not dependent on splenic hematopoiesis for survival.

Portal hypertension is not a contraindication to splenectomy, but it affects the surgical approach. It is helpful to determine before surgery whether the patient is likely to need a shunt to reduce portal hypertension and manage esophageal varices.

Surgical Options

When splenectomy is clearly indicated, acute complications are rarely a consideration in the decision to perform surgery. Nevertheless, advances in surgical procedures have minimized the short-term risks of the procedure itself and of postoperative complications such as intestinal obstruction from adhesions. Subtotal splenectomy can be performed when total splenectomy is not desirable, such as for the removal of a cyst, a pseudocyst, or tumors; after trauma; or for Gaucher disease.[78] [86] Wedge resection with mattress sutures and cyanoacrylate adhesions and microfibrillar collagen omental packs have greatly improved partial splenectomy procedures in the past decade. These procedures require a laparotomy, as do any procedures in which extensive peritoneal adhesions are present; the staging for Hodgkin disease;[88] [89] and the removal of most massively enlarged spleens.[90] [91] A sufficiently large incision to permit full visualization and mobilization is essential when the spleen is very large or when inspection is a major part of the surgical procedure. A retroperitoneal approach is useful when the spleen is not massively enlarged but needs to be fully removed, such as when cytopenias are the indication for the procedure. This approach shortens the postoperative recovery time and avoids induction of peritoneal adhesions.

Laparoscopy is now the procedure of choice for splenectomy when possible. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, the risk of damage to the pancreas, the likelihood of development of subphrenic abscess and peritoneal adhesions postoperatively, and the nutritional and metabolic challenges to the patient are considerably reduced.

Appreciation of the risk of postsplenectomy septicemia[92] [93] and refinements in noninvasive, accurate radiologic monitoring techniques have led to more conservative approaches to splenic injury.[78] [94] After traumatic rupture, splenic tissue may regenerate minisplenules in the peritoneal cavity, a process termed splenosis. [94] Although splenosis is partially protective against postsplenectomy infection in animals, [95] its protective value in humans is not known, and probably depends on the adequacy of perfusion of splenic tissue. It is generally valuable to attempt preservation of splenic function when possible after traumatic rupture.

Complications After Splenectomy

Acute complications in the perioperative period include rupture of the spleen, the development of subphrenic abscess, and injury to the pancreas with the operative procedure. In a healthy patient, the acute risk of splenectomy is low. The degree of splenomegaly greatly affects the risk of rupture and pancreatic injury. The technical difficulty of splenectomy is much greater when the spleen is massively enlarged than when the spleen is small. Rupture of the spleen once the arterial supply has been ligated is rarely a problem. The splenic hilum is retroperitoneal, so that when the spleen is very large, mobilization to access the splenic artery and

vein can be difficult.

After recovery from surgery, intestinal obstruction due to formation of peritoneal adhesions is a complication that usually occurs within the first few months, if it is to occur at all.

Two late complications of splenectomy give the greatest concern: overwhelming postsplenectomy septicemia and atherosclerotic heart disease. Postsplenectomy septicemia is rare but may be rapidly lethal. It is due to the inability of hepatic and pulmonary macrophages to effectively clear organisms from the bloodstream in the absence of protective levels of opsonic (IgG) antibody. Organisms that enter the bloodstream and would ordinarily be removed by splenic macrophages are able to evade recognition by macrophages whose Fc C3b receptors appear to be less avid than those of splenic macrophages. Circulation of the blood through the liver and lung is more rapid than through the spleen, and there is little opportunity for macrophages to recognize organisms whose surfaces contain no IgG and only small amounts of C3bi. Generation of cytokines, including tumor necrosis factor-, and bacterial endotoxins leads to cardiovascular collapse and shock. It is rare to revive an asplenic patient once the patient is in shock, even with effective antibiotic therapy. The risk that this will happen varies with the indication for splenectomy (Table 46-3) and the patients medical condition. Factors that impair host defenses significantly increase the risk of infection. These include deficient opsonins (hypogammaglobulinemia, specific antibody production deficiency); reticuloendothelial blockade related to increased phagocytic activity of macrophages in other organs; impaired antigen processing or recognition (AIDS, lymphoma, other malignancies,

TABLE 46-3 -- Incidence of Postsplenectomy Sepsis

Indication for Splenectomy	Cumulative Incidence of Bacterial Sepsis (%)
Trauma	1.5
Hematologic disorders	3.4
Portal hypertension	8.2
Hodgkin disease	10
Sickle cell disease	15
Thalassemia	25

From Gorse,[96] with permission.

some collagen vascular diseases); neutropenia; and high iron load (thalassemia). Patients at the lowest risk are those in whom splenectomy cures the underlying problem, such as isolated ITP, hereditary spherocytosis, and trauma. Whereas patients undergoing splenectomy for trauma have a 50-fold greater risk of septic death than those with spleens intact, the risk in patients with sickle cell disease is increased 350-fold over that of the general population.

Atherosclerosis developing many years after splenectomy may be related to the thrombocytosis that occurs, with enhancement of plaque formation. Statistically, the increased risk of atherosclerosis is not great, [30] but for individuals with other risk factors such as high levels of cholesterol or homocysteine, heterozygous protein C or S deficiency, or factor V Leiden, splenectomy may pose a more significant risk. No data are currently available in this area.

Prevention of Complications

Postsplenectomy Septicemia

The major risk of postsplenectomy sepsis is infection with encapsulated organisms such as *S. pneumoniae, H. influenzae* type b, and *Neisseria meningitidis*, which require opsonization for effective phagocytosis. Purified polysaccharide vaccines are available for all three groups: 23-valent pneumococcal, quadrivalent meningococcal, and Hib. These vaccines are highly effective when administered to persons >2 years old and are rarely associated with adverse effects. However, they are more effective in the presence of the spleen than in its absence. [18] [20] [83] [96] Thus, it is recommended that immunization be done 3 weeks before the anticipated splenectomy to optimize antigen recognition and processing and induce more effective immunity. [97] Adults are presumed to be immune to *H. influenzae* type b, and thus may receive the pneumococcal and meningococcal vaccines alone. Re-immunization for children is recommended 25 years after initial immunization. Repeat administration of pneumococcal vaccine is recommended every 10 years. [98] Because these recommendations change with experience and vaccine usage, it is wise to consult current guidelines for individual patients.

There is less data on the efficacy of prophylactic antibiotics for asplenic patients, except for young children with sickle cell disease, in whom antibiotics should be initiated as soon as the diagnosis is established. Present recommendations are that twice daily oral penicillin or amoxacillin be continued in sickle cell patients until 6 years of age. High-risk patients with surgical or functional asplenia, including those with diagnoses of thalassemia, Hodgkin disease, other malignancies, immunodeficiency disease, or chronic graft-versus-host disease, should receive prophylactic antibiotics unless specific contraindications exist. Whether or not such patients receive prophylactic antibiotics, and regardless of their immunization status, they may develop overwhelming infections with other organisms, including gram-negative organisms and *S. aureus*.

The single most important measure to prevent postsplenectomy septicemia is education of patient, family, and physician. Recognition of the risk, the institution of appropriate preventative measures, and the rapid administration of antibiotics to a patient who is showing signs of infection (fever, chills) can be lifesaving.

Atherosclerosis

The magnitude of the risk of development of atherosclerosis is not clear. Appropriate preventative measures include identifying and minimizing concurrent risk factors, such as obesity, dietary patterns, a sedentary lifestyle, and the presence of other hereditary factors that would predispose to thrombosis. Low-dose aspirin could be considered, but no data exist regarding its efficacy in this situation.

Chapter 47 - Basophils, Mast Cells, and Systemic Mastocytosis

Robert I. Parker
Dean D. Metcalfe

INTRODUCTION

Mast cells and basophils share common, although not identical, functions in the immune response, express on their surface the receptor that binds with high affinity the Fc portion of the IgE antibody (Fc RI), and exhibit metachromatic staining granules in their cytoplasm. [1] [2] [3] [4] Consequently, they have in the past been thought to represent tissue-based (mast cell) and blood-borne (basophil) forms of the same cell. Indeed, we know that basophils share a common committed stem cell with eosinophils.[5] [6] More recent studies have demonstrated that despite their similarity, mast cells and basophils represent distinct terminally differentiated cells derived from bone marrow CD34+ myeloid progenitors.[7] [8] [9] Whereas basophils mature in the marrow and circulate in the blood fully mature, mast cells migrate to the tissues when immature and complete maturation at these sites.[1] Major biologic differences between basophils and mast cells are listed in Table 47-1 . Differences in surface immunophenotypes between mature mast cells and basophils are shown in Table 47-2 . Both basophils and mast cells are major repositories of histamine and other chemo- and vasoactive mediators, and have been implicated in the initiation and propagation of a variety of allergic and inflammatory processes. These include atopic disorders such as allergic rhinitis, asthma, and anaphylaxis. [2] [4] [10] However, there are distinct differences in cytokine/mediator responses and content of mast cells and basophils (Table 47-3). [1] [2] In addition to the direct actions mediating allergic responses exhibited by both cell types, mast cells and basophils have also been shown to contribute to host defenses against parasites in a cooperative manner. [11] [12] [13]

TABLE 47-1 -- Natural History, Major Mediators, and Surface-Membrane Structures of Human Mast Cells and Basophils

Characteristic	Basophils	Mast Cells
Biology		
Origin of precursor cells	Bone marrow	Bone marrow
Site of maturation	Bone marrow	Connective tissue (a few in bone marrow)
Mature cells in circulation	Yes (usually <1% of blood leukocytes)	No
Mature cells recruited into tissues from circulation	Yes (during immunologic inflammatory responses)	No
Proliferative ability of morphologically mature cells	None reported	Yes (under certain circumstances)
Life span	Days (like other granulocytes)	Weeks to months (according to studies in rodents)
Mediators		
Major mediators stored in preformed cytoplasmic granules	Histamine, chondroitin sulfates, neutral protease with bradykinin-generating activity, -glucuronidase, elastase, cathespin G-like enzyme, major basic protein, Chercot-Leyden crystal protein	Histamine, heparine, or chondroitin sulfates: neutral proteases (tryptase with or without chymase); many acid hydrolases; cathespin G, carboxypeptidase
Major lipid mediators produced on appropriate activation	Leukotriene C_4	Prostaglandin D_2 , leukotriene C_4 , platelet-activating factor
Cytokines released on appropriate activation	IL-4	TNF-, IL-4, IL-5, IL-6
Surface structures		
Immunoglobulin receptors	Fc RI, FcRIII (CDw32)	Fc RI, FcRII (CDW32) c-*kit* receptor
Cytokine or growth-factor receptors	Receptors for IL-2 (CD25), -3, -4, -5, and -8 and for SCF (some basophils express low numbers of c-*kit* receptors)	
Cell-adhesion structures	LFA-1 -chain (CD11a), C43bi receptor (CD11b), gp 150, 95 (CD11c), LFA-1 chain (CD18), IL-2R (CD25), ICAM-1 (CD54), and CD44	CD11c, CD18, ICAM-1 (CD54), CD44, VLA-4

BASOPHILS

Basophils are the least common of the human granulocytes, comprising <0.5% of nucleated bone marrow and peripheral blood leukocytes. In contrast to mast cells which generally have oval, unilobed nuclei, basophils have a bilobed nucleus and cytoplasm that contains fewer but larger metachromatic granules than do mast cells.[10] Using tritium-labeled thymidine techniques, basophils are shown to mature in the marrow over 2.5 to 7 days before release into the peripheral circulation, and then to survive for up to 2 weeks thereafter. Basophils arise from a common basophil-eosinophil progenitor cell which can be isolated from marrow, peripheral blood, and cord blood.[5] [6] [14] Differentiation of the eosinophils and basophils derived from these colonies is regulated in a reciprocal fashion. [14] Further maturation of basophils does not occur in the circulation. Upon stimulation, or initiation of an allergic response, basophils may be recruited out of the vascular space to affect allergy or inflammation in tissue sites.[1] [2] [3] [4]

Basophils are key mediators of immediate hypersensitivity

reactions such as asthma, urticaria, allergic rhinitis, and anaphylaxis. In addition, they have also been implicated in the pathophysiology of delayed cutaneous hypersensitivity and in the late-phase responses of anaphylaxis. [4] IgE is the primary stimulator of basophils, although other mediators such as IL-3, C5a, GM-CSF, and morphine have been shown to stimulate histamine release from these cells.[10] Under normal conditions, the ultimate effect of basophil activation is to produce a localized inflammatory and allergic reaction. However, under pathologic conditions in which basophils are increased in number, either systemically or locally, or in which basophil responses are not appropriately modulated, systemic, severe, allergic/inflammatory reactions may result from basophil activation.

Basophil Structure

Granules

The cytoplasmic granules of basophils and mast cells contain sulfated glycosoaminoglycans. In normal basophils, these are predominantly heparin, whereas in leukemic basophils, chondroitan sulfate is more prevalent. There is little systemic anticoagulant effect of these glycosoaminoglycans although localized anticoagulation with bleeding may occur. These sulfated glycosoaminoglycans are responsible for the intense metachromatic staining of the mast cell and basophil granules. Basophil granules are the major source of circulating histamine, which is synthesized and stored in these granules. Release of histamine accounts for many

of the elements of the immediate hypersensitivity reaction (so called allergic or Type 1 hypersensitivity reaction). Histamine reacts with tissue-based receptors increasing

vascular permeability and tissue edema and is also a potent eosinophil chemoattractant, recruiting eosinophils to the area of basophil activation. Trypsin and chymotrypsin released from basophil granules are responsible for some of the tissue damage and functional disruption of the vascular membrane (e.g., capillary leak) that occurs during chronic inflammation. Basophil granules also contain kallekrein, which, when released, acts directly to affect tissue and vascular integrity and complement and coagulation activation.[10]

Plasma Membrane

Basophils and mast cells express a high-affinity receptor for the Fc portion of IgE (Fc RI) in large numbers on their surface. These receptors allow basophils and mast cells to bind and cross-link specific IgE on the cell surface resulting in the generation of a transmembrane signal and ultimately the release of granule contents. In addition, the plasma membrane lipids serve as a substrate for the metabolism of arachidonic acid. Several metabolites of arachidonic acid are released from basophils upon activation. These include leukotriene C4 (LTC4), which can further enhance the inflammatory reaction and result in tissue damage. [3] [15] [16] Basophils express plasma membrane receptors for adhesion molecules that enhance the selective recruitment of basophils to areas of inflammation (Table 47-2).[2] The expression of these receptors on the basophil surface is markedly upregulated by a number of inflammatory stimuli including endotoxin (LPS), IL-1, IL-3, IL-4, TNF-, and INF-. The upregulation is maximal at 2448 hours following stimulation. The pattern of adhesion receptor expression following exposure to IL-3 greatly favors basophil recruitment and adhesion over that of neutrophils [17] thereby selectively promoting the sticking and diapedesis of basophils into areas of inflammation. Basophils are recruited to areas of inflammation by the chemoattractant action of IL-5. IL-4 upregulates endothelial cell expression of VCAM-1 further enhancing basophil adhesion to endothelial cells.

Basophil Function

Interaction between IgE and basophil IgE receptors, with multivalent antigens bridging the receptors, leads to an anaphylactic secretion of basophil granule contents.[18] In addition to IgE, other stimuli, including C5a, C3, neutrophil lysosomal proteins, insect venoms, hormones, and some drugs can also affect basophil degranulation (Table 47-4).[1] [10] [19] [20] [21] [22] [23] Clinically significant symptoms may also result from the release of other mediators from stimulated basophils. These include kallekrein, the slow-reacting substance of anaphylaxis (SRS-A, leukotriene D4 [LTD4]), platelet-activating factor (PAF-acether), and eosinophilotactic factors (ECFAs). Eosinophilotactic factors recruit eosinophils to areas of inflammation, where they can downregulate the allergic reaction by inactivation of SRS-A and oxidation of histamine.[24]

Basophils in Health and Disease

Few patients have been described to have a deficiency of either basophils or mast cells. Consequently, the role these cells play in host defenses is difficult to discern. However, it appears that both cell types play a central role in immediate hypersensitivity reactions and play supporting roles in chronic inflammatory conditions of both allergic and non-allergic etiologies, and in host responses to parasitic infections. In all of these conditions, basophils and mast cells appear to serve as localizers of the allergic reaction. A role for basophils in primary hematologic disorders is not at all clear, although the finding of increased numbers of basophils heralding a terminal blast crisis in CML, and the demonstration that basophilia is associated with a poorer

MAST CELLS AND SYSTEMIC MASTOCYTOSIS

Mastocytosis has been confounding both clinicians and scientists for more than a century. In 1869, Nettleship and Tay [27] described what we now know as urticaria pigmentosa in a 2-year-old girl. In 1877, Paul Ehrlich [28] was the first to describe mast cells in his study of granulated connective tissue cells. He believed that these cells represented overnourished or overfed connective tissue cells and termed them mastzellen. At the same time, Unna [29] demonstrated mast cells in the skin lesions of urticaria pigmentosa, the term suggested by Sangster[30] the following year. Nearly 50 years later, uriticaria pigmentosa was recognized as the characteristic skin lesion of mastocytosis;[31] finally, in 1949 the systemic nature of mastocytosis was recognized by Ellis [32] in his report of the autopsy findings of a 1-year old infant with diffuse organ infiltration by mast cells. This systemic organ infiltration by mast cells often results in protean clinical manifestations that frequently obscure the underlying disease process. Although the most commonly involved organ in systemic mastocytosis is the skin, a significant number of cases eventually show mast cell infiltration in multiple organs. It is in this clinical setting that the term disseminated or systemic mastocytosis has generally been used. The classification schema proposed by Travis et al.[33] and modified by Friedman and Metcalfe[34] to include lymphadenopathic mastocytosis with eosinophilia, points out the difficulty clinicians and researchers have in classifying this disorder (Table 47-5). Some researchers suggest that mastocytosis can be considered primarily a biochemical disorder that results from the uncontrolled release of

mediators contained within the mast cell or induced by mast cell activation (Table 47-6).[35] However, this approach understates the significance of the pathologic effects of the organ infiltration by mast cells and does not adequately address the spectrum of hematologic disorders and mutations in c-kit [36] observed in this disease. A consensus classification schema suggested in 1991 [37] is widely employed as a reasonable approach to the classification and diagnosis of this disease (Table 47-7).

BIOLOGY AND PATHOGENESIS OF MAST CELL DISEASE

Mast cells and basophils are recognized as the effector cells of the immediate allergic reaction by virtue of their high-affinity receptors for IgE. The wide distribution of mast cells throughout the human body, especially in proximity to blood vessels in atopic and nonatopic individuals alike, and the recognition of mast cell and basophil activation by nonimmunologic means, suggest that these cells may also be involved in nonatopic conditions. Recent evidence that these cells synthesize and release cytokines in response to IgE and non-IgE mediated stimuli adds further support to the hypothesis that these cells play a role not only in the pathobiology of several disease processes, but also in maintaining homeostasis. Mast cell- and basophil-mediated events have been postulated to play a role in host defense against parasitic diseases, in wound healing, in tumor angiogenesis, and in immunoregulation. Furthermore, the early appearance of Fc RI during cell differentiation may be important for these cells to respond to IgE-mediated stimuli before degranulation, possibly by mediating cytokine production.

Although basophils and mast cells are similar in their ability to bind IgE to their surface and to be stimulated after antigen-mediated cross-linking of surface bound IgE, these cells do not represent blood and tissue forms of the same cell type. [38] [39] They differ in significant ways with regard to their morphology, biology, and cell-surface structures (Table 47-1). [39] [40] [41] [42] [43] These cells also exhibit significant differences in response to cytokines and the complement system. [39] [42] [43] [44]

It is now accepted that mast cells are derived from pluripotential hematopoietic cells. [45] This was first demonstrated by Kitamura with in vivo experiments using genetically mast cell-deficient mutant mice and their co-geneic normal littermates. One of the mutants, the WBB6 $_{F1}$ -*W/W^{V}* mouse, is ordinarily devoid of mast cells but can develop mast cells if it receives a bone marrow graft from its normal littermates (WBB6 $_{F1}$ +/+ mice) or from semisyngeneic C57BL/6-bg/bg ("beige") mice. These experiments established that mouse mast cells develop from bone marrow precursors. Mast cells originate from a cell more primitive than those precursors committed either to the neutrophil/macrophage or erythroid cell lineages. [46]

In contrast to the WBB6$_{F1}$ -*W/W^{V}* mouse, the genetically mast cell-deficient WBB6$_{F1}$ -*Sl/Sl^{d}* mouse fails to develop mature mast cells after either systemic or local injection of WCB6$_{F1}$ -+/+ cell populations containing mast cell precursors. [47] *Sl/Sl^{d}* mouse bone marrow cells can, however, differentiate into tissue mast cells after intravenous injection into *W/W^{V}* mice. Taken together, these findings indicate that the mast cell deficiency of the

W/W^{V} mouse reflects the abnormality of the mast cell precursors themselves, whereas the mast cell deficiency of the *Sl/Sl^{d}* mouse reflects an abnormality of tissue microenvironmental factors regulating mast cell differentiation. Products of the *W* or *Sl* loci that influence mast cell development have been identified. The *W* locus encodes the c-kit tyrosine kinase receptor, [48] whereas Sl encodes the c-kit ligand often referred to as a stem cell factor (SCF). [49] [50] [51]

Several molecules are known to promote or augment murine mast cell proliferation: interleukin (IL)-3, IL-4, SCF, IL-9, and IL-10. [52] [53] [54] Bone marrow cells cloned in a collagen gel in the presence of IL-3 produced either pure or mixed mast cell colonies. [55] Mouse bone marrow cultured in IL-3 for 3 weeks gives rise to cultures that consist of >85% mast cells. In contrast, colony-stimulating factor-granulocyte/macrophage (CSF-GM) or transforming growth factor- (TGF-) inhibit the differentiation of IL-3-dependent mast cells. [56] [57] IL-4 has little or no ability to sustain the proliferation of mouse mast cells in the absence of IL-3. [53] In the presence of IL-3, IL-4 promotes mast cell proliferation and maturation in vivo. Administration of anti-IL-4 antibodies to mice on days 0 and 7 of infection with *Nippostrongylus brasiliensis* results in a 50% reduction in mucosal mastocytosis. [58] SCF or c-kit ligand can induce the proliferation in mast cells both in vitro [49] [50] [51] and in vivo. [59] Although SCF alone can increase colony-forming unit-spleen (CFU-S) number in vivo, its capacity to do so in vitro is dependent on its interaction with other growth factors. [60] IL-10, when used in combination with IL-3 or IL-4, also enhances mast cell proliferation. These data suggest that IL-3 is both necessary and sufficient for murine mast cell growth from bone marrow, but SCF and other cytokines are necessary for long-term mast cell survival and maturation. In fact, the removal of IL-3-dependent murine mast cell cultures leads to apoptosis. [61] These mast cells are rescued from apoptosis by the addition of SCF. [38]

The proliferation and differentiation of mast cells may also be influenced by adhesive interactions with components of the marrow matrix. Mast cells adhere spontaneously to vitronectin. This interaction increases the proliferative rate of mast cells maximally stimulated by IL-3. [62] Human mast cells have now been cultured from blood or bone marrow in sufficient numbers to permit the study of mast cell growth and differentiation. Human bone marrow CD34+ cells maintained in IL-3 containing liquid suspension cultures produce basophils and small numbers of immature mast cells after 23 weeks of incubation. [63] Similarly, single-lineage and mixed CFUs containing basophils are observed when mononuclear cells are assayed in semisolid media in the presence of recombinant human IL-3. [64]

As in rodents, c-kit and its ligand SCF are involved in the growth and differentiation of human mast cells. Human SCF acts synergistically with human IL-3 to produce a three- to fivefold increase in total mast cell and basophil numbers over human IL-3 alone. [65] The percentage of cell types in the cultures grown in human IL-3 with or without SCF remain the same, with basophils constituting 1835%, and mast cells 3% at 3 weeks of culture. In the presence of human IL-3 followed by SCF alone, the percentage of mast cells increases over 6 weeks. Mast cells cultured in the presence of IL-3 plus SCF, but not IL-3 alone, are berberine sulfate-positive, suggesting the presence of heparin proteoglycans within granules, a sign of mast cell differentiation. Electron microscopic examination of cultures supplemented with IL-3 and SCF, but not IL-3 alone, also revealed maturational changes in which mast cell granules contain tryptase and exhibited scroll, reticular, and homogenous patterns as seen in CD34+ hematopoietic progenitor cells cultured on 3T3 fibroblasts. [65] Thus, to produce mast cells from human bone marrow, the optimal conditions require at least a brief exposure of CD34+ cells to IL-3, followed by SCF. In contrast, mast cells may be produced from human fetal liver [66] or from human peripheral blood following the addition of SCF only.

Although mast cells originate in the bone marrow, they migrate to connective tissue sites and mature. Under normal conditions, mast cells are found throughout connective tissues and are particularly numerous in the epithelial surface of the skin and respiratory tract, in the gastrointestinal and genitourinary tracts, and in the perivascular areas. [37] [38] [39] [40] [41] [67] [68] At these sites, mast cells exhibit one of two predominant phenotypes, as determined by staining characteristics and granule enzyme content. Mast cells within the skin and other connective tissue sites stain intensively with dyes, probably due to their heparin content. [36] Historically, these mast cells have been referred to as connective tissue mast cells. Mast cells at mucosal locations, such as the lamina propria of gastrointestinal tract, stain less intensively and are referred to as mucosal mast cells. IL-3-dependent murine bone marrow-derived mast cells exposed to IL-4 and IL-10 contain more mouse mast cell protease (MMCP)-2 mRNA, which is more characteristic of the mucosal phenotype. [69] In contrast, murine mast cells exposed to SCF stain more intensely and synthesize heparin, [59] which is more characteristic of the connective tissue mast cell. In humans, the mucosal phenotype contains a specific tryptase, whereas the connective tissue phenotype contains both this tryptase and a chymotryptase. [70] Both human mast cell phenotypes appear to contain heparin. [71] The human mucosal mast cell is sometimes referred to as the T mast cell for its tryptase content, and the human connective tissue mast cell as a CT mast cell for its content of both tryptase and chymotryptase.

Mast cells express adhesion molecules that are involved in their attachment to connective tissue matrix or to other cell types. Co-culture of murine mast cells and activated murine T cells results in formation of heterotypic aggregates. Both the size and number of aggregates are reduced by the addition of antibodies directed

against ICAM-1 and leukocyte function-associated antigen-1 (LFA-1). [42] [72] Human lung and uterine mast cells express surface antigens for ICAM-1. [73]

Mast cell adherence to laminin appears to explain, in part, the distribution of mast cells in tissues. Mast cells accumulate on the under surface of the endothelial cell basement membrane, which is known to be rich in laminin. Exposure to laminin and its degradation products may promote the migration of mast cells into a wound site with subsequent attachment. [74] [75] [76] In addition, mouse bone marrow cells, cultured for 1 week in the presence of IL-3 and sorted on the basis of IgE receptors, adhere to laminin after activation. [77] The ability of such mast cell precursors to adhere to laminin before their expression of mature phenotypic characteristics provides a mechanism by which cells can be localized. The mast cell precursors may then develop their terminal phenotype, dependent on the local tissue environment. Mast cell adhesion receptors that have been defined include a RGD-sensitive fibronectin receptor, [78] vitronectin receptor, [62] laminin receptor, [79] and Peyers patch homing lymphocyte and adhesion molecule (LPAM-1). [80]

The demonstration of adhesion surface antigens on both human lung and uterine mast cells by immunofluorescence and flow cytometry has provided further insight into possible interactions between mast cells and extracellular matrix that may permit mast cell migration. Mast cell migration can be stimulated by IL-3 or SCF and further potentiated by the combination of IL-3 and SCF. [81] Similarly, mast cell adhesion is promoted by SCF or aggregation of Fc RI or Fc RIII. [82] [83]

The pathophysiology of systemic mast cell disease is largely a reflection of increased mast cell numbers in abnormal and normal sites. In at least some instances, the focal accumulation of mast cells is associated with increased local production of soluble mast cell growth factor (c-kit ligand) [84] and may be a reversible event. Although the tissue accumulation of mast cells per se does not induce mast cell activation or degranulation, their presence in large numbers may facilitate dysregulated degranulation.

More recently, an activating mutation in c-kit that may increase mast cell numbers has been reported in patients with

mastocytosis. [36] The original observation was suggested by the report that CD34+ cells from the peripheral blood of patients with mastocytosis, when cultured in vitro in the presence of SCF, gave rise to higher numbers of mast cells per CD34+ cell compared with cells from normal subjects. [85] A search for activating mutations in c-kit based on this observation led to the identification of the somatic mutation Asp816 to Val in c-kit in peripheral blood mononuclear cells (PBMC) from patients with mastocytosis. [36] This mutation has now also been identified in the skin and tissues of mastocytosis patients, [86] and is identical to one of two mutations identified in a human mast cell line. [87] Other polymorphisms of c-kit have also been noted, but are to date of uncertain significance. [88] Expression of c-kit in PBMC of patients with mastocytosis may correlate with disease category. [89] Such observations offer the possibility of improved diagnosis and prognosis based on molecular assays.

The granules of human mast cells are known to contain histamine, heparin, neutral proteases, and IL-4. Upon activation, mast cells release these substances to the surrounding environment. It is believed that many of the manifestations of systemic mastocytosis are the consequence of mast cell degranulation. Although early work focused on histamine and other primary mediators released by mast cells, the recognition that mast cells are a potential source of cytokines has suggested new mechanisms by which mast cell activation may result in pathologic responses. It has now been clearly shown that stimulation of mast cells by the Fc $_{epsilor.}$ RI (the high-affinity for the Fc portion of IgE) or by other mechanisms, induces mouse mast cells to synthesize increased levels of mRNA or to secrete products for multifunctional proinflammatory or mitogenic cytokines such as IL-1, -3, -4, -5, and -6. [90] In addition, high local levels of CSF-GM, interferon- (IFN-), tumor necrosis factor (TNF-), and macrophage inflammatory proteins 1 and 1, T-cell activation antigen-3, and JE are produced in mouse mast cells. [38] [90] Human mast cells have been shown to synthesize and release TNF-, IL-4, IL-5, and IL-6. [38] [91] [92] [93] These cytokines play a critical role in the regulation of not only inflammation, but also hemostasis, hematopoiesis, angiogenesis, and tissue remodeling, and potentially have critical roles in tumor development or resistance. [38] The recognition that mast cell stimulation results in the initiation of both an acute and a sustained inflammatory response has brought us closer to understanding the true nature of the tissue pathology noted in mastocytosis.

PATHOPHYSIOLOGY AND PATHOLOGY

The pathophysiology of mast cell disease can be divided into systemic and local effects. The systemic effects of this disorder arise from the release of significant amounts of mediators into the systemic circulation and can result in either flushing or syncope. The local manifestations of this disease result largely from the effects of local collections of mast cells. However, other systemic effects of mast cell disease may result largely from the consequences of severe end-organ dysfunction (e.g., cardiomyopathy, bone marrow dysfunction).

The classic pathologic lesion of cutaneous mast cell disease is the lesion of urticaria pigmentosa. However, in nearly one-half of patients with systemic mastocytosis, cutaneous lesions are lacking, and other organs must be biopsied to make the diagnosis. The most frequently involved organs in systemic mastocytosis are the bone marrow, skin, lymph nodes, spleen, liver, and gastrointestinal tract; the lungs and kidneys are almost never involved. Because of the high frequency of bone marrow involvement and the relatively high frequency of bone marrow biopsy in the diagnosis of this disorder, a description of the mast cell lesion most frequently found in the bone marrow is presented.

Bone Marrow

Focal mast cell lesions of the bone marrow, identified on bone marrow biopsy specimens, have been reported to be present in about 90% of adults with systemic mast cell disease (Table 47-8). [33] [94] [95] [96] [97] [98] The typical bone marrow lesions observed in a bone marrow biopsy are foci of spindle-shaped mast cells in a fibrotic background (Figs. 47-1 (Figure Not Available) and 47-2). Usually there is an abundant mixture of eosinophils and lymphocytes, creating the so-called MEL lesion. These lesions may be located in perivascular, peritrabecular, or intertrabecular sites. They usually are characterized by increased reticulin staining; occasionally, Masson trichome staining reveals collagen deposition. Occasional mast cell lesions are infiltrated by normal-appearing small noncleaved lymphocytes, or are ringed by a cuff of mature small noncleaved lymphocytes (Fig. 47-3). Frequently, in bone marrow extensively involved by mast cell lesions, the bony trabeculae are moderately to markedly thickened.

Although some studies of patients with systemic mast cell disease have reported increased marrow mast cells in the absence of focal mast cell lesions, [94] [95] [96] most patient marrows reviewed contain focal mast cell lesions. On hematoxyolin and eosin staining, the dominant granulated cell in these lesions is often the eosinophil. Eosinophils can be distinguished from mast cells by the presence of round, often bilobed, nuclei and abundant deeply granulated cytoplasm. In contrast, the typical mast cell has a spindle-shaped or oval nucleus and fine eosinophilic granules that are generally apparent only at high power magnification. Mast cells with bilobed nuclei are occasionally seen in these lesions; some investigators consider them an indicator of a poor prognosis. [33] Wright-Giemsa and toluidine blue stains of the biopsy are often necessary for a definitive demonstration of mast cells (Plate 47-1AC). Frequently these stains are negative on EDTA-decalcified paraffin-embedded material as a consequence of the decalcification process. Marrow biopsies, rather than aspirate smears or clot sections, are most likely to demonstrate mast cell disease. When histochemical stains are performed on the plastic-embedded marrow biopsy and in

blood smears, the mast cells stain positively for chloracetate esterase and aminocaproate esterase (Table 47-9).

Increased numbers of mast cells are frequently present on the marrow aspirate smears of patients with systemic mast cell disease; however, other non-mast cell disorders may be associated with the finding of increased marrow mast cells as well. In systemic mast cell disease, a more specific finding is the presence of clusters of confluent mast cells (20) in which individual cells frequently cannot be discerned. [99] [100] In diseases producing a reactive increase in marrow mast cells, the mast cells are usually found singly or in small clusters. In comparison to adults with systemic mast cell disease, marrow involvement in children appears to be much less common.[100] In a study of 19 children with cutaneous or disseminated mast cell disease, only 10 patients demonstrated small focal mast cell lesions in the marrow biopsy and only 5 demonstrated increased mast cells on aspirate

smear. In contrast to the focal lesions found in the marrow of adults with systemic mast cell disease, the lesions seen in children were uniformly small and subtle, and were most frequently found in perivascular sites. Aside from the small size, however, these lesions had the other characteristics of the larger lesions seen in adult marrow.[100]

Although the typical mast cell lesions in adults with systemic mast cell disease are highly specific for that disorder, they are not necessarily diagnostic; they should only be considered diagnostic of systemic mast cell disease when other clinical and laboratory parameters indicative of a mast cell disorder are present. The finding of clusters of confluent mast cells on aspirate smear appears to be highly specific for systemic mast cell disease, but only some patients (<30%) manifest this finding. This number may, however, represent a significant underestimation, since the ability to obtain adequate marrow spicules on aspiration in regions of marrow fibrosis is quite variable. The progression of marrow involvement in systemic mast cell disease is unknown. Although many adults appear to have stable, or possibly decreasing, marrow involvement over time,[97] the clinical significance of the extent of marrow involvement by mast cells remains elusive. Studies of children with systemic mast cell disease have not included large enough numbers, or extended over a long enough time period, to justify any statements regarding either the significance of marrow mast cell lesions at initial presentation or the incidence or significance of the progression of mast cell involvement of the marrow.

Lymph Node

Although lymph node, liver, and spleen are rarely biopsied in patients with mast cell disease, pathologic studies have documented significant involvement in these organs in patients with systemic involvement.[96] [100] [101] [102] [103] Travis and Li[101] demonstrated peripheral lymphadenopathy in 26% and central lymphadenopathy in 19% of patients at diagnosis. Lymphadenopathy was more pronounced in patients with associated hematologic malignancies and aggressive nonleukemic disease. Within the lymph nodes, mast cell infiltrates were most common in the paracortex, followed by the follicles, the medullary cords, and the sinuses. Early infiltrates were exemplified by clusters of mast cells. Eosinophils accompanied mast cell infiltrates in lymph node tissues in approximately one-half of lymph nodes studied. Blood vessel proliferation in the paracortical areas infiltrated by mast cells and extramedullary hematopoiesis were demonstrated in a few patients. Mast cell infiltrates in lymph node tissues can resemble T-cell lymphomas in their pericortical distribution, clear cytoplasm of the mast cells in some cases, and an associated vascular proliferation and eosinophilia. When mast cells replaced the lymphoid follicles, the pattern often bore a resemblance to follicular hyperplasia or lymphoma.

Spleen

Splenic involvement is also common in mastocytosis, seen in 4050% of patients with systemic disease at presentation. [97] [101]

Travis and Li[101] reviewed the pathologic features of 16 spleens; 14 were involved with mast cell disease. All but one spleen showed a paratrabecular distribution of mast cell infiltrates; 10 (64%) perifollicular, 2 (14%) follicular, and 1 (7%) diffuse. Various degrees of trabecular and capsular fibrosis and eosinophilic infiltration were present in biopsies; 71% of biopsies revealed extramedullary hematopoiesis. Cross-sections of the parenchyma showed multiple small nodular areas attributed to fibrosis or infiltrations. Mast cell infiltrations in the spleen produce a lesion that could be confused with T-cell lymphoma, follicular hyperplasia, follicular lymphoma, Kaposis sarcoma, or a granulomatous process. Mast cell infiltrates can also resemble a myeloproliferative disorder or hairy cell leukemia. Although splenomegaly has been demonstrated in up to three-quarters of patients with systemic mast cell disease, only one-half of patients have been shown to have splenic infiltration by mast cells.[104] Markedly increased splenic weights (>700g) generally occurred in patients who fit into unfavorable categories of mastocytosis such as aggressive mastocytosis or mastocytosis associated with a hematologic disorder.

Liver

Liver disease with mast cell infiltration is a common finding in patients with mastocytosis. [102] However, severe liver disease was uncommon, except in patients with aggressive splenomegaly (those with an associated hematologic disorder or lymphadenopathic mastocytosis with eosinophilia). Alkaline phosphatase directly correlated with hepatomegaly, liver mast cell infiltrations, and fibrosis. Elevations in alkaline phosphatase are observed more frequently in patients with categories of aggressive disease. Some patients with aggressive disease develop ascites or portal hypertension and die of complications of mastocytosis. Mast cell infiltrations are more severe in patients with aggressive forms of mastocytosis. Portal fibrosis is observed in two-thirds of patients and correlates with inflammation and mast cell infiltrates.

Organ Fibrosis

The lymph nodes, liver, spleen, and bone marrow are common sites of involvement in mastocytosis. Involvement of these organs is most common in patients in whom the disease is aggressive or associated with a hematologic disorder. Fibrosis associated with mast cell proliferation and eosinophilic infiltrations are common accompaniments of the disease process. Fibrosis accompanies mast cell infiltrates, particularly in lymphoid tissue and in the marrow. Mast cells themselves may produce certain connective tissue components, and mast cells synthesize TGF- and other agents that may promote fibrosis. Histamine has been shown to promote fibroblast proliferation both in vivo and in vitro through an H_2 -receptor-mediated process.[105] [106] Other mast cell constituents have also been implicated in radiation, chemotherapy, inflammation, and injury-induced pulmonary fibrosis.[107] [108] [109] [110] Ultimately, fibrosis of the liver may lead to ascites, requiring aggressive therapy.

CLINICAL MANIFESTATIONS

The consensus revised classification schema [34] for systemic mast cell disease is clinically useful in categorizing the various forms of the disease (Table 47-7). This classification schema divides mast cell disease into four categories of increasing clinical aggressiveness and is adapted from the work of Travis et al. [33] The first category is termed indolent mastocytosis. By a large margin, most mastocytosis patients will fall into this category. Their disease eventually involves the target organs listed and results in a pathophysiologic process that can be managed successfully for decades and does not appear to shorten life span. Eight manifestations of indolent mastocytosis were proposed and are listed in Table 47-7: (1) hemodynamic instability manifested as repeated episodes of flushing and syncope; (2) cutaneous mast cell disease with clear dermatopathology resulting from an increase in dermal mast cells; (3) ulcers of the stomach and duodenum associated with increased gastric acid; (4) malabsorption due to systemic mediators and mast cell infiltration of the intestine; (5) mast cell infiltration of the bone marrow; (6) skeletal disease due to the activity of mast cells on bony surfaces; (7) hepatosplenomegaly; and (8) lymphadenopathy resulting from mast cell infiltration. These manifestations do not define subgroups, since a particular patient may have more than one manifestation. The second category consists of mastocytosis associated with a hematologic disorder. Affected patients have increased mast cells in one or more target organs plus a demonstrable bone marrow abnormality such as a myeloproliferative or myelodysplastic disorder; the skin is variably involved. In this category, the prognosis is determined primarily by the associated hematologic disorder. The third category, aggressive mastocytosis, was previously called lymphadenopathic mastocytosis with eosinophilia. It is typically a rapidly progressive disease involving first the bone marrow and then the gastrointestinal tract, liver, spleen, and lymph nodes. The prognosis is much more guarded. The last category of systemic mastocytosis is mast cell leukemia, a primary leukemic process with increased mast cell burdens in both bone marrow and blood. The prognosis for patients with mast cell leukemia is extremely poor and duration of survival is typically less than 1 year, even with aggressive chemotherapy. [111]

The typical clinical presentation for patients with a systemic mast cell disorder is hard to define, as any patient may have more than one organ involved with mast cells. In addition, many patients exhibit vague or nonspecific constitutional symptoms such as weakness, fatigue, night sweats, and weight loss that cannot be attributed to any particular organ dysfunction. Some patients present with neurologic or neuropsychiatric manifestations, including alterations in cognitive abilities, or depression that may be related to the underlying disease process or, in the case of neuropsychiatric abnormalities, to the inability of the medical community to reach a diagnosis. The etiology of these symptoms is unclear, although mediator-induced hypotensive effects on the brain, a mixed organic brain syndrome, or both, have been hypothesized. [112] [113]

Syncope/Flushing Disorders

Typically, a patient will describe attacks characterized by flushing or sensations of warmth, usually accompanied by palpitations, shortness of breath, chest discomfort, nausea and diarrhea, headache, lightheadedness, and occasionally overt syncope. A unique characteristic of this syndrome is that after the episodes, patients may experience fatigue lasting several hours. Syncopal episodes may be precipitated by heat exposure, emotional stress, or physical exertion, or may occur premenstrually. Some patients may have a variant of the syncopal disorder manifested solely as hemodynamic abnormalities. During episodes of flushing, many patients experience a significant decrease in blood pressure accompanied by tachycardia, whereas other patients may exhibit tachycardia accompanied by an elevation in blood pressure. In this second group of patients, pheochromocytoma must be ruled out. These hemodynamic variants of the mast cell syncope/flushing disorder may be related to mast cell mediator release involving prostaglandin D_2 (PGD_2). [35] [114] PGD_2 is a potent vasodilator metabolized in vivo by 11-ketoreductase to the metabolite 9, 11-PGF_2, a potent pressor substance. [115] It is attractive to speculate that the hemodynamic instability noted in some patients, and the variation noted among patients, is a consequence of differences in prostaglandin metabolism resulting

in marked differences in acute levels of PGD_2 relative to its metabolite 9, 11-PGF_2.

Cutaneous Disease

Cutaneous manifestations of systemic mast cell disease may appear early in life. In a series of 112 patients, [116] solitary mastocytomas, when observed, were present at birth or developed within the first week of life. Multiple lesions of urticaria pigmentosa may also be found at birth, or may appear during early childhood. The onset of urticaria pigmentosa follows a biphasic curve with one peak at 2.5 months of age and the second peak at 26.5 years. [117] Lesions are present in 80% of affected children by 6 months of age. Skin lesions are reported in 50100% of patients with systemic mastocytosis. [33] [94] [95] [118] [119] [120] There appears to be no sex predilection, and a familial association is generally not seen. In fewer than 50 families, mastocytosis of one form or another has affected more than one member, including several instances of affected twins. [121] [122] [123] [124]

Mast cell disease has four cutaneous manifestations: urticaria pigmentosa, mastocytoma, diffuse/erythrodermic disease, and telangiectasia macularis eruptiva perstans. The most common cutaneous mast cell lesion is urticaria pigmentosa, which appears as red-brown macules, papules, and plaques (Fig. 47-4 (Figure Not Available)). Lesions occur in a generalized and random distribution, and may form clusters with a cobblestone appearance. Erythema, edema, and blister formation with subsequent crusting of the lesions has been reported, particularly in young children. Gross hemorrhage into bullous lesions can occur, presumably secondary to high local levels of heparin released from mast cells. After the age of 10, vesicles generally do not occur, and the lesions tend to be smaller and more numerous. Approximately one-half of patients in whom urticaria appears in infancy or childhood experience resolution by adolescence; in

Figure 47-4 (Figure Not Available) Urticaria pigmentosa. *(From Soter NA: The skin in mastocytosis. J Invest Dermatol 96:32S, 1991. Reprinted by permission of Blackwell Science, Inc.)*

the remainder of patients, only lightly pigmented macules remain. [116] [125] Lesions that appear after age 10 tend to persist and remain symptomatic. The lesions of urticaria pigmentosa are usually most dense on the trunk, although they may affect all skin areas, including mucous membranes. The palms, soles, face, and scalp are often free of disease or only lightly affected. Telangiectasias, petechiae, or ecchymosis may occur in the lesions or in adjacent clinically normal skin. The most common clinical manifestations include pruritis, dermatographism, and the presence of a Darier sign (wheal and erythema occurring after a brisk stroke to a lesion). A positive Darier sign may result in blister formation with hemorrhage, particularly in infants. Flushing has been reported to occur in up to one-third of patients with urticaria pigmentosa. In various studies, 1070% of patients with urticaria pigmentosa have been shown to have systemic disease, with bone marrow the most frequently involved site. However, the absence of urticaria pigmentosa and the absence of skin symptoms are poor prognostic features in patients with systemic disease. [33]

Mastocytomas may be present at birth, although most appear within the first 3 months of life and are rarely described in adults. [95] [126] [127] Lesions are generally few in number and may be solitary or show focal clustering. The most common presentation is as a macule, plaque, or nodule, but bullous lesions have been described. Most mastocytomas form on the extremities and rarely involve palms or soles. In most cases, the lesions are thought to involute spontaneously; however, this has not

invariably been reported. Rare patients have had systemic manifestations such as flushing. [128]

Diffuse cutaneous mastocytosis is a rare disorder that generally presents before the age of 3 and involves the entire cutaneous integument. The skin may appear normal; more commonly, it has a yellow-red-brown color with an orange-peel appearance. Yellow to cream-colored papules that resemble xanthomas and pseudoxanthoma elasticum have also been described. [129] A generalized erythroderma form of diffuse cutaneous mastocytosis is manifested by severe edema and a doughy thickening of the skin. [130] Dermatographism with the formation of hemorrhagic blisters is a common finding in this disorder. Extensive bullae with rupture and crusting may be the first presentation in an infant who later develops diffuse cutaneous mastocytosis. Thus, bullous erythrodermic mastocytosis must be included in the differential diagnosis of neonatal blister disorders. [131] Diffuse cutaneous mastocytosis reportedly may resolve spontaneously by age 515 months; in other patients the disease persists; however, when present, these children are at risk for complications such as flushing, hypotension, shock, and occasionally death. Diarrhea and other gastrointestinal manifestations are common in this disorder and occasional patients have significant gastrointestinal bleeding. [132]

Telangiectasia macularis eruptiva perstans is a rare form of mastocytosis traditionally thought to be limited to the skin. In isolated instances, splenomegaly, increased numbers of mast cells in the bone marrow, and abnormal skeletal radiographs suggest that this form of mastocytosis may have systemic features. [133] Many of the original patients reported with this disorder were obese middle-aged women; however, one report involves a 10-year-old girl. [134] The lesions in this disorder are generalized, red, telangiectatic macules on a tan to brown background. Individual lesions are 26 mm in diameter and are without sharply defined borders. Sites become edematous when rubbed. Pruritis, purpura, and blister formation are generally not associated with this disorder. In occasional patients, the lesions may coexist with those of urticaria pigmentosa. [135]

Gastrointestinal Hyperacidity

Gastrointestinal symptoms have commonly been reported in patients with systemic mastocytosis (Table 47-10). Both retrospective

TABLE 47-10 -- Gastrointestinal Manifestations of Systemic Mastocytosis

Abdominal pain
Diarrhea
Nausea
Peptic ulcer disease
Malabsorption

and prospective studies [94] [95] [136] [137] have documented abdominal pain, diarrhea, nausea, vomiting, and peptic ulcer disease in one-fourth to one-half of individuals with systemic mastocytosis. Studies with the mast cell-deficient mouse [138] suggest that mast cells may be essential for normal gastric acid secretion. Cherner et al. [139] have demonstrated a broad range of basal acid secretion values in a prospective study of 16 patients with systemic mastocytosis. Six of these patients were shown to have clinically significant acid hypersecretion. The importance of histamine in inducing the acid hypersecretion in these patients was borne out by the finding of low gastrin levels in many of the patients.

Gastrointestinal Malabsorption

Up to one-third of patients with systemic mastocytosis have been demonstrated to have some laboratory evidence of fat malabsorption. [139] However, the degree of malabsorption is generally not of clinical importance. Although the etiology of this mild malabsorption is unclear, potential explanations include acid hypersecretion and mucosal dysfunction. Shortened intestinal transit time does not appear to contribute to the malabsorption syndrome. [139] Studies have indicated that mast cells may be increased in the small intestine of some patients with systemic mastocytosis, although a clear correlation between mucosal mast cell numbers and gastrointestinal symptoms has not been noted. Mucosal biopsies from some patients do demonstrate a variation in mast cell number, depending upon the site measured. [140]

Skeletal Disease

Occasional patients with marked bony infiltration with mast cells have been noted. The most common radiographic abnormality is diffuse ostopenia, which is frequently an incidental finding. [139] [141] [142] [143] [144] In some patients, osteoporosis may be the sole initial manifestation of systemic mast cell disease. [145] Both lytic and sclerotic lesions have been described. Bone scans may be normal or may show focal or diffuse abnormalities. [146] In patients with aggressive disease, diffuse bone pain as well as pathologic fractures have been reported. [147]

Visceral/Hepatosplenomegaly

Hepatic involvement with mast cell lesions is a common finding in systemic mastocytosis, although a significant degree of hepatic dysfunction is generally not observed. [102] Alkaline phosphatase is frequently elevated, but this elevation is largely attributable to bone disease. Webb et al. [94] demonstrated hepatomegaly in 45% and splenomegaly in 50% of 26 patients they studied. Rarely, patients with systemic mastocytosis have been demonstrated to have portal hypertension, [102] and significant splenomegaly may be a contributing factor to the hematologic abnormalities noted in many patients.

Lymphadenopathy

Lymphadenopathy has been demonstrated in about 60% of patients with systemic mast cell disease. [101] The presence of lymphadenopathy, by itself, does not signal aggressive disease, and no specific symptoms are referable to lymphadenopathy. However, patients who present with lymphadenopathy and significant hepatosplenomegaly should be followed closely for possible evolution into a more aggressive systemic disorder.

Bone Marrow Mast Cell Aggregates and Hematologic Abnormalities

In 90% of patients with systemic mastocytosis, either a focal or diffuse increase of mast cells in the bone marrow will be demonstrated. This likely represents an overestimation of the incidence of bone marrow involvement, since most early studies used bone marrow involvement as a necessary criterion for the diagnosis of systemic mast cell disease. Although marrow involvement may not be necessary for the diagnosis, the bone marrow is the extracutaneous organ most commonly documented to be involved in systemic mast cell disorders.

A number of hematologic abnormalities are reported in patients with systemic mast cell disease. Table 47-11 lists the hematologic

abnormalities noted in several large studies of patients with systemic mast cell disease. Anemia is the most common finding, occurring in one-third to one-half of all patients. Thrombocytopenia and leukopenia have been demonstrated in roughly 1520% of patients. Leukocytosis has been demonstrated in 2030% of patients, and eosinophilia in up to 40% of patients with systemic mast cell disease. Lymphocytosis and thrombocytosis are unusual findings.

Although a study conducted by Travis and colleagues demonstrated that up to 7% of patients with systemic mastocytosis have a basophilia, and up to 4% have circulating mast cells,[33] these findings have not been universally demonstrated in other similarly large studies. Although mast cells in the bone marrow are densely granulated cells, when seen in the peripheral blood they frequently have the appearance of atypical monocytes containing scattered large basophilic granules. They also frequently appear somewhat dysplastic, making identification on Wright stain difficult. Frequently, stains specific for mast cells must be performed to identify the cells in the peripheral blood conclusively and to distinguish them from either basophils or hypergranulated monocytes. Table 47-9 lists several histochemical stains used to differentiate mast cells from basophils.

According to the revised consensus classification, the second category of systemic mastocytosis includes patients who present with systemic disease and a hematologic syndrome resembling a myeloproliferative or myelodysplastic process. Several premalignant or overtly malignant syndromes have been described with systemic mast cell disease (Table 47-12). A relatively small subgroup of adult patients with systemic mast cell disease has been documented to have either a myeloproliferative or myelodysplastic process.[33] [94] [97] [119] [148] [149] The peripheral blood picture in these patients may be consistent with that of either chronic myeloid leukemia (CML) or chronic myelomonocytic leukemia (CMML). The presence of either of these disorders is associated with a poor prognosis. [97] [98] As with primary myeloproliferative and myelodysplastic syndromes, a secondary acute leukemia may develop in patients with systemic mast cell disease. Many patients with systemic mast cell disease who have significant cytopenias have overtly dysplastic myeloid or erythroid maturation on bone marrow examination. In addition, a small number of patients have developed diffuse fibrosis of the bone marrow with marked hypocellularity. Patients with systemic mast cell disease with a CML-like picture are Philadelphia chromosome-negative. Surprisingly, some patients may have decreasing marrow mast cell involvement, in spite of increasing systemic symptomatology.[97]

Lymphadenopathic Mastocytosis with Eosinophilia

A subset of patients with systemic mastocytosis who present with, or subsequently develop, significant lymphadenopathy, hepatosplenomegaly, and peripheral eosinophilia has been described. [33] [34] [96] Lymph node biopsies in these patients frequently show a hyperplastic picture suggestive of a malignant lymphoproliferative disorder. However, tissue pathology does not support a diagnosis of lymphoma. Clinically, these patients have an aggressive form of the disease with marked visceral and bony involvement and dramatically shortened survival. Many of these patients display a marked eosinophilia on peripheral blood. Frequently, the eosinophils are dysplastic and hypogranular, similar to those seen in the idiopathic hypereosinophilic syndrome.

Mast Cell Leukemia

These patients are characterized by having a large number of atypical-appearing mast cells in the peripheral blood, a leukocytosis and granulocytosis, and a compressed clinical course.[111] Survival with aggressive chemotherapy is 29 months, with a mean of <6 months. This syndrome appears to represent the most aggressive form of mast cell disorder and appears to be a de novo malignant proliferation of mast cells.

LABORATORY EVALUATION

A suggested diagnostic evaluation for systemic mast cell disease is presented in Table 47-13 . If mastocytosis is suspected on clinical grounds, the evaluation should consist of examination of the skin, both grossly and microscopically; a bone marrow biopsy and aspirate; serum for tryptase levels; and a 24-hour urine for mediators (particularly histamine and/or its metabolites). Additional studies, as suggested by symptomatology or findings during the routine evaluation, may include a bone scan or skeletal survey, or both; a gastrointestinal evaluation involving radiographic studies of the upper gastrointestinal tract and small intestines, computed tomography scan, and endoscopy; and a neuropsychiatric workup. In all patients, the fundamental requirement for the diagnosis of mastocytosis remains the presence of significant increases in mast cell numbers in one or more target tissues. The classic lesions of mastocytosis, namely, mast cell aggregates, are required for the diagnosis of bone marrow involvement. However, a dramatic increase in the mast cells within the lamina propria of the gastrointestinal tract may establish the diagnosis of systemic mast cell disease without evidence of cutaneous, marrow, or other visceral involvement. Although it is clear that symptoms of mast cell disease can reflect local increases of mast cells, slight increases in mast cell numbers in target tissues, such as the skin, gastrointestinal tract, or bone marrow, are not diagnostic because they may only reflect a normal inflammatory or reactive process. Likewise, while plasma or urinary levels of histamine are frequently increased in systemic mastocytosis,[150] the solitary finding of increased levels of histamine or histamine metabolites may reflect other situations, such as anaphylaxis or response to unusual immunologic stimuli. Similarly, serum tryptase may be elevated after anaphylaxis, and may sometimes be normal despite marrow involvement. Thus, no single laboratory test can establish the diagnosis of mastocytosis. Rather, the demonstration of mast cell mediators in blood or urine prompts the clinician to investigate further for the presence of abnormal collections of mast cells.

TABLE 47-13 -- Consensus Diagnostic Workup

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of systemic mast cell disease must be considered on two levels (Table 47-14). The first is that of clinical grounds, where other disease processes that may produce symptoms similar to those seen in systemic mast cell disorders must be excluded. These disorders include diseases such as hyper-IgE syndrome, parasitic infestations of the gastrointestinal tract or viscera, hereditary or acquired angioneurotic edema, idiopathic anaphylaxis, complement disorders, or idiopathic capillary leak syndrome. When episodic hypertension is a major symptom component, pheochromocytoma must be considered; when significant unexplained ulcer disease is present, a Zollinger-Ellison/gastrinoma syndrome must be ruled out. *Helicobacter pyelori* infection should be considered in patients with ulcer disease.

The second level at which one must consider a differential diagnosis is at the level of histopathology. In this regard, three particular disorders may present with bone marrow lesions similar to those seen in systemic mastocytosis. These disorders are primary myelofibrosis, angioimmunoblastic lymphadenopathy, and eosinophilic fibrohistiocytoma. The distinction of mastocytosis from these three disorders is generally accomplished by close review of the histopathologic material, and correlation with other clinical and laboratory features. When the marrow is diffusely infiltrated with an increased number of mast cells, there is frequently a background of fibrosis to these lesions. In this setting, differentiation from primary myelofibrosis is often difficult. [95] [151] In areas of fibrosis, the mast cells are often elongated and relatively agranular on routine staining. Toluidine blue stain or other stains to bring out the metachromatic granules of the mast cell may be particularly useful in these cases. The differentiation of systemic mastocytosis from angioimmunoblastic lymphadenopathy generally relies on the lack of plasma cells and immunoblasts and the absence of neovascularity in the lesions of mastocytosis. Differentiation of systemic mastocytosis from the bone marrow lesions of fibrohistiocytoma is much more problematic. Large histiocytic cells described in eosinophilic fibrohistiocytic lesions have a striking resemblance to the large mast cells seen in many mastocytic lesions.[96] [152] [153] It may be that eosinophilic fibrohistiocytic lesions of the bone represent an indolent form of systemic mast cell disease. [113]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

THERAPY

No cure has been found for mastocytosis, and little documentation suggests that symptomatic therapy substantially alters the course of disease. A primary concern in therapy for both cutaneous and systemic mast cell disease is the avoidance of triggering factors (which vary from patient to patient) such as temperature extremes, physical exertion, or in some instances, the ingestion of agents such as ethanol, nonsteroidal anti-inflammatory drugs, or opiate analgesics. Physical trauma to lesions or environmental factors may also trigger acute episodes, with reports of anaphylaxis after *Hymenoptera* stings and exposure to iodinated contrast materials in patients with systemic mast cell disease.[154] Epinephrine remains the drug of choice in the treatment of anaphylaxis, either idiopathic or that induced by environmental factors. Patients with mast cell disease and a history of anaphylaxis should be advised to carry epinephrine-filled syringes and taught to self-medicate. These patients may also benefit from the concurrent use of H_1 and H_2 antihistamines prophylactically. Tables 47-15 and 47-16 list some of the more common therapeutic modalities used in both cutaneous and systemic mast cell disease.

of pruritis. Amelioration can be achieved, but total ablation of signs and symptoms rarely occurs. Hydroxyzine and doxepin are two potent H_1 antihistamines found quite useful. Doxepin is particularly useful for patients who have central nervous system manifestations of mast cell disease. Frequently the dose-limiting side effect of antihistamine therapy is sedation. Patients sensitive to the sedative effects of antihistamines may benefit from the use of newer nonsedative antihistamines. For patients who continue to have significant disease symptoms while on H_1 antihistamines, the combination of H_1 and H_2 antagonists has been shown to be occasionally effective in relieving pruritis and wheal formation. [155] H_2 antihistamines, such as ranitidine and famotidine, have been quite useful in the treatment of gastritis and peptic ulcer disease associated with mastocytosis. Doses of these H_2 antihistamines can be titrated on the basis of symptom control, or to a particular level of gastric acid secretion. Proton pump inhibitors (omeprazole) are also useful in the management of gastric acid hypersecretion.

Oral administration of disodium cromoglycolate has been reported to reduce pruritis and wheal formation in urticaria pigmentosa with or without systemic disease. [153] [156] [157] [158] [159] This agent has also been reported to be of benefit in cutaneous mast call disease in children and infants. [155] [156] It has also proved useful for the control of gastrointestinal complaints often seen with systemic disease. [140] Sometimes other symptoms, such as headache and bone pain, have also been reported to improve with the use of cromolyn sodium.

Ketotifen has been widely used in Europe. It has been reported to prevent mast cell degranulation and to be effective in the relief of pruritis and wheal formation in urticaria pigmentosa and other forms of diffuse cutaneous mastocytosis. [160] [161] [162] One patient has been reported in whom findings of osteoporosis improved after therapy with ketotifen.[163] In contrast, one pediatric study found ketotifen no more effective than hydroxyzine. [164] Similarly, the drug azelastine, an antihistamine with mast cell-stabilizing properties, offered little benefit over chlorpheniramine. [165] Diphosphonates have also been reported useful in the treatment of mastocytosis-associated ostopenia.[143]

Although systemic corticosteroids have not been shown to be effective in the treatment of cutaneous mastocytosis, topical administration or intralesional injections of corticosteroids have resulted in symptomatic and cosmetic improvement. Caution must be exercised with repeated or extensive application of corticosteroids, as this may result in cutaneous atrophy or adrenocortical suppression. [166] The oral administration of 8-methoxypsoralen plus ultraviolet A (PUVA) photochemotherapy has resulted in a decrease in pruritis and wheal formation in patients with urticaria pigmentosa with or without systemic disease. [167] [168] [169] [170] Frequently, prolonged control of disease results after a single course of PUVA therapy, but relapses occurring 36 months after cessation of therapy are common. PUVA therapy has been associated with decreased levels of urine and blood mediators. [167] [168] [171] Occasional patients experience a decrease in cutaneous lesions after exposure to natural sunlight; however, there are no controlled studies using ultraviolet B phototherapy. [117]

Significant malabsorption, hepatic fibrosis, and ascites have been noted in patients with severe mastocytosis. [137] [172] [173] Systemic corticosteroids have been useful in decreasing the malabsorption and ascites in some of these patients. In adults, oral prednisone (4060 mg/day) usually results in a decrease in symptoms over a 23 week period.[174] After initial improvement, steroids can frequently be tapered to an alternate-day regimen. However, with time, the ascites frequently recurs; it has been suggested that these patients may benefit from a portacaval shunt. [173]

Aspirin and nonsteroidal anti-inflammatory agents have been useful in some patients whose primary manifestation is recurrent episodes of flushing or syncope, or both. The use of these agents may be problematic in patients with significant ulcer disease. Calcium channel blockers and platelet-activating factor inhibitors have been effective anecdotally. [175] [176]

A small percentage of patients with systemic mast cell disease may have a syndrome mimicking non-Hodgkins lymphoma, an aggressive myeloproliferative disease, or, rarely, an overt nonlymphocytic leukemia. [34] [97] [148] [177] Two patients have been reported with systemic mast cell disease associated with primary mediastinal germ cell tumor. [178] [179] In these patients, traditional chemotherapy directed toward their neoplastic process may be appropriate. Chemotherapy with cyclophosphamide, vincristine, and prednisone has been used in some patients whose clinical picture is that of a non-Hodgkins lymphoma, although the response to chemotherapy is variable.[178] Radiotherapy has been used in some patients to control local disease. [180]

Splenectomy has been performed on a number of patients with severe aggressive mastocytosis, in an attempt to improve their limiting cytopenias. [181] With splenectomy, survival increased by an average of 12 months. Patients who had undergone splenectomy appeared better able to tolerate chemotherapy. Although splenectomy is of no value in the management of indolent mast cell disease, it should be considered in selected patients with more aggressive forms of mastocytosis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PROGNOSIS

The prognosis for patients with mast cell disorders is clearly related to the extent of the disease. Patients who present with cutaneous disease, flushing disorders, or limited extracutaneous organ involvement frequently have an indolent course requiring chronic medical management. Few, if any, of these patients have been documented to progress into a more advanced form of the disease. [97] [146] In contrast to the clinical course of patients with limited disease, a prospective analysis of 46 patients identified elevated lactate dehydrogenase levels, late age of onset, and the presence of a significant hematologic abnormality (such as myeloproliferative, myelodysplastic, or overt leukemic picture) as indicators of a poor prognosis and shortened survival. [97] Of the parameters studied by multivariate analysis, only late age of onset of symptoms and elevated serum lactate dehydrogenase levels were found to be predictive of a poor prognosis. Some groups have also identified the presence of a myeloproliferative or myelodysplastic blood picture as conferring a poorer prognosis.

FUTURE DIRECTIONS

In addition to the therapeutic modalities already mentioned, some innovative therapies for the future are worth discussing separately. Mastocytosis involves both mast cell hyperplasia and systemic mediator release. Mast cells release primary mediators that induce the production and secretion of secondary mediators, but these mediators also effect mast cell proliferation and degranulation. An approach using an antiproliferative mediator to treat mastocytosis is attractive and may warrant investigation. CSF-GM has been shown to inhibit the growth of IL-3-dependent mast cells in murine bone marrow [182] as does IFN-.[183] Clinical responses to IFN-2B have been mixed.[184] [185] Immunotherapy using an anti-IgE antibody may have potential to decrease mast cell stimulation and proliferation. [186] Much clinical work is necessary before any such therapies can be brought into the clinical arena. However, given our inability to significantly affect survival in individuals afflicted with the more aggressive forms of mastocytosis, it may be reasonable to consider these therapies on a selected basis.

Chapter 48 - Cytogenetics and Neoplasia

Michelle M. Le Beau
Richard A. Larson

INTRODUCTION

The malignant cells in many patients who have leukemia, lymphoma, or another hematologic neoplasm have acquired clonal chromosomal abnormalities. A number of specific cytogenetic abnormalities have been recognized that are very closely, and sometimes uniquely, associated with morphologically and clinically distinct subsets of leukemia or lymphoma.[1] [2] [3] The detection of one of these recurring abnormalities can help in establishing the correct diagnosis and can add information of prognostic importance. The appearance of new abnormalities in the karyotype of a patient under observation often signals a change in the pace of the disease, usually to a more aggressive disorder. The detection of a cytogenetic abnormality clearly distinguishes between benign reactive lymphoid or myeloid hyperplasia and a monoclonal malignant proliferation.

This chapter focuses on the genetics of the leukemias and lymphomas from primarily a cytogenetic perspective. Although these disorders do occasionally exhibit familial aggregation, this is for the most part uncommon, poorly defined, and has yielded few biologic insights or clinical recommendations. In contrast, the delineation of recurring cytogenetic abnormalities correlated with specific hematologic malignancies has helped to delineate disorders with distinct prognoses and etiologies and, in combination with molecular biologic studies, has led to important insights into their pathogenesis. This understanding of the relationship between cytogenetic abnormalities and the pathogenesis and natural history of cancer is much farther advanced for the leukemias than for other malignancies. In large part, this is the result of the relative ease of obtaining and processing bone marrow or peripheral blood samples from patients with leukemia. Nonetheless, recent improvements in cell culture and processing techniques have resulted in the identification of a number of recurring abnormalities in solid tumors, and the analysis of these neoplasms is an exciting area of cancer research. have been identified (Table 48-1). Molecular analysis has revealed that alterations in the expression of the genes or in the properties of the encoded proteins resulting from the rearrangement play an integral role in the process of malignant transformation. [3] [4] The transforming genes that are involved in chromosomal translocations fall into several functional classes, including tyrosine protein kinases, serine protein kinases, cell-surface receptors, and growth factors (Table 48-1). However, the largest class of genes involved in translocations encodes transcriptional regulatory factors. [4] Transcription factors are proteins that are involved in the initiation of gene transcription; they recognize and bind to target sequences located in the regulatory elements of genes or to other DNA-binding proteins, often functioning in a tissue-specific fashion. In this way, they play critical roles in differentiation and development as well as in maintaining the function of differentiated cells. These genes have been implicated in the pathogenesis of T-cell and B-cell neoplasms as well as of some myeloid leukemias (Table 48-1). Many of these genes were first identified as a result of the molecular characterization of translocations in tumor cells.

There are several mechanisms by which chromosomal translocations result in altered gene function. The first is deregulation of gene expression. This mechanism is characteristic of the translocations in the lymphoid leukemias and lymphomas that involve the immunoglobulin genes in B-lineage tumors and the T-cell receptor genes in T-lineage tumors. These rearrangements result in inappropriate expression (either overexpression or aberrant expression in a tissue that does not normally

express the gene) of the partner gene involved in the translocation, with no alteration in its protein structure.

The second mechanism is the expression of a novel fusion protein as a result of the juxtaposition of coding sequences from two genes that are normally located on different chromosomes. Such fusion proteins are tumor specific in that the fusion gene does not exist in nonmalignant cells; thus, the detection of such a fusion gene/protein can be important in diagnosis and in the detection of residual disease or early relapse. Examples of chimeric proteins include the BCR/ABL protein or the PML/RARA protein, resulting from t(9;22) in chronic myelogenous leukemia or t(15;17) in acute myeloid leukemia (AML)-M3, respectively. Of note, all of the translocations cloned to date in the myeloid leukemias result in a fusion mRNA and a chimeric protein (Tables 48-1 and 48-2).

Chromosomal translocations result in the activation of genes in a dominant fashion. A number of human tumors, including retinoblastoma, Wilms tumor, and colon carcinoma, are believed to result from recessive mutations that, when present in a homozygous state, lead to tumor formation. [5] These mutations lead to the *absence* of the protein product, suggesting that these genes function as suppressor genes whose normal role is to limit cellular proliferation. The hallmark of tumor suppressor genes is the loss of genetic material in malignant cells. Such a loss may result from chromosomal loss or deletion or may occur through other genetic mechanisms, such as mitotic recombination. The identification of recurring chromosomal losses or deletions in the leukemias and lymphomas suggests that, as for a number of solid tumors, tumor suppressor genes may be involved in the pathogenesis of some hematologic malignant diseases. [3] [5]

METHODS

Cytogenetic analyses of malignant diseases must be based on the study of the tumor cells themselves. In leukemia, the specimen is usually obtained by bone marrow aspiration and is either processed immediately (direct preparation) or cultured for

TABLE 48-2 -- Recurring Chromosome Abnormalities in Malignant Myeloid Diseases

[a]The percentage refers to the frequency within the disease overall. The numbers within the parentheses (also percentages) refer to the frequency within the morphologic or immunologic subtype of the disease.[2]

[b]Genes are listed in order of citation in the karyotype; e.g., for CML, *ABL* is at 9q34 and *BCR* is at 22q11.

[c]Some patients with CML have an insertion of *ABL* adjacent to *BCR* in a normal-appearing chromosome 22.

2448 hours. When a bone marrow aspirate cannot be obtained, a bone marrow biopsy specimen (bone core specimen) can often be processed successfully. Alternatively, for patients who have a white blood cell (WBC) count of >10,000/l with more than 10% immature myeloid or lymphoid cells, a sample of peripheral blood can be cultured without adding phytohemagglutinin (PHA). The karyotype of the dividing cells will be similar to that obtained from the bone marrow. Mitogens such as PHA are not routinely added to peripheral blood cultures in acute leukemia, because stimulation of division of normal lymphocytes may interfere with the analysis of spontaneously dividing malignant cells. An involved lymph node or tumor mass specimen or malignant effusion may be processed similarly for the analysis of lymphomas. The use of amethopterin or fluorodeoxyuridine to synchronize dividing cells, combined with brief exposures to mitotic inhibitors such as colchicine or DNA-binding agents (ethidium bromide), is practiced by some laboratories to obtain elongated chromosomes that have an increased number of bands.

Cytogenetic studies are feasible only for specimens that contain viable dividing cells. For this reason, it is critical that the specimen be transported to the cytogenetics laboratory without delay. In some cases analyses may be performed on specimens that have been transported by overnight delivery services; however, the shipment of specimens frequently results in loss of cell viability, and most laboratories experience a high proportion of inadequate analyses when using such specimens. For optimally handled specimens, 9598% of all cases should be adequate for cytogenetic analysis.

Chromosomal abnormalities are described according to the International System for Human Cytogenetic Nomenclature (Appendixes 48-1 and 48-2).[6] The

observation of at least two cells with the same structural rearrangement (e.g., translocations, deletions, or inversions) or gain of the same chromosome, or of three hypodiploid cells, each showing loss of the same chromosome, is considered evidence of the presence of an abnormal clone. However, one cell with a normal karyotype is considered evidence of the presence of a normal cell line. Patients whose cells show no alteration or nonclonal (single cell) abnormalities are considered to be normal. That is, one abnormal cell is generally not considered evidence of the presence of an abnormal clone because occasional abnormalities (primarily numerical abnormalities) may result from technical artifact. An exception is a single cell characterized by a recurring abnormality. It is likely that such a cell represents the karyotype of the malignant cells in that particular patient.

Many laboratories have incorporated the technique of fluorescence in situ hybridization (FISH) into their diagnostic services. In FISH, labeled probes are hybridized to either metaphase chromosomes or interphase nuclei, and the hybridized probe is detected with fluorochromes. This technique is a rapid and sensitive means of detecting recurring numerical and structural abnormalities.

CHRONIC MYELOPROLIFERATIVE DISORDERS

The chronic myeloproliferative disorders are a group of diseases characterized by the neoplastic proliferation of hematopoietic stem cells and their differentiated progeny within the bone marrow and in extramedullary sites. Although each of these disorders has distinctive clinical and laboratory features, there is a great deal of overlap in clinical and pathologic characteristics and natural history. The clonal nature of each of these diseases has been demonstrated by cytogenetic and isoenzyme techniques. In each disorder, multiple cell lineages are quantitatively and qualitatively abnormal, providing evidence that the neoplastic transformation occurs in a multipotential hematopoietic stem cell.

Chronic Myelogenous Leukemia

Chronic Phase

Chronic myelogenous leukemia (CML) is a particularly important subtype of leukemia because it was in this disease that the first consistent chromosomal abnormality in a malignant disease was noted (Table 48-2). This abnormality, the Philadelphia or Ph chromosome, was first described in 1960 by Nowell and Hungerford as a deletion of part of the long arm of a G-group chromosome, and later, with the use of quinacrine fluorescence banding techniques, as a 22q. [7] The nature of the chromosomal aberration was clarified in 1973, when Rowley reported that the Ph chromosome resulted from a reciprocal translocation involving chromosomes 9 (break at band q34) and 22 (break at band q11) rather than from a terminal deletion, as many investigators had previously assumed (Fig. 48-1).[8]

Historically, 85% of patients diagnosed as having CML were found to have the Ph chromosome (Ph+). [9] Identification of patients as Ph+ or Ph negative (Ph neg) was found to be clinically significant in that Ph+ patients had a better prognosis than patients with Ph neg CML (42 vs. 15 months survival). Patients with a Ph chromosome and additional chromosomal abnormalities (130% of patients examined at initial diagnosis during the chronic phase) have not had a substantially poorer survival rate in some series than patients with only a Ph chromosome. [9] [10] A change in the karyotype, however, is considered to be a grave prognostic sign indicating progression to the acute blast phase; the usual duration of survival after such a change is 25 months. [9]

Evidence has accumulated which suggests that CML should be defined by the presence of the Ph chromosome or its molecular consequence, the *BCR*/*ABL* fusion gene (see later), and that patients without this abnormality should be considered to have a different myeloproliferative disorder. Pugh et al. reviewed 25 patients initially diagnosed as having CML but whose cells lacked the Ph chromosome and showed that most of these patients had some type of myelodysplastic syndrome (MDS), most commonly chronic myelomonocytic leukemia or refractory anemia with excess blasts.[11] The most common abnormality in these patients was trisomy 8. These observations, which have been confirmed by others, suggest that, with very few exceptions, Ph neg CML does not exist. The absence of the Ph chromosome thus raises the suspicion that the patient actually has a myelodysplastic syndrome or a myeloproliferative disorder

Figure 48-1 Schematic diagram of a specific chromosomal abnormality, namely, the reciprocal translocation involving chromosomes 9 and 22, t(9;22)(q34;q11), which gives rise to the Philadelphia (Ph) chromosome in the malignant cells of patients with chronic myelogenous leukemia. Chromosomal breaks occur in bands q34 and q11 of chromosomes 9 and 22, respectively, followed by a reciprocal exchange of chromosomal material. This rearrangement results in the translocation of the *ABL* oncogene, normally located at 9q34, adjacent to the *BCR* gene on chromosome 22, giving rise to a chimeric *BCR*/*ABL* gene, whose protein product plays a role in the transformation of myeloid cells.

other than CML. It is notable, however, that the leukemia cells in occasional individual cases that lack the Ph chromosome appear to contain a DNA rearrangement in which the molecular consequences are identical to those of t(9;22) (described following).

About 92% of Ph-positive patients with CML have the standard 9;22 translocation. The remaining patients have variant translocations, such as three-way translocations involving chromosomes 9, 22, and a third chromosome. [12] [13] Molecular analysis of the DNA sequences that are located at the chromosomal breakpoints of both the standard and variant translocations in CML has revealed that the oncogene *ABL* is consistently translocated adjacent to the *BCR* gene on chromosome 22 (Fig. 48-1).[14] [15] Analysis of leukemia cells from rare patients with CML who lack the Ph chromosome has revealed a rearrangement involving *ABL* and *BCR* that is detectable only at the molecular level. [16] However, this rearrangement is not present in most patients who have been diagnosed as having Ph neg CML, providing further evidence that t(9;22) and subsequent fusion of the *ABL* and *BCR* genes is characteristic of all CML cases.

On chromosome 22, most breaks cluster in a small, 5.8-kilobase (kb) region known as the breakpoint cluster region (bcr). [14] [15] In contrast, the breaks on chromosome 9 occur over >200 kb, usually upstream (5) of exon II, and the *ABL* coding sequences are translocated to chromosome 22 and fused in-frame with the *BCR* gene. A novel 8.5-kb mRNA is found in all CML patients, because the *BCR* exons are spliced to *ABL* exon II, resulting in a chimeric mRNA that is translated into a chimeric protein ($p210^{BCR\text{-}ABL}$).[15] Experiments in the mouse, either with myeloid cell lines transfected with the fusion gene or in transgenic mice, have clearly shown that the fusion gene leads to leukemia.[17] The ABL protein is normally a nuclear protein and may function as a transcription factor that is regulated by the retinoblastoma protein, RB1. The BCR/ABL protein is located on the cytoplasmic surface of the cell membrane and acquires a novel function in transmitting growth-regulatory signals from cell-surface receptors to the nucleus via the RAS signal transduction pathway. [18] [19] The *BCR*/*ABL* fusion gene can be detected with standard Southern blot analysis of DNA or by polymerase chain reaction (PCR) analysis of mRNA by reverse transcription (RT-PCR) [20] for the diagnosis and detection of residual disease. FISH can also be used to detect the Ph chromosome in both metaphase and interphase cells. [21]

When patients with CML are treated with busulfan or hydroxyurea and a hematologic remission is achieved, the bone marrow morphology and leukocyte alkaline phosphatase (LAP) score may return to normal. However, when such a remission bone marrow is analyzed cytogenetically, the Ph clone persists, and the percentage of Ph+ cells in the bone marrow usually remains unchanged (the Ph chromosome is usually found in 100% of cells examined). Attempts have been made to eradicate the Ph+ clone with aggressive cytotoxic therapy, but only rarely can this be achieved, and even then, the benefit is transient. Studies using glucose-6-phosphate dehydrogenase (G-6-PD) isoenzyme techniques together with cytogenetic studies have shown that all three hematopoietic cell lines (myeloid, erythroid, and megakaryocytic) are involved in the malignant process, as well as lymphocytes of B-cell origin. [22] This suggests that the cell of origin of CML is a multipotential stem cell. Intensive chemoradiotherapy followed by allogeneic bone marrow transplantation has been successful in eradicating the Ph+ cell line and restoring normal hematopoiesis of donor origin. Of great importance is the evidence that daily use of interferon- (IFN-) can induce complete cytogenetic remission in approximately 20% of patients with CML in the chronic phase.[23] [24] The reappearance of cytogenetically normal marrow cells requires several months of treatment. In most cases, molecular methods can still detect cells with the *BCR*/*ABL* fusion transcript. However, patients who have a cytogenetically complete response to interferon therapy have a longer survival than nonresponders or those treated only with hydroxyurea.

Acute Phase

As they enter the terminal acute phase (blast crisis of CML), most patients (80%) show karyotypic evolution, with the appearance of new chromosomal abnormalities in very distinct patterns in addition to the Ph chromosome. For this reason, cytogenetic studies may be useful in confirming the clinical impression of the accelerated or acute phase of the disease. A change in the karyotype is considered to be a grave prognostic sign. [9] The available data suggest that with the exception of an isochromosome of the long arm of chromosome 17 (i(17)(q10)), which is usually associated with a myeloid type of blast transformation, there is no association of a particular karyotype with the lymphoid or the myeloid type of blast transformation, and that these additional abnormalities are not correlated with the response to therapy during the acute phase. [12] [25] The most common changes, a gain of chromosomes 8 or 19, or a second Ph (by gain of the first), or an i(17q), frequently occur in combination to produce modal chromosome numbers of 4750. [12]

As described later, the t(9;22) can be observed in acute lymphoblastic leukemia (ALL); patients who present with the lymphoblastoid blast phase but who have no prior history suggestive of CML can be difficult to differentiate from those with Ph+ ALL. In CML patients, the Ph chromosome is present in granulocytic, erythroid, and megakaryocytic cells, in some B cells, and probably in a few T cells. Recent studies have shown that Ph+ ALL is a lymphoblast-restricted disease and usually involves a different breakpoint in *BCR*, whereas the lymphoid blast phase of CML is a multilineage disease involving a break in the bcr of the *BCR* gene. [26] [27] The overall survival of patients with multilineage disease is significantly better than that of patients with lymphoblast-restricted disease. [26] [27]

Polycythemia Vera

Polycythemia vera is the second most extensively studied chronic myeloproliferative disorder (for review, see Rowley and Testa [12]). Abnormalities are less common (14%) in untreated patients than in those who have been treated with cytotoxic agents prior to the first cytogenetic examination (39%). An abnormal karyotype, frequently with multiple abnormalities, is detected in 85% of patients studied after they have developed leukemia. In polycythemia vera, the presence of cytogenetic abnormalities at diagnosis does not necessarily predict a short survival or the development of leukemia. [12] [28] An evolutionary change in the karyotype during the disease course, however, may be an ominous sign.

In the polycythemic phase, a gain of chromosomes, which usually involves chromosomes 8 (15%) or 9 (20%), is frequently observed. It is notable that a number of patients with polycythemia vera show gains of both chromosomes 8 and 9; clones containing both +8 and +9 are seldom observed in other hematologic diseases and thus may be unique to polycythemia vera. Structural rearrangements most often involve a deletion of chromosome 20 (q11.2q13.3) (30%) or a duplication of 1q (20%), especially bands 1q2532. A deletion of 20q is not specific for polycythemia vera and has been noted in other malignant myeloid diseases; a duplication of 1q has been observed in other hematologic diseases as well as in solid tumors. [1] [2] [3]

The cytogenetic pattern of the malignant cells in polycythemia vera patients who have developed AML show some similarities to the patterns observed in the polycythemic phase (e.g., +8, +9, del(20q)), but there are certain striking differences as well. For example, loss of chromosome 7 is rarely observed in the polycythemic phase but is seen in 20% of patients in the leukemic phase. Rearrangements of chromosome 5, particularly

a del(5q), are the most frequent changes noted in advanced disease (40% of patients). [1] [29] [30] As discussed later, abnormalities of chromosomes 5 or 7 (or both) are the most common abnormalities noted in therapy-related leukemia, suggesting that the leukemia in some patients with polycythemia vera may have a similar cause. It has been shown that the chronic use of oral alkylating agents such as chlorambucil or the use of phosphorous-32 during the chronic phase of polycythemia vera significantly increases the rate of transformation to leukemia.

Essential Thrombocythemia and Myeloid Metaplasia with Myelofibrosis

One hundred seventy cases of essential thrombocythemia were analyzed during the Third International Workshop on Chromosomes in Leukemia, and only 5% of patients had a definite chromosomal abnormality that was accepted by all of the workshop participants. [31] Moreover, no recurring abnormality could be identified in these patients.

Cytogenetic analysis of bone marrow cells of patients with myeloid metaplasia with myelofibrosis (MMM) has revealed the presence of clonal abnormalities in 35% of patients. In general, these abnormalities are similar to those noted in other malignant myeloid disorders. The most common anomalies are +8, 7 or a del(7q), and del(11q) or del(20q). [1] [32] [33] A recurring deletion of the long arm of chromosome 13 has been reported in patients with MMM as well as with other malignant myeloid disorders. [2] [3] [34] In these rearrangements, the consistently deleted band is 13q14. As for CML and polycythemia vera, a change in the karyotype in MMM may signal evolution to acute leukemia.

PRIMARY MYELODYSPLASTIC SYNDROMES

The myelodysplastic syndromes are a heterogeneous group of hematopoietic stem cell disorders characterized by anemia, neutropenia, or thrombocytopenia in various combinations.[35] [36] Several laboratories have reported that clonal chromosomal abnormalities can be detected in bone marrow cells in 4070% of patients with primary MDS at the time of diagnosis.[37] [38] [39] [40] [41] [42] This contrasts with the 7095% incidence of cytogenetic abnormalities detected in patients with AML de novo. Although +8,5/del(5q), 7/del(7q), and del(20q) are common in both disorders, the specific structural rearrangements that are closely associated with distinct morphologic subsets of AML de novo (Table 48-2) are almost never seen in MDS (Table 48-3). With several exceptions (such as the 5q syndrome), chromosomal abnormalities in MDS have not correlated with specific clinical or morphologic subsets when the criteria of the French-American-British (FAB) group were applied.

Patients with MDS may have single or multiple chromosomal changes (Table 48-3). A single chromosome change involves

[a]Chromosomal breakpoints of the interstitial deletions of 5q are variable, but band q31 is invariably deleted; proximal breakpoints frequently occur in bands 5q1315 and distal breakpoints frequently occur in bands q3335.
[b]q23.1 is always involved in either interstitial or terminal deletions.
[c]q14 is always involved in interstitial deletions of variable size.

a single numerical change or a structural abnormality involving only one chromosome or a balanced translocation involving only two chromosomes. Occasionally, several unrelated abnormal clones may be detected (5% of cases); the frequency of such unrelated clones is higher than that observed in AML de novo (<1%). Additional chromosomal aberrations may evolve during the course of MDS or an abnormal clone may emerge in a patient with a previously normal karyotype; these changes appear to portend transformation to leukemia.

The ability of cytogenetic analysis to predict the outcome of any individual patient with MDS is made more difficult because MDS is a life-threatening disorder as a result of persistent and profound pancytopenia (marrow failure), regardless of whether transformation to acute leukemia occurs. Nonetheless, several studies have demonstrated the prognostic significance of cytogenetic abnormalities in MDS in relation to survival and progression to AML. Patients with abnormal karyotypes (particularly those with complex abnormalities) were found to have a shorter survival time and a higher incidence of progression to AML than patients with normal karyotypes.[37] [38] [39] [40] [41] Patients with a del(5q) or del(20q) alone appear to have a favorable outcome, patients with other single abnormalities have an intermediate outcome, and patients with complex karyotypes (most have abnormalities of chromosome 5 or 7, or both) have a poor outcome.[40] In a recent study, the International MDS Risk Analysis Workshop combined cytogenetic, morphologic, and clinical data for 816 patients from seven large, previously reported risk-based studies. [42] Univariate analysis indicated that the major variables predictive of evolution to AML were cytogenetic abnormalities, percentage of bone marrow blasts, and number of cytopenias; those variables predictive of survival included the above as well as age and sex. Patients with a good outcome had normal karyotypes, Y alone, del(5q) alone, or del(20q) alone; those with an intermediate outcome had other abnormalities; and those with a poor outcome had complex karyotypes (three or more abnormalities, typically with abnormalities of chromosome 5 or 7, or both) or chromosome 7 abnormalities. The median survival of patients within these three groups was 3.8, 2.4, and 0.8 years, respectively, and the median survival for 25% of the patients to undergo evolution to AML was 5.6, 1.6, and 0.9 years. These cytogenetic subgroups were also significant independent variables for predicting outcome in multivariate analysis.

The 5q syndrome is a distinctive hematologic disorder that occurs primarily in older women. [29] [30] [43] In contrast to other MDS, where males predominate, the male:female ratio in the 5q syndrome is 0.5. Eighty percent of patients with the 5q syndrome are >50 years old. Patients present with a refractory macrocytic anemia and normal or elevated platelet counts. The marrow is characterized by the presence of micromegakaryocytes with monolobulated and bilobulated nuclei. Approximately two-thirds of patients have less than 5% blasts in the marrow (refractory anemia [RA] or RA with ringed sideroblasts [RARS]) and the remainder have RA with excess blasts (RAEB). Although 75% of cases have a del(5)(q13q33), other interstitial deletions (del(5)(q15q33) or del(5)(q22q33)) may be present. These patients may experience a relatively benign disease course that extends over several years.

ACUTE MYELOID LEUKEMIA DE NOVO

The acute leukemias are generally classified as either lymphoblastic or myeloid. In either case, they result from neoplastic transformations of uncommitted or partially committed hematopoietic stem cells. Traditionally, classification of the acute leukemias has relied on morphology, reflecting the predominant cell type and relating that cell to its presumed normal counterpart.[44] In large part, the correlation of cytogenetic abnormalities with the morphologic features of the leukemia was made possible

by the development of a classification system for the acute leukemias by the FAB Cooperative Group. [44] [45]

Numerous reports have now described the cytogenetic findings in relatively large series of unselected patients with AML as well as in individual patients. [12] [46] [47] [48] In earlier series, abnormal karyotypes were reported in approximately 50% of all patients with AML de novo whose bone marrow cells were examined with banding techniques. At the Fourth International Workshop on Chromosomes in Leukemia, held in Chicago in September 1982, 54% (354 of 660) of patients had chromosomal abnormalities.[49] The detection of cytogenetic abnormalities increases markedly when techniques for culturing leukemia cells and for obtaining prophase and prometaphase chromosomes are used. Currently, at our institution we are detecting an abnormal clone in 85% of AML patients. Initially, it appeared that AML patients with a normal karyotype had a significantly longer survival time than those with any detectable chromosomal abnormality. More recently, it has become clear that the prognostic importance resides in specific chromosomal changes, several of which are associated with higher response rates and longer survival times than the medians observed in AML patients who have no detectable abnormality. [46] [47] [48] [49] [50] [51] [52] The following discussion emphasizes some specific aberrations that occur frequently and also appear to be of exceptional biologic interest (Table 48-2).

Chromosomal Gain and Loss

Although the karyotypes of patients with AML may be variable, both a recurring gain and loss of chromosomes and an involvement in structural rearrangements are evident. The number of chromosomes gained or lost in 354 patients with a clonal abnormality was examined at the Fourth International Workshop on Chromosomes in Leukemia.[49] With the exception of chromosome 16, which was never observed as a gain, and chromosome 1, which was never lost, each of the autosomes and sex chromosomes contributed to the numerical changes. Some chromosomes were clearly overrepresented as gains or losses, while others were underrepresented. Thus, a gain of chromosome 8, the most frequent abnormality seen in AML, was found in 13% (47 of 354) of patients. Loss of chromosome 7, another frequent numerical change, was observed in 9% (30 of 354) of patients, and loss of chromosome 5 was noted in 6% (20 of 354) of cases. A gain of either of these chromosomes is rarely observed. These abnormalities are seen in most subtypes of AML, although there are some interesting differences in frequency. [46] [49] [53] [54]

For example, in an analysis of 26 patients with acute erythroblastic leukemia (M6) who were seen at the University of Chicago, 77% had clonal abnormalities, and in 85% of these cases there was a loss of all or part of chromosomes 5 and/or 7. [55] In addition, the karyotypes were often complex, with multiple abnormalities and subclones. These patients were older than patients with M6 disease with normal karyotypes or simple chromosomal changes, and they had a shorter survival time. In addition, they showed striking similarities, biologically and clinically, to patients with therapy-related AML (discussed following).

Loss of the Y chromosome, the second most frequent numerical change in the patients examined at the workshop, or loss of the X chromosome often occurred in association with an 8;21 translocation (8090% of these patients). [49] Loss of a Y chromosome as the sole abnormality is also observed, but the significance of this abnormality is uncertain because a missing Y chromosome has been reported in bone marrow cells of hematologically normal males, particularly those >60 years old.[2] [12] In contrast, the t(8;21) in acute myeloblastic leukemia (AML-M2) is usually observed in younger adults. [12] [45] [46] [49] [50]

Specific Structural Rearrangements

t(8;21) in Acute Myeloblastic Leukemia (M2)

In 1973, Rowley first described a balanced translocation between chromosomes 8 and 21 (t(8;21)(q22;q22), Fig. 48-2A). The

Figure 48-2 Schematic diagram of four recurring chromosomal abnormalities characteristic of acute myeloid leukemia. **(A)** t(8;21) (q22;q22), AML-M2. **(B)** t(15;17)(q22;q1112), AMLM3. **(C)** inv(16) (p13q22), AMMoL-M4Eo. **(D)** del(5)(q13q33), observed in MDS and AML. A del(5q) is frequently observed in t-MDS/t-AML.

t(8;21) is common, being observed in 18% of all AML cases with an abnormal karyotype and in 30% of patients with M2 leukemia. This translocation is the most frequent abnormality in children with AML, being reported in 17% (10 of 60) of karyotypically abnormal cases. This abnormality initially appeared to be restricted to patients with a diagnosis of M2 leukemia (acute myeloblastic leukemia with maturation) according to the FAB classification. [44] However, 7% (3 of 44) of patients analyzed at the Fourth International Workshop who had a t(8;21) and had adequate bone marrow material available for morphologic review had a diagnosis of acute myelomonocytic leukemia (M4).[49]

In the t(8;21), the *AML1* gene on chromosome 21 is fused with the *ETO* gene on chromosome 8 to form an AML1/ETO chimeric product (Fig. 48-3).[56] The AML1 protein (also known as core-binding factor-, CBFA2) is a member of a family of transcription factors with homology to the pair-rule *Drosophila* gene, *Runt*. AML1 heterodimerizes with another protein, CBFB, to form a transcription factor. Of note is that the *CBFB* gene is located at 16q22, as the breakpoint in the inv(16)/t(16;16) associated with AML-M4 with abnormal eosinophils. The AML1/CBFB transcription factor binds directly to an enhancer core motif that is present in the transcriptional regulatory regions of a number of genes that are critical to myeloid cell growth, differentiation, and function, and thereby regulates expression of the genes. [57] The target genes include the genes encoding interleukin-3 (IL3), granulocyte-macrophage colony-stimulating factor (GM-CSF), the CSF-1 receptor, myeloperoxidase, and neutrophil elastase.[57] Mutant mice with loss of *AML1* or *CBFB* gene function are deficient in hematopoiesis and die during embryogenesis, indicating that the AML1/CBFB-regulated target genes are essential for hematopoiesis of all lineages. [58]

AML1/ETO retains the ability to interact with the enhancer core motif, but it interferes with normal activation of gene expression by the normal AML1/CBFB transcription factor.[57] [58] Moreover, AML1/ETO has gained a new function within the cell, and is capable of activating expression of the *BCL2* gene, an anti-apoptosis

gene, and possibly other genes.[59] Thus, transformation by AML1/ETO likely results from altered transcriptional regulation of normal AML1 target genes, combined with the activation of new target genes that prevent programmed cell death.

Although the M2 type of AML is heterogeneous, the presence of t(8;21) identifies a morphologically and clinically distinct subset. In this disorder, blasts tend to have indented nuclei, and the cytoplasm is generally basophilic with a prominent paranuclear hof that may contain a few azurophilic granules. [60] Promyelocytes, myelocytes, and metamyelocytes are often quite prominent and may be large. Their cytoplasm has a waxy, orange appearance and lacks a granular texture in Romanowsky-stained specimens. Auer rods are easily identified, and several may be seen in a single cell. Bone marrow eosinophilia is also common. [60] Malignant cells in some of these patients may appear cytogenetically normal or to contain only a Y or del(9q). However, FISH or RT-PCR methods will demonstrate the *AML1*/*ETO* rearrangement.[61]

AML-M2 with t(8;21) appears to have a favorable prognosis in adults. The median age of these patients is 2530 years, significantly younger than that of patients with AML overall.[46] [49] [50] Some patients have <30% myeloblasts in the marrow at diagnosis and are therefore inappropriately classified as having MDS rather than AML. Some patients have granulocytic sarcomas. The complete remission rate is uniformly high, and with intensive postremission consolidation chemotherapy, the expected disease-free survival exceeds 2 years, after which time relapses are uncommon.[50] [62] Remarkably, however, some patients in continuous remission for as long as 8 years have *AML1*/*ETO* mRNA detectable in circulating leukocytes.[63] In contrast, children with a t(8;21) have a poor outcome. [64]

Figure 48-3 Schematic diagram of the normal AML1B, ETO, and TEL proteins, and the AML1/ETO and TEL/AML1 fusion proteins. **(A)** Diagram of the heterodimeric AML1/CBFB transcription factor. The transcription factor binds via the DNA-binding domain of AML1 (runt homology domain, or RHD) directly to a specific core motif present in the regulatory region of a number of genes that are involved in myeloid cell growth, and thereby regulates their expression. **(B)** Schematic diagram of the normal AML1B and ETO proteins and the AML1/ETO fusion protein; schematic model of the role of AML1/ETO in the pathogenesis of myeloid leukemias. For AML1, RHD refers to the runt homology domain and TA refers to the trans-activation domain. The ETO protein contains three domains characteristic of transcription factors: TAF110 refers to a domain with homology to the *Drosophila* TAF110 transcriptional co-activator, HHR refers to a leucine zipper-like hydrophobic heptad repeat, and ZF refers to a zinc finger domain. Nervy refers to a domain homologous to the *Drosophila* gene, nervy. **(C)** Schematic diagram of the normal AML1B and TEL proteins and the TEL/AML1 fusion protein. For TEL, HLH refers to a helix-loop-helix domain and ETS refers to an ETS DNA-binding domain.

t(15;17) in Acute Promyelocytic Leukemia (M3)

A structural rearrangement involving the long arms of chromosomes 15 and 17 in acute promyelocytic leukemia (APL; AML-M3) was first recognized by Rowley et al. in 1977. For many years, the precise breakpoints involved in this translocation were controversial; however, the rearrangement is defined as

t(15;17)(q22;q1112)(Fig. 48-2B). At the Fourth International Workshop only 25% (15 of 61) of patients with APL analyzed had a normal karyotype. Seventy percent (43 of 61) of patients had a t(15;17), and three had other abnormalities.[49] In our laboratory, each of more than 150 patients with APL whom we have examined have had a t(15;17) (M.M. Le Beau, unpublished data).[65] This rearrangement is highly specific for APL and has not been found in patients with any other type of leukemia or with a solid tumor.

The breakpoint on chromosome 17 occurs within the first intron of the -retinoic acid receptor gene (*RARA*) in most patients, whereas the break on chromosome 15 occurs within the *PML* gene.[66] *RARA* is a member of the steroid/thyroid hormone receptor superfamily. Retinoic acid is a ligand that binds to the nuclear receptor homodimer complex; this complex acts as a transcription factor (activates transcription of other genes) and thereby induces cellular differentiation. The translocation results in a fusion *PML*/*RARA* gene that contains most of the *PML* coding sequences and the DNA-binding and ligand-binding domains of the *RARA* gene. The PML protein complexes with other proteins to form a novel nuclear domain of unknown function.[67] [68] On exposure to all-trans retinoic acid (ATRA), the PML/RARA fusion protein is released from the complexes, and may then activate retinoid-responsive gene transcription, resulting in differentiation of APL cells. [67]

APL is widely recognized as a unique clinicopathologic entity characterized by infiltration of the bone marrow by promyelocytes in association with a hemorrhagic diathesis. The characteristic folded, reniform (kidney-shaped), or bilobed nucleus is invariably found in some of the promyelocytes. Coarse azurophilic granules and multiple Auer rods are common.[60] [65] The microgranular variant of APL differs from the more frequent hypergranular type only in that the cytoplasmic granules of the leukemia cells are smaller and sometimes beyond the limit of resolution of the light microscope. [60] [65] Auer rods may also be fewer in number and the peripheral WBC count is higher in the M3 microgranular variant, but the t(15;17) is similarly present.

Patients with APL and t(15;17) are younger than other individuals who have AML. [46] [49] [65] Clinical or laboratory evidence of disseminated intravascular coagulation (DIC) is almost invariably present at diagnosis and may worsen during the initial cytolytic response to chemotherapy. APL cells are exquisitely sensitive to the differentiating effect of ATRA, and evidence of DIC rapidly resolves after this treatment is begun. [69] Cases that lack the t(15;17) do not respond to ATRA. Patients with APL may enter complete remission without experiencing a period of marrow hypoplasia; the malignant promyelocytes are often slow to clear from the marrow even as normal hematopoiesis recovers.[50] The optimal use of ATRA therapy has not yet been determined, but it is clearly a mandatory component of treatment. Having achieved a remission, many patients remain disease-free after intensive consolidation chemotherapy.

inv(16) and t(16;16) in Acute Myelomonocytic Leukemia with Abnormal Eosinophils (M4Eo)

In 1983, Arthur and Bloomfield described five cases (three with AML-M2 and two with AMMoL-M4 leukemia) in which the bone marrow contained an excess of eosinophils (854%); all five patients were reported to have a deleted chromosome 16 (del(16q)). [70] Le Beau et al. reported on a related entity in 18 patients, all of whom had M4 leukemia with eosinophils that showed alterations of morphology, cytochemical reactions, and ultrastructure; these alterations included the presence of large and irregular basophilic granules and positive reactions with periodic acidSchiff and chloroacetate esterase. [71] [72] Many of these patients did not have an increased percentage of marrow eosinophils; one-third had <5% eosinophils. Fifteen patients had a pericentric inversion of chromosome 16, inv(16)(p13q22) (Fig. 48-2C), and in three patients a reciprocal translocation involving both chromosome 16 homologs (t(16;16)(p13;q22)) was noted. [71] [72] [73] [74] Among M4 patients in the University of Chicago series, 23% have had an inv(16) or t(16;16). This correlation between abnormal eosinophils and structural rearrangements of chromosome 16 was confirmed at the Fourth International Workshop. [49] Of 25 patients with M4 and >5% marrow eosinophils, ten had either a del(16) or an inv(16). Our experience suggests that breakpoints at both 16p13 and 16q22 are required for manifestation of the complete M4Eo syndrome, as patients with only del(16)(q22) have had different morphologic and clinical features. [74] Patients with inv(16) or t(16;16) have a good response to intensive chemotherapy. [62] In our updated series, 78% (25 of 32) of treated patients entered a complete remission.[74] The median survival for all 32 treated patients was >66 weeks, and the median survival for those 25 patients who had a complete remission was >104 weeks. This survival markedly exceeded the median of 29 weeks attained by 58 treated AMMoL patients who did not have this chromosomal rearrangement.

The inversion breakpoint at 16q22 occurs near the end of the coding region of the *CBFB* gene (also known as *PEBP2B*), [75] which encodes one subunit of a novel heterodimeric AML1/CBFB transcription factor. A smooth muscle myosin heavy chain gene (*MYH11*) is interrupted by the breakpoint on 16p. A fusion protein containing the 5 region of *CBFB* (165 of 182 amino acids), including the domain that heterodimerizes with *AML1*, fused to the 3 portion of *MYH11* is produced. This portion of MYH11 contains a repeated -helical structure involved in myosin filament interactions and thus may be important in dimerization of the fusion protein in M4 leukemia cells. The CBFB/MYH11 fusion protein presumably disrupts the function of the AML1/CBFB transcription factor.

Rearrangements of the Long Arm of Chromosome 11 in Acute Monoblastic Leukemia (M5)

In 1980, Berger and co-workers first reported a higher than expected frequency of abnormalities of the long arm of chromosome 11 (11q) in 10 patients with acute monoblastic leukemia (AMoL). In an expanded series of cases, rearrangements of 11q were observed in 35% (12 of 34) patients with M5, and the investigators emphasized an especially strong association between abnormalities of 11q and the poorly differentiated form of AMoL (M5a). [76] Rowley in 1983 noted that the association between 11q abnormalities and M5a was particularly strong in children. [77] At the Fourth International Workshop on Chromosomes in Leukemia, the associations between 11q abnormalities, M5, and young age were confirmed. [49] Abnormalities of 11q23 are seen in 35% of M5 patients and in slightly less than one-half of patients with M5a.[76] [78] [79] [80]

Recurring translocations involving chromosome 11, band q23, are of great interest in human acute leukemia for at least three reasons. First, there are >30 different recurring rearrangements that involve 11q23 and, thus, along with band 14q32, 11q23 is one of the bands most frequently involved in rearrangements in human tumor

cells.[1] [3] [79] [80] The breakpoints in the 11q23 translocation partners include 1p32, 4q21, and 19p13.3 in ALL, and 1q21, 2q21, 6q27, 9p22, 10p11, 17q25, 19p13.3, and 19p13.1 in AML, especially the monoblastic and myelomonocytic subtypes. Second, these translocations occur in both lymphoid and myeloid leukemias. One common translocation in infants, t(4;11)(q21;q23), usually has a lymphoblastic phenotype, although the leukemia cells may express some myeloid surface markers; in some cases, variable numbers of monocytoid blast cells have been identified. [60] Other translocations, such as t(9;11) and t(11;19)(q23;p13.1), are common in monoblastic leukemias. These data suggest that a gene at 11q23 may be involved in determining the differentiation of primitive hematopoietic stem cells into lymphoblasts or monoblasts, or

that it may be a gene that is active in both cell lineages. Finally, translocations involving 11q23 have a very unusual age distribution; they account for about three-fourths of the chromosomal abnormalities in leukemia cells of children <1 year old. [78] [79] [80]

Translocations of 11q23 involve the *MLL* gene (also called *ALL1* or *HRX*). The *MLL* gene is a very large gene (>100 kb) with multiple large-sized transcripts in the 1215 kb range.[81] [82] All breakpoints fall within an 8.3-kb breakpoint cluster region of the gene encompassing exons 511; thus, *MLL* translocations can be detected by Southern blot analysis of DNA using a small cDNA probe containing these exons. [83] The MLL protein contains two potential DNA-binding motifs (zinc fingers and AT hooks), a transcriptional activation domain in the COOH-terminus, and a repression domain in the N-terminal portion. [84] This protein has homology to the *Drosophila* trithorax gene product, a transcription factor that regulates embryonic development and tissue differentiation in this organism. Thus, by homology to other proteins, it is likely that MLL can bind DNA and regulate the expression of downstream genes, presumed to be important in hematopoietic and lymphoid cell development.

Translocations of *MLL* result in the formation of a chimeric gene on the derivative 11 chromosome, consisting of the 5 region of *MLL* and the 3 region of the partner gene from the other chromosome, with subsequent expression of fusion mRNAs. The AT hook and repression domain are retained in the fusion protein; however, the strong activation domain is lost.[84] The splitting of these domains may alter the function of MLL and contribute to leukemogenesis. Chimeric mice containing an *MLL*/*AF9* fusion gene from the t(9;11) develop AML, whereas leukemia is not observed in mice with a disrupted *MLL* gene.[85] These results suggest that the *MLL*/*AF9* fusion gene plays a role in leukemogenesis and that the partner gene is required for this process. Whether the genes on the partner chromosomes interact with *MLL* to affect the myeloid versus lymphoid phenotype of the corresponding leukemias or the cell lineage and stage at which the translocation occurs dictate the phenotype is unknown.

t(3;3) and inv(3) in AML with Thrombocytosis

Several groups of investigators have identified an association of certain cytogenetic abnormalities of 3q with thrombocytosis in AML patients. [86] [87] The specific cytogenetic abnormalities associated with thrombocytosis in these patients involve bands 3q21 and 3q26 simultaneously, and they include inv(3)(q21q26), t(3;3)(q21;q26), and ins(5;3)(q14;q21q26) (insertion of chromosomal material from 3q into 5q). The t(3;3) and inv(3) account for 34% of AML cases in our series. Seven of the eight patients in our series with these abnormalities had platelet counts of >100,000/l before the initiation of cytoreductive therapy. Four patients had significant thrombocytosis with platelet counts of up to 1,731,000/l. This finding is quite striking when compared with the low incidence of thrombocytosis in a large group of patients with AML who were studied at the Fourth International Workshop on Chromosomes in Leukemia. [49] At that workshop, only eight (including two with inv(3)) of 716 patients had elevated platelet counts (unpublished data).

As might be expected, the most consistent bone marrow finding in these patients is an increase in the number of megakaryocytes, many of which are morphologically abnormal. In some of the patients, nearly all of the identifiable megakaryocytes are micromegakaryocytes. A few circulating megakaryoblasts were identified by the presence of platelet peroxidase activity in one of two patients whom the authors studied with this reaction. [87] These histopathologic findings alone are not indicative of acute megakaryoblastic leukemia.

The *EVI1* gene, located at 3q26, is not normally expressed in hematopoietic cells. This gene is activated by chromosomal rearrangements either 5 of the gene in t(3;3) or 3 of the gene in inv(3) by juxtaposition of the gene to enhancer elements of the ribophorin gene located at 3q21. [88] Activation of *EVI1* can also occur in t(3;21)(q26;q22) as part of the fusion mRNA, *AML1*/*EVI1*, that is transcribed from the der(3) chromosome. Abnormal expression of *EVI1* has also been detected in patients with myeloid leukemia and a normal karyotype,[89] suggesting that inappropriate activation of this gene occurs through various mechanisms. EVI1 is a transcription factor and contains a seven-zinc finger domain at the N-terminal end, a three-finger domain in the central part of the molecule, and an acidic domain distal to the second group of zinc fingers. Inappropriate gene expression induced by this transcription factor may mediate malignant transformation.

Environmental Associations with Acute Myeloid Leukemia

Mitelman et al. reported on a retrospective study of 162 Swedish patients with AML de novo; 52 of these patients gave a history suggesting occupational exposure to chemical solvents, insecticides, or petroleum products, whereas 110 patients had no such exposure. [90] Seventy-five percent of the exposed group had clonal chromosomal abnormalities, compared with 32% of the nonexposed group. There was a distinctly nonrandom pattern of changes in the exposed group, with 79% of the chromosomally abnormal cases (60% of all patients) having at least one of four specific abnormalities: 5/del(5q), 7/del(7q), +8, or +21. Other investigators have found similar associations.[91] [92] More recently, the Cancer and Leukemia Group B (CALGB) has reported on the association between smoking, irradiation, and exposure to solvents and hair dyes, and specific cytogenetic abnormalities and *RAS* oncogene activation in a prospective study of patients with AML or ALL. [93]

THERAPY-RELATED MYELODYSPLASTIC SYNDROME AND ACUTE MYELOID LEUKEMIA

Characteristic chromosomal abnormalities have been found in patients who develop a therapy-related MDS or AML (t-MDS or t-AML) after chemotherapy or radiation therapy (or both) for an earlier disorder such as Hodgkin disease, non-Hodgkin lymphoma (NHL), carcinoma, rheumatoid arthritis, or renal transplantation. [94] [95] Several clinical and biologic subsets of t-MDS or t-AML have been recognized; distinct subsets are correlated with the specific therapy administered for the primary disease (Table 48-4). The most common type typically presents after a latency period of 5 years in patients who received alkylating agents. Therapy-related disease in two-thirds of these patients is first recognized from evidence of myelodysplasia (usually trilineage dysplasia), marrow failure, and pancytopenia. Not uncommonly, the initial disease is still present at the time of secondary bone marrow dysfunction. Half of cases diagnosed as t-MDS (<30% marrow blasts) will evolve to t-AML within a median of 6 months, but the other half of patients will die of infectious or hemorrhagic complications of pancytopenia first. Survival times are usually short (median, 8 months). Abnormalities of chromosomes 5 or 7 (or both) are characteristic of this subtype of t-MDS/t-AML. [94] [95] [96] [97] Chromosomal abnormalities are found in most patients with t-MDS prior to evolution to overt leukemia, and these changes are often multiple and complex. Thus, the detection of a clonal abnormality in a pancytopenic patient is convincing evidence of the existence of a malignant secondary neoplasm even though the percentage of blasts in the marrow is not yet elevated.

A second subtype of t-AML has been identified that is distinctly different from the more common leukemia that follows the use of alkylating agents or irradiation. This type of t-AML

TABLE 48-4 -- Contrasting Features of Therapy-Related Myeloid Leukemia Secondary to Either Alkylating Agents or Topoisomerase II Inhibitors

	Chromosome Abnormality	Preleukemia Phase	French-American-British Classification	Age	Latency	Response to Induction Chemotherapy	Long-term Survival	Chemotherapy Drugs
Alkylating agents	5/del(5q) 7/del(7q)	Myelodysplastic syndrome	Not classifiable by current criteria	Typically older patients	57 yr	Poor	Poor	Melphalan, mechlorethamine, chlorambucil, cyclophosphamide, carmustine, lomustine, semustine, procarbazine, dacarba-zine, mitolactol
Topoisomerase II inhibitor	t(11q23) t(21q22)	None	Usually M4, M5; some M1, M2, and ALL-L1	Younger patients	6 mo5 yr	Good	Poor	Etoposide, teniposide, actinomycin D, doxorubicin, 4 epi-doxorubicin, mitoxantrone
Various agents	t(15;17) inv(16)	None None	M3 M4Eo	Younger patients	23 yr <3 yr	Good Good	Good Good	Bimolane

Adapted from Thirman and Larson,[94] with permission.

was first observed among patients receiving extremely high cumulative doses of etoposide for lung cancer, but it has also been seen in patients receiving other drugs known to inhibit topoisomerase II (e.g., teniposide, doxorubicin). [94] [97] [98] Clinically, the secondary disease has a shorter latency period (12 years), manifests with overt leukemia, usually with monocytic features (patients rarely present with MDS), and responds to intensive remission induction therapy (Table 48-4). Balanced translocations involving the *MLL* gene at 11q23 and the *AML1* gene at 21q22 are common in this subgroup. [94] [97] [98] [95] A third subtype of t-AML is therapy-related APL characterized by t(15;17) and prior treatment for psoriasis with bimolane, a dioxopiperazine derivative that also interacts with topoisomerase II. [94]

Findings in the updated University of Chicago series of 270 patients with t-MDS/t-AML are summarized here (Le Beau et al. [96] and unpublished data). Seventy-two had Hodgkin disease, 61 had NHL, 22 had multiple myeloma or another hematologic malignant disease, 101 had various solid tumors, and 14 had nonmalignant disease, primarily an autoimmune disease or organ transplantation. One hundred eighteen of the patients had received both radiation therapy and chemotherapy prior to the development of the myeloid malignancy and 112 patients had received only chemotherapy. Thirty-eight patients had undergone only radiation therapy and, in the majority of these, major areas containing active marrow had been irradiated. The median time between the original diagnosis and the diagnosis of secondary bone marrow dysfunction was 62 months. The median latency period was shorter for patients who had been treated for solid tumors (56 months) and shorter for those who had received only chemotherapy (54 months).

Ninety-three percent (252 of 270) of our patients with therapy-related leukemia were chromosomally abnormal (Le Beau et al. [96] and unpublished data). More important, one or both of two consistent changes were noted in 70% (191 of 270) of patients. Among these 191 patients, 35 had loss of chromosome 5, 55 had a del(5q) (Fig. 48-2D), 25 had loss of 5q following unbalanced translocations, 96 had loss of chromosome 7, 26 had a del(7q), 15 had loss of 7q as a result of an unbalanced translocation, and 1 patient had a balanced translocation of 7q22. Sixty-two patients had abnormalities of both chromosomes 5 and 7. Overall, 115 patients (43%) had loss of 5q and 138 (51%) had loss of 7q. A del(5q) was the most common structural aberration in our series.

By analogy to retinoblastoma and Wilms tumor, there may be certain as yet unidentified critical genes located on 5q that are related to leukemogenesis. By cytogenetic analysis of 177 patients with malignant myeloid diseases and a del(5q), we identified a small segment of 5q, consisting of band 5q31, that was deleted in each patient.[100] [101] This segment has been termed the commonly deleted segment. Distal 5q contains a number of genes encoding growth factors, hormone receptors, and proteins involved in signal transduction or transcriptional regulation. [100] [101] These genes include several genes that are good candidates for a tumor suppressor gene as well as the genes encoding five hematopoietic growth factors (GM-CSF [CSF-2], IL-3, IL-4, IL-5, and IL-9). By FISH analysis of probes to metaphase cells with overlapping deletions involving 5q31, we have narrowed the commonly deleted segment to a region of approximately 1 Mb, flanked by the D5S479 and D5S500 markers and containing the *EGR1* and *CDC25C* genes.[100] [101] The five hematopoietic growth factor genes and seven other genes are excluded from this region. A similar commonly detected segment has been identified by other investigators. [102] To date, we have detected no mutations of the remaining *EGR1* or *CDC25C* alleles, suggesting that a novel tumor suppressor gene in 5q31 is involved in the pathogenesis of t-AML characterized by a del(5q). [101]

Boultwood et al. examined three patients with the 5q syndrome who had small deletions extending from q31q33, using gene dosage and in situ hybridization

analysis.[103] The commonly deleted segment was an 3 Mb region between *ADRB2* and *NKSF1* and includes the gene encoding the receptor for CSF-1. This region is distal to that identified in other studies, [100] [101] [102] suggesting that there is likely to be more than one region and hence more than one gene involved in the pathogenesis of myeloid disorders associated with abnormalities of chromosome 5. Whether the putative tumor suppressor gene in 5q33 is involved in myeloid leukemias or is restricted to the 5q syndrome is unknown.

To determine the location of genes on 7q that may be involved in myeloid leukemogenesis, Le Beau et al. examined the breakpoints and the extent of the del(7q) in 81 patients with MDS or de novo AML (55 patients) or t-MDS/t-AML (26 patients).[104] This analysis suggested that the deletions were interstitial, similar to the deletions of chromosome 5, and there may be two distinct deleted segments of chromosome 7. The majority of patients (65 of 81) had proximal breakpoints in q1122 and distal breakpoints in q2236; the smallest overlapping deleted segment was within q22. A subset of 16 patients had interstitial deletions involving the distal q arm (q3136), with a commonly deleted segment consisting of q3233. To define the deleted segment at 7q22 using molecular probes, the investigators used FISH with a panel of probes from 7q to examine 15 patients with deletion breakpoints in 7q22. The commonly deleted segment was 23 Mb and was flanked by the markers

D7S1503 and D7S1841.[104] Using similar techniques, Fischer et al. identified a slightly more distal, but overlapping, commonly deleted segment on 7q. [105] There are no known candidate tumor suppressor genes in this interval; thus, 7q22 may contain a novel tumor suppressor gene involved in t-AML.

ACUTE LYMPHOBLASTIC LEUKEMIA

The most useful prognostic indicators in ALLthe most frequent leukemia in childrenare age, WBC count, immunophenotype, and karyotype. Children who are between 2 and 10 years old with a WBC count of <10,000/l and whose leukemia cells express the common ALL antigen (CALLA, CD10) have the best prognosis. It was rigorously demonstrated for the first time at the Third International Workshop on Chromosomes in Leukemia that the karyotype is an important independent prognostic factor in ALL.[31] A number of recurring cytogenetic abnormalities are associated with distinct immunologic phenotypes of ALL (Table 48-5), with distinct outcomes.[31] [106] [107] [108]

This review includes data on the chromosomal patterns of 330 patients evaluated at the Third International Workshop, [31] [109] as well as chromosomal patterns in four other large series of 443 adults[110] and 547 children.[111] [112] [113] The study of 173 adults and 157 children at the Third International Workshop revealed that a high proportion (65%) of the patients had clonal abnormalities. [31] [109] Also, of the 213 aneuploid patients, 51% were pseudodiploid, 37% were hyperdiploid, and only 12% were hypodiploid. Notable differences in the frequency of recurring abnormalities between children and adults were observed for t(9;22) and hyperdiploidy (>50 chromosomes). The t(9;22) was observed in 5% of children but in 30% of adults with ALL, whereas a hyperdiploid karyotype was found in 30% of children but rarely in adults (25%). The presence of the specific translocations, t(4;11) or t(9;22), was associated with treatment failure even when intensive therapy was used, whereas t(12;21) and hyperdiploidy (5060 chromosomes) were associated with a favorable outcome.

Specific Abnormalities in Acute Lymphoblastic Leukemia

t(8;14)

A reciprocal translocation involving the long arms of chromosomes 8 and 14 (t(8;14)(q24;q32)) has been detected in a high proportion of patients with Burkitt tumors of both African and non-African origin. An identical translocation is observed in ALL patients with L3-type leukemia cells, indicating that Burkitt lymphoma and most B-cell ALL of the L3 type are probably different manifestations of the same disease (Table 48-5). Sixteen patients with this rearrangement were studied at the Third International Workshop (7% of all cases with abnormalities). [31] In this group, there was an excess of males over females and of adults over children. Most notable was the finding that, with one exception, all patients tested had B-cell markers and in all but one case the disease was FAB type L3. In the exceptional patient, the leukemia cells had a pre-B-cell phenotype. This group of patients had a high incidence of central nervous system involvement at diagnosis and a poorer prognosis (complete remission rate: children, 83%; adults, 44%; median survival: 5 months) than any other group of patients classified according to chromosomal patterns. A poor outcome was also noted in a recent series of 21 adult patients with a t(8;14), all of whom had B-cell ALL (62% complete remissions; median event-free survival [EFS], 2 months). [110] Most recently, however, the use of short-duration, high-intensity chemotherapy programs has markedly improved the outcome of patients with B-cell ALL.[114]

Variant translocations have been reported in Burkitt lymphoma and B-cell ALL (t(2;8)(p12;q24) and t(8;22)(q24;q11)). The first chromosomal abnormalities to be analyzed at the molecular level were the three translocations characteristic of L3 leukemia and Burkitt lymphoma; the outcome of these studies is described later in the section on lymphomas.

t(4;11)

Translocations involving 11q23 are observed in 57% of ALL patients. [31] [110] [111] Of these, the most common is t(4;11)(q21;q23). The t(11;19)(q23;p13.3) is second in frequency; however, this rearrangement is not limited to ALL in that 50% of these patients have AML, usually AML-M5. Patients with t(4;11) have high leukocyte counts (median WBC count, 183,000/l), L1 or L2 morphology, an immature immunophenotype (CD10, CD19+), B-cell lineage leukemia, and a poor outcome. [31] [110] [111] [112] [113] [114] [115] [116] [117] [118] [119] In one series, adults with t(4;11) had a remission rate of 75% but a median EFS of only 7 months. [110] Children with t(4;11) have a similar poor outcome (88% complete remissions, median survival of 10 months).[31] [111] [112] [113]

A notable finding is that acute leukemia with t(4;11) may express myeloid antigens (50%). In most cases of t(4;11) acute leukemia, blasts have been described as lymphoid in appearance and have been classified by light microscopy as L1 or L2 according to the FAB system. [31] [110] In some cases that otherwise appear to be lymphoid, occasional blasts may appear monocytic, and in some, populations of lymphoid and monocytoid blasts may occur in approximately equal proportion. [115] By ultrastructural examination, Parkin and associates confirmed the presence of a myeloid component in the leukemia of many of their patients. In addition to noting monocytoid blasts in some patients, they observed dysplasia of myeloid cells. Positive staining for myeloperoxidase or with Sudan black B (myeloid cytochemical markers) may be present in some cases, and the nonspecific esterase reaction (granulocyte-monocyte cytochemical marker) may be positive in variable numbers of cells.[60] [115] These leukemia cells are generally terminal deoxynucleotidyl transferase (TdT) positive, and they have expressed pan-B-cell antigens in the majority of cases studied.[60] [115] CD10 positivity has been observed in some instances. T-cell markers have consistently been negative.

Of note is the association of translocations involving 11q23 in infant ALL (6080%); this association is particularly interesting in view of the low incidence of ALL in this age group (acute leukemias in the very young are usually of the myeloid type). [31] [117] As described earlier, the breakpoint on 11q23 involves the *MLL* gene. Several recent studies have examined the frequency of *MLL* rearrangements in infant ALL using Southern blot analysis, [117] [118] or RT-PCR[119] to detect the t(4;11). These studies revealed *MLL* rearrangements in 70% and 81%, respectively, including some cases that were normal or inadequate by conventional cytogenetic analysis. [117] [118] [119] Abnormalities of *MLL* were associated with early treatment failure and a very poor outcome; in one series, the estimated EFS for patients with *MLL* rearrangements was 19% at 3 years, compared with 46% for patients with germline *MLL*.[118] Similar results were observed in a second series (EFS at 24 months: 24% for patients with rearranged *MLL* and 100% for patients with germline *MLL*).[119] Among patients with *MLL* rearrangements, t(4;11) may confer a particularly poor prognosis, and some authors have recommended intensified therapy, including bone marrow transplantation, for this group of patients. [119] Thus, rearrangements affecting *MLL* represent a major class of mutations in acute leukemia and identify patients with a poor outcome.

t(9;22)

Ph+ leukemia occurs in two major forms, CML (described earlier) and ALL. Thirty-nine Ph+ ALL patients (18% of patients with abnormalities) were evaluated at the Third International

Abbreviations: SIg, surface immunoglobulin; DLCL, diffuse large cell lymphoma; MCL, mantle cell lymphoma; LPL, lymphoplasmacytoid lymphoma; SLL, small lymphocytic lymphoma; MALT, mucosa-associated lymphoid tumor; Ki-1, anti-CD30 antibody; ALCL, anaplastic large cell lymphoma; CTCL, cutaneous T-cell lymphoma.

[a] The percentage refers to the frequency within the disease overall. The number within parentheses (also a percentage) refers to the frequency within the morphologic or immunologic subtype of the disease.

[b] Genes are listed in order of citation in karyotype; e.g., for precursor B-cell ALL, *TEL* is at 12p12 and *AML1* is at 21q22.

[c] By cytogenetic analysis, the frequency in children is 5% and in adults is 25%; using molecular probes, this frequency is 30% in adults.

Workshop on Chromosomes in Leukemia; 30 were adults and nine were children. [31] [109] The incidence of Ph+ patients with ALL was 17% for adults and 6% for children. Thus, the Ph chromosome is the most frequent rearrangement in adult ALL. Thirty-six patients had the typical t(9;22) and the remaining three had variant translocations. The incidence of the variant form was 8%, which is similar to that observed in CML patients. About one-half of the patients showed abnormalities in addition to the Ph chromosome, a frequency that is substantially higher than that observed in CML in the chronic phase. With the exception of trisomy 8, which is seen occasionally, these abnormalities differ from those observed in the acute phase of CML. Monosomy 7 is a common secondary abnormality in Ph+ ALL and is associated with a poorer outcome. [120] A chromosomally normal cell line is frequently noted in the bone marrow of Ph+ ALL patients (70%), whereas normal cells are rarely observed in untreated CML patients.

The results of more recent studies using newer immunophenotyping techniques have suggested that Ph+ ALL is of pre-B-cell lineage; however, some cases have had both B-cell and myeloid markers. [121] [122] In a prospective study of ALL patients conducted by CALGB, 23% of adult ALL patients had t(9;22); this frequency was 30% when molecular techniques were used to detect the *BCR/ABL* fusion. [122] Approximately half of patients with B-cell lineage ALL were Ph positive. These prospectively identified patients were no older than Ph negative patients (median age, 39 vs. 37 years), nor was their complete remission rate significantly lower (71% vs. 77%). However, median remission duration (10 vs. 18 months) and survival (11 vs. 22 months) were considerably shorter for Ph+ ALL patients.

Molecular studies of Ph+ ALL have revealed two distinct subgroups of patients. In the first group (about 30% of Ph+ adult cases), the molecular rearrangement is identical to that observed in CML, in that the breaks occur within the *ABL* gene and within the bcr region of the *BCR* gene, giving rise to a chimeric gene and the production of an 8.5-kb message and a 210-kd fusion protein. In the remaining patients, the breakpoint occurs upstream (5) of bcr but still within the *BCR* gene, giving rise to smaller fusion messages (6.57.4 kb) and smaller proteins (185190 kd). [123] [124] The clinical outcome for both groups of patients appears to be similar. At present, we do not know whether the structural difference in the 210-kd and 185-kd proteins corresponds to functional differences in the leukemia cells. Both proteins are involved in constitutive signaling via the RAS pathway of signal transduction. In a mouse model, animals given transplants of cells transfected with $p185^{BCR/ABL}$ develop tumors more rapidly than those given transplants of $p210^{BCR/ABL}$ -containing bone marrow cells. Such a functional difference might account for the biologic and clinical differences of Ph+ ALL, which, although characterized by the same chromosomal abnormality, is a disease entity distinct from CML. Patients in whom the Ph chromosome is restricted to lymphoblasts have shorter survivals than those with multilineage involvement. [26] [27]

t(1;19)

In 1978, pre-B-cell ALL was recognized as a distinct immunologic subtype of ALL that can be distinguished from null cell and B-cell ALL by the presence of cytoplasmic immunoglobulin -chain (C) expression. Subsequently it was recognized that pre-B-cell leukemias have rearrangements of the immunoglobulin heavy chain genes, and occasionally of the light chain genes, and that patients with this form of leukemia have a less favorable response to therapy than do patients who have common ALL (CALLA positive). In 1984, Williams et al. described the association of a recurring chromosomal abnormality, namely, a reciprocal translocation involving chromosomes 1 and 19 (t(1;19)(q23;p13)), with pre-B-cell ALL. The t(1;19) is observed in 30% of patients with pre-B-cell ALL and in 6% of all ALL cases. This association was subsequently confirmed by other investigators, who also noted that children with pre-B-cell ALL and a t(1;19) had low WBC counts and were CD10+. [125] A characteristic surface antigen profile is CD19+, CD10+, CD22+, CD34, and CD20+/. Patients with the t(1;19) experience early treatment failure, suggesting that this translocation may distinguish a subgroup of patients with pre-B-cell ALL who have a poor prognosis. [126] [127] In one large study, the adverse outcome of patients with the t(1;19) remained significant even after adjustment for recognized adverse clinical features, indicating that it is an independent risk factor. [127] The t(1;19) occurs in two forms: a reciprocal translocation, t(1;19)(q23;p13), noted in 25% of cases, and an unbalanced form characterized by two normal chromosome 1 homologs and a rearranged chromosome 19, der(19)t(1;19)(q23;p13) (75%). Patients with the balanced, reciprocal translocations have a poorer outcome than do patients with the unbalanced form.

The t(1;19) involves the *E2A* gene at 19p13, which encodes two transcription factors (E12 and E47), which bind to enhancer elements in the *IGK* gene, as well as the regulatory elements of other genes. [128] [129] The *E2A* gene is juxtaposed with *PBX1*, a homeobox (HOX) gene on chromosome 1. *HOX* genes encode DNA-binding transcription factors that regulate developmental processes. *E2A/PBX1* fusion mRNAs code for chimeric proteins that consist of the transcriptional activating domain of E12/E47 and the DNA-binding and protein dimerization domains of PBX1. [128] [129] *E2A* is expressed in all tissues, but the *PBX1* gene is not expressed in lymphoid cells, although it is expressed in many other fetal and adult tissues.

PBX1 normally forms complexes with select HOX proteins, and these heterocomplexes then regulate transcription of target genes in a positive or negative manner. [128] [129] The E2A/PBX1 fusion protein is a potent transactivator and thus may directly activate gene transcription of PBX1-HOX complex target genes. A second possibility is that E2A/PBX1 may bind DNA cooperatively with a specific HOX protein, and the potent transactivation domain of E2A may activate gene transcription. Alternatively, PBX-HOX complexes formed with other ubiquitously expressed PBX family members, PBX2 and PBX3, might normally inhibit transcription, whereas E2A/PBX1/HOX complexes may induce transcription of genes normally repressed in lymphoid cells. In each of these scenarios, the presence of the E2A/PBX1 fusion protein may result in the transactivation of a cadre of genes that are not normally expressed in lymphoid tissues.

t(12;21) in Precursor B-Cell Acute Lymphoblastic Leukemia

Recently, a new recurring translocation, t(12;21)(p12;q22), has been identified in a high proportion (25%) of childhood B-lineage ALL, specifically, precursor B-cell leukemia. [130] [131] The translocation is not easily detected by cytogenetic analysis because of the similarity in size and banding patterns of 12p and 21q. However, the rearrangement can be reliably detected using RT-PCR or FISH analysis. [131] The t(12;21) defines a distinct subgroup of patients characterized by age between 1 and 10 years, B-lineage immunophenotype (CD10+, CD19+), and a favorable outcome. [132] [133] It is not seen in T-cell ALL and is uncommon in adults (4% of ALL cases). In a recent series, patients with the t(12;21) had a 5-year EFS of 91%, compared with 65% for patients without this rearrangement. [132] One-half of these patients would have fallen into a high-risk group according to standard risk factors; thus, the presence of this rearrangement may identify a subset of patients within the high-risk group who would benefit from less toxic and less intensive therapy.

The t(12;21) fuses the *TEL* gene at 12p12 with the *AML1* gene at 21q22 and results in the production of a fusion protein (Fig. 48-3). [134] TEL is a ubiquitously expressed 453-amino acid protein

that contains two domains found in other ETS family transcription factors: a helix-loop-helix (HLH) protein dimerization domain and an ETS DNA-binding domain. The consequence of the translocation is fusion of the 5 HLH domain of TEL with the 3 DNA-binding and transactivation domain of the AML1 transcription factor. [134] Via the HLH domain, TEL/AML1 can form homodimers as well as heterodimers with the TEL protein. [133] Moreover, the TEL/AML1 complex inhibits transactivation of gene

expression by the normal AML1 protein, and the HLH domain of TEL is required for repression. Recent studies have shown that in the majority of ALL cases with the t(12;21), the *TEL* allele on the other chromosome 12 homolog is deleted.[135] Alteration of both *TEL* alleles in leukemia cells suggests that TEL may be a negative regulator of cell proliferation, i.e., a tumor suppressor gene. The *TEL* gene is also involved in several other recurring translocationst(5;12)(q33;p12) in chronic myelomonocytic leukemia (CMMoL), t(9;12)(q34;p12) in AML, ALL, and CML, and t(12;22)(p12;q11) in myeloproliferative disorderssuggesting that interference with the regulation of TEL-targeted genes plays a significant role in leukemogenesis.

Hyperdiploidy with 5060 Chromosomes

The leukemia cells of some patients with ALL are characterized by a gain of many chromosomes and relatively few structural abnormalities. Two distinct subgroups are recognized: a group with 14 extra chromosomes (4750), and the more common group with >50 chromosomes. Chromosome numbers usually range from 51 to 60, and a few patients may have a clone with up to 65 chromosomes. Certain additional chromosomes are commonly seen, typically the X chromosome and chromosomes 4, 6, 10, 14, 17, 18, and 21.[136] [137] Chromosome 21 is gained most frequently (97100% of cases), and multiple additional copies of this chromosome are also frequent.[31] [136] [137]

Patients who have hyperdiploidy with >50 chromosomes have all of the previously recognized clinical factors that indicate a good prognosis, including age between 1 and 9 years, low WBC count (median, 6,700/l), and favorable immunophenotype (early pre-B or pre-B). [31] In a recent analysis of 186 children with hyperdiploid ALL, Raimondi et al. suggested that ALL defined by 5155 chromosomes may be a distinct clinical entity, different from that characterized by 5665 chromosomes. [138] The 105 patients in the first group (5155 chromosomes) had an EFS at 5 years of 72%, compared with 86% (*P* = 0.04) for those patients with >56 chromosomes (63 patients). Structural rearrangements occur in hyperdiploid ALL cells more frequently than was previously recognized, perhaps in as many as 50% of cases. [138] The most common structural abnormalities are duplication of 1q (15%) and an i(17q) (5%). [138] The t(9;22) and t(1;19) have also been observed. Overall, the presence of structural abnormalities does not appear to influence EFS; however, specific recurring abnormalities, such as t(9;22), have a poor prognosis. [138]

T-Cell Acute Lymphoblastic Leukemia

A distinct pattern of recurring karyotypic abnormalities in T-cell neoplasms has emerged. [1] [2] Rearrangements involving the proximal bands of chromosome 14 (14q11) and two regions of chromosome 7 (7q3435 and 7p15) are particularly frequent in T-cell malignancies (Table 48-5). The majority of the T-cellspecific abnormalities involve 14q11. The first recurring abnormality to be defined was the reciprocal translocation involving chromosomes 8 and 14, t(8;14)(q24;q11). Subsequently other abnormalities involving 14q11 were recognized. Chromosome 7 is involved in multiple recurring abnormalities, several of which involve 7p15 (t(7;7)(p15;q11), t(7;14)(p15;q11)), and others which involve the distal long arm (t(7;14)(q3435;q11), t(7;9) (q3435;q34), t(7;9)(q3435;q32), and t(7;19)(q3435;p13)). [1] In addition to their occurrence in T-cell leukemia, these T-cell-specific abnormalities have also been observed in lymphomas of T-cell origin. The genes that are located at the breakpoints of a number of these abnormalities have been identified and are described in a later section (Table 48-5). Patients with T-ALL are most often young males and often have a mediastinal tumor mass, high WBC count, and leukemia cells in the cerebrospinal fluid. These same clinical characteristics are associated with lymphoblastic lymphoma, another T-cell malignancy.

MALIGNANT LYMPHOPROLIFERATIVE DISORDERS

Cytogenetic analyses of NHL have been reported in several large series. [139] [140] [141] [142] [143] [144] [145] These investigations have demonstrated that a high proportion of cases (>90%) are characterized by clonal chromosomal abnormalities and, more important, that many of the recurring abnormalities correlate with histology and immunophenotype (Table 48-5). For example, t(14;18) is observed in a high proportion of follicular small cleaved cell lymphomas (7090%), most patients with t(3;22)(q27;q11) or t(3;14)(q27;q32) have B-cell diffuse large cell lymphomas (DLCL), and patients with t(8;14)(q24;q32) have either small noncleaved cell or diffuse large cell lymphomas. Band 14q32, the location of the Ig heavy chain gene (*IGH*), is frequently involved in translocations in neoplasms of B-cell lineage (70%) (Table 48-5). In contrast, a large proportion of neoplasms of T-cell origin are characterized by rearrangements that involve 14q11, 7q3435 or 7p15, the locations of the T-cell-receptor genes, *TCRA/D, TCRB*, and *TCRG*, respectively (Table 48-5).

A number of karyotypic parameters have been reported to influence survival in NHL. [142] [146] [147] [148] [149] [150] [151] [152] [153] [154] [155] [156] [157] Adverse factors include the complexity of the karyotype,[141] [144] the number of rearranged chromosomes,[144] and the presence of specific chromosomal abnormalities, such as t(8;14), +7, breaks at 1q2123, and breaks at 6q2125. [143] [144] [146] [147] [148] In contrast, t(14;18) and rearrangements of *BCL6* are associated with a favorable prognosis. [142] [144] [147] Histology remains the most important prognostic factor in predicting response to therapy and survival in lymphoma. Chromosomal abnormalities correlate with histology in NHL, albeit incompletely, and they may be independent prognostic factors. Within histologic subtypes, they may identify patients who are likely to be long-term survivors. Thus, a major focus of future studies will be to determine the prognostic significance of recurring chromosomal abnormalities in NHL, including that of the less frequent abnormalities and secondary changes.

Burkitt Lymphoma

In 1972 Manolov and Manolova identified a consistent abnormality (14q+) in the cells of fresh Burkitt lymphomas and in cultured cell lines. Several years later Zech and associates suggested that the rearrangement was a reciprocal translocation involving chromosomes 8 and 14, t(8;14)(q24;q32). The t(8;14) has also been observed in nonendemic Burkitt tumors in patients from America, Europe, and Japan; thus, this rearrangement is a highly characteristic anomaly in Burkitt tumors. This translocation was identified in Burkitt tumors that lacked any markers for the Epstein-Barr virus (EBV) as well as in EBV-positive tumors. It should be noted that the t(8;14) has also been observed in other lymphomas, particularly small noncleaved cell (non-Burkitt) and large cell immunoblastic lymphomas, AIDS-associated Burkitt lymphoma (100%), and AIDS-related DLCL (30%), as well as in B-cell ALL. [139] [149] [152] [153] [154]

As additional Burkitt tumors were examined, it became apparent that at least two other related translocations occur. All three translocations involved chromosome 8 with a break in the same band, 8q24. One variant translocation involved chromosome 2 with a break in the short arm (t(2;8)(p12;q24)), and

the other involved chromosome 22 with a break in band q11 (t(8;22)(q24;q11)). As discussed earlier, these same translocations have been seen in some patients with B-cell ALL.

The t(8;14) involves a break within the *IGH* locus on chromosome 14 and either 5 or within *MYC* on chromosome 8 in a head-to-head orientation. The translocations correlate roughly with the two forms of Burkitt lymphoma: endemic Burkitt lymphoma usually contains breaks upstream of *MYC*, whereas sporadic or AIDS-related Burkitt lymphoma usually contains breaks within *MYC*.[153] [154] MYC is a ubiquitous nuclear protein whose expression is normally tightly controlled, with an extremely short half-life. MYC plays a role in a number of cellular processes, including proliferation and apoptosis, and its oncogenic properties are due to its constitutive expression. It is an immediate early response gene and is rapidly up-regulated during mitogenic stimulation in lymphocytes. Furthermore, *MYC* antisense oligonucleotides prevent activated lymphocytes from entering S phase, cause growth arrest of hematopoietic cells, and induce differentiation of lymphoid cells. Both in vitro and in vivo studies have demonstrated its transforming abilities: expression of *MYC* results in the transformation of EBV-immortalized B-cell lines, [155] while E-*Myc* transgenic mice frequently develop lymphoblastic lymphoma. [156] The biologic function of MYC resides in two regions. The amino-terminus is important in activating transcription, whereas the carboxy-terminus contains a basic-helix-loop-helix-leucine zipper domain that promotes interaction with a related protein, MAX. [157] Binding to MAX appears to be essential for the transforming activity of MYC. MAX has been shown to have two other partners that are important in regulating its function: MAD and MXI1.[157] Both of these proteins are thought to influence MYC-mediated activation of target genes, either by binding to MAX and sequestering it from forming complexes with MYC or by competing with MYC-MAX heterodimers for binding to common target sites.[157]

t(14;18)

Between 70% and 90% of follicular lymphomas and 20% of diffuse B-cell lymphomas have the t(14;18) in which the *BCL2* gene at 18q21 is juxtaposed to the *IGH* J segment, [141] [158] leading to the deregulated expression of *BCL2*.[153] [154] [159] Other lymphocytic malignancies that overexpress *BCL2* but do not harbor t(14;18) include hairy cell leukemia and chronic lymphocytic leukemia (CLL). The cloning of this gene led to the discovery of a new class of oncogenes that, instead of promoting proliferation, contribute to development of a neoplastic state by preventing programmed cell death. [160]

The gene encodes a 26-kd protein that is localized to the mitochondrial outer membrane, as well as the smooth endoplasmic reticulum and perinuclear membrane, [161] and functions to increase cell survival. For example, BCL2 protects lymphoid cells against a number of apoptotic stimuli, including -irradiation, glucocorticoids, and the cross-linking of cell surface receptors. [161] Targeted gene disruption studies have shown that BCL2 is required for survival beyond the first few weeks of life. *Bcl2/* mice developed polycystic kidney disease, hair hypopigmentation, and immunodeficiency as a result of massive B- and T-lymphocyte death. [161] Transgenic mice containing a *Bcl2-Ig* minigene developed polyclonal follicular hyperplasia, and some, after a long latency, developed high-grade lymphomas, many of which possessed translocations involving *Myc*.[162] Of note, many normal individuals harbor the t(14;18) in tonsils and peripheral blood lymphocytes. [163] These findings suggest that the t(14;18) occurs as an early event in the multistep process of lymphomagenesis. Moreover, *BCL2* overexpression is not transforming per se, but requires the presence of other transforming events, such as *MYC* or *TP53* mutations.

BCL2 interactions with other proteins, specifically BAX [164] and BAD,[165] regulate its function. BAX is capable of dimerizing with itself and with BCL2. In cells in which BAX is overexpressed, apoptosis is accelerated in response to apoptotic stimuli. In cells in which BCL2 is overexpressed, heterodimers with BAX predominate, and cell death is repressed. [164] Thus, the ratio of BCL2 to BAX determines the likelihood of a cell undergoing apoptosis on exposure to a given stimulus. BAD, another partner of BCL2, promotes cell death by dimerizing with either BCL-XL or BCL2, decreasing the amount of BAX bound to either BCL-XL or BCL2 and thereby increasing the amount of BAX homodimers present.[161]

The prognostic significance of having the t(14;18) or of overexpressing *BCL2* is unclear, and studies have been conflicting. One study suggested that rearrangements in the major breakpoint region of the *BCL2* gene were associated with a shorter disease-free period in patients with extranodal lymphomas, but this proposition

remains to be confirmed.[166] Another study examining diffuse large B-cell lymphoma[167] showed that high levels of *BCL2* expression predicted a shorter disease-free survival. The biologic basis for the poorer prognosis may be that such cells have increased resistance to chemotherapeutic drugs. [168]

t(11;14)

The t(11;14)(q13;q32) is most commonly seen in a relatively new pathologic entity known as mantle cell lymphoma. [169] In the Kiel classification, these tumors were classified as centrocytic lymphomas and in the Working Formulation as small cleaved cell, diffuse or nodular, or, rarely, diffuse mixed or large cleaved cell lymphomas. In most series, the reported percentage of cases with the t(11;14) by molecular analysis has varied between 30% and 55%, but these figures may be underestimates, as only the major translocation cluster regions have been looked for. Besides mantle cell lymphomas, the t(11;14) has been reported in 3% of multiple myelomas and in up to 20% of prolymphocytic leukemias.[169] Mantle cell lymphomas are currently associated with a poor prognosis, with a median survival from diagnosis of 3 years.

This translocation results in the juxtaposition of the *IGH* gene, specifically the JH segment of the *Ig* gene locus, to a putative oncogene, *BCL1*. However, the gene itself was not identified until 1991, after the discovery of the parathyroid adenomatosis 1 (*PRAD1*) gene, identified at 11q13 by virtue of its clonal rearrangement with the parathyroid hormone locus, in a subset of benign parathyroid adenomas. *PRAD1* was overexpressed in lymphoid malignancies with the t(11;14)(q13;q32) and was found to be 100130 kb away from the *BCL1* locus. Subsequently, *PRAD1*(*BCL1*) was found to have significant sequence homology with the known cyclins, specifically cyclin D1 (*CCND1*).[170] The D-type cyclins appear to act as growth factor sensors, causing cells to go through the restriction start point of the cell cycle at G_1 and committing them to divide. CCND1 together with activated cyclin-dependent kinase 4, or CDK4, phosphorylates and inactivates retinoblastoma protein, releasing from it E2F, a transcription factor responsible for activating a series of genes required for cell division. [171] The ectopic expression of *CCND1* under the control of the E promoter in mice is not transforming per se, as E-*Bcl1* mice do not develop lymphoma. In lymphoid cells, the oncogenic ability of *CCND1* appears to depend on synergy with other oncogenes, specifically *MYC*.[172] Circumstantial evidence of its involvement in other tumors includes the frequent amplifications of 11q13 and overexpression of *CCND1* in solid tumors, including head and neck, esophageal, bladder, breast, small cell lung, and hepatocellular carcinomas. [173]

Translocations of 3q27

The *BCL6* oncogene was cloned from the recurring breakpoint at 3q27 in cells characterized by a t(3;22)(q27;q11), t(3;14)(q27;q32), or, rarely, t(2;3)(p12;q27). [174] [175] *BCL6* rearrangements occur in 40% of diffuse large cell lymphomas and, in some series, up to 10% of follicular lymphomas. [176] The translocations lead to truncation of the gene within the first exon or the first intron, substitution of its promoter sequences with an *Ig* promoter, and deregulated expression.

The *BCL6* gene product is a 96-kd nuclear protein that is predominantly expressed in the B-cell lineage, particularly in mature B cells, but not in immature bone marrow precursors or the more mature plasma cell. The protein contains six zinc finger motifs and an N-terminal POZ domain, which in related proteins have been shown to regulate the DNA binding of zinc finger proteins. [177] *BCL6* has been shown to be a potent transcriptional repressor. [178] A role in germinal center formation is suggested by topographic restriction of *BCL6* expression to germinal centers in normal human lymphoid tissue, and by the observation that mice with targeted disruptions of *BCL6* are incapable of forming germinal centers. Such mice also develop an inflammatory disorder that appears to be Th2-like lymphokine dependent, implicating a role for *BCL6* in the control of inflammatory responses. [179]

Two retrospective studies have assessed the clinical significance of *BCL6* rearrangements. One found a more favorable outcome in terms of survival and freedom from progression among diffuse lymphomas with a large cell component,[180] whereas the other failed to confirm these findings.[181] At present, the prognostic relevance of *BCL6* rearrangements or expression is unclear.

T-Cell Non-Hodgkin Lymphoma

A number of recurring chromosomal abnormalities have been recognized in lymphomas of T-cell origin (Table 48-5). These abnormalities are also observed in T-cell leukemias. Similar to B-cell neoplasms, in which rearrangements frequently involve the chromosomal bands containing the immunoglobulin gene loci, T-cell neoplasms often have rearrangements involving band q11 of chromosome 14, the site of the T-cell receptor -chain and -chain genes (*TCRA, TCRD*),[182] [183] or, less often, one of two regions of chromosome 7 (7q3435 and 7p15) to which the T-cell receptor -chain (*TCRB*) and -chain (*TCRG*) genes have been localized, respectively (Table 48-5).[1] With few exceptions, the involved gene on the partner chromosome encodes a transcription factor whose expression is deregulated or activated in an aberrant tissue as a result of the rearrangement (Table 48-5).[3] [4] These studies indicate that, perhaps as a result of their capacity to be specifically rearranged, transcribed, and mutated in B cells or in T cells, the immunoglobulin and T-cell receptor gene loci are appropriate DNA sequences to mediate the activation of cellular oncogenes. A chromosomal rearrangement that brings an oncogene under the controlling influence of promoters or enhancers that are active for immunoglobulin synthesis in B-cells or for T-cell receptor synthesis in T cells may as a consequence impart a proliferative advantage to that cell and result in malignant clonal expansion.

Ki-1 Anaplastic Large Cell Lymphomas

A distinctive subtype of NHL, namely, Ki-1-positive anaplastic large cell lymphoma (Ki-1+ ALCL), has been characterized during the past few years. The Ki-1 antigen (CD30) is observed in nearly all cases of Hodgkin disease; however, this antigen is also expressed by a variable proportion of lymphoma cells in a variety of non-Hodgkin lymphoma subtypes. A subset of non-Hodgkin lymphoma with distinctive clinical and morphologic features is strongly Ki-1 positive. These patients tend to be young and present with skin or lymph node infiltration (or both) by large, often bizarre lymphoma cells that preferentially involve the paracortical areas and lymph node sinuses.[184] [185] The majority of such tumors express one or more T-cell-associated antigens, and a minority express B-cell antigens. However, a significant number express both T- and B-cell antigens (the null phenotype).

A reciprocal translocation, t(2;5)(p23;q35), appears to be restricted to ALCL of either T-cell or null phenotype and is present in a high percentage of these cases. [186] [187] Since its initial description in ALCL, this translocation has also been found in the CD30-positive primary cutaneous lymphomas and the related entity of lymphomatoid papulosis, suggesting a common pathogenesis of these cutaneous disorders and ALCL. The initial report that the fusion transcript resulting from t(2;5) was also present in the Reed-Sternberg (RS) cells of some Hodgkin disease cases has not been confirmed, and the consensus is that, at the cytogenetic and molecular level, both t(2;5) and the resultant fusion gene are absent in RS cells. [188] The molecular consequence of the translocation is the production of a unique fusion protein consisting of the nucleophosmin (*NPM*) gene on 5q35 fused to a tyrosine protein kinase gene (*ALK*) on 2p23. ALK encodes a tyrosine kinase that is normally expressed in intestine, testis, and brain but not in normal lymphoid cells. [189] The NPM/ALK fusion protein is localized to the cytoplasm and is able to transform NIH 3T3 cells, suggesting that the translocation is the primary transforming event in ALCL. [190] The intracellular targets for phosphorylation by normal ALK and for the fusion protein have yet to be elucidated.

Post-transplant Lymphomas

Post-transplant lymphoproliferative disease (PTLD) denotes a heterogeneous group of lymphoproliferations occurring in patients who are immunosuppressed after organ transplantation. There have been relatively few cytogenetic studies of this disease, but trisomy 11 and translocations of *MYC* have been reported.[191] [192] In a recent series, cytogenetic analysis of 16 cases (five cases polymorphic, 11 monomorphic) revealed six distinct subgroups with recurring abnormalities: (1) six patients (38%) had nonclonal abnormalities or normal karyotypes, (2) three patients (19%) had *MYC* translocations, (3) three patients (19%) had +9, (4) three patients (19%) had +11, (5) two patients (13%) had *BCL6* translocations, and (6) one patient (6%) had a translocation involving *IGH* at 14q32.[193] All cases in group 1 were classified histologically as polymorphic and diffuse large cell-centroblastic, all cases in group 2 were Burkitt lymphoma, and all cases in groups 36 were diffuse large cell-immunoblastic. Thus, the majority of monomorphic cases (10 of 11) had abnormal karyotypes, and the different recurring abnormalities segregated with the histologic subtype of the tumor.

Other Lymphoproliferative Disorders

Less is known about the chromosomal abnormalities in malignant lymphoproliferative disorders other than those already discussed. In part, this lack of knowledge is due to the low proliferative rate and mitotic index in these diseases and to the inability to stimulate mitoses in the malignant lymphoid cells without also stimulating cell division in the residual normal T or B lymphocytes. Thus, karyotypes have most often been reported to be normal in patients with CLL, multiple myeloma, or hairy cell

leukemia, for example.

Trisomy 12 is the most common cytogenetic abnormality reported in patients with B-cell chronic lymphocytic leukemia (B-CLL); it is found in 2060% of those with a cytogenetic abnormality.[194] Abnormalities involving band 14q32 are also common,

---

e.g., t(14;19)(q32;q13) (Table 48-5).[195] Unfortunately, only half of patients with B-CLL will have an adequate number of metaphase cells in unstimulated cultures for thorough evaluation. Several groups have shown that FISH is a simple and sensitive method for detecting trisomy 12 in interphase CLL cells; 30% of patients had trisomy 12, and this abnormality was associated with a poorer survival. [196] Similarly, a del(13q) can be detected in 30% of CLL cases by FISH technology.

Chronic T-cell leukemia (T-CLL) and large granular lymphocytic leukemia are uncommon disorders in which the malignant mature lymphocytes have a T-cell immunophenotype. Rearrangements involving bands 14q11 with or without an accompanying break in 14q32 have been reported in T-CLL as well as other T-cell lymphomas (Table 48-5). [1] [197] Cutaneous T-cell lymphoma, a malignant proliferation of CD4-positive (helper/inducer) cells that involves the skin (mycosis fungoides), blood (Sézary syndrome), and lymph nodes, has been reported to have a high incidence of random heteroploidy; less often, complex clonal abnormalities are present, sometimes involving chromosome 6.

Hairy cell leukemia is an uncommon B-cell disorder with a low proliferative rate. Recurring chromosomal abnormalities have been difficult to identify in hairy cell leukemia because of the low yield of mitotic cells. Del(6q), trisomy 3 and 12, and translocations involving 14q32 have been reported in several patients each. [1] Unrelated structural abnormalities may also be present in individual patients.

Angioimmunoblastic lymphadenopathy with dysproteinemia is another rare lymphoproliferative disorder. Although it has been linked to drug hypersensitivity reactions, progression to a high-grade immunoblastic lymphoma of T-cell origin occurs in some cases. Clonal abnormalities involving trisomy 3 or 5 have been reported. [198] Although better understanding of these recurring abnormalities will no doubt increase our knowledge of malignant transformation, the greatest clinical importance of cytogenetic analyses in these disorders currently is to differentiate a reactive (polyclonal) lymphoid proliferation from a malignant (monoclonal) one. The identification of a clonal chromosomal abnormality in an enlarged lymph node or in peripheral blood cells provides convincing evidence of a neoplasm.

NEW TECHNIQUES TO DETECT CHROMOSOMAL ABNORMALITIES

Cytogenetic analysis of human tumors is often technically difficult owing to the presence of multiple abnormal cell lines and the complexity of the chromosomal pattern. Moreover, it requires highly skilled personnel. These factors have led investigators to seek alternative methods for identifying chromosomal abnormalities, such as Southern blot analysis of DNA or RT-PCR analysis of RNA from tumor cells (described following), or FISH. [199]

The technique of FISH is based on the same principle as Southern blot analysis, namely, the ability of single-stranded DNA to anneal to complementary DNA. In the case of FISH, the target DNA is the nuclear DNA of interphase cells, or the DNA of metaphase chromosomes that are affixed to a glass microscope slide. FISH can also be accomplished with bone marrow or peripheral blood smears, or fixed and sectioned tissue. The test probe is labeled with biotin- or digoxigenin-labeled nucleotides, and detected with fluorescein isothiocyanate (FITC)-conjugated avidin or rhodamine-labeled antidigoxigenin antibodies. Probes that are directly labeled with fluorochrome are also available for hybridization, thereby simplifying the technique by eliminating the probe detection steps. With the development of dual- and triple-pass filters, most laboratories now have the capacity to hybridize and detect two to three probes simultaneously.

Several types of probes can be used to detect chromosomal abnormalities by FISH. Hybridization of centromere-specific probes has been used to detect monosomy, trisomy, and other aneuploidies in both leukemias and solid tumors (Fig. 48-4). Chromosome-specific libraries, which paint the chromosomes, are particularly useful in identifying marker chromosomes (rearranged chromosomes of unidentified origin) or structural rearrangements such as translocations. Chromosomal translocations can also be identified in interphase or metaphase cells by using probes (phage, cosmid, or yeast artificial chromosome probes) that are derived from the breakpoints of recurring translocations. Recently, investigators have demonstrated the use of FISH to detect allele loss in tumor cells, specifically the loss of the *RB1* gene in CLL.

FISH techniques have a number of applications (Table 48-6). In some cases, FISH analysis provides more sensitivity, in that cytogenetic abnormalities have been identified by FISH in samples that appeared to be normal by morphologic and conventional cytogenetic analyses. FISH is most powerful when the

Figure 48-4 (A) Schematic diagram of the hybridization pattern observed in metaphase cells or interphase cells hybridized with a centromere-specific repetitive probe. Centromere-specific probes hybridize to the repetitive DNA sequences that are present at the centromeres of human chromosomes. These probes result in two intense signals at the centromeres of the target chromosome in diploid metaphase cells or interphase nuclei. **(B)** Photomicrographs of metaphase cells and interphase cells following FISH. Hybridization of a chromosome-specific centromere probe for chromosome 8 to metaphase and interphase cells with trisomy 8 from a bone marrow sample of a patient with acute myeloid leukemia. The chromosome 8 homologs are identified with arrows.

TABLE 48-6 -- Applications and Advantages of FISH

Applications
Detection of numerical and structural chromosomal abnormalities
Identification of marker chromosomes (rearranged chromosomes of uncertain origin)
Monitoring the effects of therapy, and detection of minimal residual disease or early relapse
Identification of the origin of bone marrow cells after bone marrow transplantation
Identification of the lineage of neoplastic cells
Examination of the karyotypic pattern of nondividing or interphase cells
Detection of gene amplification
Advantages
Rapid technique
Efficiency of hybridization and detection is high
Sensitivity and specificity are very high
Large numbers of cells can be analyzed in a short time
Cytogenetic data can be obtained from nondividing or terminally differentiated cells, from tumors with a low mitotic index (e.g., CLL), or from poor samples that contain too few cells for routine cytogenetic studies
Permits direct correlation of cytogenetic and cytologic/morphologic features, which enables pathologists to differentiate malignant from benign conditions in equivocal cases
Automated systems for analysis of hybridized slides are available

analysis is targeted toward those abnormalities that are known to be associated with a particular tumor or disease. An example of how FISH could be used in a clinical setting is as follows. Cytogenetic analysis could be performed at the time of diagnosis to identify the chromosomal abnormalities in an individual patients malignant cells. Thereafter, FISH with the appropriate probes could be used to detect residual disease or early relapse, and to assess the efficacy of therapeutic regimens.

Our new sophistication regarding the genetic changes in hematologic malignant diseases provides us with some very critical new diagnostic tools. Standard Southern blot analysis of tumor DNA can reveal clonal rearrangements of genes (e.g., immunoglobulin or T-cell receptor genes) using the appropriate probes, as well as a number of recurring translocations. PCR can increase the sensitivity of detection of these aberrations; sometimes the sensitivity is too great to be clinically applicable. Translocations that result in fusion genes are especially suited for RT-PCR, a technique in which the fusion mRNA is copied into cDNA and then, with appropriate primers from each gene, the fusion gene is amplified by PCR. Based on the position of the primers, the size(s) of the expected fusion product is known and can be compared with that actually obtained. The correctness of the amplified product can be confirmed using a smaller probe that contains the expected portion of the fusion gene. We and others have used this strategy to detect the rearranged genes in t(8;21). [63] Using probes from *AML1* and *ETO* on standard Southern blot analysis, rearrangements can usually be detected in DNA from about 80% of patients known to have a t(8;21). With RT-PCR, the detection rate is 100%. We found positive signals of fusion mRNA in patients in complete remission who were negative on cytogenetic analysis and standard Southern blotting. More recently, we have detected

the translocation in peripheral blood cells from three patients in unmaintained remission for 58 years. [63] This indicates that these patients have circulating t(8;21)-positive cells even though they appear to be cured of their leukemia. The biologic significance of these observations remains to be determined; it seems clear, however, that decisions on whether to continue therapy cannot be based solely on a positive signal with RT-PCR methods. Other translocations that can be detected routinely by RT-PCR include t(9;22) and t(15;17).

This increasing precision in identifying the genetic changes in the malignant cells comes at a most opportune time, because physicians may soon be in a position to use targeted therapy aimed at the specific genetic defect in the malignant cells. To use this targeted therapy effectively requires a precise genotype of the malignant cells. Although a number of genes will be involved, with various genetic changes, those reflected in chromosomal changes may be amongst the easiest to monitor.

CLINICAL IMPLICATIONS OF CYTOGENETICS

Cytogenetic analysis provides clinicians with a powerful tool for the diagnosis and classification of hematopoietic malignant diseases. The detection of an acquired somatic mutation establishes the diagnosis of a neoplastic disorder and rules out a reactive hyperplasia or morphologic changes due to toxic injury or vitamin deficiency. When the pathologic diagnosis is equivocal, the detection of a clonal chromosomal abnormality in a bone marrow specimen or in lymph node tissue is sufficient reason to institute cytotoxic treatment with radiation therapy or chemotherapy.

Specific cytogenetic abnormalities identify homogeneous subsets of various malignant diseases and enable clinicians to predict their clinical course and their likelihood of responding to particular treatments. In many cases, the prognostic information derived from cytogenetic analysis is independent of that provided by other clinical features. Patients with favorable prognostic features benefit from standard therapies with well-known spectra of toxicities, whereas those with less favorable clinical or cytogenetic characteristics may be better treated with more intensive or investigational therapies. The disappearance of a chromosomal abnormality that is present at diagnosis is an important concomitant of complete remission following treatment, and its reappearance invariably signals relapse of the disease. More recently, molecular methods have provided evidence of clonal remissions, suggesting that cytogenetic changes may be a late step in malignant transformation and not always present in the neoplastic stem cell. FISH analyses allow differentiated or nondividing cells to be studied, and molecular methods allow a whole population rather than just individual cells to be analyzed.

The presence of the Ph chromosome differentiates CML from other myeloproliferative disorders or MDS and also serves as an important marker of persistent disease during interferon therapy or following allogeneic bone marrow transplantation. Karyotypic evolution in a patient with CML portends transformation to the acute phase and provides a useful signal to proceed, if possible, with bone marrow transplantation in higher-risk groups, such as older patients or those without HLA-identical sibling donors.

Currently, there is controversy concerning the optimal timing of marrow transplantation in the treatment of AML and ALL. Pretreatment cytogenetic analysis can be useful in choosing

among post-remission therapies that differ widely in cost, acute and chronic morbid effects, and effectiveness.

Our own treatment results suggest that the majority of patients with AML and favorable cytogenetic featuresi.e., t(8;21), t(15;17), inv(16) or t(16;16), and perhaps t(9;11)can be cured with intensive consolidation chemotherapy and therefore should not undergo allogeneic transplantation when in first remission. [50] Those in whom disease relapses can generally be salvaged with bone marrow transplantation in early relapse or second remission. Alternatively, AML patients with loss or deletion of chromosome 5, or ALL patients with t(9;22) or t(4;11) have relatively drug-resistant disease and are seldom cured with conventional chemotherapy alone. Thus, the use of investigational agents or transplantation in first remission is warranted.

As molecular probes for the genes involved in recurring translocations become more readily available, it will be possible to evaluate marrow or blood samples of patients in clinical remission to determine the persistence of minimal residual disease at the level of 1 in 10^5 cells. As yet, however, it is too soon to know whether patients who are persistently positive by PCR methods are always destined to experience disease relapse. However, it seems likely that patients who are negative by current PCR methods are most likely cured of their disease.

APPENDIX: Examples of Cytogenetic Nomenclature

46,XX or 46,XY: Nomenclature description of a normal female or male karyotype, respectively.

47,XX,+8,t(9;22)(q34;q11): Female with an extra chromosome 8 as well as a translocation affecting chromosome 9 with a break in the long arm, band q34, and chromosome 22 with a break in the long arm, band q11. The latter is the usual translocation seen in chronic myelogenous leukemia. The abnormal chromosome 22 is known as the Philadelphia (Ph) chromosome.

46,XX,t(9;22;10)(q34;q11;q24): Female with a variant (complex) Philadelphia translocation affecting chromosome 9 with a break in band q34, chromosome 22 with a break in band q11, and chromosome 10 with a break in the long arm at band q24. Chromosomal material from 9q is translocated to 22q, material from 22q is translocated to 10q, and material from 10q is translocated to 9q.

46,XY,inv(16)(p13q22): Male with a pericentric inversion of chromosome 16 resulting from breaks in the short arm in band p13, and in the long arm in band q22. The inv(16) is a recurring chromosomal abnormality that is associated with acute myelomonocytic leukemia with abnormal eosinophils.

46,XY,del(5)(q13q33): Deletion of part of the long arm of chromosome 5, including bands q1333.

Chapter 49 - The Molecular Basis of Neoplasia

Naomi Rosenberg
Theodore G. Krontiris

INTRODUCTION

Malignant transformation involves both somatic and heritable changes in some of the genes that control normal cell growth and development. These genes are of two general types: oncogenes, genes whose products induce oncogenic growth when expressed in appropriate cell types, and tumor suppressor genes, genes whose products negatively regulate cell growth. Many oncogenes were initially discovered because of their presence in a variety of retroviruses that induce tumors in animals. Others were identified because their expression is directly affected by retrovirus infection, leading to tumor development. Although they are all involved in malignant transformation, oncogenes are a diverse group, encoding proteins involved in many aspects of cellular growth and metabolism. Some function by mimicking the action of growth factors, growth factor receptors, and signal transducers, while others are transcription factors that directly affect gene expression. Tumor suppressor genes were largely discovered through genetic analyses of familial cancers. Like oncogenes, the products of tumor suppressor genes are functionally diverse. However, many influence progression

through the cell cycle, providing cues for either cell cycle arrest or apoptosis; others influence growth by sensing environmental signals. This chapter reviews some of the historical experiments that defined the molecular basis of neoplasia and set the stage for current basic and translational research on the pathogenesis and management of hematologic malignancies.

RETROVIRUSES AND CANCER: HISTORICAL PERSPECTIVE

Except for human T-cell leukemia virus 1 (HTLV-1), retroviruses are not involved in human malignancies. However, two seminal discoveries focused attention on oncogenic retroviruses as tools to study human malignancy. First, the finding that retroviral oncogenes are derived from highly conserved normal cellular genes demonstrated that these transforming genes are not unique to retroviruses. Second, the discovery that many of the same oncogenes are altered in non-retrovirus-induced tumors cemented the relationship of these sequences to oncogenesis. More recent work has demonstrated that retroviral and cellular oncogenes can cooperate to influence tumor incidence and latency and that inactivation of at least some tumor suppressor genes can play an important role in retrovirus-induced tumors. In addition, the simple genetic structure of retroviruses and the ability to study many of them in the genetically defined background provided by inbred strains of mice have given investigators important tools that are not available to researchers studying human tumors.

RetrovirusesA Brief Introduction

Oncogenes originally came to light in experiments that used retroviruses as model systems to understand tumorigenesis. Retroviruses are RNA viruses that contain two copies of their genome in each virion.[1] These viruses have the unique ability to transcribe these sequences into a double-stranded DNA copy, which is then integrated into the genome of the infected cell (Fig. 49-1). This occurs early in the infectious process within a capsid-like viral structure and is catalyzed by an enzyme called reverse transcriptase.[2] This enzyme uses both copies of the viral genome in a complex jumping process to generate a complete DNA copy called a provirus that, once integrated, behaves as any other cellular gene. It is expressed from a viral promoter by the cellular transcription machinery and is passed to daughter cells as are other cellular sequences. RNA transcribed from the provirus can function either as mRNA, directing the synthesis of viral gene products, or as new retroviral genomes that can be packaged and released from the cell as virus particles.

Retroviruses that induce tumors in chickens were discovered in the early 1900s. One of these viruses, Rous sarcoma virus (RSV), became the subject of intense research in succeeding years. These efforts demonstrated that induction of fibrosarcomas in chickens and transformation of chicken embryo fibroblasts in tissue culture required a viral gene[3] named *src* (pronounced sark). What has revolutionized the field since the mid-1970s has been finding that the *src* gene is homologous to a normal cellular gene present not only in birds but also in many other eukaryotes, including *Drosophila.*[4] [5] Studies soon revealed that virtually all retroviruses that transform tissue culture cells or induce tumors with a short latency in vivo contain transforming genes that are distinct from *src* but are also derived from normal cellular genes.[6] Indeed, by the early 1980s more than ten different oncogenes had been identified. The term proto-oncogene was introduced to distinguish the normal cellular form of these genes from their viral counterparts. Also, a three-letter designation was introduced to standardize the nomenclature of individual oncogenes; the three-letter code is often preceded by a c- or a v- to denote the cellular or viral form, respectively. Today, investigators have identified more than 30 different viral oncogenes.

Origin of Retroviral Oncogenes

A large body of work has shown that oncogenes found in rapidly transforming retroviruses are not only related to normal cellular proto-oncogenes but also are actually derived from the cellular genes by recombination between the viral and cellular genomes. Although the actual steps in the recombination process have not been duplicated in a reconstructed system, analysis of the structure of retroviruses that contain oncogenes and proto-oncogenes has suggested that recombination between the

Figure 49-1 Replication of retroviruses. Retroviruses interact with cells via specific receptors, a process called adsorption (1). Following binding to the receptor, the virus/receptor complex is taken up by the cell in a process of penetration (2). The virus core is released into the cytoplasm, and the RNA genomes are copied into a double-stranded DNA form (3). The core structure migrates to the nucleus, and the viral genome integrates into the cellular DNA (4). Cellular RNA polymerase transcribes the viral genes (5), and the RNA is processed and transported to the cytoplasm, where it is translated to give rise to viral proteins (6). Other transcripts serve as genomes for new virions, which are assembled (7) and bud from the cell (8).

Figure 49-2 Incorporation of oncogenes into viruses. **(A)** In the first step, a proviral form integrates into a cellular gene between two exons, represented by the open boxes. Following integration, two possible paths can be followed. On the left, a DNA deletion involving viral and cellular sequence occurs (*) and a fused virus and cell transcript is produced. On the right, a fraction of the normal viral transcripts fail to undergo normal processing and continue beyond the virus into flanking cellular sequences. **(B)** Either pathway can give rise to some virions that contain both a normal viral transcript and a hybrid transcript generated from viral and cellular sequences **(C).** When such a virion infects a new cell, recombination occurs during reverse transcription **(D)** and generates a recombinant virus containing the cellular sequences.

sequences occurs in a minimum of two steps.[2] The first step in the process occurs at the DNA level when a provirus integrates near or into a proto-oncogene. Next, one of two events is thought to occur. According to one scenario, a deletion occurs and the viral and cellular sequences are fused in the DNA. The second possibility predicts that some of the viral transcripts that would normally terminate in the 3 end of the long terminal repeat (LTR) extend beyond this point into the proto-oncogene sequence, generating a hybrid transcript (Fig. 49-2). In either case, RNAs containing both viral and cellular sequences are generated. Because retroviruses can package RNAs that differ in structure from the usual genome, some of the virions released from the cell will contain one conventional genome and one hybrid RNA. When such a virion infects a new cell, the second step in oncogene capture occurs. Reverse transcription of the two different RNA molecules results in generation of a proviral form in which the cellular sequences are now completely incorporated into a viral genome.

Differences Between Oncogenes and Proto-oncogenes

Proto-oncogenes are highly conserved genes, which suggests that their proteins play key roles in cellular metabolism and growth. This feature raises a fundamental question: How does a gene involved in a normal cellular process become a gene that induces malignant growth? A single answer, beyond the obvious unifying feature of incorporation into retroviral genomes, does not exist. Indeed, several types of alterations can occur as a consequence of the capture of these genes. [6] First, the cellular genes are removed from the elements that normally control their expression. In a retrovirus, expression of the gene is controlled by the viral promoter and enhancer elements located at the 5 end of the integrated retrovirus, in the LTR. Polyadenylation signals are contributed by LTR sequences located at the 3 end of the viral genome. Second, because the gene is contained in an infectious element, it can be introduced into cell types that would not normally express the sequences. Finally, in most cases the coding sequence of the cellular gene is altered as a consequence of recombination with the viral genome. These alterations can result in expression of truncated proteins or of fusion proteins containing a portion specified by the cellular oncogene and a portion specified by a viral gene. Proteins that

contain more subtle mutational changes may also occur.

Insertional Mutagenesis and Oncogene Activation

Most oncogenic retroviruses do not carry oncogenes. Indeed, although incorporation of proto-oncogene sequences into retroviruses can create highly oncogenic viruses, such viruses are generated rarely and are involved in a minority of naturally occurring retrovirus-induced tumors. The majority of oncogenic retroviruses induce tumors by proviral insertional mutagenesis. [6] The key event in this process, integration of the provirus in the vicinity of a proto-oncogene, is similar to the first event in oncogene capture. The introduction of the strong promoter and enhancer elements located in the retroviral LTR, and the disruption of proto-oncogene structure caused by proviral insertion, can have drastic effects on proto-oncogene expression in the absence of incorporation into a virus. For example, hybrid RNAs similar to those formed during oncogene capture can be translated, leading to production of an altered proto-oncogene product. The presence of strong promoter and enhancer elements in viral LTRs can also activate the expression of proto-oncogenes if the provirus has integrated in the vicinity of the cellular gene. Although most integrations are within 1020 kb of the proto-oncogene, in some instances these effects appear to be mediated when the provirus is >300 kb away. Integration can also disrupt sequences within the proto-oncogene that control turnover of the mRNA, resulting in production of an abnormally

stable RNA and elevated levels of protein. Less commonly, integration of a provirus can inactivate gene expression; in certain types of retrovirus-induced tumors, proviral integration into the *TP53* and *NF1* tumor suppressor genes plays a role in tumor development. [7] [8]

An important aspect of proviral insertional mutagenesis is the flexibility provided; insertion can alter gene expression in several different ways (Fig. 49-3). Thus, integration into a precise location relative to the proto-oncogene is not necessary. In addition, generation of an RNA with the size and structure required for incorporation into a virion is not necessary. As long as the integration event leads to aberrant proto-oncogene expression and confers a distinct growth advantage, a tumor can develop without production of a retrovirus that carries an oncogene. Although some of the proto-oncogenes that are affected by insertional mutagenesis are identical to those that have been captured by retroviruses, many have never been recovered in an infectious form. Indeed, >70 different loci have been identified as targets for proviral insertion. [6] This large number probably reflects both the flexibility inherent in proviral insertional mutagenesis and the fact that altered expression that induces even subtle changes in growth can contribute to tumor development. Tumors induced by proviral insertional mutagenesis develop over a long period of time and often involve activation of more than one proto-oncogene. As might be expected, many

Figure 49-3 Three common mechanisms by which retroviral integration affects gene expression. **(A)** A typical eukaryotic gene with four exons represented by the open boxes. RNA is transcribed as indicated by the wavy line, with transcription proceeding in the direction indicated by the arrow. The protein product is represented below the RNA as the fused products of each of the exons. **(B)** Consequences of promoter insertion. Here a retrovirus integrates between exons 1 and 2 of the gene, and promoter sequences at the 3 end of the virus are used to direct synthesis of a truncated protein. **(C)** Consequences of enhancer insertion. Here a retrovirus integrates near a cellular gene in the opposite transcriptional orientation. Enhancer sequences located in the retroviral LTR affect transcription from the normal promoter of the gene and elevate the level of expression. **(D)** Consequences of leader insertion. Here the retrovirus integrates within the gene as in B, but promoter sequences at the 5 end of the virus in concert with viral leader sequences lead to the translation of an altered form of the cellular gene product.

of the proto-oncogenes that have been identified as targets for proviral insertion are altered by other types of mutations in spontaneous, carcinogen-induced, or genetically influenced tumors in animals, including humans.

TYPES OF RETROVIRUS ONCOGENES

The current list of known oncogenes involved in retrovirus-induced tumors contains nearly 100 entries (Table 49-1), and new oncogenes or candidate oncogenes are still being identified. Although some of these genes are clearly capable of inducing tumors and transforming cells in tissue culture, others have been identified as genes expressed in spontaneous tumors that are related by nucleic acid homology to known oncogenes. Still others are loci known to be targets of proviral insertion for which no gene has yet been identified. In these latter cases, the actual role of the gene in the tumor and its potential to induce malignant transformation have not always been proved. This chapter does not attempt to cover all oncogenes but focuses on the major groups involved in retrovirus-induced tumors, using examples that illustrate general mechanisms.

Oncogenes can encode secreted, membrane-associated, cytoplasmic, or nuclear proteins that appear to affect virtually every aspect of cellular metabolism (Fig. 49-4). Indeed, it is possible that any gene playing a key role in cellular growth can become an oncogene if mutated in the appropriate way. Most of the known oncogenes can be divided into groups based on their apparent mechanism of action and functional similarities. Oncogenes encoding secreted proteins include several that encode growth factors. Those that encode membrane-associated proteins include tyrosine kinase growth factor receptors and membrane-bound intracellular tyrosine kinases that interact with these receptors. Other proteins that are sometimes associated with membrane complexes include adaptor molecules, which transmit signals from receptors to downstream signaling intermediates, members of the G protein superfamily, and serine/threonine kinases that transmit signals to the nucleus. Oncogenes that encode nuclear proteins that regulate transcription and cell cycle progression have also been identified. Indeed, it is difficult to find an aspect of cellular growth control that cannot be disrupted in some retrovirus-induced tumor.

Protein Tyrosine Kinase Oncogenes

The first oncogene protein to be assigned an enzymatic activity was *src,* a protein tyrosine kinase (PTK). [9] [10] Prior to this discovery a role for tyrosine phosphorylation in cellular growth had not even been proposed. Today, not only do PTKs constitute a major group of oncoproteins, but tyrosine phosphorylation and dephosphorylation are recognized as one of the principal signaling mechanisms in higher eukaryotic cells. [11] Proteins with PTK activity include many growth factor receptors and intracellular, membrane-associated molecules. Most of these latter proteins interact with transmembrane receptors, many of which are PTKs themselves. The kinase activity of these proteins is required for transmission of signals. Normally, the kinase activity of the receptors is activated when ligand binds the receptor; the activity of the intracellular PTKs is also activated in response to a specific signal, which is usually transmitted as a consequence of a receptor-ligand interaction. In both cases, the kinase activity initiates a signal by phosphorylating other proteins, which transmit the signal downstream through multiple pathways, leading to altered gene expression.

Unlike their normal counterparts, which are tightly regulated, the kinase activity of oncogenic forms of these proteins is not dependent on interaction with ligand, allowing these proteins to transmit growth signals constitutively. Several different types of alterations can lead to constitutive activation. For

TABLE 49-1 -- Retrovirus Oncogenes

Function of Gene Product	Name of Gene	Species of Origin	Disease(s) Associated	Comments
Nonreceptor tyrosine kinase	*src*	Chicken	Sarcoma	
	fps	Chicken	Sarcoma	*fes* homolog
	yes	Chicken	Sarcoma	
	fgr	Chicken	Sarcoma	
	fes	Cat	Sarcoma	*fps* homolog
	abl	Mouse, cat	Lymphoma, sarcoma	
Receptor tyrosine kinase	*ros*	Chicken	Sarcoma	Related to insulin receptor
	*erb*B	Chicken	Erythroblastosis	EGF receptor
	fms	Chicken	Sarcoma	CSF-1 receptor
	kit	Chicken	Sarcoma	SCL receptor
	sea	Chicken	Sarcoma	*HGFR* family member
	eyk	Chicken	Sarcoma	
G-protein	*ras*	Chicken, rat, cat, mouse	Sarcoma	Some isolates induce several types of tumors
Serine/threonine kinase	*raf*	Mouse	Sarcoma	*mil* homolog
	mil	Chicken	Sarcoma, carcinoma, myelocytoma	*raf* homolog
	akt	Mouse	T-cell lymphoma	
	mos	Mouse	Sarcoma	
Growth factors	*sis*	Monkey	Sarcoma	PDGF- chain
Growth factor receptor	*mpl*	Mouse	Myeloproliferative disease	Thrombopoietin receptor
Adaptor protein	*crk*	Chicken	Sarcoma	
	cbl	Mouse	Pre-B lymphoma, myeloid leukemia	

Transcription factor	*ski*	Chicken	None	
	*erb*A	Chicken	Erythroblastosis	Thyroid hormone receptor
	jun	Chicken	Sarcoma	AP-1 component
	fos	Mouse, chicken	Sarcoma	AP-1 component
	myc	Chicken	Sarcoma, myelocytoma	Complexes with Max
	myb	Chicken	Myeloblastosis	
	rel	Chicken	Reticuloendotheliosis	NF-B family member
	ets	Chicken	Erythroblastosis, myeloblastosis	
	maf	Chicken	Sarcoma	bZip protein interacting with Fos and Jun
	qin	Chicken	Sarcoma	Winged helix family member

example, *erb*-b, an oncogene related to the epidermal growth factor receptor (EGFR), expresses an altered protein that no longer interacts appropriately with its normal ligand.[12] Similar changes have occurred in the v-*kit,* v-*sea,* v-*eyk,* and v-*ros* oncoproteins.[13] [14] [15] [16] In some cases, alterations affecting the sequence of the kinase domain and other portions of the molecule are also present. Mutations altering the sequence of the extracellular portion of the *fms* protein outside the ligand-binding domain, as well as changes in the carboxyl-terminus of the molecule, play a role in activating the oncogenic potential of this gene. [17]

Receptor PTK oncogenes have been captured by several different retroviruses associated with tumors in chickens and cats, and one proto-oncogene in this group is a common target of proviral insertional mutagenesis. Although the receptors have specific functions in normal cells, the types of tumors associated with the oncogenic forms do not always have an obvious association with the normal expression pattern. For example, a retrovirus expressing an altered form of the colony-stimulating factor-1 receptor (CSF-1), a molecule involved in myeloid cell differentiation, induces sarcomas in cats; [18] the *sea* oncogene, related to the hepatic growth factor receptor, is associated with both erythroblastosis and sarcoma in chickens. [15] The *erb*-b gene, related to the EGFR, has been captured by several different chicken retroviruses that induce erythroblastosis; the gene can also be activated by proviral insertional mutagenesis, leading to erythroblastosis. [19] These examples reveal two features common to many oncogenic systems: activation of different oncogenes can induce similar types of tumors, and the cell type involved in the tumor is not always the same as that in which the cellular form of the oncoprotein normally functions.

A number of oncogenes encode PTKs that bind to the inner surface of the plasma membrane. These proteins share essential features with the membrane-associated PTKs in the region of the molecule that is responsible for enzyme activity but do not contain transmembrane or extracellular domains. [20] Many of these oncoproteins contain two regions, called SH2 and SH3. These regions are not found in receptor PTKs and mediate interactions with other signaling molecules. [21] The specificity of these interactions is influenced by the exact sequences present in the SH2 and SH3 domains. Oncogenes in this group include v-*src,* v-*fgr,* v-*yes,* v-*abl,* and v-*fes.* All these genes were originally identified in retroviruses. The *src, fps,* and *yes* genes were obtained from independent isolates of chicken sarcoma virus, [22] [23] the *fgr* and *fes* genes (a gene identical to *fps*) were isolated from cat sarcoma viruses, [24] [25] [26] and the *abl* oncogene was isolated from a murine virus that induces pre-B-cell lymphoma and a cat retrovirus that induces

Figure 49-4 Some signaling pathways important in oncogene-mediated transformation. The scheme depicts some of the signaling pathways that are activated when a growth factor interacts with its receptor. In transformation, one or more of these signaling molecules can be constitutively active. In many cases the receptor is a receptor protein tyrosine kinase. Binding of ligand triggers signaling events that eventually lead to changes in gene expression. Molecules involved include nonreceptor protein tyrosine kinases (NR PTKs); adaptor proteins such as Grb-2; GTP-binding proteins such as Ras; and other protein kinases such as Raf, MEK, ERK, MEKK, and Jnk. Phosphatases (PP2A) and GAPs can downregulate these signals as indicated by the lines with flat tips.

sarcomas.[27] [28] The *lck* oncogene can be activated by proviral insertion, an event that can be associated with induction of thymic tumors in rats. [29] Most of these oncoproteins lack small regions of sequence that normally regulate the enzymatic activity of the molecule. [30] [31] [32] However, overexpression of these proteins caused by the strong retrovirus promoter and enhancer elements can also activate the oncogenic potential of these proteins.

Oncoproteins Related to G-Proteins

The proteins encoded by the different *ras* oncogenes are the classic examples of oncoproteins of the G protein superfamily. The first members of this family of oncogenes were initially discovered in two murine retroviruses that induce sarcomas in rodents. Members of this group are all called *ras* but are distinguished by prefixes that denote the cellular gene from which they were derived or the names of the retroviruses in which the genes were first discovered. For example, Ki-*ras,* homologous with the viral oncogene found in the Kirsten strain of murine sarcoma virus, denotes one cellular gene locus of the *ras* family,[33] while Ha-*ras,* homologous with the viral oncogene isolated from the Harvey murine sarcoma virus, refers to another, distinct locus. [33] [34] The *ras* oncogenes have also been recovered in several other retroviruses, and activation of *ras* by proviral insertion has been noted rarely. [35] [36] [37] [38] [39] [40] [41] In contrast, altered *ras* genes are relatively common in several types of human tumors.

Although each *ras* gene encodes a distinct product, all of these proteins are found on the inner surface of the plasma, where they interact with guanosine di- and triphosphate (GDP and GTP).[42] [43] When GTP is bound to Ras, the protein transmits signals downstream; the molecule is inactive in the GDP-bound state. The amount of Ras-GTP and Ras-GDP is controlled by signals received from several interacting proteins, including Grb-2/Sos, a complex that activates Ras, and GAP, a protein that inactivates Ras. All oncogenic forms of Ras display a reduced ability to be converted to the inactive state, and a disproportionately high level of Ras-GTP is found in the cells. Thus, as with the PTK oncoproteins, transformation by *ras* oncogenes is a consequence

of constitutive expression of the active or signal-transducing state of the molecule. In most cases, oncogenic Ras proteins have one of several amino acid substitutions that alter the ability of the molecule to interact with GTP, GDP, and GAP. [44] [45] [46] [47] [48] [49]

PROTEIN SERINE/THREONINE KINASE ONCOGENES

Two retrovirual oncogenes, v-*mos* and v-*raf/mil,* encode proteins that are protein serine/threonine kinases. [50] [51] [52] Two other serine/threonine kinases, encoded by the related *pim*-1 and *pim*-2 oncogenes, can be targeted by proviral insertional mutagenesis in murine hematopoietic tumors. [53] [54] The v-*mos* gene was first identified in a murine sarcoma virus,[55] while v-*raf* was first isolated from a murine virus that induces fibrosarcomas.[56] The v-*mil* gene, the avian homolog of the *raf* gene,[57] was isolated in an avian virus that induces myeloid leukemia. As with the PTK group, the enzyme activity of these oncoproteins is essential for transformation. [50] [51] The Raf/Mil proteins interact with Ras and can transmit Ras-mediated signals downstream to components of the MAP kinase pathway. [58] [59] Oncogenic forms of Raf lack amino-terminal sequences that are involved in regulating the activity of the protein. [60] [61] The Mos protein normally plays a key role in oocyte maturation by controlling meiosis at several points;[62] most somatic cells do not express the protein, and simple overexpression of the molecule in cells that do not normally express Mos is sufficient for transformation.[63] [64] This is an example of the general principle that inappropriate expression of an oncogenetoo much product, wrong cell type, or wrong time of the cell cycleis often sufficient to result in transformation.

GROWTH FACTOR ONCOGENES

Growth factor oncogenes include one retroviral oncogene, v-*sis,* and several targets of proviral insertional mutagenesis. Among the latter are several members of the gene family encoding fibroblast growth factor (*fgf*), the gene encoding granulocyte-macrophage colony-stimulating factor, and genes of the *Wnt/Int* family of growth factors. The v-*sis* gene that encodes an altered form of the platelet-derived growth factor chain was discovered in a primate sarcoma virus. [65] [66] [67] The *fgf* and *Wnt* genes are targets of common proviral insertion in murine mammary carcinoma. [68] [69] [70] [71] [72] Oncogenes of this type appear to transform cells by direct autocrine stimulation; that is, their products are produced by the very cells they induce to grow. [72] [73] [74]

TRANSCRIPTION FACTOR ONCOGENES

Unlike all the oncogene products previously discussed, these genes encode proteins that are primarily localized to the nucleus; many of these products are directly involved in regulating gene expression. Among these are the products of the v- *erb*-a, v-*jun,* v-*fos,* v-*myc,* v-*ski,* v-*ets,* v-*rel,* v-*maf,* v-*qin,* and v-*myb* genes.[75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] Many of these and a variety of other genes encoding transcriptional regulatory proteins are also targets of proviral insertional mutagenesis.[6] As might be expected for a diverse group of oncogenes that control expression of an equally diverse group of genes, the members of this group are associated with many different types of tumors. For example, v-*myc* has been isolated in retroviruses that induce a form of myeloid leukemia and carcinomas in chickens, and a T-cell lymphoma in cats. [91] [92] [93] [94] [95] Proviral insertional activation of *myc* has been found in both B- and T-cell lymphoma, erythroleukemia, and, rarely, in plasmacytoma.[96] [97] [98] [99] [100] The v-*erb*-a oncogene was discovered in a virus that induces erythroleukemia in chickens, [101] [102] and the v-*fos* oncogene was found in two different viruses that induce osteosarcoma in mice and in an avian virus that induces fibrosarcoma and nephroblastoma. [103] [104] [105]

Several types of structural changes are involved in the activation of these types of oncogenes. For some of these, particularly those that are regulated by pairing with other cellular factors, increased levels of expression are particularly important in activating their oncogenic potential. The Myc protein, which is normally tightly regulated at the transcriptional level and is highly active only when bound to the Max protein, is a classic example of this type of activation. [106] [107] [108] Other members of this group, including v-*myb* and v-*jun,* express proteins that are lacking important regulatory regions that would normally down-modulate transcriptional activation. The v-*erb*-a gene encodes an altered form of the thyroid hormone receptor, which can no longer interact with its ligand. [73] [74] Under normal circumstances, binding of thyroid hormone activates expression of genes regulated by the factor. In the absence of ligand, the normal receptor represses expression of these genes; [75] the oncogenic form of *erb*-a appears to act by constitutive repression of genes normally up-regulated by ligand-receptor interaction.

OTHER NUCLEAR PROTEINS

Several genes that encode proteins involved in cell cycle regulation have been identified as targets of proviral insertional mutagenesis. Among these are the genes encoding cyclin D1 and cyclin D2 and the *TRP53* gene (the mouse version of *TP53*) encoding the p53 tumor suppressor protein.[6] The D cyclins are normally expressed during the G_1 phase of the cell cycle, where they complex with cyclin-dependent kinases, forming a complex that phosphorylates the retinoblastoma protein (pRb).[109] This modification causes release of E2F transcription factors and stimulates progression from the G_1 phase of the cell cycle to the S phase. Targeting of the cyclin D genes results in overexpression of these proteins, leading to aberrant cell cycle regulation during the G_1 phase.

Unlike genes whose expression is activated by proviral insertion, consistent with its role as a tumor suppressor gene, integration into the *TRP53* locus causes loss of p53 expression.[7] The p53 protein is a multifunctional protein involved in the regulation of G_1 progression and cellular responses to DNA damage and hypoxia; its absence facilitates tumor formation by allowing damaged cells to proceed through G_1.[110] [111] Integrations into *TRP53* have been documented in retrovirus-induced erythroleukemias and more rarely in several other types of retrovirus-induced tumors. [6] [7] As might be expected based on the frequent targeting of *TRP53* in spontaneous tumors, mutations in this tumor suppressor gene have also been documented in several retrovirus tumor systems.

CELLULAR PROTO-ONCOGENE ACTIVATION

Proto-oncogenes normally play a role in controlling the cellular response to mitogenic signals as well as passage through various compartments of the cell cycle. The initiation of DNA replication, cell division, and the commitment to cellular differentiation are all considered to be levels at which proto-oncogenes and their products may exert a regulatory influence. Consequently, proto-oncogenes represent obvious targets for processes that damage the growth control apparatus of the cell and lead to malignant transformation. Such damage is often referred to as the activation of a proto-oncogene, resulting in the creation of an oncogene. In both leukemias and solid tumors, these processes have two basic effects. The first is to alter the protein product of the proto-oncogene so that a qualitative change in function occurs. Mutation may lead to a protein with an enhanced catalytic activity or an activity no longer subject to the control of cognate regulatory factors. The second principal effect is to alter the regulation of proto-oncogene expression so that a quantitative effect on function results. The overproduction of an otherwise normal oncogene product is an example of this type of activation.

Damage to cellular proto-oncogenes leading to their activation occurs by one of three mechanisms: genetic mutation, genetic rearrangement, or gene amplification. The first of these is usually associated with qualitative changes in function and the last with quantitative changes. Genetic rearrangement can have quite spectacular consequences, leading either to changes in the regulation of proto-oncogene transcription or to the creation of entirely new oncogene products.

Oncogene Mutation

The first defined alteration of a proto-oncogene to be discovered in a human tumor was the single-base mutation of a *ras* family member, Ha-*ras*-1.[112] [113] Point mutations affecting other *ras* genes (Ki-*ras*-2 and N-*ras*) have subsequently been described in a wide variety of human leukemias and solid tumors. [114] The activating point mutations occur in quite specific locationsthe bases of codons 12, 13, or 61and yield single amino acid substitutions in what is now known to be the GTP-binding site of the *ras* gene product, p21. The biochemical phenotype of such mutations is the most prominent example of a qualitative change arising out of oncogene activation, namely, the p21-associated reduction in GTPase activity. [114] Since the GTP-bound form of p21 is considered to be the active one, the net effect of *ras* mutations is to increase the proportion of activated p21 molecules in the cell. Given the previously described role of p21 as G protein in a signaling apparatus, the consequence of this shift toward the active form presumably is enhanced or constitutive transduction of mitogenic signals.

Although mutation was first detected in the Ha-*ras*-1 gene, Ki-*ras*-2 and N-*ras* are far more frequently the targets of somatic mutation in human tumors; Ha-*ras*-1 mutations are, in fact, rarely observed. Interestingly, a pattern of tissue-specific mutation has emerged. For example, Ha- *ras*-1 mutations are apparently limited largely to transitional epithelial tumors. Codon 13 mutations of the N- *ras* gene were found in 2570% of acute myelocytic leukemia (AML) samples examined.[115] Observations such as these have several important implications. First, the path traversed to produce, say, a specific leukemia subtype must be quite similar in most patients. This validates observations on the nature of the pathogenetic lesions and gives hope that the complexity of carcinogenesis will be resolved into a manageable number of combinatorial events. Second, despite this strong pattern of similarities, a significant fraction of tumors within a given class arise by a different pathdifferent at least in the choice of *ras* substitutes. Finally, the specificity of these mutations hints at underlying functional attributes peculiar to each member of the *ras* gene family. In some experimental systems, for example, the introduction of a mutant Ha-*ras*-1 gene may actually lead to differentiation rather than to unregulated proliferation. [116] Taking these disparate observations into account, we may speculate that each *ras* family member plays a role in signal transduction pathways with potentially distinct outcomes. Furthermore, the action of a given *ras* gene may be quite different from cell type to cell type.

Evidently, *ras* mutations can occur before the transformation to frank malignancy takes place. There is abundant indirect evidence for this assertion in humans and direct evidence in animal tumor models. First, *ras* mutations may be detected in a significant proportion of myeloid cells present in a myelodysplastic bone marrow. [117] The mutations occur principally in patients destined to progress to AML but can occur in patients who remain free of leukemia. Second, the mutations can be demonstrated in a significant fraction of the precursor lesions to colon carcinoma (i.e., adenomatous polyps). [118] In the murine skin carcinoma model, benign epitheliomas generated by the application of chemical carcinogens uniformly contain Ha- *ras*-1 mutations.[119] The epitheliomas may progress to invasive squamous carcinoma, or they may regress. Finally, transgenic mice bearing mutant *ras* genes are viable and develop normally but show a marked predisposition to the development of cancer.[120]

Although mutational activation in human tumors principally affects members of the *ras* family, several other candidate oncogenes have recently been described whose somatic mutations are involved, rarely, in pathogenesis. In addition, six distinct oncogenes bearing mutations have been isolated from animal tumors. Each of these oncogenes has a human counterpart, although human mutations have not yet been observed. The most prominent of this set is the *neu* oncogene (lately *her* or *erb*-b2), representing a transmembrane protein highly related to the EGF receptor. [121] This oncogene has been implicated in breast cancer.

Oncogene Amplification

The expression of a given gene can be augmented in a variety of ways. Under normal circumstances, the complex interaction of control sequences located near genes with DNA-binding proteins that function as transcriptional regulatory factors leads to properly timed production of mRNA in a tissue- or cell-cycle-specific manner. Any disorganization of the plan of expression in genes responsible for the regulation of cell proliferation can result in loss of growth control. The first described occurrence of inappropriately elevated proto-oncogene expression in humans revealed activation by the mechanism of gene amplification. In this process, errors of DNA replication, followed by large-scale somatic recombination, result in the appearance of a large tandem array of DNA sequences not previously present in the normal cell genome. The array represents an increase in the number of copies of genes that happen to be present in the amplified DNA segment of the affected cell. This increase can be as large as several thousand-fold.

Gene amplification in somatic cells was originally described for the dihydrofolate reductase gene, in which amplification led to methotrexate resistance. [122] In human tumors the consequence of proto-oncogene amplification is usually a large increase in the level of transcribed mRNA and a corresponding increase in proto-oncogene protein product. Unlike dihydrofolate reductase amplification, in which a mutant enzyme is often the target of amplification, the product of an amplified proto-oncogene is usually qualitatively unchanged. Amplification most often involves genes whose transcripts have short half-lives. Therefore, the net result of amplification is the prolonged presence of mRNA end product, especially at inappropriate points in the cell cycle. This leads to a disruption of growth control, since the product of the amplified gene, which would ordinarily be absent after a specified segment of the cell cycle passes, continues to provide the stimulus for cell DNA synthesis and/or cell division.

The discovery of proto-oncogene (and drug resistance gene) amplification provides an explanation for two of the most prominent changes observed in tumor cell karyotypes. Double minutes (bipolar chromatin bodies without centrioles) commonly occur in malignant cells. The other chromosome abnormality, known as the homogeneously staining region, appears when variable lengths of pale-staining chromatin are inserted into chromosomes. It is now recognized that these structures,

which are apparently interconvertible within a given cell, represent the locations of gene amplification. Therefore the amplification process can be so extensive that it results in grossly visible changes in chromosome structure.

The most prominent proto-oncogenes that undergo amplification in human tumors are members of the *myc* family. First observed in promyelocytic leukemia,[123] *myc* amplification has subsequently been documented in a broad range of cancers, including carcinomas of the lung, colon, and breast.[124] A consistent pattern of *myc* amplification in a number of tumor subtypes has come to be associated with a poor prognosis. For example, a particularly aggressive subset of small cell carcinoma of the lung that responds poorly to chemotherapy consistently demonstrates

amplification of one or another of the three *myc* genes.[125] Amplification of N-*myc* is a marker for poor prognosis in neuroblastoma.[126]

Another example of oncogene amplification with prognostic significance is c-*erb*-b2. Overexpression of the c-*erb*-b2 (*her/neu*) oncogene in breast cancer has been associated with a poor prognosis.[127] The overexpression occasionally results from gene amplification, although excessive transcription of the gene can be seen in the absence of such amplification. This observation is potentially of great prognostic value, since *erb*-b2 identifies individuals who are considered to be at low risk for recurrence on the basis of other criteria, such as node status.

We now know that the process of oncogene amplification requires abrogation of cellular functions that guard the integrity of genetic information. For example, amplification does not occur in normal cells challenged by drug selection. However, when the *TP53* gene is knocked out, amplification of several drug resistance genes can be observed following addition of the drugs to culture medium. The initial stages of the process involve double strand breaks that are not properly repaired as a consequence of p53 inactivation (see following discussion). This leads to multiple cycles of bridge-breakage-fusion that advance the amplification process.[128]

Oncogene Rearrangement

The most dramatic examples of proto-oncogene activation occur by genetic rearrangement, usually as a result of reciprocal chromosome translocations. These events are of particular pathogenetic significance in leukemias and lymphomas, for which specific translocations have been identified and analyzed in detail (see Chap. 50).

The significance of chromosome translocations, although long suspected to reflect the recruitment of genes important in carcinogenesis, was first demonstrated conclusively in human undifferentiated lymphoma and murine plasmacytoma.[129] [130] [131] In both instances the cellular proto-oncogene, *myc,* was translocated from its normal position (in humans, chromosome 8) to sites adjacent to or within the immunoglobulin heavy chain or Ig or Ig light chain constant region genes. The resulting human translocations were t(8;14), t(2;8), and t(8;22), respectively. The mechanisms responsible for abnormal *myc* rearrangements are poorly understood; perhaps they represent errors in the normal rearrangement process that results in functional immunoglobulin genes.

The c-*myc* gene consists of three exons. The first exon does not encode protein and is thought to be one of the elements involved in regulating the level and timing of c-*myc* expression. In most translocations this exon is truncated from the remaining two, which are then transferred to, say, the switch region of the heavy chain constant region genes. In the minority of translocations in which all three exons of the gene are translocated to an immunoglobulin gene locus, somatic mutations are often observed to occur in exon 1. However, the DNA sequence of the protein product, which is encoded in exons 2 and 3, is nearly always unaffected.[132] Therefore, the c-*myc* protein produced by a translocated c-*myc* gene is usually identical to that produced by the normal gene. Finally, it has been observed that c-*myc* transcription from the translocated gene is constitutive, if not always elevated. Transcription from the normal gene ceases in a tumor with a c-*myc* translocation (Fig. 49-5).

The picture that emerges from this set of observations, although not yet verified in significant details, is compelling. Moving a proto-oncogene away from resident influences that control the level and timing of transcription and into a locus that is actively expressed in a given state of differentiation (e.g., immunoglobulin genes in B lymphocytes) can result in oncogene activation and subsequent tumorigenesis. In the specific instance of c-*myc,* removal or mutational alteration of exon 1 seems critical to deregulation of transcription. Under circumstances in which the normal c-*myc* allele is silent, the translocated one continues to be expressed. This is an example of quantitative alteration of oncogene function.

Another prominent example of this type of activation is the

Figure 49-5 Translocation of the c-*myc* oncogene. **(A)** Many c-*myc* translocations result from breakage of c-*myc* within intron 1, in which a cryptic promoter (P) is located. The c-*myc* chromosome 8 fragment is then joined to a C_H gene switch region. This creates the 14q+ karyotypic anomaly noted in Burkitt lymphoma. **(B)** Translocation of C . Translocation to distal (rightward) C_H genes also occurs. **(C)** Transcription of the translocated c-*myc* gene ensues from the cryptic promoter (now without parentheses) in the direction of the arrow. The boxes indicate c-*myc* exons.

t(14;18) translocation of human follicular lymphoma.[133] Once again, the immunoglobulin heavy chain gene is the recipient of a chromosome fragment bearing an oncogene from another chromosome, this time the *bcl*-2 oncogene from the long arm of chromosome 18. As with c-*myc,* transcription of *bcl*-2 is inappropriately constitutive in tumor cells as a result of the translocation.
