to treatment with GTX plus antibiotics (study group) was compared to that of comparable patients given antibiotics alone and evaluated concurrently (control group). The design, size, and results of these seven studies are presented in Tables 137-2 and 137-3 . Three of the seven studies reported a significant overall benefit for GTX.[7] [8] [9] In two additional studies,[4] [6] overall success was not demonstrated for GTX, but certain subgroups of patients were found to benefit significantly. For example, in the first controlled study,[4] many patients received an inadequate dose of GTX by current standards, and overall success was not demonstrated. However, 100% of patients who received GTX on at least four occasions and 80% of those who received GTX on at least three occasions survived, compared with only a 30% survival among controls. In the other study that found partial benefit, no advantage for GTX could be demonstrated when all patients were analyzed. However, when the subgroup of patients with persistent bone marrow failure were analyzed separately, 75% of those receiving GTX responded favorably, compared with only 20% of controls. Thus, some measure of success for GTX was evident in five of the seven controlled studies. However, this success was counterbalanced by four studies that were negative in some respect, two totally[5] [10] and two partially negative.[4] [6]

An explanation of these inconsistent results is evident on critical analysis of the adequacy of GTX support (Table 137-3). Patients in the three successful trials received relatively high doses of PMNs (generally 1.7 × 10^{10} /day).[7] [8] [9] Moreover, donors were selected to be both erythrocyte and leukocyte compatible. By contrast, the four controlled studies yielding negative results can legitimately be criticized in light of current technology. Data for three [4] [5] [6] of the four negative studies were collected before 1977, when the PMNs transfused were clearly inferior, in both quality and quantity, to those available today. Two of the four studies with negative conclusions used PMNs collected by filtration leukapheresis for at least some patients. [4] [6] It is now known that such PMNs are defective, and they are no longer transfused. Although three of the four negative studies used PMNs collected by centrifugation leukapheresis, [5] [6] [10] the dose was extremely low (0.410.56 × 10^{10} per concentrate). This daily dose is approximately one-tenth the dose that could be transfused currently, and it is not surprising that GTX were unsuccessful when given in such a grossly inadequate fashion. As another factor, investigators in two of the four negative studies [4] [10] made no provision for the possibility of leukocyte alloimmunization and selected donors solely on the basis of erythrocyte compatibility. Finally, control subjects responded reasonably well to antibiotics alone in three of the four negative studies, [4] [6] [10] suggesting that some patients have no apparent need for additional therapeutic modalities.

The preceding analysis is qualitative and suffers from the imprecision of combining data from studies that, although controlled, are not truly comparable (i.e., nonuniformity among

control subjects, patient clinical status, GTX dose, compatibility, etc.). Recently, data from the seven controlled GTX trials were analyzed quantitatively by formal meta-analysis,[11] and many of the impressions of the preceding qualitative analysis were confirmedspecifically, that the dose of PMNs transfused and the survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of the studies. In clinical settings in which the survival rate of nontransfused control subjects was low, study subjects benefited from receiving adequate doses of GTX. The authors concluded that severely neutropenic patients with infections known to carry a high mortality should be considered for GTX given in an adequate dose. [11]

The most frequent infection for which GTX were considered previously was bacterial sepsis, and many patients treated with GTX for septicemia have been reported (Table 137-1 (Table Not Available)). Most neutropenic patients with bacterial sepsis, who experience bone marrow recovery during the early days of infections, will respond to antibiotics alone.[2] [3] Most patients with newly diagnosed acute leukemia and in whom induction chemotherapy is successful fit into this category and will not need GTX. By contrast, septic patients with persistent neutropenia due to continuing marrow failure may benefit from GTX added to antibiotic therapy. [2] Examples are patients in the later stages of leukemia undergoing investigational chemotherapy or recipients of marrow grafts, in whom hematopoietic recovery may be delayed for >23 weeks.

Regarding the other infections listed in Table 137-1 (Table Not Available) , information published to date is insufficient to determine definitively whether therapeutic GTX offer benefits over those of antibiotics alone. Currently, yeast and fungal infections pose difficult problems that deserve additional discussion. Occasional case reports, experimental studies in animals, and experience in treating patients with chronic granulomatous disease support the success of GTX in some patients with yeast and fungal infections. In addition, an uncontrolled study of 15 patients [12] found a 60% favorable response to transfusion of granulocytes collected from G-CSF-stimulated donors when the granulocytes were given to neutropenic patients with fungal infectionsa success rate higher than expected from the usual clinical experience. In contrast, a large clinical study[13] comparing infected bone marrow transplant patients given GTX ($n = 50$) to those treated without GTX ($n = 37$) found no benefit for GTX in treating fungal and yeast infections. This study was not designed to provide definitive answers. It was a retrospective review. Patients were not randomly selected for therapy; instead, the decision to use GTX or not was determined according to individual physician preference, making it impossible to exclude selection bias. Neither patient characteristics nor the types of infection being treated were evenly distributed between the GTX group and the patients not given GTX. The dose of PMNs transfused was known for only 15% of the GTX administered and likely was quite low because of the collection techniques used. [13]

To determine the optimal role for therapeutic GTX, individual physicians must survey the outcome of life-threatening infections with bacteria, yeast, and fungi in their own neutropenic patients. If infections in these patients respond promptly to antibiotics alone and survival approaches 100%, GTX are unnecessary and should not be used, as the benefits would not outweigh the potential risks. However, if significant numbers of infected neutropenic patients fail to respond to antibiotics alone, the addition of GTX should be considered, along with other modifications of therapy (e.g., selection of different antibiotics, closer monitoring of antibiotic blood levels, intravenous immunoglobulin [IVIG] therapy, G-CSF or other recombinant growth factors, and immune-modulating agents). Once the decision to use therapeutic GTX has been made, they must be given effectively, and recommendations for PMN collection are discussed later in this chapter. A daily infusion of approximately 48×10^{10} PMNs should be given to patients with persistent neutropenia ($<0.5 \times 10^9$ /L blood PMNs) and infections that have failed to respond to a reasonable course (48 hours) of combination antimicrobial agents. GTX are continued until the infection has resolved or until the blood PMN count is maintained at $>1.0 \times 10^9$ /L. This end point may be difficult to detect because transfused PMNs, when collected from G-CSF-stimulated donors and transfused at doses of 48×10^{10} PMNsmay elevate the recipients blood PMN count to 13×10^9 /L for several hours post infusion. Thus, accurately distinguishing transfused PMNs from marrow recovery is challenging and must be based on a sustained increase in blood PMN counts.

THERAPEUTIC GRANULOCYTE TRANSFUSIONS IN SPECIAL CIRCUMSTANCES

Most patients with congenital disorders of PMN dysfunction have adequate numbers of blood PMNs, but they are susceptible to serious infections because their PMNs fail to kill pathogenic microorganisms. Patients with severe forms of PMN dysfunction are relatively rare, and few definitive studies have been reported to establish the efficacy of therapeutic GTX in their management. Thus, firm recommendations about the use of GTX to treat patients cannot be made. However, several patients with chronic granulomatous disease complicated by progressive life-threatening fungal infections have been reported to benefit. [14] [15] [16] [17] [18] [19] [20] [21] [22] Because of the possibility of alloimmunization and transfusion-transmitted infections, therapeutic GTX are recommended only for progressive infections that cannot be controlled with antimicrobial drugs. Because of lifetime problems with infections, prophylactic GTX are impractical.

Neonates (infants within the first month of life) are another

group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia. [23] [24] Neutropenia must be viewed differently in neonates than in older patients, in whom GTX are considered usually when the blood PMN count falls to $<0.5 \times 10^9$ /L. By contrast, absolute blood PMN counts as high as 3.0×10^9 /L might prompt consideration of GTX in neonates. [20] [21] The blood neutrophil count varies greatly during the first days of life, and a transient neutrophilia with absolute PMN counts of 1025×10^9 /L is commonly seen in healthy neonates. Although not completely specific, sepsis should be suspected in any sick neonate with an absolute PMN count of $<3.0 \times 10^9$ /L during the first week of life. The mechanism of neutropenia cannot always be identified, but in some infants a marked decrease in the marrow PMN storage pool can be demonstrated. For example, these forms (metamyelocytes and segmented PMNs) account for 2665% of all nucleated cells in normal marrow, but in some neonates with sepsis this value will be <10% of nucleated marrow cells.

Several investigators have reported using GTX to treat neonatal sepsis. Four [25] [26] [27] [28] of the six controlled studies[25] [26] [27] [28] [29] [30] demonstrated a significant benefit of GTX (Table 137-4). However, these studies can be criticized for small size, faulty design, and heterogeneity of both patients and quality of GTX. Thus, the use of GTX for neonatal sepsis remains controversial and, as discussed in the following section, alternative therapies must be considered.

ALTERNATIVE OR ADDITIVE MEASURES TO THERAPEUTIC GRANULOCYTE TRANSFUSIONS

Neonates and older patients with severe neutropenia, particularly those undergoing chemotherapy or bone marrow transplantation, exhibit a variety of abnormalities in body defense mechanisms, not all of which can be corrected by GTX. Consequently, infections that occur in these patients do not always respond to GTX, and a number of additional therapies have been evaluated. Two that appear to hold promise are the use of recombinant myeloid growth factors and IVIG.

Recombinant myeloid growth factors such as G-CSF and granuloctye-macrophage colony-stimulating factor (GM-CSF) are glycoprotein cytokines that enhance the production, differentiation, and function of myeloid cells. [30] In neonates, studies of cytokine production have yielded conflicting results, with investigators reporting values that are higher than, equal to, or lower than adult values. [32] [33] [34] [35] [36] [37] [38] [39] Generally, G-CSF and GM-CSF levels are lower in preterm than in term neonates, and the ability of preterm leukocytes to further increase production when stimulated is diminished. Plasma G-CSF levels were reported to be markedly elevated in neonates with infection, [33] [34] but other investigators found G-CSF mRNA expression and protein production to be decreased in neonatal leukocytes, particularly in activated cells. [35] [36] In a controlled study, [40] 42 neonates with presumed bacterial sepsis were randomized to receive three doses of either G-CSF or placebo. Therapy with G-CSF significantly increased the marrow PMN storage pool, blood PMNs, and expression of PMN membrane C3bi. [40] In a similar study of GM-CSF, [41] 20 preterm neonates were randomized within 72 hours of birth to receive either GM-CSF or placebo for 7 days; GM-CSF increased marrow PMNs, blood PMNs, and C3bi receptor expression. Unfortunately, neither the G-CSF nor the GM-CSF studies reported sufficient information to assess their efficacy in the prevention or treatment of neonatal sepsis. However, two randomized clinical trials have been conducted, more recently, to assess the efficacy of G-CSF and GM-CSF. Neither has demonstrated clear clinical benefit. In the G-CSF trial, 20 infants with neutropenia and sepsis received either G-CSF (10 g/kg/day) or placebo for three days. [42] Recognizing that the number of study subjects was quite small, G-CSF did not significantly improve severity of illness, morbidity, or mortality. In a preliminary report of GM-CSF, [43] preterm infants received either GM-CSF (8 g/kg/day) or placebo for the first 28 days of life in an attempt to reduce the incidence of infections. Although GM-CSF was well tolerated and significantly increased blood leukocyte counts, it did not significantly decrease infection rates.

In older children and adult patients, both G-CSF and GM-CSF have been used to accelerate marrow recovery following chemotherapy and to successfully diminish the rate of acquiring infections and the need for prolonged hospitalization. [31] In contrast to this success in preventing neutropenic infections, the role of G-CSF and GM-CSF in treating already established infections is not as firmly documented. Regardless, these growth factors frequently are given to patients with neutropenia and severe infections, and it seems reasonable to consider adding GTX to the treatment of severe bacterial, yeast, or fungal infections that are progressing in neutropenic patients despite the use of appropriate antibiotics plus recombinant myeloid growth factors.

The use of IVIG, either to prevent or to treat neonatal sepsis, has appeal because this therapy may correct abnormalities of both humoral immunity and neutrophil function. In studies of experimental infections, IVIG proved beneficial by increasing opsonic activity and by improving PMN kinetics in animals. [44] [45] [46] Although the precise role of IVIG in the management of human infants is incompletely defined, this therapy has been given (with mixed results) both to prevent and to treat infections. Most prophylactic studies evaluating IVIG to prevent infections have found little or only modest benefit, [47] with a few studies suggesting true benefit. [48] [49] [50] In contrast, several therapeutic studies reported benefit from adding IVIG to antibiotics during the treatment of neonatal infections. [47] However, the data remain insufficient to justify the routine use of IVIG as standard therapy to prevent and/or treat infections in preterm infants. Moreover, caution is warranted before IVIG is broadly applied as treatment for neonatal sepsis. In high doses, IVIG has been demonstrated to impair body defense mechanisms and to increase susceptibility to fatal infections. [51] [52] [53] IVIG has great appeal because of the ease with which it can be prescribed, its apparent benefits to multiple body defense systems, and, finally, its safety in terms of failing to transmit donor infectious diseases. However, the genuine benefits and risks of IVIG must be carefully examined before it is prescribed with impunity.

Thus, the role of GTX, IVIG, and recombinant myeloid growth factors in the treatment of neonatal infections is unclear, and none of these approaches can be recommended as a standard of routine neonatal practice. Moreover, in many studies,

standard supportive care with antibiotics seems to provide adequate therapy. Each institution must assess its own experience with neonatal sepsis and local management. If nearly all infants survive without apparent long-term morbidity, GTX or alternative therapies are unnecessary, and attention should be focused on prompt diagnosis and optimal antibiotic therapy. If the outcome of standard supportive therapy is less than optimal, additional therapies such as GTX must be explored.

PROPHYLACTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS

Based on existing reports, prophylactic GTX are of marginal value. In 12 reports, [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] benefits were few, while risks and expenses were substantial. However, partial success was demonstrated when certain subgroups of patients were examined separately. Some measure of success was found in seven of 12 studies; the remaining five studies failed to show a benefit for prophylactic GTX. [61] [62] [63] [64] [65] (R.M. Cooper, personal communication). In none of these five negative studies were large numbers of PMNs obtained from matched donors and transfused daily. Thus, in a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, at least in part, by inadequate transfusions.

A major concern raised by prophylactic GTX has been that of transfusion-related risks, a concern heightened because of the marginal benefits of prophylactic GTX. In the therapeutic setting, where GTX efficacy is more apparent, risks are more acceptable. Leukocyte alloimmunization poses a risk of special importance for GTX therapy. Although reports are controversial, it seems likely that most patients receiving multiple GTX from random donors will develop antileukocyte antibodies. Antileukocyte antibodies mediate transfusion reactions, have an adverse effect on post-transfusion increments in blood PMN counts, alter the circulating kinetics of infused PMNs, and decrease the antimicrobial effects of GTX. [66] [67] [68] [69] Many of the other risks of GTX have been greatly diminished by current practices, such as -irradiation to prevent graft-versus-host disease and the use of cytomegalovirus-seronegative units to eliminate cytomegalovirus transmission.

Clearly, prophylactic GTX cannot be recommended at this time to treat patients with acute leukemia undergoing first remission induction or consolidation therapy. However, consideration should be given to the use of prophylactic GTX in bone marrow transplant recipients. Progressive infections, particularly with yeast and fungi, occur frequently in bone marrow transplant recipients who are neutropenic, exhibit PMN dysfunction, and manifest defective cellular and humoral immunity for months following transplantation. Altered immunity is particularly profound when marrow is T-lymphocyte depleted to diminish graft-versus-host disease. Although all types of infection pose a threat, 10% of 1,186 marrow transplant patients developed a noncandidal fungal infection, with only 17% of infected patients surviving. [70] Thus, the possible role of GTX, collected by modern techniques from G-CSF-stimulated donors, needs to be reexamined as a means to approach this important clinical problem.

Autologous bone marrow transplantation has been supplanted by transfusion of peripheral blood hematopoietic/immunologic progenitor cells collected following cytokine (usually G-CSF) stimulation. This technique is being used increasingly in the allogeneic setting because it is convenient, economical, and leads to relatively rapid engraftment.[71] Recovery to a blood PMN count of 0.5×10^9 /L occurs within 614 days after transfusion of progenitor cells. In some patients, the period of severe neutropenia <0.2×10^9 /L) persists only a few days, particularly when G-CSF is given to the patients following myeloablation. Thus, the complete elimination of severe neutropenia

AUTHORS APPROACH TO THERAPEUTIC GTX

Indicated for severe bacterial, yeast, or fungal infection in a neutropenic patient (<0.5×10^9 PMN/L blood) when the infection progresses despite optimal antimicrobial therapy.
Collect PMNs (48×10^{10}) from allogeneic blood donors, as follows:

1. Stimulate neutrophilia by giving the donor 300 g of G-CSF subcutaneously 12 hours before beginning leukapheresis, plus three doses of oral prednisone, 20 mg, taken approximately 18, 12, and 4 hours before beginning leukapheresis.
2. Process 10 L of donor blood using a continuous-flow blood separator with citrated hydroxyethyl starch solution infused throughout the collection.

Transfuse one granulocyte concentrate (48×10^{10} PMNs) daily until either bone marrow recovery (blood PMNs >1.0×10^9 /L without GTX) or clinical resolution of infection.

using this transplantation approach plus prophylactic GTX is a distinct possibility that deserves careful study.

Allogeneic peripheral blood progenitor cell donors receive G-CSF daily for 47 days, with leukapheresis usually performed on days 57 to collect sufficient progenitor cells for transfusion. Donor blood PMN counts increase, often to >50×10^9 /L, with G-CSF, and extraordinarily large doses of PMNs could be collected on the days following progenitor cell leukapheresis. Obviously, systematic studies are needed to define optimal G-CSF dose and to schedule the proper timing of leukapheresis procedures, first to collect progenitor cells for transplantation and then to collect PMNs for GTX; to examine the coordination of myeloablation, progenitor cell collection, storage, and transfusion, and subsequent PMN collection and transfusion; and to identify potential risks and inconvenience to the donor of prolonged G-CSF stimulation and multiple leukapheresis procedures. Moreover, the efficacy of prophylactic GTX used as part of this progenitor cell then PMN transfusion approach versus peripheral blood progenitor cell transfusion followed by cytokine therapy of the patient without GTX must be investigated by properly designed randomized trials.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PREPARATION AND STORAGE OF NEUTROPHIL CONCENTRATES

To ensure adequate numbers and quality of PMNs, granulocyte concentrates must be collected from stimulated donors by automated leukapheresis using an erythrocyte sedimenting agent such as hydroxyethyl starch.[72] A major limitation of GTX efficacy has been the inability to transfuse adequate numbers of perfectly functioning PMNs. Under the stress of a severe bacterial infection, the marrow of an otherwise healthy adult will produce between 10^{11} and 10^{12} PMNs in 24 hours. Granulocyte concentrates collected from healthy donors who are not stimulated with corticosteroids or G-CSF will contain between 0.2 and 0.8 × 10^{10} PMNsabout 1% of a healthy marrows output. Hence, donor stimulation is mandatory to achieve even a hope of a reasonable PMN dose per GTX. Donor stimulation with properly timed corticosteroids (4 hours before leukapheresis) will increase the yield to about 2 × 10^{10} PMNs.[73] Stimulation with G-CSF alone or in combination with corticosteroids will produce higher but variable PMN yields, depending on G-CSF dose and schedule of administration. Yields of 48 × 10^{10} PMNs

are achieved regularly, and post-transfusion blood PMN counts frequently increase to 13 × 10^{9} /L, with PMNs detected in the recipients bloodstream for several hours following GTX.[74] [75] [76] Thus, PMN donors are optimally stimulated using G-CSF plus corticosteroids, with the dose and schedule best determined by local needs. [75]

Granulocyte concentrates should be transfused as soon as possible after collection because PMN functions begin to deteriorate almost immediately. [77] [78] Some delay between collection and transfusion is inevitable, and granulocyte concentrates are usually stored briefly at 22°C, with little or no agitation. Lane et al. [78] have published a number of reports on the properties of PMNs collected for transfusion, and aberrations of nearly every function become evident within 2472 hours. It is highly desirable to transfuse granulocyte concentrates within 6 hours of collection; they should not be given if >24 hours old.

Chapter 138 - Transfusion of Plasma Derivatives: Fresh-Frozen Plasma, Cryoprecipitate, Albumin, and Immunoglobulins

Silvana Z. Bucur
Eugene M. Berkman
Christopher D. Hillyer

INTRODUCTION

Plasma and its derivatives represent a valuable resource, but the risk of infectious disease transmission, although rare, and other adverse effects mandate their appropriate use. The increased use of plasma and plasma derivatives has led to a decline in the use and availability of whole blood. Plasma can be separated from packed red cells (PRBC) through centrifugation of whole blood at the time of collection, or plasma can be collected by apheresis as a single product or as a byproduct of platelet apheresis or red blood cell apheresis. Plasma is further processed into its derivatives through the cold ethanol fractionation (method of Cohn). [1] In this chapter, the features and uses of fresh-frozen plasma (FFP), cryoprecipitate, albumin, and intravenous (IVIg) and intramuscular immunoglobulins are discussed. The use of plasma-derived clotting factor concentrates for therapy of specific congenital clotting factor deficiencies is discussed in Chapter 140 .

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

FRESH-FROZEN PLASMA

Plasma is the fluid compartment of blood and consists of 90% water, 7% protein and colloids, and 23% nutrients, crystalloids, hormones, and vitamins. The protein fraction contains the soluble clotting factors, the constituents for which transfusion of plasma is most often required.

Plasma frozen at 18°C or colder within 6 hours of donation is labeled FFP. This product may be stored up to 1 year before use, at which time it is thawed over 2030 minutes. The activities of the labile coagulation factors (V and VIII) decrease after thawing but remain adequate for at least 24 hours. Plasma that is not immediately frozen as FFP becomes either liquid plasma (stored at 16°C) or source plasma (stored at 18°C or colder). These products are used for the preparation of plasma derivatives: albumin, clotting factor concentrates, and immunoglobulin preparations. When FFP is thawed at 4°C, a precipitate forms that is separated by centrifugation; the

supernantant is decanted. These are termed cryoprecipitate and cryo-poor-supernatant, respectively. Their use is discussed later in this chapter.

Solvent Detergent-Treated Plasma

Recently, the Food and Drug Administration (FDA) approved the clinical use of a new plasma product, solvent detergent (SD) plasma. SD plasma is a pooled product (2,500 donor units per pool) and subjected to solvent detergent treatment, a process combining organic solvent tri(n-butyl)phosphate with nonionic detergent, Triton X-100. The SD process inactivates lipid-enveloped viruses, including human immunodeficiency virus (HIV) type 1 and 2, hepatitis B virus (HBV), hepatitis C virus (HCV), human T-cell lymphotropic virus (HTLV) type 1 and 2, hepatitis G virus (HGV), vesicular stomatitis virus, Sindbis virus, and Sendai virus, and preserves the structural and functional integrity of selected plasma proteins. It does not, however, inactivate nonenveloped viruses, particularly parvovirus B19 and hepatitis A virus (HAV), or the causative agents of various encephalopathies, or Creutzfeldt-Jakob disease. [1A] [1B] [1C] [1D] Although the transfusion-related transmission of Creutzfeldt-Jakob disease is only a theoretical one (no cases have been reported), the increased prevalence of parvovirus B19 and HAV make transmission by transfusion of pooled blood components a real concern. [1E] [1F] [1G] Unlike other factor concentrates and FFP, pooled SD plasma contains significant amounts of neutralizing antibody to both parvovirus B19 and HAV, which have protective value. [1H] [1I] Although the indications for SD plasma are similar to those for FFP, the per-unit cost of SD plasma is much greater than that of FFP.

Indications

The indications for the use of FFP, the clinical conditions for which FFP administration is not indicated, and investigational uses are listed in Table 138-1 . Audits of transfusion practices have consistently demonstrated that FFP use is inappropriately high. [2] Specifically, FFP should not be used (1) to reconstitute whole blood by coadministration with red blood cells (RBCs), (2) as a volume expander, or (3) as a source of nutrients. Appropriate uses are described in detail in the following sections.

TABLE 138-1 -- Administration of Fresh-Frozen Plasma

Indicated
Multiple acquired coagulation factor deficiency [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16]
Liver disease
Massive transfusion
Disseminated intravascular coagulation
Rapid reversal of warfarin effect
Plasma infusion or exchange for thrombotic thrombocytic purpura, hemolytic uremic syndrome, syndrome of hemolysis, elevated liver enzymes, and low platelets or Refsums disease[17] [18] [19] [20] [21]
Congenital coagulation defects (see Chap. 140)[a]
C1-esterase inhibitor deficiency[a] acute episodes and prophylaxis of angioedema [22] [23]
Investigational
Meningococcal sepsis[24] [25]
Acute renal failure in the context of multiorgan failure [26]
Not indicated
Immunodeficiency
Burns
Wound healing
Reconstitution of packed red blood cells
Volume expansion
Source of nutrients

[a]Fresh-frozen plasma is used in the absence of specific factor concentrate.

Liver Disease and Transplantations

Patients with severe liver disease may have low levels of the vitamin K-dependent clotting factors (II, VII, IX, and X) (see Chap. 115). These patients develop a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). In addition, the thrombin time (TT) may be prolonged, fibrin split products may be elevated, and in later stages the fibrinogen level decreases. Hemorrhage, most often secondary to an anatomic lesion, may be complicated by the coagulopathy represented by these abnormalities.

Infusion of FFP is indicated during severe bleeding if the coagulation test results are abnormal. In the absence of anatomic lesions, bleeding does not usually occur until the PT is >1618 seconds or the PTT is >5560 seconds. FFP is not recommended prophylactically before a surgical challenge or liver biopsy unless these values are exceeded.[3] In fact, the PT and PTT are poor predictors of surgical bleeding, and mild abnormalities in these coagulation tests may be impossible to correct even with infusion of large quantities of FFP. [4] [5] Orthotopic liver transplantation complicated by pre-existing severe liver disease, lack of clotting factor synthesis during the anhepatic stage, massive PRBC transfusion, and disseminated intravascular coagulation (DIC) may require large volumes of FFP. [6] Transfusion should be guided by clinical assessment of bleeding, coagulation test results, and thromboelastographic changes. [7] [8]

Massive Transfusion

The administration of FFP to patients receiving large quantities of PRBC (>1 blood volume in 24 hours) is often recommended because of a dilutional coagulopathy arising from blood replacement with PRBC and crystalloid solutions, both of which lack coagulation factors. Studies addressing the use of FFP in massive transfusion have yielded confusing and conflicting results. [9] [10] Dilutional thrombocytopenia may also complicate the coagulopathy in these patients. [11]

In general, FFP transfusions are of little value in nonbleeding patients who have received <610 units of PRBC. In some patients, however, shock associated with DIC and dilutional coagulopathy may occur, necessitating FFP. [12] While several studies have demonstrated the ineffectiveness of routine FFP infusions in patients receiving >10 units of PRBC within 24 hours, many physicians still opt to transfuse FFP in the face of continued bleeding. It is far more effective to use FFP to replace depleted clotting factors reflected by abnormal laboratory tests than to use predetermined formulations (e.g., 1 unit of FFP for every 5 units of PRBC transfused). [13]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation may be secondary to sepsis, liver disease, hypotension, surgery-associated hypoperfusion, trauma, obstetric complications, leukemia (usually promyelocytic), or underlying malignancy (see Chap. 117). Successful treatment of the underlying cause is paramount. Patients with DIC and bleeding should be given FFP in amounts sufficient to correct or ameliorate the hemorrhagic diathesis, although in patients with severe liver disease, bleeding, and DIC, FFP infusions in any amount often fail to normalize the PT and PTT. [14]

Rapid Reversal of Warfarin Effect

Warfarin inhibits the hepatic synthesis of vitamin K-dependent clotting factors (II, VII, IX, and X) by blocking the recovery of the form of vitamin K that is active in the carboxylation of these proteins (see Chap. 115). Thus, warfarin therapy induces functional deficiencies of these factors, which correct within 48 hours after the discontinuation of warfarin if diet and vitamin

K absorption are normal. Vitamin K administration corrects the coagulopathy in 1218 hours. [15] In patients anticoagulated with warfarin who have active bleeding, require emergency surgery, or have serious trauma, the deficient clotting factors can be immediately provided by FFP transfusion. To replenish the vitamin K-dependent coagulation factors such that adequate hemostasis (normalized PT) is established, a large volume of FFP may be required. Thus, when volume overload is a concern, prothrombin complex concentrates may be used to reverse the warfarin effect. In patients without bleeding but with significantly prolonged PTs, the potential danger of significant hemorrhage is often overemphasized and must be weighed against the risks of FFP infusion. [16]

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

In some patients with thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), or the syndrome of hemolysis, elevated liver enzymes, and low platelets, FFP transfusion or exchange has induced clinical remission. [17] [18] [19] Plasmapheresis may be preferred in patients who are at risk for fluid overload, such as those with renal or cardiac impairment (see Chap. 128). Several mechanisms through which FFP exerts its beneficial effects have been suggested: FFP may restore prostaglandin I_2 (PGI_2), it may inhibit the agglutinating activity of the abnormal plasma, or it may inhibit the release of large-molecular-weight von Willebrand factor (vWF) multimers or restore their normal processing in the circulation. Some authorities have suggested the use of cryo-poor-supernatant for refractory TTP. [20] [21]

Dosage

One unit of FFP derived from a unit of whole blood contains 200280 ml. When plasma is collected by apheresis, as much as 800 ml can be obtained from one individual (jumbo plasma units). On average, there are 0.71 unit/ml of activity of each coagulation factor per ml of FFP and 12 mg/ml fibrinogen. The appropriate dose of FFP may be estimated from the plasma volume, the desired increment of factor activity, and the expected half-life of the factor being replaced. Alternatively, the FFP dosage may be estimated as 810 ml/kg, and should be ordered as the number of milliliters to be infused. [27] The frequency of administration depends on the clinical response to the infusion and normalization of laboratory parameters.

Compatibility and Side Effects

Fresh-frozen plasma is screened for unexpected RBC antibodies and should be ABO-type compatible. Tests for serologic compatibility are not performed before administration. The Rh(D) type is matched in only some parts of the United States because immunization to Rh(D) antigen has rarely been reported as a result of transfusion of Rh(D)-positive plasma to Rh(D)-negative individuals. [28] Plasma from multiparous women should not be used. Hemolytic reactions due to infusion of an undetected antibody directed toward recipient RBC antigens have been reported, but these cases are extremely rare. [29] Alloimmunization to RBC antigens may occur with FFP transfusion, but this is also rare. [30]

Fever, chills, and allergic reactions may occur and are treated symptomatically. Occasionally, severe allergic reactions with symptoms of bronchoconstriction or noncardiogenic pulmonary edema are seen. These cases are thought to be due to antibodies present in donor plasma that react with recipient leukocytes. Anaphylactic reactions may occur after infusion of plasma (containing IgA) into patients with IgA deficiency and antibodies to IgA. [31] For such patients, it is possible to obtain IgA-deficient plasma from donors in the national registry.

Transmission of infectious disease by FFP has been significantly reduced, but the risk is not yet completely eliminated. FFP is not thought to transmit the cell-associated cytomegalovirus. [32]

CRYOPRECIPITATE

Cryoprecipitate is prepared from 1 unit of FFP thawed at 4°C. The precipitate is then refrozen in 10 to 15 ml of plasma and stored at 18°C or colder for 1 year. Cryoprecipitate contains 80100 units of factor VIII, 100250 mg of fibrinogen, and 5060 mg of fibronectin. Initially the plasma also contains 4070% of vWF. Anti-A and anti-B antibodies may also be present.

For clinical purposes, cryoprecipitate should be considered the blood product most rich in factor VIII, vWF, XIII, fibrinogen, and fibronectin. Cryoprecipitate is used predominately to treat bleeding associated with fibrinogen or factor XIII deficiency states, occasionally in vWF deficiency, and only rarely in factor VIII deficiency. Congenital deficiencies of these factors are discussed in Chapters 109 , 111 , and 114 .

Indications

The indications and clinical conditions for which the administration of cryoprecipitate is not indicated are listed in Table 138-2 . Specific indications and inappropriate uses are discussed in the following sections.

Fibrinogen Deficiency

Fibrinogen deficiency is the primary indication for cryoprecipitate transfusion. It may be in the form of congenital afibrinogenemia (rare) or dysfibrinogenemia due to severe liver disease and DIC.[41] These patients often have concomitant decreases in clotting factor levels and require the coadministration of FFP. It is important to obtain fibrinogen measurements because levels <100 mg/dl cause prolongation of both the PT and PTT despite adequate clotting factor replacement. Very low levels of fibrinogen occur during liver transplantation, where transfusion support with cryoprecipitate is vital. [6] [16]

von Willebrand Disease

von Willebrand factor, required for platelet binding to disrupted vascular endothelium, is low or dysfunctional in von Willebrand disease. DDAVP (desmopressin acetate[1-deamino, 8-D-arginine], vasopressin) remains the treatment of choice, although severe bleeding may require cryoprecipitate. Recent

TABLE 138-2 -- Administration of Cryoprecipitate

Indicated
Some patients with hemophilia A or von Willebrands disease [34]
Fibrinogen deficiency
Congenital afibrinogenemia
Dysfibrinogenemia[33]
Factor XIII deficiency[a]
Fibrin glue[35] [36] [37] [38] [39] [40] [41] [42] [43] ,[b]
Renal stone removal[48]
Investigational
Wound healing (as a source of fibronectin) [49]
Not indicated
Uremic bleeding
Sepsis (postoperative)

[a]Cryoprecipitate is used in the absence of specific factor concentrate.
[b]This product is not FDA-approved in the United States.

advances in clotting factor concentrates and viral inactivation methods may make the use of wet cryoprecipitate obsolete. [34]

Fibrin Glue

Fibrin glue results from the mixture of a fibrinogen source (either from FFP, platelet-rich plasma, or heterologous [90%] or more recently autologous cryoprecipitate) with bovine thrombin. The enhanced local hemostasis achieved by fibrin glue is through the action of thrombin on fibrinogen. As adjunct therapy, this product has been used successfullly in cardiac surgery to control multiple small blood leaks due to adhesions, [35] and to reduce blood loss and the factor concentrate requirement in patients with von Willebrands disease undergoing various surgical procedures. [36] Both autologous and heterologous fibrin clot preparations have been used in meniscal tear repair,[37] in establishing patency of anastomosis in vasovasostomy,[38] in the treatment of postoperative neonatal chylothorax,[39] and in other surgical procedures.[40] [41] [42] In otologic and neurotologic procedures, autologous fibrin glue is extensively used (e.g., ensuring a watertight seal in wound closure, securing prosthetic devices during reconstruction procedures, stabilizing fascial and dural homografts, and in nerve anastamosis [43]). The infectious risks (e.g., human immunodeficiency virus [HIV], hepatitis) associated with the use of heterologous fibrin glue are eliminated by replacement with the autologous source. Other complications related to bovine thrombin (anaphylaxis, formation of antibodies to factor V) or related to the activation of coagulation have been reported. [44]

Uremic Bleeding

Abnormal bleeding is a common complication of uremia. In 1980, a single study led to the widespread but temporary use of cryoprecipitate for the treatment of uremic

bleeding.[45] No data currently support this use.[46] Cryoprecipitate should not be used in the routine management of uremic bleeding, but its use may be considered if other therapeutic interventions have failed.[47]

Dosage

The dosage of cryoprecipitate is calculated on the basis of the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The difficulty in determining the correct amount to administer is due primarily to variability in the fibrinogen content of cryoprecipitate, secondary to variable storage volume and pooling methods used. The goal of therapy should be to maintain the measured fibrinogen at >100 ml/dl. This can usually be accomplished by the transfusion of 24 units/10 kg if the fibrinogen content of the concentrate is low and by 12 units/10 kg if the fibrinogen content is high.

Compatibility and Side Effects

Because cryoprecipitate can contain anti-A and/or anti-B antibody, infused units should be ABO compatible. The risks of fevers, chills, allergic reactions, and infectious disease transmission are similar to those of FFP.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ALBUMIN

Albumin, an important plasma protein, contributes primarily to the maintenance of plasma colloid oncotic pressure. It is clinically available in three forms: a 5% solution in saline, a 25% solution in distilled water, and purified protein fraction (PPF), which is 5% total protein (88% albumin, 12% globulins). These products are heat-treated and unable to transmit viruses. The high cost, periodic shortages, and lack of efficacy in some clinical situations have led to increased scrutiny over the appropriate use of this important plasma derivative. [50] [51] In many clinical situations, the use of albumin remains controversial and is the subject of continued debate. We believe that albumin is extensively overused. Thus, in Table 138-3 , we have listed our preferences for indications, possible indications, investigational uses, and clinical situations in which we believe albumin administration is not indicated. Under common usages, we have listed clinical situations in which albumin is frequently used.

Indications

A decrease in measured plasma albumin is found in many situations and is often not a clinical concern. Mild edema due to hypoalbuminemia does not require albumin therapy. However, inadequate synthesis, as seen in severe liver disease and severe malnutrition, or excessive loss, as seen in nephrotic syndrome and protein-losing enteropathy, can lead to significant hypoalbuminemia with intravascular volume depletion, anasarca, ascites, and pleural effusions. Historically, albumin has had a broader use (i.e., nutritional support, correction of hypoalbuminemia, volume replacement), but recent studies support its benefit in fewer situations, including nephrotic syndrome resistant to potent diuretic therapy, following large-volume paracentesis, and in ovarian hyperstimulation

TABLE 138-3 -- Administration of Albumin

Indicated
After large-volume paracentesis[62] [63] [64] [65]
Nephrotic syndrome resistant to potent diuretics[66] [67]
Ovarian hyperstimulation syndrome[69] [70] [71] [72]
Volume/fluid replacement in plasmapheresis[116]
Possibly indicated
Adult respiratory distress syndrome
Cardiopulmonary bypass pump priming[54] [55]
Fluid resuscitation in shock/sepsis/burns [56] [57] [58]
Neonatal kernicterus
To reduce enteral feeding intolerance[117]
Not indicated
Correction of measured hypoalbuminemia or hypoproteinemia [56]
Nutritional deficiency, total parenteral nutrition [118] [119]
Pre-eclampsia[120]
Red blood cell suspension
Simple volume expansion (surgery, burns)[57] [58]
Wound healing
Investigational
Cadaveric renal transplantation[121]
Cerebral ischemia[122] [123]
Stroke[124]
Common usages
Serum albumin <20 g/dl
Nephrotic syndrome, proteinuria and hypoalbuminemia
Labile pulmonary, cardiovascular status
Cardiopulmonary bypass, pump priming
Extensive burns
Plasma exchange
Hypotension
Liver disease, hypoalbuminemia, diuresis
Protein-losing enteropathy, hypoalbuminemia
Resuscitation
Intraoperative fluid requirement exceeding 56 L in adults
Premature infant undergoing major surgery

syndrome (OHSS). The indications and inappropriate uses of albumin are described in detail in the following sections.

Intravascular Volume Expansion

Albumin provides the majority (80%) of plasma colloid oncotic pressure. Infused albumin provides colloid oncotic pressure; however, 50% of the infused protein is lost to the extravascular fluid compartment within 4 hours. Crystalloid may also provide volume expansion and is more quickly redistributed into total body fluids. Studies investigating the use of albumin in various situations including volume expansion during and after surgery, [52] [53] as priming solution in cardiopulmonary bypass, [54] [55] or in maintaining colloid oncotic pressure, [56] [58] found no clinical benefit compared with controls. An apparent benefit of albumin followed by diuretic therapy may be found in postoperative patients with intrapulmonary shunting, although the studies have been criticized. [59] [60] One prospective trial of colloid and crystalloid solutions has been performed in burn patients; [61] it found a difference in cardiac index in the albumin group but failed to show a significant difference in outcome. Thus, albumin therapy cannot be recommended for simple volume expansion or for the maintenance of albumin levels or colloid oncotic pressure.

Cirrhosis

The use of albumin in cirrhotic patients dates to before 1950. In this setting, albumin is recommended for temporary improvement in hyponatremia or prevention of the complications associated with paracentesis, including volume shifts and hyponatremia. Several studies demonstrated that after large-volume paracentesis, both hyponatremia and renal insufficiency were improved with albumin infusion compared with other volume-expanding agents. [62] [63] [64] [65]

Nephrotic Syndrome

Albumin has been used to increase colloid oncotic pressure with the intention of increasing diuresis. This use is currently limited to patients in whom diuretic therapy is poorly tolerated or ineffective or those with massive ascites or anasarca. [66] [67]

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome is characterized by ovarian enlargement and increased capillary permeability that results in ascites and renal impairment with fluid and electrolyte imbalance. This potentially lethal syndrome is associated with exogenously administered gonadotrophins for the induction of ovulation in women undergoing reproductive procedures. [68] Several vasoactive substances, including an unidentified factor released by the hyperstimulated ovary, have been implicated in the pathogenesis of OHSS. In high-risk patients, the use of prophylactic IV human albumin at the time of oocyte retrieval has been shown to decrease significantly the incidence and severity of OHSS, [69] [70] [71] although the pregnancy rate may be less than that associated with embryo cryopreservation. [72] It is postulated that albumin exerts its beneficial effect through binding and inactivating the OHSS-associated factor.

Dose

The volume and speed of administration should be determined by the patients volume status, condition, and response to the product. Albumin 5% is oncotically equivalent to normal human plasma. Albumin 25% provides less infusion volume per amount of albumin.

Compatibility and Side Effects

Albumin is a plasma derivative used widely and associated with rare adverse reactions. Still, allergic reactions, including urticaria, may be encountered. Volume overload may occur with excessive doses, and a decrease in ionized calcium is at least a theoretical possibility. Albumin is an excellent growth medium for bacteria, and bacterial contamination can lead to febrile, and more serious, reactions. Albumin lots are tested for contaminants and pyrogens before shipment. Transmission of infectious diseases is no longer a concern.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin is prepared by fractionation of large pools of human plasma. There are numerous preparations available in the United States and throughout the world. Each preparation is slightly different and has theoretical advantages and disadvantages and specific licensed indications. Ideally, IVIg should contain each IgG subclass; retain Fc receptor activity; have a normal half-life; demonstrate virus neutralization, opsonization, and intracellular killing; and have antibacterial capsular polysaccharide antibody. Further, vasoactive impurities should be absent, and no transmissible infectious agents should be present. [73]

Indications

Indications, possible indications, and investigational uses of IVIg are listed in Table 138-4 .

Primary Immunodeficiency Syndromes

Primary congenital immunodeficiency syndromes have been treated with intramuscular immunoglobulin for the past 30 years. The use of intramuscular immunoglobulin has certain disadvantages: delayed absorption, delivery of inadequate amounts due to small muscle mass, and pain at the injection site. IVIg overcomes these disadvantages, and used prophylactically in patients with primary immunodeficiency [74] [75] [76] has been demonstrated to reduce the number of febrile and infectious episodes as well as improve survival rate. [77] IVIg use in IgG subclass deficiencies is also beneficial. [78] [79]

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) may be associated with hypogammaglobulinemia and complications of repeated bacterial infections (see Chap. 72). IVIg decreases the incidence and severity of bacterial infections in CLL patients with hypogammaglobulinemia and has become accepted prophylactic therapy. [80] [81]

Bone Marrow Transplantation

The use of prophylactic IVIg or cytomegalovirus (CMV)IVIg in CMV-negative bone marrow transplant recipients during the first 100 days post-transplant has been demonstrated to reduce the incidence of symptomatic CMV-associated disease, including CMV interstitial pneumonia, in some trials. [82] [83] [84] Due to the high cost of this treatment and the increasing use of prophylactic ganciclovir, IVIg is currently not indicated for the

TABLE 138-4 -- Administration of Intravenous Immunoglobulins

Indicated
Primary immunodeficiency syndromes
Common variable immunodeficiency[94]
X-linked agammaglobulinemia
Severe combined immunodeficiency
Ataxia-telangiectasia
Wiskott-Aldrich syndrome[76]
IgG subclass deficiency[78] [79]
Cytomegalovirus-interstitial pneumonia after bone marrow transplant
Chronic inflammatory demyelinating polyneuropathy [134] [135] [136]
Chronic lymphocytic leukemia[80] [81]
Guillain-Barré syndrome[139] [140] [141] [142]
Idiopathic thrombocytopenic purpura (refractory) [92] [93] [94] [95] [96] [97] [98] [99] [100]
Inflammatory myopathies (refactory, dermatomyositis and polymyositis)[148] [149]
Mucocutaneous lymph node syndrome[102] [103]
Pediatric HIV infection[90] [91]
Parvovirus infection
Possibly indicated
Antiphospholipid syndrome in pregnancy[128] [129]
Autoimmune hemolytic anemia (warm-type unresponsive to prednisone)[130] [131]
Factor VIII inhibitors (refractory)[103] [185]
Graves ophthalmopathy[154]
Immune neutropenia[146]
Multiple myeloma (stable disease, high risk for infections) [152] [153]
Myasthenia gravis (refractory, acute severe decompensation) [155]
Systemic lupus erythematosus (refractory, severe active) [179] [180]

Thrombocytopenia refractory to platelet transfusion [181] [182]
Vasculitis (refractory to standard therapy) [183] [184]
Investigational
Acquired von Willebrand disease [126]
Amyotrophic lateral sclerosis[127]
Burn patients[132] [133]
Chronic fatigue syndrome[137] [138]
Fetomaternal alloimmune thrombocytopenia[162] [163]
Graft-versus-host disease[88] [89]
Human immunodeficiency virus infection[125] [143] [144] [145]
Immune-mediated aplastic anemia[81]
Inflammatory bowel disease[147]
Intractable childhood epilepsy (West syndrome and Lennox-Gastaut syndrome) [150] [151]
Multiple sclerosis[156] [157]
Neonatal hemolytic disease[164] [165] [166]
Neonatal sepsis[158] [161]
Prevention of nosocomial postoperative infections [167] [168]
Prophylaxis in transplant recipients against cytomegalovirus infection [169] [170]
Recurrent unexplained spontaneous abortions [171] [172] [173]
Rheumatoid arthritis[174] [175]
Solid organ transplantation[176] [177] [178]

prophylaxis of CMV infections in bone marrow transplant recipients. In established CMV-interstitial pheumonia, IVIg in combination with ganciclovir has been shown to reduce the mortality rate and has become the recommended treatment modality.[85] [86] [87] Its role in preventing severe graft-versus-host disease is controversial. [88] [89]

Pediatric Human Immunodeficiency Virus Infection

The defects in humoral and cellular immunity observed in children with HIV infection predispose them to life-threatening bacterial infections. Studies have shown that the administration of IVIg to HIV-infected children can reduce the incidence and severity of bacterial infections as well as the frequency of hospitalization. [90] [91] Prevention of maternalfetal transmission of HIV infection through the use of hyperimmune HIV-IVIg is being investigated.

Idiopathic Thrombocytopenic Purpura

The use of IVIg represents a major advance in the treatment of both acute and chronic idiopathic thrombocytopenic purpura (ITP) (see Chap. 126). IVIg significantly raises the platelet count within 5 days in both adults with chronic ITP and children with acute ITP. [92] [93] The mechanism of action of IVIg in ITP is unknown, but most believe that Fc receptor blockade decreases the removal of antibody-coated platelets. Other proposed mechanisms include suppressed antiplatelet antibody synthesis, increased antiviral immunity, and blockage by anti-idiotypic antibodies. [94] In general, IVIg induces responses in most patients within 12 days. Responses are of variable duration and rarely sustained, although maintenance therapy may be of some value. [95] IVIg may be effective in chronic ITP refractory to corticosteroids or splenectomy,[96] may show greater efficacy in conjunction with corticosteroids, [93] [97] and has been demonstrated to be superior to oral corticosteroids in children with acute ITP.[98] [99] [100]

Although IVIg has shown equal efficacy with corticosteroids in pediatric acute ITP and in 75% of adults with chronic ITP, because of the transient responses and high cost, its use is justified only in clinical situations requiring rapid elevation of platelet count or if standard therapy has failed. IVIg is therefore indicated in acute bleeding episodes or before urgent surgery, including splenectomy; in patients at high risk of intracranial hemorrhage; and in those in whom corticosteroids are contraindicated or ineffective. IVIg has also been used to treat ITP during pregnancy, postinfectious thrombocytopenia, ITP associated with HIV infection, and neonatal thrombocytopenia. Intravenous anti-D immune globulin has demonstrated efficacy in Rh-positive, nonsplenectomized individuals with ITP. It has been suggested that the mechanism of action may involve a shift in the immune-mediated destruction from platelets to the antibody-coated RBCs. [101]

Mucocutaneous Lymph Node Syndrome

The mucocutaneous lymph node syndrome (Kawasaki disease) has been treated with aspirin with or without concomitant IVIg administration. Coronary artery aneurysm, a serious complication of this disease, was significantly reduced in the IVIg-treated group. [102] [103]

Dosage

Patients with primary immunodeficiency syndromes and IgG levels <200 mg% are candidates for immunoglobulin replacement. Most patients require 100200 mg/kg IV every 34 weeks to achieve adequate IgG levels (usually >800 mg%) and protection against infection. Initially, serial IgG level determination may allow the physician to individualize the dose and schedule. These are affected by the recovery, half-life, redistribution, and catabolism of IVIg, which vary from product to product and patient to patient. Patients with ITP are usually treated with 400 mg/kg daily for 5 days or 1,000 mg/kg daily for 2 days (see Chap. 123). Repeat single doses (400 mg/kg) have been used intermittently in some patients (particularly children) to maintain platelet counts >50,000/l. Kawasaki disease is also treated with 400 mg/kg daily for 35 days. The adult dose of IV anti-D is 2 mg over 30 minutes.

Compatibility and Side Effects

Infusions of IVIg should be started slowly and patients should be closely monitored. If the initial rate (0.5 ml/kg/hr) is well

tolerated, the rate can be increased gradually, but not more than eightfold. Fever, headache, nausea, vomiting, fatigue, backache, leg cramps, urticaria, flushing, elevation of blood pressure, and thrombophlebitis may be seen. IgA-deficient patients may have IgG anti-IgA antibodies, which can cause anaphylactic reactions. [104] This complication is rare and may be avoided by using products with a lower concentration of IgA. [105] Aggregated IgG may produce chills, nausea, flushing, chest tightness, and wheezing. Rarely, IVIg preparations contain IgG anti-A and/or anti-B RBC antibodies that can produce hemolysis [106] or interfere with serologic evaluations, including RBC compatibility testing. [107] Serum sickness can occur. Improved manufacturing processes currently in place render IVIg free of envelope and non-envelope viruses.[108] Nevertheless, hepatitis C virus transmission has been reported in certain patient populations. [109] [110] High-dose IVIg therapy has been associated with reversible, acute renal failure [111] and aseptic meningitis.[112]

HYPERIMMUNE AND INTRAMUSCULAR IMMUNOGLOBULINS

Hyperimmune immunolglobulin is prepared from large pools of plasma known to contain elevated antibody titers against specific infectious agents. The intramuscular and hyperimmune immunoglobuins[73] are listed in Table 138-5 .

Antithymocyte globulin (ATG) is a purified concentrated -globulin made from hyperimmune serum of horses immunized with human T lymphocytes. ATG is used in renal transplant patients as an adjunct therapy in the treatment of graft rejection. [113] [114] It is also used in patients with aplastic anemia who are not candidates for bone marrow transplantation (see Chap. 19). [115]

Hyperimmune immunoglobulin is used to prevent the development of specific clinical disease or alter its symptomatology. CMV Ig is indicated in all kidney and liver transplant recipients who are seronegative for CMV and who receive the respective organ from a seropositive donor and in bone marrow transplant patients with CMV interstitial pneumonia. [85] [86] Hepatitis B immunoglobulin is used to provide passive immunity to hepatitis B virus associated with needlestick exposure or sexual contact with HBsAg-positive individuals.

Rh immunoglobulin is used when fetal Rh(D)-positive RBCs may have entered the maternal circulation of an Rh(D)-negative mother. This means that Rh(D) immunoglobulin is given to Rh(D)-negative mothers after abortion or amniocentesis, as well as before delivery and again postpartum if the child proves to be Rh(D) positive. [186] [187] [188] The therapeutic effect is thought to be due to antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-Rh antibody. Rh immunoglobulin can also be given to prevent immunization in Rh(D)-negative individuals given Rh(D)-positive components such as platelets. Transfusion of Rh(D)-positive RBCs to Rh(D)-negative recipients is occasionally necessary, and prevention of immunization is not possible unless IV Rh immunoglobulin is

Western equine encephalitis immunoglobulin

made available by the manufacturers. Rh immunoglobulin has also been used to treat ITP.

Experimentally, immunoglobulin has also been administered via oral, intrathecal, and aerosolized routes. Oral administration has been tried with some success in the prevention of rotavirus infection and necrotizing enterocolitis in premature infants, in the treatment of *Cryptosporidia*-associated diarrhea, and in the prevention of viral gastroenteritis after bone marrow transplant. Intrathecal administration has been tried in the treatment of viral encephalitis and tetanus, aerosolized administration in infections with respiratory syncytial virus.

Chapter 139 - Preparation of Plasma-Derived and Recombinant Human Plasma Proteins

William N. Drohan
David B. Clark

INTRODUCTION

The development of large-scale methods for the preparation of human plasma proteins began more than 50 years ago. In 1940, after the outbreak of World War II, a meeting was called to discuss the urgent request of the United States Armed Forces for 300,000 units of human whole blood or plasma for transfusion, which at that time seemed an impossibly large amount.[1] [2] Dr. Edwin J. Cohn of the Harvard Medical School was approached to determine whether animal plasma could be made safe for human use. Cohn drew together a task force of investigators and developed a method for the fractionation of bovine plasma based on differential precipitation of various plasma proteins achieved by appropriate combinations of ethanol concentration, pH, low temperature, ionic strength, and protein concentration. Within a short time, highly purified preparations of bovine serum albumin were available for clinical trials. Although there were no immediate reactions, the frequency of severe delayed reactions made it obvious that these preparations were unsuitable for clinical use. Meanwhile, Cohn had arranged with the American Red Cross to provide his laboratory with a supply of human plasma, and the ethanol method was quickly adapted for human plasma fractionation. Although albumin was the only product distributed during the war, the remaining plasma fractions were carefully preserved, and other preparations, including fibrinogen and immunoglobulins, were soon developed.

Since World War II, major improvements have occurred in the preparation of human plasma proteins. The ethanol process has been supplemented by more selective purification techniques. A variety of methods have been developed for inactivation or removal of viruses that might be present in the starting materials, which may be pooled from the plasma of thousands of human donors.[3] [4] Advances in recombinant DNA technology have allowed recombinant human plasma proteins to be produced in tissue culture systems. This chapter describes current methods and future directions for the preparation of plasma-derived and recombinant human plasma proteins for clinical use.

FRESH FROZEN PLASMA

Plasma that has been frozen solid within 6 hours after phlebotomy and stored at 18°C meets the criteria for labeling as fresh frozen plasma (FFP). [5] Clinical indications for the administration of FFP are described in Chapter 138 . At the present time, the viral safety of FFP depends entirely on donor selection and blood screening techniques. However, a method has recently been developed for the treatment of plasma with a solvent/detergent mixture to inactivate any lipid-enveloped viruses that might be present.[6] The coagulation factor content of solvent/detergent-treated plasma (SD-plasma) has been found to be comparable to that of untreated FFP.[7] Clinical trials have shown that SD-plasma is efficacious in the treatment of acquired or inherited coagulation factor deficiencies and thrombotic thrombocytopenic purpura (TTP).[8] [9] The product is currently available in Europe and was recently licensed in the United States.

ALBUMIN AND PLASMA PROTEIN FRACTION

Albumin is still one of the major products of human plasma fractionation. During the 50 years since the initial use of human serum albumin in treating the casualties at Pearl Harbor, literally tons of albumin have been isolated and millions of units have been infused. [10] Cohns method 6 is the basis for most of the large-scale production of albumin today. [11] Most manufacturers use cryoprecipitation as the first step in order to obtain the factor VIII/von Willebrand factor (Factor VIII/vWF) complex, which can then be further purified by a variety of techniques. Factor IX complex and antithrombin III (AT III) may be separated from the cryosupernatant before it is processed by the ethanol method to obtain immunoglobulins and albumin. Albumin, having the highest solubility and the lowest isoelectric point of all the major plasma proteins, remains in solution as the ethanol concentration is raised in stages from zero to 40%, with an overall decrease in pH from neutrality to 5.8 and a temperature adjustment to 5°C. It is only when the pH is adjusted to 4.8, in the presence of 40% ethanol at 5°C, that the bulk of the albumin is finally precipitated in fraction V. [10] [12] After the removal of ethanol and salts, sodium acetyltryptophanate and sodium caprylate are added as stabilizers, and the albumin is sterile-filtered and bottled. The vials are then heated for 10 hours at 60°C to inactivate any remaining blood-borne viruses.

Three albumin products are manufactured in the United States: Albumin (human) 25%, Albumin (human) 5%, and plasma protein fraction (PPF). To be designated Albumin, >96% of the protein content must be albumin by cellulose acetate electrophoresis (CAE). PPF is an albumin product of lower purity, obtained by co-precipitating fraction IV-4 with fraction V. [13] The total protein in PPF must be 83% albumin by CAE, with 17% globulins, and 1% -globulin. PPF is more economical to produce than albumin, [14] but the rapid infusion of PPF has been associated with hypotensive episodes. [15] [16] Clinical indications for the use of Albumin and PPF are described in Chapter 138 . Albumin (human) 25% is also often used as a stabilizer in the formulation of other highly purified plasma products.

IMMUNOGLOBULINS

Immuno- and Hyperimmunoglobulins

Since the early 1950s, immunoglobulins have been prepared from the fraction II + III precipitate obtained by Cohns method 6, with additional precipitation steps to remove lipoproteins, IgA, IgM, and other plasma proteins.[17] [18] [19] Immunoglobulin is prepared from the plasma of unselected normal donors, while hyperimmunoglobulins are prepared from the plasma of donors with high antibody titers against specific antigens (e.g., rho(D), hepatitis B, rabies, and tetanus). These donors may be identified during convalescent periods after infection or transfusion, or they may be specifically immunized to produce the desired antibodies. Immunoglobulin products currently available in the United States are described in Chapter 138 .

Intravenous Immunoglobulins

The original immunoglobulin concentrates, termed immune serum globulin (ISG), were administered by the intramuscular route, with the associated problems of limited injectable volume, poor bioavailability, and discomfort at the injection site. [20]

Intravenous injection of ISG caused serious clinical reactions, attributed to complement-activating aggregates in these products. [21]

To overcome these limitations, intravenous immunoglobulin (IVIg) products have been developed using a variety of methods to remove or inactivate anticomplementary aggregates. Processing and formulation techniques have been improved, and conditions have been identified, to permit these products to be prepared as either freeze-dried or liquid concentrates. [22] Today most intramuscular ISG usage is limited to hyperimmune products. Immunoglobulin products tend to be self-protecting from viral transmission because of the large pools of antibodies they contain. [23] However, postinfusion viral infections have occurred in a few instances. As a result, most manufacturers have incorporated viral inactivation or removal steps in the production of IVIg. [24]

The development of IVIg has permitted the administration of much higher doses, with a subsequent expansion in immunoglobulin therapy. In addition to providing passive immune protection, IVIg has been found to modulate the immune response to autoimmune diseases such as idiopathic thrombocytopenic purpura. Clinical indications for the use of IVIg are described in Chapter 138 .

COAGULATION FACTOR CONCENTRATES

The distinction between hemophilia A and B was unknown when it was first shown that the transfusion of whole blood could be used to curtail bleeding in patients with hemophilia.[25] [26] By 1940, bleeding episodes were being routinely treated with plasma. However, large amounts of plasma were needed, and this method of therapy could not provide normal levels of coagulation factors without producing hypervolemia. [27] The development of coagulation factor concentrates has resulted in dramatic increases in the life expectancy and the quality of life of patients with hemophilia.

The major issues in the preparation and use of coagulation factor concentrates are viral safety and purity. With the exception of cryoprecipitate, all these concentrates are now subjected to some form of treatment for the inactivation or removal of viruses that might be present in the starting materials. The purity may be important for both immediate and long-term safety. As discussed below, the purity of factor IX (FIX) concentrates has definitely been shown to affect product safety; however, the situation for factor VIII products is less clear. Although in vitro testing has shown deleterious effects on immunocompetence with lower purity products, the few in vivo studies performed have shown no signs of immunomodulation.[28] The development of improved coagulation factor concentrates continues to be a major focus of research.

Factor VIII Concentrates

Factor VIII or antihemophilic factor (human) (AHF) concentrates for the treatment of hemophilia A have evolved from cryoprecipitates to very-high-purity immunoaffinity-purified products.[29] Four recombinant products have also been licensed for clinical use. The various AHF concentrates available in the United States are shown in Table 139-1 .

Cryoprecipitate

In 1959, Pool and Robinson[30] reported that when frozen plasma is slowly thawed, a residual cryoprecipitate results that contains

TABLE 139-1 -- Antihemophilic Factor Concentrates Marketed in the United States[a]

Antihemophilic Factor	Manufacturer/Distributor	Product Name	Specific Activity[b]	Purification Methods	Virus Inactivation/Removal Methods
Human	Alpha	Alphanate	140[c]	Cryoprecipitation, IEC, heparin affinity chromatography	S/D (TNBP/Polysorbate 80), dry heat treatment at 80°C for 72 hours, heparin chromatography, PEG precipitation
	Centeon	Monoclate-P	>3,000[c]	Cryoprecipitation, cold purification, $Al(OH)_3$ adsorption, IAC, AH-Sepharose chromatography	Pasteurization at 60°C for 10 hr
	Baxter/American Red Cross	MONARC-M	2,000[c]	Cryoprecipitation, cold precipitation, IAC, IEC	S/D (TNBP/Triton X-100), IAC, IEC
	Baxter	Hemofil M	2,000[a]	Cryoprecipitation, cold precipitation, IAC, IEC	S/D (TNBP/Triton X-100), IAC, IEC
	Centeon	Humate-P	25	Cryoprecipitation, $Al(OH)_3$ adsorption, glycine precipitation	Pasteurization at 60°C for 10 hr
	Bayer	Koate HP	922	Cryoprecipitation, SEC	S/D (TNBP/Polysorbate 80)
Recombinant	Baxter	Recombinate	>3,000[c]	IAC, IEC, IEC	Purification steps
	Bayer	Kogenate	>3,000[c]	IAC, SEC, IEC	Inactivation/purification steps
	Baxter/Centeon	Bioclate	>3,000[c]	IAC, IEC, IEC	Purification steps
	Bayer/Centeon	Helixate	>3,000[c]	IAC, SEC, IEC	Inactivation/purification steps
Porcine	Speywood	HYATE:C	>50[d]	Polyelectrolyte fractionation	Purification steps

Abbreviations: IAC, immunoaffinity chromatography; IEC, ion-exchange chromatography; SEC, size exclusion chromatography; S/D, solvent/detergent; TNBP, tri-*n*-butyl phosphate; PEG, polyethylene glycol.

[a] These concentrates were marketed in the United States in 1997. Data were obtained from manufacturers, distributors, and available literature.

[d] Porcine factor VIII g/mg of protein.

most of the factor VIII activity from the original plasma. By 1965, single-donor cryoprecipitate with factor VIII concentrations 520 times that of plasma became widely available for use in the treatment of hemophilia A.[31] Although single-donor cryoprecipitate now has only limited clinical use, cryoprecipitation is still the first step in most procedures for the preparation of plasma derivatives containing high concentrations of the factor VIII/vWF complex, fibrinogen, fibronectin, and/or factor XIII. [32] Cryoprecipitate contains approximately one-half of the factor VIII/vWF complex and one-third of the fibrinogen and factor XIII in whole plasma. [33]

Intermediate- and High-Purity AHF Concentrates

The development of intermediate-purity AHF concentrates was the next significant advance in the treatment of hemophilia A. Cryoprecipitate was used as the starting material, and a variety of methods were developed to remove fibrinogen, immunoglobulins, and other proteins. Fibrinogen can be removed at specific conditions of

temperature and pH[34] or by precipitation with polyethylene glycol, [35] while aluminum hydroxide may be used to adsorb and remove the vitamin K-dependent clotting factors II, VII, IX, and X.[35] However, even though these concentrates are enriched approximately 400-fold over plasma, factor VIII is still <1% of the total protein. [36] Thus, patients receiving these concentrates are exposed to large quantities of other plasma proteins. In addition, each lot is prepared from cryoprecipitate obtained from the plasma of several thousand donors. Until effective methods were developed for viral inactivation, patients receiving these concentrates were exposed to all of the blood-borne viruses in the donor population. It is not surprising that frequently treated patients uniformly became infected with hepatitis [37] [38] and, later, often HIV.[39]

Intermediate-purity AHF concentrates were the mainstay of hemophilia A treatment until the development of high-purity concentrates in the late 1980s. Various ion-exchange and gel filtration techniques have been added to the precipitation methods to produce concentrates with specific activities of 50200 IU/mg of protein, in contrast to 150 IU/mg for intermediate-purity AHF and <1 IU/mg for cryoprecipitate.[26] However, even though these concentrates are highly purified in comparison with the intermediate-purity concentrates, high molecular weight proteins such as fibrinogen, fibronectin, and vWF tend to fractionate with factor VIII and remain in these preparations.[40]

AHF Concentrates Purified by Immunoaffinity Chromatography

The next major advance in the preparation of AHF concentrates was the use of murine monoclonal antibodies (mAbs) for the purification of factor VIII by immunoaffinity chromatography. Two different methods have been developed that both start with low-purity factor VIII concentrates partially purified by conventional means.[41] [42] [43] One procedure uses an mAb that binds to the vWF portion of the factor VIII/vWF complex; the other uses an mAb that binds directly to factor VIII. In both processes, the columns are loaded with the low-purity intermediate, washed extensively to remove unwanted proteins, and then eluted, respectively, by separation of factor VIII from the vWF/mAb complex or directly from the mAb itself. Both processes use a final chromatography step to remove the harsh elution solutions as well as any mAb that might have leached off the column. These processes produce factor VIII that is essentially pure prior to the addition of albumin as a stabilizer. Both processes include several steps that inactivate or remove viruses.

Recombinant AHF Concentrates

One of the remarkable accomplishments of molecular biologists has been the elucidation of the structure of factor VIII, its molecular cloning, and the successful production of recombinant human factor VIII. Almost simultaneously, two groups cloned the entire factor VIII gene, the largest gene cloned at that time, and isolated a cDNA encoding the structural regions of the factor VIII molecule. [44] [45] [46] [47]

Because post-translational processing is essential to factor VIII functionality, both groups have expressed the recombinant factor VIII molecule in mammalian cells. One group uses Chinese hamster ovary cells that co-express recombinant factor VIII and recombinant vWF, as the recombinant vWF substantially increases the recovery of recombinant factor VIII from the culture medium.[48] The recombinant factor VIII is purified by immunoaffinity and ion-exchange chromatography. [49] The other process uses baby hamster kidney cells to express recombinant factor VIII, which is purified by immunoaffinity, size exclusion, and ion-exchange chromatography.[50] [51] Both products contain minimal or no recombinant vWF and only trace quantities of mouse immunoglobulin, hamster protein, and cellular DNA. The products are essentially pure prior to the addition of human albumin to stabilize the recombinant factor VIII. These recombinant factor VIIIs have been shown to be similar to plasma-derived factor VIII in in vitro [49] [52] [53] [54] as well as clinical [55] [56] [57] studies. These products are termed antihemophilic factor (recombinant). A fully functional recombinant factor VIII has also recently been expressed in the milk of transgenic pigs. [58] The large amounts of protein that can be produced relatively inexpensively in transgenic animals may someday permit the widespread prophylactic treatment of hemophilic patients so that joint and soft tissue bleeding can be prevented.

Factor IX Concentrates

Two types of factor IX concentrates are available today: factor IX complex, which contains significant amounts of the other vitamin K-dependent proteins, including factors II, VII, and X; and coagulation factor IX (human), a preparation substantially free of these other proteins. The factor IX concentrates available in the United States are shown in Table 139-2 .

Factor IX Complex Concentrates

The vitamin K-dependent clotting factors, because of their similar structures, tend to co-purify by most of the methods used to isolate them from plasma. Thus, the initial preparations containing factor IX for treatment of hemophilia B were in fact complex mixtures of the vitamin K-dependent proteins. Because the protein in highest concentration in these products is prothrombin, they have also been identified as prothrombin complex concentrates; however, factor IX complex is the generic name in the United States.

The first factor IX-rich concentrate used for the treatment of hemophilia B was developed in France more than 30 years ago. [59] It was produced by the adsorption of the plasma vitamin K-dependent clotting factors with tricalcium phosphate and was successfully used to treat hemophilia B for a number of years. The original production process had a number of disadvantages and was eventually discontinued. [60] However, this method led to the development of several other processes based on tricalcium phosphate adsorption. [61] Factor IX complex produced by these methods contains approximately equal amounts of factor II, VII, IX, and X activity units.

The next major development in the production of factor IX complex concentrates was the introduction of ion-exchange chromatography. [62] This represented one of the first major uses of chromatography in plasma fractionation. As shown in the box, the vitamin K-dependent clotting factors can be removed from cryoprecipitate-poor plasma by adsorption onto DEAE-cellulose or DEAE-Sephadex, and the plasma can then be further fractionated by Cohns method for the production of

TABLE 139-2 -- Factor IX Concentrates and Related Products Marketed in the United States[a]

Product Type	Manufacturer/Distributor	Product Name	Specific Activity[b]	Purification Methods	Virus Inactivation/Removal Methods
Factor IX complex	Alpha	Profilnine SD	45	DEAE cellulose adsorption	S/D (TNBP/polysorbate 80), DEAE cellulose chromatography
	Baxter	Proplex T	NA	Tricalcium phosphate adsorption	Dry heat treatment at 60°C for 144 hr
	Immuno	Bebulin VH	NA	NA	Vapor heating: 60°C for 10 hr at 190 mbar, then 80°C for 1 hr at 375 mbar
	Bayer	Konyne 80	1	IEC	Dry heat treatment at 80°C for 72 hr
Coagulation factor IX (human)	Alpha	AlphaNine SD	150	DEAE adsorption, barium citrate adsorption, dual AC	S/D (TNBP/polysorbate 80), nanofiltration, dual AC, DEAE cellulose chromatography
	Centeon	Mononine	150	IEC, IAC, AH-Sepharose chromatography	Sodium thiocyanate; IAC, ultrafiltration
Anti-inhibitor coagulant complex	Baxter/NABI	Autoplex T	NA	NA	Dry heat treatment at 60°C for 144 hr
	Immuno	FEIBA VH	NA	NA	Vapor heating: 60°C for 10 hr at 190 mbar, then 80°C for 1 hr at 375 mbar
Coagulation factor IX (recombinant)	Genetics Institute	BeneFix	200	Q Sepharose, Cellufine sulfate, ceramic hydroxyapatite, and IMAC chromatographies	Chromatography, nanofiltration

Abbreviations: NA, not available; S/D, solvent/detergent; AC, affinity chromatography; IAC, immunoaffinity chromatography; IEC, ion-exchange chromatography; IMAC, immobilized metal affinity chromatography; TNBP, tri-*n*-butyl phosphate.

[b] Factor IX U/mg of protein.

immunoglobulin and albumin. The eluate from the DEAE resin may be further purified by additional precipitation or adsorption steps. [63] [64] Such processes give 100-fold or more purification of factors II, IX, and X. Factor VII does not bind to DEAE under the conditions used, however, and is present in only very low concentrations in concentrates prepared in this way.

Coagulation Factor IX

With the widespread use of factor IX complex, it soon became apparent that serious thromboembolic episodes and acute myocardial infarction were major complications of their infusion, especially when used in large quantities for extended periods, such as for surgical procedures or in patients with liver disease. [65] [66] As discussed in Chapter 140 , the cause of the thrombogenicity has not been rigorously defined. It may be due to the presence of activated clotting factors. [67] [68] contaminating phospholipids,[69] or the result of zymogen overload.[70] Zymogen overload refers to the co-administration of large, unnecessary quantities of factors II and X in the factor IX complex preparations.[70] [71] These factors persist in the circulation (half-lives of about 4 days and 3050 hours, respectively, compared with about 20 hours for factor IX), so that they accumulate after repeated infusions of the complex, upsetting the normal balance and leading to a hypercoaguable state. [66]

On the basis of these hypotheses, methods have been developed for the preparation of second-generation factor IX concentrates that are more highly purified and essentially free of the other vitamin K-dependent clotting factors. These have been designated coagulation factor IX (human). Coagulation factor IX concentrates are manufactured from factor IX complex by one or more additional steps, such as chromatography on sulfated dextran, [71] a second DEAE column and a heparin-Sepharose column,[72] or barium citrate adsorption followed by an affinity column. [73] Coagulation factor IX concentrates are also prepared by immunoaffinity chromatography using mAbs to factor IX.[74] [75] All these methods also include viral inactivation steps. These preparations have been shown to be nonthrombogenic when compared with factor IX complex in animal models[76] and also in clinical studies. [77]

A recombinant coagulation factor IX has also been developed and was recently licensed in the United States. Recombinant factor IX is produced by cell culture in Chinese hamster ovary cells that co-express a protease needed to properly modify the factor IX molecule. [78] It is purified with several chromatography steps and treated to remove viruses.[79] The final product has been shown to be structurally and functionally similar to plasma-derived factor IX. [80] [81] However, for reasons not yet determined, it gives a lower recovery when infused into patients. [82]

Other Coagulation Factor Concentrates

As described in Chapter 140 , one of the major complications in the treatment of hemophilic patients is the development of inhibitors, antibodies directed against factor VIII or factor IX. While low-titer inhibitors can be saturated by administering large amounts of factor VIII or factor IX, this may not be feasible when the inhibitor level is >510 Bethesda U/ml plasma.[83] [84] One of several approaches for treating hemophilia A patients with high-titer inhibitors is the use of a porcine factor VIII concentrate. Porcine factor VIII is efficacious in controlling hemostasis and is less readily inactivated by some human factor VIII inhibitors. [85] [86] [87] [88] The critical factor for repeated use of porcine factor VIII, anamnesis with the development of high-titer inhibitor levels against porcine factor VIII, is seen in approximately one-third of patients. [87] Another widely used method of treatment for patients with high-titer inhibitors is administration of either factor IX complex or a specially activated factor IX complex termed anti-inhibitor coagulant complex to bypass the factor

PLASMA ALGORITHM BASED ON COHN'S METHOD 6[a]

[a] *Dotted lines indicate optional steps used by manufacturers.*

VIII step in the coagulation cascade.[89] [90] These concentrates are effective in 5060% of cases, but thromboembolic complications have occurred in some patients treated in this way.

The bypass rationale has led to the use of activated factor VII (factor VIIa) for the treatment of both hemophilia A and B patients with inhibitors. [91] Factor VII or factor VIIa may be the active substance in the anti-inhibitor coagulant complexes. [92] [93] Early work with plasma-derived factor VIIa gave good results.[94] However, since it is impossible to purify enough factor VIIa from plasma for widespread patient use, recombinant factor VIIa concentrates have been developed. [95] Recombinant factor VIIa is produced in tissue culture in baby hamster kidney cells and spontaneously activates during purification by immunoaffinity chromatography. [95] [96] Recombinant factor VIIa has been used successfully in a number of clinical trials [91] [93] [94] [97] but is not yet licensed in the United States. However, the manufacturer has made the product available on a compassionate use basis for several years. [84]

Patients with von Willebrand disease (vWD) have been treated with plasma, with cryoprecipitate, and with some AHF concentrates that contain vWF. Cryoprecipitate has a population of vWF multimers similar to that of normal plasma, while AHF concentrates are often deficient in the multimeric forms. However, during the past 10 years the ratios of ristocetin cofactor activity (vWF:Rco) to vWF antigen (vWF:ag) in many plasma-derived AHFs have increased to the point that they are now preferred over cryoprecipitate because of their viral safety. [98] The vWF:Rco/vWF:ag ratio appears to be a good indicator of vWD treatment efficacy. Current AHF products vary considerably, with vWF:Rco/vWF:ag ratios ranging from 0.25 to 1.4 and 0.5 to 5.3 units of vWF:Rco per unit of factor VIII. [98] A vWF concentrate depleted of factor VIII has also been developed in Europe, with plans to seek licensure in the United States.

FIBRIN SEALANTS

Fibrin sealants, or fibrin glues, are topical hemostatic agents that have been used in a variety of surgical situations for their hemostatic and adhesive properties. [99] The preparations consist of two components that are mixed together immediately prior to use. The first component is derived from human plasma and contains fibrinogen, along with factor XIII, and other plasma proteins. Depending on the manufacturer, the fibrinogen may be isolated directly from Cohn fraction I or from cryoprecipitate as a by-product of AHF manufacture. [99] These fibrinogen concentrates also typically contain either an added plasmin inhibitor to delay clot lysis [99] [100] or else are purified to remove endogenous plasminogen. [100] [101] The second component contains either bovine or human plasma-derived thrombin and possibly other proteins. Although bovine thrombin has been in widespread use for many years, recent research suggests that it may be responsible for many postsurgical hemostatic problems. [100] [102]

Fibrin sealant has been advocated by many surgeons as the material that best approaches the ideal operative sealant. [103] It appears to have no tissue toxicity, forms a firm seal within seconds, is completely readsorbed within days or weeks following application, and may promote local tissue growth and repair. [99] [100] [103] Although preparations of fibrin sealant have been available in Europe since the mid-1970s, the United States Food and Drug Administration revoked all licenses for the manufacture of fibrinogen concentrates in 1978 owing to frequent viral contamination. [104] However, several manufacturers have developed improved, virally inactivated products that have been licensed or that are currently pending licensure in the United States. [100] Additional products containing fibrin sealant, such as a fibrin sealant-coated bandage, are also being developed. [100] [105]

In the absence of licensed products, a variety of methods had been used to prepare fibrin sealant for use in the treatment of individual patients. The preparations are made from single-donor cryoprecipitate or other plasma fractions plus bovine thrombin. [106] [107] However, the methods are somewhat cumbersome, the concentration of fibrinogen in these preparations is highly variable, and, most important, the products are not treated to prevent viral transmission. [99] The use of a standardized manufactured product should increase the likelihood of safe, uniform performance in the surgical field.

PLASMA PROTEINASE INHIBITORS

The proteinase inhibitors that are present in human plasma play critical roles in the regulation of the proteolytic cascades of the coagulation, fibrinolytic, complement, and kinin systems. Most of these inhibitors have similar amino acid and structural properties and are members of a superfamily of proteins designated serpins (serine proteinase inhibitors).[108] Hereditary deficiencies in $_1$ -antitrypsin, AT III, and C_1 esterase inhibitor can cause specific disease states, and inhibitor concentrates have been developed. The plasma proteinase inhibitor concentrates available in the United States are shown in Table 139-3 .

$_1$ -Proteinase Inhibitor

$_1$ -Antitrypsin, licensed as $_1$ -proteinase inhibitor (human) (API), was the first of the serpins to be isolated and characterized. [109] Although the protein was originally named for its antitrypsin activity, its primary physiologic function appears to be the inhibition of neutrophil elastase. Patients with hereditary deficiencies of this inhibitor develop pulmonary emphysema and liver disease. [110] [111]

API therapy is indicated for chronic treatment of individuals with hereditary deficiency who have clinical evidence of panacinar emphysema. Weekly intravenous infusions are recommended in order to maintain an adequate level of functional API in the epithelial lining of the lower respiratory tract. [110] [111]

TABLE 139-3 -- Plasma Proteinase Inhibitor Concentrates Marketed in the United States[a]

Product Type	Manufacturer/Distributor	Product Name	Specific Activity	Purification Methods	Virus Inactivation/Removal Methods
$_1$ -Proteinase inhibitor (human)	Bayer	Prolastin	0.35[b]	Ethanol fractionation, PEG precipitation, IEC	Pasteurization at 60°C for 10 hr
Antithrombin III (human)	Kabi/Baxter Bayer	ATnativ Thrombate III	NA 8[c]	AC, IEC Ethanol fractionation, dual AC	Pasteurization at 60°C for 10 hr Pasteurization at 60°C for 10 hr

Abbreviations: AC, affinity chromatography; IEC, ion-exchange chromatography; PEG, polyethylene glycol; NA, not available.

[a]These concentrates were marketed in the United States in 1997. Data were obtained from manufacturers, distributors, and available literature.
[b]Milligrams functional $_1$ -PI/mg protein.
[c]AT III U/mg of protein.

However, intravenous administration is an inefficient therapy; it has been estimated that only 2% of the infused API is present in the lung. Clinical studies suggest that aerosol delivery of API directly into the lungs by inhalator would be efficacious and could replace intravenous administration because of its lower cost and greater convenience.[112] API is also currently in clinical trials for the treatment of cystic fibrosis.

An API concentrate prepared from human plasma is licensed for use in the United States. The product is prepared from Cohn fraction IV-1 by fractional precipitation with polyethylene glycol followed by ion-exchange chromatography on DEAE-Sepharose. It is pasteurized by heating in solution for 10 hours at 60°C to ensure viral inactivation.[113] [114] Several new plasma-derived API concentrates are being developed, as are recombinant concentrates from both cell culture [115] [116] and transgenic animals. The large amounts of API that can be produced in the milk of transgenic animals may be important in the future. Because relatively large doses of API are needed even with aerosol delivery, the amount available from plasma will be insufficient, especially with the additional indications being studied. Using recombinant DNA techniques, it may also be possible to modify the API molecule so as to give it advantageous new properties, such as resistance to oxidation and a broader antiprotease inhibitory spectrum. [112]

Antithrombin III

Antithrombin III, as the major physiologic inhibitor of thrombin and factor Xa, plays a critical role in the regulation of hemostasis. Heterozygous hereditary deficiency of AT III has been linked to an increased tendency to thrombosis. [117] [118] Acquired deficiencies have also been reported in women taking oral contraceptives and as a consequence of pregnancy, surgery, cirrhosis, and hepatic malignancies.

The affinity of heparin for AT III, essential for the pharmacologic effect of the drug, has also been employed as a means of purifying AT III. Use of immobilized heparin as an affinity adsorbent for AT III [119] is the key step in large-scale preparation of AT III concentrates for clinical use. [120] As shown in the box, AT III may be isolated from cryosupernatant,[121] from Cohn fraction I supernatant,[122] or from Cohn fraction IV-1.[123] Although heparin-based adsorbents are not specific for AT III, other plasma proteins are bound less tightly and may be washed off with medium-ionic-strength buffers prior to the elution of AT III with a high-ionic-strength buffer. Although these eluates may contain small amounts of other proteins, additional purification steps produce concentrates that contain >95% AT III. [120] All the AT III concentrates now being manufactured are pasteurized by heating in solution for 10 hours at 60°C to inactivate blood-borne viruses. Clinical studies by a number of investigators have shown that these AT III concentrates are effective in the prophylaxis or treatment of thromboembolic disorders in patients with hereditary AT III deficiency.[117] [124]

C_1 Esterase Inhibitor

C_1 esterase inhibitor (C_1 -INH) plays an important role in the regulation of the complement system cascade. In 1963 it was established that a deficiency in C_1 -INH is the underlying biochemical defect in hereditary angioedema, an autosomal dominant disease that is characterized by episodic swelling of the subcutaneous tissues and the mucosa of the gastrointestinal and respiratory tracts.[125] The swelling can lead to acute airway obstruction, a major cause of mortality among patients with this disease.[126] FFP has been used in replacement therapy for the treatment of acute attacks as well as for short-term prophylaxis prior to surgery, but the volume of plasma needed and the time required for thawing and infusion are drawbacks to this approach. [127]

C_1 -INH concentrates are not yet licensed in the United States, although preparations have been available in Europe for several years. [128] [129] [130] [131] C_1 -INH concentrates have been used there for short-term and long-term prophylaxis, as well as for treatment of acute episodes of hereditary angioedema. The products are

treated for viral inactivation and are supplied as freeze-dried concentrates.

FUTURE DIRECTIONS

Almost all plasma proteins licensed for human use have been cloned and expressed in a biologically active form in animal cells, and several have been developed into licensed products.[132] [133] Other plasma proteins such as fibrinogen and albumin have been cloned and expressed by a variety of laboratories, but remain untested in clinical trials. The reasons for this include the inability to produce these proteins in adequate quantities or in the inappropriate post-translational modification of the recombinant protein.[134] [135] The main advantages of recombinantly produced plasma proteins include freedom from human viruses and a potentially unlimited supply. Recombinant proteins can also be produced in modified forms that may give them advantageous new properties such as increased potency, longer half-life, or varied specificity.

Transgenic Animal Production of Human Plasma Proteins

Advances in molecular biology and embryology have led to the production of plasma proteins in the milk of genetically engineered farm animals. [136] [137] [138] This technology has overcome at least one of the apparent shortcomings of tissue culture production systems. Transgenic cows, goats, pigs, and sheep can produce large quantities of human proteins, typically 110 g/L in milk, whereas animal tissue culture systems routinely produce substantially less protein, typically 10100 mg/L. [139] In addition, transgenic animals appear to be able to perform most of the post-translational modifications required for protein activity, even when the protein is being made at relatively high levels of production.[139] Most recently, even the highly modified coagulation factor VIII protein has been made in the milk of pigs in a biologically active form.[56] Proteins produced in transgenic animals should be free of human viruses, less expensive to produce, and available in unlimited quantities. Thus, the production of human plasma proteins in transgenic animals is an attractive alternative to their isolation from human plasma or production in tissue culture systems.

Gene Therapy

Of course, the most satisfying solution to human genetic deficiencies would be the replacement of the dysfunctional gene in the affected individual so that the consequence of the gene abnormality goes unnoticed. This process, termed gene therapy, is the subject of intense research, especially for treatment of hemophilia A and B.[140] [141] [142] Although the number of hemophilia B patients is relatively small, the characteristics of both the disease and the factor IX molecule are such that it has become an excellent model system for the development of generic gene therapies.[140] There are two general approaches. Fully functional new genes may be inserted into various body cells using a modified virus or other carrier. Alternatively, cells containing functional genes may be implanted into various body tissues. The main issues with either approach are the production of sufficient protein and the persistence of the production. In addition, hemophiliacs could still develop inhibitors to these proteins. Although these problems are far from being solved, the pace of the research has been rapid and an actual cure for diseases like hemophilia may be in sight.

Chapter 140 - Transfusion Principles for Congenital Coagulation Disorders

Joan Cox Gill

INTRODUCTION

Rapid advances in knowledge over the past several decades have led to an increased understanding of both hemorrhagic and thrombophilic plasma deficiency states and to the development of sophisticated therapeutic products to replace many of the deficient proteins. This chapter outlines the general principles of replacement transfusion therapy for clotting factor and other plasma protein deficiencies and provides recommendations for the use of transfusion and pharmacologic products for these disorders.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

GENERAL PRINCIPLES OF PLASMA PROTEIN TRANSFUSION THERAPY

Of major importance in the consideration of therapeutic options for a particular patient is the establishment of an accurate diagnosis and determination of the severity of the patients coagulopathy. Because hemostasis testing is often technically difficult and time-consuming, the clinician who relies on an inexperienced laboratory will have great difficulty in the treatment of a patient when the proper diagnosis is masked by laboratory artifact. Therefore, a high-quality and experienced coagulation laboratory should be used.

Once an accurate diagnosis has been established and the severity of the plasma protein deficiency has been determined, replacement therapy and other therapeutic maneuvers can be planned to restore balance to the hemostatic system. For a rational approach, one must first know the hemostatic level that must be achieved to treat a particular clinical manifestation. [1] For example, it has been established that patients with hemophilia A require 30-40% of normal factor VIII levels to control joint hemorrhages;[2] however, for major surgery, a 100% correction is desirable. [3] Hemostatic levels have been established for most of the coagulation factors and are summarized in Table 140-1 .

Second, the in vivo volume of distribution of the plasma protein must be considered. The volume of distribution differs for each protein because of varying molecular size, interaction with other plasma proteins, and interaction with cellular elements of blood as well as the endothelial cell. The dose needed to raise the plasma level a desired amount has been determined by recovery and half-life studies for the various coagulation factor proteins and is included in Table 140-1 . For example, infusion of 1 U factor VIII/kg results in a 2% (2 U/dl) rise in plasma factor VIII. Thus, a 70-kg man with severe hemophilia A (<1 U/dl factor VIII) would require 20 U/kg or 1,400 U factor VIII to achieve a 40% (U/dl) factor VIII level, the effective hemostatic level known to achieve hemostasis for a significant hemarthrosis.

Third, knowledge of the half-life of the infused protein is necessary if the plasma level of the coagulation factor must be maintained over time, as is necessary in perioperative management. For example, in the postoperative treatment of hemophilia A, because factor VIII has a 12-hour half-life, to maintain a plasma factor VIII level >4050% (U/dl), a 50% (25 U/kg) correction every 12 hours must be administered. The biologic half-lives of the coagulation factors are listed in Table 140-1 .

Finally, the concentration of the coagulation factor in the product must be known to calculate the amount of product to be administered. Fresh-frozen plasma, because of its content of approximately 1 IU/ml of each of the coagulation factors, can theoretically be used to treat any plasma protein deficiency, but frequently the dose needed to attain a particular in vivo hemostatic level would result in circulatory volume overload. Therefore, the coagulation factor concentrates, because of their convenience and now increased safety over most plasma and cryoprecipitate products, have become the preferred product for treatment of most disorders; the amount contained in each vial is printed on the label. In cases of life-threatening bleeding or major surgery, or if the patient is not responding clinically as expected, laboratory monitoring of factor levels is advisable. A detailed description of the preparation and properties of products containing coagulation factor proteins is found in Chapter 139 .

THERAPY FOR PROCOAGULANT DEFICIENCIES

Hemophilia A

Once the diagnosis of hemophilia A (factor VIII deficiency) has been established, the clinician may choose from a variety of therapeutic alternatives to treat bleeding manifestations or to prepare the patient for surgery, tooth extractions, or other invasive procedures. The desired concentration of plasma factor VIII (hemostatic level) to be achieved depends on the type and location of the bleed or planned procedure. Two dose classifications are generally accepted. For tooth extractions, routine joint and muscle hemorrhages, and lacerations, one should attain a plasma factor VIII level of 3040% (U/dl) (Table 140-2). In contrast, more aggressive replacement therapy (80100% [U/dl]

TABLE 140-1 -- Characteristics of Coagulation Factors Important for Transfusion Therapy

Factor	Factor Source (concentrate)	Minimum Hemostatic Level[a]	Desired Initial Level for Major Surgery	Increase in Plasma Level with Dose of 1 U/Kg	Biologic Half-life	Initial Dose[b]
Fibrinogen (I)	Cryoprecipitate (200300 mg/bag)	75150 mg/dl	150 mg/dl	[c]	45 days	23 bags/15 kg daily
Prothrombin (II)	Plasma PCC[d]	1540 U/dl	40 U/dl	1 U/dl	3 days	1520 ml/kg 40 U/kg
V	Plasma	1025 U/dl	30 U/dl	1.5 U/dl	1236 hours	1520 ml/kg
VII	Plasma PCC[d]	510 U/dl	25 U/dl	1 U/dl	46 hours	1520 ml/kg 2050 U/kg
VIII	Factor VIII concentrate	3050 U/dl	100 U/dl	2 U/dl	1215 hours	50 U/kg
IX	Factor IX concentrate	2050 U/dl	80 U/dl	1 U/dl	1830 hours	80 U/kg
X	Plasma PCC[d]	1020 U/dl	25 U/dl	1 U/dl	1.52.5 days	1520 U/kg 25 U/kg
XI	Plasma	1030 U/dl	30 U/dl	2 U/dl	13 days	1520 ml/kg
XIII	Plasma Cryoprecipitate (50100 U/bag)	15 U/dl	5 U/dl	13 U/dl	310 days	10 ml/kg 1 bag/20 kg
von Willebrand factor	Humate-P	3050 U/dl	80 U/dl	2 U/dl	1215 hours	4050 U/kg

[a] The lower value is the minimum hemostatic level required for treatment of minor bleeding and the higher value is the maintenance nadir level required for treatment of major bleeds and surgery.
[b] For severe deficiency for surgery.
[c] 1020 ml/kg fresh-frozen plasma or 1 donor unit (bag)/5 kg cryoprecipitate will raise the plasma fibrinogen level 50100 mg/dl.
[d] Prothrombin complex concentrate; factor VII content variable.

TABLE 140-2 -- Treatment of Specific Hemorrhages in Hemophilia

Type of Bleed	Hemophilia A	Hemophilia B
Hemarthrosis[a]	20 U/kg FVIII concentrate;[b] 15 U/kg if treated early. Repeat dose the following day if severe bleed.	30 U/kg FIX concentrate;[c] 20 U/kg if treated early
Muscle or significant subcutaneous hematoma	20 U/kg FVIII concentrate; may need every-other-day treatment until well controlled	30 U/kg FIX concentrate;[c] may need treatment every 2 or 3 days until well controlled
Mouth, deciduous tooth, or tooth extraction	20 U/kg FVIII concentrate; antifibrinolytic therapy; remove loose deciduous tooth	30 U/kg FIX concentrate;[c] antifibrinolytic therapy;[d] remove loose deciduous tooth
Epistaxis	Pressure for 1520 min; pack with Vaseline gauze; antifibrinolytic therapy; 20 U/kg FVIII concentrate if above fails	Pressure for 1520 min; pack with Vaseline gauze; antifibrinolytic therapy; 30U/kg FIX concentrate if above fails (4 hrs after antifibrinolytic dose)
Major surgery, life-threatening hemorrhage (e.g., CNS, GI, airway)	50 U/kg FVIII concentrate, then 25 U/kg q 12 hrs or continuous infusion to maintain FVIII >100 U/dl for 24 hrs, then >50 U/dl for 57 days and then >30 U/dl for 57 days	80 U/kg FIX concentrate,[c] then 2040 U/kg q 1224 hrs to maintain FIX >40 U/dl for 57 days and then >30 U/dl for 57 days[c]
Iliopsoas hemorrhage	50 U/kg FVIII concentrate, then 25 U/kg q 12 hrs until asymptomatic, then 20 U/kg qod for total 1014 days[e]	80 U/kg FIX concentrate,[c] then 2040 U/kg q 1224 hrs to maintain FIX >40 U/dl until asymptomatic, then 30 U/kg qod for total 1014 days[c] [e]
Hematuria	Bed rest; 1.5 × maintenance fluids; if not controlled in 12 days, 20 U/kg FVIII concentrate; if not controlled, prednisone if HIV negative	Bed rest; 1.5 × maintenance fluids; if not controlled in 12 days, 30 U/kg FIX concentrate; if not controlled, prednisone if HIV negative

[a] For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable.
[b] For mild or moderate hemophilia, DDAVP (0.3 mcg/kg) should be used instead of FVIII concentrate if patient is known to respond with a hemostatic level of FVIII; if repeated doses are given, monitor FVIII levels for tachyphylaxis.
[c] If repeated doses of FIX concentrate are given, highly purified coagulation FIX concentrate should be used. If recombinant FIX concentrate (BeneFix) is used, multiply the dose by a factor of 1.2.

[d]Do not give antifibrinolytic therapy until 46 hrs after a dose of prothrombin complex factor IX concentrate.
[e]Repeat radiologic assessment should be performed before discontinuation of therapy.

plasma factor VIII) should be instituted for patients undergoing major surgery or with limb- or life-threatening bleeding episodes such as central nervous system bleeding, hemorrhage around the neck or retroperitoneum, and compartment syndromes from muscle or subcutaneous hemorrhage. Calculation of the dose required to achieve a desired hemostatic level is based on the following formula: [4]

Thus, for treatment of a hemarthrosis in a 70-kg man with severe hemophilia A, the dose would be 40 (U/dl) × 70 (kg) × 0.5 = 1,400 IU factor VIII.

For patients undergoing major surgery or with serious hemorrhage, the plasma factor VIII level should rapidly be corrected to 100% (U/dl) or if for surgery, immediately before the procedure, and then maintained at 75100% for 24 hours, then >4050% (U/dl) for 57 days and >2030% (U/dl) for an additional 57 days (Table 140-2). This can be accomplished by infusion of intermittent doses of factor VIII based on the half-life of 12 hours; for example, by administration of 25 U/kg (50% [U/dl] correction) every 12 hours. Alternatively, a 50% (U/dl) level can be maintained by continuous infusion of 2 IU factor VIII/kg/hr (0.4 IU/kg/hr/% [U/dl] desired factor VIII level).[5] It is advisable to administer a 50% (U/dl) correction of factor VIII concentrate immediately after major surgery to compensate for the loss of factor VIII by increased consumption and blood loss during the surgical procedure. If a continuous infusion is chosen for postoperative therapy, a dose of 4 IU factor VIII/kg/hr for the first 24 hours will maintain the factor VIII level in the 75100% range. For surgical procedures and limb- and life-threatening hemorrhages, a factor VIII assay should be monitored at least daily. Central nervous system bleeding requires a full 2 weeks of therapy, and patients are at increased risk of recurrence for approximately 6 months after an episode. Iliopsoas and other retroperitoneal hemorrhages must be treated aggressively with maintenance of a 50% (U/dl) plasma factor VIII level until symptoms have abated; it is then possible to taper the factor VIII therapy to every other day for a total of 1014 days.

For treatment of more routine bleeding, such as hemarthrosis, usually only a single dose of clotting factor replacement (plasma factor VIII level 3040% [U/dl]) is required. However, with severe joint bleeds or in the case of many muscle bleeds, additional infusions of factor VIII must be given. Generally, administration of a 40% correction every other day for 710 days, or until a muscle hemorrhage or large subcutaneous hematoma has nearly resolved, is adequate. For tooth extractions, mouth lacerations, or recurrent epistaxis, it is often helpful to use antifibrinolytic therapy as an adjunct (Table 140-2).

Prophylaxis is routinely being used in many centers now that recombinant concentrates are available. This strategy has been shown to prevent the chronic arthropathy seen when hemarthroses are treated episodically. A dose of 2040 U/kg of factor VIII concentrate is given every other day or three times weekly. The dose and frequency are adjusted to maintain a plasma nadir level of >1 U/dl. [6] [7]

Therapy Products

Recombinant Factor VIII Concentrates

The factor VIII gene has been cloned, sequenced, and successfully transfected into mammalian cell cultures to produce recombinant factor VIII. [8] [9] Two recombinant factor VIII products are currently available, Recombinate and Kogenate. Clinical trials have documented that the half-life, recovery, and efficacy of recombinant factor VIII is indistinguishable from plasma-derived factor VIII. [10] [11] The clear advantage to the use of recombinant factor VIII is safety from human viral contamination, making these products preferable to plasma-derived concentrates in most cases if cost is not an issue. The need for human albumin as a stabilizer in these preparations is a disadvantage, however, because any human blood-derived protein could theoretically become contaminated with an as-yet-unknown infectious agent; for example, the agent of Creutzfeldt-Jakob disease has recently been a source of anxiety, although there have been no known cases of transmission of the disease by any blood product. [12] [13] Two newly developed recombinant factor VIII concentrates, one a B-domain-deleted preparation, are currently in clinical trials; the absence of human albumin as a stabilizer in these products should provide an additional measure of safety from human bloodborne infectious agents. Initial concern that the incidence of inhibitor development was increased in previously untreated patients treated with highly purified factor VIII concentrates was probably due to the differences in follow-up and data collection performed in the setting of these clinical trials. [14] [15] Subsequent carefully performed retrospective studies of patients treated with intermediate-purity products suggested that there is no difference in the incidence of inhibitor development. [16]

Plasma-Derived Factor VIII Concentrates

Several commercial plasma-derived factor VIII concentrates are available. Concentrates of intermediate purity are produced from large pools of plasma by combinations of cryoprecipitation and precipitation with glycine, polyethylene glycol, or ethanol. [17] These products contain, on the average, 25 units of antihemophilic factor (AHF) (factor VIII) per mg protein. More recently, products of high purity have been developed. These products, also derived from large pools of human plasma, are produced by immunopurification of cryoprecipitate on monoclonal antibody columns using mouse monoclonal antibodies to factor VIII [18] or von Willebrand factor (vWF). [19] Extraneous proteins are washed from the column, the factor VIII is eluted, albumin is added as a stabilizer (resulting in 215 AHF U/mg protein), and the final product is lyophilized. Products produced by gel filtration chromatography are also considered to be of high purity and contain approximately 922 AHF U/mg protein, similar to the monoclonal antibody-purified factor VIII concentrates after albumin has been added during the formulation. The diversity of foreign antigens contaminating the products is higher, however, because the specific activity is 3560 AHF U/mg protein before the addition of albumin, whereas the monoclonal antibody immunopurification results in 1,5002,500 AHF U/mg protein before the addition of albumin.

With improved purity of plasma-derived products, the frequency of complications due to exposure to extraneous plasma proteins has greatly diminished. Complications such as allergic reactions, isohemagglutinin-induced hemolytic anemia, immune complex-mediated hematuria, and granulocyte antibody-induced acute lung injury are rarely seen. Use of monoclonal antibody immunopurified concentrates appears to stabilize CD4 counts in human immunodeficiency virus (HIV)-infected hemophilic patients.[20] [21]

All plasma protein concentrates now undergo a viral attenuation process in addition to purification. Dry heating in the lyophilized state from 60°C to 68°C for 3072 hours, initially developed to eliminate hepatitis from concentrates, was soon shown to be ineffective for this purpose; hepatitis C developed in most treated patients. [22] However, it was fairly effective in reduction of HIV transmission, although a few cases were reported. With the development of improved viral attenuation methods, all dry-heated factor VIII concentrates of intermediate purity were removed from the market. Newer virus attenuation methods include heating in the wet state (pasteurization),

solvent/detergent treatment with a variety of agents, vapor heating, superdry heat (80°C for 72 hours), and affinity chromatography plus dry heat or solvent/detergent treatment. These methods have been successful in eliminating HIV seroconversions and possibly hepatitis C. [23] The exceptions have included the transmission of hepatitis C in products heated in n-heptane and probable transmission of hepatitis A in products treated with a particular solvent/detergent method. [24] Parvovirus can be transmitted by all current virus-inactivated human plasma-derived concentrates. [25] The risk of hepatitis B transmission can be further diminished by scrupulous immunization at the time of diagnosis of all patients, including infants, with one of the hepatitis B vaccines. [26] If clotting factor replacement therapy is needed at the time of diagnosis, hepatitis B immunoglobulin with the first dose of vaccine may provide passive protection until vaccine-induced antibodies are formed. Family members of chronic carriers of hepatitis B antigen and those involved in the preparation and administration of clotting factor concentrates should also be immunized. Patients older than 2 years should undergo immunization with the hepatitis A vaccine as well. [27]

Factor VIII concentrates are formulated in vials that may be stored either refrigerated or, for short periods, at room temperature. These commercial products are packaged in vials with the number of units of activity of the coagulation factor printed on the label, and most packages also contain diluent and needles necessary for

reconstitution and administration of the product; thus, they are very convenient for outpatient use and home care.

Cryoprecipitate

The first widely used concentrated factor VIII preparation, cryoprecipitate, was prepared by Judith Graham Poole in 1965. [28] Since that time technical advances have improved the yield of factor VIII in cryoprecipitate, and the preparations now generally contain approximately 100 IU factor VIII/bag. Thus, the patient with hemophilia A would require exposure to 216 donor U (bags) for treatment of a single routine hemorrhage, in comparison with the 10,00020,000 donor exposures associated with exposure to a single lot of commercial concentrate. Before the development of effective viral attenuation of commercial lyophilized factor VIII concentrates, cryoprecipitate was safer from transfusion-transmitted viral disease because of the reduced number of donor exposures. However, recombinant or viral attenuated concentrates are now preferred because cryoprecipitate is not easily viral attenuated. [20]

Desmopressin

Desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]), a synthetic vasopressin analog, increases factor VIII and vWF levels, allowing successful treatment of dental and surgical patients with mild and moderate hemophilia A and von Willebrand disease (vWD) with desmopressin alone. [29] [30] [31] Desmopressin is now considered the treatment of choice in patients with mild and moderate hemophilia A who respond to the drug. It is not efficacious in the treatment of severe hemophilia A or severe type III vWD or in patients with any form of hemophilia B.

The individual response to desmopressin is variable; [32] in hemophilia A, the range of responses has been reported to be 225-fold over baseline factor VIII levels. Thus, patients should undergo a trial dose with laboratory measurement of the factor VIII (or vWF) response before the use of desmopressin for the treatment of bleeding episodes and prophylaxis for dental and other surgical procedures. A single individual usually responds to a similar degree with repeated doses; [33] thus, the plasma level of factor VIII attained after a trial dose of desmopressin can be used to predict responses for the design of future therapy. For example, a patient with mild hemophilia A who achieves a 40% factor VIII level after desmopressin stimulation should be treated with desmopressin for routine hemarthroses, tooth extractions, and so forth, but desmopressin would not be sufficient for treatment of limb- or life-threatening hemorrhages or preparation for major surgery, situations in which a 100% factor VIII level is indicated.

Desmopressin is now available in both an intravenous form and a concentrated intranasal form (Stimate). [34] [35] Care must be taken to ensure that pharmacies do not substitute the dilute intranasal preparation formulated for the treatment of enuresis and diabetes insipidus; it is not effective for treatment of hemophilia and vWD. The recommended dose of intravenous desmopressin is 0.3 g/kg;[29] [32] the calculated dose is diluted in 2550 ml normal saline and given as an intravenous infusion over 30 minutes. The dose of intranasal desmopressin is 150 g (one puff) for patients <50 kg and 300 g (two puffs, one in each nostril) for those >50 kg. Because the maximal rise in factor VIII occurs at 3060 minutes, it is advisable to time the infusion as close to the surgical procedure as possible.

Tachyphylaxis may occur with repeated doses of desmopressin and varies from patient to patient. [36] Therefore, if repeated dosing is contemplated, factor VIII levels should be monitored and exogenous factor VIII given as needed. In general, if 24 days have elapsed between doses, a response similar to baseline can be expected.

Side effects are usually minimal and include facial flushing, headache, or mild increases in pulse rate or blood pressure that resolve when the infusion is slowed or discontinued. Rare cases of seizures associated with hyponatremia have been reported. [37] Fluids should be restricted to maintenance for 24 hours when desmopressin is administered, and serum sodium should be monitored in the patient treated with repeated doses; hyponatremia generally responds to fluid restriction. Thrombosis has occurred rarely;[38] thus, the drug should be used with caution in patients with an increased risk of thrombosis.

Antifibrinolytic Therapy

Antifibrinolytic therapy is a useful adjunctive therapy, particularly for treatment of injuries involving the oral and nasal mucous membranes. It is not effective in obtaining initial hemostasis, but it prevents clot lysis once hemostasis has been achieved by clotting factor replacement or local measures. For example, in the treatment of dental extractions, usually a single dose of clotting factor replacement before the procedure is sufficient for hemostasis, and maintenance with an antifibrinolytic agent can be substituted for maintenance clotting factor replacement. [39] [40] Tranexamic acid has recently been shown to be effective when used as a mouthwash, as well.[41] Antifibrinolytic agents have not shown any efficacy in the treatment of hemarthroses and are contraindicated in the presence of hematuria. Patients treated with prothrombin complex concentrates should not be given antifibrinolytic drugs simultaneously with an infusion (it is advisable to wait at least 46 hours) because of the increased risk of thrombotic complications.

Two antifibrinolytic agents are available in the United States, -aminocaproic acid (EACA; Amicar) and tranexamic acid (Cyclokapron). EACA is formulated in an oral tablet and an oral elixir form. The tablet is a very large 500-mg size, and with the usual adult dose of 5 g (10 capsules), even adults prefer the elixir. The oral dose of EACA is 100 mg/kg (maximum 10 g) initial dose followed by 50 mg/kg/dose (maximum 5 g) every 6 hours. The second agent, tranexamic acid, is also available in 500-mg capsules, but they are smaller and the lower recommended oral dose (25 mg/kg/dose every 68 hours) is more tolerable. Both are available in intravenous forms, but the dosing schedules are different.

Hemophilia B

The clinical manifestations of hemophilia B (factor IX deficiency) are quite similar to those of hemophilia A. Therefore,

the approach to management of hemorrhages with products containing factor IX is analogous to that using factor VIII in hemophilia A. Recovery of factor IX in plasma after an infusion is approximately half that of factor VIII (1% [U/dl] rise after 1 U/kg); therefore, twice as much product must be given to achieve a desired plasma level (Table 140-1). However, the minimal hemostatic level is lower than that of factor VIII and the biologic half-life of factor IX is longer (1824 hours). [42]

Two generally accepted dose classifications are used for hemophilia B as well (Table 140-2). Routine bleeds such as hemarthrosis and muscle hemorrhage require 2030% (U/dl) plasma factor IX levels; with major surgery and life-threatening hemorrhage, an 80% (U/dl) factor IX level should be achieved initially and levels should be maintained at >3045% (U/dl) for 57 days and then >1520% (U/dl) for another 57 days. Calculation of the dose required to achieve a desired rise in plasma factor IX is as follows:

The dose calculation for the use of recombinant factor IX (BeneFix) must be multiplied by a factor of 1.2 to compensate for the decreased in vivo recovery of the transfused product (see the section on recombinant factor IX).

Thus, for treatment of hemarthrosis in a 70-kg man with severe hemophilia B, the dose would be 30% (U/dl) × 70 kg = 2,100 IU factor IX. If recombinant factor IX is used, the dose would be 30% (U/dl) × 70 kg × 1.2 = 2,500 IU. For maintenance therapy for major bleeds or surgery, doses are smaller because of the longer biologic half-life of factor IX. For major hemorrhage, factor IX levels should be monitored.

Therapy Products

Recombinant Factor IX Concentrate

A recombinant factor IX concentrate [43] (BeneFix) has recently been licensed for the treatment of hemophilia B. In addition to the added viral safety provided by the recombinant nature of the product, the final formulation is also free from albumin or other human plasma-derived protein, adding an additional measure of safety. Thus, this product is now preferred for the treatment of hemophilia B. Transfused recombinant factor IX concentrate has a decreased in vivo recovery compared to plasma-derived products, presumably due to dissimilar post-translational processing of the protein during synthesis in cell culture. Thus, previously established dose

calculations based on plasma-derived products must be multiplied by a factor of 1.2 to compensate for the decreased recovery of the recombinant protein. However, the in vivo half-life of the product is the same as that of human plasma-derived factor IX.

Both recombinant factor IX concentrate and the highly purified coagulation concentrates have been associated with the recently recognized syndrome of anaphylaxis in the setting of inhibitor development in young children with severe hemophilia B treated with these products. [44] Therefore, previously untreated patients with severe hemophilia B should receive their initial 1020 infusions at a medical facility able to manage anaphylaxis should it occur.

Coagulation Factor IX Concentrates

Coagulation factor IX concentrates are highly purified plasma-derived products that are nonthrombogenic. [45] If a human plasma-derived factor IX concentrate is chosen over recombinant factor IX, it is strongly recommended that these highly purified products be used instead of prothrombin complex concentrates when using high or repeated doses of factor IX for major surgery or life-threatening hemorrhages, in patients with impaired ability to clear activated coagulation factors such as those with hepatocellular disease or infants, those with crush injuries or massive muscle hemarthroses, or those with a history of thrombosis. The two currently available products are virus inactivated by solvent/detergent treatment (AlphaNine) in one and ultrafiltration plus thiocyanate treatment (MonoNine) in the other. As with the use of recombinant factor IX concentrate, precautions for the management of anaphylaxis in previously untreated patients should be taken as outlined in the preceding section.

Prothrombin Complex Concentrates

Fractionation procedures developed to produce intermediate-purity factor IX concentrates use barium sulfate precipitation and column chromatography with a variety of adsorbents.[46] [47] Because the physical and chemical properties of the vitamin K-dependent clotting factors are highly similar, factors II and X, as well as varying amounts of factor VII and the physiologic anticoagulant protein C, are copurified with factor IX. Although this similarity has been used for treatment of other vitamin K-dependent coagulation factor deficiencies, the presence of these factors in an activated form is thought to be the cause of rare but life-threatening thrombotic complications, including deep venous thrombosis, pulmonary emboli, myocardial infarctions, and disseminated intravascular coagulation. [48] [49] The risk appears to be increased in patients receiving high or multiple doses of concentrate or concurrent antifibrinolytic therapy or in those with significant liver disease and impaired ability to clear activated clotting factors from the circulation. Therefore, the recommendation was made to add 100 U heparin/500 U factor IX concentrate to the vials after the product is reconstituted when using these products in high doses or when more than a single infusion is anticipated. [50] However, nonthrombogenic highly purified factor IX concentrates, either recombinant or plasma-derived, have been developed and should be used when more than a single dose of factor IX is anticipated. [51] Currently available prothrombin complex concentrates undergo dry heating at high temperatures (80°C) or vapor heating to inactivate viruses; no HIV seroconversions have been noted, and hepatitis C transmission may also have been eliminated. [23]

Plasma

Until the recent availability of pure, safe factor IX concentrates, fresh-frozen plasma was used, particularly in young children and mild and moderate hemophilia B patients in whom infrequent use and smaller doses did not result in untoward numbers of donor exposures. However, recombinant factor IX concentrate or one of the highly purified, viral-attenuated concentrates is now preferred for treatment of hemophilia B. If fresh-frozen plasma is used for the treatment of coagulation deficiencies for which there is no safe, effective concentrate, consideration should be given to the use of small pools of well-screened volunteer donors to limit the possibility of HIV or hepatitis transmission. Some blood centers are using a delayed release strategy whereby a plasma donation is not released for transfusional use until the donor has returned some months later and been found to have negative viral serology, thus reducing the chance that the initial donation was made during the window period between viral infection and the ability of screening tests to detect the infection. A viral-attenuated solvent/detergent-treated plasma product has been licensed and should add an additional increment of viral safety. [52] If parental heterozygous carriers are considered for directed donations, clotting factor levels should be evaluated before donation of plasma for affected children. Maternal plasma should be avoided because it is more likely to be implicated in the rare complication of transfusion-related acute lung injury, mediated by granulocyte antibodies. [53] Fresh-frozen plasma should be ABO type-compatible to avoid the complication of isohemagglutinin-induced hemolytic anemia. Fresh-frozen plasma should be administered immediately after thawing. [54]

Patients with intact cardiovascular systems can safely tolerate a dose of 1520 ml/kg.

Hemophilia with Inhibitors

Of patients with severe hemophilia A, 1530% develop a circulating inhibitor (antibody) to factor VIII, and thus treatment with factor VIII concentrates becomes extremely difficult or impossible. Development of an inhibitor should be suspected in a patient who does not respond to coagulation factor replacement therapy in the expected manner. Clinically, inhibitor patients can be divided into two general categories: those who develop higher titers of antibody with exposure to factor VIII (high responders) and those who maintain a low-titer inhibitor despite repeated doses of factor VIII (low responders). [55] Treatment recommendations differ for the two groups.

Low-Responder Factor VIII Inhibitors

Patients whose inhibitor titers, measured by the standard method of Kasper et al., [56] do not rise >10 Bethesda units despite exposure to factor VIII are considered low responders. Most of these individuals can continue to be treated with factor VIII concentrate, but in higher doses. For serious limb- or life-threatening bleeding, current recommendations include a bolus infusion of 100 U/kg factor VIII initially, followed by 20 U/kg/hr. Factor VIII assays should be obtained 1 hour after the bolus infusion and then at least daily so that the dose may be adjusted depending on the factor VIII level.

Joint and muscle hemorrhages and other more minor hemorrhages can usually be managed with bolus infusions of factor VIII; the exact dose should be determined in each patient based on a factor VIII recovery study after an infusion of factor VIII. Adjunctive therapy with antifibrinolytic agents is effective in the management of dental extraction and nasal and mucous membrane injury, as discussed above for noninhibitor patients.

High-Responder Factor VIII Inhibitors

Numerous therapies and combinations of therapies have been devised for treatment of the high-responder inhibitor patient; however, to date none of these is as uniformly successful as factor VIII replacement in the noninhibitor patient.

Prothrombin Complex Concentrates

Prothrombin complex concentrates are often used to treat routine joint and muscle hemorrhages in inhibitor patients. A multicenter study conducted in the late 1970s showed that the two prothrombin complex concentrates then available promoted hemostasis in 50% of bleeding episodes at a dose of 75 factor IX U/kg in comparison with a 25% placebo effect with albumin.[57] The addition of heat treatment to the manufacturing process has not altered the response rate. [58] Most physicians initially manage hemarthroses and other routine bleeds in these hemophilia patients with prothrombin complex concentrates. The dose for joint and muscle bleeds has varied from 50 to 100 U/kg; most physicians administer 75 U/kg/dose in this setting. If no response occurs after 2 or 3 infusions given 12 hours apart, it is unlikely that additional infusions will achieve hemostasis; instead, they will only increase the risk of thrombotic complications.

Activated Prothrombin Complex Concentrates

Currently two activated prothrombin complex concentrates (APCCs) are commercially available, Autoplex and FEIBA. They have been purposefully activated during fractionation, resulting in increased amounts of activated factor VII, factor X, and perhaps thrombin. These products are intended for use in patients with circulating inhibitors. Two double-blind controlled trials comparing the efficacy of APCC with standard prothrombin complex concentrates showed a small but significant advantage of FEIBA (64% efficacy) over a standard prothrombin complex concentrate (52% efficacy) in one trial [59] and no additional benefit of Autoplex over Proplex (standard prothrombin complex concentrate) in the second trial. [60] The introduction of viral attenuation of these products has had no apparent effect on their

hemostatic efficacy or safety in noncontrolled studies. [61] Although the high cost of the APCCs and their unproved efficacy over standard prothrombin complex concentrates has led most investigators to discourage their use for routine management of inhibitor patients, anecdotal reports of their utility in the management of serious bleeding episodes have led to the recommendation of their use as an initial therapy in serious hemorrhages when other available therapy would not be expected to be efficacious (e.g., patients with inhibitor titers >50 Bethesda units). The dose usually recommended is 75 U/kg. This can be repeated within 612 hours, but >3 consecutive doses and simultaneous use of antifibrinolytic therapy should be avoided, if possible. If not, the patient should be monitored for the possibility of disseminated intravascular coagulation and myocardial infarction, which has been reported with the use of APCCs as well as the standard prothrombin complex concentrates.[62]

Recombinant Factor VIIa

A recombinant factor VIIa (activated factor VII) concentrate has been developed and has been shown to achieve hemostasis in surgical and life-threatening hemorrhage in high-responder inhibitor patients who have failed conventional therapy. [63] [64] It is postulated to interact with tissue factor expressed on endothelial cells at the site of vascular injury and to activate factor X, thus bypassing the inhibited factor VIII cofactor step in factor X activation. [65] This promising product continues to undergo clinical trials and is currently available only for investigational or compassionate use.

Porcine Factor VIII Concentrates

Most investigators prefer to use a factor VIII-containing product for limb- or life-threatening bleeding if it is at all feasible to achieve a hemostatic level. Human factor VIII concentrate in high doses (see previous recommendations for low-responder inhibitors) can be tried if the inhibitor titer is <10 Bethesda units or can be lowered to <10 with plasma exchange or immunoadsorbant columns, but this is a temporary solution, because a rapid anamnestic response usually limits the ability to maintain a hemostatic level for >13 days in high-responder inhibitors. [66] A porcine factor VIII concentrate, highly purified by polyelectrolyte ion exchange chromatography, is particularly useful for treatment of hemorrhages in patients with an inhibitor titer <50 Bethesda units. [67] Occasionally, it has been efficacious in patients with higher-titer inhibitors who have antibodies that are less cross-reactive with porcine factor VIII. It is preferable to high-dose human factor VIII because of the lower risk of anamnesis.[68] In patients who do not have anamnesis, the product can be considered for routine bleeding as well. The recommended starting dose is 100150 U/kg, with measurement of plasma factor VIII levels to guide continued therapy. It is advisable to measure the antiporcine factor VIII antibody titer periodically in high-responder inhibitor patients to be prepared when a life-threatening hemorrhage occurs.

Other Therapy

In the 1970s, the first attempts were made to induce immune tolerance to factor VIII in inhibitor patients by infusions of twice-daily high doses of factor VIII (100150 U/kg) plus APCC over prolonged periods (months to years).[69] This very expensive and demanding treatment, although successful in 15

---

who completed the Bonn Protocol, led others to modify the regimen by eliminating the APCC and reducing the amount and frequency of factor VIII infusions, with some success.[70] [71] Other modifications reported to have varying success rates have included the use of intravenous gamma-globulin, immunosuppressive therapy, removal of antibody by extracorporeal immunoadsorption on Staph Protein A columns, and combinations of those modalities. [72] Induction of immune tolerance in four of five patients on home-based therapy with porcine factor VIII was also recently reported. [73]

Factor IX Inhibitors

In patients with hemophilia B and factor IX inhibitors, treatment with prothrombin complex concentrates for routine hemorrhages or APCCs for more serious bleeding at the dose recommended for factor VIII inhibitor patients has been successful. However, it is not helpful for patients with the syndrome of anaphylaxis in the setting of inhibitor development because it too contains factor IX. Recombinant factor VIIa has been shown to be efficacious in the patients with factor IX inhibitors in whom it has been tried.[74] Immune tolerance induction with high-dose factor IX concentrate has been disappointing, and several cases of nephrotic syndrome have developed when factor IX was given in high doses for immune tolerance induction.[74]

von Willebrand Disease

Treatment of vWD depends on the type of vWF defect and on the patients response to desmopressin. Either quantitative or qualitative vWF defects may be present. Transfusion products appropriate for each type are summarized in Table 140-3 .

The most common quantitative defect, a functional molecule present in decreased amounts (hypoproteinemia), is termed type I vWD; [75] most vWD patients (approximately 90%) are type I, and most of these respond to administration of desmopressin with a three- to fivefold increase in plasma vWF. [29] [30] [31] [32] [36] A single dose of desmopressin is generally sufficient for minor bleeding and tooth extractions. For oral bleeding and tooth extractions, antifibrinolytic therapy is also recommended, as discussed for hemophilia. It is advisable to perform a desmopressin trial to determine the individual response before its use for major surgical procedures; in general, if the vWF activity (ristocetin cofactor) rises to >100% (U/dl), the patient can be treated with desmopressin alone. For major surgery, doses given every 1224 hours for 23 days postoperatively are usually sufficient to maintain hemostatic levels of vWF >4050 U/dl (%). vWF:ristocetin cofactor levels should be measured daily and exogenous vWF (Humate-P or vWF concentrate) administered if tachyphylaxis occurs. In patients in whom factor VIII:C levels are also low, factor VIII:C should be monitored and maintained at a hemostatic level as recommended for hemophilia A with either desmopressin or factor VIII concentrate as needed.

Patients with qualitative vWF defects (type II) [76] can be subgrouped into those with absent high-molecular-weight multimers on the basis of failure of multimerization or increased proteolysis of vWF (type IIA), or those with a loss of high-molecular-weight multimers from plasma on the basis of an increased affinity of vWF for the platelet surface due either to a vWF defect (type IIB) [77] or to a platelet glycoprotein Ib defect (platelet-type vWD). [78] Some patients with type IIA vWD have a transient response to desmopressin, and minor bleeding may be treated with desmopressin. However, for major bleeds and surgery, replacement therapy with factor VIII concentrate containing normal vWF multimers (Humate-P) (see Chap. 139) is usually required. Type IIB patients and those with platelet-type vWD may have thrombocytopenia that is exacerbated by the administration of desmopressin; therefore, desmopressin is generally considered to be contraindicated in this group, although some investigators believe that it may be useful in some patients in this group. [79] Replacement therapy with Humate-P or vWF concentrate is required for treatment of type IIB vWD; platelets may need to be given if thrombocytopenia is severe, but normal vWF should be given first. For patients with platelet-type vWD, platelet transfusion is indicated for treatment of hemorrhages; rarely, vWF replacement is also needed.

Patients with severe type III vWD lack detectable vWF; the factor VIII:C level is also low (35%) because vWF serves as a stabilizer for factor VIII in the circulation. Desmopressin is ineffective in this group because vWF stores are also absent. Therefore, vWF and factor VIII must be replaced for treatment of hemorrhages. Because vWF has a 12-hour half-life in the circulation, management of bleeding episodes with vWF replacement is similar to that described above for factor VIII replacement for hemophilia A. Humate-P is currently the only licensed factor VIII concentrate in the United States that contains normal vWF. A purified plasma-derived vWF concentrate is currently in clinical trials. A recombinant vWF has been developed, but human clinical trials have not yet begun.

Other Inherited Procoagulant Deficiencies

Factors II, VII, and X

Transfusion therapy for these very rare vitamin K-dependent procoagulant deficiencies should be approached through analysis

TABLE 140-3 -- Therapeutic Alternatives for the Treatment of von Willebrand Disease

Type of vWD	Desmopressin	vWF or FVIII Concentrate	Platelets
I	Preferred treatment if desmopressin results in therapeutic level in trial	If desmopressin is not effective or if higher levels are required	Not indicated

IIA	Not usually effective; may cause improvement for 12 hours	Preferred treatment	Not indicated
IIB	May cause further decrease in platelet count	Preferred treatment	If thrombocytopenia remains severe after vWF replacement. Not usually effective alone
Platelet-type von Willebrand disease	May cause further decrease in platelet count	May cause further decrease in platelet count	Preferred treatment
Untyped von Willebrand disease	Use with caution; follow platelet count and vWF levels	Preferred treatment in untyped patient with von Willebrand disease	Not usually required unless patient has platelet-type von Willebrand disease

of minimal hemostatic levels, as well as recovery and half-life of the transfused protein (Table 140-1). As with other clotting factor deficiencies, the use of plasma may be limited by volume constraints but is usually quite efficacious at a dose of 1020 ml/kg because of the low minimal hemostatic levels of these procoagulants. If higher plasma levels of the vitamin K-dependent clotting factors are needed, one can either use plasma exchange procedures or begin the use of prothrombin complex concentrate. The content of the various vitamin K-dependent procoagulants in each prothrombin complex concentrate is variable. [80] [81] The specific concentration of the required clotting factor in a concentrate can often be obtained from the manufacturer. Precautions regarding adverse effects are outlined above for plasma and prothrombin complex concentrates. A factor VII concentrate is in development. Vitamin K administration has no role in the treatment of these inherited coagulopathies.

Fibrinogen and Factors V, XI, and XIII

Although most patients with fibrinogen deficiencies are asymptomatic, the afibrinogenemic and some of the dysfibrinogenemic patients may occasionally have hemorrhage that requires replacement therapy. Fibrinogen can be replaced with either plasma (1020 ml/kg) or cryoprecipitate (1 donor U/5 kg) to raise the fibrinogen level to 50100 mg/dl.[82] [83] Because of its long half-life, repeated infusions need only be given every 45 days if prolonged correction of the deficiency is required.

Factor V deficiency, also called parahemophilia, is rarely associated with bleeding severe enough to require replacement therapy. When required, the only available product is plasma; preferably the product should be <1 month old. Hemostatic level is approximately 25%, and the half-life of the transfused protein is 36 hours; thus, the condition is highly amenable to treatment with plasma. [84] [85]

Factor XI deficiency, also known as hemophilia C, is variably associated with symptoms, even in those with moderate or severe deficiencies. Therefore, treatment should be reserved for bleeding episodes or for surgery in those who are known to be symptomatic. Transfusion with plasma (1020 ml/kg) results in a rise of 2550% of factor XI, which is an adequate dose for hemostasis even for severe bleeding episodes and surgery. [86] Plasma exchange may also be useful.[87] Cryoprecipitate supernatant and one of the prothrombin complex concentrates (Konyne) contain factor XI and have been used in the extraordinary circumstance in which prolonged high-dose therapy is needed.[88] A factor XI concentrate is available in Europe.

Congenital factor XIII deficiency is an extremely rare deficiency characterized by bleeding with injuries and delayed healing. The very low hemostatic level (23%) and long half-life (6 days) permit most bleeding to be treated with plasma. [89] Alternatively, cryoprecipitate may be used;[90] a factor XIII concentrate is available in Europe.[91]

The contact factors, factor XII (Hageman factor), prekallekrein (Fletcher factor), and high-molecular-weight kininogen (Fitzgerald factor), are not associated with bleeding manifestations and require no transfusion therapy.

THERAPY FOR INHERITED ANTICOAGULANT DEFICIENCIES

Inherited deficiencies of the naturally occurring anticoagulants are associated with an increased risk of thrombosis, both arterial and venous. The most widely recognized is antithrombin III deficiency, but deficiencies of other physiologic anticoagulants, such as the vitamin K-dependent factors protein C and protein S, as well as the fibrinolytic protein plasminogen, have also been implicated in thrombophilic disorders. [92] The general approach for management of the heterozygous states is similar. Specific treatment is not instituted until the first thrombotic episode occurs because many heterozygotes never develop a thrombotic complication. At that point, after treatment of the acute thrombosis with standard therapy, lifelong anticoagulation with coumarin is usually recommended after the first or second thrombotic episode. In some cases, replacement therapy is warranted.

Antithrombin III Deficiency

Antithrombin III deficiency, a fairly rare heterozygous deficiency, has been well described as associated with venous thrombosis and pulmonary emboli. Because heparins anticoagulant activity to inactivate thrombin and factor Xa is effected through induction of a conformational change in antithrombin III, patients with antithrombin III deficiency may manifest heparin resistance when attempts are made to treat their thrombotic episodes. If significant heparin resistance is encountered, treatment with antithrombin III may be indicated. Antithrombin III may be replaced by infusion of a pasteurized antithrombin III concentrate licensed for prophylaxis of deep vein thrombosis and treatment of thrombosis in patients with inherited antithrombin III deficiency. [93] The transfused protein has a recovery of 1.4% (U/dl)/U/kg of antithrombin III administered and a biologic half-life of 3.8 days.

Protein C Deficiency

Heterozygous protein C deficiency has been variably associated with thrombotic tendencies. [94] Therefore, the incidental discovery of protein C deficiency is not an indication for lifelong anticoagulation. However, if thrombotic complications occur after treatment of the acute thrombotic event, long-term anticoagulation with coumarin is indicated. It is important that the patient be adequately heparinized during the initial administration of coumarin because protein C is a vitamin K-dependent protein with a very short half-life (46 hours); a more thrombophilic state is induced until the level of the procoagulants is also lowered and may be the cause of coumarin-induced skin necrosis. [95]

Homozygous protein C deficiency is an extremely rare disorder; affected infants have nearly all presented in the newborn period with purpura fulminans and disseminated intravascular coagulation. [96] Infants with these symptoms should have assays obtained for protein C and then be treated immediately with fresh-frozen plasma (912 ml/kg every 12 hours has been shown to control symptoms) or, if available, the vapor-heated protein C concentrate currently in clinical trials. [97] Replacement therapy should be continued until all lesions are healed. Once lesions have healed, most patients can be maintained on coumarin with occasional replacement therapy if symptoms recur.

Other Inherited Anticoagulant Deficiencies

Protein S, another vitamin K-dependent plasma anticoagulant, functions as a cofactor in protein C inactivation of factors Va and VIIIa. Heterozygous deficiency of free protein S has been described in families with an increased incidence of thrombotic episodes. [98] Currently no replacement product for protein S deficiency is available, and patients should be placed on lifelong anticoagulation after treatment of the initial thrombotic episode. Coumarin-induced skin necrosis has also been reported in association with heterozygous protein S deficiency. [99]

Other inherited deficiencies associated with hypercoagulability include dysfibrinogenemias (abnormal plasmin-binding site), plasminogen deficiencies, and tissue plasminogen activator release defects. [100] An inherited abnormality of factor V, factor V Leiden, resulting in the protein C resistance syndrome, and a mutation in the prothrombin gene leading to increased circulating levels of prothrombin have also been implicated in

the etiology of thrombosis. [101] No replacement products are currently available for treatment, and therapy depends on anticoagulation.

Chapter 141 - Hemapheresis and Cellular Therapy

Ellen F. Lazarus
Harvey G. Klein

INTRODUCTION

Bloodletting is an ancient therapy, fashionable, albeit unproved, well into the 19th century. About the time that scientific skepticism began to temper the widespread use of therapeutic phlebotomy, a new technique for blood removal, apheresis, appeared in the research laboratory. [1] The term *apheresis,* derived from a Greek verb meaning to take away or withdraw, was coined to describe removal of one component of blood with return of the remaining components to the donor. Like phlebotomy, apheresis was used first to treat patients but later became more important for collecting blood components for transfusion. In the United States, >6 million units of platelets are collected by plateletpheresis and >10 million plasmapheresis procedures are performed annually; an estimated 100,000 therapeutic apheresis procedures are performed each year in the United States for a wide variety of indications. [2]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PRINCIPLES OF APHERESIS

The principal objective of apheresis is efficient removal of some circulating blood component, either cells (cytapheresis) or some plasma solute (plasmapheresis). For most disorders, the treatment goal is to deplete the circulating cell or substance directly responsible for the disease process. Apheresis can also mobilize cells and plasma components from tissue depots. For example, lymphocytes may be mobilized from the spleen and lymph nodes of some patients with chronic lymphocytic leukemia, and low-density lipoproteins can be removed from tissue stores in patients with familial hypercholesterolemia. Apheresis may have other, less obvious effects. Lymphocyte depletion may modify immune responsiveness in some disease states, possibly by disturbing the control mechanisms of cellular immune regulation. Plasmapheresis enhances splenic clearance of immune complexes in certain autoimmune disorders. [3] When therapeutic effect is judged by clinical improvement rather than by efficiency of solute removal, apheresis is more often a helpful adjunct than a form of first-line therapy.

Several mathematic models formulated for different clinical conditions describe the kinetics of apheresis. [4] [5] [6] Removal of most blood components follows a logarithmic curve (Fig. 141-1). This model assumes that the component removed is neither synthesized nor degraded substantially during the procedure, remains

Figure 141-1 Relation between volumes removed by apheresis and percentage of the target component remaining. The relation is valid for blood volumes during red cell exchange or for plasma volumes during plasmapheresis if the target solute remains primarily within the intravascular compartment. Solid line, continuous exchange; large dashes, discontinuous exchange with initial removal; small dashes, discontinuous exchange with initial infusion.

within the intravascular compartment, and mixes instantaneously and completely with any plasma replacement solution. When the goal of plasmapheresis is to supply a deficient substance, for example plasma factors in the treatment of thrombotic thrombocytopenic purpura, replacement follows logarithmic kinetics similar to those developed for solute removal. From Figure 141-1 it is evident that removal of 1.52 volumes will reduce an intravascular substance by about 60% and that processing larger volumes results in little additional gain.

Specific cell removal with centrifugal automated cell separators depends on the number of cells available, the volume of blood processed, the efficiency of the particular instrument, and the separation characteristics of the different cells. Most commercially available instruments remove platelets and lymphocytes extremely efficiently. Granulocytes and monocytes cannot be cleanly separated from other cells by standard centrifugal apheresis equipment (Fig. 141-2). Optimal harvesting of these cells requires special techniques such as stimulating the donor with corticosteroids or cytokines and adding sedimenting agents to enhance cell separation.

TECHNOLOGY AND TECHNIQUES

The plasmapheresis technique that originated in the animal laboratory required manual resuspension of red cells and posed a substantial risk of microbial contamination of the components being reinfused.[1] With the introduction of sterile, disposable, interconnected plastic blood bags, plasmapheresis became relatively safe and easy. However, manual apheresis proved too inefficient and labor-intensive for collecting large component volumes and raised concerns that the separated units of red blood cells might be reinfused accidentally into the wrong donor or patient. The introduction of automated on-line blood cell separators solved these problems.[7] [8]

Automated apheresis instruments use microprocessor technology to draw and anticoagulate blood, separate components either by centrifugation or by filtration, collect the desired component, and recombine the remaining components for return to the patient. [9] The equipment contains disposable plastic software in the blood path and uses anticoagulants containing citrate or combinations of citrate and heparin that do not result in clinical anticoagulation of the patient. Most instruments function well at blood flow rates of 3080 ml/min and can operate from peripheral venous access or from a variety of multilumen central venous catheters.

Because the ideal method for treating disorders mediated by abnormal plasma components is to remove the offending substance selectively, a variety of on-line filtration and column adsorption techniques have been introduced or proposed. Ligands bound to a column matrix may be relatively nonspecific chemical sorbents, such as charcoal or heparin, or specific ligands, such as monoclonal antibodies and recombinant protein antigens. The two most successful clinical columns use staphylococcal protein A and dextran sulfate cellulose. Staphylococcal protein A has high affinity for the Fc portion of IgG1, 2, and 4 and for immune complexes containing these IgG subtypes. The dextran sulfate cellulose columns selectively remove low-density lipoproteins and have proved effective in managing patients with homozygous hypercholesterolemia (Fig. 141-3).

THERAPEUTIC CYTAPHERESIS

Common indications for therapeutic cell removal are listed in Table 141-1 . Red cell exchange (erythrocytapheresis) is used most often to manage or prevent the acute vaso-occlusive complications of sickle cell disease. Mechanical cell separators offer the advantages of speed and ease compared to manual exchange transfusion and reduce the risks of rapid blood volume alteration and increased blood viscosity that may occur with simple transfusion. Automated procedures can be performed with all centrifugal instruments (Fig. 141-4).

Figure 141-2 Schematic distribution of cells at the collection port of a centrifugal cell separator. The number and percentage of each cell type collected can be varied by adjusting the site of collection along the interface or by changing centrifugal force, blood flow rate, or rate of cell removal.

Figure 141-3 Two-stage therapeutic plasmapheresis. Plasma is separated from cells by filtration, then passed through parallel adsorption columns to remove low-density lipoproteins from a patient with homozygous familial hypercholesterolemia.

TABLE 141-1 -- Common Indications for Therapeutic Cytapheresis

Red cell exchange
Sickle cell disease
Acute complications
Prophylaxis for recurrent stroke
Frequent severe pain crises
Hyperparasitemia (malaria, babesiosis)
Leukapheresis
Leukemia with hyperleukocytosis syndrome
Cutaneous T-cell lymphoma (photopheresis)
Peripheral blood stem cell collection
Plateletpheresis
Symptomatic thrombocytosis

Sickle cell anemia occurs in individuals who are homozygous for a single mutation in codon 6 of the -globin gene, resulting in substitution of a single amino acid. Although the defect appears simple, the pathophysiology of the vaso-occlusive crises is complex, involving hemoglobin polymerization, change in cell shape, adhesion to endothelial cells, and release of inflammatory cytokines. Clinical manifestations may vary from patient to patient. [10] The rationale behind exchange transfusion involves improving tissue oxygenation and preventing microvascular sickling by diluting the patients abnormal red cells, simultaneously correcting anemia and favorably altering whole blood viscosity and rheology. No clinical data support a single optimal level of hemoglobin A (HbA); however, as few as 30% of transfused cells markedly decrease blood viscosity; at mixtures of 50%, resistance to membrane filterability approaches normal. [11] [12] In nonemergency situations, such levels can often be achieved with a simple transfusion regimen. For simple and

Figure 141-4 Schematic of an automated red cell exchange transfusion using a two-arm procedure.

exchange transfusions, raising the level of HbA to 70% while lowering the level of HbS to 30% is generally efficacious, although even higher levels of HbA may be required to treat an ongoing crisis.

Clinical indications for exchange transfusion remain controversial. Simple transfusion has improved renal concentrating ability and splenic function in young sickle cell patients; exchange transfusion has improved exercise tolerance and reversed the periodic oscillations in cutaneous blood flow associated with this disease. [13] [14] [15] [16] Such observations have encouraged the use of exchange transfusion for acute complications of sickle cell disease such as acute chest syndrome, priapism, cerebrovascular accident, and intrahepatic cholestasis. Exchange transfusion for sickle cell patients has also been used for prophylaxis during pregnancy, before surgery, or for patients who have suffered a stroke.[17] A multicenter randomized trial of transfusion during pregnancy has shown that transfusion sufficient to reduce the incidence of painful crises did not reduce other maternal morbidity or perinatal mortality. [18] In a randomized study of sickle cell disease patients undergoing surgery, a conservative simple transfusion regimen (to increase the hemoglobin level to 10 g/dl) was as effective as an aggressive regimen (to lower the HbS level to <30%) with respect to perioperative nontransfusion-related complications. The patients in the aggressive regimen group received twice as many units of blood, had a proportionally increased red blood cell alloimmunization rate, and had more hemolytic transfusion reactions. [19] The results of this and other studies suggest that if prophylactic preoperative exchange transfusion is used, it should be limited to patients undergoing high-risk procedures in whom simple transfusion could not effectively raise the HbA level to 70%.

Transfusion prophylaxis is now clearly indicated for children at high risk for stroke. A randomized controlled study [20] demonstrated a risk reduction of 90% in the

patients who were maintained at levels of HbS <30% by simple or exchange transfusion. This result confirms earlier experience and indicates that in this group of children with sickle cell anemia, transfusion therapy should begin before the first event and continue indefinitely. Long-term erythrocytapheresis may be preferable for patients at high risk for stroke who have developed iron overload to levels associated with organ damage. [21]

Exchange transfusion, although relatively safe and convenient, carries all the complications of red cell transfusion. Patients are exposed to a large number of donors and are at a small but significant risk of contracting hepatitis and other blood-born infections. As many as 33% of all patients develop alloantibodies, and life-threatening delayed hemolytic transfusion reactions have been reported. [22] [23] In addition, an immunohematologic study of multiply transfused sickle cell patients shows that 85% of heavily transfused patients are alloimmunized to HLA and/or platelet-specific antigens. [24] Most centers avoid inducing nonhemolytic transfusion reactions and HLA alloimmunization by using leukodepleted red cells. Extended red blood cell phenotyping at diagnosis and provision of phenotypically matched blood, when practical, can reduce the risk of red cell alloimmunization and associated hemolytic transfusion reactions. [25] Despite the removal of cells during exchange, patients remain in positive iron balance, although iron accumulation is slow and chelation is rarely required to prevent transfusional hemosiderosis. [21]

Other indications for red cell exchange are rare. The procedure has been used for patients with overwhelming red cell parasitic infections, such as severe and complicated malaria and babesiosis. [26] [27] In these situations, red cell exchange decreases the concentration of circulating parasites and may help sustain life until conventional therapy and natural immunity take effect. Although the efficacy of this therapy has not been evaluated by controlled trials, prospective studies and review of published cases[26] [28] suggest the use of erythrocytapheresis for parasitemia >1015%. Automated red cell removal with volume replacement, isovolemic hemodilution, can be performed rapidly and safely in polycythemic subjects. [29] This maneuver should be reserved for polycythemic patients with an urgent clinical indication to lower the hematocrit (e.g., evolving thrombotic stroke) for which standard single-unit manual phlebotomy might be inadvisably slow.

Therapeutic leukapheresis has been used most successfully to help manage patients with acute or chronic leukemia and extremely high white blood cell (WBC) numbers, so-called hyperleukocytic leukemias. When the fractional volume of leukocytes (leukocrit) exceeds 20%, blood viscosity increases and leukocytes can interfere with pulmonary and cerebral blood flow and compete with tissue for oxygen in the microcirculation. [30] A single leukapheresis procedure generally reduces the WBC count by 2050%. Ordinarily, leukapheresis is indicated when the blast count is >100,000/mm [3] or when rapidly rising blast counts are >50,000/mm[3] (leukocrit >10%), especially when evidence of central nervous system or pulmonary symptoms appears. [31] Although repeated leukapheresis has adequately reduced the WBC count in a series of patients with chronic myeloid leukemia, the median patient survival rate was not significantly different from that of similar patients treated with conventional chemotherapy.[32] Chronic leukapheresis can provide acceptable control of the peripheral WBC count in clinical situations such as pregnancy, when cytotoxic agents may best be avoided, but cytoreduction alone does not appear to alter the course of chronic myeloid leukemia.

Cytoreduction for managing other leukemic processes has limited value. Some studies of patients with chronic lymphocytic leukemia suggested short-term clinical benefit, but long-term support of patients when the disease is refractory to chemotherapy does not appear to prolong life. [33] [34] Transient responses to leukapheresis used alone or in combination with low-dose chemotherapy have been reported in a variety of lymphoproliferative disorders. However, most patients relapse quickly and do not respond to further leukapheresis therapy. [35] [36] [37]

Lymphocyte depletion has been used therapeutically to modify patient immune responsiveness. Removal of large numbers of lymphocytes over a period of a few weeks can suppress peripheral lymphocyte counts in rheumatoid arthritis patients for up to 1 year and alter skin-test reactivity and lymphocyte mitogen responsiveness to a variety of stimulants. [38] Selected patients experience a modest but significant reduction in disease activity; however, the subset of patients who may derive substantial benefit from this therapy is difficult to identify. [39] [40] Lymphocyte removal by apheresis has also been used to treat patients with multiple sclerosis, to enhance allograft survival, and to reverse graft rejection, but evidence of clinical efficacy in these situations is sparse.

Photopheresis is an automated extracorporeal photochemotherapy treatment that involves oral administration of a light-sensitizing agent, 8-methoxypsoralen, followed by leukapheresis and ex vivo ultraviolet A irradiation of leukocytes. The treated cells are reinfused. This therapy has minimal toxicity and is highly effective in the treatment of patients with advanced cutaneous T-cell lymphoma. Additional disease states that may respond to photopheresis therapy include systemic sclerosis and other autoimmune disorders,[41] solid organ graft rejection, [42] [43] and graft-versus-host disease following bone marrow transplantation. [44] Experience with photopheresis in these settings is limited.

Therapeutic plateletpheresis is generally reserved for patients with myeloproliferative disorders and hemorrhage or thrombosis associated with an increase in circulating platelets. Many centers consider using plateletpheresis when the patients peripheral platelet count is >10^6 /mm^3 , although no consistent relation between the level of platelet elevation and the occurrence of symptoms has been found, [45] [46] and no generally accepted assay of platelet dysfunction predicts which patients are at risk. A single cytapheresis procedure can lower the platelet count by 3050%. Attempts to maintain thrombocythemic patients at normal platelet counts by cytapheresis alone have not been successful; more practical long-term chemotherapy should be instituted concurrently. Since most patients with thrombocytosis, even those with myeloproliferative disorders, do not develop symptoms, prophylactic plateletpheresis is unwarranted, regardless of the platelet count. [47]

THERAPEUTIC PLASMAPHERESIS

Growth of therapeutic plasmapheresis during the past 50 years owes more to the development of new technology than to new insight into the pathophysiology of the diseases under treatment. Technical developments continue to outpace clinical applications. The prevailing developmental strategy has been to complement plasmapheresis with more specific procedures to remove pathologic plasma constituents. An impressive array of immunologic and physicochemical techniques, including cascade filtration, adsorption, immunoadsorption, cryoprecipitation, and photoinactivation, have been added to the plasmapheresis system for laboratory research and early clinical studies. [48]

Common clinical indications for therapeutic plasmapheresis are outlined in Table 141-2 . Committees appointed by the American Society for Apheresis, American Association of Blood Banks, and the American Academy of Neurology have published practice guidelines for using plasmapheresis in a wide variety of disease states.[49] [50] [51] Some of the least controversial indications for plasmapheresis are supported by small series of uncontrolled cases that rely on some objective clinical or laboratory measurement of patient improvement. This is the case for paraproteinimia with hyperviscosity syndrome, cold agglutinin disease, cryoglobulinemia, and poisoning with albumin-bound toxins. [52] [53] [54] [55] [56]

Evidence that both cutaneous and vascular lesions regress in familial hypercholesterolemia as low-density lipoprotein levels are controlled by plasmapheresis has encouraged the use of several related procedures in patients with homozygous disease and in poorly controlled heterozygous patients. Low-density lipoprotein apheresis is a procedure for removing apolipoprotein B-containing lipoproteins specifically from the blood by a variety of techniques, including dextran sulfate cellulose adsorption, immunoadsorption, and heparin-induced extracorporeal precipitation. Short-term safety and efficacy have been demonstrated. [57] Continuing experience with this therapy will be required to prove long-term clinical benefit in patients with refractory hypercholesterolemia and coronary artery disease.

Plasmapheresis may be used in patients with other inherited metabolic disorders, such as Refsums disease. [58] The frequency of exchange depends primarily on total body burden, rate of synthesis, and plasma concentration of the solute to be removed

TABLE 141-2 -- Common Indications for Therapeutic Plasmapheresis

Paraproteinemia with hyperviscosity syndrome
Cold agglutinin disease
Cryoglobulinemia
Drug overdose and poisoning (protein-bound toxins)
Homozygous familial hypercholesterolemia
Refsums disease
Myasthenia gravis
Post-transfusion purpura
Goodpastures syndrome
Pemphigus vulgaris
Chronic inflammatory demyelinating polyneuropathy
Guillain-Barré syndrome
Thrombotic thrombocytopenic purpura

Figure 141-5 Plasma exchange to remove plasma neutral glycolipids in a patient with Fabry disease. The plasma lipid recovery curve appears to be biphasic, reflecting initial re-equilibration from tissue stores and subsequent new synthesis of that glycolipid. Solid line, cerebrosides; dotted line, dihexosylceramides; large dashes, trihexosylceramides; small dashes, globosides.

(Fig. 141-5). Less evidence exists to support a role for repeated treatments in these disorders.

Plasmapheresis appears to have at least a temporary adjunctive role in managing some disorders characterized by circulating autoantibodies. Early success was reported in patients with Goodpastures syndrome, a disorder characterized by a specific pathogenic autoantibody directed against the renal glomerular and pulmonary alveolar basement membrane. Plasmapheresis has demonstrated similar success in a variety of disorders associated with specific autoantibodies, including myasthenia gravis, pemphigus, and Eaton-Lambert syndrome. In other autoimmune disorders, such as immune thrombocytopenic purpura and immune inhibitors to coagulation proteins, plasmapheresis may be helpful during a catastrophic event, but benefit in chronic disorders is less well established. [59] [60] [61] [62] [63] [64] [65] Controlled clinical trials of plasmapheresis have demonstrated efficacy in at least two of the polyradiculoneuropathies. [66] [67] However, intravenous immunoglobulin alone may be equally effective in the treatment of severe Guillain-Barré syndrome. [68] Although therapeutic plasma exchange has been used in a variety of other immune disorders, such as systemic lupus erythematosus and rheumatoid vasculitis, such use remains unproved and should be reserved for circumstances where a vital organ or life itself is endangered.

Controversy surrounds the practice of combining cytotoxic drug therapy with plasmapheresis to prevent rapid resynthesis of antibody, so-called antibody rebound. Although the rebound phenomenon is well established in animal models, investigational studies in healthy volunteers suggest that antibody rebound is not common. Controlled trials of plasmapheresis therapy in lupus nephritis and polymyositis have been criticized for not including a plasmapheresis-with-immunosuppression arm. Since many uncontrolled treatment protocols stipulate simultaneous use of immunosuppressive drugs and plasmapheresis, an apparent favorable outcome may result from the independent effects of the different treatments or some synergistic effect, or from neither.

Replacement Fluids for Plasma Exchange

The success of therapeutic apheresis procedures seldom depends on the composition of the replacement solution that is used. The single exception seems to be thrombotic thrombocytopenic purpura. Numerous reports support the use of fresh-frozen plasma or cryoprecipitate-poor plasma as a specific

therapeutic replacement fluid.[69] [70] The effectiveness of plasma exchange in this setting may derive from removal of antibody and/or replacement of a factor such as von Willebrand factor-cleaving protease.[71] [72] With therapeutic plasmapheresis for most other disorders, the primary function of the replacement solution is to maintain intravascular volume. Additional requirements include restoration of important plasma proteins, maintenance of colloid osmotic pressure, maintenance of electrolyte balance, and preservation of trace elements lost during a prolonged course of plasmapheresis procedures. In moderately well-nourished subjects, homeostatic mechanisms normally obviate the need for precise plasma replacement, and 5% albumin or combinations of albumin and crystalloid are usually sufficient. Other patients should receive solutions prepared specifically to meet their individual requirements. Routine supplementation with calcium, potassium, or immunoglobulins is unnecessary. Problems of decreased availability and high cost of albumin have led some centers to develop protocols for alternatives to plasma-derived volume expanders, such as hydroxyethyl starch, for full or partial volume replacement with plasma exchange.[73] These solutions are generally well tolerated. Since less than 500 ml is removed during most cell collection procedures and therapeutic cell depletions, no replacement beyond the anticoagulant and saline priming solution is required.

Complications of Therapeutic Apheresis

Automated apheresis is a minimal-risk procedure for normal healthy donors. The current generation of blood cell separators is remarkably reliable and equipped with sensitive detection and alarm systems to alert the operator to potential problems. Nevertheless, at least 59 deaths have been associated with therapeutic procedures, an estimated mortality of 3 in 10,000 procedures. However, in most reports, deaths are related to cardiac and respiratory causes in patients critically ill before apheresis, and the contributory role of the apheresis procedure is often questionable.[74] If citrate-induced hypocalcemia, vasovagal reactions, clotting of fistulas and catheters, and urticaria are included, about 10% of all therapeutic apheresis procedures have medical complications. The frequency of adverse reactions is influenced primarily by the experience of the operator and the nature of the patient population under treatment.[75]

Expected and predictable effects of therapeutic apheresis include alterations in laboratory parameters due to removal and dilution by replacement fluids. A 520% decrease in hemoglobin/hematocrit, a 2030% decrease in platelet count, and mild leukocytosis are commonly observed. Significant but transient abnormalities in coagulation tests often occur after serial plasma exchange procedures, as well as clinically insignificant decreased levels of other plasma proteins.[76]

The most common adverse effect of both donor and therapeutic apheresis is symptomatic hypocalcemia due to infusion of calcium-chelating citrate ions in the anticoagulant, and, if used as replacement fluid, anticoagulated donor plasma. This is usually manifested by mild perioral and/or acral paresthesia, requiring no intervention other than slowing the reinfusion rate. The benefit of oral calcium supplements in this setting is questionable, although the practice is widespread. Hyperventilation may exacerbate these symptoms. More severe citrate toxicity is very uncommon; signs may range from involuntary carpopedal spasm to frank tetany with spasm in other muscle groups, including life-threatening laryngospasm.[77] Controlled infusions of 10% calcium gluconate are effective in the management of these complications. Acute severe hypocalcemia leading to fatal cardiac arrhythmia has rarely been reported in apheresis patients. Because metabolism of citrate occurs predominantly in the liver and kidney, patients with conditions affecting these organs are at increased risk for severe citrate reactions. In addition, citrate toxicity has been reported due to mechanical dysfunction of the automated apheresis instrument.[78] A recent study of therapeutic plasma exchange procedures performed with and without 10% calcium gluconate infusion showed the effectiveness of continuous calcium infusion for the prevention of mild to moderate citrate toxicity;[79] however, careful monitoring is necessary to prevent inadvertent overdose if this procedure is adopted.

The most severe allergic complications occur when plasma is used as the replacement solution, and this risk increases with repeated exposure.[75] Allergic reactions to ethylene oxide, an agent used in the sterilization of plastic disposable equipment, have been reported.[80] Intravenous diphenhydramine is usually effective in managing these reactions; premedication with steroids and precautions against anaphylaxis may be necessary for sensitized individuals. Atypical (hypotension and flushing) and anaphylactic reactions have been reported in patients receiving angiotensin-converting enzyme inhibitors undergoing different apheresis procedures; these medications should be discontinued for 24 hours before apheresis.[81] Serious complications indirectly associated with therapeutic apheresis include adverse consequences of vascular access, namely hemorrhage, pneumo- or hemothorax, thrombosis, nerve damage, and infection. A retrospective review of 381 therapeutic plasma exchange procedures at one institution reported an approximately 1% incidence of severe complications, all of them related to central venous catheters.[82]

CELLULAR THERAPY

Blood cell separators developed for hemapheresis are used increasingly for novel forms of cellular therapy. In the cell-processing laboratory, separation techniques have been developed for removing T lymphocytes, for purging tumor cells, and for selecting progenitor cells from autologous bone marrow harvests and peripheral blood stem cell collection products. [83] Hematopoietic progenitor cells can be collected from peripheral blood and cryopreserved. Such progenitors are used to reconstitute bone marrow in patients who receive ablative chemotherapy. Lymphocyte concentrates prepared from leukocyte collections are used as immunotherapy for solid tumors, leukemia, and viral complications of bone marrow transplantation. Preliminary studies promise a role for both circulating hematopoietic progenitor cells and other mononuclear cells in the therapy of immunosuppressed patients and in gene therapy.

Peripheral Blood Stem Cells

Pluripotent hematopoietic progenitor cells, most likely including primordial hematopoietic stem cells capable of reconstituting the bone marrow and the immune system, have long been known to circulate in the peripheral blood. [84] Substantial numbers of peripheral blood (progenitor) stem cells (PBSCs), as measured by colony-forming assays, can be identified in plateletpheresis collections from normal donors. Numerous recent studies have confirmed the potential for rapid and durable engraftment of PBSCs mobilized into the circulation by hematopoietic growth factors and harvested by large-volume hemapheresis procedures. [85] PBSC infusions have been used both for complete marrow replacement and for bone marrow rescue after high-dose chemotherapy. PBSC collections have several practical advantages compared to bone marrow harvests: they eliminate the risk associated with anesthesia, permit collection of hematopoietic progenitor cells despite tumor involvement of the marrow or previous pelvic irradiation, facilitate graft manipulations by obtaining greater numbers of CD34+ cells, permit repeated collection as necessary, and can be safely performed on small children and even infants. [86] [87] Numerous recent studies show that PBSC transplantation consistently results in rapid hematopoietic recovery and durable engraftment in both

autologous and allogeneic transplant settings. [88] [89] [90] [91] PBSCs are rapidly replacing bone marrow for transplantation after myeloablative therapy. Despite the 10-fold increase in the number of T lymphocytes in unmanipulated allogeneic PBSC collections, there does not appear to be an increase in the incidence or severity of acute graft-versus-host disease, although the risk of chronic graft-versus-host disease may be higher. [92] The explanation for this seeming paradox is an area of active investigation.

Ordinarily, PBSCs circulate in small numbers. The concentration of stem cells in the peripheral blood can be increased by the administration of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage CSF (GM-CSF), and by the administration of chemotherapy. CD34+ hematopoietic stem cell levels in the peripheral blood generally rise 2050-fold (from 13 cells/L to 40-70 cells/L) following G-CSF alone, and they may show an even greater increase (1001000-fold) when chemotherapy rebound is enhanced by administration of G-CSF. New cytokines in development, or combinations of cytokines, may further improve PBSC mobilization, resulting in reduced numbers and smaller volumes of leukapheresis procedures required to obtain adequate transplants. The appropriate mobilization strategy to use depends on the clinical situation. In the autologous transplant setting, the mobilization regimen may consist of chemotherapy with or without cytokine administration, depending on the patients diagnosis and medical condition. Patient age >50 years and the number of prior chemotherapy cycles correlate inversely with efficacy of PBSC mobilization. [93] [94]

Efforts to define optimal collection conditions have been hindered by the lack of a standardized assay. In vitro functional hematopoeitic colony assays have been used to characterize and quantitate stem/progenitor cells collected by hemapheresis. Colony assays have limited clinical utility because they require 1014 days to perform. Assays that use the CD34 antigen as a marker for primitive hematopoietic progenitor cells can be used to predict the yield of PBSCs collected by leukapheresis, and have the advantage of a relatively rapid turn-around time. [85] Despite ongoing problems with interlaboratory standardization, flow cytometric analysis of CD34 immunostained blood cells can be used effectively for real-time decision-making about the timing and adequacy of PBSC collections. [85] [94] [95] Many studies show poor correlation between rebound leukocytosis or mononuclear cell counts and PBSC product CD34+ cell and colony counts. Optimal timing to achieve an adequate single leukapheresis collection of autologous PBSCs may be more accurately predicted by preceding-day [96] or same-day measurement of peripheral blood CD34+ cell concentration. Recent and ongoing studies are evaluating a variety of approaches to achieve standardization and clinical utility of CD34+ cell quantitation, including enhanced flow cytometry and microvolume fluorimetry. [97] [98]

Although definition of a therapeutic dose remains controversial, most centers recommend a minimum of 25×10^6 CD34+ cells/kg. Within this range, recovery of neutrophil and platelet counts as early as 12 weeks post-transplant is commonly observed. Greater numbers of CD34+ cells confer a shorter time to hematopoietic recovery and concomitantly fewer blood component transfusions; however, significant improvement in transplant-related mortality or overall survival has yet to be demonstrated in this setting. Several clinical scale devices for positive selection of CD34+ hematopoietic cells are available. CD34+ selection by immune-affinity techniques (positive selection) results in removal of unwanted cells, including occult malignant cells that do not express the CD34 antigen and T lymphocytes, without compromising the engraftment potential of the purified product. [99] [100] As yet, no data confirm the clinical benefit of positive selection.

Several problems complicate the widespread use of PBSCs. For allogeneic donors, the discomfort of multiple-day cytokine administration may be a significant deterrent. Citrate toxicity is a common complication of PBSC collections (see previous section); although usually mild and transient, it may be severe and even life-threatening in some individuals. Venous access requires large-bore multilumen catheters, and these appear particularly susceptible to clotting, especially when patients receive recombinant cytokine stimulation. Hemorrhage, especially in thrombocytopenic patients, is another potentially severe complication of central venous catheter placement. Patients who have received multiple prior cycles of chemotherapy occasionally fail to respond adequately to mobilization regimens. Finally, PBSCs are stored frozen in liquid nitrogen with the cryoprotectant dimethylsulfoxide. Cryopreservation is expensive, and rapid infusion of dimethylsulfoxide causes bradycardia, hypertension, fever, nausea, and vomiting. Toxicity is readily averted, however, by appropriate premedication and careful attention to infusion rates.

Adoptive Immunotherapy

Advances in cellular immunology and cell culture technology, the availability of recombinant human cytokines, and the ability to collect large numbers of lymphocytes have resulted in the development of adoptive immunotherapy, the passive transfer of immunologically active cells. Autologous adoptive immunotherapies require the harvest and ex vivo manipulation of peripheral blood mononuclear cells for reinfusion as potent cytotoxic effector cells. The most extensive clinical studies have been performed with autologous lymphocytes, collected by hemapheresis or separated from resected tumors and expanded ex vivo 1001,000-fold. [101] [102] Peripheral blood lymphocytes, cultured in high concentrations of the lymphokine interleukin-2, generate clones of cells capable of lysing fresh tumor cells in short-term cytotoxicity assays. The effector cells, termed lymphokine-activated killer (LAK) cells, consist of a heterogeneous population of cells, primarily natural killer cells and T cells, that mediate tumor regression in animal models. They have produced objective responses in patients with advanced renal cell carcinoma, melanoma, colorectal cancer, and non-Hodgkin lymphoma. The effects appear to be dose-dependent and non-MHC-restricted and require the simultaneous administration of high-dose systemic

interleukin-2. The postulated mechanism of action involves lymphocyte trafficking to the site of tumor, followed by local expansion and cytokine release under the influence of interleukin-2. Lymphocytes separated from resected tumors, termed tumor-infiltrating lymphocytes (TIL), can be similarly expanded, to up to 10 [12] cells, and infused. TIL are reportedly 50100 times more potent than LAK cells. [103] Unlike LAK cells, TIL often recognize specific tumor antigens, and their action is MHC-restricted. Recent trials of cytokine-primed TIL in the treatment of metastatic renal cell carcinoma and resected non-small cell lung carcinoma demonstrate clinical efficacy in selected subgroups of patients. [104] [105]

The ability to identify and isolate human tumor antigens by advanced molecular genetic techniques has resulted in the formulation of novel strategies for adoptive immunotherapy of cancer.[106] Peptides derived from these tumor antigens are pulsed onto antigen-presenting cells such as dendritic cells, [107] which can then be directly infused as cancer vaccines. Alternatively, the cancer peptide-pulsed antigen-presenting cells can be used to sensitize TIL or peripheral blood lymphocytes ex vivo for reinfusion as specific antitumor effector cells. Techniques to translate these experimental strategies into clinically practicable therapies are under development.

While adoptive immunotherapy has been used primarily in the treatment of solid tumors, cellular immunotherapy has also been investigated for the treatment of acquired immunodeficiency syndrome and for relapsed chronic myeloid leukemia after allogeneic bone marrow transplantation. Initial studies in

acquired immunodeficiency syndrome involved adoptive transfer of syngeneic peripheral blood lymphocytes and bone marrow; treatment resulted in short-term immune reconstitution, but no antiviral benefit. [108] Later studies with cells expanded 1524-fold in culture resulted in increased circulating CD4 cell numbers sustained for up to 6 weeks. Current approaches include the ex vivo expansion of HIV-specific cytotoxic T lymphocytes (CTL), and modification of the T-cell receptor by gene engineering techniques to permit target cell lysis in a non-MHC-restricted fashion. [109]

Infusion of donor leukocytes in chronic myeloid leukemia patients who relapsed after bone marrow transplantation resulted in cytogenetic remission after inducing graft-versus-host disease, suggesting a role for infusional cellular graft-versus-leukemia therapy. [110] Although small numbers of cells (10^7) generally suffice, cells collected by lymphocytapheresis are often aliquoted and stored for repeated treatment. A retrospective analysis of donor leukocyte infusion for relapsed hematologic malignancies after allogeneic bone marrow transplantation shows a complete response rate of 60% in chronic myeloid leukemia patients overall, with an even higher response rate in patients with relapsed chronic-phase disease. [111] Donor lymphocyte infusions also may effect complete or partial remissions in patients with relapsed multiple myeloma after allo-bone marrow transplantation. [112] Other complications of bone marrow transplantation that may be responsive to donor leukocyte infusion include Epstein-Barr virus-associated lymphoproliferative disorders and cytomegalovirus. [113] [114] Response to donor leukocytes is often associated with the development of acute and chronic graft-versus-host disease, although the severity is usually mild to moderate and controlled by immunosuppressive therapy. Another complication of donor leukocyte infusion is transient or persistent marrow aplasia, which may be attributed to the destruction of residual host hematopoiesis by the infused mononuclear cells before recovery of normal donor hematopoiesis. [115] Strategies to minimize these toxicities without compromising the graft-versus-leukemia effect are under development.

Cellular Gene Therapy

Cellular gene therapy is a technique in which a functioning gene is inserted ex vivo into somatic cells to correct an inborn genetic error or to provide some new function to the cell. The gene-modified cells, often selected and expanded, are infused into the patient. Successful therapy requires gene identification and isolation, efficient insertion and expression, and sufficient circulation or engraftment of the corrected cells. A variety of gene insertion techniques have been employed, but current strategies focus on a variety of replication-defective viruslike vectors. [116] [117] Most of the clinical studies have involved either lymphocytes or hematopoietic progenitor cells collected by apheresis as gene targets; however, numerous other target cells (e.g., myoblasts, hepatocytes) are possible. Some strategies take advantage of a survival advantage of the gene-corrected cells in the particular patient population, while other strategies involve using gene insertion to protect the desired population from the cytotoxic effects of chemotherapy or to render cells more immunogenic. Some gene therapy protocols, such as the adoptive transfer of receptor-modified syngeneic T cells for immune restoration in human immunodeficiency virus, combine elements of adoptive immunotherapy with gene therapy techniques.[118] As yet, few patients have derived definite benefit from cellular gene therapy trials. However, a great deal of information regarding therapeutic strategy, cell biology, host immune response, and techniques for cellular biologics has been derived from these pioneering attempts.

The ability to collect large numbers of leukocytes and PBSCs and to expand and manipulate their growth and differentiation in vitro makes these cells logical candidates for cellular gene therapy. Lymphocytes collected by hemapheresis were used in the first therapeutic gene transfer protocol. [119] Two children with severe combined immunodeficiency as a result of an inherited deficiency of adenosine deaminase (ADA) received autologous T cells that had been expanded ex vivo and corrected by the insertion of a normal ADA gene. Monthly collections and reinfusions of gene-corrected cells resulted in normalization of peripheral blood T-cell counts and significantly improved immune function and clinical status in both children. ADA gene expression in T cells has persisted for 3 years after the last gene treatment infusion, suggesting that the in vivo survival of reinfused transduced T lymphocytes may be longer than previously thought. [120] In these cases, lymphocytes have functioned as a temporary biologic drug-delivery system. Leukocytes are potential vehicles for replacing defective or deficient genes in a variety of other inherited disorders and for delivery of new genes (e.g., in the immunotherapy of cancer).

Permanent correction of genetic and acquired defects might be effected by inserting the missing or defective gene into hematopoietic stem cells. A broad range of inherited disorders are candidates for gene therapy using hematopoietic progenitor cells, including those with generalized (not hematopoietic-restricted) expression. Some candidate disorders involving a defective gene not normally expressed by hematopoietic cells are the hemophilias A and B and -1-antitrypsin deficiency. [116] Hematopoietic stem cell gene insertion with retroviral vectors has been accomplished in murine and nonhuman primate models, and in pilot human clinical trials, but the numbers of gene-marked cells are small and gene expression is poor. [122] In addition to inherited disorders, some strategies under investigation involve gene therapy for hematopoietic malignancies.[124]

Chapter 142 - Transfusion Reactions

Edward L. Snyder

INTRODUCTION

A transfusion reaction can be defined as any untoward reaction that occurs as a consequence of infusion of blood or one of its components. Reactions are considered to be acute when they occur during transfusion or within several hours after the transfusion has been terminated (Table 142-1). Reactions also can be classified as delayed. Delayed hemolytic transfusion reactions, for example, usually occur days after the transfusion. Other types of delayed reactions occur long after the blood has been infusedmonths or even yearsas in the case of some transfusion-transmitted diseases. The acute fatality rate after transfusion is 11.2/100,000 patients who receive a transfusion, or about 35 acute transfusion-related deaths/year in the United States. [1] This chapter reviews various types of transfusion reactions.

TABLE 142-1 -- Differential Diagnosis of Acute Transfusion Reactions

Reaction Type	Presenting Signs and Symptoms
Acute intravascular hemolytic	Fever, chills, dyspnea, hypotension, tachycardia, flushing, vomiting, back pain, hemoglobinuria, hemoglobinemia, shock
Acute extravascular hemolytic	Fever, indirect hyperbilirubinemia, post-transfusion hematocrit increment lower than expected
Febrile reaction	Fever, chills
Allergic (mild)	Urticaria, pruritus, rash
Anaphylactic	Dyspnea, bronchospasm, hypotension, tachycardia, shock
Hypervolemic	Dyspnea, tachycardia, hypertension, headache, jugular venous distention
Septic	Fever, chills, hypotension, tachycardia, vomiting, shock

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are caused by the immune-mediated lysis of transfused red cells. Immune-mediated hemolysis can be divided conveniently into four categories by time of reaction (acute or delayed) and by site of hemolysis (intravascular or extravascular). Thus, the four types are acute intravascular, acute extravascular, delayed intravascular, and delayed extravascular reactions (Table 142-2 (Table Not Available)).

Acute Intravascular Hemolytic Transfusion Reactions

Acute reactions occur when incompatible red cells are transfused into a patient who already possesses the corresponding antibody, and a reaction occurs within minutes. Because of naturally occurring ABO antibodies, infusion of ABO-incompatible blood is the most likely cause of a clinically significant acute intravascular hemolytic transfusion reaction.[2] Such a reaction could occur, for example, after transfusion of A red cells into an O recipient who has significant amounts of circulating anti-A. Although the titer and avidity of the antibody affect the extent of the hemolytic reaction, the clinical severity of an ABO-incompatible blood transfusion is greatly influenced by the degree of complement activation and cytokine stimulation. In an ABO-incompatible transfusion reaction, fixation of the C5b-9 complex occurs with release of C3a and C5a (anaphylatoxins 1 and 2, respectively). These low-molecular-weight peptides produce bronchospasm, mast cell degranulation, hypotension (C3a), and pulmonary dysfunction (C5a); the latter is secondary to migration of granulocytes to the pulmonary capillary bed, resulting in V/Q abnormalities.[3] Fixation of the C5b-9 complement membrane attack complex produces pores in the red cell membrane, and the resultant osmotic lysis produces hemoglobinuria and hemoglobinemia.[3] [4] Indeed, the sine qua non of an acute intravascular hemolytic transfusion reaction is the presence of both red plasma and red urine.

It is critical to distinguish, as quickly as possible, hemoglobinuria and hemoglobinemia secondary to an acute hemolytic transfusion reaction from similar signs due to other causes. Hemoglobinuria can be confused with hematuria from bladder hemorrhage, or myoglobinuria. Hemoglobinemia due to non-immune-mediated lysis can occur secondary to mechanical hemolysis from an improperly collected blood sample. The direct antiglobulin test (DAT) usually becomes positive in an immune hemolytic reaction; preparation of an antibody eluate is necessary to identify the offending antibody. An antibody elution is the removal of antibody from the red cell by various physical or chemical techniques with concentration of the antibody in the eluting solution, which is usually albumin/saline. This antibody-containing solution, the eluate, is then treated as a serum sample and used to identify the offending blood group antibody.

The time lost in making a clinical diagnosis can turn a mild treatable reaction into one that is life-threatening. Indeed, a full-blown acute intravascular hemolytic transfusion reaction is a true medical emergency. Antibody-coated red cell stroma produced during an immune hemolytic transfusion reaction induces renal vasoconstriction, resulting in acute tubular necrosis. [3] [5] Another contributing cause of ischemic renal failure involves the release of free plasma hemoglobin. It has been shown that cell-free hemoglobin binds tightly to nitric oxide. Endothelium-derived relaxing factor, a powerful vasodilator, is composed in part of nitric oxide. By binding to nitric oxide, free plasma hemoglobin blocks relaxing factor and prevents renal vasodilation and promotes renal vasoconstriction and thus renal tubular ischemia and eventual tubular necrosis.[6] The C3a and C4a generated may cause hypotension and tachycardia and may produce shock. Clinical symptoms include shortness of breath, chest pain, dizziness, and nausea. Patients often report a sense of impending doom. C3a can also cause bronchospasm, and C5a generation causes further pulmonary dysfunction. Many patients, curiously even anephric patients, often complain of lower back pain. [7] This is believed to be due to ischemic muscle pain or vasospasm, rather than to kidney pain from developing renal failure.

In addition to complement components, another class of biologic response modifiers, cytokines and interleukins (ILs), also plays a role in the clinical symptom complex associated with acute intravascular hemolytic transfusion reactions. For example, IL-1, IL-6, and tumor necrosis factor- (TNF-) have pyrogenic activity; IL-8 is a neutrophil chemotactic and activating factor. These four cytokines have been generated in in vitro models of intravascular hemolysis and IgG-mediated red cell incompatibility. [8] [9] [10] [11] The clinical variability of hemolytic transfusion reactions is likely explained by the relative balance of cytokine production in the transfusion recipient. Factors that increase the circulating levels of proinflammatory cytokines and chemokines result in more severe reactions. [12]

(Not Available)

Adapted from Blood Transfusion Therapy: An Audiovisual Program. 2nd ed. American Association of Blood Banks, Arlington, VA, 1991, with permission.

Therapy

Initial therapy consists of immediately stopping the transfusion, maintaining a patent intravenous line, supporting the cardiorespiratory system, and ensuring a brisk diuresis. Increasing renal blood flow is the best way to prevent acute oliguric renal failure. The usual therapeutic maneuver used to induce a diuresis is infusion of 0.9% NaCl or some other suitable crystalloid solution. Crystalloid should be given to maintain a urine output of 100 ml/hr for about 24 hours. Diuretics, such as furosemide, also can be used and are preferred by some to infusion of mannitol to increase intravascular volume. [13] [14] Mannitol, if chosen, must be used with caution; if acute tubular necrosis (ATN) occurs before mannitol infusion, pulmonary edema may occur due to the acute increase in intravascular volume secondary to fluid expansion. Similarly, excessive crystalloid infusion should be avoided in patients with borderline congestive heart failure. Renal damage must be minimized, however, and increasing renal blood flow helps to prevent anuric renal failure. The mechanisms responsible for the beneficial effect of increased renal blood flow likely include increased clearance of free hemoglobin, resulting in decreased binding of nitric oxide, and a return of more physiologic control of renal vasodilation. Creatinine and blood urea nitrogen (BUN) should be closely monitored; dialysis may be necessary for therapy of acute renal failure. As difficult as ATN therapy is, it is easier to treat a patient in the diuretic phase than in the oliguric phase of ATN. Support of blood pressure and respiration may require the use of vasopressors, bronchodilators, and, when necessary, intubation. Low renal levels of dopamine (12 g/kg/min) promote renal vasodilation, support renal function, and offset the likelihood of anuric renal failure. Higher levels of dopamine cause vasoconstriction and should be avoided unless the patients blood pressure requires the increased dosage. Disseminated intravascular coagulation (DIC) can occur in severe cases, and heparin may be indicated if a significant coagulopathy is evident. Heparin, however, is rarely needed in mild cases. The prothrombin time, partial thromboplastin time, and fibrinogen level should be closely monitored.

WORKUP OF AN ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTION

If an acute transfusion reaction occurs:

1. *Stop blood component infusion immediately.*
2. Maintain IV access with a suitable crystalloid or colloid solution.
3. Maintain blood pressure, heart rate.
4. Maintain an adequate airway.
5. Give a diuretic and/or institute a fluid diuresis, or both.
6. Obtain blood/urine for transfusion reaction workup.
7. Blood bank workup of suspected transfusion reaction:

    Check paperwork to ensure correct blood component was transfused to the right patient.
    Observe plasma for hemoglobinemia.
    Perform direct antiglobulin test.
    Repeat compatibility testing (cross-match).
    Repeat other serologic testing as needed (ABO, Rh).
    Analyze urine for hemoglobinuria.

If intravascular hemolytic reaction is confirmed:

1. Monitor renal status (BUN, creatinine).
2. Monitor coagulation status (prothrombin time, partial thromboplastin time, fibrinogen).
3. Monitor for signs of hemolysis (lactic dehydrogenase, bilirubin, haptoglobin).
4. If sepsis is suspected, culture as appropriate.

Laboratory Evaluation

Laboratory findings include hemoglobinuria, hemoglobinemia, and a haptoglobin level that is low to 0 mg/dl. During the hemolytic episode, the bilirubin usually increases only to 23 mg/dl if the patient has normal liver function. Elevations of bilirubin to 2030 mg/dl are not seen in otherwise normal patients, even with florid hemolysis. Very elevated bilirubin levels are seen only in patients with concurrent hepatocellular disease, such as viral hepatitis or hepatic carcinoma. Due to the lysis of red cells, levels of lactate dehydrogenase (LDH) may rise markedly. If the patient shows no signs of vasomotor instability and if hemostatic and renal function is unchanged 24 hours after the incompatible transfusion, the episode can be considered to be over, with serious sequelae unlikely.

Although ABO-incompatible blood transfusions are the most common cause of an acute intravascular hemolytic transfusion reaction, other complement-fixing antigen-antibody systems, such as the Jk^a (Kidd) or Fy^a (Duffy) blood group systems, can also produce these reactions. [15]

Acute Extravascular Hemolytic Transfusion Reaction

In an extravascular hemolytic transfusion reaction, complement either is not fixed at all or is fixed only to C3b. In either situation, because of the nature of the antigen-antibody reaction, complement activation with fixation of the C5b-9 complex does not occur. The presence of IgG on the red cell and/or fixation of complement to C3b results in an extravascular reaction because the antibody-coated cells are cleared by either the IgG receptors in the spleen or the C3b receptors in the liver. Red cell lysis does not occur in the intravascular space. Largely as a result of the lack of generation of C3a or C5a, an extravascular hemolytic transfusion reaction does not usually present as a clinical emergency. It is characterized, as are all immune hemolytic transfusion reactions, by development of a positive DAT due to recipient red cell alloantibody binding to the circulating donor red cells. Moreover, an increase in indirect bilirubin, an increase in LDH, a decline in hematocrit, and an increase in colorless urine urobilinogen occurs; hemoglobinuria and hemoglobinemia, however, are rarely present. The patient typically remains clinically stable, and renal failure, shock, and hemostatic abnormalities, such as DIC, are rarely seen unless the amount of incompatible blood infused is excessive. However, patients often have a low-grade fever, probably secondary to the generation of IL-1 or other proinflammatory cytokines. [12]

The diagnostic test of choice is, again, a DAT with an eluate. The eluate is performed to identify the antibody coating the red cells. [15] The positive DAT, again, is due to the patients antibody coating the donor red cells. This is not autoantibody, and the patients own red cells are not usually involved in the reaction.

Typically an acute extravascular hemolytic transfusion reaction requires no special therapeutic intervention. Maintaining a good urine output and monitoring renal and hemostatic function are usually sufficient. The patient characteristically recovers in a few days as the offending donor red cells are cleared from the circulation. The pathogenic alloantibody can often be identified in the patients serum. These acute transfusion reactions may occur if the patients pre-existing alloantibody was missed by the blood bank during the antibody screening process, if the unit of blood was labeled for the wrong patient, or if the unit was hung in error on the wrong patient. [2]

Delayed Hemolytic Reactions

The pathogenesis of a delayed intravascular transfusion reaction is similar to that described for an acute intravascular hemolytic reaction. However, in the delayed type, the patient develops

the antigen-antibody reaction some time (510 days) after the transfusion. The process thus occurs more slowly and is less likely to present as a clinical emergency. Hemoglobinuria and hemoglobinemia can occur but often are less profound and pronounced than with an acute intravascular reaction. This likely is due to the continual and gradual removal of antibody-coated red cells as the antibody titer rises, as well as to the more gradual generation of C3a and C5a. The same serologic diagnostic and treatment concepts used for an acute intravascular hemolytic reaction apply here. However, the need for acute intervention is much less likely. Initiating a diuresis and monitoring renal and hemostatic function may be sufficient.

Delayed extravascular hemolytic transfusion reactions occur as well. Such antigen-antibody reactions often involve the Rh system. The clinical presentation is similar to that of an acute extravascular reaction: the patient often has no acute clinical symptoms but may present with a fever, a falling hematocrit, and the development of a new DAT. Serologic evaluation of a transfusion reaction in a patient who had a positive pretransfusion antiglobulin test result, caused by autoantibody or medication, may be confusing. Such a workup requires an expert serologist to detect the new alloantibody in the patients serum and make a diagnosis of a hemolytic transfusion reaction.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A febrile nonhemolytic transfusion reaction (FNHTR) is suspected when a temperature rise of 1°C or more occurs during or after transfusion when no other cause can be found. In addition to fever, an FNHTR is often accompanied by shaking chills. These reactions are due to cytotoxic or agglutinating antibodies in the patients plasma reacting against antigens present on transfused donor lymphocytes, granulocytes, or platelets. [16] [17] [18] [19] The antibodies often have human leukocyte antigen (HLA) specificity, although they also may be neutrophil- or platelet-specific. [20] [21] Conversely, the donor plasma also can contain antibody that can react with the corresponding cellular antigens in the recipients blood. [22] The cause of the fever relates to antibody-leukocyte or antibody-platelet interactions. The febrile reaction is mediated largely by the release of cytokines such as IL-1, IL-6, and TNF- from macrophages, monocytes, granulocytes, or lymphocytes. [23] IL-1 (endogenous pyrogen), via prostaglandin PGE_2 synthesis, probably stimulates the thermoregulatory center of the hypothalamus to produce fever. Other mediators such as macrophage inflammatory proteins (MIP-1) may also participate in the febrile response, but this reaction is not mediated through prostaglandin synthesis. [24]

The cytokines could be derived from three possible sources in the transfusion setting. The first is synthesis by recipient leukocytes in response to transfusion. The second is production by donor leukocytes after infusion into the recipient. The third mechanism is generation by donor leukocytes in vitro during storage before transfusion. [25] Red cells and units of platelet concentrates have sufficient potential sources of cytokines in the ample number (10^7 10^8) of mononuclear leukocytes capable of cytokine synthesis. Studies have shown that generation of cytokines does indeed occur in units of blood during storage and that such generation is directly proportional to the leukocyte count of the unit and the duration of storage. [26] [27] [28] Use of third-generation leukocyte reduction filters can lower the incidence of febrile reactions. Judging from reports of persistent febrile reactions despite use of these 34 $\log_{10}$ leukocyte reduction filters, such filtration needs to occur before storage and before the donor leukocytes begin to generate these proinflammatory cytokines in the blood storage bag. Heddle et al. [29] showed that febrile reactions to platelet transfusions were more likely due to proinflammatory cytokines present in the supernatant platelet-poor plasma than to the cellular elements in the platelet concentrates. Proinflammatory cytokines are not removed by bedside blood filters and enter the circulation. [30] Chemokines, however, such as IL-8, and RANTES and complement components C3a and C5a are removed, to varying degrees, by some bedside leukoreduction filters. [31] [32] Prevention of cytokine generation by prestorage leukoreduction, however, is more efficient and effective than is scavenging of the biologic response modifiers by using bedside filtration technology.

The frequency of febrile reactions has been estimated to be 0.5%/unit transfused. [33] [34] Reactions are most commonly seen in recipients who have been exposed to multiple white cell or platelet antigens, such as oncology patients or multiparous women. Oncology patients are at risk as a result of frequent transfusions, multiparous women from multiple exposures during childbirth. Both of these groups of patients can form multiple HLA, granulocyte, or platelet-specific antibodies that will react with white cells or platelets on subsequent exposure. Antigen-antibody reactions are capable of stimulating cellular activation with resultant complement fixation, cytokine generation, and activation of other biologic response modifiers. [35] [36]

Clinical Manifestations

Clinically, an FNHTR is characterized by fever and chills occurring shortly after the transfusion has begun. [37] The patient may have nausea and vomiting. Various factors, including rate of infusion of the blood and leukocyte content of the transfused blood (antigen load), may affect the severity of the clinical presentation of the febrile reaction. Febrile reactions also can occur several hours after the transfusion has ended. [17] Although an FNHTR often starts with the patients complaining of feeling uneasy or chilly, symptoms often progress from a slight tremor to true rigors. The chills or rigors are a manifestation of heat-conserving cutaneous vasoconstriction and result in muscular heat production. [38] These thermogenic responses, coupled with any effects due to release of IL-1 or other cytokines, may cause the patients temperature to rise several degrees above pretransfusion levels. Although these reactions are rarely dangerous, the severity often increases as the rate and dose of the infusion increase. Mild reactions are generally more uncomfortable and frightening than life-threatening. FNHTRs are usually self-limited, with fever persisting for no more than 810 hours. Elderly patients with a tenuous cardiovascular status and critically ill patients may develop respiratory complications, hypotension, or shock. Young adults, however, are less likely to become seriously ill even with development of a high fever. As in any transfusion reaction, the onset of fever and chills requires that the transfusion be stopped, the intravenous line kept open with normal saline or a suitable crystalloid, and appropriate samples sent to the blood bank. The patient should be reassured, as anxiety may be extreme.

Laboratory Evaluation

The workup of a febrile reaction must be undertaken promptly. Fever may also be the first sign of an acute hemolytic reaction or infusion of a unit of red cells or platelets contaminated with bacteria. The workup consists of ruling out a hemolytic reaction by reconfirming the ABO type of the patient and the donor unit, re-cross-matching to confirm patient-donor compatibility, evaluating the results of the pre and post-transfusion direct antiglobulin tests, evaluating the serum for hemolysis, and rechecking the accuracy of paperwork. [39] [40] [41] The post-transfusion DAT should yield negative findings, as an FNHTR does not involve red cell alloantibody.

As laboratory testing is being completed, the workup should extend beyond the blood bank to include bedside patient evaluation. Because fever and chills also may be caused by drugs or by diseases associated with infection or inflammation, these

factors also should be evaluated. Blood cultures of both the patient and the blood product, to rule out infusion of a contaminated unit of blood, is becoming more common at many medical centers. The difficulty lies in knowing when to order blood cultures: they are expensive and there is a 3% incidence of positive cultures due to contamination during collection (see the Bacterial Contamination section). Most routine hospital blood banks do not have the expertise or reagents needed to identify specific HLA, platelet, or granulocyte antibodies. Accordingly, the diagnosis of a febrile hemolytic transfusion reaction is usually made without isolating an identifiable antibody. The FNHTR is often a diagnosis of exclusion arrived at after ruling out a hemolytic reaction, a septic transfusion, or other possible causes of fever.

Fever usually responds to antipyretics, including aspirin, nonsteroidal anti-inflammatory agents (NSAIDs), and acetaminophen. For thrombocytopenic adult patients, acetaminophen (325650 mg PO) is the antipyretic of choice. Thrombocytopenic patients should avoid aspirin: it further compromises platelet function because of its inhibitory effect on platelet cyclo-oxygenase, an enzyme involved in the platelet release reaction. Nonthrombocytopenic patients may receive aspirin if its use is not contraindicated for other medical reasons. Many house officers routinely order diphenhydramine for treatment of febrile reactions. This therapy, however, should be reserved for pretreatment or treatment of possible allergic reactions. Unless the patient has a history of allergic reactions or shows signs of an allergic component to an FNHTR, such as flushing, hives, or pruritus, there is no benefit from the use of antihistamines for febrile reactions. In addition, antihistamines produce drowsiness in some patients.

For patients with no history of febrile reactions, routine premedication is unnecessary. Adult patients with severe reactions despite premedication may require more

intensive pharmacotherapy, including hydrocortisone sodium succinate (100 mg IV) given immediately before transfusion. Patients with severe shaking chills can be treated with meperidine intramuscularly or subcutaneously. Meperidine can stop shaking chills almost immediately. [42] Febrile reactions after granulocyte transfusions and, less frequently, after platelet transfusions can be so severe that hypotension and cardiovascular collapse can occur.

Prevention of febrile reactions when pharmacologic therapy fails relies on the use of leukocyte-depleted blood components. Several leukocyte depletion techniques are available. Centrifugation can remove approximately 70% of the leukocytes in a unit of blood; cell washing or use of frozen deglycerolized red cells can remove up to 95% of contaminating white cells. Older microaggregate blood filters can reduce leukocyte content by approximately 12 logs (9093%). [43] [44] [45] [46] [47] [48] [49] Third-generation leukocyte depletion red cell filters are also useful for preventing febrile reactions. [50] [51] [52] They can remove up to 4 logs (99.99%) of white cells, often lowering the level of white cells in a unit of blood from 10^9 to 10^5 . They also may be useful for preventing or delaying the onset of HLA alloimmunization. [53] [54] Leukocyte depletion platelet filters are also available. [55] [56] [57] [58] [59] [60] [61] Further, the results of a multi-institutional trial to reduce alloimmunization to platelets (TRAP Trial) have shown that reduction of leukocytes by filtration and UV-B irradiation of platelet concentrates were equally effective in preventing alloantibody-mediated refractoriness to platelets during chemotherapy for acute myeloid leukemia. [62]

The degree of usage of leukocyte-depleted blood components is still controversial. [63] [64] [65] Data show that a patient who has had one febrile transfusion reaction has a 1 in 8 chance of having another one. [34] Individuals with a history of recurrent severe febrile reactions should have notations made in their blood bank record to ensure future use of leukocyte-reduced components.

Although they clearly are indicated for people with multiple and recurrent febrile reactions, many physicians question whether leukodepleted blood products should be used indiscriminately for all patients. [63] [64] [65] Indeed, the immunomodulatory effects of allogeneic blood transfusions on tumor growth and recurrence and susceptibility to viral infection is poorly understood, and much research has yet to be performed. [66] [67] The cost of filtration is often cited as a reason to limit use of leukoreduction technology. Cost considerations, however, are often discounted when a significant threat, imagined or real, to the worlds blood supply is posed. Such a threat may be associated with the risk of transmission of new variant Creutzfeldt-Jakob disease. [68] There is concern that this new variant form may be transmitted by eating tissue from cows with bovine spongiform encephalopathy. In a murine model, there are some data that the agent may be present in the blood and can be associated with B cells. [69] There are already discussions as to whether all blood should be leukodepleted to address this potential risk to the worlds blood supply. [68] [70] Studies such as these [62] [68] [69] [70] may begin to influence physicians to use leukoreduction technology for more patients. Clearly, such increased use, while possibly improving the safety of the blood supply, will significantly raise the cost of medical care.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions are believed to be most commonly due to infusion of plasma proteins. [71] The allergic manifestations produced vary. They include skin erythema with associated mild urticaria and pruritus; a confluent rash, which is intensely pruritic; extensive urticaria; severe vasomotor instability; bronchospasm; and anaphylaxis. A patient who develops hives and a mild allergic reaction during a blood transfusion does not progress to a more severe anaphylactic reaction after infusion of additional blood from the same unit. Thus, the severity of allergic transfusion reactions is not necessarily dose-related.

The exact nature of the antibodies involved in the various types of allergic reactions is unclear. The mild allergic reactions are usually IgG-mediated, but IgE may also be involved; anaphylactic reactions are most often IgG mediated. [7] Allergic transfusion reactions are quite common, occurring in approximately 1% of all transfusions. [72] [73] Most of these reactions start with pruritus, followed by the development of hives. At this point, the transfusion should be stopped and the patient given 2550 mg diphenhydramine, if there are no medical contraindications and if the patient had not already been maximally premedicated. After a short interval the transfusion can be continued, but only if the rash decreases and/or the hives disappear and the patient feels well and shows no signs of fever, chills, or vasomotor instability. For mild allergic transfusion reactions not associated with any cardiorespiratory problems, such as bronchospasm, dyspnea, hypotension, or tachycardia, it is acceptable to continue the transfusion after the reaction has subsided, as it is not likely to recur. The risk of transfusion-transmitted disease posed by infusion of another unit of blood is greater than the risk posed by continuing a transfusion that has produced only mild urticaria. This is not true, however, if the patient shows signs of systemic toxicity from the transfusion, such as hypotension, bronchospasm, or tachycardia.

The treatment of mild allergic reactions involves the use of diphenhydramine. Reactions are rarely serious and often do not recur with subsequent transfusions. The pathogenesis is thought to be recipient antibody directed against donor plasma proteins. Most blood banks, however, cannot identify the etiologic antibody; identification usually requires research laboratory techniques. Accordingly, the diagnosis of an allergic transfusion reaction is a diagnosis of exclusion. Washed red cells can be used to prevent reactions. [43] [44] Leukocyte depletion or microaggregate filters are of no value because the plasma protein passes through the filter.

Most patients who have one allergic reaction should continue to receive routine bank blood. Washed cells should not be provided until a second reaction has occurred and generally should be provided only for patients with severe or recurrent reactions. The occurrence of one or two hives or mild pruritus post-transfusion is not an indication for the use of washed cells. Anaphylactic reactions, however, can be life-threatening and may require intubation and pressor agents. The use of washed cells for patients experiencing these reactions is appropriate.

Although it is convenient to characterize a transfusion reaction as being purely febrile or allergic, in reality there is often a mix of the two symptoms, and the reaction is designated according to the predominant clinical sign.

OTHER ADVERSE EFFECTS OF TRANSFUSION

Microaggregate Debris and Adult Respiratory Distress Syndrome

Much has been published regarding the use of microaggregate filters for preventing adult respiratory distress syndrome after massive transfusion. [63] [64] [74] [75] [76] [77] [78] Microaggregate debris consists of dead platelets, granulocytes, and fibrin strands that form in blood during storage. [79] [80] [81] It has been hypothesized that infusion of blood containing microaggregate debris through standard 170-m-pore filters results in the passage of these 20- to 120-m-microaggregates into the pulmonary vasculature, producing occlusion of the pulmonary capillaries and pulmonary failure. Published studies have shown, however, that microaggregate filters are not required and do not appear to influence the onset of adult respiratory distress syndrome. [82] [83] This syndrome is most likely, and most often, attributable to concurrent hypotension and sepsis rather than to infusion of microaggregate debris, per se. Microaggregate filters may be of value during cardiopulmonary bypass surgery, when the microaggregate debris can enter the arterial circulation directly. It is likely that improvements in surgical techniques, post-trauma medical care, perfusion technology, and especially treatment of shock and sepsis have contributed more to the decreased incidence of postperfusion respiratory distress syndrome than has use of microaggregate filters. [84]

Leukocyte Reduction

There are multiple reasons emerging to leukoreduce units of blood and components. Standards of the American Association of Blood Banks require that to be considered leukoreduced for any indication, the level of leukocytes in the final component should be $<5 \times 10^{6}$. [85] This value applies to units of red blood cells and single-donor apheresis platelets. For platelets prepared from whole blood, the value is $<8.3 \times 10^{5}$ in all bags. Since the final pooled component also must have $<5 \times 10^{6}$ leukocytes, this implies that the final pool size should not exceed 6 units. Indications for leukocyte reduction range from those for which data exist (such as to decrease the incidence of HLA alloimmunization) [53] [54] [62] to other areas with fewer data (such as to decrease the incidence of tumor recurrence [86]). As more data are published, the indications for use of leukocyte reduction filters will become clearer. Although a conservative approach to their use for well-established indications would seem most prudent, changes for the indications are always being reviewed. [65] [66] [67] [68] [69] [70]

Bacterial Contamination

Bacterial contamination of stored blood can pose grave risks to the recipient. Bacteria can enter the blood bag during venipuncture as a result of inadequate skin preparation or during component preparation. [87] Some bacteria grow best at room temperature; other (psychrophilic) organisms grow optimally at refrigerated blood bank (16°C) temperatures. Gram-negative bacteria, including *Pseudomonas, Yersinia, Enterobacter,* and *Flavobacterium,* are organisms commonly associated with a contaminated unit of refrigerated blood. [88] [89] Platelet concentrates, stored at room temperature, are also known to be subject to bacterial contamination; several reports have described fatal septic transfusion reactions due to platelets containing *Salmonella* or *Staphylococcus*. [90] [91] [92] Units of blood that are contaminated need not be obviously discolored, malodorous, or clotted; by simple visual inspection it is extremely difficult to determine whether a unit is contaminated. However, Kim et al. [93] reported that visual inspection, with comparison of the blood bag segmented tubing with that of the blood bag itself, can on occasion identify units likely to be bacterially contaminated.

Individuals who receive a unit of contaminated blood may develop fever, rigors, skin flushing, abdominal cramps, myalgias, DIC, renal failure, cardiovascular collapse, and cardiac arrest. Clinically the patient presents in warm shock. These reactions may be immediate, or there may be a delay of several hours before the symptom complex becomes apparent. Reaction to infusion of a unit of contaminated blood is distinguishable from FNHTR by the formers more severe clinical presentation and is distinguishable from intravascular hemolytic transfusion reaction by the absence of the latters characteristic hemoglobinuria and hemoglobinemia. Reactions following transfusion of infected units of blood are often attributable to endotoxin produced by gram-negative bacteria. The presence of bacteria alone, however, can also cause many of these symptoms. Also, the symptom complex is often attributable, in part, to cytokines and interleukins that are generated in the contaminated, stored blood in vitro. These biologic response modifiers produce severe reactions in vivo following transfusion. [26] [27] [28] [94] [95] [96] Nitric oxide, for example, produced locally in smooth muscle by the synergistic action of TNF-, IL-1, and -interferon, probably mediates refractory hypotension and vasoplegia associated with septic shock. [95] [97]

If, during transfusion, a patient who appeared well suddenly develops rigors and shock, infusion of an infected component should be considered. If on further evaluation this diagnosis is still considered likely, the patient should be treated immediately, since delay significantly contributes to the chance of a fatal outcome. Blood pressure, pulse, respiration, and renal blood flow need to be supported. Blood infusion should be stopped the moment any transfusion reaction is suspected, and appropriate samples should be sent to the blood bank for a DAT and other studies. Cultures of the untransfused blood remaining in the blood bag should be sent as they may be diagnostic. Broad-spectrum antibiotics should be started immediately if infusion of contaminated blood is suspected and continued until the culture results are reported. These reactions are rare [98] but can be fatal. Use of recombinant IL or cytokine inhibitors is still too experimental to be useful clinically.

Circulatory Overload (Hypervolemia)

Hypervolemia is a form of transfusion reaction that should be considered in patients who, during a blood infusion, develop sudden severe headache, dyspnea, tachycardia, tachypnea, congestive heart failure, or other signs of fluid overload. Unless the patient is actively hemorrhaging, blood should never be infused rapidly, as the acute expansion of the patients intravascular volume may exceed the capacity of the cardiovascular system to compensate. [99] Rapidly transfusing a patient who is anemic but who is euvolemic and not actively bleeding produces no benefit and may cause harm. This caveat applies to transfusion of any blood component. Patients with compromised cardiopulmonary status may not tolerate acute blood volume expansion and may develop right- or left-sided heart failure. This is especially true for infants and the elderly. If symptoms occur, the

transfusion should be stopped and some form of volume reduction, either diuretics or phlebotomy, instituted. If there is a concern that the patient may not tolerate infusion of a full unit of blood or component within the 4-hour period of time allotted for infusion of blood components, the blood bank can divide the product into smaller portions, which can be transfused in aliquots. As a general guide, infusions in nonbleeding adults should occur at <23 ml/kg/hr. The rate should be lowered to 1 ml/kg/hr for patients at risk of fluid overload. Diuretics may be given to patients with compromised cardiopulmonary status before transfusion.

The initial stages of transfusion-induced hypervolemia may be difficult to distinguish from hemolytic transfusion reaction as well as from febrile or allergic reactions. The absence of hemoglobinuria and hemoglobinemia or the absence of a positive post-transfusion DAT result should serve to distinguish the reaction from one due to

immune hemolysis, and the absence of fever, chills, or urticaria from the febrile or allergic types of reactions.

Transfusion-Related Acute Lung Injury (Noncardiogenic Pulmonary Edema)

On rare occasions individuals being transfused with red cells or platelets develop pulmonary edema within 4 hours of starting a transfusion, without an elevation in cardiac pressure.[22] [100] [101] [102] [103] [104] [105] [106] Several reports of this type of transfusion-related acute lung injury (TRALI) suggest that these cases may be more common than expected. The chest radiograph reveals a pulmonary edema pattern, and there is respiratory insufficiency with a decrease in O_2 saturation, but without development of elevated left-side cardiac pressure. Copious amounts of pulmonary edema fluid are produced, as is characteristic of hypervolemia; however, the noncardiogenic reaction usually follows infusion of volumes of blood too small to produce fluid overload. The patient may also develop fever, chills, cyanosis, dyspnea, tachypnea, or hypotension. The postulated pathologic mechanism includes a reaction between donor HLA or white cell antibody and recipient leukocytes; complement activation also may occur when leukoagglutinins present in the recipient react with leukocytes contained in the infused donor blood, with aggregation of white cells.[107] [108] As a result of the HLA, Ag-Ab reaction, the activated leukocytes generate adhesive molecules on their surface (CD11/CD18). These proteins permit the leukocytes to attach to the cell membrane of the pulmonary endothelial cells and by diapedesis enter the interstitial space between the pulmonary capillaries and the alveolar epithelium. Once they are in the interstitial space, the neutrophils degranulate and release destructive enzymes, which produce a capillary leak, resulting in fluid filling the alveolar air sacs. Thus, pulmonary leukostasis with pulmonary edema occurs as a result of microvascular occlusion and capillary leakage. [109] [110] Complement-activated granulocytes also produce toxic oxygen radicals that damage pulmonary endothelial cells, resulting in an increase in pulmonary vascular permeability and further passage of fluid into alveolar spaces. TRALI has been estimated to occur once in 4,500 transfusions. [103] [105] [106] Silliman et al.[111] have postulated a two-step approach to the pathogenesis of TRALI. After an initial neutrophil activation step, neutrophil-priming lipids, which they believe play a key role in the process, further activate the granulocytes and produce the clinical syndrome. [106] [111] Rodent model systems for TRALI have also been described.[112]

Since this diagnosis usually requires that cardiac monitoring (Swan-Ganz) catheters be in place, TRALI is difficult to diagnose outside the operating room or intensive care unit. When a patient shows signs of noncardiogenic pulmonary edema, as with all other reactions, the infusion should be stopped. These HLA/neutrophil antigen-antibody reactions may be idiosyncratic and often do not recur.

TABLE 142-3 -- Diagnosis of Transfusion-Related Lung Injury (TRALI)

Onset	Within 4 hours of start of transfusion
Frequency	1:4,500 transfusions (probably underreported)
Signs/Symptoms	Decreased O_2 saturation, fever, hypotension, tachypnea, dyspnea, diffuse pulmonary infiltrates, normal cardiac pressures (requires Swan-Ganz catheter), copious amounts of pulmonary edema fluid
Pathogenesis	HLA/granulocyte-specific antibodies (usually of donor origin) reacting with recipient leukocytes. Activates recipient neutrophils; stimulates complement activation; generates CD11/18 on PMN surface, resulting in pulmonary capillary adherence and diapedesis and eventual pulmonary capillary leak syndrome. Latter is associated with generation of proteolytic enzymes and toxic O_2 metabolites, which cause endothelial cell damage. Neutrophil priming lipids may also play a role.
Diagnosis	Chest x-ray; blood gases; blood for HLA or anti-neutrophil antibodies
Differential Dx	Fluid overload; septic transfusion; anaphylaxis
Treatment	STOP TRANSFUSION; ventilatory support (administer O_2 , intubate PRN), support blood pressure, administer steroids; diuretics of *no* value

Data from Levy et al.[167]

To remove leukocyte antigens from units of red cells or platelets, leukocyte reduction filters may be useful; washed red cells are useful for that component as well. Treatment is symptomatic (Table 142-3). Multiparous women who are blood donors and blood donors who have been multiply transfused should not be used as plasma donors, as their serum may contain high titers of leukoagglutinating antibodies. [113]

Anaphylactic Reactions

When plasma containing IgA is transfused to patients with IgG anti-IgA antibodies, anaphylactic reactions can occur. Anaphylactic reactions have also been reported following transfusion of platelets administered through some types of bedside leukoreduction filters. [114] [115] [116] [117] [118] [119] The pathogenesis of this syndrome appears to be the activation of the contact pathway (prekallikrein converting to kallikrein) induced in plasma by the negatively charged surface of some leukoreduction filters. Kallikrein activation stimulates the conversion of high-molecular-weight kininogen to bradykinin. The bradykinin thus generated by the negatively charged bedside filter enters the circulation and produces a symptom complex characterized by pain, cutaneous flushing, and hypotension without fever or chills. The syndrome is often much more severe in patients already taking angiotensin-converting enzyme (ACE) inhibitors. ACE is identical to kininase II, which is responsible for degrading brady-kinin. Blockage of the kininase II degradation of bradykinin by ACE inhibitors results in a prolonged bradykinin half-life and a reaction that can be very severe. Accordingly, physicians should let the blood bank know of any patients taking ACE inhibitors who require blood transfusion. Prestorage leukoreduction avoids this problem, as the half-life of bradykinin is about 15 seconds. Reactions have been reported with platelet as well as red cell transfusions, but most commonly with platelet transfusions administered through a bedside leukoreduction filter, with a negative surface charge. While these reactions are rare, they can be quite serious.

Hypothermia

Hypothermia can occur with rapid infusion of large quantities of refrigerated (16°C) blood. [120] [121] [122] Data have shown that rapid infusion of blood (1 unit every 5 minutes) may lower the temperature of the sinoatrial node to <30°C, at which point ventricular fibrillation may occur. [123] Most transfusions need not be given this rapidly. Thus, for routine transfusion, blood does not have to be warmed. Indeed, overwarming blood can cause thermal injury and produce hemolysis, DIC, or shock. Further, a delay in infusing blood due to the extra time required for warming could impede resuscitation. Although routine warming of blood for trauma patients is not recommended, use of warming techniques for some trauma patients may reduce the incidence of coagulopathies associated with major trauma.

If blood is to be warmed, only an electric blood warmer should be used. The temperature must be monitored and kept below a level that could cause hemolysis. [85] [124] Usually this is <42°C. Heating blood under running hot tap water or heating in a microwave device is unacceptable; microwave devices produce hot spots that can cause hemolysis.[125] [126]

Electrolyte Toxicity

Citrate, a component of the preservative solution used in blood storage, functions as an anticoagulant by chelating calcium and interfering with the coagulation cascade. Rapid transfusion of citrated blood thus can be associated with a drop in ionized calcium levels. [127] [128] [129] Citrate-containing blood products, however, are routinely infused without any problem, as the citrate is rapidly metabolized to bicarbonate. In patients with normal liver function, citrate infusion is thus very unlikely to produce reactions. Mild to severe citrate toxicity can be seen, however, in individuals undergoing cytapheresis when large volumes of citrated plasma are reinfused.[130] [131] [132]

The effects of hypocalcemia range from mild circumoral paresthesias to frank tetany. However, severe citrate toxicity, even with massive transfusion, is very rare. More commonly, the reaction is mild and self-limiting and can be treated by merely slowing the rate of reinfusion. [133] If prolonged Q-T intervals or signs of tetany are seen, calcium can be administered. Infusion of calcium is itself often associated with the development of ventricular arrhythmias and cardiac arrest. [134] Calcium should not be infused routinely, even after large-volume blood transfusions. *Under no circumstances should calcium be added to a unit of blood, as it would recalcify the unit and cause clots to form in the bag.*

Hypomagnesemia, presumably due to chelation of magnesium by citrate, has also been reported. Actual clinical complications of transfusion-induced

hypomagnesemia, however, have not been well documented.[135]

Hyperkalemia due to infusion of stored blood is a rare occurrence. Although hyperkalemia is often thought to be a problem in massive transfusion, in reality development of hypokalemia is of greater concern. With storage, leakage of potassium from red cells to the extracellular fluid occurs. However, following infusion into a recipient, the red cells reverse the biochemical storage lesion, and intracellular potassium levels are restored. Further, as the citrate is metabolized to bicarbonate, the blood becomes alkalotic, contributing to hypokalemia.[136] [137] [138] In massive transfusion, this may not uncommonly result in the need for administration of potassium. Extracellular potassium increases at the rate of about 1 mEq/day during the first few weeks of storage. If this presents a concern for neonates or patients with renal failure, fresher blood can be requested. As there is increased potassium leakage from red cells following exposure to 25 Gy irradiation to prevent post-transfusion graft-versus-host disease, a maximum 28-day shelf life from the day of irradiation is imposed on this blood component. [85] Ammonia toxicity, previously a concern with stored blood, rarely presents problems today. [139]

Plasticizers

Plasticizers are chemicals used to make the rigid polyvinyl chloride plastic used in blood bags more malleable. The traditional plasticizer is di-2-ethylhexylphthalate (DEHP).[140] There has been some question as to whether DEHP is carcinogenic and whether its breakdown product, monoethylhexylphthalate, may produce problems due to production of peroxisomes, which may be destructive to vital organs. [141] [142] [143] [144] This plasticizer is being replaced with a citrate-based [145] [146] plasticizer, and new-generation blood bags are commercially available. Ironically, DEHP plasticizers may actually serve a useful function in that they appear to stabilize the red cell membrane and also may have a beneficial effect on platelet morphology. [147] [148] [149]

Graft-versus-Host Disease

Graft-versus-host disease (GVHD) occurs when immunologically competent lymphocytes are introduced into an immunoincompetent host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, recognize the host as foreign, and then attack host tissues. GVHD occurs after allogeneic bone marrow transplantation and less often after transfusion of nonirradiated cellular blood components, especially when the blood donor and recipient share some HLA antigens.[150] There is an increased danger from post-transfusion GVHD, in part because of the frequent failure of physicians to recognize and treat the reaction promptly. Another major factor, however, is the propensity of the donors lymphocytes to produce recipient bone marrow aplasia. In postbone marrow transplant GVHD, the bone marrow is of donor origin, and bone marrow aplasia does not occur. In post-transfusion GVHD, however, the bone marrow is of foreign (host) origin and the donors lymphocytes attack it, thus producing aplasia.

Post-transfusion GVHD is fatal in >90% of cases, primarily because of aplasia of the recipients bone marrow. Reports have shown that haploidentical directed donor units of blood may produce fatal post-transfusion GVHD even in immunocompetent recipients. [151] [152] The use of irradiated blood (>2500 cGy) is now recommended in clinical situations in which post-transfusion GVHD is considered likely, such as when patients receive blood transfusions from their relatives. Leukocyte reduction filters should not be used as prophylaxis against GVHD, as the exact number of leukocytes needed to produce

RISK GROUPS FOR TRANSFUSION-ASSOCIATED GVHD

Risk well defined

- Bone marrow transplant recipients
- Congenital immunodeficiency syndromes
- Intrauterine transfusion
- Transfusions from first-degree blood relatives
- Hodgkin disease

Risks under review

- Premature newborns
- Hematologic malignancies other than Hodgkin disease
- Solid tumors
- Organ transplant recipients

No risks defined

- Term newborns
- AIDS

From Anderson KC, Goodnough LT, Sayers M et al: Variation in blood component irradiation practice: implications for prevention of transfusion-associated graft-versus-host disease. Blood 77:2096, 1991, with permission.

the disease is not known with certainty. Case reports of fatal GVHD in patients who received leukoreduced but not irradiated blood have been published. [153] Several articles have addressed this subject.[154] [155] [156] [157] Radiation of red cells produces a membrane defect, however, which causes a slow leakage of potassium and hemoglobin.[158] Accordingly, the FDA has ruled that irradiated units of red cells shall have an outdate not to exceed 28 days from the time of irradiation. GVHD continues to be a rare but extremely serious complication of blood transfusion. [159] [160] [161]

Hemosiderosis

One milliliter of red cells contains 1 mg iron. A unit of blood with 250 ml red cells thus contains approximately 250 mg iron, and 4 units of blood 1 g iron, roughly the amount stored in the bone marrow. Males and nonmenstruating women lose only about 1 mg iron/day. Continued use of transfusion therapy in individuals with an extravascular type of hemolytic anemia, such as those with thalassemia or sickle cell anemia, in which iron is not lost from the body but is recycled, can thus result in the accumulation of excessive tissue stores of iron. Over long periods of time, the iron that is stored in parenchymal cells results in death of the cell and eventual organ failure.[162] Transfusion of reticulocyte-rich blood (neocytes) generally has not been found to be of value for decreasing the transfusion requirement in patients with chronic hemolytic anemias.[163] While young red cells have a longer half-life and should decrease the transfusion requirement, neocytes are not widely accepted as being clinically useful. Iron chelation therapy, such as that with deferoxamine, is now widely used and in conjunction with neocyte therapy actually may be able to

maintain patients with chronic hemolytic anemias in negative iron balance. [164] [165]

Air Emboli

With replacement of evacuated glass bottles by plastic blood bags, the risk of air embolism from phlebotomy or transfusion has virtually disappeared from transfusion practice. Air, however, still may be pumped into patients by the roller pumps contained in various transfusion devices, especially apheresis and intraoperative salvage machines.[166] All such devices currently manufactured, however, contain air in-line sensors. However, any operators using this equipment must be well trained and remain alert to the potential risk of air embolization at all times while the patient is being treated. Patients who receive air intravenously experience acute cardiopulmonary insufficiency. The air tends to lodge in the right ventricle, preventing blood from entering the pulmonary circulation. Acute cyanosis, pain, cough, shock, and arrhythmia may occur, and death may result unless immediate action is taken. The patient should be placed head down on the left side; this will usually displace the air bubble from the pulmonary valve.

Chapter 143 - Transfusion-Transmitted Diseases

Jay E. Menitove

INTRODUCTION

The risk of acquiring a transfusion-transmitted infection decreased significantly during the past decade as a result of improvements in testing, donor screening, and permanent deferral of donors with positive viral test results. Current estimates indicate that 1 or 2/1,000 transfusion recipients are at risk of receiving a unit contaminated with a viral, bacterial, or parasitic agent. In contrast, an estimated 50% of recipients are at risk of significant morbidity or mortality if not transfused. [1] (Table 143-1) Transfusion medicine specialists anticipate further improvements in transfusion-transmitted disease risk reduction through nucleic acid amplification assays, implementation of viral inactivation techniques, and further improvements in donor screening. [2] [3] [4] [5] [6]

RETROVIRAL INFECTION

Human Immunodeficiency Virus-1

The initial report of hemophilic patients with the acquired immunodeficiency syndrome (AIDS) appeared in 1982. Subsequently,

TABLE 143-1 -- Risk of Transfusion-Transmitted Infection

Infection	Risk per Unit
Human immunodeficiency virus-1	1:676,000
Human T-lymphotropic virus-I/II	1:640,000
Hepatitis A	1:1,000,000
Hepatitis B	1:63,0001:233,000
Hepatitis C	1:103,000
Hepatitis G	1:25100
Malaria	1:4,000,000
Chagas disease	(?)
Creutzfeldt-Jakob disease	No cases reported
Symptomatic Bacterial Sepsis	
Red blood cells	1:500,000 (?)
Platelets	1:2,0001:12,000 (?)

donor history questioning was revised and by 1985, antibody testing for human immunodeficiency virus (HIV) was available. The window period between HIV infection and seroconversion decreased to 22 days from 56 days between 1985 and 1996. [5] [7] [8] In 1996, blood centers implemented p24 HIV-1 antigen testing to narrow the window to 16 days. Antigen testing supplements rather than replaces HIV antibody testing because HIV-1 p24 antigen appears transiently during the acute phase of HIV infections (Fig. 143-1). Genomic amplification techniques, such as polymerase chain reaction (PCR) assays, offer the potential for further reducing the transfusion-transmitted infection risk and are under investigation currently. Preliminary studies suggest that HIV-1 PCR testing detects HIV genomic signals 11 days after infection. [7] [8]

The Centers for Disease Control and Prevention (CDC) reported 8,450 cases of AIDS in recipients of blood transfusion through June 30, 1997 including 37 adults/adolescents and 3 children who received blood from HIV-seronegative donors. [9] In addition, during the 1980s, 4,799 hemophilic and other patients with coagulation disorders acquired AIDS as a result of plasma derivative therapy. Viral inactivation processes for coagulation factor concentrates and immune globulin preparations using heat (pasteurization) or physical chemical properties (solvent/detergent treatment) dramatically reduced the risk of transfusion-transmitted HIV.

Mathematical models using estimates of the seronegative window interval, the probability that donations occur during this window, and the frequency blood donors develop new or incident infections provide the basis for calculating the residual risk of transfusion transmitted infections. [10] [11] Based on an observed rate of 7.7 confirmed positive HIV donations per

Figure 143-1 The lines depict the serologic and nucleic acid profile of an acute HIV infection. *(Reprinted from Busch,[6] with permission of Marcel Dekker, Inc.)*

100,000 collections, a predicted rate of 1/380,000 donations would transmit HIV using anti-HIV testing alone. However, HIV-seropositive donors react positively in other blood screening tests; 31% of anti-HIV-seropositive donations have anti-hepatitis B core antibodies. [12] This reduces the residual risk to 1/450,000660,000. [10] [11] HIV-1 p24 antigen testing reduces the window period an additional 27%, 16 days instead of 22 days. Preliminary estimates suggested HIV-1 p24 antigen testing would prevent 510 transfusion-associated HIV infections in the United States annually, reducing the residual risk to 1/676,000 (range: 572,000838,000). Eighteen months after HIV-1 p24 antigen testing was implemented, only two donors were HIV-1 p24 antigen positive and HIV antibody negative. [13]

Blood centers notify donors found repeatably reactive in HIV antibody screening tests despite indeterminate or negative Western blot or immunofluorescence test results. Experimental data indicate very few blood donors with HIV indeterminate supplemental tests are infected with HIV. [14] Low-risk blood donors, on occasion, have false-positive supplementary test results. [15]

Human Immunodeficiency Virus-2

Human immunodeficiency virus-2, a retrovirus linked more closely to the simian immunodeficiency virus than to HIV-1, was recognized initially in West Africa. Sixty-two cases of HIV-2 were reported in the United States as of June 30, 1995. [16] The interval between HIV-2 infection and AIDS is longer than that associated with HIV-1.

Antibody testing for HIV-1 detects 6091% of HIV-2 infected persons, whereas HIV-2 antibody test kits detect >99%. [17] Blood donor testing for both HIV-1 and HIV-2 antibodies began in 1992. HIV-1/2 combination test kits identified only two donors with HIV-2 infection during the 36 months following test introduction. [16] [18]

HIV-1 Group O and Group M, Subtype G Infection

The HIV-1 group O viruses were isolated from central and west African patients in 1994. These HIV-1 variants share 6570% homology with HIV-1 and 56% homology to HIV-2. Through 1997, two HIV-1 group O-infected persons were identified in the United States. [19] [20] Prior to the development of test kits designed specifically to identify HIV-1 group O-infected donors, donors are deferred if they were born in, lived in, traveled to and received a blood transfusion, or had risk exposures in HIV-1 group O endemic African countries.

Most HIV-1 infections are caused by a group M subtype B viruses. An AIDS case attributed to infection with an HIV-1 group M subtype G virus was reported in 1997. The serum reacted in routinely available HIV antibody test kits. Ongoing surveillance studies monitor emergence of new HIV variants and the effectiveness of routine HIV test kits for detecting these viruses. [20]

Human T-Lymphotropic Virus-I and -II

Human T-lymphotropic virus type I (HTLV-I) antibody testing for blood donations started in 1988. HTLV-I is the etiologic agent for adult T-cell leukemia/lymphoma (ATL), HTLV-I-associated myelopathy/tropical spastic paraparesis (HAM/TSP), and uveitis. Patients with ATL have HTLV-I provirus integrated into CD4+ flower-like cells. [21] ATL occurs in 24% of infected persons following a latent period that extends to several decades. The illness is characterized by leukemia, generalized peripheral lymphadenopathy, hepatomegaly, impared liver function tests, splenomegaly, skin lesions, bone lesions, and hypercalcemia. [22] HAM/TSP occurs in <1% of HTLV-I infected

individuals. Patients with transfusion-associated HAM/TSP develop neurologic symptoms for a median of 3.3 years after transfusion. [22] This illness is characterized by slowly progressive chronic spastic paraparesis, lower limb weakness, urinary incontinence, impotence, sensory disturbances, low back pain, hyper-reflexia, and impaired vibration sense.

As a retrovirus closely related to HTLV-I, HTLV-II shares 60% sequence homology with HTLV-I. The two major subtypes of HTLV-I, African and Austronesian, maintain 90% homology and the two major subtypes of HTLV-II, A and B, have 94% homology. [23] HTLV-II is tropic for CD4+ lymphocytes but does not appear to cause any hematologic malignancy. Persons infected with HTLV-II have an increased risk of pneumonia, tuberculosis, fungal infections, bladder and kidney infections, urinary incontinence, and arthritis. The few cases of HTLV-II HAM reportedly involved HTLV-IIa. Because HTLV IIa predominates in the United States, HTLV-IIb cannot be considered less neuropathologic. [24] [25]

Risk factors for HTLV-I and -II infections in blood donors include low educational attainment, accidental needle sticks, previous blood transfusion, seven or more lifetime sex partners, and a sex partner from an HTLV endemic area. Injection drug use or having sex with a drug user associates significantly with HTLV-II but not with HTLV-I infection. [26]

By 1992, 0.1% of first-time blood donors had positive HTLV-I antibody results; repeat donors had lower rates. [10] The 51-day (range: 3672 days) interval between exposure and HTLV-I antibody detection creates a mathematically derived residual risk of 1/640,000 (range: 260,0002,000,000). However, only 30% of infected cellular components transmit the virus. [27] Antibody test kits for HTLV-I detect 5591% of specimens infected with HTLV-II. HTLV is not transmitted by noncellular components such as plasma and cryoprecipitate. The residual risk should decrease following implementation of test kits designed specifically to detect HTLV-II in addition to HTLV-I in 19971998.

HEPATITIS INFECTION

Hepatitis A

Hepatitis A virus (HAV) is a nonenveloped RNA virus in the Picornaviridae family. It is transmitted primarily by the fecal-oral route and has an incubation period of 2045 days, with an average of 28 days. The virus replicates in hepatocytes followed by viremia and simultaneous shedding in the bile and feces. Subsequently, patients develop anorexia, fever, malaise, and nausea. Alanine aminotransferase (ALT) levels become abnormal and jaundice develops. Detectable anti-HAV antibodies arise contemporaneously with clinical symptoms. Unlike hepatitis B, C, D, and G, there is no carrier state. Transfusion-transmitted HAV infection occurs as a result of donation during the asymptomatic period. [28]

Numerous cases of hepatitis A transmission occurred in recipients of factor VIII and IX concentrate despite treatment with the solvent/detergent process. [29] [30] In addition to solvent/detergent resistance, HAV is relatively thermostable. It is inactivated by pasteurization and vapor heating. [31]

Hepatitis B

Hepatitis B virus (HBV) is a double-stranded, enveloped DNA virus in the Hepadnaviridae family. The viral particles contain an inner viral DNA core and an outer lipoprotein envelope that includes the hepatitis B surface antigen (HBsAg). The e antigen (HBeAg) is a soluble product that is co-translated with the core protein and serves as a marker for viral replication. HBV is transmitted through contaminated needles, sexual contact, occupational and other exposure to blood, and at birth. The average incubation period is 59 days (range: 3787 days) and may be asymptomatic in 50%. [1] [32] Five to 10% of those infected become chronic viral carriers.

Approximately 4 weeks after exposure, hepatitis B core (HBcAg) and hepatitis Be antigens (HBeAg); pre-S2, pre-S1, and S antigens (HBsAg); polymerase and transcriptase activity; and the X antigen protein appear. HBsAg persists in acute infection for up to 4 months (average 63 days). [33] ALT levels increase within a few weeks of HBs antigenemia. At approximately the same time as IgM antibodies occur against HBcAg (IgM anti-HBc), symptoms develop. Antibodies against HBsAg(HBsAb) occur several weeks later and protect against HBV infection. [32] Because anti-HBc is present during the interval between disappearance of HBsAg and appearance of anti-HBs, anti-HBc serves as a marker for preventing potentially infectious blood donations by HBsAg-negative persons who do not have sufficient quantities of HBsAb. Anti-HBc also identifies chronically infected HBV donors with undetectable HBsAg levels. [34] [35]

Transfusion-associated HBV infection occurs because not all HBV DNA carriers have detectable HBsAg and anti-HBc, and HBV variants with mutations may be silent serologically. [11] [36] Calculating HBV residual risk on the basis of HBsAg positivity in repeat donors identifies only 42% of incident HBV cases. [11] [33] [37] Using this approach and disregarding an effect for anti-HBc testing, the HBV risk is 1/63,000 units. If estimates are made on the basis that 0.03% of blood donors are positive for HBV, HBsAg test sensitivity is 99.9%, and anti-HBc test sensitivity is 99%, then the residual risk is 1/233,000 units. [1]

Hepatitis C

The hepatitis C virus (HCV), a single-stranded RNA virus of 9,500 nucleotides coding for 3,000 amino acids, is a member of the Flavivirdae family.

The 5 end of the HCV genome contains a highly conserved noncoding region that is used in PCR amplification assays. Structural elements are downstream and include the nucleocapsid or core and the two envelope regions, E1 and E2/NS1. The first nonstructural (NS) region, NS1, blends with E2. The subsequent NS2, NS3, NS4, and NS5 regions have protease, membrane binding, and polymerase functions [38] (Fig. 143-2). The initial genomic isolate, 5-1-1, is located at the 3 end of NS4. Expansion of the 5-1-1 clone produced the c-100-3 antigen used in first-generation HCV antibody detection kits. Second-generation anti-HCV assays include c22-3 core region antigens, and c33c NS3 antigens. Newer assays contain NS5 region antigens and a reconfiguration of antigens used in earlier assays without the c100-3 antigen. [38] Enhanced sensitivity appears related to increased detectability of c33c. [39]

Blood donors and patients with chronic hepatitis from the United States and western Europe are infected usually with HCV genotypes 1a, 1b, 2a, 2b, and 3a. Type 1b is prevalent in southern and eastern Europe. In Japan, Taiwan, and parts of China genotypes 1b, 2, and 2b predominate. [38] The various genotypes are associated with similar replication, transmission, and immune clearance rates. [40]

Hepatitis C virus is transmitted by injection drug use, percutaneous exposure such as tattooing, health care-related exposure, blood transfusion, and possibly sexual or household contact with HCV-infected persons. No identifiable risk appears for 50% of cases. Among blood donors, up to 0.36% are seropositive for HCV. [41] Donors 3039 years of age had the highest HCV seropositivity rate, as did those with a remote history of injecting drugs, prior blood transfusion, and possibly intranasal cocaine use. [42]

HCV Frequency in Recipients

Surrogate or indirect testing to reduce the risk of non-A, non-B post-transfusion hepatitis began in 1986 and 1987 in the United

Figure 143-2 The HCV genome encodes a single-stranded RNA virus in the Flaviviridae family. The structural organization contains 9,500 nucleotide bases that encode 3,000 amino acids. The figure denotes recombinant antigens comprising the various HCV test kits. *(From Alter.* [36] *)*

States and included ALT and anti-HBc assays. In retrospective analyses, these tests reduced the transmission of hepatitis C by 70%. [43] [44]

Introduction of first-generation HCV test kits in May 1990 reduced the risk of acquiring HCV per unit to 0.03% from 0.19%. [45] Second-generation HCV assays detect HCV 82 days (range: 54192 days) after infectivity or almost 6 weeks earlier than first-generation assays. [46] Based on studies of repeat blood donors, the residual risk following second-generation HCV testing is 9.70 (range 3.4736.11) per million donations or 1/103,000 units. [11] Newer assays decrease the window period between infectivity and detection to 70 days. [47] It is uncertain whether these new tests alter the residual risk because no cases of transfusion-transmitted HCV infection occurred at several institutions after second-generation assay implementation. [48] [49]

Approximately 90% of hemophilic patients treated with nonvirally inactivated coagulation factor concentrates are anti-HCV positive. HCV RNA remains in dry-heated (60° or 80°C) concentrates, but is not present when concentrates are heated in the lyophilized state at 80°C for 72 hours. HCV RNA was detected in some wet-heated or solvent/detergent-treated concentrates derived from anti-HCV unscreened plasma. HCV RNA is eliminated by wet-heating or solvent/detergent treatment of plasma from anti-HCV negative donors.[50]

Several lots of intravenous immune globulin preparations transmitted HCV between January 1993 and February 1994. [51] [52] [53] [54] [55] Although the plasma donors were second-generation anti-HCV negative, putative neutralizing antibodies were insufficient to inactivate contaminating HCV viruses. Currently, immune globulin preparations undergo viral inactivation procedures. In one report, immunodeficient patients receiving implicated lots of intravenous immune globulins developed significant liver failure and associated hepatitis-related mortality in contrast to idiopathic thrombocytopenic purpura patients who had clinically mild courses despite evidence of chronic infection.[55]

Natural History

Acute post-transfusion HCV infection causes no symptoms or jaundice in 7080% of cases.[38] The bilirubin level exceeds 2.5 mg/dl in only 30% and the mean peak ALT level is 708 /L. Nonetheless, the illness becomes chronic in 6080% of patients. Liver biopsies in HCV-positive blood donors who had a risk exposure 1620 years previously showed mild to moderate chronic active hepatitis and cirrhosis in 90%. Although donors with normal ALT levels had milder forms of disease, only 15% had normal liver histology.[56]

In a report from a tertiary care institution, 67% of patients had fatigue and hepatomegaly after a mean follow-up interval of 22 years. [57] Twenty percent had chronic hepatitis, 23% chronic active hepatitis, 51% cirrhosis, and 5% hepatocellular carcinoma. Other investigators found an 20% incidence of liver failure among patients surviving 15 years after developing post-transfusion hepatitis. [58] A study involving pediatric oncology patients with HCV infection showed a relatively benign clinical course after an average 14 year follow-up period.[59] The insidious nature of HCV infections and the deleterious effect of alcohol are demonstrated in a study involving patients observed an average of 18 years after transfusion. [60] Those with transfusion-related acute hepatitis had liver disease-related mortality rates of 3.3% compared to 1.12.0% in patients without clinical evidence of hepatitis. Although the difference is significant statistically, 71% of those with liver disease suffered from alcoholism.

HCV Testing Strategies

Hepatitis C virus RNA viremia appears within several days to 2 weeks after HCV infection. ALT levels increase, on average, 68 weeks postexposure. The highest HCV RNA levels occur just before clinical or laboratory evidence of hepatitis. Anti-HCV becomes detectable 1012 weeks after exposure. Antibodies against c 100-3 and 5-1-1 often disappear in patients with resolving infections, but c22-3 and c33c antibodies persist in chronic hepatitis. [38]

Rarely, seroconversion is delayed. A health care worker suffering a needle stick injury and simultaneous exposure to HIV and HCV seroconverted 9.513.5 months after exposure.[61]

In practice, the benefit of newer HCV tests containing NS5 epitopes may be more theoretical than observed. [39] [46] [48] [49] [62] [63] These assays potentially are more effective in identifying persons infected with type 2b and 3a HCV subtypes. [62] [63]

Nonspecific test reactions occur with the enzyme-linked immunosorbent assay (ELISA)-based screening tests. Supplemental tests, such as the recombinant immunoblot assay (RIBA), use HCV recombinant antigens on nitrocellulose membranes. Fifty to 85% of recipients of blood from RIBA-positive donors become infected, approximately the same rate as recipients of blood from HCV RNA-positive donors. ELISA-positive donors found negative by RIBA or PCR testing are unlikely to be infected with HCV.[64]

Currently, ALT as a surrogate or indirect test for hepatitis is not recommended in light of anti-HCV test effectiveness. [43] [44] [47] Nucleic acid amplification testing of volunteer blood donors is under investigation. During a pilot study, one HCV-seronegative, RNA-positive specimen was detected among 20,000 samples tested. [65] Nucleic acid amplification assays, potentially, could detect 650 HCV-infected donations annually in the United States.

Notification of Transfusion Recipients About HCV Risk

Approximately 7% of the estimated 4 million US citizens infected with HCV acquired their infection from blood transfusion. Most of these transmissions occurred before second-generation tests were implemented. Because many HCV infected patients are unaware of their infection and some therapeutic interventions may be effective, programs for notifying those at risk for HCV, including transfusion recipients, were initiated in 1998.

Hepatitis D

Hepatitis D virus, or delta hepatitis, is a defective RNA virus that replicates only in the presence of HBsAg. All patients are HBsAg positive, antibodies are present against HBV, HDV antigen is found in the liver, or HDV RNA is present in the serum. Approximately 1.48% of HBV donors are coinfected with HDV. [1] [66] Transmission occurs simultaneously with HBV or is superimposed on chronic carriers of HBV. Screening donors for HBsAg decreases the risks of HDV transmission.

Hepatitis E

Hepatitis E is a nonenveloped RNA virus associated with water-borne epidemics and fecal-oral spread. Viremia may be protracted, 45112 days. [67] The illness is associated with significant morbidity and mortality, particularly in developing countries.

Hepatitis G

The GB agent derives from the serum of a 34-year-old surgeon, GB, that was obtained 3 days after he developed jaundice in the 1960s. Plasma from marmosets containing the GB agent was passaged serially into tamarins (*Sanguinui labiatus*). Acute hepatitis developed 711 days later. Using a subtractive PCR methodology, characterization of two unique RNA molecules with limited amino acid identity to nonstructural HCV proteins led to identification of two flavivirus-like genomes in the GB-agent plasma, GBV-A and GBV-B.[68]

Degenerate PCR primers designed to amplify the helicase regions of GBV-A, GBV-B, and HCV aided in the identification of the helicase gene sequence of a novel virus from patients with non-A, non-B, non-C, non-D, non-E (non-A-E) hepatitis. The

Figure 143-3 (Figure Not Available) GB viruses A and C are related closely but share less homology with GBV-B and HCV. *(From Leary TP, Muerhoff AS, Simons JN et al: Sequence and genomic organization of GBV-C: a novel member of the flaviviridae associated with human non-A-E hepatitis. J Med Virol 48:60, 1996. Reprinted by permission of Wiley-Liss, Inc., a division of John Wiley & Sons, Inc. © 1996.)*

flavivirus, GBV-C, shares 59% nucleotide identity and 64% amino acid identity with GBV-A and is distinct from HCV. [69] In another laboratory, investigators identified an RNA flavivirus containing 9,392 nucleotides from the serum of a patient initially thought to have non-A, non-B viral hepatitis. Although subsequent testing showed evidence of HCV, a new virus, (HGV), related closely to GBV-A and distantly to HCV and GBV-B was identified. [70] Extensive analyses of the polyprotein sequences of GBV-C and HGV showed amino acid sequence identity at 95% and nucleotide identity at 85%. As a result, GBV-C and HGV are considered isolates of the same virus[71] [72] (Fig. 143-3 (Figure Not Available)).

Frequency of HGV Infection in Blood Donors

In studies conducted shortly after the identification of the HGV/GBV-C virus, 13 (1.7%) of 779 consecutively screened volunteer blood donors in the United States with normal ALT levels contained HGV/GBV-C RNA. Of 709 donors with elevated ALT levels, 11 (1.5%) were HGV/GBV-C RNA positive. One of the donors with elevated ALT levels was HGV/GBV-C and HCV positive and another was HGV, HBV, and HCV positive. [70]

Studies conducted subsequently in several international locations found 1.34.2% of donors HGV/GBV-C RNA positive. At one center, the prevalence increased to 7.4% among donors with anti-HCV and HCV RNA.[73]

Frequency of HGV/GBV-C Infection in Transfusion Recipients

Transmission of HGV/GBV-C occurs through transfusion. [70] [74] [75] [76] [77] [78] The incidence of HGV/GBV-C in transfusion recipients followed prospectively for acute hepatitis in the 1970s and from whom serum samples from all donors are available, reveals that only 4%, 3 of 79 patients, with non-A, non-B hepatitis have HGV/GBV-C as the only viral marker.[74] Eighty percent of the transfusion-associated hepatitis cases were caused by HCV. Ten percent of those with acute HCV hepatitis were co-infected with HGV/GBV-C. In contrast, only 0.6% of nontransfused patients followed in the control group were HGV/GBV-C RNA positive, reinforcing the concept that HGV/GBV-C is transmitted by transfusion. Approximately one-third of HGV/GBV-C-infected patients showed viral clearance within 3 years of infection.

The patients with HGV/GBV-C infection after transfusion had ALT levels less than five-fold elevated, no jaundice, and no symptoms. No correlation between HGV/GBV-C RNA levels and ALT levels was seen. The severity of hepatitis in HGV co-infected patients paralleled that seen in HCV-alone infected patients, suggesting that the extent of liver disease in co-infected patients is related to HCV infection, not HGV/GBV-C.

More than 14.2% of transfusion recipients in a French study

were HGV/GBV-C infected including 24.7% of bone marrow transplant patients.[75] In the United Kingdom, 61% of patients receiving a bone marrow transplant for acute leukemia were HGV/GBV-C positive compared to 33% receiving chemotherapy despite similar transfusion histories. No differences in HGV/GBV-C positivity was seen in patients treated before or after HCV screening was introduced. Liver function test abnormalities were seen in the same proportion in HGV/GBV-C infected and noninfected patients.[77]

Among patients undergoing cardiac surgery, the risk of transmission is 0.46% per donor unit in Tawian. The risk did not change following introduction of HCV testing.[78] Thirty-six percent of infected patients were viremic for >6 months. Patients on dialysis also have a higher incidence of HGV/GBV-C; ALT levels are not elevated.[79]

Approximately 918% of hemophilic patients are HGV/GBV-C RNA positive.[70] [80] [81] In addition, 32% of hemophilic patients in one study had anti-HGV envelope protein E_2 . Accumulating evidence suggests antibodies to the HGV/GBV-C envelope protein E_2 develop in those clearing HGV/GBV-C RNA, and thereby, may serve as a marker for identifying transiently viremic persons. [81] [82] [83] [84] Solvent/detergent treatment appears to inactivate HGV/GBV-C in coagulation factor concentrates. [80] [81]

Frequency of HGV/GBV-C Infection in Community-Acquired Non-A-E Hepatitis

Selected serum samples from patients with acute viral hepatitis enrolled in the CDC Sentinel Countries Viral Hepatitis Study were tested for HGV/GBV-C RNA. [85] HGV/GBV-C RNA was present in 9% of patients with non-A-E hepatitis, 20% of those with HCV infection, 25% of those with HAV infections, and 32% of those with HBV infection. HGV/GBV-C did not change the clinical course of acute disease in patients with hepatitis A, B, or C. Liver function test abnormalities were not seen in patients with HGV/GBV-C infection alone. Chronic hepatitis occured in 60% of patients with HCV alone and 61% of patients co-infected with HCV and HGV/GBV-C. That is, this study did not implicate HGV/GBV-C as the etiologic agent of non-A-E hepatitis. In another study involving histopathologic examination, HGV/GBV-C infection did not modify the course of HCV infection. [86]

Is HGV/GBV-C a Hepatitis Virus?

The results of studies in transfusion recipients and in patients with community-acquired HGV/GBV-C suggest that HGV/GBV-C does not cause significant liver disease.[48] [74] [77] [78] [85] [87] Occassional patients with fulminent hepatitis have HGV/GBV-C. [88] [89] It appears that HGV/GBV-C infection in patients with aplastic anemia is the result of transfusion rather than etiologic. [90] In situ hybridization studies have not been conducted to show HGV/GBV-C replication in hepatocytes. It appears the designation of HGV/GBV-C as a hepatitis virus is premature. Nonetheless, it is clear that HGV/GBV-C is tranfusion transmitted.

HERPES VIRUS INFECTION

Cytomegalovirus Infection

Cytomegalovirus (CMV), a large, enveloped, double-stranded DNA herpes virus, resides intracellularly in leukocytes. The subpopulation of leukocytes responsible for transmitting CMV is undergoing debate currently. CMV causes acute episodes and also latent recurrences. Secondary or reinfections are less well documented. Cellular blood components transmit CMV, not plasma or cryoprecipitate. CMV infection causes clinical symptoms predominantly in immunosuppressed patients. [91] [92] Immunocompetent patients infected through transfusion rarely develop significant clinical illness.

In immunosuppressed patients, CMV infection leads to pneumonitis, hepatitis, gastroenteritis, retinitis, and other inflammatory conditions. Primary infection in pregnancy does not result in unusual toxicity for the woman. However, congenital CMV infection is associated with jaundice, hepatosplenomegaly, microencephaly, and thrombocytopenia. Fetal mortality rates approach 20%.[91] [93] Premature infants (<1,200 g birth weight) born to CMV-seronegative women are at risk for similar disorders including hemolytic anemia. Morbidity varies considerably from a few percent to 50% of seronegative infants receiving unscreened blood. CMV-seronegative marrow transplant patients appear particularly susceptible to CMV infection with 30% of those infected developing symptomatic CMV disease. [94] Seronegative renal and liver transplant recipients are at risk for transfusion-transmitted CMV infections, but the risk associated with receiving seropositive solid organs outweighs that attributed to blood transfusion. CMV-seronegative HIV-infected patients represent another group at risk for transfusion-transmitted primary CMV infection (Table 143-2).[91]

At least 50% of blood donors have antibodies against CMV, thereby indicating prior CMV infection. One study found CMV DNA in only 0.9% of normal blood donors, but 44% of CMV antibody-negative donors had evidence of CMV RNA.[95] Another study found the risk of transfusion-acquired CMV infection to be <1/698 donor exposures.[96]

Two percent of CMV-seronegative marrow transplant patients given CMV-seronegative blood develop CMV compared to 2857% following infusion of CMV unscreened blood components.[94] Serologic screening failures reflect antibody titer levels below detectable limits despite continued presence of intracellular virus, transent viremia that binds circulating antibody, or other limitations in test efficacy.

Other techniques for reducing the risk of transfusion-transmitted CMV infection include leukocyte reduction, saline washing, and use of frozen deglycerolized blood components. Currently, filters that reduce the leukocyte content to $<5 \times 10^6$ leukocytes per transfusion and selection of blood from CMV-seronegative donors are the predominate methods used to reduce the risk of transfusion-transmitted CMV.[91] [94] [97]

Comparison of Leukocyte-Reduced and CMV-Seronegative Blood Components

A prospective, randomized, controlled study compared the effectiveness of components leukocyte-reduced by filtration and CMV-seronegative blood for preventing CMV infection and disease in 502 seronegative allogeneic and autologous marrow transplant recipients. [94] Seropositive patients were not studied because of the confounding effect of CMV reactivation. Five patients developed CMV infection 21100 days after transplant, 0.8% of those receiving seronegative blood and 1.2% of those receiving filtered blood. The actuarial probability of CMV infection 100 days after transplant was 1.3% for patients receiving seronegative blood and a statistically similar 2.4% for those receiving filtered blood. In a secondary analysis that included all

TABLE 143-2 -- Indications for Use of CMV-Reduced Blood Products

Premature infants (<1,200 g) born to CMV-seronegative mothers
CMV-seronegative allogeneic and autologous progenitor cell transplant recipients
CMV-seronegative HIV-positive patients
CMV-seronegative recipients of solid organs from CMV-seronegative donors
CMV-seronegative patients who are potential progenitor cell transplant recipients
CMV-seronegative pregnant women

CMV infections occurring immediately after transplant to day 100, the CMV infection rates and CMV disease rates were 1.4% and 0% in the seroselected group and 2.4% and 2.4% in the group receiving filtered components. The difference in disease acquisition is significant statistically but may reflect CMV infection prior to blood component randomization. Most transfusion medicine experts, on the basis of this and other studies, believe appropriately performed leukocyte reduction provides results equivalent to those associated with selection of seronegative components.

CMV Reactivation and Co-infection (Second Strain Infection)

Second strain infections have been reported in recipients of solid organ transplants, but evidence linking blood transfusions as the source is not available. Because reactivation of previous infections occurs in seropositive patients, the benefit of providing reduced-risk CMV components for these patients is uncertain. In addition, the use of leukocyte-reduced components for CMV-seropositive patients to decrease the risk of reactivation is under investigation.

Epstein-Barr Virus Infection

Tranfusion transmission of Epstein-Barr virus (EBV), a herpes virus, is unlikely because 90% of the adult population has evidence of previous exposure and infection is deterred by host virus-specific cytotoxic T lymphocytes. The cytotoxic T lymphocytes lyse EBV-infected B lymphocytes when viral peptides are expressed on the lymphocyte surface.[98]

Human Herpes Virus 8 Infection

Human herpes virus 8 (HHV-8), a herpes virus linked by molecular and serologic studies to Kaposis sarcoma, has been detected in a blood donor. In vitro

experiments document transmission to virus-negative B lymphocytes and umbilical cord blood mononuclear cells. These observations suggest the virus may be transmitted by transfusion. However, Kaposis sarcoma occurs infrequently among HIV-infected transfusion recipients and hemophilic patients indicating the risk is remote.[99] [100] [101]

PARASITIC INFECTIONS

Malaria

In the United States, malaria occurs in travelers, military personnel, and immigrants from endemic countries. Occasional cases result from mosquito transmission, blood transfusion, or organ transplantation. Approximately three transfusion-associated malaria cases occur per year in the United States. [102] [103] Malarial parasites, *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* maintain viability in red blood cells (RBCs) stored at 4°C, platelet concentrates stored at room temperature, and following RBC cryopreservation and thawing. Malaria is not transmitted by RBC-free components such as plasma and cryoprecipitate. The incubation period following transfusion ranges from 7 to 50 days (average 20 days).

The clinical presentation includes chills, fever, and splenomegaly. Fatigue, nausea, vomiting, headache, and diarrhea occur. Anemia may be severe with associated hemoglobinemia and hemoglobinuria, especially with *P. falciparum* infection. Glucose-6-phosphate dehydrogenase-deficient RBC are resistant to malaria. Persons lacking Duffy RBC antigens are refractory to *P. vivax* infection.[104] Patients with sickle cell trait have partial resistance to *P. falciparum*. Babesiosis should be considered in the differential diagnosis. Prevention of transfusion-transmitted malaria results from deferring blood donors emigrating or returning from malaria endemic regions.

Babesiosis

Babesiosis is caused by *Babesia microtia* or *B. equi* that is transmitted by the bite of an infected *Ixodes scapularies* or *I. pacificus* tick. Approximately 15 cases of transfusion-transmitted babesiosis have been reported in the United States. [1] Persons with a history of babesiosis are deferred from donating blood. [103] [105]

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite, *Toxoplasma gondii*, whose usual host is the domestic cat. The parasite is transmitted by infected cats or cat litter and eating raw or undercooked pork, goat, lamb, beef, or wild game. Approximately 2025% of the US population is infected. [1] Transfusion-associated disease occurs in immunocompromised patients.[103]

Leishmaniasis

Visceral leishmaniasis, such as that reported among veterans of the Persian Gulf War in 19901991, follows infection with *Leishmania tropica.* No cases of transfusion-transmitted visierotropic leishmaniasis have been reported. [103]

Chagas Disease

American trypanosomiasis or Chagas disease consists of an acute phase that varies from no symptoms to fever, skin rash, conjunctivitis with palpebral edema, lymphadenopathy, or hepatosplenomegaly. The acute phase usually resolves in 48 weeks unless severe myocarditis or meningioencephalitis intervenes. The latter is associated with fatal outcomes. Following a latent stage of undetermined duration, the chronic phase occurs in up to 3040% of infected patients manifest by cardiac disease, megacolon, or achalasia. [106] [107]

The flagellate protozoan parasite, *Trypanosoma cruzi* causes Chagas disease. The disorder is widespread in Latin America. Humans become infected when bitten by *T. cruzi*-infected insects of the Reduviidae family. Once infected, low-level parasitemia persists. Vector transmission is unlikely in the United States, but 50,000100,000 infected Latin American immigrants reside in the United States. Among the four transfusion-associated cases of Chagas disease reported in the United States and Canada, *T. cruzi*-infected Latin American immigrants provided platelets in three. All four patients were immunocompromised. The organisms remain viable in whole blood stored at refrigerator temperatures for 18 days, for >8 months in citrated blood samples stored at room temperature, and following freezing and thawing. In South America, 1349% of recipients of parasitemic blood become infected. There is concern that additional transfusion-associated Chagas disease cases will occur as immigration increases to the United States from Central and South America. [106] [107] [108]

Risk factors for *T. cruzi* infection include birth or residence in endemic regions such as Central America, South America, or Southeastern Mexico; living in dwellings with palm leaf-thatched roofs or mud walls where vector insects reside; or receipt of a blood transfusion in Latin America. Studies in which blood donors are asked about these risk factors identify a cohort for additional serologic screening. Using assays for *T. cruzi* antibodies, 34% of donors who lived in poor housing or received a blood transfusion in endemic areas had *T. cruzi* antibodies.[108] One study, conducted in California, found 1/340 donors had a risk factor for Chagas disease. [109]

Recommendations for screening donors by history questions, antibody testing, or a tiered approach remain in abeyance pending further investigation of test sensitivity and specificity. Chemoprophylaxis with Gentian violet or other agents and blood filtration offer alternative approaches. [107] [110] [111] Because infection

occurs in endemic regions rather than the United States, testing donors with risk factors on one occasion offers a potential alternative to testing each donation. Of note, infection did not occur in 11 recipients of blood obtained in Los Angeles and Miami from donors seropositive for *T. cruzi*.[108] [112]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

CREUTZFELDT-JAKOB DISEASE

Creutzfeldt-Jakob disease (CJD) is a subtype of the spongioform encephalopathies. Similar neurodegenerative disorders occur in sheep (scrapie), cattle (bovine spongioform encephalopathy [BSE]), and humans (Kuru, Gerstmann-Straussler-Schneiner disease, fatal familial insomnia, and new variant CJD). The median age of onset is 6167 years and few patients with CJD are younger than 30. The incidence of classic CJD is approximately one case per million population, an estimate that has not fluctuated.[113] [114] [115]

The disease arises sporadically, has a familial association, or follows an environmental exposure. Sporadic cases have no known cause. The acquired cases are linked to iatrogenic events that include use of contaminated human pituitary-derived growth hormone, dura mater transplants, a single case report involving a corneal transplant, and contaminated depth electroencephalographic electrodes. The latency period following human growth hormone factor administration ranges from 3 years to >20 years. The average duration between dura mater graft placement and onset of CJD is 89 months (range: 16193 months). [115] [116] Accumulating evidence suggests that new variant CJD and BSE, or mad cow disease, are caused by the same agent. Transgenic or inbred mice innoculated with brain tissue from sporadic, iatrogenic, new variant CJD, or BSE developed spongioform encephalopathy. [117] [118] The familial cases have a mutation in chromosome 20.[113]

According to the most widely accepted theory, an infectious agent, a prion protein (PrP) on proteinaceous infectious particle, causes CJD. The agent has some attributes of a virus, such as strain variation, but resists inactivation by boiling and ionizing or ultraviolet irradiation. The prion is a modified form (PrP^{Sc}) of a host-encoded glycoprotein (PrP^{c}). The 35,000-dalton PrP^{c} glycoprotein is not pathogenic but is required for replication of the infectious agent. PrP^{Sc} occurs through a post-translational process involving a conformational change in PrP^{c}.[113] [115] In spontaneous or familial cases, PrP^{c} is converted to PrP^{Sc}.

Approximately 85% of CJD cases occur randomly. These sporadic CJD cases present clinically with memory loss or confusion, behavioral changes, or gait instability. Myoclonic or choreoathetoid movements associated with electroencephalographic periodicity occur during the 4-month illness. Histologic examination of the brain shows spongioform changes, gliosis, and neuronal loss. Immunologic staining reveals prion-positive amyloid deposits.

The inherited forms of CJD are autosomally transmitted and are associated with coding disorders in the prion protein gene (PRNP). Recognized mutations occur at codons 102, 105, 117, 145, 178, 180, 198, 200, 210, 217, and 232. The phenotypic expression of inherited CJD is variable and inconsistent within families. [119]

Sporadic, iatrogenic, and new variant CJD occurs predominantly in persons homozygous for methionine in PRNP codon 129. In iatrogenic CJD, heterozygosity or homozygosity for valine in codon 129 does not alter disease expression but may affect the incubation time. [120]

To date, no cases of transmission by blood or plasma derivatives have been reported. In preliminary reports, no cases of CJD occurred in 179 recipients of blood components from 14 US blood donors who later developed CJD.[121] In the United Kingdom, 21 patients who received blood transfusions and 29 who donated blood among 202 definite and possible cases of CJD were investigated. [122] Transfusion recipients did not differ from age- and sex-matched controls. Six individuals who subsequently developed CJD donated >10 units of blood; the incidence of CJD in the geographic areas in which the transfusions occurred was unchanged.

Despite these data, concern related to transmission by other tissues led to recommendations deferring blood donation by those at high risk for developing CJD: persons who received human pituitary-derived growth factor and dura mater transplants and persons whose families are at increased risk for CJD, including those with more than one genetically related family member with CJD. If a donor develops CJD subsequent to donation, in-date blood components must be retrieved and destroyed. Physicians caring for recipients of previous blood donations from at-risk donors (with exceptions of those with only one family member with CJD), are notified so they can decide whether to inform patients that they received such blood components. Plasma derivatives, albumin, and antihemophilic factor concentrates are recalled if plasma donors subsequently develop CJD. More than 37 such recalls of plasma derivatives occurred between 1993 and 1997 involving >1,500 lots and products worth several million dollars. Because CJD occurs in older individuals, exclusion of plasma from donors older than 50 or 60 years would prevent some recalls. This approach is controversial because risks of other transfusion-transmitted diseases should be lower in this group than in younger donors needed to replenish the lost donations.[114]

SPIROCHETE INFECTIONS

Syphilis

Serologic tests for syphilis (STS) were introduced for blood screening in the United States in 1938 and were required by regulation in 1958. No cases of transfusion-transmitted syphilis have been reported recently. [123] [124]

Treponema pallidum, the spirochete causing syphilis, loses viability after 7 days storage at refrigerated temperatures. Experiments to determine viability following storage at room temperature have not been performed. The concomitant administration of antibiotics to some patients receiving transfusions probably decreases the occurrence of transfusion-associated syphilis.

A report shows STS-reactive donations are HIV seropositive 12 times more frequently than STS-seronegative donations. However, syphilis testing removes only 1.4% of HIV antibody-negative, HIV-1 p24 antigen-negative, infectious donations at an estimated cost of more than $16 million per case prevented, compared to $17,00032,000 per case prevented by HIV antibody screening and $810 million per HIV case prevented by HIV antigen testing. [124]

Lyme Borreliosis and Other Tick-Borne Illnesses

Borrelia burgdorferi, the agent responsible for Lyme disease, is transmitted to humans by *Ixodes scapularis* tick bites. Spirochetemia likely occurs postinfection and may be present in asymptomatic persons. Nonetheless, no clinical or serologic evidence of transfusion-transmitted Lyme disease was demonstrated in cardiothoracic surgery patients receiving blood collected in New England during the peak deer tick season. [105]

Donors potentially exposed to Rocky Mountain spotted fever and ehrlichosis have been deferred for 4 weeks following endemic exposure.

PARVOVIRUS INFECTION

Parvovirus B19, a nonenveloped DNA virus, causes a viral exanthum called fifth disease. Approximately 50% of adults are seropositive for parvovirus B19 antibodies; most infections occur in those 615 years of age. The virus is tropic for hematopoietic

---

progenitor cells through its receptor, the RBC P antigen. The P antigen is expressed on megakaryocytes, endothelium, placenta, fetal liver, and fetal heart cells, but erythroid cells are most susceptible. Following infection, neutralizing antibodies appear. Some patients with sickle cell anemia, thalassemia, and other entities associated with enhanced RBC production develop acute aplastic or hypoplastic anemia following infection. Others at risk for aplasia following parvovirus infection include immunodeficient patients, HIV-infected patients, solid organ transplant recipients, and children with malignancies. Fetal loss may follow acute parvovirus infection during pregnancy.[125] Immune globulin infusion reverses aplasia in some patients.

Neither solvent/detergent nor heat treatment at 100°C for 30 minutes after lyophilization inactivates parvovirus. [126] [127] [128] More than 80% of hemophilic patients have evidence of previous parvovirus infection. In general, these patients do not suffer serious or long-term hematologic sequelae regardless of HIV serostatus. [129] Albumin solutions are pasteurized at 60°C for 10 hours, a process that probably does not destroy the virus. However, the ethanol fractionation process used to prepare albumin inactivates or eliminates the virus.[126]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BACTERIAL CONTAMINATION

Bacterial contamination of RBC and platelet components occurs as a result of bacterial entry during component pooling or aliquoting, minute holes in blood containers, transient bacteremia at the time of phlebotomy, or contaminated containers.

Criteria for suspecting septic transfusion reactions include temperature elevations of 13.5°F or 12°C accompanied by rigors, tachycardia, and systolic blood pressure changes indicating significant hypertension (>30 mm Hg) or hypotension (<30 mm Hg) within 90 minutes of transfusion onset. Additional signs and symptoms include nausea, vomiting, diarrhea, chest or back pain, and cyanosis.

Septic complications caused 16% of the 182 transfusion-associated fatalities reported to the United States Food and Drug Administration between 1986 and 1991. Of the reported fatalities, 72% followed platelet transfusion and 28% followed RBC transfusions. Microorganisms contaminating platelet concentrates included coagulase-negative staphylococci, diphtherioids, streptococci, *Salmonella* species, *Escherichia coli, Serrati marcescens, Pseudomonas aeruginosa, Bacillus cereus*, and *Klebsiella* species.[130] [131] [132] Recent reports found *Aspergillius terreus* and *Yersinia enterocolitica* in contaminated platelet units.[134] [135] Under-reporting of septic platelet transfusion fatalities may understate the actual incidence 10-fold. [131] Assuming bacteria enter the container at the time of phlebotomy, the microorganisms enter log phase growth after several days in these room temperature-stored components. In vitro studies indicate contaminated platelet concentrates stored for 14 days had 2.6×10^3 10×10^4 colony-forming units per milliliter compared to 1.2×10^7 4.4×10^{13} colony-forming units per milliliter in concentrates stored for 5 days. [132] The contamination rate varies between 0.04% and 0.3% per unit for platelet concentrates prepared from whole blood and from 0% to 0.42% per single donor (apheresis) platelet concentrate.[132] [134] [135] [136] [137] [138] [139]

Yersinia enterocolitica causes the majority of septic RBC transfusion reactions. Twenty-one episodes resulting in 13 deaths were reported between 1985 and 1996. [140] During this interval, approximately 44 million patients received RBC transfusions. Because RBCs are stored at 16°C, it is not surprising that psychrophilic organisms such as *Yersinia, Pseudomonas putida*, and *P. fluorescense* predominate. A lag period of 3 weeks intervenes between organisms entering the collection container and accumulation of sufficient bacteria and endotoxin to produce clinical symptoms. The contamination rate in filtered, leukocyte-reduced blood may be lower than that observed in nonfiltered components.[130] [131] [139]

When septic reactions are suspected, the transfusion must be stopped immediately and followed by supportive care and broad-spectrum antibiotic coverage. The laboratory investigation includes container and patient blood cultures. A Gram stain of the remaining fluid in the container is most likely to be positive when bacterial counts exceed 10^6 colony-forming units per milliliter. In several reports involving platelet transfusions, the Gram stain was positive in more than two-thirds of symptomatic cases.[130]

Chapter 144 - Autologous Blood Transfusion

Margot S. Kruskall

INTRODUCTION

Although the concept of collecting, saving, and transfusing autologous blood has existed for more than 100 years, practical applications for these techniques appeared limited until recently. With the emergence of the human immunodeficiency virus and its highly efficient transmission via blood has come an increased interest in using the patients own blood for transfusion.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ADVANTAGES OF AUTOLOGOUS BLOOD TRANSFUSION

The substitution of autologous blood components for those collected from other (allogeneic) donors eliminates transfusion-transmitted diseases such as hepatitis and AIDS. Immunologic complications related to the transfusion of foreign cells, including hemolysis and febrile reactions to white cells, are also prevented. Other advantages are less clearly established. For example,

---

erythropoiesis may be sufficiently stimulated in the repeatedly bled autologous donor to hasten recovery from postoperative anemia. [1] Intraoperatively salvaged red cells are spared the acquired membrane defects (storage lesion) and 2,3-diphosphoglycerate deficiency of refrigerated allogeneic cells. [2] Some investigators believe that allogeneic blood transfusions may contribute to immunosuppression in the recipient, [3] and therefore to an increased risk of cancer spread; [4] autologous blood should not. However, a recent randomized trial of autologous versus allogeneic blood transfusion in patients with colon cancer was unable to detect any differences in prognosis, thereby rendering doubtful the contribution of allogeneic blood transfusion to immunosuppression. [5]

An important drawback to techniques of autologous blood transfusion is their increased expense relative to the technically and administratively simpler allogeneic transfusions they replace. [6] In addition, the availability of autologous components may result in their use in situations in which transfusion might not have otherwise been considered, [7] and patients with suboptimal compensatory erythropoiesis and donation-induced anemia at the time of surgery are also more likely to receive transfusions. [8] Recent analyses have estimated very large cost-benefit ratios associated with autologous collections in advance of surgery (for example, $500,000 per quality-adjusted life-year in the setting of coronary artery bypass surgery). [9] Such costs could be reduced if autologous protocols were used only in appropriate settings and if the procedures for such collections were streamlined. [10] [11] Other potential problems, such as the risks of blood donation in patients with cardiac disorders [12] [13] or complications from reinfusion of red cells damaged during their salvage from the surgical field, [14] [15] are of debatable significance.

METHODS OF COLLECTION

Three approaches are popular and sometimes used in combination in an individual patient: autologous blood donations in advance of an anticipated blood loss during surgery, salvage of intra- and postoperatively shed blood, and intraoperative acute hemodilution.

Autologous Blood Donations

Preoperative

The typical volunteer allogeneic blood donor is allowed to give 1 unit of blood (450 ml ± 10%) no more than once every 8 weeks, in order to prevent such complications as iron deficiency. However, provided that bone marrow erythropoiesis can be stimulated and satisfactory iron supplies maintained, blood can be collected as frequently as once a week from an autologous donor.[16] Although the shelf life of refrigerated red blood cells is limited to 42 days, storage for up to 10 years is possible at 65°C or lower, using glycerol as a cryopreservative.

From a cardiovascular standpoint, phlebotomy is well tolerated by a variety of seemingly high-risk donors, including the elderly, [17] [18] children,[19] pregnant women,[20] [21] and patients with coronary artery disease. [1] [22] By contrast, anemia frequently develops during the donation interval and limits the number of autologous units that can be collected. In addition to marginal iron stores, erythropoietin levels often do not increase during the donation interval, probably because the hematocrit of most donors is not allowed to fall to below 30%. [23] Recent research suggests that this situation may be improved by the administration to autologous donors of the recombinant growth hormone erythropoietin.[24] Many variables affect the response to this drug in blood donors, including the route of administration (intravenous vs. subcutaneous), baseline iron stores, and the method of iron supplementation (oral vs. parenteral). [25] These variables are under active study. The expense of erythropoietin therapy has limited its application to situations in which autologous blood donation might otherwise be difficult or impossible, such as in the already anemic patient.[26] [27]

Patients planning to undergo an elective orthopedic surgical procedure make ideal autologous donors (Table 144-1): these patients typically require blood transfusions either during surgery or during the first few postoperative days, and most have sufficient time before the operative date to make multiple donations. [28] [29] Autologous blood has also been collected from patients undergoing elective open heart surgery and other vascular bypass grafts. [1] [18] The reduction or elimination of allogeneic blood use by these patients is testimony to the value of autologous collections in such operations (Fig. 144-1). The use of preoperatively donated autologous blood has also been reported for a variety of other surgical procedures, including radical prostatectomy, hysterectomies and other gynecologic procedures; colorectal, biliary, and gastric surgical procedures; and neurosurgical procedures. [18] [30] The need for autologous blood deserves periodic reevaluation, because its role may be affected by improvements in surgical techniques. Radical retropubic prostatectomy is one such example. Ten years ago many hospitals encouraged patients undergoing this procedure to donate autologous blood; [31] [32] [33] now, in some hands, less than 2% of patients require any blood whatsoever, and autologous blood donations can be eliminated. [34] Plastic surgical procedures also rarely require allogeneic blood transfusions, and the collection and use of autologous blood appears unnecessary.[35]

Other Uses

Autologous blood has been collected from women during pregnancy for use during childbirth, but this approach is controversial. A number of recent clinical studies of blood donations during pregnancy have found no complications for either the mother or the fetus. [20] [21] Nevertheless, the transfusion rate at delivery is quite low, less than 2.5% in many institutions,[36] and most autologous donations are unused. The use of autologous donations may best be directed toward patients with multiple gestations or placenta previa, in which populations the likelihood of transfusion may exceed 25%. [37]

Long-term (frozen) storage of autologous red cells in the absence of a planned transfusion episode is largely ineffective and expensive. Medical emergencies requiring transfusion are of an unpredictable but low incidence, and the likelihood is not very great that sufficient blood could be donated and stored and that

TABLE 144-1 -- Common Indications for Autologous Blood Techniques

Surgical/Obstetric Procedures	PreoperativeDonations	Perioperative Salvage
Intra-abdominal vascular procedures	Yes	Yes
Open heart surgery	Yes	Yes
Total hip replacement	Yes	Yes[a]
Total knee replacement	Yes	Yes[b]
Scoliosis repairs	Yes	Yes
Radical prostatectomy	Yes	Yes[c]
Placenta previa	Yes	No[d]
Multiple gestations	Yes	No[d]

according to the number of units of autologous blood donated. White bars, no transfusion; gray bars, autologous blood transfusions only; red bars, allogeneic blood transfusions. *(From Owings et al.,[1] with permission.)*

such blood could be sent where it was needed and prepared in a timely fashion (i.e., thawed and washed free of its glycerol cryoprotectant).

Other autologous components have applications in surgery. Although autologous plasma is easily separated and stored, there is little need for this component in elective surgery.[38] However, autologous fibrin glue can be prepared using the cryoprecipitated portion of the plasma mixed immediately before use with thrombin. This tissue adhesive has been used for a variety of purposes in surgical procedures, including the control of bleeding in cardiovascular and thoracic surgery, [39] adhesion in middle ear surgery,[40] closure of the dura in neurosurgery, [41] adhesion of skin grafts,[42] and closure of gastrointestinal fistulas.[43] Fibrin glue has also been used in pancreatic and hepatic resection and trauma,[44] [45] although episodes of severe hypotension have been reported, possibly related to allergic reactions to systemically absorbed bovine thrombin.[46] Another rare complication, the development of life-threatening bleeding in association with acquired factor inhibitors, is caused by immunization to small amounts of bovine factor V in the thrombin; these antibodies recognize cross-reactive epitopes on human factor V. [47] [48] [49]

Autologous platelet-rich plasma has been prepared at the start of open heart surgery, before bypass, using apheresis equipment, for return to the patient following heparin reversal.[50] Both thrombocytopenia and an acquired platelet defect, due to activation and -granule release, occur when blood passes through the membrane oxygenator during cardiopulmonary bypass.[51] The theoretical advantages of transfusing autologous platelet-rich plasma are improved hemostasis and a reduction in transfusion requirements. Initial studies provided enthusiastic confirmation. [50] [52] [53] [54] More recent prospective, blinded studies have been unable to demonstrate a reduction in blood use after either primary or repeat open heart surgery. [55] [56] Furthermore, the harvesting of platelet-rich plasma has been followed by intraoperative heparin resistance, possibly due to the release of platelet factor 3 and other procoagulants from platelets damaged during collection. [57] Further studies of this autologous component are needed before its utility can be advocated.

Intraoperative Blood Salvage

Interest in salvaging blood shed at surgery has been stimulated by the introduction of automated instruments for autologous blood salvage over the past 30 years. The first model suctioned blood from the surgical field into a reservoir, from which it could be rapidly reinfused into the patient. [14] Unfortunately, a design flaw allowed the reinfusion pump to continue to operate even when the reservoir was empty, and several deaths from air embolism were reported.[58] This situation improved with the availability of other high-speed models with safer air detectors. Techniques for washing blood to remove excess surgical irrigant fluids and other contaminants appeared at around the same time.[59]

Systems for blood collection without further washing are usually modifications of disposable suction devices (Table 144-2). Blood is collected under low vacuum pressure into a

TABLE 144-2 -- Autologous Blood Salvage Systemsa[a]

System	Hardware	Software	Characteristics of Collected Blood				
			Hematocrit	Free Hemoglobin	Platelet Count	CoagulationFactors	Fibrin Degradation Products
Collection without washing	Rigid plastic cannister	Plastic bag	Low (25%)	Very high (200 mg/dl)	Low (100,000/mm^3)	Low (3575%)	High (300 mg/dl)
Collection followed by washing	Integral or separate blood cell processor	Disposable plastic bowl and tubing	High (60%)	Low (<50 mg/dl)	Very low (10,000/mm^3)	Absent (0%)	Absent (0%)

Data from Noon[2] and Silva et al.[117]

[a] Typical results of laboratory tests are shown. Transfusion of large volumes of salvaged blood results in similar alterations in these tests in the recipient.

plastic bag seated within a hard outer cannister. An anticoagulant such as citrate can be added. As soon as the bag is full, or within 4 hours of the start of collection (to prevent bacterial overgrowth), the contents of the bag are reinfused into the patient by gravity without any further processing, except passage through a standard blood filter.

Alternatively, the contents in the bag can be washed to remove free hemoglobin, surgical irrigant solutions, and other debris. Although this step is theoretically attractive and increasingly popular, its necessity before reinfusion of shed blood has not been established. [60] [61] Instruments that include both a reservoir for collecting salvaged blood and a centrifugal washer have been developed. Large aliquots (500 ml) can be fully washed in as little as 3 minutes. As a result of this speed, autologous blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation.

The hematocrit of unwashed blood is typically low because of dilution from irrigating surgical fluids and some degree of mechanical hemolysis. [62] Free hemoglobin levels are sometimes greater than 1,000 mg/dl in unwashed blood, and hemoglobinemia and hemoglobinuria may occur after the transfusion, but renal sequelae are surprisingly infrequent.[61] [63] Despite this evidence of red cell injury, the survival rate of [51] Cr-labeled salvaged cells is normal in most patients studied. [64] [65]

Transfusion of salvaged blood has resulted in coagulation abnormalities in animals and humans, including hypofibrinogenemia, prolonged prothrombin time and partial thromboplastin time, elevated concentrations of fibrin degradation products, and thrombocytopenia. [15] [66] Some authors originally interpreted these results as evidence of disseminated intravascular coagulation, possibly incited by phospholipids and other material released from damaged red cells and platelets. A more likely alternative is that the laboratory data reflect the characteristics of the salvaged blood itself, which, after exposure to serosal surfaces, becomes deficient in coagulation factors and platelets and, in the case of unwashed blood, has high levels of fibrin degradation products (Table 144-2).[67] In those few cases in which the progression of coagulation abnormalities over time has pointed to disseminated intravascular coagulation rather than simple hemodilution, [14] [68] the patients underlying condition (shock due to massive hemorrhage) appears to have been the cause. A relationship between postoperative coagulopathies and salvaged autologous blood remains tenuous.

Fat, fibrin, bone fragments, and microaggregates often contaminate salvaged autologous blood. However, infusion of unwashed blood has not been proved harmful in either animals or humans, possibly because most particulate material is removed by routine blood filters. [69] [70] Other contaminants, such as heparin, topical antibiotics, hemostatic agents, and biological substances such as tissue enzymes, can be removed, but not necessarily completely, by washing. [71] [72] Complete removal of bacteria also is not possible, even when the salvaged blood is washed with antibiotics. [73] Thus, collection of blood from a contaminated site (e.g., with intestinal contents) is probably contraindicated, although some investigators have argued that, if no other blood is available, such transfusions may be lifesaving. [74] [75] Tumor cells have also been found in blood salvaged during cancer operations; their malignant potential after salvage and transfusion is unknown, and many consider cancer another contraindication. [76] [77]

Approximately one-half the blood lost during surgery can be salvaged; the rest is usually irretrievably absorbed in drapes and sponges or damaged during collection.[65] The use of salvaged autologous blood has been associated with a 50% reduction in allogeneic blood use in orthopedic procedures such as spinal surgery[78] and hip replacement[79] [80] and is also effective in such vascular surgical procedures as aortic reconstruction. [81] In cardiac surgery, the largest volume of blood that can be processed for return to the patient comes from the membrane oxygenator.[82] [83] Although the blood is technically not shed, in that it is still in the extracorporeal circuit, the processing is helpful in concentrating the red cells and removing cardioplegic solutions. Autologous blood salvage has also proved useful in large volume blood loss such as that occurring in liver transplantation, in which the volume salvaged averaged 25 units in one study, [84] [85] and in trauma.[86] Blood has also been salvaged from the hemoperitoneum associated with ectopic pregnancy,[87] during radical prostatectomy, [88] and during splenectomy.[89] Autologous salvage has been a useful adjunct in the treatment of some Jehovahs Witnesses, whose literal interpretation of the Bible includes abstention from routine allogeneic blood transfusion.[90]

Both the cannister systems and red cell processors used to collect intraoperatively shed autologous blood can also be employed to collect postoperative blood drainage, such as that from the mediastinum after open heart surgery, [91] from the knee or hip after orthopedic procedures, [92] or from the peritoneal cavity after hepatic injury.[93] Because blood salvaged from a serosal cavity has little residual fibrinogen and platelets, clotting is not a problem, and the addition of anticoagulants is usually unnecessary.[94] As in intraoperatively salvaged blood, free hemoglobin levels are substantially elevated. Nonetheless, red cells in the shed blood exhibit normal survival on radioisotopic studies. [95] Shed mediastinal blood following open heart surgery contains high levels of cardiac muscle enzymes, especially creatine kinase, as well as lactate dehydrogenase from hemolyzed red cells; [96] [97] reinfusion of shed blood results in elevated levels of both enzymes and can confound the diagnosis of myocardial infarction in the postoperative period. [98] [99] Reinfusion of shed mediastinal blood reduces the need for allogeneic transfusions. [100] However, the volume of red cells salvaged may be variable. For example, although the volume of postoperative drainage is often substantial in orthopedic surgery, [101] [102] red cells may represent only a small portion; thus, one study reported a mean of only 55 ± 29 ml of red cells in drains following hip surgery. [103] Arthroplasty procedures performed without cement are associated with larger perioperative blood losses, and postoperative red cell salvage may be more effective in such cases. [104]

Hemodilution

The collection of autologous blood during surgery for later reinfusion at the end of the procedure was first suggested in open heart operations, in which it was hoped that a supply of platelets undamaged by exposure to the membrane oxygenator might reduce the incidence of coagulopathies. [105] Hemodilution itself reduces red cell loss: a patient with a hematocrit of 45% and a 2-liter blood loss during surgery loses roughly 900 ml of red cells but with a hematocrit of 20% from hemodilution loses only 400 ml of red cells. Hemodilution is probably less expensive to accomplish than preoperative autologous blood donation and may be the only option available when surgery is performed in other than elective settings. [106] Proponents claim that the induced anemia may even be beneficial to the patient, in that oxygen delivery at a hematocrit of 30% is enhanced by an increased cardiac output resulting from the decreased blood viscosity. [107]

Reductions in allogeneic blood needs have been reported after marked intraoperative hemodilution (after the hematocrit is lowered by 50%). [108] [109] More modest hemodilution (e.g., removal of 2 units of blood at the beginning of surgery) is also beneficial according to some workers, [109] [110] [111] but not others.[34] [112] [113] [114] Furthermore, one group has provided evidence that hemodilution may jeopardize patients at risk of ischemic myocardial injury. [115] More research is needed to establish the safety and ideal protocols for this form of blood conservation.

FUTURE DIRECTIONS

Even if human immunodeficiency virus and hepatitis could be completely eliminated from blood components, the risk of other transfusion-transmissible diseases (both known and undiscovered) is ample reason for the continued use of autologous blood protocols wherever feasible. Recombinant erythropoietin is likely to play an increasingly important role in facilitating autologous blood donation, as are improvements in blood salvage devices that make their use easier and less costly.

Kenneth C. Anderson

BONE MARROW TRANSPLANTATION

Introduction

Bone marrow transplantation (BMT) is currently used to treat a broad spectrum of malignant and nonmalignant diseases. Refinements in testing for HLA compatibility, coupled with new approaches to both prevent and treat graft-versus-host disease (GVHD), have resulted in widespread use of allogeneic BMT. [1] Only 40% of patients have HLA-matched related donors; however, allogeneic BMT using either related donors other than HLA-identical siblings or unrelated HLA-matched donors has demonstrated promising preliminary results.[2] Moreover, there is increased use of autologous BMT, with or without purging of marrow tumor cells, to treat both hematologic cancers and solid tumors.[3] Increasingly, hematopoietic transplantation is being effected not only with bone marrow but also with stem cells derived from mobilized peripheral blood (PBSC) [4] and umbilical cord blood (UCB), [5] leading to the more generic term hematopoietic stem cell transplantation (HSCT). [6] These products are being further processed by positive or negative selection, in vitro expansion, and genetic manipulation (see Chap. 142). Likewise, blood components are increasingly being manipulated by irradiation, filtration, and washing, and apheresis components are being selected to provide highly enriched sources of platelets, plasma, granulocytes, and lymphocytes. Taken together, these products are all part of the developing field of hematopoietic cellular therapy in which the blood bank plays a lead role. Whether or not the HSC processing facility falls directly under the blood bank, the transfusion medicine experience is crucial, especially with the expanding interest that the United States Food and Drug Administration (FDA) is taking in this area.

Other chapters in this edition cover in detail elements of HSCT that integrally involve the blood bank, including the mobilization and optimal collection of PBSC, and the functions of the HSC processing facility, including the in vitro manipulation of bone marrow, PBSC, and UCB products. This chapter will restrict its focus to the traditional blood bank role of providing safe and effective blood component therapy to HSCT patients: ABO incompatibility in allogeneic HSCT, alloimmunization, transfusion-associated (TA) GVHD, cytomegalovirus (CMV) infection, basic HSC processing as it relates to good manufacturing practices and federal regulation, documentation of engraftment, immune cytopenia after HSCT, and the use of hematopoietic growth factors to hasten engraftment and to lessen the toxicity of high-dose ablative treatment. Transfusion medicine expertise is essential in all these aspects of HSCT, both in current practice and in furthering research efforts. [6]

Blood Component Support

The blood component laboratory plays a critical role in HSCT by providing appropriate red blood cell (RBC), platelet, and blood component support both before and after HSCT. The criteria for transfusion of blood components to patients undergoing HSCT are not different from transfusion criteria used more generally, but the magnitude of support required is great. The unique nature of HSCT patients, however, does require specific transfusion strategies to avoid alloimmunization, CMV infection, and TA GVHD, as well as strategies to prevent the potential complications of ABO incompatibility in allogeneic transplants. Finally, as is true in other settings, the blood bank should not only determine which products are required but also review ongoing transfusion practice.

Several donor and/or patient factors may influence hematologic engraftment, immune reconstitution, and the blood product support required after HSCT. [7] In all marrow recipients, engraftment may be compromised due to disease and/or treatment-related effects on the marrow microenvironment. Reconstitution after allogeneic HSCT may be relatively enhanced since the donor marrow is healthy; however, engraftment may be adversely affected by regimens employed in the recipient to prevent or treat GVHD. Moreover, in vitro T-cell depletion of donor marrow, which can effectively abrogate GVHD, has in some patients resulted in failure to engraft and graft rejection. Autologous marrow may be intrinsically compromised due to the patients underlying disease and cytotoxic therapy received prior to marrow harvesting, to in vitro techniques used for removal of tumor cells, or to cryopreservation. In syngeneic HSCT, donor marrow is histocompatible and healthy and neither manipulated nor cryopreserved. However, the underlying disease and prior treatment of the recipient may, as is true in other types of HSCT, compromise the marrow microenvironment and thereby adversely affect engraftment.

After HSCT, there is a period of pancytopenia lasting 14 weeks when patients require multiple RBC and platelet transfusions. [6] [8] [9] [10] For example, patients with aplastic anemia undergoing allogeneic HSCT received a median of 9 (182) and 44 (6468) units of RBCs and platelets, respectively, primarily during the first 4 weeks after grafting.[9] Clinical parameters may correlate with transfusion needs. In patients with acute nonlymphocytic leukemia in first remission who underwent HSCT, for example, the method of prophylaxis against GVHD, the development of acute GVHD, the method of prophylaxis against infection, and donorrecipient ABO compatibility all influenced the magnitude of transfusion support required. [11] In particular, patients with grades 3 and 4 acute GVHD required more blood product support than those with grades 1 and 2 acute GVHD: a median of 217 units of platelets and 27.5 units of RBCs in the former group, compared to 91 units of platelets and 14 units of RBCs in the latter patients. In recent years, a major focus has been to reduce the period of pancytopenia by the use of growth factors (e.g., G-CSF, GM-CSF, and erythropoietin) and the use of peripheral blood stem cells (PBSC) grafts rather than bone marrow. The latter, in particular, may reduce the period of pancytopenia to 1014 days, with a significant decrease in platelet and RBC use. [12]

Although complications related to GVHD and infection are fewer in autologous than in allogeneic HSCT recipients, the magnitude of transfusion support nonetheless is also significant in recipients of autografts. In a study of patients with non-T-cell acute lymphoblastic leukemia who underwent either monoclonal antibody (MoAb)-purged autologous HSCT or allogeneic HSCT, autologous marrow recipients engrafted more quickly, had shorter hospital stays, and had fewer early deaths, suggesting that they may have less transfusion requirements than allogeneic HSCT recipients. [13] The blood component laboratory must therefore be an integral part of the planning for and daily management of the HSCT service to meet these demands in a timely fashion.

Importance of ABO Compatibility in Allogeneic HSCT

ABO incompatibility between marrow donor and recipient may be major, with isohemagglutinin in the recipient directed against donor RBC antigens; minor, with isohemagglutinin in the donor directed against recipient RBC antigens; or both (Table 145-1). Major ABO incompatibility carries the risk of severe hemolytic reactions at the time of HSCT, graft rejection, or delayed engraftment in the setting of high-titer hemolytic isohemagglutinin in the marrow recipient. [6] [10] Attempts to overcome major ABO incompatibility have included depletion of RBCs from the bone marrow graft prior to HSCT [14] [15] and/or removal of isohemagglutinin from the recipient by large-volume plasma exchanges or immunoadsorption.[16] In addition, some investigators have supplemented these techniques with pre-HSCT transfusions of donor type blood or purified A or B substance to adsorb recipient isohemagglutinins completely. [17] [18] Although studies suggest that major ABO-incompatible HLA-matched transplants have resulted in no increase in patient mortality, incidence of rejection, delayed engraftment, or GVHD compared with ABO-compatible controls,[19] [20] [21] some reports suggest that RBC engraftment can be delayed in this setting.[6] [10] [15] Current practice in major ABO-incompatible HLA-matched HSCT is to deplete RBCs from all marrow before HSCT, but to use methods for depletion of recipient isohemagglutinin only when it is present in high titer and may result in delayed erythropoiesis and hemolysis after HSCT. Prolonged red cell aplasia despite adequate granulocyte and platelet engraftment has been described in a number of case reports. Therapies have included plasmapheresis, high-dose steroids, and erythropoietin, with variable results to date. [22] [23]

Potential adverse outcomes of minor ABO incompatibility between donor and recipient include rapid immune hemolysis at the time of infusion of donor marrow due to passive transfer of isohemagglutinin in the marrow plasma, or delayed immune hemolysis caused by anti-RBC antibodies produced by the donor marrow. [6] [10] There is no effect of minor ABO incompatibility on graft rejection, incidence or severity of GVHD, or patient survival. [19] [20] Although exchange transfusion of the recipient before HSCT using red cells of the donors blood group has been used

TABLE 145-1 -- Examples of Transfusion Restrictions After ABO-Incompatible HSCT

ABO Type		Type of Mismatch	Transfusion Restriction	
Recipient	Donor		RBC	Plasma
A	A	None	A or O	A or AB
A	O	Minor	O	A or AB
A	AB	Major	A or O	AB
A	B	Major/Minor	O	AB

to prevent hemolysis caused by passive transfer of isohemagglutinin in the marrow product, this is rarely a clinically significant problem and can more easily be avoided by removing plasma from the marrow prior to infusion. Minor ABO incompatibility can result in adverse reactions due to the production of anti-A and/or anti-B antibodies by donor marrow lymphocytes early (13 weeks) post-transplant, particularly in patients on cyclosporine therapy or those receiving T cell-depleted allografts.[24] [25] [26] This may be particularly severe and associated with reactive hemolysis in the setting of minor ABO-incompatible HLA-matched HSCT using unrelated donors.[27] The rapidity of engraftment and early related production of isohemagglutinins is somewhat surprising, given the delay in humoral reconstitution noted after HSCT.[7] Current practice is to transfuse either group O or donor group RBCs to dilute the recipient red cells and to monitor patients closely for evidence of hemolysis; in rare cases, exchange transfusion has been required due to very rapid engraftment of donor lymphocytes, production of anti-RBC antibodies, and related hemolysis. As a general principle, ABO-incompatible transplants require separate specific restrictions in terms of the type of RBC and plasma to be infused (Table 145-1). RBCs should be compatible with both donor and recipient plasma, while plasma should be compatible with both donor and recipient RBCs. ABO antigens are widely expressed on endothelial tissues; thus, HSCT recipients may be considered ABO chimeras even after full RBC engraftment.

Alloimmunization and Platelet Refractoriness

Patients undergoing HSCT are dependent on large numbers of cellular blood product transfusions, often before and always after HSCT. Studies suggest that sensitization to HLA antigens increases with number of transfusions and related donor exposures; [28] therefore, patients eligible to undergo HSCT are at high risk to develop alloimmunization. HLA sensitization, in particular, may have adverse effects on response to platelet transfusion and on marrow engraftment. The latter is most evident in the setting of aplastic anemia: an analysis of 625 patients with aplastic anemia who received allografts from HLA-identical donors demonstrated either no or transient engraftment in 68 (11%) patients.[29] Of a variety of clinical parameters analyzed, post-HSCT treatment with cyclosporine and avoidance of pre-HSCT blood transfusions were associated with improved survival. Although graft failure associated with histocompatibility differences between donor and recipient is often attributed to rejection by host T lymphocytes, persistent host antibodies specific for donor antigen may also mediate graft failure, whether by antibody-dependent cell-mediated cytotoxicity or complement-mediated cytotoxicity. Specifically, host anti-HLA class I antibodies have been associated with graft failure and death; host anti-ABO antibodies have persisted for up to 18 months post-HSCT and resulted in erythroid hypoplasia. [30] There is therefore a need to prevent alloimmunization in patients who are candidates for later HSCT. While the use of family members as blood donors pre-HSCT has been reported not to be harmful in patients with malignancy,[31] transfusions from the potential marrow donor should be avoided due to the risk of sensitization of the patient to both HLA and non-HLA antigens in this setting.

Patients are also at high risk to become alloimmunized post-HSCT. In this setting, repeated failure to obtain satisfactory responses to platelet transfusions, as measured by the 1-hour post-transfusion corrected count increment (CCI), is a well-recognized problem. There are many patient-specific, nonimmune causes of refractoriness (Table 145-2) that are common in as many as 67%[32] of post-HSCT thrombocytopenic patients. Platelets, however, express HLA class I antigens, small amounts of ABO, and a number of platelet-specific antigens, all of which

TABLE 145-2 -- Causes of Platelet Refractoriness

Patient Factor	Clinical	Blood Bank
Alloimmunization	Fever	ABO match
Bone marrow transplant	Sepsis	Platelet storage time
Gender	Splenomegaly	Platelet crossmatch
Circulating IV Ig	Clinical bleeding	HLA match
Transfusion number	RBC use	
	DIC	
	Neutropenia

may be the target of an immune response. Strategies to prevent alloimmunization and to provide suitable platelet products are a major focus of the transfusion service in treating HSCT patients. A retrospective analysis of patients with severe aplastic anemia who underwent allogeneic HSCT documented the development of refractoriness to transfusion of random donor platelets in 34% of patients; indeed, the number of platelets transfused (if 40 units) as well as lymphocytotoxic antibodies correlated with refractoriness.[33] Finally, Galel et al.[34] also documented alloimmunization in 31% of transplant patients, with similar incidence in recipients of autologous (34%) and allogeneic (27%) recipients. Half of the alloimmunization in each group was demonstrated pre-HSCT. They identified patients with Hodgkins disease and women with children to be at particular risk for developing alloimmunization. Most importantly, they concluded that HSCT does not prevent the development of alloimmunization in either autologous or allogeneic HSCT recipients. It is therefore important to test for anti-HLA antibodies whenever transplant recipients become refractory to random donor platelet transfusion, since response to random donor platelet transfusion is poor in the sensitized host, and HLA-matched, family member, or crossmatch-compatible platelets may be useful in this setting (see Chap. 137).[35] [36] [37] [38] [39]

It would appear that patients undergoing HSCT would be an appropriate group in which to employ strategies to avoid alloimmunization. These include minimizing donor exposure by ensuring the appropriateness of all transfusions, the use of single-donor platelets, [40] [41] or HLA-matched platelets,[42] and/or ultraviolet (UV) irradiation[43] [44] or leukodepletion[45] [46] [47] [48] of platelets for transfusion. Leukodepletion has received particular attention as a means of reducing alloimmunization, as filtration and apheresis technology can now economically provide blood products with <10 ^{6} residual leukocytes. Both prospective and uncontrolled studies have indicated that the risk of alloimmunization and platelet refractoriness can be reduced with the use of leukopoor products. [45] [46] [47] [48] For example, Saarinen et al.[46] showed that 0 of 26 pediatric patients receiving leukopoor blood components became refractory, compared to 11 of 21 historical control patients who received standard products. Likewise, van Marwijk Kooy et al.[45] found in a prospective randomized trial that 46% (12 of 26) of patients receiving standard platelets (mean of 35 × 10^{10} leukocytes/dose) became clinically refractory, while this occurred in only 11% (3 of 27) of patients receiving leukopoor products. De novo anti-HLA antibodies were detected in most refractory patients in both groups. Further, recipients of leukopoor products who became refractory did so later (>4 weeks) than the standard therapy group.

Most recently, the TRAP trial[49] has reported that there was no difference in the rate of alloimmunization when comparing pooled, filtered platelet concentrates, filtered single-donor apheresis platelets, and UV-B-irradiated platelet concentrates in patients with newly diagnosed acute myeloid leukemia. Although still the subject of investigation, these data may imply that leukodepletion by filtration is the most effective method for the prevention of alloimmunization. Further, the timing of filtration may be important. An animal model study[50] has suggested that prestorage filtration is more effective than poststorage filtration in preventing primary refractoriness. Indeed, in a prospective study of aplastic thrombocytopenic patients receiving prestorage leukoreduced platelets and RBC, Novotny et al. [51] found that anti-HLA antibodies developed in only 3 of 112 (2.7%) patients with negative risk factors for prior HLA sensitization. Conversely, 16 of 52 (31%) patients with a history of prior pregnancy or transfusion of nonleukoreduced blood developed antibodies. Nevertheless, most (95%) of the alloimmunized patients could be supported with prestorage leukoreduced products without the need for HLA-matched or crossmatched platelets.

Available data suggest that leukodepletion does not prevent secondary alloimmunization in recipients previously sensitized by transfusion or pregnancy, and there is as yet no effective means of reversing alloimmunization once it occurs. Taken together, prevention of alloimmunization is probably best achieved by the combination of prestorage leukodepletion and limiting donor exposure, avoiding unnecessary transfusion, and the use of single-donor apheresis platelets. Overall, the only potential adverse effect of depleting leukocytes from blood products would be removal of a purported graft-versus-leukemia effect, [52] but whether white blood cells within transfused cellular blood components mediate such an effect remains controversial. [53]

Once platelet refractoriness is documented, there are a number of strategies that may assist in obtaining therapeutic platelet concentrations in vivo. Obviously, if a nonimmune cause is apparent such as sepsis or disseminated intravascular coagulation, treatment of the underlying cause is indicated, and the use of ABO-matched, fresh (12 days old) platelets may be beneficial. [54] A recent survey showed that nonimmune causes may be present in up to 88% of patients treated for hematologic malignancy that become platelet-refractory,[32] while immune causes could be demonstrated in 25%, either by positive lymphocytotoxicity assay or in platelet crossmatch. In the latter cases, the use of HLA-matched platelets or crossmatched platelets are indicated. Even so, overall 4050% of HLA-matched or crossmatched platelets fail[39] to produce an expected increment. Due to the polymorphism of the HLA loci, it is often not possible to find complete (grade A) HLA-A and -B locus matches, leading to the use of platelets mismatched at one or more loci. Available evidence suggests that the optimal response requires either a grade A or BU match (Table 145-3), in which case up to 80% of transfusions may be successful.

TABLE 145-3 -- Degree of HLA Matching for HLA-Matched Platelets

Match Grade	Description	Examples of a Donor Phenotype for a Recipient Who Is A1,3;B8,27
A	Four antigen match	A1,3;B8,27
B	No mismatch present	
B1U	One antigen blank or unknown	A1,-;B8,27
B1X	One crossreactive group	A1,3;B8,7
B2UX	One antigen blank and one crossreactive	A1,-;B8,7
C	One mismatched antigen	A1,3;B8,35
D	Two or more antigen mismatch	A1,32;B8,35

Data from Vengelen-Tyler.[116]

Cytomegalovirus Infection

Cytomegalovirus infection and disease is a major cause of morbidity and mortality in immunocompromised patients. Especially at risk are CMV-seronegative patients who receive allogeneic BMTs, as these patients receive the most intensive conditioning regimens and are further immunocompromised by GVHD and its prophylaxis and treatment. Such patients may demonstrate a 2857% infection rate, with approximately 30% developing CMV disease, including interstitial pneumonitis and gastroenteritis, more often with fatal outcomes, despite significant advances in anti-CMV treatment protocols. [55] [56] Cellular blood components transfused from CMV-seropositive donors to seronegative recipients are a major cause of seroconversion, [56] as evidenced by early studies with prophylactic granulocyte infusions showing that lack of seroconversion was found only in seronegative recipients of granulocytes from seronegative donors. Transfusion with seronegative blood products appears to lessen the CMV infection after allogeneic HSCT when both donor and recipient are seronegative, but not when either is seropositive. [57] [58]

In some studies, treatment of patients with immunoglobulin has been efficacious in this setting and may also reduce CMV sequelae in seropositive recipients. [59] The use of both immunoglobulin and CMV-seronegative blood products appears to confer no additional benefit. CMV antigen can be detected in peripheral blood leukocytes after allogeneic transplantation, but whether antigenemia is more sensitive than rapid culture methods to focus antiviral prophylaxis in HSCT patients remains to be determined.[60] CMV infection, strongly associated with GVHD,[61] may become less frequent in all patients undergoing allogeneic HSCT due to the development of effective prophylaxis for GVHD. In addition, acyclovir can lessen the incidence of CMV infection and related morbidity, thereby improving the survival of seropositive allogeneic HSCT recipients. [62] [63] Finally, reports document successful therapy for CMV pneumonia that has developed after HSCT, with ganciclovir and either intravenous immunoglobulin or CMV immunoglobulin. [64] [65] On the basis of these and other studies, it has been the practice to reserve the exclusive use of CMV-seronegative blood components for allogeneic HSCT when both the donor and recipient are seronegative.

Cytomegalovirus infection in autologous HSCT recipients is less common, perhaps related to the rarity of GVHD in autologous HSCT recipients. Indeed, equivalent numbers of autologous and allogeneic HSCT recipients seroconvert to or excrete CMV, but clinical sequelae are less common than in allogeneic HSCT recipients. [66] Therefore, methods for CMV prophylaxis, such as immunoglobulin, seronegative blood products, or post-transplant acyclovir therapy, have not been used in autologous HSCT recipients. However, pretransplant CMV serology is also predictive of CMV infection after autologous HSCT [67] and engraftment may be delayed after autologous HSCT in patients with CMV infection. Moreover, analysis of 159 autologous HSCT recipients, all of whom received CMV-unscreened blood products, documented a probability of CMV infection in 22.5% in CMV-seronegative patients and 61.1% in CMV-seropositive recipients. [68] In this series, CMV pneumonia developed in 11 patients at a median of 100 days post-HSCT and was fatal in 9 cases. This study concluded that the risk of CMV disease is not negligible. While previously the standard of practice was not to use CMV-seronegative blood products in the setting of autologous HSCT, the recent acceptance of widely available, leukodepleted components as "CMV-safe" (see following) has led many centers to use these components in all HSCT recipients, both autologous and allogeneic.

The traditional source of CMV-negative blood components has been blood derived from seronegative donors, identified by either enzyme-linked immunoassay or latex agglutination testing. As CMV seropositivity may vary from 50% to 90% in different communities, seronegative donors are often in limited supply. While the use of CMV-seronegative blood components in seronegative recipients greatly reduces CMV transmission, a CMV infection rate of 14% is still observed, most likely due to the inadequacies of the serologic testing methods employed and the natural background rate of seroconversion. [69] In the last two decades there has been mounting evidence that latent CMV resides in the leukocytes and that their removal can render seropositive blood CMV-safe. Early trials of leukoreduced blood products in this setting were uncontrolled and hampered by the relatively crude methods available for leukoreduction. As early as 1977, an open trial in seronegative heart surgery patients showed that whole blood leukoreduced by centrifugation (58% reduction of leukocytes) resulted in 12.5% seroconversion, as compared to 67% in uncentrifuged blood recipients.[70] Since then a number of reports have shown decreased seroconversion with blood products leukoreduced by saline washing,

freeze-deglycerolization, and filtration. For example, filtration of red cells was shown to decrease transfusion-acquired CMV infection in infants, [71] and the use of filtered blood components was shown to decrease CMV seroconversion in patients undergoing treatment for acute leukemia. [72] [73] Data from Seattle suggest that provision of filtered red cells and platelet transfusions from unscreened donors to CMV-seronegative patients undergoing autologous HSCT may prevent seroconversion or infection in the recipient. [74] In addition, De Witte et al. [75] showed that leukocyte depletion of blood products by centrifugation, coupled with acyclovir prophylaxis, may also prevent primary CMV infection in CMV-seronegative allogeneic HSCT recipients. Each of these studies has supported the idea that leukoreduction significantly decreases the risk of CMV transmission.

Most recently, Bowden et al.[76] reported a randomized prospective trial of >500 HSCT patients selected to receive either seronegative products or filtration-leukoreduced products to test the hypothesis that they are equivalent at preventing CMV transmission. Although the conclusion of the studythat the rates of CMV transmission are no different for the two preparationshas been widely accepted, the study has been criticized on a number of counts that should be considered carefully. The statistical analysis excluded patients who seroconverted within 21 days of HSCT, on the basis that these patients must have been exposed to CMV prior to transplant. Five patients seroconverted in the first 21 days, and their inclusion significantly affects the results of the study (Table 145-4); some patients in the leukocyte reduction arm received seropositive unfiltered blood in error; and finally, bedside filtration was used, which has subsequently been shown to suffer from a relatively high rate of failure. [77] [78] Nevertheless, patients receiving leukoreduced blood showed a low level (2.4%) of CMV infection, which is in keeping with the historical figures of 14% CMV seroconversion with the use of CMV-seronegative components. The authors conclude with the statement: We believe that the results

TABLE 145-4 -- Incidence and Actuarial Probability of CMV Infection and Disease After BMT by Study Arm

	Analysis Period (days post-BMT)	Actuarial Probability		p Value
		Seronegative (%)	Leukoreduced (%)	
CMV infection	21100 days	1.3	2.4	1.00
CMV disease	21100 days	0	1.2	0.25
CMV infection	0100 days	1.4	2.4	0.50
CMV disease	0100 days	0	2.4	0.03

Data from Bowden RA, Slichter SJ, Sayers M et al.[76]

of this study justify abandoning the maintenance of dual inventories of seronegative and unscreened blood products. In fact, the need to perform serologic screening of blood products of CMV could be eliminated altogether. [76]

Leukoreduced components are now widely accepted as being equivalent to seronegative products for the prevention of CMV transmission. Efficient means of leukocyte removal from platelets and red cells using filtration methods have been developed, and the AABB has set standards that define leukopoor blood as containing $<5 \times 10^6$ leukocytes.[79] It is not clear what the optimal level of leukodepletion is to prevent CMV transmission; however, 5×10^6 represents a reasonable goal attainable by current technology.

The widespread availability of CMV-safe leukoreduced blood raises the question as to whether there is a role for the use of such components in CMV-infected HSCT patients. Two factors need to be considered: second-strain infections and viral reactivation. In solid organ transplants, it is well documented that CMV-positive recipients may develop CMV disease derived from the viral strain associated with the graft. [80] To date, there is no substantial evidence of second-strain infections associated with HSCT or transfusion. Of greater concern in HSCT is the possibility that transfusion may lead to reactivation of latent infections in the CMV-seropositive recipient. For example, Adler et al. [81] observed that CMV-seropositive cardiac surgery patients who receive CMV-seronegative blood are more likely to show a postsurgery increase in anti-CMV titer than those who received no blood products. Other studies have shown that CMV reactivation is higher than the background rate in transfused sick patients. The possibility that transfusion in itself may cause viral reactivation, and whether this activation can be prevented by the use of leukoreduced blood components, is the subject of a current large NIH-sponsored trial (Viral Activation Transfusion Study) among patients with human immunodeficiency virus (HIV) infection.

The AABB has published recommendations based on the above studies that suggest the use of CMV-seronegative or leukoreduced blood components for all CMV-negative HSCT recipients, both allogeneic and autologous, as well as all CMV-negative HIV-infected patients, pregnant women, and patients receiving chemotherapy likely to induce severe neutropenia. [69] It is left to individual physicians to decide whether the equivalent CMV-positive patient group should receive similar CMV-safe products, pending the outcome of the viral activation studies.

Transfusion-Associated Graft-versus-Host Disease

All patients undergoing HSCT are at risk for the development of TA-GVHD after receiving cellular blood products. The most commonly reported manifestations are skin rash, abnormal liver function tests, and severe pancytopenia. The degree of pancytopenia has generally been profound, perhaps related to the HLA disparity evident between donor and recipient in TA-GVHD. In contrast, GVHD occurs after allogeneic HSCT when marrow and donor have been chosen by virtue of histocompatibility. Transfusion-associated GVHD results in an overall 84% mortality rate after a median of 21 days (range 81,050 days). [82]

Transfusion-associated GVHD is effectively prevented by gamma irradiation of the blood product prior to transfusion. Moreover, if any transfusions are given to the marrow donor during marrow harvest, they must also be irradiated. A survey of blood component irradiation practices in the United States in 1991 found that 88% and 81.4% of allogeneic and autologous HSCT recipients, respectively, received irradiated cellular components. [83] Although it is reassuring that the overwhelming majority of patients received irradiated components, it is disturbing that not all patients received them. A recent documentation of several cases of fatal TA-GVHD in recipients of autologous HSCT[84] further suggests that irradiation of cellular components transfused to HSCT recipients is not yet uniform practice. Doses of radiation used to treat cellular blood components before transfusion have varied in the past from 1,500 to 3,500 rads; [83] however, at least one case of TA-GVHD has been documented following irradiation with 1,500 rads, [85] and recent studies suggest that irradiation to 2,000 rads is required to reduce mitogen-responsive lymphocytes by 5 to 6 logs compared to unirradiated controls.[86] [87] Based on these observations, the FDA has established guidelines regarding irradiation doses of blood products intended for clinical use. These guidelines require 2,500 rads (25 Gy) to the central part of the container, with 1,500 rads (15Gy) as the minimum dose to any other point. [88]

A potential alternative method to prevent TA-GVHD would be to deplete lymphocytes from blood products prior to transfusion. It has been demonstrated in murine systems, as well as in humans, that T lymphocytes mediate GVHD and that the incidence and severity of GVHD after allogeneic HSCT can be reduced if T cells are eliminated from the donor marrow prior to grafting by a variety of techniques. [89] [90] [91] While techniques are available for the preparation of leukopoor red cells and platelets that contain 10^6 lymphocytes, cases of GVHD after transfusion of leukopoor components have been reported. [92] [93] A canine model has been used to demonstrate that UV rather than gamma irradiation of transfused leukocytes can abrogate TA-GVHD in recipient animals. [94] However, future studies are needed to determine whether UV light can avoid TA-GVHD in transfusion recipients without adverse effects on in vitro function or in vivo recovery of UV-treated red cells or platelets. At present, irradiation remains the only widely accepted method of preventing TA-GVHD, although it is associated with RBC membrane changes that shorten their life span and potassium leakage that may pose problems in pediatric patients and those undergoing massive transfusion. [86]

Finally, immunocompetent patients may also be afflicted with TA-GVHD. Risk factors include the use of fresh blood, transfusion of recipients who share an HLA haplotype with HLA homozygous blood donors,[95] [96] and the recipients of HLA-matched platelet transfusions. Homozygosity for HLA types is more likely to occur among first-degree family members (e.g., parents, children, and siblings) and in population groups with limited HLA heterogeneity. Thus, the risk of transfusion of blood from HLA homozygous donors to unrelated HLA heterozygous patients is 1 in 874 in Japan and may be as high as 1 in 7,174 in the United States. [97] Petz et al.[98] pointed out that the incidence of TA-GVHD in the United States is substantially less than the population at risk. While underreporting may play a role, it is likely that other factors, including the use of blood that is stored for up to 6 weeks (with decreased leukocyte viability) and the rejection of HLA homozygous cells based on minor transplantation antigens, may play a role. Nevertheless, TA-GVHD is an eminently preventable disorder that is often untreatable once diagnosed. The FDA and AABB[88] now require that all transfusions from (1) any donor who is a blood relative of the recipient; (2) a donor unit intended for intrauterine transfusion; (3) to an immunoincompetent or immunodeficient recipient; or (4) a recipient of HSCT be irradiated. There is also a strong rationale for irradiation of products given to any

patient receiving intense chemotherapy, HLA-matched products, [99] [100] or granulocyte transfusions.

Prestorage Leukodepleted Products and Febrile Nonhemolytic Transfusion Reactions

Adverse consequence of residual white blood cells within platelet and RBC products include febrile nonhemolytic transfusion reactions (FNHTRs), alloimmunization, transmission of infection, GVHD, and immunomodulation.[101] Current filtration and apheresis technologies can yield leukopoor cellular components, RBCs and platelets that contain <10[6] residual leukocytes. [45] [46] [47] [48]

As noted above, it would appear that transfusion of such components can abrogate alloimmunization and avoid CMV transmission. Leukoreduced products are also beneficial in preventing FNHTR. Defined as an increase in temperature >1°C during or soon after transfusion, these reactions occur more commonly with platelet transfusions (30.8%) than with RBCs (6.8%).[102] The routine use of antipyretics may prevent most episodes of fever, but not the accompanying chills, cold, and discomfort. It was thought that these reactions were due to antibodies in the recipient to donor leukocyte antigens (including HLA), and it was known that their incidence could be reduced by removal of leukocytes prior to transfusion. [48] In a series of seminal papers, Heddle et al. [102] [103] [104] showed that FNHTRs to platelets correlate not with white cell content, but with the age of the product. Further, if the plasma is removed from platelets and infused separately, reactions occur significantly more often to the plasma than to the platelet content. These data support the concept that many FNHTRs are caused by cytokines released by leukocytes in blood components. Indeed, these and other authors have demonstrated a progressive rise in interleukin (IL) 1-, IL-6, IL-8, and tumor necrosis factor on storage of platelet and RBC products. [102] [105] [106] [107] [108] This cytokine increase is abolished by prestorage leukodepletion, which may provide an alternative explanation for the prior observations that leukoreduction decreases the incidence of FNHTR.

In summary, it would appear that transfusion of exclusively leukoreduced cellular blood components has proven efficacy in abrogating alloimmunization in patients at risk, in preventing CMV transmission, and in reducing the occurrence of FNHTR. Taken together, these findings provide a strong rationale for the exclusive use of leukoreduction products for HSCT recipients, [109] with leukoreduction preferably occurring soon after collection (prestorage) to maximize the benefit with respect to reduction of cytokine accumulation and FNHTR.

Federal Regulation and Bone Marrow Processing

As the use of BMT has increased as a treatment strategy, the blood component laboratory has become increasingly involved in HSC processing. Historically, bone marrow was not a licensed blood component, and no federal regulations concerning its collection, transportation, processing, storage, or transfusion existed. The FDA has signaled its intent to begin active regulation, and it is instructive to review the history of such regulation in blood banks: blood components are regulated both as drugs and biologicals. Good manufacturing practice regulations were defined for the drug industry in 1962 and were incorporated into law for both drugs and blood in the late 1970s. The Clinical Laboratory Improvement Act in 1967 and its amendment in 1988 specified additional regulations for blood bank laboratories. Early on, the blood industry was regulated primarily under the biologicals regulations in the Code of Federal Regulations. [110] In the 1980s the FDA began enforcing standards for drugs. Examples of such standards include the use of current good manufacturing practices, equipment validation, personnel proficiency and competency testing, and the establishment of independent quality assurance units within each establishment. [111] The blood industry responded by voluntary self-policing through the standard-setting and inspection functions of the AABB. [112] Nevertheless, many hospital blood banks are now subject to multiple regular inspections by the FDA, AABB, and Joint Commission for the Accreditation of Health Care Organizations. In 1995 the FDA proposed extending these regulations to HSCs, envisioning at least three categories: minimally manipulated products, which include bone marrow and PBSCs that are reinfused either directly after collection or after cryopreservation; manipulated products, which would include any enrichment strategy or genetic manipulation; and UCB transplants. The latter two categories would be subject to the investigational new drug (IND) process whereby the FDA controls clinical drug trials. [113] [114] The draconian nature of these proposals has been a cause of major concern in the HSCT community. More recently, the FDA has reaffirmed its intent to regulate highly manipulated HSC products, including genetically altered or in vitro expanded cells, by the IND process, and has proposed a different approach for minimally manipulated stem cell products. The latter now includes positively and negatively selected HSC from PBSC and UCB. These products would not require IND approval but would be subject to similar regulations as are in place for standard blood components, such as a requirement for establishment registration with the FDA and regular FDA inspection. [115]

In response to these developments, the community has begun to develop self-policing mechanisms. The AABB has published standards for HSC laboratories since 1993.[116] [117] Recently, the International Society for Hematotherapy and Graft Engineering and the American Society for Blood and Marrow Transplantation have established the Foundation for Accreditation of Hematopoietic Cell Therapy as an independent standard-setting and inspection entity devoted to establishing enforceable standards for the collection, storage, and manipulation of HSC grafts and the clinical practice of HSCT. [117] [118]

These developments make it clear that HSCT will be increasingly regulated and inspected. The blood bank, with many years of experience in these matters, offers a logical source of leadership in ensuring compliance with federal regulations and the provision of safe, effective HSC grafts.

Previous chapters dealt with the collection of PBSCs and the manipulation of HSC grafts to decrease GVHD and graft rejection while enhancing graft-versus-tumor effects, as well as the rapidly developing area of gene therapy. We will only briefly review the principles of processing here. Basic HSC processing may vary from performing simple cell counts and bacterial cultures prior to immediate reinfusion of allogeneic HSC to processing consisting of several steps, including concentration and washing; sedimentation with hydroxyethyl starch, Ficoll-Hypaque, or Percoll; positive or negative (purging) selection; cryopreservation and storage; and thawing and transfusion. The first goal of HSC processing is depletion of RBCs, plasma, and fat with minimal loss of progenitor cells. Marrow processing was originally done manually by simple centrifugation; at present, cell separators are used for the preferential concentration of progenitor cells with increased elimination of other hematopoietic cells. A variety of automated procedures have now been published for marrow processing using various cell separators, and engraftment has been documented after transfusion of such marrow.[119] [120] [121] [122] As is true in the preparation of other blood components, it is also critical to develop techniques to avoid bacterial contamination during the collection and processing of bone marrow. [123] [124] [125]

In allogeneic BMT, purging has been used to deplete T cells in donor marrow before grafting to prevent GVHD. [90] [126] Although the incidence of GVHD has thereby been decreased, concomitant increases in graft failure and rejection and relapse rates have lessened enthusiasm for this approach to abrogate GVHD.

HSC processing may also include depletion (purging) of tumor cells from autologous marrow or PBSC before grafting. The various methods of purging are based on physical properties, sensitivity to chemotherapy, and/or expression of cell surface antigens, [126] and may involve either negative selection of tumor cells or positive selection of stem cells. Each of these has its own set of optimal conditions, some of which have been well defined and others of which are still under investigation. One may postulate that malignancies that either arise from the marrow (e.g., leukemias, myelomas) or are histologically evident within the marrow (e.g., relapsed lymphomas, breast cancer, neuroblastoma) will require purging. Purging of tumor cells from

autologous marrow is being evaluated to allow patients with overt tumor involvement to undergo autologous BMT and to deplete subclinical residual malignant cells when tumor is not evident on cytopathologic examination. In particular, three lines of evidence suggest that there may be up to 10^8 tumor cells in marrow when histopathologic examination is normal: (1) the ability to derive tumor cell lines from marrows that appear to be pathologically normal; [127] [128] (2) the observed time to relapse and known tumor-doubling times in patients with hematologic cancers, which suggest that tumor cells were present when not pathologically evident; and (3) the use of more sensitive techniques, such as gene rearrangement or polymerase chain reaction (PCR) technology, [129] [130] which can confirm the presence of a single malignant cell within 10^6 marrow cells.

The conditions for pharmacologic purging of autologous marrow tumor cells on a cell separatorthat is, marrow RBC and drug concentrationhave been established. [131] [132] Moreover, when using cell separator technology for MoAb-based purging of autologous marrow tumor cells, a 45 $\log_{10}$ depletion can be achieved using only 50% of the MoAb and complement in 50% of the time required for manual techniques.[131] Purging of tumor cells from autologous grafts prior to BMT has permitted this approach to be used in patients with up to 20% histopathologic involvement with tumor. [133] PCR has demonstrated that immunologic purging using anti-B cell MoAbs and complement lysis could successfully remove PCR-detectable lymphoma cells from autografts in only half of the patients; [134] importantly, those patients who were reinfused with autologous marrow containing residual lymphoma cells detectable by PCR had an increased incidence of relapse. [131] Sharp et al.[135] have used a

culture technique sensitive for detecting occult lymphoma cells in marrow to analyze histologically normal marrow harvested from patients with lymphoma who were candidates for high-dose therapy and autologous BMT, and showed that detection of lymphoma cells in marrow was an adverse prognostic factor, independent of other clinical features. Finally, Gorin et al. [136] examined 263 patients with standard-risk acute myelocytic leukemia in first complete remission who underwent autografting after total body irradiation, and noted a higher leukemia-free survival rate and a lower relapse rate in recipients of mafosfamide-purged marrows than in recipients of nonpurged marrows. Most importantly, Rill et al. [137] used gene marking techniques to demonstrate directly that tumor cells contaminating a bone marrow graft can contribute to disease relapse. [137] These authors used retroviral-mediated gene transfer of neomycin resistance to mark the bone marrow cells of eight patients with neuroblastoma in clinical remission. Marked marrow was reinfused at the time of autologous BMT. Three patients relapsed within 8 months of BMT. Analysis of tissue derived from these patients demonstrated that the neomycin-resistant tumor cells were present in each case. Similar results have been reported by Deisseroth et al.[138] in chronic myelogenous leukemia (CML) patients. These experiments are not able to address the issue of whether relapse is exclusively derived from contaminating cells in the marrow graft, a finding that would argue strongly for purging of autologous grafts. An alternative strategy, indirect purging by positive selection of HSCs, has found recent favor, with at least three CD34 selection systems at or near commercialization. [139] [140] [141] These systems all use the CD34 expression of hematopoietic precursor cells for positive selection, with yields and purities in the 5090% range. In this manner, a 1010,000 fold depletion of contaminating tumor cells is achieved. Numerous studies have now demonstrated that CD34-selected cells can engraft and reconstitute the hematopoietic system; however, the clinical efficacy of such treatment in reducing tumor relapse is the subject of ongoing clinical trials. CD34-selected HSCs also provide the ideal substrate for gene therapy trials and for in vitro expansion experiments.

A major component of current good manufacturing practice in both autologous and allogeneic HSC processing is quality control of the product at each step in the procedures. These assays include the viability and sterility of the product and an assessment of the number of stem cells present, using blood stem cell assays. Although there is as yet no standardized assay for the pluripotential HSC, routinely used assays include colony forming units-granulocytes/macrophages (CFU-GM) and CD34+MNC content.[142] [143] Ultimately, rapid and complete engraftment remains the true test of successful in vitro manipulation.

Autologous and allogeneic HSC products that are not infused on the same day as collection are depleted of erythrocytes, granulocytes, and plasma; frozen in 10% dimethylsulfoxide (DMSO) in a rate-controlled freezer, set to cool at a constant 1°C per minute; and then stored until the time of infusion in either liquid or vapor phase of liquid nitrogen. [144] Alternatively, recovery of CFU-GMs from unfractionated bone marrow stored in vapor phase liquid nitrogen has been reported to be higher in 5% DMSO and 6% hydroxyethyl starch than in that from marrow stored in 10% DMSO alone.[145] Moreover, marrows frozen by simple immersion in a 80°C freezer, without controlled-rate freezing, and stored at this temperature have resulted in satisfactory engraftment after autotransplantation. Quality-control measures in both cryopreservation and thawing again must ensure both sterility and viability of stem cells.

The RBCs that are separated from donated marrow can be transfused to the marrow donor, either the patient undergoing autologous BMT or the allogeneic marrow donor, after the marrow harvest.[146] [147] Homologous transfusions can thereby be avoided.

Documentation of Engraftment

Use of HSCT in the treatment of patients with hematologic malignancies is based on the assumption that the high doses of chemotherapy eradicate the malignant clone, but also result in permanent ablation of host hematopoiesis and lymphopoiesis. Ablation of the recipients marrow eliminates cells that could cause rejection of the donor bone marrow and also provides space for engraftment of donor cells. Infused HSCs, then free of competition, can replace recipient marrow and re-establish normal hematologic and immune function.

Although the transplant preparative regimens are thought to be ablative, there have been several previous reports demonstrating recovery of recipient hematopoiesis after BMT.[148] [149] These surviving recipient cells can be either normal hematopoietic host cells or tumor cells. When neoplastic cells are identified post-HSCT, they often but not invariably result in clinical relapse. [150] When these cells are normal recipient hematopoietic cells, they can either reject the donor bone marrow cells [151] or become tolerant to donor cells and contribute to the establishment of mixed hematopoietic chimerism. [152] The phenomenon of graft rejection has been studied extensively both in experimental animal models and in clinical transplants, but the phenomenon of coexisting donor and recipient cells has only recently been recognized.

Several techniques have been used to evaluate mixed chimerism after allogeneic HSCT. Cytogenetic analysis has been used frequently to differentiate between donor and recipient cells in patients with sex-mismatched donors; when donor and recipient are sex-matched, characteristic polymorphic regions or satellites can be used to distinguish the donor or recipient origin of the dividing cells. [152] [153] Donor and recipient RBCs have been distinguished by analysis of surface antigens and enzymatic content.[154] [155] This is possible only if donor and recipient differ in a given red cell antigen, and transfusion with red cells bearing this antigen is avoided. More recently, DNA analysis using Y-chromosome probes[156] or probes for highly polymorphic regions on other chromosomes have been used to evaluate

chimerism.[157] [158] These DNA restriction fragment length polymorphisms (RFLPs) are used more often because they allow distinction and quantitation of donor recipient cells in almost all BMT patients also because they can identify the origin of nondividing cells. In an analysis at our institution, mixed chimerism after transplant was found by RFLP analysis in 53% of patients, by cytogenetic analysis in 21% of patients, and by RBC phenotyping in 44% of patients. [159]

Immune-Mediated Cytopenias

Hemolysis can be avoided in the setting of ABO incompatibility between donor and recipient of allogeneic BMT as described earlier. Autoimmune hemolytic anemia has also rarely been reported after allogeneic BMT. [160] After bone marrow grafting, severe unexplained thrombocytopenia and granulocytopenia may also complicate the postgraft recovery of the patient.[161] Antibodies to platelets and granulocytes of donor origin have been demonstrated in recipients of both allogeneic and autologous bone marrow grafts. In the case of autografts, such antibodies are by definition autoantibodies, and similar antibodies after allografting may also have an autoimmune origin. It is likely that this is the result of transient immune system imbalance, common to both allo- and autografts, in the early postgraft period. The extent to which these antibodies affect the peripheral counts probably depends on the ability of the grafted marrow to compensate for the rate of antibody-mediated cell destruction. Patients have, in many cases, responded to conventional therapy including steroids, splenectomy, and intravenous immunoglobulin.

Role of Recombinant Hematopoietic Growth Factors

The hematopoietic growth factors are glycoprotein hormones that regulate the proliferation and differentiation of hematopoietic progenitor cells and function of mature blood cells. Erythropoietin (EPO), a glycoprotein produced in response to hypoxia in the kidney, induces RBC production by stimulating the mitotic activity of erythroid progenitor cellsburst-forming units-erythroid (BFU-E) and colony-forming units-erythroid (CFU-E) and early erythroid precursor cellsin the bone marrow. Recombinant human (rHu) EPO is already of proven efficacy in the treatment of the anemia of chronic renal failure [162] and anemia in patients with acquired immune deficiency syndrome treated with zidovudine.[163] It may also be useful to treat the anemia of cancer, since endogenous EPO levels may be inappropriately low. [164] [165] [166] Specifically, levels of endogenous EPO have been reported to be inappropriately low for the degree of anemia in patients after both autologous and allogeneic BMT.[166] [167] Supplemental rHu EPO may therefore also be useful to hasten RBC engraftment and to decrease RBC transfusion requirements. [166] [167] [168] In the case of pure RBC aplasia following major mismatched allogeneic HSCT, EPO has also proven efficacious in promoting red cell engraftment. [22] [23]

Infectious complications during prolonged neutropenia remain a major cause of morbidity and mortality in HSCT. The advent of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) for the reduction of the duration and depth of postchemotherapy neutropenia has led to an explosion of their use in oncology services. The clinical experience with G-CSF and GM-CSF has been extensively reviewed, and the American Society of Clinical Oncology has published formal recommendations for their indications for use. [169] [170] [171] [172] With respect to HSCT, it is clear that G-CSF and GM-CSF can successfully shorten the period of neutropenia and reduce infectious complications in patients undergoing high-dose cytotoxic chemotherapy with autologous BMT and PBSC transplantation, although recent reports have questioned the cost-effectiveness and benefit of such therapy in treating febrile neutropenia. [173] [174] G-CSF and GM-CSF are also highly effective at mobilizing CD34+ progenitor cells into the peripheral circulation. These cells may be harvested by apheresis and have been shown to be sufficient for full hematopoietic reconstitution in both the autologous and allogeneic HSCT setting. [4] [175] G-CSF and GM-CSF may also be used to treat patients with graft failure after BMT[176] and appear not to exacerbate GVHD when used early after allogeneic BMT. [177] No formal trial has compared the use of G-CSF versus GM-CSF, but a recent survey suggests that 82% of physicians prefer the use of G-CSF to GM-CSF, based on a more favorable profile of side effects. [178] With G-CSF, this is predominantly in the form of bone pain, which occurs in about 20% of patients given G-CSF after myelotoxic chemotherapy and is responsive to simple analgesics. GM-CSF has been reported to induce lethargy, myalgia, bone pain, anorexia, weight change, skin eruptions, and flushing, all of which are generally well

tolerated by patients.

Cytokines that stimulate platelet production have been a major focus of research, as thrombocytopenia remains an important dose-limiting constraint and a major expense related to chemotherapy. A number of cytokines have been shown to be involved with megakaryocyte differentiation and platelet formation. While clinical data is available on a range of potential thrombopoietic agents, such as IL-1, IL-3, stem cell factor (SCF), and IL-6, the most promising are IL-11 and thrombopoietin (TPO) and its truncated, pegylated form called megakaryocyte growth and development factor (MGDF). [179]

IL-11 has completed phase III trials as a postchemotherapy thrombopoietic drug and a small body of clinical data is available. IL-11 is a pleotropic cytokine expressed in hematopoietic tissue, as well as in brain, spinal cord neurons, gut, and testis. In hematopoietic tissue it stimulates myeloid, erythroid, and all stages of megakaryocytic progenitors, in synergy with IL-3, IL-4, IL-7, IL-12, IL-13, SCF, flt3 ligand, and GM-CSF. [179] In vivo treatment of rodents, nonhuman primates, and humans with IL-11 leads to marked stimulation of megakaryocytopoiesis. Following successful animal studies, IL-11 has been tested clinically. In phase I studies, 16 women with advanced-stage breast cancer on high-dose chemotherapy were treated with increasing doses of IL-11 (up to 100 g/kg/d) before and after four cycles of combined chemotherapy. IL-11 was associated with a dose-dependent attenuated thrombocytopenia after chemotherapy with increased bone marrow cellularity, megakaryocyte maturation, and platelet production. Side effects including a reversible anemia, probably due to fluid retention, arthralgias, myalgias, fatigue, nausea, headache, and edema. No fever was noted, but a rise in acute phase reactants, including C-reactive protein, fibrinogen, and haptoglobin, was apparent. [180]

Tepler et al.[181] extended these studies in a group of 27 cancer patients who had required platelet transfusion during a prior round of chemotherapy. They found that while placebo-treated patients invariably (26 of 27 patients) required platelet transfusions on a subsequent round of chemotherapy, 30% (8 of 27 patients)($p = 0.23$) did not require platelet transfusions when given 50 mg/kg of IL-11 daily. No difference in the number of days of hospitalization, neutropenic fever, or RBC transfusions was noted. More recently, Isaacs et al.[182] randomized 77 women with advanced breast cancer to receive either 50 g/kg/d of IL-11 or placebo for either 10 or 17 days during two cycles of dose-intensive chemotherapy. Again, the use of IL-11 significantly reduced the need for platelet transfusions. These studies suggest that IL-11 has the potential to reduce significantly the duration and extent of postchemotherapy thrombocytopenia. This may allow greater dose intensification and will reduce the costs and risks associated with platelet transfusions in these patients.

Thrombopoietin, or as it was previously known c-MPL ligand, appears to be a specific platelet-inducing cytokine that is

also showing promise in early clinical trials. TPO supports all stages of platelet production in vitro, affecting progenitor proliferation and increasing megakaryocyte number and ploidy in synergy with other cytokines.[183] Thrombocytopenic states that are associated with decreased megakaryocyte number induce high levels of plasma TPO, and preclinical studies show that TPO, and its truncated, pegylated form MGDF, are effective at inducing high platelet counts and reducing chemotherapy-induced thrombocytopenia in nonhuman primate models. Phase I trials of MGDF, or more correctly polyethylene glycol-conjugated (PEG)-rHu MGDF have been reported. Basser et al.[184] administered PEG-rHu MGDF to patients with advanced cancer in incremental doses and found a dose-dependent increase in platelets in the 13 patients receiving drug compared to the 4 patients receiving placebo. Patients receiving 0.3 or 1.0 g/kg had an increase in blood platelets of 51584%, starting on day 6 of administration and continuing after the drug was stopped. Platelet count peaked between days 12 and 18 and remained above normal for up to 21 days. These studies were extended to 41 patients with advanced cancers receiving carboplatin (600 mg/m ^{2}) and cyclophosphamide (1,200 mg/m^2) chemotherapy plus filgrastim (G-CSF) 5 g/kg.[185] PEG-rHu MGDF given for 720 days at doses of 0.035.0 g/kg/d enhanced platelet recovery in a dose-related manner when compared to placebo. The platelet nadir occurred earlier, but there was no difference in the depth of the postchemotherapy nadir. Recovery to baseline platelet counts occurred significantly earlier in patients treated with PEG-rHu MGDF (median 17 days for 0.3 or 0.5 g/kg PEG-rHu MGDF versus 22 days for placebo; $p = 0.014$). Of special interest was the finding that circulating peripheral blood progenitor cell counts were increased in patients receiving the combination of filgrastim and PEG-rHu MGDF, compared with the group receiving filgrastim alone. Further, patients who had previously received PEG-rHu MGDF as part of the phase I trial exhibited faster recovery, suggesting that pretreatment with PEG-rHu MGDF before chemotherapy may be beneficial.

Similar results have recently been reported by Fanucci et al. [186] who treated 53 stage III or IV non-small cell lung cancer patients receiving carboplatin and paclitaxel chemotherapy without other cytokine support. PEG-rHu MGDF was given for 16 days until the platelet count reached 600,000/l. All patients also received the study medication for 10 days prior to chemotherapy. These authors found that the 38 patients receiving PEG-rHu MGDF experienced a median platelet nadir of 188,000 compared to 111,000 in the placebo (12 patient) group ($p = 0.013$). Baseline platelet levels were recovered by day 14 in the treated group, compared with day 21 in the placebo group ($p < 0.001$).

PEG-rHu MGDF therapy in the above trials was not associated with fever or symptoms or signs of inflammation or activation of an acute phase response. Of note were the findings that PEG-rHu MGDF therapy sometimes resulted in thrombocytosis of >1,000,000/l and that two patients in both the Fanucci and Basser studies had thrombotic events in the treated groups, while none occurred in the placebo groups. Overall, PEG-rHu MGDF appears to be a safe drug without major systemic side effects: however, no reported study has yet evaluated the role of PEG-rHu MGDF in preventing platelet transfusions in severely thrombocytopenic patients.

Conclusion

The provision of appropriate blood component support has in the past been critical for the development of curative treatment programs, such as aggressive combination chemotherapy in childhood leukemias. The blood component laboratory will continue to play a central and broadening role in the treatment of cancer, specifically in the harvesting, processing, and transfusion of HSCs from marrow, UCB, and peripheral blood sources to restore hematologic and immune function after high-dose ablative therapies. The use of recombinant growth factors appears to facilitate the harvesting of HSCs from peripheral blood and to hasten engraftment after transplantation. Innovative treatment strategies, including intensive myeloablative therapies, may now be used for a broad spectrum of patients with currently incurable cancers. Transfusion medicine expertise will be essential to ensure that appropriate blood components are provided before and after HSCT, to collect HSCs, and to avoid immune and infectious complications in patients treated in this fashion.

SOLID ORGAN TRANSPLANTATION

Improved surgical technique and advances in prevention of allograft rejection have led to the tremendous growth in solid organ transplantation during the past decade. Readers are referred to the United Network for Organ Sharing (UNOS) web site (www.unos.org). During 1996, 20,000 solid organ transplants were performed in the United States, including >11,000 kidney, 4,000 liver, and 2,000 heart transplants. The use of cyclosporine and tacrolimus, either singly or in combination, has extended graft and patient survival.[187] These drugs are not cytotoxic agents and thus lack marrow toxicity. They block transcription of IL-2 by interfering with Ca++-activated transcription factors. Release of other T-cell cytokines, such as interferon-, is also downregulated. The overall effect is directed primarily at suppression of T-cell activation. Because corticosteroids prevent the release of IL-1 from accessory cells, the combination of cyclosporine or tacrolimus with prednisone has been highly successful. Azathioprine remains a commonly used adjunctive immunosuppressive. Newer agents such as rapamycin (sirolimus) and mycophenolate mofetil are under active investigation. [188] [189] [190] [191]

Transfusion-Transmitted CMV Infection

The implications of CMV infection are different in solid organ transplant recipients compared with BMT recipients. Following solid organ transplantation, the recipients immune system is not chimeric, and immunosuppression is less extensive than that required for allogeneic marrow transplants. As a result, solid organ recipients appear to have better immunity against infections such as CMV, which cause less postoperative morbidity. Nevertheless, for some patients CMV is an important pathogen and appears to accelerate rejection of most transplanted organs. Most serious CMV infections result from primary transmission from the donor allograft rather than from blood transfusion.[192] CMV-seronegative recipients of CMV-seropositive allografts are therefore at greatest risk. Lung transplant recipients are especially prone to morbidity and mortality related to CMV infection. [193] CMV infection occurs more often if the immunosuppressive regimen includes MoAb therapy such as OKT3. In a study of liver transplant recipients, symptomatic CMV disease, CMV hepatitis, invasive fungal disease, and death were all more likely to occur in patients who acquired CMV from the donor organ rather than from transfusion.[192] Thus, when either the donor or the recipient is CMV-positive, the use of CMV-negative blood components should be considered investigational. However, in the case of heart, lung, kidney, or pancreas transplants when both donor and recipient are CMV-negative, blood components with a reduced risk of transmitting CMV should be used. Transfusion with either CMV-seronegative blood or leukoreduced blood will effectively prevent CMV transmission by transfusion. CMV-negative or leukoreduced blood is not generally used for adult liver transplant cases because of the large number of products required. CMV infection syndromes in the postoperative period are usually adequately

treated by antiviral agents such as ganciclovir. [194] In the setting of renal transplantation, multicenter studies have suggested benefit from the use of CMV hyperimmune globulin. However, such globulin preparations are extremely expensive and are not considered to be a cost-effective therapy. Current interest has centered on the use of PCR for the early detection of CMV infection as a guide to the pre-emptive use of ganciclovir. [195] [196]

Pretransplant Blood Transfusions

Following the initial investigations by Opelz et al., [197] numerous studies documented that pretransplant blood transfusions promoted prolonged renal allograft survival. As a result, deliberate use of random donor transfusions before cadaver donor renal transplantation and donor-specific transfusions (DSTs) before living-related donor transplants became widespread. A proportion of deliberately transfused patients became HLA alloimmunized, however, and the resulting HLA incompatibilitydetected during pretransplant crossmatchingeliminated them as candidates for transplantation. The introduction of cyclosporine in the 1980s led to improved graft survival, and the benefit of pretransplant transfusions became more difficult to document. [198] As a result, most transplant centers abandoned deliberate pretransplant transfusions in favor of a strategy that avoided HLA alloimmunization through the use of erythropoietin and leukoreduced blood components. [199] [200] However, even in the cyclosporine era, some studies have shown benefit from pretransplant transfusions, [201] especially when the donor and the recipient share HLA haplotypes.[202] The beneficial effect of pretransplant blood transfusions appears to be long-lasting. [203] The exact role of pretransplant conditioning by transfusion for kidney or heart transplants[204] remains controversial.

Despite decades of investigation, the mechanism(s) responsible for the immunomodulatory effect of pretransplant transfusions remains uncertain. [205] Three basic mechanisms have been proposed: (1) pretransplant transfusions may select for patients who are immunologic nonresponders because responders to DSTs would make HLA antibodies directed against the donor and thus be eliminated from transplant due to an incompatible crossmatch. (2) Transfusions may exert an immunosuppressive effect if donor cells or HLA peptides locate to the recipient thymus where responding clones are deleted (so-called central tolerance). [206] (3) Transfusions may exert an immunosuppressive effect by altering T-cell reactivity outside the thymus (peripheral tolerance). Peripheral tolerance may result from the production of anti-idiotypes,[207] [208] from the development of suppressor T cells, [188] from the persistence of donor veto cells,[209] from Fas-mediated or other cell-mediated signals to apoptosis or anergy, [210] [211] from downregulation of natural killer cell function, [212] or from an alteration in recipient immunity that favors a shift from Th1-type cells to Th2-type cells.[213]

Renal Transplantation

ABO Compatibility

ABO compatibility between donor antigens and recipient antibodies is critical for successful renal transplantation. ABH antigens are richly expressed on vascular endothelial cells[214] and renal cells[215] and are excreted in the urine.[216] As a result, ABO-incompatible grafts are at high risk for rejection, and transplantation against ABO barriers is generally contraindicated. [217] [218] Because group O recipients are restricted to group O donors, several experimental protocols have investigated the use of group A_2 donors (who express group A antigens less strongly than group A_1 individuals) for group O recipients. [219] [220] Group O recipients of A_2 kidneys require greater degrees of immunosuppression, and graft survival is inferior to that obtained with group O donors. Transplantation of nonmatched but compatible grafts (e.g., group B donor into AB recipient) does not result in accelerated graft rejection. However, passenger lymphocytes that accompany the graft may continue to secrete ABO antibodies during the early postoperative period. Therefore, recipients of ABO-compatible but unmatched allografts may experience hemolysis secondary to ABO alloantibodies of graft lymphocyte origin. (See the next section on Orthotopic Liver Transplantation.)

HLA Compatibility

The importance of serologic HLA compatibility between donor antigens and recipient antibodies is well established for renal transplantation. Recipients who express warm-reactive antibodies to HLA class I antigens of the donor are at risk for hyperacute rejection characterized by complement activation, intravascular coagulation in the graft, organ ischemia, and necrosis that may occur within minutes of establishing blood flow to the graft. [188] [221] A variety of techniques are used for HLA crossmatching, and there is controversy regarding which method has the highest predictive value. Standards of the American Society for Histocompatibility and

Immunogenetics (www.swmed.edu/homepages/ASHI) require that the final crossmatch employ a technique with greater sensitivity than the basic microlymphocytotoxicity test. Such techniques may use longer incubation times, wash steps, an antiglobulin reagent, B-cell targets, dithiothreitol, or flow cytometry. [222]

Recognition of the importance of HLA-serologic compatibility led to the practice of monthly HLA antibody screening of serum from HLA-sensitized patients awaiting kidney transplants. Antibody specificities that are identified are recorded, and the corresponding antigens are avoided when allocating suitable kidney allografts. Some programs also consider compatibility results using archived serums when allocating allografts to recipients who are known to be HLA-sensitized. Analysis of recipient HLA specificities has revealed that identification of antibodies directed against common public antigens may be more clinically meaningful than antibodies to private HLA antigens. [223] [224] [225]

HLA Matching

Routine practice does not require HLA matching of donor and recipient when allocating cadaver kidneys. However, retrospective studies of graft survival have suggested that certain HLA mismatches are more likely to result in graft rejection than others, [226] and large retrospective analyses have provided evidence that greater degrees of HLA matching between the donor and recipient result in longer graft survival. [227] [228] While not all have agreed with these findings, [229] the potential benefits have prompted some organ banks to allocate cadaver organs based on the degree of HLA match rather than simply on the results of HLA compatibility testing. [230] [231] A review of >23,000 renal transplants reported to the United Network for Organ Sharing registry showed that the half-life for a subset of matched allografts was 17.3 years, in contrast to a half-life for unmatched allografts of only 7.8 years. [232] Nevertheless, matched cadaver transplants do not survive as well as matched living-related transplants. The difference may reflect not only injury to the graft during preservation but also the influence of histocompatibility mismatches not recognized by existing HLA typing techniques.

DNA-based typing methods are being used to make HLA antigen assignments to donors and recipients. HLA DR and DQ typing by DNA-based methods has become routine, and molecular typing for HLA A, B, and C antigens is being widely introduced. Molecular typing methods have revealed that the HLA region is extraordinarily complex, with far more alleles than had been recognized by serologic methods. Because as many as 15% of samples may be incorrectly typed by serologic

methods, [230] prior data on the benefit of HLA matching may have been clouded by admixture of unmatched grafts that were thought to have been matched. Reanalysis based on improved molecular typing and elimination of mismatches has revealed a beneficial effect on graft survival for HLA DR-matched kidney transplants. [233] It has also been suggested that the degree of molecular matching may indicate which patients can be treated with reduced amounts of postoperative immunosuppressives.

Orthotopic Liver Transplantation

Orthotopic liver transplantation (OLT) has become the treatment of choice for life-threatening end-stage hepatic failure. [234] Successful OLT requires a close working relationship among the surgical team, anesthesia services, and blood services because the operation sometimes requires spectacular quantities of blood support. Improved surgical technique, use of venovenous bypass for those cases in which the vena cava is interrupted, argon laser-directed electrocoagulation, and better preservative solutions for storing the donor liver ex vivo have contributed to decreased transfusion requirements during surgery. [235] [236] Nevertheless, considerable variation exists among blood use in different programs.

Causes of Extreme Bleeding

Intraoperative transfusion requirements for OLT cannot be predicted on the basis of preoperative coagulation screening. [237] Rather, severe portal hypertension, previous right upper quadrant surgery, vascular abnormalities of the portal vein, poor left ventricular function, pulmonary hypertension, poor nutritional state, and comorbid diseases are the most important predictors of massive transfusion and decreased survival. Prior transjugular intrahepatic portosystemic stent shunt does not appear to worsen surgical outcomes during OLT. [238] [239] [240]

OLT requires a difficult right upper quadrant dissection of the recipient hepatic bed that can be complicated by severe portal hypertension, friable collateral vessels, adhesions from prior procedures, or inflammation from the patients underlying disease. Removal of the liver requires isolating the blood supply of the organ and clamping and cutting the portal vein, hepatic artery, common bile duct, and either the hepatic vein or the inferior vena cava above and below the liver. The period after the recipient hepatectomy and before re-establishing blood flow to the new graft is referred to as the anhepatic phase of surgery. During this phase, venous blood draining the bowel and lower extremities may need to be diverted through an extracorporeal circuit if a portion of recipient vena cava was removed during the hepatectomy. A more recent surgical technique preserves the vena cava and results in less bleeding.

Patients who require OLT usually have multiple hemostatic abnormalities associated with acute or chronic liver failure. Decreased coagulation factors, splenomegaly with thrombocytopenia, dysfibrinogenemia, and chronic fibrinolysis with elevated fibrin split products may all be present in varying combinations. In addition, some patients develop a profound intraoperative fibrinolysis. [241] [242] Tissue plasminogen activator (tPA), presumably released from recipient blood vessels or from the vessels of the graft in response to shock, acidosis, pharmacologic pressors, ischemia, or preservation injury, circulates in high concentration. Normally cleared by the liver, tPA released during and immediately after the anhepatic phase of surgery is not cleared from the bloodstream. As a result, tPA activity can reach 10100 times normal levels, and a pathologic systemic lytic state ensues. A sudden decrease in all coagulation factors occurs, with particularly marked declines in fibrinogen and factor VIII. [243] Proteolysis of von Willebrand factor may also occur. [244] Less severe cases may not demonstrate systemic lysis but may lyse clot at sites of previous hemostasis. As the liver allograft begins to function, tPA is rapidly cleared and fibrinolysis decreases. The administration of antifibrinolytic agents such as epsilon-aminocaproic acid, [245] tranexamic acid, [246] or aprotinin [247] [248] can significantly improve hemostasis and may prevent exsanguination in selected patients.

A properly functioning graft is essential to the success of OLT. Grafts damaged during the demise of the donor, during harvesting or ex vivo preservation, or during transplantation are associated with both severe hypotension and coagulopathy. Hypotension results from a pronounced decline in total systemic vascular resistance and is often refractory to aggressive pharmacologic pressor support. The cause of the vascular collapse is not known. The ensuing shock exacerbates the derangement in hemostasis. With the introduction of better graft-preserving solutions, the incidence of severe primary graft nonfunction has decreased. [249]

Transfusion Support

A transfusion device designed to deliver large volumes of blood components in a rapid fashion is essential for OLT. These devices consist of a sterile holding reservoir, high-capacity blood filter, roller pump, in-line blood warmer, and air detection device. Blood is pumped through large-bore catheters placed in the antecubital or central veins. Intraoperative blood-recovery devices are a useful adjunct to blood support during OLT, particularly in cases requiring massive transfusion. [250] [251] Blood suctioned from the operative field is anticoagulated with citrate and collected in a sterile holding reservoir. The shed blood is then centrifuged, the supernatant is discarded, and the residual packed red cells are washed with saline. The saline-suspended packed red cells may then be pumped to the rapid transfusion device or transferred to a plastic blood-collection bag for later reinfusion.

OLT demands careful but aggressive component therapy guided by the clinical course and the results of intraoperative coagulation monitoring. [236] [252] Serial intraoperative hematocrit and coagulation monitoring using a limited number of tests with rapid turnaround time provides valuable information for rational blood component management. Some OLT centers monitor coagulation using the thromboelastogram, a device that measures whole blood coagulation by impedance to an oscillating cylinder. [253] [254] Other programs use traditional measurements such as the prothrombin time, fibrinogen, and platelet count. Either method of monitoring is valuable provided that testing is done serially, that results are reported rapidly, that changes are correlated in the operating room with the clinical picture, and that abnormalities are interpreted by someone with experience in the coagulopathy of OLT.

Red cell support for patients with multiple red cell alloantibodies can present a special challenge to blood services supporting OLT programs. [235] [255] For difficult patients with clinically significant, low-titer, high-frequency alloantibodies, preoperative plasmapheresis can be used to remove antibody. Patients with medium-titer clinically significant alloantibodies can sometimes be managed initially with antigen-negative cells and then switched to antigen-untyped cells should massive blood support be required. Antigen-negative units are then reinstituted at the end of surgery to prevent postoperative hemolysis. Patients with high-titer alloantibodies may require special planning and cooperation among blood suppliers to provide a sufficient quantity of antigen-negative blood. Patients with primary biliary cirrhosis or other causes of end-stage liver failure who also have IgA deficiency may have anti-IgA antibodies and require special preparation for transplant surgery. [256] Probably as a consequence of postoperative immunosuppression, Rh-negative individuals transfused with Rh-positive blood at the time of transplant are not likely to make

anti-D.[256] Nevertheless, Rh-negative women of childbearing age without anti-D are initially supported

in many programs with a reasonable number of D-negative units and then switched to D-positive cells should more blood be needed. In our program, Rh-negative males and females who are not of childbearing potential are treated from the outset with Rh-positive blood. Because many OLT patients are massively transfused, delayed hemolytic transfusion reactions in the postoperative period, if directed against high-frequency antigens, can result in dramatic hemolysis.

The use of fresh-frozen plasma (FFP), platelet concentrates, and cryoprecipitate is guided by the clinical course and by the results of intraoperative monitoring. [236] Although care must be given to prevent dilutional coagulopathy, it is not necessary to mix equal ratios of red cells and FFP or platelet concentrates. Reasonable goals of component therapy in the absence of fibrinolysis or other complications include an INR <2 or <2.5, a platelet count >50,000100,000/l, and a fibrinogen >100 mg/dl. Antifibrinolytic agents are indicated during or shortly after the anhepatic phase of surgery in patients who demonstrate a systemic lytic state. [257] A loading dose and continuous infusion of epsilon-aminocaproic acid, tranexamic acid, or aprotinin has been used with success. Hourly bolus doses have also been used. Tranexamic acid reduced operative blood loss during OLT when studied in a randomized, prospective, placebo-controlled trial. [246] However, in a separate randomized, placebo-controlled trial of 80 patients, the routine use of aprotinin was not shown to reduce overall transfusion requirements. [258] Antifibrinolytics should probably be applied to selected patients who show evidence of fibrinolysis. For all patients, local hemostasis provided by meticulous and advanced surgical skill remains critically important.

Complications of Massive Transfusion During OLT

Patients undergoing massive transfusion during OLT are susceptible to all the major complications of massive transfusion, including hypothermia, dilutional coagulopathy, electrolyte imbalance, pulmonary dysfunction, and transfusion-transmitted infections. Despite massive transfusion and the immunosuppression of the recipient, TA-GVHD is a rare complication in the setting of solid organ transplantation. [235] [255]

OLT patients are uniquely at risk for life-threatening hypocalcemia as a result of citrate toxicity. [260] Magnesium is also chelated by citrate, and low magnesium concentrations may accompany massive transfusion during OLT surgery. [261] Since the liver is the main organ for citrate metabolism, and since OLT patients can receive very rapid infusions of large volumes of FFP that is rich in Na_3-citrate, the quantity of citrate infused per kilogram body weight per minute can quickly exceed the rate of citrate removal.[262] Citrate toxicity is more pronounced if concomitant renal failure is present because the kidney is the major site of citrate excretion. The principal effects of citrate toxicity are cardiovascular. An initial blunted response of cardiac output to left ventricular volume loading is followed by hypotension resulting from poor cardiac output and decreased systemic vascular resistance. If misinterpreted as hypotension due to hypovolemia, a more rapid transfusion of citrate-rich blood components will worsen cardiac output. Citrate toxicity is aggravated by hypothermia and hyperkalemia. Because a widened Q-Tc interval on the electrocardiogram has low specificity and poor predictive value, intraoperative monitoring of the ionized calcium level is very important during OLT. With severe depression of the ionized calcium or magnesium, bizarre electrocardiographic disturbances and fatal arrhythmias can develop.

ABO Compatibility

Under normal circumstances, the donor liver must be ABO-compatible with the recipient. Transplantation of ABO-incompatible livers has occurred by error or under urgent circumstances and has had limited success. [263] [264] [265] ABO-incompatible liver transplants may occur more frequently in pediatric cases when a compatible donor organ is not available and recipient blood group alloantibodies are poorly developed. Data from the UNOS scientific registry found that ABO mismatch was among the strongest independent predictors of adverse outcome after emergency liver transplant. [266] In another series, survival of emergency ABO-incompatible grafts was 30% compared with 76% for emergency ABO-compatible grafts.[267] The immune response to ABO-incompatible grafts is consistent with a pattern of hyperacute rejection.[267] [268] Transfusion support for ABO-incompatible grafts is not standardized, but the use of RBCs and FFP compatible with both donor and recipient would seem desirable. ABO-nonmatched but compatible donors (e.g., group O donor for group A_1 recipient) occasionally occurs in OLT, but nonmatched compatible grafts may have decreased survival rates compared with matched grafts. Approximately 30% of patients transplanted with compatible but nonmatched livers suffer postoperative hemolysis of recipient red cells mediated by ABO antibodies produced by passenger lymphocytes of donor origin. [269] This complication has been reported after all major solid organ transplants, including liver, [269] kidney,[270] heartlung,[271] spleen,[272] and pancreas.[273] It is most common after liver transplantation, probably by virtue of the greater number of passenger lymphocytes that accompany this large organ. Hemolysis develops approximately 1 week after surgery and is generally detected by the development of a positive direct antiglobulin test (DAT) with ABO alloantibodies recovered in the eluate. Although the DAT may be only weakly reactive, rather brisk hemolysis typical of complement-fixing ABO antibodies can occur with a rapid fall in hematocrit and a dramatic rise in bilirubin. Acute renal failure from intravascular hemolysis is rare but has been reported. [274] Treatment is based on transfusion of red cells compatible with antibodies produced by both the recipient and the graft. Red cell exchange is usually not required. Care must be taken in routine postoperative compatibility testing for patients who receive unmatched transplants. A group A_2 recipient whose group O hepatic graft is producing warm-reactive IgG anti-A_1 can have an acute hemolytic transfusion reaction to a group A_1 donor unit transfused postoperatively despite a negative antibody screen, negative DAT, and a compatible immediate-spin pretransfusion crossmatch.

HLA Testing for OLT

HLA testing for OLT has not reached the level of clinical importance found in renal transplantation. Donor livers are not allocated on the basis of the degree of donor/recipient HLA matching, and an HLA-incompatible pretransplant crossmatch does not preclude the use of the graft. Nevertheless, there are reports suggesting that recipient HLA antibody directed against donor antigens may contribute to graft rejection under some circumstances. [275] [276] [277] In addition, highly sensitized recipients who are refractory to routine platelet transfusions are difficult to support during massive blood loss at the time of surgery. [259] An unexpected finding was that recipients with demonstrable HLA antibodies in a pretransplant serum sample often no longer react with donor-type antigens after the transplant, suggesting that HLA antibodies are adsorbed in vivo from the recipients plasma by the incompatible graft. [278] As a result, patients have had successful combined kidneyliver transplants using a donor kidney that was originally HLA-incompatible but became compatible hours after liver transplantation from the same donor.

Cardiac Transplantation

Cardiac transplantation has become an established therapy for life-threatening cardiac dysfunction. One-year graft survival

rates of approximately 80% have been achieved through the use of effective immunosuppressive regimens, improved recipient selection criteria, the use of heart assist devices to bridge the waiting time between diagnosis and transplant, the development of percutaneous endomyocardial biopsy for improved detection of early rejection episodes, and more effective management of postoperative infectious complications. As a result of these improvements, research has shifted from short-term problems such as acute rejection to factors influencing long-term morbidity-free survival. Factors that most influence allograft survival after heart transplantation include ABO compatibility, HLA matching, HLA compatibility, upregulation of adhesion molecules on vascular endothelium, duration of cold ischemia, and infection with CMV.

ABO and HLA Testing

Because ABO antigens are present on cardiac endothelial tissue, ABO compatibility of donor and recipient is a prerequisite for heart transplantation. As with other solid organ transplants, ABO-compatible but unmatched allografts are used. However, ABO-identical transplants may have a better overall survival than ABO-compatible but unmatched grafts.

The contribution of HLA matching to improved graft survival is difficult to assess. Because of the short allocation time, HLA typing of the donor organ is mostly retrospective. Numerous reports, however, suggest that HLA DR matching may improve graft survival. [279] [280] Opelz and Wujciak[281] found no further decline in graft survival rate as the number of HLA mismatches increased beyond three. They speculated that the higher doses of immunosuppressive drugs administered to heart transplant recipients compared with kidney transplant recipients might have accounted for their findings. With the advent of rapid HLA typing by PCR using

allele-specific primers, allocation of hearts based on HLA matching may become more feasible and widespread.

The clinical significance of HLA antibody testing in cardiac transplantation remains controversial. Some groups have found significant differences between long-term survival of patients with a panel reactive antibody level of <10% compared with >10%. [282] [283] Other groups have reported that the presence of specific antidonor HLA antibodies rather than the level of panel reactive antibody was a better predictor of rejection. [284] [285] HLA antibodies induced by pregnancy may represent a different risk factor from those induced by prior transfusion or transplantation. [286] Pregnancy-related HLA antibodies are generally monospecific to paternal antigens and tend to become nondetectable either because the antigenic stimulus is gone or because of the development of anti-idiotypes.

Other Risk Factors for Cardiac Rejection

During the last decade it has become clear that allograft rejection is associated with expression of cell adhesion molecules (CAMs). [287] Specific CAMs including ICAM-1, ICAM-2, and LFA-3 are found to be upregulated on vascular endothelial cells of rejecting heart transplants. [288] By promoting leukocyte adhesion to the endothelium, CAMs appear to participate in the development of cardiac allograft vasculopathy. [289] Expression of VCAM-1 and E-selectin may result from CMV infection. CMV infection appears to correlate with shortened allograft survival, a higher frequency of repeat-rejection episodes, [290] and the development of accelerated coronary atherosclerosis. [291] [292] As with other solid organ transplants, most serious CMV syndromes originate with infection from the allograft. Nevertheless, CMV-seronegative recipients of CMV-seronegative cardiac allografts should be transfused with either CMV-seronegative or leukoreduced blood components. Prolonging the duration of cold ischemia has a significant negative effect on the survival of heart transplants. In addition, postoperative ischemia appears to play an important role in myocardial injury and rejection. [287] Differentiation of ischemia from acute rejection is important for management of immunosuppression in the early post-transplant period. [293]

Other Solid Organ Transplants

Single lung, pancreas, small bowel, combined organ, and multivisceral transplants have each been successfully performed in patients with a variety of end-stage organ failure syndromes. Cadaver lung transplants and living-related partial lung transplants have been used in the treatment of end-stage pulmonary disease, including cystic fibrosis. A variety of techniques have been developed to prevent rejection of the bronchial anastomosis between donor and recipient. Two-year survival rates of 6080% have been reported. [294] Good success has been achieved with pancreas or combined kidneypancreas transplants for diabetes, particularly if transplantation is used before the onset of retinopathy. [295] The pancreatic graft is placed in the pelvic bed with the pancreatic duct draining into the urinary bladder. Small bowel and multivisceral transplants have been successfully performed in a limited number of individuals, but recipient and graft survival has been limited by problems of rejection, infection, and postoperative lymphoproliferative disorders. Chapter 146 - Red Cell Substitutes

Robert M. Winslow

INTRODUCTION

Red cell substitutes are designed to replace red blood cells for transfusion. Solutions such as saline, Ringers lactate, albumin, dextran, and the starches are widely used to replace lost blood volume in surgery and trauma, but the term blood substitutes is usually used in reference to oxygen-carrying solutions such as those based on some form of hemoglobin or perfluorocarbon emulsions. These substitutes would carry out the primary function of red cells: transport of oxygen to tissues. The goal of developing a red cell substitute has been elusive: for centuries, an alternative to allogeneic blood for transfusion has been sought by scientists, the military, and industry. Early attempts included the use of milk, wine, gum, and red cell hemolysates. [1] In the modern era (since about 1965), three general types of products have been under development: modified hemoglobin solutions, perfluorocarbon emulsions, and lipid vesicle-encapsulated hemoglobin. None is yet approved for clinical use.

The current driving force for the development of red cell substitutes is the perceived danger of transfusion of allogeneic blood (Table 146-1). In fact, blood is safer now than it ever has been. However, the aggregate risks listed in this table are frightening to many patients, their families, and their doctors as well, and the demand for a safe and efficacious alternative is increasing. Beyond the risks listed, in regions of the world where the

TABLE 146-1 -- Risks of Transfusion of Allogeneic Blood in the United States

Event	Risk
HIV 1÷2	1÷676,000
HTLV I÷II	1÷641,000
Hepatitis B	1÷66,000
Hepatitis C	1÷125,000
Fever, chills	1÷100
Hemolytic transfusion reaction	1÷6,000
Fatal hemolytic transfusion reaction	1÷100,000

Data from Klein[2] and Schreiber.[3]

frequency of human immunodeficiency virus infection is high, development of these solutions would be particularly important.

Because of the risks of allogeneic blood transfusion, and because of the large markets that could be generated for red cell substitutes, considerable efforts are now being expended by industry to develop safe products. It is likely that red cell substitutes will find their way into clinical practice within the next decade.

PRINCIPLES

Several major issues must be addressed to develop a successful red cell substitute.

1. *Oxygen transport:* Must a red cell substitute transport oxygen in the same way as red cells do? Oxygen affinity of cell-free or encapsulated hemoglobin may be very different from that of red cells. Perfluorocarbons carry oxygen physically dissolved rather than chemically bound, and therefore the dissociation curve is linear. Whether these factors are important, physiologically or clinically, is still not known.
2. *Plasma retention:* The normal red cell life span is about 120 days. However, the plasma half-life of cell-free hemoglobin may be only 12 hours and that of encapsulated or surface-modified hemoglobin and perfluorocarbon emulsions 2448 hours. Are these times clinically useful? If the effect of a red cell substitute is so short that a transfusion with allogeneic blood is only delayed, not eliminated, then the usefulness of the product becomes questionable.
3. *Efficacy:* It will be necessary to demonstrate efficacy for any red cell substitute to be used clinically. At present, it is taken as a matter of faith that a solution carrying oxygen will be more useful than one with no oxygen carrier, if it is without side effects. However, conclusive demonstrations will be necessary because no red cell substitute currently being developed is without side effects. For example, if a particular substitute increases systemic pressure and vascular resistance (as many hemoglobin-based solutions do), this property could counteract any increase in oxygen transported.
4. *Toxicity:* No candidate product developed to date is without toxicity. Cell-free hemoglobin has vasoconstrictor properties that could limit its use in shock and trauma. Lipid vesicles and perfluorocarbon emulsions stimulate macrophages to elaborate cytokines that can produce diverse effects, including fever and flulike symptoms.
5. *Commercial viability:* To be successful, a red cell substitute must be competitive with allogeneic red blood cells in effect, toxicity, and cost. The cost of providing human red cells for transfusion is now very low.[2] The technology required for the production of red cell substitutes is complex and likely to be expensive.

CLINICAL APPLICATIONS

Products

Hemoglobin-based Products

The red cell substitute products that have gained the most attention are based on hemoglobin, an extraordinarily complex molecule consisting of four polypeptide chains, each made up of about 140 amino acids. Normally packaged in the red cell, free in solution it is fragile: it tends to oxidize, is unstable and toxic, and is excreted by the kidneys as the subunits fall apart. Over the years, the strategy for making a hemoglobin-based red cell substitute has been based on cross-linking hemoglobin to correct these problems.[1]

Hemoglobin has the desirable properties of a high capacity to bind oxygen and to release it cooperatively; this makes it attractive for use as a red cell substitute. However, hemoglobin, free in solution, has several unique properties. Its oxygen affinity is high because outside the red cell the allosteric effectors (2,3-diphosphoglycerate [2,3-DPG] and ATP, for example) are not present. Its effectiveness as an oxygen carrier is limited because it dissociates into half-molecules (dimers) (haptoglobin is rapidly saturated, and excess dimers are quickly removed from the circulation by the kidney after filtration in the glomerulus). Once filtered, a high concentration of protein in the renal tubules can cause tubular obstruction and consequent renal failure. Cell-free hemoglobin binds nitric oxide, an endothelium-derived relaxing factor that may contribute to vasoconstriction. Outside the red cell, hemoglobin exerts an oncotic pressure similar to that of albumin; thus, if large amounts are to be administered to a patient, shifts of fluid between the interstitial and intravascular spaces would be expected. Finally, iron, when released from hemoglobin, can promote the formation of toxic oxygen radicals.

Thus, to be an effective oxygen carrier in the cell-free state, hemoglobin must be chemically modified to avoid these problems. Whether all these must be solved completely for a product to be useful is a matter of intense debate. All the reactions currently considered useful in the production of hemoglobin-based red cell substitutes use chemical modification at one or more sites on the surface of the protein (Table 146-2). Differences in the reactions are determined by the dimensions and reactivity of the cross-linking reagents. Since the function of hemoglobin in binding and releasing oxygen is intricately connected to the transition between T and R conformation (see Chap. 22), it is not surprising that the P_{50} and yield are highly variable. Even small differences among structures of the reagents can yield products with quite different properties. In addition, the conditions of the reaction are very important, not only in regard to the state of ligation (i.e., oxygen saturation), but also to the presence of agents or molecules that lack or compete for certain reactive sites.

A further complication of these reactions is that many nonhemoglobin proteins, copurified with hemoglobin, contain reactive groups and may also be modified to produce new,

TABLE 146-2 -- Classes of Hemoglobin Modifications

Molecular Size	Modification	Examples
Monomers	Amino-terminal modification	Carbamylation Carboxymethylation Pyridoxylation Acetaldehyde dialpha (genetic)
	Lysine EF6(82) modification	Mono-(3,5-dibromosalicyl) fumarate
	Valine NA1(1)-lysine EF6(82) cross-link	2-Nor-2-formylpyridoxal 5-phosphate (NFPLP) $(Bis\text{-}PL)P_4$
	Lysine $G6(99)_1$ -lysine $G6(99)_2$ cross-link	Bis-(3,5-dibromosalicyl) fumarate (DBBF)
	Three-point	Trimesoyl tris(methyl phosphate)
	2,3-DPG analog	Pyridoxal 5-phosphate Bezafibrate, clofibrate
Multimers	Surface, multisite	Glutaraldehyde Polyaldehydes Ring-opened dials Diimidate esters
Conjugates	Surface, multisite	Dextran-aldehyde Polyethylene glycol Polyoxyethylene

potentially toxic contaminants. It has been difficult to produce a pure modified hemoglobin for toxicity studies when most processes start with relatively crude "stroma-free" hemoglobin.[4]

An example of a cross-linked hemoglobin currently being commercialized is a product studied intensively by the U.S. Army and a number of academic laboratories. Cross-linking of hemoglobin isolated from outdated human blood is carried out with bis-(3,5-dibromosalicyl)fumarate (DBBF) [5] (Table 146-2). The reaction results in

a four-carbon covalent link between adjacent chains at position 99 (Lys $_1$ 99-Lys$_2$ 99) (Fig. 146-1). This covalently cross-linked hemoglobin cannot break down into subunits in the circulation and therefore cannot be excreted as filtered globin chains.

The production process is complex.[6] Stroma-free hemoglobin is separated from red cell membranes and deoxygenated to achieve the proper molecular conformation for cross-linking, and the 2,3-DPG pocket is blocked reversibly with an allosteric effector. It is then cross-linked, heated to pasteurize it and also to remove unreacted hemoglobin, and passed through a series of cross-flow filters. It is finally sterilized by filtration through a 0.2-m filter.

The product has many favorable properties (Table 146-3). Oxygen dissociation curves show a P_{50} under physiologic conditions of 28 mmHg. The degree of cooperativity (the slope of the

dissociation curve) is quite similar to that of blood (Hill coefficient 2.62 for blood, 2.31 for cross-linked hemoglobin), and the Bohr [8] and carbon dioxide[9] effects are nearly intact.

Theoretically, this product should have in vivo oxygen transport properties quite similar to those of whole blood. The intravascular persistence is markedly extended in the rat: uncross-linked hemoglobin has a half-life of about 1.2 hours and cross-linked hemoglobin one of 4.3 hours. In the rabbit, the persistence is longer, about 16 hours for cross-linked hemoglobin, for monkey about 14 hours, and for pig about 7 hours. [10] There is no doubt that cell-free hemoglobin transports oxygen: many studies in the literature have demonstrated the ability of hemoglobin solutions to resuscitate animals in lethal hemorrhagic shock. [1]

Other hemoglobin-based products are also being developed. For example, a product very similar to the cross-linked hemoglobin described above has been produced as a recombinant protein in *Escherichia coli*. [11] Starting material for hemoglobin modification can also be produced in transgenic animals. [12] Hemoglobin also can be polymerized using a number of polyfunctional reagents (Table 146-2) to yield molecules with markedly increased molecular weights. One example is human hemoglobin reacted first with pyridoxal-5 phosphate and then polymerized with glutaraldehyde. [13] This product has a reduced colloidal osmotic (oncotic) pressure and longer intravascular persistence compared to smaller molecules, but the polymerization reaction is notoriously difficult to control. [14] [15]

Another promising approach is to couple hemoglobin to polyethylene glycol (PEG) [16] or a similar molecule, such as polyoxylethylene[17] or dextran.[18] These conjugated hemoglobins may also have prolonged plasma retention times and might have reduced interactions with the reticuloendothelial system.

Liposome-Encapsulated Hemoglobin

Since hemoglobin is normally packaged inside a membrane, it seems intuitively correct that encapsulated hemoglobin would be the ultimate solution to the red cell substitute problem. In 1957, Thomas Chang reported the use of microencapsulated hemoglobin as artificial red blood cells. [19] Since that time, dramatic results have been reported in the complete exchange transfusion of laboratory animals, [20] [21] but progress toward development of an artificial red cell for human use has been slow because of problems of reticuloendothelial and other macrophage stimulation. [22] Other problems include maintaining sterility and large-scale production.

In the 40 years that have followed Changs initial descriptions of encapsulated hemoglobin, much work with lipid vesicles (liposomes) has been carried out. Liposomes have served as models for understanding natural cell membranes. They also have been used investigationally as vehicles for gene transfer, as targeted carriers, for pharmacologic agents, and even as lubricants for degenerated joint surfaces. The most extensively studied liposomes used to encapsulate hemoglobin are composed of phospholipid in combination with cholesterol and other lipids that confer flexibility and stability, such as ganglioside GM $_1$ or cholesterol. [23] When injected into animals, such liposomes are rapidly coated with IgG, albumin, and other opsonins. [24] Newer formulations include the use of surface components such as PEG or dextran, which can stabilize the liposomes in the circulation. [25]

The limitations to the development of liposome-encapsulated hemoglobin as a red cell substitute are difficulties in stabilizing the final product and the massive scale-up that would be required to produce a commercial product. The size of most liposome particles is approximately 0.21.0 m, too large to be filter-sterilized. Also, neither the liposome nor its hemoglobin contents can withstand pasteurization temperature. Other potential approaches to the solution of these problems involve

nonphospholipid liposomes[26] and those made from polymerizable phospholipids[27] and other polymers.[28]

Perfluorocarbon-based Products

A recent resurgence has occurred in the development of perfluorocarbons for two reasons. First, Fluosol-DA 20% (Fluosol, Green Cross Corporation, Osaka, Japan) was approved for marketing by the FDA for use in coronary angioplasty in 1990. Second, new perfluorocarbon emulsions now being developed by industry carry much more oxygen than previous products.[29] Still, there is a fundamental difference between perfluorocarbon- and hemoglobin-based red cell substitutes: oxygen is transported by perfluorocarbons as dissolved gas, whereas hemoglobin carries oxygen chemically bound to the protein itself (Fig. 146-2). The oxygen dissociation curve for hemoglobin is sigmoid, while oxygen dissociation from perfluorocarbons is linear. The lower curve in Figure 146-2 is for Fluosol, the upper one for an emulsion of Perflubron and egg-yolk phospholipid (Oxygent, Alliance Pharmaceutical Corporation, San Diego, CA), which contains about five times more fluorocarbon and therefore five times more dissolved oxygen.[30]

Initially, it would appear that it is better to have a sigmoid oxygen dissociation curve because (1) it is natural and (2) maximal oxygen carriage in blood is achieved at an alveolar P_{O_2} of about 100 mmHg, whereas only about 20% of the perfluorocarbon carries oxygen at the same P_{O_2} . To carry as much oxygen in this fluorocarbon as 7 g/dl hemoglobin, an arterial P_{O_2} of about 450 mmHg is needed. Therefore, it seems that the utility of fluorocarbon red cell substitutes will depend on a high inspired P_{O_2} . However, in many elective surgical procedures, arterial P_{O_2} well above 300 mmHg can be achieved.

In practice, a margin of safety could be achieved with relatively low doses of perfluorocarbon emulsions, which could have a significant impact; increased tolerance to a reduced hematocrit would further reduce the transfusion trigger. In a theoretical analysis of transfusion, mixed venous P_{O_2} is nearly constant from a hematocrit of 2545% because as oxygen is added in the form of transfused red cells, cardiac output decreases. [31] If the hematocrit is kept low but oxygen is added in the form of perfluorocarbon, a significant increase in mixed venous P_{O_2} occurs because the cardiac output remains high. Cell-free hemoglobin solutions would not offer this

advantage if their use does not result in increased cardiac output.

Figure 146-2 Oxygen capacity of Oxygent compared to blood. The Oxygent is a 60% (w/v) emulsion described by Flaim, [30] and the blood contains 15 g/dl hemoglobin.

Safety

Demonstration of the safety of red cell substitutes is a critical issue, because the risks of transfusion of allogeneic blood are well known. A substitute should be at least as safe as red cells unless a decisive therapeutic advantage can be demonstrated.

In a review of almost a century of clinical trials with red cell substitutes, reported side effects involved renal dysfunction, systemic symptoms (fever, chills, nausea, headache, flushing, vomiting, allergic reactions, tachycardia, bradycardia, hypertension, rigors, low back pain, chest pain, abdominal pain, decreased platelets, and increased partial thromboplastin time.[1] Many of these effects could be explained by the depletion of nitric oxide, in the case of hemoglobin-based products, or by stimulation of macrophages, in the case of liposomes or perfluorocarbon emulsions. Many are smooth muscle effects, and some involve macrophages and platelets. Recent clinical trials with hemoglobin-based products have not been extensively reported in the literature. However, it is clear that preclinical animal studies have not been completely successful in predicting human reactions to the products. [32]

Cell-free hemoglobin is widely distributed in the tissues after administration. Studies of the distribution of cross-linked hemoglobin in the intact animal show that significant amounts of hemoglobin are retained in the kidney, spleen, liver, adrenal gland, lung, heart, brain, and muscle well after any hemoglobin is detected in the plasma.[33] [34] [35] Thus, cell-free hemoglobin is distributed in almost every tissue of the body, and therefore we might expect toxic effects that could be quite unpredictable or unknown. Extensive histologic studies have been carried out in animals after exchange transfusion and have been summarized. [1]

Perhaps the effect of cell-free hemoglobin of most concern is its known ability to cause vasoconstriction and hypertension. This vasoconstriction can be mediated in part by the reaction of hemoglobin with nitric oxide, an endothelium-derived relaxing factor. [36] Nitric oxide is synthesized from arginine in endothelial cells (as well as in other cells) by an enzyme, nitric oxide synthase, that produces nitric oxide and citrulline. It binds to a heme group in guanylate cyclase that activates cGMP. Nitric oxide diffuses extremely rapidly out of endothelial cells into the interstitium and into smooth muscle cells, where it binds to a heme group in guanylate cyclase, activating cGMP and moving calcium from the unbound to bound state. The result is smooth muscle relaxation.

Nitric oxide diffuses into the lumen of the vessel, where it stimulates platelets and polymorphonuclear leukocytes, and into tissue, where it can stimulate macrophages. Hemoglobin binds nitric oxide very tightly, more tightly, in fact, than it binds oxygen, whether hemoglobin is in the red cell or free in solution. [37] The reaction is virtually irreversible. After synthesis of nitric oxide in endothelial cells, it diffuses into the smooth muscle cells, causing relaxation. Whether this interaction of hemoglobin with nitric oxide will limit clinical usefulness of hemoglobin-based red cell substitutes remains to be determined.

In addition to its effect as a scavenger of nitric oxide, cell-free hemoglobin may also induce vasoconstriction by disrupting normal autoregulation of vascular tonethat is, it may make oxygen so readily available to regulatory arterioles that reflexive vasoconstriction might occur, which paradoxically limits blood flow. [38] [39] This concept is suggested by the direct observation in the microcirculation [40] and might lead to new design strategies for cell-free blood substitutes.

Perfluorocarbon emulsions have the most extensive history of use in humans. Fluosol was approved by the FDA for use in coronary angioplasty and therefore has been given to many humans. In addition, similar formulations have been used on the battlefield in China and Afghanistan, although data are generally

not available. Perfluorocarbon emulsions have also been tested in humans as imaging agents.

The principal toxicity of perfluorocarbon emulsions appears to be their stimulation of macrophages. [41] [42] This can result in pulmonary hypertension and elaboration of thromboxane in swine and could lead to nonspecific symptoms such as fever, chills, and flulike symptoms in humans. [43]

Biocompatibility studies with liposome-encapsulated hemoglobin have been generally favorable, [21] but such products tend to be removed from the circulation by the phagocytic cells in the reticuloendothelial system. [44] This leads to significant enlargement of the liver and spleen. The direction of current research is to attempt to prolong the intravascular persistence to minimize this problem.

Efficacy

It seems intuitively obvious that a plasma expander that carries oxygen would be superior to one that does not, and that experimental proof of this concept would be relatively straightforward. However, the problem of efficacy can be appreciated by considering the difficulties in showing efficacy for red cell transfusion. The problem is a lack of clear end points: no single measure of oxygen transport is accurate and easily obtainable. It might be possible to show improved clinical outcome after transfusion of red cells to patients with extremely low hematocrits, but the bulk of allogeneic blood is given intraoperatively in response to blood loss, not severe anemia.

Most demonstrations of efficacy have been either by exchange transfusions with test material, or resuscitation from shock. [24] However, shock resuscitation is exceedingly complex: the most urgent requirement is for volume replacement. Clinical trials involving trauma patients are particularly difficult to design because of the problems of controls and informed consent. Future clinical trials will most likely be aimed at, for example, reduced use of allogeneic blood rather than at specific oxygen transport parameters, which may be controversial at best. For example, one trial with Fluosol during surgery showed that its use did not reduce the need for allogeneic blood transfusions in the postoperative period. [45]

Clinical Trials

Early trials with various cell-free hemoglobin solutions were reviewed and showed an array of side effects that affect every organ of the body. [1] However, most of these are mild or reversible, and only 1 death in >211 patients was reported in the early literature; this patient was terminally ill and would likely have died even without administration of hemoglobin.[46]

Several blood substitute products are in various stages of advanced clinical trials (Table 146-4). The greatest concern for hemoglobin-based products is that the known vasoactivity of the solutions could lead to hypertension or underperfusion of ischemic tissue. Perfluorocarbon emulsions are also being tested in humans, and a major concern appears to be thrombocytopenia.[47] No liposome-based product has yet been approved for use in human trials.

IMPLICATIONS/FUTURE APPLICATIONS

Potential Clinical Applications

Replacing all use of allogeneic blood with red cell substitutes is both unnecessary and naive. The red cell substitute candidates now being developed will probably be used initially in surgical hemodilution to provide a margin of safety and perhaps to reduce the need for the two or three units of blood used in most surgeries.

Many clinical applications in addition to hemodilution for the products now being developed will be targeted by industry (Table 146-5).[48] Applications for perfluorocarbon emulsions other than as red cell substitutes could be even more important than the use in trauma, surgery, and shock. For example, emulsions have been shown to increase the radiosensitivity of solid tumors, [49] to be excellent nuclear magnetic resonance and ultrasound imaging agents, [50] to be capable of removing gaseous microemboli during cardiopulmonary bypass, [51] and to measure tissue P_{O_2} .[52]

Availability in the Future

It seems unlikely that a cell-free hemoglobin as a red cell substitute with vasoactive effects will be accepted broadly by cliniciansindeed, vasoconstriction is a hallmark of the shock state. Perfluorocarbon emulsions may very well be the first red cell substitutes to reach the clinic. However, it is unlikely they will find wide application as such. More likely, they will find use as imaging agents, liquid-breathing agents, or adjuncts to radiotherapy of solid tumors. In addition, the low cost and simplicity of production of perfluorocarbon emulsions are favorable qualities for commercialization.

Liposome-encapsulated hemoglobin may very well be the ultimate solution to the red cell substitute problem. However, to be successful, an inexpensive and simple process will need to be developed, and any problems of reticuloendothelial blockade and engorgement of organs such as the liver and spleen will have to be thoroughly studied and understood.

The present commercial climate is such that few if any of these products will be used in scientific studies that can be reviewed in the peer-reviewed literature until they are approved for use by the FDA. This unfortunate situation has retarded development in the past and is likely to do so in the future. [32]

TABLE 146-4 -- Commercial Blood Substitute Products

Product (Manufacturer)	Composition	Indications
PHP (Apex Bioscience)	Pyridoxylated human hemoglobin conjugated to polyoxyethyene	Septic shock
HemAssist (Baxter Healthcare)	Human hemoglobin internally cross-linked with bis(3,5-dibromosalicyl) fumarate (DBBF)	Trauma Hemodilution
Hemopure (Biopure Corp.)	Glutaraldehyde-polymerized bovine hemoglobin	Hemodilution Sickle cell disease
PEG-Hemoglobin (Enzon)	Bovine hemoglobin conjugated topolyethylene glycol	Radiosensitization of solid tumors
PolyHeme (Northfield Laboratories)	Glutaraldehyde-polymerized human hemoglobin	Trauma Surgery
Optro (Somatogen)	Recombinant di-alpha human hemoglobin	Hemodilution Erythropoiesis
Oxygent (Alliance Pharmaceutical)	Emulsified Perflubron	Hemodilution Cardiopulmonary bypass
Oxyfluor (HemaGen/PFC)	Emulsified perfluorodichlorooctane	Cardiopulmonary bypass

Chapter 147 - Hematologic Complications of Liver Disease and Alcoholism

Ralph Zalusky
Bruce Furie

INTRODUCTION

Liver disease and its major handmaiden, alcohol abuse, have profound effects on hemostasis and hematopoiesis. Liver disease, regardless of etiology, can be associated with abnormal bleeding due to anatomic derangements and impairment of hepatic synthetic and clearance functions. Abnormal lipid metabolism may cause red blood cell (RBC) structural defects. Alcohol and its metabolites have direct effects on hematopoiesis, behaving as a toxin and impairing nutritional physiology. Although a few well-described hematologic syndromes have been described, in most instances multiple and complex derangements are present simultaneously in the same patient, challenging the diagnostic and therapeutic skills of the hematologist.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

EFFECTS OF LIVER DISEASE ON HEMOSTASIS

Abnormal hemostasis is a common complication of liver disease, and determination of its underlying pathogenesis is essential for rational management. Mechanisms resulting in these defects include

1. Diminished hepatic synthesis of coagulation factors V, VII, IX, X, and XI, prothrombin, and fibrinogen (reflected in prolongation of the prothrombin time [PT] and partial thromboplastin time [PTT])
2. Dietary vitamin K deficiency due to inadequate intake or malabsorption (based on intrahepatic or extrahepatic cholestasis or intestinal malabsorption)
3. Dysfibrinogenemia
4. Enhanced fibrinolysis, due to decreased synthesis of $_2$ -plasmin inhibitor
5. Disseminated intravascular coagulation (DIC)
6. Thrombocytopenia due to hypersplenism

Abnormalities of Protein Synthesis

With the exception of factor VIII, [1] the liver is the major site of synthesis of the blood coagulation proteins and related regulatory proteins. [2] [3] [4] Parenchymal diseases of the liver, including cirrhosis, hepatitis, and infiltrative disorders, can impair synthesis leading to a deficiency of plasma proteins involved in hemostasis. [5] [6] [7] [8] Often, these abnormalities may be subclinical. Measurement of specific coagulation factors may be reduced but not attended by clinical bleeding or prolongation of the PT or PTT. In inflammatory liver disorders, the plasma levels of some coagulation proteins, such as factor VIII and fibrinogen, may increase as an acute phase reaction.[6] [9] [10] When the PT and PTT are prolonged, however, more extensive hepatic dysfunction is present and is associated with a poor prognosis. Hypofibrinogenemia, with plasma fibrinogen levels <100 mg/dl, is an especially grave sign. [11]

Acquired Defects of Vitamin K-Dependent Carboxylation

The vitamin K-dependent blood coagulation proteins, including prothrombin and factors VII, IX, and X, are synthesized in the liver. These proteins undergo a unique post-translational processing step where glutamic acid residues in the N-terminal region of these proteins are converted to -carboxyglutamic acid residues by a vitamin K-dependent carboxylase.[12] [13] [14] [15] [16] In some liver disorders, such as cirrhosis and hepatitis, an acquired deficiency of this carboxylation step may occur. Although generally mild, it may lead to the circulation of des--carboxylated proteins in the blood (Fig. 147-1).[17] Although biologically inactive and synthesized at the expense of biologically active forms, their levels are sufficiently low that they do not contribute significantly, if at all, to coagulation abnormalities associated with liver disease. They can, however, serve as useful markers of this acquired vitamin K-dependent carboxylation defect. Des--carboxy (abnormal) prothrombin, normally absent from plasma, circulates at detectable levels in >90% of patients with hepatoma (Fig. 147-2).[18] [19] [20] The tumor itself is responsible for the production of this protein because surgical removal or reduction in tumor mass with chemotherapy is associated with reduction or elimination of the abnormal prothrombin. Unlike the situation in vitamin K deficiency, levels of both the abnormal and normal prothrombin may be high simultaneously in patients with hepatoma. Therefore, this defect is not associated pathophysiologically with bleeding that may complicate management in primary hepatocellular carcinoma. Together with

Figure 147-1 Plasma levels of abnormal (des--carboxy) prothrombin in liver disease. The abnormal prothrombin level (g/ml) is displayed on the y axis on a logarithmic scale. The fully carboxylated native prothrombin is shown on a linear scale on the x axis. Severe vitamin K deficiency, pink triangle; warfarin therapy, white square; acute hepatitis, gray circle; cirrhosis, red square; normal, black circle. *(From Blanchard et al., [17] with permission.)*

Figure 147-2 Plasma levels of abnormal (des--carboxy) prothrombin in primary hepatocellular carcinoma. Comparison in patients with primary hepatocellular carcinoma, chronic active hepatitis, and metastatic carcinoma. The abnormal prothrombin level (ng/ml) is displayed on the y axis on a logarithmic scale. *(From Liebman et al., [18] with permission.)*

measurement of serum levels of -fetoprotein, serologic measurement of abnormal prothrombin allows identification of >84% of patients with hepatomas.

Vitamin K Deficiency

Nutritional deficiencies are common in alcoholism and alcoholic liver disease. However, with a daily minimal requirement of 100200 g, [21] inadequate intake does not lead to clinically significant vitamin K deficiency even with substandard diets. Because vitamin K is a fat-soluble vitamin, defects related to absorption can occur. This is especially so when impairment of bile acid metabolism occurs in primary biliary cirrhosis, [22] intrahepatic or extrahepatic cholestasis, [23] and during therapy with bile acid binders (e.g., cholestyramine).[24] In addition, because vitamin K is synthesized by intestinal bacteria, the use of oral antibiotics may result in frank deficiency. [25]

Dysfibrinogenemias

A defective functional form of fibrinogen has been described in some patients with liver disease, including cirrhosis and hepatocellular carcinoma. [26] [27] The defect in the molecule appears to be a post-translational event resulting in excess sialic acid residues following glycosylation in the hepatocyte. [26] [28] The action of thrombin on this abnormal fibrinogen appears to result in the formation of defective fibrin monomers with impaired ability to polymerize. [29] [30] Both the thrombin time (TT) and the reptilase time are usually prolonged, whereas the fibrinogen level measured immunochemically remains normal.

Increased Fibrinolysis, Fibrinogenolysis

Several types of pathophysiologic derangements can lead to factor deficiencies through increased factor consumption. Depressed synthesis of the major plasma inhibitor of plasmin, $_2$ -plasmin inhibitor, which is produced by the liver, results in enhanced fibrinolytic activity of the blood. [31] [32] This plasma protease inhibitor forms a complex with and inactivates plasmin.[33] Impaired synthesis correlates with the severity of the liver disease and pathologic fibrinolysis is manifested by decreased fibrinogen levels, increased fibrin degradation products (FDP), and accelerated euglobulin lysis. [34] [35]

Tissue-type plasminogen activator (t-PA) levels and its plasma inhibitors have been studied in patients with liver cirrhosis. Abnormal fibrinolysis, as measured by the dilute whole blood clot lysis time, correlated with a disproportionate reduction in the t-PA-inhibitor activity, even when t-PA and its inhibitor were increased. [36] Attempts to inhibit fibrinolysis through the use of antifibrinolytic agents have not been uniformly successful [37] and in the presence of possible DIC are contraindicated. [5]

DIC

A clear role for DIC in the pathogenesis of bleeding in liver disease is complicated by other causes of factor and platelet depletion, the cardinal signs of this disorder. Thus, decreased titers of clotting proteins and thrombocytopenia secondary to hypersplenism make it difficult to assess the contribution of DIC in an individual patient.[38] In some patients with cirrhosis, accelerated catabolism of fibrinogen, prothrombin, and plasminogen is improved by administration of heparin. [37] [38] [39] [40] Accelerated catabolism of fibrinogen occurs in acute liver necrosis, biliary tract obstruction, cholangitis, and liver contusion. [41] [42] [43] Entry of endotoxin into the circulation from the gastrointestinal tract in patients with portal hypertension has been suggested as another mechanism inducing DIC, as has impaired reticuloendothelial function, especially in alcohol-induced liver disease. [44]

Although the pathogenesis of DIC in cirrhosis is often puzzling, DIC is frequent in patients who have had surgical peritoneovenous shunts (LeVeen and Denver shunts) placed between ascitic fluid and the venous circulation. [45] [46] [47] [48] The cells suspended in ascitic fluid may induce coagulation. [48] [49] Collagen-like protein may induce platelet aggregation [50] or activate factor XII.[5] A concomitant drop in fibrinogen level and platelet count occurs, and occasionally, a disproportionate fall in the former has suggested a primary role for activation of fibrinolysis. [51] Clinically significant bleeding requires interruption of the shunt. Therapy with heparin has not been helpful. Although a role for antiplatelet agents, aspirin and dipyridamole, has been suggested, [50] they may add to the bleeding tendency in these patients.

Reduced levels of antithrombin III in chronic liver disease may contribute to the development of DIC [52] and reflect impaired hepatic synthesis. Correction of the antithrombin III deficiency by transfusion increases the survival of fibrinogen. [52] Low levels of heparin cofactor II have been reported in a few patients who may have undergone DIC.[53]

Platelets

Thrombocytopenia is commonly observed in patients with chronic liver disease and is ascribed to portal hypertension with its accompanying congestive splenomegaly.[54] This results in a shift in the platelets from the circulation to the enlarged spleen and may not affect platelet survival. [55] The reduction in the effective circulation is seldom in itself sufficient to induce a bleeding disorder but may contribute by additive effects to the other coagulation disturbances.

MANAGEMENT OF THE HEMOSTATIC DEFECTS IN PATIENTS WITH LIVER DISEASE

Evaluation and management of defective hemostasis in patients with liver disease should include a careful history and physical examination, appropriate laboratory testing to establish etiology, and institution of corrective therapy when required. Laboratory abnormalities in the absence of clinically significant bleeding may require only careful monitoring, whereas overt bleeding or preparation for invasive or surgical procedures requires replacement therapy.

Prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT) usually indicates plasma clotting factor deficiency either as a result of impaired hepatic synthesis or secondary to vitamin K deficiency. When combined with diminished levels of factor V, factor XI, or fibrinogen, which are not vitamin K dependent, then liver dysfunction is apparent. Some of these abnormalities may be complicated by the presence of inhibitory activity in the plasma such as fibrin degradation products (FDP). In addition, a low fibrinogen level can result from increased fibrinolysis/ fibrinogenolysis, disseminated intravascular coagulation (DIC), or structurally abnormal fibrinogen. Measurement of the thrombin time (TT) shows a prolongation under all these conditions. Evidence for increased fibrinolytic activity is obtained by finding elevated FDP or the D-dimer. Distinction between plasma clotting factor deficiency and plasma inhibitory activity is obtained by determining whether the PT and PTT can be corrected in a 1:1 mix of normal plasma and patient plasma. Reduction of the platelet count commonly accompanies the coagulation factor disturbances and is attributable to hypersplenism, recent alcohol abuse, and if especially severe, to DIC.

If the PT is >3 seconds prolonged, and if the patient is not actively bleeding, a trial of vitamin K can be given when the laboratory findings are consistent with plasma clotting factor deficiency. A dose of 10 mg daily subcutaneously for 3 successive days is sufficient to correct the abnormality in those few patients in whom malabsorption of the vitamin is present.

More characteristically, hepatic dysfunction is the underlying mechanism and replacement therapy is warranted in patients actively bleeding or who are to undergo invasive diagnostic or therapeutic procedures. Fresh frozen plasma (FFP) remains the mainstay of replacement therapy. Its major drawback is the large volume that may be required in patients with unstable cardiovascular conditions. Although small volume replacement factor IX concentrates, which are rich in vitamin K-dependent factors, have occasionally been used, their administration has been associated with thromboembolic problems or DIC. The amount of FFP infused will vary with the clinical status of the patient and the frequency of administration dictated by the plasma half-life of the clotting factors. The desired initial infusion is 2530% of the plasma volume (12001500 ml in a 70-kg adult) to achieve at least partial correction of the hemostatic defect. With continued active bleeding, half the initial dose may be required as often as every 6 hours, considering that the half-life of several clotting factors varies from 5 to 8 hours. In the presence of ascites, in which the volume of distribution is increased, or in the presence of fibrinolysis or DIC, an increased dose of FFP will be required as determined by serial measurement of the PT and PTT. Red blood cell transfusions will also be required in the actively bleeding patient to maintain adequate hemoglobin levels and a normotensive state. In very advanced liver disease, hypofibrinogenemia may be severe (i.e., <100 mg/dl); cryoprecipitate can be transfused at the rate of 1 U/3 kg body weight. Each bag contains about 300 mg fibrinogen and, because one-half the transfused fibrinogen is metabolized within 3 or 4 days, a daily transfusion of 1 U/15 kg of body weight can maintain the fibrinogen concentration at adequate levels. Many of these patients may have some degree of thrombocytopenia, but when the platelet count is <20,000/mm^3 and bleeding is active, platelet transfusions should be considered. Determining the platelet count 1 hour after transfusion provides a useful guide to the adequacy of retention. In the presence of splenomegaly, this may be minimal due to platelet pooling in the spleen. In instances where a qualitative platelet dysfunction is suspected, desmopressin may be tried at a dose of 0.3 g/kg intravenously.

Establishing a diagnosis of DIC in bleeding patients with liver disease is especially challenging. Prolongation of the PT, PTT, TT, low fibrinogen levels, elevated FDP, and thrombocytopenia may have multiple pathophysiologic mechanisms. Because factor VIII coagulant activity is often elevated in liver disease and reduced in DIC, its measurement helps to distinguish these disorders. A diagnosis of DIC is more likely to be associated with precipitating factors such as sepsis, shock, or peritoneovenous shunts. The use of heparin in these situations has always been controversial, especially in the presence of active bleeding, so that reliance must be placed on replacement therapy with FFP, cryoprecipitate, and platelets. In the setting of liver diseases and DIC, a role for antithrombin III concentrates or antifibrinolytic agents has not been established.

Orthotopic Liver Transplantation

Hemostatic alterations in orthotopic liver transplantation can be divided into preoperative, anhepatic, reperfusion, and convalescent phases. [56] Superimposed on the preoperative hemostatic defects, hepatic clearance is absent during the anhepatic phase so that levels of t-PA increase while the plasminogen activator inhibitor-1 disappears, and fibrin(ogen)-related antigens increase. [57] [58] During reperfusion, there is further increase in excessive fibrinolysis, perhaps as a result of the release of tissue plasminogen activators from the vessels of the transplanted liver. [57] [59] Some evidence suggests that the administration of aprotinin throughout the operation may decrease hemorrhagic blood loss.[60] However, the role for this agent or purified human antithrombin III remains to be determined. [61] [62] [63] Within a few days of the convalescent phase, the coagulation factor levels return to normal, and the inhibitors of coagulation (antithrombin III, plasminogen, protein C, and protein S) normalize over 12 weeks.[56]

EFFECTS OF LIVER DISEASE ON HEMATOPOIESIS

Chronic liver disease causing cirrhosis leads to portal hypertension and congestive splenomegaly. Portal hypertension can then lead to excessive blood loss from variceal and other types of upper gastrointestinal bleeding, whereas congestive splenomegaly represents a major cause of hypersplenism. When blood loss continues on a chronic basis, iron deficiency can supervene. Thrombocytopenia, leukopenia and anemia, or any combination thereof, may result from excessive trapping by the enlarged, congested spleen. In addition, the anemia of chronic disease, as seen in other disorders of inflammation, infection, or

malignancy, further complicates the hematologic presentation in these patients. Altered lipid metabolism may lead to structural changes in the RBC membrane, occasionally causing unusual hemolytic syndromes.

Hypersplenism

Splenomegaly is a common finding in patients with chronic liver disease and portal hypertension. The degree of reduction in the blood counts is a reflection of both splenic size and the capacity of the bone marrow to compensate for this reduction. Anemia results from RBC pooling in the enlarged spleen, decreased RBC survival, and increased plasma volume.[64] [65] [66] Neutropenia has been attributed both to increased pooling and decreased survival. [64] [67] Thrombocytopenia is primarily the result of increased platelet pooling. [54] Because of the moderate degree of these cytopenias and the operative risks in these patients, splenectomy is rarely indicated. Shunting procedures, both splenorenal and portocaval, have variable results on the hematologic manifestations. [68] [69] [70]

Effects of Liver Disease on Erythrocyte Membranes

Structural abnormalities causing RBC shape changes are common in liver disease. Target cells are frequently seen in the peripheral blood smear and result from increased surface area due to excess membrane cholesterol and phospholipid transferred from lipoproteins in the plasma. [71] These cells have a normal survival and resist osmotic lysis.[71]

Spur cells are a grave finding in some patients with advanced liver disease. This shape transformation can occur in normal RBCs incubated with plasma from affected patients.[72] Although membrane cholesterol is increased, total phospholipids are normal, and the cells show decreased resistance to osmotic lysis. [73] Splenic modeling of these cells contributes to their reduced survival, and hemolysis is usually moderate to severe. [74] Although splenectomy may improve the anemia, patients with this acquired disorder are rarely surgical candidates.

A unique feature of patients with chronic liver disease is the presence of thin macrocytes in the peripheral smear, unrelated to vitamin B_{12} or folic acid deficiency.[75] RBC diameter is increased, but the mean corpuscular volume (MCV) remains normal. Unlike target cells and spur cells, thin macrocytes do not become normal when transfused into normal subjects, nor are normal cells transformed into thin macrocytes when transfused into patients with liver disease. [75] [76] RBC survival does not appear to be affected.

Anemia Associated with Viral Hepatitis

Viral hepatitis may be associated with a mild anemia secondary to bone marrow suppression and shortened RBC survival. [77] [78] Because hepatic clearance of oxidizing metabolites may be impaired in patients with viral hepatitis, depression of reduced glutathione occurs. [79] This can be especially problematic for patients with glucose-6-phosphate dehydrogenase deficiency. [80] [81]

Aplastic anemia (Chap. 19) is a potential consequence of viral hepatitis; one study has estimated an incidence of 0.10.2%. [82] The average age is 18 years, with a male preponderance.[83] Hepatitis C is a more common cause of hepatitis-associated aplastic anemia. [84] Aplasia usually develops within 2 months of the hepatitis, and without bone marrow transplantation, has a high mortality rate. In a large interinstitutional study, 9 of 32 patients undergoing orthotopic liver transplantation for acute non-A, non-B hepatitis, developed aplastic anemia 17 weeks after transplant. No evidence for aplasia was found prior to transplant. No other cases of aplastic anemia were identified among 1,463 patients undergoing transplantation for all other indications, confirming the high risk for development of aplastic anemia in patients with acute non-A, non-B hepatitis after this procedure. [85]

HEMATOLOGIC EFFECTS OF ALCOHOL ABUSE

Metabolism of Ethanol

Hepatocyte cytosol contains alcohol dehydrogenase, which constitutes the major pathway for the catalytic conversion of ethanol to acetaldehyde. [86] In this reaction, hydrogen is transferred from the substrate to the cofactor, nicotinamide adenine dinucleotide (NAD), and then to its reduced form, NADH, producing acetaldehyde. This oxidation step results in an excess of reducing capacity of the cell, and the shift in redox potential alters the lactate pyruvate ratio. [87] [88] The acetaldehyde produced is then converted in the mitochondria to acetate, which is catalyzed by acetaldehyde dehydrogenase, generating further NADH, a major factor in the toxicity of ethanol.[86] Increased lactic acid contributes to acidosis, and decreased uric acid excretion by the kidney leads to hyperuricemia. Gluconeogenesis is impaired and triglyceride accumulation favored. Impaired oxidation of fatty acids, resulting from reduced availability of NAD in the citric acid cycle, leads to the accumulation of esterified fatty acids. Further deposition of triglyceride and phospholipids occurs as a result of activation of the second pathway for ethanol metabolism, the cytochrome P-450-dependent microsomal ethanol-oxidizing system located in the endoplasmic reticulum. In the presence of oxygen and NAD phosphate as cofactor, acetaldehyde accumulates. With heavy ethanol intake, <20% of the substrate is metabolized through this pathway. [86] [89] The lipid accumulation in the hepatocyte is further enhanced by the direct toxic effect of acetaldehyde. Mitochondrial function is altered, as is the impairment of microtubule formation. This effect of acetaldehyde on protein synthesis interferes with the transport of lipoprotein from the liver, this defect may be the pathobiologic basis for the formation of the fatty liver. Engorgement of the hepatocyte by an increased protein load when accompanied by necrosis and polymorphonuclear inflammation characterizes alcoholic hepatitis. Although this manifestation is not necessarily a precursor to the development of cirrhosis, it is frequently a prelude. [86]

The hematologic sequelae of alcoholism are the consequences of those alterations secondary to portal hypertension and hypersplenism, lipid abnormalities reflected in membrane structural defects, disturbed synthesis of the coagulation proteins, and the direct toxic effects of alcohol and acetaldehyde.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DIRECT EFFECTS OF ETHANOL ON HEMATOPOIESIS

Bone Marrow

Excessive alcohol consumption affects the bone marrow in several ways. These include vacuolization of hematopoietic precursors, megaloblastic changes in the absence of folate deficiency, sideroblastic changes, hypocellularity, and increased numbers of plasma cells. [90] [91] [92] [93] [94] [95] [96] Because a characteristic pattern of bone marrow injury is not diagnostic of alcoholism, some or all of these features may not necessarily coexist. Because the progeny of bone marrow precursors may lack certain synthetic capacities, it is likely that some of the described abnormalities of the peripheral blood cells may have been inflicted in the bone marrow. [97]

Vacuolization of proerythroblasts occurs with high frequency in heavy imbibers (12 pints of 80-proof whiskey daily). Vacuoles can be seen within 1 week of such intake and quickly disappear within a few days of abstinence. [91] They appear to result from surface invagination of the cell membrane, leading to endocytosis and subsequent vacuole formation. [98] Cytoplasmic localization in the proerythroblast is characteristic although occasional nuclear vacuoles can be seen. Promyelocytes share the injury to a lesser extent, as do other precursor cells. In vitro studies with normal bone marrow incubated in the presence of alcohol reproduce these findings. [98] Chemical identification of

---

the inclusions has not been achieved. Similar morphologic changes had been described in association with chloramphenicol use and in other clinical disorders. [99]

Marrow hypocellularity has been observed in occasional patients with excessive alcohol intake and was attributed to the toxic effect of ethanol or its metabolites because of the absence of other factors. [94] [100] Further evidence of a toxic effect of alcohol on the bone marrow has come from in vitro studies of this agent on in vitro colony formation. [101] [102] [103] Depressed burst-forming unit erythroid and colony-forming unit (CFU) erythroid have been observed, [101] whereas higher ethanol concentrations impair CFU-granulocyte/macrophage and CFU-macrophage. [102] [103] The pluripotential stem cell escapes this injury, thus accounting for the common in vivo observation that these toxic effects are reversible on cessation of alcohol abuse. [101] [104]

Sideroblastic changes are commonly present in erythroid precursors of alcoholic patients. [105] [106] [107] Structural studies show accumulation of siderotic granules in the mitochondria surrounding the nucleus and give the characteristic ringed appearance on Prussian blue stains of the marrow. Generally, these morphologic findings are more readily appreciated in the more mature erythroid cells. Defective iron utilization for hemoglobin synthesis underlies this process, producing a dimorphic anemia that generally reverses within days to 2 weeks of alcohol withdrawal. [108] In most instances, this is not the sole cause of the anemia but may occur in up to one-third of alcoholic patients, usually in association with folate deficiency and acute blood loss. [105] [107] Earlier studies suggested that the defect resulted from ethanol impairment of the conversion of pyridoxine to pyridoxal phosphate, which is catalyzed by pyridoxine kinase. [108] Pyridoxal phosphate, the cofactor for aminolevulinic acid synthase, although measurably low in the serum of chronic alcoholics, does not necessarily correlate with the finding of ringed sideroblasts. [106] [109] [110] In addition, decreased kinase activity has not clearly been demonstrated to account for low pyridoxal phosphate levels, although the latter has been shown to undergo enhanced degradation in the presence of acetaldehyde. [110] [111] [112] Because a direct role for vitamin B_6 deficiency has not been clearly shown in these alcoholic patients, an inhibitory role of ethanol on heme biosynthetic pathways (Chap. 27) may be more likely. Overall heme production is reduced in the presence of ethanol, as is globin synthesis. [113] [114]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MACROCYTOSIS

Macrocytic RBCs are a common finding in alcoholism.[115] When present in the absence of folate deficiency or reticulocytosis, a diagnosis of alcohol abuse can be considered.[116] [117] The MCV is generally in the 100110 fl range, the cells are round and not ovalocytic, and, together with the finding of an elevated, -glutamyl transpeptidase in the serum, can be of diagnostic import. In a significant number of heavy drinkers, an increased value for RBC distribution width obtained from automated cell counters has also been described,[118] but others have not substantiated the value of this determination.[116] Unlike the readily reversible cell injury described for alcohol-mediated toxicity, this form of RBC change remains for 24 months of abstinence.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

FOLATE AND B_{12} METABOLISM

When megaloblastic anemia (Chap. 28) is found in the alcoholic patient, it is almost always secondary to folate deficiency; the hematologic manifestations of macrovalocytosis, hypersegmentation of polymorphonuclear leucocytes, leukopenia, and thrombocytopenia are indistinguishable from other causes of folate deficiency. Although liver disease is common in this group of patients, the vitamin deficiency primarily arises as a result of poor dietary intake and the effect of ethanol on folate metabolism.[96] [119] [120] Other causes of nonalcoholic cirrhosis are uncommonly associated with folate deficiency, nor is it seen in well-nourished drinkers. Secondary effects on folate homeostasis may occur as a result of poor retention by the cirrhotic liver and increased urinary loss. [121] [122]

Evidence for a direct effect of ethanol on folate metabolism has come from several studies, both human and animal, in which alcohol and dietary intake were carefully controlled. In folate-deficient humans, megaloblastic changes can be seen within a few days when ethanol is added, but such changes take longer to develop when it is not.[96] Furthermore, folate supplements prevent these morphologic changes. Hematosuppression, including white blood cell and platelet counts, reverts to normal within 12 weeks of a hospital diet.[107] The explanation for these observations has not been fully clarified. Among the suggested mechanisms have been impairment of jejunal absorption,[123] block in the delivery of *N*-5-methylfolate from the liver to the circulation,[119] interruption of a putative enterohepatic circulation, [120] [124] and increased urinary excretion of folate.[121] [122] In animal models, conflicting data have emerged on the effect of ethanol on hepatic polyglutamate folate synthesis and retention. Both increased synthesis and decreased formation have been described. [119] [125] Furthermore, the clearance of methyltetrahydrofolic acid is normal in alcoholic patients, and its uptake is stimulated by ethanol in hepatocytes in vitro. [126] [127] Extraneous factors such as gastrointestinal blood loss, hypersplenism, hemolysis, and infection further confound the interpretation of folate balance in these patients.

Clinically significant vitamin B_{12} deficiency rarely occurs in the alcoholic patient. This is rather surprising because impairment of absorption could occur secondarily to the frequently seen gastritis (parietal cell injury), pancreatitis (interference with pancreatic enzyme release of B_{12} from R-binders), or ileal malabsorption (vitamin B_{12} uptake) in these patients.[128] [129] Whether as a result of liver injury or abnormal transcobalamin binding, serum levels of the vitamin are frequently elevated. Even when low serum levels have been observed, concomitant folate deficiency may have been causal because serum vitamin B_{12} levels reverted to normal within a few days of adequate folate intake.[130]

Iron Metabolism

Iron deficiency is commonly seen in alcoholic patients, usually as a result of gastrointestinal bleeding. However, because of the frequent association with folic acid deficiency, the usual laboratory parameters (MCV, serum iron, and transferrin saturation) may be normal or even increased. [91] [96] Serum ferritin levels may be unreliable because of coexisting liver disease or complicating inflammatory disorders. [131] Simple chronic anemia, with low serum iron and low serum iron-binding capacity, will be found in patients with infection or malignancy. Bone marrow iron stores are probably the most reliable means of ruling out iron deficiency in this complicated setting when folate deficiency has been ruled out.

Alcohol abuse may increase the body iron burden. This can result from excessive ingestion of iron-containing spirits (e.g., red wine) or increased iron absorption. [132] [133] There has been some confusion between idiopathic hemochromatosis and alcoholic cirrhosis with increased stainable iron in the liver. Patients with alcoholic cirrhosis can be divided into two groups: (1) patients who have mild-to-moderate increase in stainable iron, but relatively normal body iron stores, and (2) patients with gross iron deposition and increased total body iron stores of the magnitude seen in idiopathic hemochromatosis (1550 g iron stores). Based on studies of human leukocyte antigens, the first group shows no evidence of the genetic disease and the liver iron concentration is usually less than twice the upper limits of normal. [134] The second group appears to have idiopathic hemochromatosis in addition to alcoholism. [135] Additionally, in alcoholic patients the synthesis of desialated transferrin may lead to preferential hepatic uptake of iron. [136] [137] Recently, a candidate

hemochromatosis gene, HFE, has been identified.[138] Located on chromosome 6, a G A transition results in a missense mutation that changes cysteine 282 with a tyrosine. Approximately 83% of the hemochromatosis patients studied were homozygous for this mutation. Although other mutations likely occur, determination of these defects by currently available methods should aid in differentiating acquired from inherited disorders of iron overload. [139]

RBC Survival

A direct effect of alcohol on RBC survival once cells leave the bone marrow has not been demonstrated. [71] However, alcohol is the most common etiologic factor in acute and chronic liver disease that may be associated with hemolysis. A mild hemolytic state is common in cirrhosis, reducing RBC survival to 50% of normal. [140] In the Zieve syndrome, alcohol-induced fatty liver is associated with hypertrigylceridemia, hemolysis, and jaundice. [141] Hemolysis is usually transient, and its pathophysiology appears to be unrelated to the hypertriglyceridemia. [71] A similar transient hemolytic state showing RBC stomatocytosis has been described. [142] Rarer still has been the hemolytic anemia associated with severe hypophosphatemia. [143] In many of these alcoholic patients, additional features such as bleeding, alcohol withdrawal, folate depletion, and hypersplenism make interpretation of the reticulocyte count difficult.

Platelet Production and Function

Thombocytopenia is a well-recognized consequence of excessive ethanol intake. [91] [93] [96] With abstinence, the platelet count begins to rise within a few days, returns to normal by 1 week, and may reach supranormal levels (rebound thrombocytosis) within 13 weeks. Ethanol, or its metabolites, is the etiologic agent, and thrombocytopenia may be present in the absence of complicating liver disease, hypersplenism, nutritional deficiency, or DIC. The major toxic effect appears to be mediated at the bone marrow level, although there is some evidence for decreased platelet survival. [144] Megakaryocytes in the bone marrow are usually adequate in number,[145] [146] but may be reduced.[96] [103] [147] CFU-megakaryocytes grown in the presence of ethanol show diminished numbers in vitro. [102]

Not only does alcohol affect platelet production, but immoderate drinking can lead to several abnormalities of platelet function. Impaired platelet aggregation, [148] [149] [150] decreased thromboxane A_2 release, [148] and prolongation of the bleeding time, even in the absence of thrombocytopenia, have been observed. [144] [151] Effects on storage pool adenosine diphosphate and platelet cyclic adenosine monophosphate have also been described. [144] [152] The degree to which impaired platelet function contributes to abnormal bleeding in alcoholic patients is not clear. Whether the decreased risk of cardiovascular disease, but an increased risk of cerebrovascular accidents, observed in these patients can be attributed to platelet function defects is not known. [153] [154]

Granulocyte Production and Function

The effect of ethanol consumption on granulocyte production is less clear than its effect on RBCs and platelets. Neutropenia is more commonly a result of hypersplenism or folate deficiency. [155] Even though alcohol injury to bone marrow can produce vacuolization of myeloid precursors, the white blood cell count and marrow granulocyte reserve remain normal. [96] [156] In vitro incubation of bone marrow with high levels of alcohol can inhibit granulocyte colony formation. [104] In occasional patients, heavy alcohol intake in combination with severe bacterial infections has been associated with marked neutropenia and bone marrow myeloid arrest at the myelocyte stage. [157]

The effect of alcohol on granulocyte function has long been suggested by the poor delivery of neutrophils to sites of acute infection. Movement into skin abrasions is decreased and has been attributed to defective adherence. [156] [158] Although chemotaxis is reduced, phagocytosis and intracellular bacterial killing are not affected. [158] [159] [160]

Immune Function

Decreased numbers of circulating lymphocytes have been described in alcoholic subjects. [155] Active drinkers fail to develop increased antibody titer responses to immune challenge and delayed hypersensitivity responses to new antigens. [155] In animal studies, ethanol ingestion decreases natural killer cell activity and delayed hypersensitivity responses. [161] Although the mechanisms underlying impaired cellular and humoral immune functions in alcoholic subjects have not been fully clarified, epidemiologic data support the association.

Chapter 148 - Hematologic Complications of Renal Disease

Nicholas Dainiak

INTRODUCTION

Chronic renal insufficiency is characterized by an elevation in serum urea nitrogen and creatinine concentrations with or without reduced urine output. It leads ultimately to functional disorders involving fluid and electrolyte balance as well as virtually every organ system in the body. Disturbances of the hematopoietic system range from cytopenias and hypocomplementemia to disorders of hemostasis. Abnormalities include the development of splenomegaly and hypersplenism and increased susceptibility to infection. In turn, these sequelae may worsen cytopenias and bleeding. Unfortunately, most of the hematologic and immunologic disturbances present in chronic renal

insufficiency progress or develop even after an optimal program of dialysis and related therapy has been initiated. [1]

PATHOPHYSIOLOGY OF RENAL DYSFUNCTION

The classic evolution of renal failure to terminal uremia and azotemia was first described by Bright in 1936. [2] Although the full clinical spectrum of abnormalities in uremia is rarely seen today because of therapeutic intervention, pallor and anemia persist as hallmarks of severe renal insufficiency. Patients with a blood urea nitrogen concentration of >100 mg/dl rarely have a hematocrit value above 30%. [3] Attempts to explain this relationship have changed in concert with evolving concepts concerning the pathogenesis of uremia. [4] Although excretory failure leading to retention of nitrogenous waste products is pathogenetically more closely related to acute neurobehavioral abnormalities, failure of renal biosynthetic processes and hormonal regulation has been recognized as related to chronic organ abnormalities. Renal biosynthetic failure encompasses not only impaired secretion of metabolites (including serine, leucine, and arginine) by the kidney but also impaired production of renal hormones. [5] Among the renal hormones are erythropoietin (EPO), renin, 1,25-dihydroxycholecalciferol vitamin D_3 and prostaglandins. Defective production or release of these hormones leads to a wide spectrum of clinical sequelae, including anemia, hypertension, disturbed calcium metabolism, altered renal blood flow, and impaired sodium and water excretion. [6] [7] [8] Recently, the concept that defective hormonal feedback systems may lead to uremia has been advanced. [9] [10] Since the diseased kidney maintains sodium balance despite a loss of functioning nephrons, circulating inhibitors of sodium transport may be present. Although little is known about the chemical identity of such inhibitors (or uremic toxins), considerable evidence indicates that sodium transport is inhibited and sodium/potassium/ATPase levels are decreased. [11] [12] [13] [14] Such abnormal regulators are distinct from low molecular mass toxins, (including >70 nitrogenous compounds), and are also distinct from oligopeptides and polypeptides (i.e., middle molecules ranging in molecular mass from 300 to 2,000 daltons), which may be retained as a consequence of impaired renal excretory function. [5] In addition, endocrine toxins, including parathyroid and natriuretic hormones, may be present in increased quantities in response to reduced renal mass. As a result of the ubiquitous actions of these substances, many features of uremia may be explained by disruption of normal hormonal feedback systems. [15] [16]

ETIOLOGY AND PATHOGENESIS OF HEMATOLOGIC AND IMMUNOLOGIC DISTURBANCES

Abnormalities in renal excretory function, renal biosynthetic processes, or hormonal regulation may be responsible for the hematologic sequelae of renal failure. Except for defective production of the hematopoietic hormone EPO, evidence for a direct relationship between a specific abnormality in renal function and a hematologic complication remains circumstantial.

Hypoproliferative Anemia

Anemia characteristically accompanies the uremic syndrome. It is virtually always present in acute forms of renal failure associated with interstitial nephritis, tubular necrosis, and glomerulonephritis, [17] and it is often the presenting symptom of chronic renal insufficiency as well. [3] Over 90% of patients receiving chronic dialysis therapy have anemia, and in 25% of these cases, the anemia is severe enough (hematocrit <25%) to require repeated blood transfusions. [18] Although the cause of renal failure correlates poorly with the degree of anemia, patients with polycystic disease are less anemic than those with other renal disorders on a per-milligram serum creatinine basis. This may in part be related to induction of EPO synthesis or release in response to local renal hypoxia that develops as a consequence of pressure exerted by space-occupying cysts. In contrast, renal failure associated with other disorders may be complicated by a greater degree of anemia than anticipated. For example, blood loss and iron deficiency invariably complicate renal failure due to Goodpasture syndrome and Henoch-Schönlein purpura. Likewise, brisk hemolysis may occur in patients with renal insufficiency associated with connective tissue disease (such as systemic lupus erythematosus), and the production of EPO by kidneys that have been damaged by radiation may be inordinately depressed. [19] [20] [21]

A low red blood cell mass in uremia is most often the result of diminished red cell production. The principal cause of this defect is a decrease in renal EPO production relative to the degree of anemia that is present. Although low, normal, and high levels of plasma EPO have been measured by radioimmunoassay and bioassay, [22] [23] [24] [25] [26] [27] EPO levels are inappropriately low when adjusted for the degree of anemia (Fig. 148-1).[28] [29] [30] Furthermore, a positive correlation is present between serum EPO level and hematocrit, and between hematocrit and creatinine clearance in patients with a relatively mild degree of renal failure (i.e., creatinine clearance of 240 ml/minute[28]). Anephric patients have the lowest EPO levels, a finding that complements the observation that erythropoiesis is severely impaired (but not abolished) in patients who have undergone bilateral nephrectomy. [28] [29] [30] [31] As

Figure 148-1 Levels of erythropoietin versus hematocrit in uremic patients with or without intact kidneys. Shaded area represents predicted values. *(From Caro et al., [6] with permission.)*

shown in Figure 148-1 , anephric individuals have extremely low but nevertheless detectable plasma EPO. The source of this extrarenal EPO is unknown but may include macrophages in the bone marrow or spleen,[31] [32] Kupffer cells in the liver,[33] [34] [35] [36] or undefined cellular components of submandibular glands. [37] [38] In addition to EPO, plasma from anephric individuals may also contain an insulin growth factor-like activity that supports the growth of mature erythroid progenitor cells.[39]

Although the presence of a circulating erythropoietic factor was postulated at the turn of the century, [40] was confirmed to exist in 1953,[41] and was demonstrated to be of renal origin in 1957,[42] remarkably little is known about its site of production. The renal cellular origin of the hormone has been ascribed to glomerular, [43] [44] [45] [46] [47] mesangial,[48] [49] cortical,[50] [51] [52] [53] tubular,[54] medullary,[55] [56] and juxtaglomerular[57] [58] cells at one time or another. Recently, the EPO gene has been used as a probe to detect EPO mRNA accumulation under hypoxic conditions.[59] [60] Results of this experimental approach suggest that tubular [61] or peritubular[62] cells produce EPO in response to hypoxia. Nevertheless, because the healthy kidney contains no detectable stores of EPO, [63] insight concerning cellular or subcellular mechanisms leading to defective EPO production in renal failure has not been forthcoming.

Even less is known about the forces that drive EPO production or release. Clinical observations in patients with patent ductus arteriosus and erythrocyte overproduction suggested that an oxygen sensor for hypoxia is located below the diaphragm. [64] [65] Although the sensing mechanism for hypoxia is believed to reside in the kidneys, virtually no information concerning its cellular localization is available. It has been suggested that the regulatory feedback mechanism for EPO production remains intact in patients with mild renal insufficiency but that the entire system operates at a reduced level. [29] [30] This may result in a suboptimal EPO response to hypoxia. Such a mechanism may be the antithesis of an abnormally high set point for EPO in production, which has been suggested to be responsible for EPO-dependent erythrocytosis.[66] Nevertheless, serum EPO levels are increased in patients with chronic renal failure who develop acute hypoxemia (Pa o_2 <65 mm Hg),[67] a finding that may be explained by extrarenal EPO production.[68]

In addition to relative EPO deficiency, other processes may contribute to hypoproliferative anemia in renal disease (Fig. 148-2). Uremic toxins that impair proliferation of erythroid progenitor cells and erythroid precursors in the bone marrow have been described. These include serum inhibitors of erythroblast maturation and heme synthesis,[69] [70] as well as inhibitors directed at progenitor cells. The latter toxins have been identified in bone marrow culture systems as spermine, [71] parathyroid hormone,[72] ribonuclease,[73] and various serum lipoproteins. However, the physiologic relevance of these observations is not established. Uremic serum has been found to inhibit colony-forming unit-granulocyte macrophage (CFU-GM) proliferation as well as megakaryocyte cell lines growth; [74] spermine has been found to inhibit CFU-GM proliferation.[75] These results are discordant with findings in vivo where both the white blood cell count and platelet count are characteristically normal in patients with renal insufficiency. Furthermore, uremic serum contains normal levels of polyamines. [76] Likewise, serum lipoproteins from healthy (nonanemic) individuals have been found to suppress hematopoietic progenitor cell proliferation. [77] Finally, the concentration of ribonuclease required for inhibition of erythroid progenitor cell growth in vitro exceeds levels found in uremic serum. [73]

Hemolytic Anemia

A diminished red cell mass may result not only from impaired red cell production but also from decreased red cell life span (Fig. 148-2). Reductions in red cell survival rates to approximately one-half normal have been measured in patients with advanced renal failure. [78] [79] This defect has been shown to be extracorpuscular and may be due to retention of uremic solutes that function as abnormal metabolites or to mechanical factors in the environment of the red cell as it travels through abnormal vasculature.[80] [81] Cross-transfusion studies indicate that uremic red cells survive normally in normal recipients, whereas the life span of normal red cells is shortened when transfused into uremic patients. [82] [83] Moreover, the red cell life span occasionally normalizes after intensification of dialysis [84] or a change to continuous ambulatory peritoneal dialysis, [85] thereby suggesting that metabolic factors are involved.

In contrast to its environment, the red cell appears to be generally normal in renal failure. Laboratory evidence for appropriately increased activities (for age) of many red cell enzymes and adenosine triphosphate (ATP) [14] [86] [87] support this concept. An appropriately elevated 2,3-diphosphoglycerate (2,3-DPG) level and depressed

hemoglobin affinity for oxygen suggest that the red cell carries and releases oxygen in a normal fashion. Although the oxygen affinity of hemoglobin is appropriately reduced in uremia, carbamylation of hemoglobin resulting from the action of isocyanic acid (the active form of cyanate formed by spontaneous dissociation of urea in plasma) at NH_2 terminal residues of - and -chains is associated with increased oxygen affinity. [88] This paradox may be explained in studies of red cells

Figure 148-2 Levels of defects in the production and life span of the red cell.

from uremic patients by a concentration effect. Relatively low urea concentrations (1060 mM) are associated with stronger binding of 2,3-DPG to hemoglobin and stabilization of the deoxyform of hemoglobin, while higher urea concentrations (120 mM) show a decrease in P50 and increased affinity of hemoglobin for oxygen. [89] Structural changes in the hemoglobin molecule (rather than carbamylation of hemoglobin) predominate at the lower urea concentrations that are typically found in uremic patients.

Nevertheless, slightly decreased transketolase and superoxide dismutase levels [90] [91] and depressed Na^+ /K^+ /ATPase[92] have been reported in red cells from uremic patients. Reduced antioxidant defense mechanisms have been found in red cells from patients with chronic renal failure. Recently, a decreased level of reduced glutathione (GSH) was measured in red cells from renal failure patients maintained on hemodialysis. [93] The defect was thought to be the result of lack of NADPH due to decreased glucose-6-phosphate dehydrogenase (G6PD) activity. These findings may be physiologically important when the red cell membrane is exposed to oxidant drugs or compounds.[94] Therefore, therapy that generates factors that stress the red cell antioxidant system may result in accelerated hemolysis (see later). In the absence of such stress, only a small minority of uremic patients have underlying anemia that is principally due to diminished red cell survival.

Erythrocytosis

In some patients with impaired renal function the red cell mass is elevated rather than depressed. Isolated erythrocytosis has been described in association with a variety of renal disorders, including hypernephroma, cystic renal disease, ureteral obstruction, and renal artery stenosis. [90] [91] [92] In addition, it may complicate the clinical course of 1020% of patients undergoing renal transplantation. [95] Erythrocytosis may be the harbinger of acute or chronic allograft rejection [96] and post-transplant renal artery stenosis. [97] [98] In many cases, it is accompanied by excessive EPO production.[96] [97] [98] [99] [100] [101] Even moderate levels of erythrocytosis can be associated with elevated serum EPO levels. [102] [103] [104] The etiology of increased EPO levels is unclear but may be related to impaired renal blood flow resulting in local hypoxia and stimulation of the renal oxygen sensor. [95] Selective catheterization of veins of native and transplanted kidneys has demonstrated elevated EPO levels in blood exiting from native (diseased) kidney or kidney remnants. [105] Whether such EPO production is autonomous or subject to feedback regulation but at an elevated EPO set point is unknown. [106] Alternatively, hepatic EPO production may be induced by administration of androgenic steroids. [107] [108] It appears that administration of exogenous EPO at the time of renal transplantation does not predispose to development of post-transplant erythrocytosis. [109]

Since erythrocytosis may occur in patients lacking native kidneys [110] and since confounding variables such as androgenic steroid administration, smoking, hepatic insufficiency, diabetes mellitus, cardiac dysfunction, and pulmonary disease may complicate renal failure, the etiology of EPO-dependent erythrocytosis in the renal transplant recipient may be multifactorial. Moreover, because uremic serum from patients with renal failure contains factors that are recognized by anti-EPO (i.e., share antigenic determinants with EPO) but that are free of biologic activity and are smaller in molecular mass than native EPO, the relationship between elevated EPO levels and erythrocytosis requires further characterization. [111]

Leukocyte Dysfunction

Renal failure is accompanied by a high rate of infection, which often leads to death. [112] [113] Mucosal barriers to infection may be defective, vascular and peritoneal access devices are frequently used, and immunosuppressive agents are sometimes administered, all of which predispose to infection, particularly by staphylococci. Multiple defects in the complex network of immunoregulation also have been described, although a clear explanation for infection has been elusive. Granulopoiesis is appropriately stimulated, provided that cytotoxic immunotherapy is not being used. Megaloblastic morphologic changes are only rarely seen and when present are usually unexplained. [114]

By contrast, granulocyte pool sizes may be prominently disturbed in uremia, particularly during hemodialysis. Mild neutrophilia is commonly seen, a finding that may be related to alterations in the distribution of granulocyte pools. [114] [115] [116] A low mobilizable marrow pool of granulocytes has been found in uremic patients after hydrocortisone injection.[117] Presumably, marrow granulocyte reserves have already been called upon, leading to diminished pool sizes that are assessed by steroid release tests. On the other hand, marrow release appears to be normal in response to complement, as assessed by the C3e-responsive pool. [118] More marked changes occur in granulocytes during hemodialysis. Severe transient neutropenia occurs within 2 hours after initiation of dialysis, a finding that initially appeared to be due to sequestration of granulocytes in the dialysis apparatus. [119] Further study of this phenomenon, however, disclosed that administration of autologous plasma that had been incubated with dialyzer cellophane resulted in complement-mediated leukostasis in pulmonary vessels. [120] [121] Precisely how complement activation alters granulocyte adhesiveness and whether this mechanism fully explains hypoxemia during hemodialysis remain unknown.

Mild functional abnormalities of granulocytes have been observed in uremia. Impaired granulocyte migration into a Rebuck skin window, [122] abnormal chemotactic activity in the presence of autologous uremic plasma or serum,[123] and uremic factors capable of inhibiting chemotaxis[124] have all been described. Some of these defects are reversible with successful renal transplantation. [125] The cause of reversible functional defects in leukocytes is poorly understood but multiple factors may be involved, including coexisting acidosis, hyperglycemia, hyperosmolarity, and protein-calorie malnutrition.

In contrast to mild disturbances of granulocytes, significant lymphopenia and lymphocyte dysfunction have been described in uremia. Absolute lymphopenia occurs in patients with renal failure with or without hemodialytic therapy. [115] [116] [117] [118] Use of high-permeability biocompatible membranes (polyacrylonitrile or ANG9) rather than low-permeability membranes may reduce plasma levels of factors that alter the number and/or function of T cells and B cells, including interleukin-1 (IL-1), IL-6, and tumor necrosis factor- (TNF-).[126] [127] Lymphopoietic hypoplasia and thymic hypoplasia have been described in neonates of women with renal insufficiency as well.[5] Whereas T cells are slightly depressed in number, B-cell lymphopenia may be prominent. [128] [129] [130] In addition, a variety of immunologic abnormalities have been found in nephrotic syndrome (Table 148-1).[131] [132] [133] [134] [135] [136] [137] [138] [139] [140] [141] [142] [143] [144] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154] These include hypocomplementemia, defective opsonization, impaired immunoglobulin production, abnormal humoral function (assessed by the presence of soluble factors that inhibit lymphocyte proliferation and factors that inhibit monocyte migration), and impaired cellular immunity.

Although serum immunoglobulin A, G, and M levels have been reported to be diminished, [135] [136] some researchers have found normal values in uremic patients.[128] [137] On the other hand, striking defects in cellular immunity have been observed consistently, both in vitro (Table 148-1) and in vivo. Reduced delayed hypersensitivity reactions to common antigens such as mumps, *Trichophyton,* and *Candida* are well described.[149] [155] [156] Extended survival of skin allotransplants [157] [158] [159] and prolonged cardiac transplant survival [160] occur as well. In addition, alterations in the immune surveillance system may be related to the high incidence of malignancy known to occur in uremic patients.[161] [162]

TABLE 148-1 -- Immunologic Disturbances in Nephrotic Syndrome

Immune Response	Disturbance	Reference
Opsonization	Low factor B, D serum levels	[131] [132]
	Impaired neutrophil chemotaxis/chemiluminescence	[133]
	Impaired reticuloendothelial cell function	[134]

Immunoglobulin production	Low serum immunoglobulin levels	[135] [136]
	Diminished immunoglobulin synthesis in vitro	[138]
	Decreased immunoglobulin reactivity	[139] [140]
Humoral immunity	Serum inhibition of lymphocyte proliferation	[141] [142]
	Serum toxicity to lymphocytes	[143]
	Production of soluble inhibitors, including monocyte migration inhibitory factor, immune response suppressor	[144] [145] [146]
Cellular immunity	Impaired lymphocyte blastogenesis	[147]
	Reduced delayed hypersensitivity reactions	[148] [149]
	Suppression of antibody-dependent cell-mediated cytotoxicity	[150] [162]
	Impaired transfer of tuberculin sensitivity	[153] [154]
	Cutaneous anergy	[153] [154]

Both natural killer cell activity and antibody-dependent cell-mediated cytotoxicity are inhibited by uremic serum, an observation that may be important in host defense against malignancy.[127] [150] [162]

Abnormalities of Hemostasis

Abnormal hemostasis, with a proclivity for bruising and bleeding, is commonly seen in chronic renal disease. Although qualitative and quantitative disturbances of the platelets, clotting cascade proteins, and blood vessels are known to occur in uremia, the pathogenesis of these defects remains obscure. One potentially important factor may be retention of low-molecular-weight toxins. Guanidinosuccinic acid and phenolic acid are known to reduce platelet factor 3 availability and to inhibit adenosine diphosphate (ADP)-induced platelet aggregation. [163] [164] By contrast, prostaglandins that have a tonic vasodilating effect in chronic renal disease [165] [166] activate platelets and induce activation of the coagulation cascade, particularly within glomerular capillary loops. [167] Dialyzer membrane composition and flow design may also play a role in activating platelets of hemodialyzed patients. [168]

In addition, clotting abnormalities, particularly those involving the platelet, may develop as a consequence of fluctuations in the hematocrit value. According to one hypothesis, platelet adhesion to the subendothelium increases progressively as the hematocrit rises. [169] As red cells flow through vessels at relatively high shear rates, platelets diffuse radially, thereby increasing the chances of platelet collision with the vessel wall. [170] This process favors thrombus formation. Disproportionate increases in hematocrit value and whole blood viscosity may be further aggravated by the therapeutic use of diuretics. An inverse correlation exists between bleeding time and hematocrit, and red cell transfusion improves several clotting parameters, including platelet retention on glass beads, prothrombin consumption, serum thromboxane B_2 production, and intraplatelet cyclic AMP levels. [171] [172]

Alterations in clotting factor levels occur in uremia as well. Decreased blood levels of factors IX, XI, and XII have been reported [168] and are believed to result from increased urinary losses of these relatively low molecular weight proteins. Blood levels of other clotting factors (factors II, V, VII, VIII, X, and XIII) are often increased.[173] [174] [175] [176] Because the latter changes correlate with the degree of hypoalbuminemia,[177] it is possible that they develop secondary to increased hepatic synthesis. Nevertheless, no direct relationship has been established between clotting factor levels and the development of the thrombotic diatheses (such as renal vein thrombosis) that are known to complicate renal insufficiency.[178]

An abnormality of the von Willebrand factor (vWF) has also been identified in uremia, a finding that may bear directly on the role of platelets in primary hemostasis. Ristocetin cofactor activity is lower than normal in chronic renal failure patients, and elevated vWF antigen levels are detected. [179] These findings are supported by the observations that in uremia, vWF activity is consistently lower than its antigen level, and that hemorrhagic tendency is corrected by infusion of either cryoprecipitate[180] or the synthetic derivation of the antidiuretic hormone 1-deamino-8- D-arginine vasopressin.[181] These findings correlate with shortening of an abnormal bleeding time and reversal of the coagulopathy, suggesting that abnormalities in the factor VIII-vWF antigen level and functional activity lead to a prolonged bleeding time and clinical coagulopathy.

Disturbances of coagulation are also common in pre-eclampsia and eclampsia. [182] [183] Intravascular hemolysis and coagulation abnormalities are no more severe in women who develop acute renal failure than in those who do not.[184] It is unknown whether the deposition of thrombi and development of renal cortical necrosis occur as the primary event or as a secondary event in obstetric acute renal failure. [185]

CLINICAL AND LABORATORY PRESENTATION

Signs and symptoms of uremia, including hypertension, metabolic acidosis, fluid overload, and disturbances of the gastrointestinal, cardiovascular, and nervous systems, are usually the major clinical manifestations of renal insufficiency. In addition, pallor, fatigue, and high-output cardiac failure due to anemia and bleeding or intravascular coagulation may become major clinical problems that demand appropriate therapy.

Anemia

Normocytic, normochromic anemia with a corrected reticulocyte count of 1% (i.e., normal reticulocyte index in the face of anemia) is characteristically present. Morphologically, the red cells frequently show the characteristic even scalloping of echinocytes or burr cells. [186] The clinical significance of this morphologic change is uncertain because the presence or absence of echinocytes does not correlate with the severity of hemolysis and because even normal red cells reversibly transform into echinocytes in vitro.[187] Occasionally, asymmetrically distributed, large spicules appear on the surface of uremic red cells (acanthocytes) or grossly deformed and fragmented red cells (schistocytes) appear. In contrast to echinocyte formation, the presence of schistocytes is a manifestation of a pathologic process involving the microcirculation that has occurred in vivo. When severe, these changes are the hallmark of the hemolytic-uremic syndrome.

In the absence of a complicating nutritional deficiency or drug-related hemolytic process, the bone marrow aspirate appears normal. Mild granulocyte hyperplasia may be observed, and erythroid precursors are normal in appearance and maturation. [188] Occasionally, marrow fibrosis (i.e., osteitis fibrosa) is apparent on bone biopsy. Here, decreased marrow space is available for erythropoiesis, regardless of circulating EPO levels. Osteitis fibrosa, a complication of secondary hyperparathyroidism and renal insufficiency, may play a pathogenic role in the

APPROACH TO EVALUATION OF WORSENING ANEMIA

Hematologists are frequently asked to evaluate worsening anemia in patients with chronic renal insufficiency. One logical approach to the diagnostic workup of such patients is outlined here. Baseline laboratory information includes examination of the blood smear and calculation of the reticulocyte index (corrected for level of hematocrit). Individuals with hypoproliferative red cell production indices may have nutritional deficiency or an abnormal process involving the bone marrow (i.e., dyshematopoiesis, myelofibrosis, or an unrelated disorder such as myelophthisis). When microcytosis is present, a serum ferritin level measurement usually confirms the diagnosis of iron deficiency. If inflammation is present, a marrow aspiration to assess tissue iron stores may be required. Alternatively, microcytic anemia can also be observed in patients with aluminum toxicity. Because aluminum is ubiquitous (being particularly concentrated in glassware), aluminum measurements may be erroneous because of contamination of plasma samples by collecting and transport materia.[348] A red cell aluminum assay whose measurements are not altered by aluminum contamination of blood samples has been developed.[349] Alternatively, aluminum excretion after deferoxamine administration can be measured[348] and aluminum concentrations in the bone can be quantitated[350] in order to establish the diagnosis of aluminum toxicity.

The diagnosis of macrocytic, hypoproliferative anemia should be approached by measurement of serum and/or red cell folate and vitamin B_{12} levels. If results are normal or equivocal, a bone aspiration may be required to establish the diagnosis of marrow nutritional deficiency or another marrow disorder. Furthermore, liver function tests must be performed since macrocytic anemia may be associated with liver disease even in the absence of folate deficiency, and particularly because uremic patients are at risk for developing hepatic dysfunction. The presence of hyperproliferative anemia characterized by an elevated reticulocyte index necessitates a hemolytic workup. Careful examination of the blood smear for spherocytes and schistocytes is necessary when chemical evidence of hemolysis is present. The spectrum of microangiopathic changes on the blood smear, thrombocytopenia, and renal insufficiency should raise the possibility of hemolyticuremic syndrome. Alternatively, microangiopathic changescan be seen with underlying vasculitis, malignant hypertension, or connective tissue disorders that may be responsible for both renal disease and hemolysis. The sudden development of accelerated hemolysis accompanied by spherocytes should raise the possibilities of immune hemolysis, dialysis-associated hemolysis (i.e., that associated with copper, chloramine, formaldehyde, nitrate, or zinc toxicity) or drug-related hemolysis (either drugs with high oxidative potential or those known to induce antibody-mediated hemolysis; see Table 148-2). Excessive use of phosphate-binding antacids may cause a similar hemolytic picture.

Assessment of hyperproliferative anemia in the absence of chemical evidence for intravascular hemolysis should raise the possibilities of brisk erythropoietic response to blood loss and red cell sequestration in an enlarged spleen. If splenomegaly is present, one should measure uptake of chromium 51-tagged red cells over the spleen. Increased uptake occurs with splenic sequestration,

Assessment of hyperproliferative anemia in the absence of chemical evidence for intravascular hemolysis should raise the possibilities of brisk erythropoietic response to blood loss and red cell sequestration in an enlarged spleen. If splenomegaly is present, one should measure uptake of chromium 51-tagged red cells over the spleen. Increased uptake occurs with splenic sequestration, suggesting several possible causes and indicating splenectomy as a potential therapeutic option. Alternatively, splenomegaly may develop as a consequence of hepatic disease and portal hypertension. In the absence of splenomegaly, a careful search should be made for blood loss (via the gastrointestinal tract, into the retroperitoneum, or via dialysis). An ultrasound examination to evaluate for a retroperitoneal collection of blood and multiple stool guaiac tests to evaluate for gastrointestinal loss may yield the appropriate diagnosis.

production of anemia since the amount of marrow fibrosis correlates well with correction of anemia that follows parathyroidectomy. [189] [190] The extent of fibrosis also correlates with response to EPO treatment (see below).[191] The relationship of elevated parathyroid hormone levels to in vivo suppression of erythropoiesis [71] or to reduction in red cell survival [192] is unknown. As osteitis fibrosa progresses, the alkaline phosphatase level rises. Ultimately, myelofibrosis develops, accompanied by extramedullary hematopoiesis and hepatosplenomegaly.

Frequently, iron deficiency associated with blood loss andor folic acid deficiency complicates renal anemia (Table 148-2). [78] [79] [80] [81] [91] [193] [194] [195] [196] [197] [198] [199] [200] [201] [202] [203] [204] [205] [206] [207] [208] [209] [210] [211] [212] [213] [214] [215] [216] [217] [218] [219] [220] [221] [222] [223] [224] [225] Gastrointestinal tract blood loss (believed to be due to platelet dysfunction) or iatrogenic blood loss (via phlebotomy, dialyzer, or fistula) may lead to depletion of iron stores and erythroid hyperplasia. Blood loss is exaggerated in hemodialysis patients because of the heparinization that is required during dialysis. Blood losses may average as much as 1 Lmonth in patients undergoing long-term hemodialysis.[193] [194] [195] [196] [197] In contrast, patients dialyzed peritoneally do not develop iron deficiency without gastrointestinal blood loss. Rarely, iron deficiency may develop in association with urinary loss of transferrin. [198]

Several factors contribute to the development of clinically apparent folic acid deficiency. Since red cell survival is decreased, demand for folate is higher than normal.[78] [79] [80] [81] [199] This demand may not be met when patients are advised to restrict protein intake, although the need for supplemental folic acid is not clearly established.[200] [201] Nevertheless, folate is removed during dialysis.[200] In addition, absorption or metabolism of dietary folate may be suppressed by many of the drugs used in treating uremic patients, including diphenylhydantoin, barbiturates, cholestyramine, dietary amino acids, oral contraceptives, and inhibitors of dihydrofolate reductase (such as methotrexate and pyrimethamine).[202] Megaloblastic maturation and dyshematopoiesis are characteristically present in marrow aspirates of uremic patients with folate deficiency.

Red cells from uremic patients with renal insufficiency are hypersensitive to oxidant challenge. [94] [204] Most enzymes of the oxidant defense system have been shown to be normal or slightly below normal in activity, [205] [206] [207] [208] rendering cells hypersensitive to hydrogen peroxide-induced hemolysis. [209] Cross-incubation studies suggest that increased oxidant sensitivity is due to uremic plasma factors since normal red cells can be made hypersensitive to ascorbate-generated oxidants by incubation in uremic plasma.[210] The production of oxidants such as chloramine during dialysis leads to brisk hemolysis (Table 148-2). Other dialysis-associated alterations in uremic red cells, such as overheating, mechanical fragmentation, and dehydration/overhydration, may also lead to accelerated hemolysis. Drugs having a high oxidative potential may also induce hemolysis and worsen anemia. Furthermore, since malignant hypertension and vasculitis may complicate renal failure, uremic patients are prone to develop microangiopathic hemolysis. [219] Finally, hypophosphatemia associated with excessive use of

TABLE 148-2 -- Correctable Causes of Anemia of Renal Failure

Mechanism	Etiology	Reference
Blood loss, iron deficiency	Iatrogenic loss Dialyzer loss Shunt or fistula loss Gastrointestinal loss Urinary loss of transferrin	[193] [194] [195] [196] [197] [198]
Folate deficiency	Increased demand Restricted oral intake Dialyzer loss Drug-induced inhibition of absorption or metabolism	[78] [79] [80] [81] [199] [200] [201] [200] [202]
Accelerated hemolysis		
Dialysis-associated toxicity	Toxicity due to exposure to copper, chloramine, formaldehyde, or nitrates Overheating of erythrocytes Mechanical erythrocyte fragmentation Dehydration/overhydration of erythrocytes	[211] [212] [213] [214] [208] [215] [216] [217]
Drug-associated	High oxidative potential agents: thiol-containing drugs, phenylhydrazine-like drugs Immunohemolytic agents: -methyldopa, penicillin, quinidine, etc.	[91] [207] [218]
Microangiopathic	Malignant hypertension Vasculitis	[219]
Red cell phosphate depletion	Excessive antacid intake	[220]
Hypersplenism	Red cell sequestration/work hypertrophy Chronic hepatitis Transfusion-induced hemosiderosis Marrow fibrosis Silicone toxicity	[221] [222] [223] [221] [222] [224] [225]

phosphate-binding antacids (i.e., aluminum gels) may lead to several red cell abnormalities, including depletion of ATP stores, impaired glycolysis, reduced red cell deformability, and hemolysis.[220]

Although uremic patients often develop hypersplenism as a complication of their underlying disease or its therapy (Table 148-2), only a small percentage actively sequester and destroy red cells in the spleen. [221] The latter patients have a red cell survival rate that is one-fourth of normal, demonstrate increased uptake of radioactive chromium-labeled red cells, and have a favorable response to splenectomy. However, most patients with mild splenomegaly do not actively sequester red cells in the spleen, suggesting that they will have a poor response to splenectomy. [226]

Aluminum toxicity has been recognized in dialysis patients. High levels of aluminum develop as a consequence of long-term use of aluminum-containing antacids that facilitate phosphate binding or of aluminum-containing dialysate. The precise level at which aluminum becomes toxic is debatable and is in part determined by exclusion of other known causes of organ dysfunction. [227] [228] An early manifestation of aluminum toxicity is microcytosis. [229] [230] Later, hypochromic anemia, dialysis encephalopathy, vitamin D-resistant osteomalacia, and muscle weakness develop. [230] [231] The mechanism responsible for the development of microcytic anemia may involve suppression of enzymes involved in heme synthesis. [232] Alternatively, aluminum may interfere with iron uptake by the red cell since it is similar to iron with respect to trivalency and avid binding to transferrin. [233] [234] Aluminum-induced anemia can be reversed by use of a dialysate containing deionized water [234] or by chelation with desferrioxamine. [235] Today, aluminum has been removed from the dialysate in many dialysis units, thereby decreasing the incidence of aluminum toxicity in the United States.

Bleeding and Abnormal Coagulation Tests

Clinical bleeding in uremia manifests most often as purpura, menorrhagia, and occult or frank gastrointestinal blood loss. Bleeding occurs in up to one-half of all patients with chronic renal insufficiency. [236] Characteristically, the platelets are quantitatively normal, although dialysis-associated thrombocytopenia with clinical bleeding may occur. [168] [173] Platelet dysfunction characterized by abnormalities in bleeding time, platelet aggregation and adhesiveness, prostaglandin (PGI_2) production, and factor VIII-vWF complex activity is well documented. [163] [164] [165] [166] [167] [168] [236] [237] Dialysis has been reported to improve abnormalities in many of these tests and to ameliorate bleeding [238] by an unknown mechanism(s).

Hemolytic-Uremic Syndrome

Brisk hemolysis and thrombocytopenia may occur in the setting of acute renal failure. This clinical picture has emerged as a distinct syndrome, the hemolytic-uremic syndrome (HUS), which is relatively common in infants and children who develop sudden anemia, renal failure, central nervous system dysfunction, and gastrointestinal bleeding. HUS often follows a prodrome of infectious symptoms involving the digestive or respiratory tracts (or both). Although the inciting agent may be viruses, bacteria, drugs, or pregnancy, little is known of the pathogenetic mechanisms involved. Several theories have been postulated, including the induction of a generalized Schwartzman phenomenon by microorganisms or their toxins, prostacyclin deficiency, and genetic predisposition. Mitomycin treatment of solid tumors may be complicated by HUS, and more rarely, other chemotherapeutic agents (i.e., cisplatin and bleomycin) may also be associated with secondary HUS. [239] Recently, HUS has been reported after transplantation of bone marrow and solid organs. [240] [241] HUS may also be the presenting clinical form of infection by the human immunodeficiency virus (HIV). [242]

Shigellosis, an acute infectious inflammatory colitis, may be complicated by oliguria and a marked drop in hematocrit (10% in 24 hours) that occur as the dysentery is resolving. *S. dysenteriae* type 1 infection and *E. coli* O157:H7 produce high levels of Shiga-family toxins that appear to trigger HUS by binding to renal vascular endothelium where ribosomal activity is inhibited. [243] [244] Binding of toxin to the Cb3 plasma membrane receptor is followed by receptor-mediated endocytosis and inactivation of the host ribosomal RNA complex. In the United States, outbreaks of life-threatening *E. coli* infection have been reported after the consumption of undercooked meat, and are responsible for 250 deaths annually. [245] [246] Most cases have been reported from the northern latitude states, including Washington, Oregon, Minnesota, and Massachusetts. [247] HUS develops in 6% of patients who are infected with *E. coli* O157:H7, and appears 214 days (median, 6 days) after the onset of abdominal cramping, diarrhea, and bloody stools. [248] Outbreaks of *Shigella* infection have been reported in day-care centers and summer camps. [249] Leukemoid reactions in excess of 50,000/L, increased numbers of CD3-CD57-CD20 cells, a low CD4/CD8 ratio, profound hyponatremia, and marked hypoglycemia have been reported in Shiga toxin-associated HUS. [250] A mortality of 510% has been reported despite prompt, aggressive therapy. In up to 40% of those who survive acute HUS associated with Shiga-like toxins, progressive renal damage develops that requires long-term dialysis or renal transplantation. [251] [252]

The histopathologic hallmark of HUS is deposition of hyalin material in arterioles of the kidney. Hyalin deposits are thought to be composed of fibrin and platelets and are indistinguishable from deposits found in thrombotic thrombocytopenia purpura. The peripheral blood smear classically shows fragmented red cells and thrombocytopenia. These changes result from mechanical trauma, as cellular elements traverse renal arteriolar and glomerular vessels whose endothelial lining has been injured. The reticulocyte index is invariably elevated, and signs of overt hemolysis are evident, including indirect hyperbilirubinemia, elevated blood lactate dehydrogenase levels, and low or undetectable haptoglobin levels. Consistent with hemolysis, EPO levels are elevated even though uremia is present. [253]

The mortality from HUS in children varies from 5% to 20%, and in adults is considerably higher. The prognosis is related to the degree of renal insufficiency and to the extent of central nervous system involvement. Neurologic sequelae develop in up to 50% of cases and include altered consciousness, seizures, and bizarre posturing. [254] Therapy is supportive in nature and includes dialysis and blood component replacement. The role of heparin is controversial; other forms of therapy, such as steroids, immunosuppressive agents, and antimetabolites, have not produced clear-cut benefit. Some patients improve following plasmapheresis or exchange transfusion. [255]

THERAPY AND PROGNOSIS

The management of anemia in acute and chronic insufficiency consists of nutritional replacement, including repletion of low iron, vitamin B_{12}, and folic acid stores, conservative blood component transfusion therapy, and an optimal program of dialysis and related therapy aimed at correcting uremia or reversing its effects. Specific therapy for anemia and bleeding complications has been employed since the mid-eighties when recombinant human erythropoietin (rhEPO) became available. The impact of rhEPO in clinical nephrology has been so great that treatment recommendations are now thought of in terms of the pre- and post-EPO eras.

Correction of Anemia in the Pre-EPO Era

Hemodialysis ameliorates symptoms of anemia, but rarely does anemia fully resolve.[256] Although the metabolic clearance (Km) of EPO decreases with the intradyalitic interval, serum EPO levels are unchanged after dialysis.[257] [258] These findings suggest that removal of uremic inhibitors of stem cells or EPO action may be clinically important. Alternatively, it is possible that amelioration of anemia is due to improved renal function. When the clinical spectrum of tachypnea, tachycardia, and other symptoms of high-output cardiac failure develop in association with tissue hypoxia disproportionate to the degree of azotemia, blood component therapy is required. Because transfusion of whole blood may place patients at risk for the development of pulmonary edema, infusion of packed red blood cells is usually recommended. When laboratory parameters for folic acid deficiency are evident, oral supplementation should be given. Routine folate administration, however, may be unnecessary.[201] It has been reported that supplementation with folic acid improves response to rhEPO, suggesting that the demand for folic acid is increased during rhEPO therapy.[259] Iron deficiency is easily correctable when documented in uremic patients. Because intestinal absorption of iron is normal in renal failure, oral supplementation of 65 mg elemental iron twice daily with meals is recommended.[203] [257] [260] Occasionally, parenteral infusion of iron may be necessary in individuals whose total rate of iron losses (Table 148-2) exceeds the daily iron absorption rate. Adequate iron replacement during EPO therapy is essential for an optimal response to rhEPO.

Androgens effectively increase the red cell mass in one-half of patients undergoing dialysis.[108] Although their efficacy in treating the anemia of primary bone marrow failure is debatable,[261] [262] their utility in treating anemia of end-stage renal disease is well established.[263] [264] [265] [266] Nevertheless, the hematocrit usually remains at <36% and rarely achieves normal levels. Symptomatic individuals with a hematocrit of <25% are good candidates for androgen therapy, although it should be kept in mind that side effects include masculinization, acne, fluid retention, and hepatotoxic effects (cholestasis, peliosis hepatitis, and hepatic adenomas). Parenteral administration of androgens may be more effective than administration by other routes.[267] Agents belonging to several classes (testosterone esters, 17-alkylated compounds, and norsteroids) are commonly used.[108] It has been suggested that androgens having an angular configuration (5-epimers) stimulate stem cell proliferation to a greater degree than those whose configuration is planar (5-epimers), which may act primarily by enhancing EPO production.[108] Nandrolone decanoate (Deca-Durabolin) and fluoxymesterone are popular choices for both nephrectomized and non-nephrectomized individuals.[268] [269] Patients are unlikely to respond to androgens if a favorable clinical outcome has not been achieved after 69 months of therapy at different dosages.[108] The cost-effectiveness of androgen therapy versus EPO therapy has been emphasized.[270] [271] A response to androgens that is equivalent to that of EPO has been observed in a subset of patients (male patients aged 50 years and older).[271] Since androgens of one class may be effective while drugs of another class may be ineffective, a method to select appropriate androgen therapy would be helpful to the clinician. An in vitro marrow culture assay has been found to predict response to androgens of a specific class.[272] It appears that both adequate numbers of erythroid progenitor cells and normal sensitivity to androgens of a specific class must be present to achieve a favorable clinical response.

Correction of Anemia in the Post-EPO Era

Perhaps in no other way has the therapy of renal anemia been more affected than by the introduction of rhEPO to clinical medicine. By analogy with other hormone deficiency states, it is predictable that a hormone will be effective when administered to individuals who either lack the capacity to generate a sufficient hormone level in response to a physiologic stimulus or produce a hormone fragment that is biologically inactive. In view of the central role played by EPO in erythropoiesis, the finding that EPO corrects the anemia of end-stage renal disease in humans[273] [274] [275] [276] [277] and small animals[278] is not surprising. Typically, rhEPO administration results in a dose-related, sequential increase in the reticulocyte count and hematocrit, accompanied by complete loss of a transfusion requirement (Fig. 148-3). Increases in red cell transferrin uptake accompany this erythropoietic effect.[275]

In the post-EPO era, clinical research on the treatment of anemia of renal failure has focused on the pharmacokinetic/pharmacodynamic properties of rhEPO. Although some dialyzer membranes have been found to adsorb EPO, calculations of Km for EPO before and after dialysis indicate that rhEPO may be safely administered at any time during the course of dialysis.[257] [258] Early studies indicated that subcutaneously administered rhEPO was not only effective but also absorbed more slowly than intravenously administered rhEPO.[279] A relatively low serum level that is sustained with a higher 48-hour serum concentration is achieved with subcutaneous administration. These serum concentrations are sufficient to stimulate erythropoiesis and maintain a target hemoglobin level of 10.5 g/dl, an effect that is equivalent to that obtained with intravenous administration of the drug.[280] [281] Most investigators have concluded that the subcutaneous route is associated with a decreased dose requirement in both the correction and maintenance phases of therapy.[282] [283] [284] [285] [286] [287] Owing to the high cost of therapy,

Figure 148-3 Effect of recombinant human erythropoietin on transfusion requirement, hematocrit, reticulocyte index, and serum iron parameters in a patient with renal insufficiency. *(From Eschbach et al.,[275] with permission.)*

recent studies have focused on decreasing the overall dose of rhEPO. Whereas the absorption rate is independent of dose, clearance is dose dependent and decreases with increasing dose.[288] Once weekly subcutaneous therapy is equivalent to three times weekly intravenous therapy.[289] Moreover, a reduction in subcutaneous dosing frequency from two or three times weekly to once weekly results in a similar target hemoglobin level in studies with follow-up of up to 45 weeks duration.[290] [291] These results are consistent with the notion that triggering of a limited number of clones of erythroid progenitors to undergo terminal differentiation is sufficient to initiate a gradual wave of accelerated erythropoiesis.[292] Finally, rhEPO can be safely administered undiluted into the dry peritoneal cavity with satisfactory results,[293] thereby avoiding local pain associated with subcutaneous injection.[294]

The efficacy of rhEPO also has been demonstrated in predialysis patients with anemia.[295] There has been no evidence that rhEPO therapy accelerates the deterioration of renal function.[295] [296] Anemia is promptly corrected, provided that iron deficiency is avoided, and health-related quality of life is improved in predialysis patients.[297] Once weekly subcutaneous injection is as efficacious as two or three times weekly injection schedules.[298] Similarly, rhEPO administration improves anemia in patients with failing renal allografts, although higher doses of drug may be needed in these patients than in patients with renal failure not associated with

allograft dysfunction.[299]

Improvement in anemia after the administration of rhEPO is accompanied by loss of fatigue, improved sexual function, enhanced brain function, and a psychological sense of well-being.[276] [278] [300] [301] A clinically minor transient increase in platelet count (from approximately 220 × 10^9 /L to 245 × 10^9 /L) has been documented.[302] [303] Because early studies suggested that the risk of thrombotic complications is increased after administration of rhEPO, [304] [305] [306] the potential effects of rhEPO in vivo on

Box 148-1. APPROACH TO INITIATION AND ADJUSTMENT OF RH EPO THERAPY

The greatest benefit to quality of life in patients with chronic renal failure is achieved when a hemoglobin level of 10.5g/dl has been achieved. [351] This represents the currently recommended target hemoglobin that should be achieved in all patients, provided that severe hypertension or venous access problems do not coexist.[352] A variety of protocols may be followed to initiate therapy with rhEPO.[353] Initial assessment of the patient should include obtaining baseline laboratory data such as a complete blood cell count, serum ferritin level, transferrin saturation, and serum aluminum level (for patients who have received oral phosphate binders or have been dialyzed using a bath containing aluminum). Because up to one-third of patients may experience hypertension following rhEPO therapy, the blood pressure must be managed, beginning with nonpharmacologic therapy (i.e., fluid control) and adding antihypertensive agents as necessary. Initial therapy with 50100 U/kg given intravenously or subcutaneously three times weekly is a reasonable approach.[354] Response to therapy should be monitored with measurements of hemoglobin and hematocrit (three times weekly), iron status (monthly), renal function tests, phosphorus level, and blood pressure (three times weekly).

When adjusting rhEPO dosage, it is important to understand that a response may take 26 weeks to appear, as it requires time for erythroid progenitor cells to undergo terminal differentiation and release into the circulation. rhEPO dosage should be increased if the hematocrit fails to increase by 56 percentage points after 68 weeks of therapy. rhEPO therapy should be withheld when the hematocrit exceeds 36% (in spite of dose), or when the blood pressure cannot be controlled by nonpharmacologic or pharmacologic methods. A reduction in weekly rhEPO dosage may be required when switching from intravenous therapy three times weekly to subcutaneous therapy once weekly. During such a change, it is reasonable to retain the same initial weekly total dose and carefully monitor for a hematologic response and potential toxicity. When changing the dosage regimen, it is important to allow for sufficient observation time (generally at least 4 weeks) in order to monitor closely for excessively rapid increases in hematocrit level (>4 percentage points in 2 weeks) and iron status at regular intervals (maintaining a minimum transferrin saturation of 20% and minimum ferritin level of 100 ng/ml).

A suboptimal response to rhEPO therapy may be due to inadequate dosing, iron deficiency, malignancy, inflammation, infection, vitamin deficiency, occult blood loss into the gastrointestinal tract, skin, or at the time of dialysis, hemolysis, aluminum toxicity, and secondary hypoparathyroidism. In addition, use of angiotensin-converting enzyme (ACE) inhibitors has been associated with resistance to rhEPO therapy.[355] [356] It is important to consider iron-deficient erythropoiesis in rhEPO-treated patients with normal or elevated serum ferritin levels since iron demand from accelerated erythropoiesis may exceed the rate of mobilization of iron stores. In this circumstance, functional iron deficiency can be diagnosed by detection of microcytosis and low transferrin saturation. [357] Therefore a careful search for one or more of these potential causes for EPO resistance should be conducted when rhEPO requirements are inordinately high.

the hemostatic and thrombolytic systems have been studied in detail. [303] [307] The results of these studies indicate that rhEPO improves the platelet/vessel wall interaction, possibly by improving platelet adhesion to the subendothelium via serotonergic mechanisms. The bleeding time is significantly shortened, while platelet aggregation in response to collagen and ristocetin is improved. Although levels of protein C and S and antithrombin III are decreased following rhEPO administration, these changes are counterbalanced by diminished activity of inhibitors of thrombolysis ($_2$ -antiplasmin, C1 esterase inhibitor, and plasminogen activator inhibitor). [303] [307]

Correction of anemia with rhEPO is associated with improvements in cardiovascular parameters, including a decrease in cardiac output and resting heart rate. [308] [309] [310] [311] Improved exercise capacity has been documented after 1 year of therapy and is accompanied by reduced left ventricular hypertrophy and exercise-induced cardiac ischemia.[310] [311] These changes in cardiovascular function may in part explain why rates of hospitalization are reduced in new hemodialysis patients receiving rhEPO versus those not receiving therapy.[312] In addition, rhEPO therapy has been associated with reversal of insulin resistance, improved glucose tolerance, and normalization of amino acid levels (valine, leucine, and isoleucine) and plasma lipid levels (triglycerides, total cholesterol, and low-density lipoprotein cholesterol). [313] [314] Although the mechanisms of these actions are unknown, improved local oxygenation of target tissues, reduced plasma lactate levels, and diminished iron toxicity to hormone-producing organs have been speculated to be important.

The side effects of EPO rarely require discontinuation of therapy. Most patients develop a mild sensation of aching in the long bones during administration of the drug. Approximately one-third of patients develop diastolic hypertension, an effect that is not explained by hypervolemia since blood pressure elevation occurs despite intensive efforts to prevent hypervolemia by maintaining patients at their dry weight. [276] It has been suggested that hemodialysis patients with a family history of hypertension are particularly susceptible to EPO-induced hypertension, whereas age, sex, etiology of renal dysfunction, and duration of hemodialysis therapy have no predisposing effect.[315] Mean 24-hour systolic and diastolic ambulatory blood pressure measurements are significantly increased, particularly in patients with borderline systolic hypertension.[316] Mechanisms of vascular wall damage in uremia are undefined. Progression of vascular injury during hemodialysis is well described.[317] [318] Although a rise in peripheral vascular resistance has been reported after EPO treatment, [319] levels of circulating vasoactive substances (including renin, adrenaline, angiotensin II, dopamine, endothelin, and atrial natriuretic peptide) remain unchanged. [320] [321] Early reports suggested that rhEPO may have a direct vasopressor effect on renal blood vessels.[322] Subsequent study using laser-Doppler flowmetry indicates that rhEPO does not alter microcirculatory blood flow. [323] Together, the results of these multiple studies show no apparent direct vasoconstrictor effect of rhEPO.

Initial concerns that correction of anemia with rhEPO might impair dialysis efficacy [300] [324] have not been verified. High-flux dialysis neither worsens azotemia nor shortens access survival, and may actually improve urea and acid-base balance. [301] Increasing the intensity of dialysis in patients with anemia who receive inadequate dialysis has been shown to improve anemia.[325] The response to rhEPO was found to correlate with a reduction in the levels of blood urea nitrogen and

serum albumin, with a poor response associated with a urea reduction rate of <65% during dialysis. [325] Together, these results suggest that correction of anemia in patients receiving rhEPO is enhanced by maintaining an intense dialysis regimen.

The correction of erythropoiesis to normal levels by EPO therapy may uncover iron deficiency and aluminum toxicity. Most patients receiving hemodialysis require 610 g of parenteral iron annually to maintain a normal serum iron level and transferrin saturation. [326] The most common cause of acquired EPO resistance is development of iron deficiency associated with increased utilization of iron as erythropoiesis is accelerated. [327] [328] Nearly one-half of patients with renal insufficiency who receive EPO therapy will need iron replacement therapy. Several screening tests have been used to identify patients with iron deficiency while receiving rhEPO therapy for anemia associated with renal failure. These include the transferrin saturation (in patients without hypoproteinemia) and the mean corpuscular volume (MCV). [329] [330] [331] [332] Administration of intravenous iron dextran improves not only the serum iron level and transferrin saturation but also the reticulocyte count and hematocrit (Fig. 148-4 (Figure Not Available)). Iron supplementation adequate for restoring a response to EPO may be given by both oral and intravenous routes of administration. [333] [334] It has been suggested that when evidence of iron deficiency has been documented (such as the development of microcytosis or a decrease in transferrin saturation), oral iron replacement therapy be initiated. [335] If oral iron therapy fails to improve the anemia, replacement of iron stores by either intravenous iron dextran therapy or blood transfusions may be considered.

Aluminum overload may diminish bone marrow response to EPO. In a study of >300 patients, an inverse correlation between serum aluminum levels and magnitude of hematologic response to EPO was documented.[336] Finally, resistance to rhEPO therapy in chronic renal failure patients on dialysis has been attributed to secondary hyperparathyroidism.[337] Those uremic patients who have a poor response to rhEPO therapy have a greater degree of fibrosis of the bone marrow (Fig. 148-5), a greater percentage of osteoplastic and eroded bone surfaces, and a higher serum level of parathyroid hormone relative to patients having a favorable response to therapy.[191] By contrast, the percentages of osteoid volume and surface, osteoid thickness, and stainable aluminum content of the bone in these individuals were similar in both the favorable and unfavorable response groups. Treatment of secondary hyperparathyroidism by parathyroidectomy or parenteral calcitriol therapy results in improvement in levels of hemoglobin and hematocrit[338] (Fig. 148-6) and regression of myelofibrosis.[339]

Correction of Bleeding

Infusions for uremic bleeding have not been confirmed by others [340] and their use is not recommended for routine management of uremic bleeding. In patients with hemorrhagic complications or those undergoing major surgical procedures, the adequacy of dialysis should be checked. [341] Acute bleeding can be treated with infusions of DDAVP at a dose of 0.3 mg/kg given intravenously or subcutaneously. [181] [341] DDAVP can also be administered intranasally at a dose of 3 mg/kg.[341] The hemostatic effect of DDAVP lasts only a few hours and may be lost if the drug is administered repeatedly. [341] Because the favorable effect of cryoprecipitate has not been uniformly observed, its use is not recommended.[340] [341] Long-lasting hemostatic competence may be achieved with infusions of conjugated estrogens[341] [342] [343] at a cumulative dose of 3 mg/kg administered over 5 days in individual doses given intravenously. [341] [342] [343]

Transfusional Hemosiderosis

Iron overload due to iron administration in the form of blood transfusion or parenteral iron supplementation frequently complicates end-stage renal failure. Serum ferritin levels of >300 mg/ml may be anticipated when iron intake exceeds daily losses over a protracted period of time. Because hemodialyzed patients with transfusional iron overload may develop widespread organ dysfunction, including glucose intolerance, impaired cardiac ventricular function, reduced pituitary reserves,

Karger AG, Basel.)*

and noncardiac myopathy,[344] care must be taken not to administer parenteral iron without careful assessment of iron stores. Because gastrointestinal absorption is diminished in iron-overloaded uremic patients, [345] oral iron may be administered safely, unless the patient is genetically predisposed to hemochromatosis. Desferrioxamine may be used to remove iron stores from dialysis patients who are iron-overloaded. [346] [347] When using chelators, it is important to calculate the interval of treatment relative to transfusional iron intake and dialyzer iron loss.

Chapter 149 - Hematologic Aspects of Pregnancy

Thomas P. Duffy

INTRODUCTION

Pregnancy constitutes a major challenge for the hematologic and hemostatic resources of a womans body and requires a dual focus on the mother and fetus to recognize and treat any complications in this arena. As pregnancy progresses, a hypercoagulable state develops in anticipation of the hemorrhagic insult that accompanies placental separation.[1] The expectant mother is thus doubly jeopardized by an increased risk of thromboembolism and the many hemorrhagic complications of the pregnant state. In addition, therapies chosen to manage a maternal problem must be modulated according to their potential for damage to the fetus.[2] Any antecedent hematologic lesion will obviously further complicate and be complicated by a pregnancy. The hematologic problems of pregnancy are therefore the shared responsibility of the obstetrician, pediatrician, and the hematologist as their varied expertise and knowledge are integrated for the benefit of the mother and child.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ANEMIA

The physiologic expansion of the expectant mothers blood volume consists of an increase in plasma volume (4060%), which is approximately twice the simultaneous expansion in the red blood cell (RBC) mass (2050%); this hydremia of pregnancy results in a fall in hematocrit to the 3032% range, requiring a revision downward (to 10 g%) of the lower limits of a normal hemoglobin during pregnancy[3] (Table 149-1). The expanded blood pool of the mother compensates for the increased metabolic and perfusion needs of the fetal-placental unit and serves as a reservoir to compensate for blood loss at delivery of the infant.

Anemia occurring during pregnancy is most frequently a reticulocytopenic, hyporegenerative anemia attributable to deficiencies of iron or folate, or both. To provide iron for fetal hemoglobin synthesis and to anticipate the losses due to bleeding, approximately 4 mg of absorbed iron each day or a total of 1,000 mg of additional iron is needed during the course of pregnancy. This amount is greater than the normal 500-mg iron storage pool present in most women, and an iron-deficient state with low ferritin levels frequently occurs in the mother.[4] [5] However, delivery of iron to the placenta continues, with a rerouting of the normal vector of iron transport to the heavy concentration

TABLE 149-1 -- Plasma Volume, Red Cell Volume, Total Blood Volume, and Hematocrit in Pregnancy

	Nonpregnant	Weeks of Pregnancy		
		20	30	40
Plasma volume (ml)	2,600	3,150	3,750	3,850
Red cell mass (ml)	1,400	1,450	1,550	1,650
Total blood volume (ml)	4,000	4,600	5,300	5,500
Body hematocrit (%)	35.0	32.0	29.0	30.0
Venous hematocrit (%)	39.8	36.4	33.0	34.1

From Hytten, [3] with permission.

of transferrin receptors on the placental trophoblastic membranes.[6] This major demand on the iron stores overwhelms most womens marginal storehouses of iron. Iron supplementation (300 mg ferrous sulfate daily) is administered to pregnant women in anticipation of this drain on their limited stores. [7]

Folate deficiency may also complicate pregnancy because of a similar escalation in the need for this essential cofactor in nucleic acid synthesis during pregnancy; folate lack not only poses the threat of anemia during pregnancy but also the complication of neural tube defects and cleft palate formation in the fetus. [8] The total body stores of this vitamin are small and short-lived. Nausea and vomiting during pregnancy may significantly impair its intake. Pure folate deficiency results in a macrocytic anemia or even pancytopenia, but the expected elevation of RBC mean corpuscular volume may be masked during pregnancy by the contribution of concomitant iron deficiency.[9] This combined deficiency may produce normocytic indices, although review of the peripheral smear often reveals a dimorphic population of RBCs and the hypersegmentation of polymorphonuclear neutrophils that indicate megaloblastic hematopoiesis. RBC sizing index curves may uncover the two distinct cell populations that characterize combined iron-folate deficiency. Most prenatal vitamins contain folate in addition to iron, so proper prenatal care of expectant mothers should obviate these problems.[10] [11] There is little concern that folate will mask vitamin B_{12} deficiency because women with this deficiency are usually older or infertile, or both.

A few other causes of reticulocytopenic anemia are directly related to pregnancy. Several cases of aplastic anemia complicating pregnancy have been described; the outcome is usually determined by the severity of the marrow lesion and the threat of leukopenia-associated infection. [12] [13] [14] Although some consider this a chance association, the resolution of the aplasia after delivery or abortion and the documented recurrence of aplasia in subsequent pregnancies makes a causal, perhaps immunologic, mechanism likely. The severity of the aplasia and the ability to support the patient help to determine the decision regarding continuation or termination of the pregnancy. Pure RBC aplasia has also been associated temporally with pregnancy. [15] Congenital aplastic anemia or Fanconi anemia may paradoxically not be manifest until the childbearing age. Instances of successful childbirth have occurred in such patients with meticulous hematologic support. [16]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

LEUKOCYTOSIS/LEUKEMOID REACTIONS/LEUKEMIA

An elevated white blood cell count with a differential revealing a rare myelocyte or metamyelocyte can occur in pregnancy. [17] Dohle bodies may also be present; this may lead to confusion in assessing the possibility of intercurrent infection. Because the count returns to normal after delivery, it is likely that the leukocyte elevation is secondary to the steroid or cytokine alterations that accompany pregnancy.

Differentiation of a leukemoid reaction from leukemia should not present any unique difficulties when this question arises during pregnancy. Flow analysis and chromosomal studies

---

help resolve any confusion in the rare pregnant patient with leukemia. When leukemia or other hematologic malignancies complicate pregnancy, management is influenced by the stage of pregnancy at which diagnosis is made, the clinical effects of the disease, and the anticipated toxic effects of chemotherapy or radiotherapy (or both) on the mother and child. [18] Because the most active stage of organogenesis is the first trimester, recommendations regarding the continuation of pregnancy would differ greatly in this setting from those of a woman with leukemia or lymphoma at a later stage of pregnancy. There are several reports of successful, uncomplicated births after chemotherapy for leukemia and lymphoma, [19] [20] but the most common outcomes are abortion and fetal loss. Promyelocytic leukemia has been treated with retinoic acid during pregnancy without fetal complications. [21] When chronic leukemias occur during pregnancy, leukapheresis may serve as a delaying device until delivery is possible. [22]

THROMBOCYTOPENIA

Although some of the data conflict, ample evidence shows that the platelet count does not deviate from normal limits during an uncomplicated pregnancy. [23] Thrombocytopenia (<150,000/L) in the expectant mother requires consideration of the usual causes of a lowered platelet count as well as diatheses unique to pregnancy. Most authors would restrict these concerns to women with platelet counts of <100,000/L; a platelet count of 100,000150,000/L, newly discovered during an otherwise uncomplicated pregnancy, is not thought to pose any threat to the fetus. [24] This so-called gestational thrombocytopenia is not considered an indication for fetal blood sampling or therapeutic intervention, although the cause of the thrombocytopenia should be investigated and identified if possible. [25]

Finding and eliminating the cause of thrombocytopenia have special significance because it can threaten both the mother and the fetus. Thrombocytopenia in the fetus has important implications for determining the method of delivery and defining the postnatal needs of the infant. The situation is even more complicated in patients with qualitative platelet abnormalities such as the Bernard-Soulier syndrome and Glanzmann thrombasthenia; these patients require platelet support during delivery, even if the numbers of platelets are normal, to compensate for their lack of effective platelet function. [26]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura (ITP) has a pronounced incidence in young adult women. The immunologic alterations of pregnancy may create the same sensitization, and thus, it is not surprising that ITP may complicate the course of pregnancy. The same diagnostic criteria are used as for standard ITP. [27] Platelet-associated IgG is frequently detectable in ITP, but this sensitive assay is relatively nonspecific. Demonstrable serum antiplatelet antibodies are more specific for this diagnosis and are usually directed against platelet glycoproteins GPIIb/IIIa or GPIb/9. [26]

Therapy for ITP during pregnancy is basically the same as during the nonpregnant state. [29] Steroids, starting at 1 mg/kg of prednisone and titering according to the platelet response, are initiated for platelet counts <30,000/L; some clinicians reserve steroid use for thrombocytopenic patients with prolonged bleeding times (>20 minutes) or with demonstrated bleeding.[30] If the patient is refractory to steroids or if there are contraindications to steroid use, intravenous immunoglobulins constitute an additional effective therapy for ITP. [31] Because the platelet-elevating effect of the latter is relatively short-lived (3 weeks), it may be necessary to punctuate the regimen with weekly to biweekly immunoglobulin infusions. With the availability of these two modalities, it is usually possible to avoid splenectomy, an operation that carries the risk of fetal loss. If splenectomy is required, the first portion of the second trimester is probably the optimal time for this intervention.

The fetus is also a candidate for development of thrombocytopenia because of transplacental passage of antiplatelet IgG in ITP. Either fetal scalp vein sampling during labor[32] or umbilical vein sampling before labor [33] is used for diagnosis and to influence the method of delivery of the affected fetus; a fetal platelet count of >50,000/L is considered adequate for vaginal delivery. Initial enthusiasm for using the level of maternal serum antiplatelet antibodies as a means for anticipating thrombocytopenia in the fetus has waned;[34] it has been documented that the infants platelet count in a previous pregnancy is an excellent predictor of the count in subsequent pregnancies of mothers with ITP. [35] There is support for the administration of steroids to mothers with ITP in the 3 weeks before delivery for their effect on the platelet count of the mother; [36] there is controversy as to the transplacental passage of steroids and their postulated positive effects on the fetal platelet count. [37] [38] Administration of immunoglobulins to a thrombocytopenic mother does not appear to influence the platelet count of the fetus. [39]

PRE-ECLAMPSIA AND ECLAMPSIA

The specific pathophysiologic mechanisms that cause eclampsia are not known. Abnormal platelet-endothelium interactions, with excessive platelet consumption, are thought to be major components of this hypertensive disorder.[40] [41] There is also support for a more minor contribution from disseminated intravascular coagulation (DIC) in eclampsia,[42] because low antithrombin III levels[43] and elevated D-dimers of fibrin split products[44] are observed. The platelet decrement usually outdistances any evidence for fibrinogen consumption in eclampsia. The marked imbalance in the thromboxane/prostacyclin plasma levels in eclamptic patients has been suggested as a causal factor in the development of this process. The sevenfold thromboxane excess contributes to both increased platelet consumption and vasoconstriction.[45] The role of acetylsalicylic acid in preventing the development of eclampsia remains controversial, creating questions regarding the primacy of platelets and arachidonic metabolites in causing eclampsia.[46] [47] [48] [49] [50] Plasma endothelin levels are also elevated, suggesting some causal role for this potent vasoconstrictor as well.[51]

When thrombocytopenia is discovered in a patient with classic evidence for pre-eclampsia (>30-mm Hg rise in systolic or >15-mm Hg rise in diastolic pressures from baseline, proteinuria 0.3 g/L/24 hours, and edema) or eclampsia (seizures/coma), the cause of the thrombocytopenia is easy to identify. Thrombocytopenia develops in 50% of patients with pre-eclampsia. However, thrombocytopenia may also accompany hepatic forms of toxemia, in which the more classic signs of pre-eclampsia are absent.[52] Acute fatty liver of pregnancy is one of these variants. Clinical attention is drawn to and focused on the hepatic abnormalities. Liver biopsy specimens of eclamptic patients demonstrate the same fatty changes with the fat content of the liver paralleling the degree of thrombocytopenia.[53]

The hematologic alterations in pregnancy sometimes extend to encompass a clinical entity that includes a hemolytic anemia.[54] The so-called HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) may or may not be associated with increased blood pressure, edema, or proteinuria.[55] Most patients with the HELLP syndrome present with malaise and right upper quadrant or epigastric pain, often diverting the physicians attention from the recognition of a toxemic state.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Several cases of thrombotic thrombocytopenic purpura (TTP) during pregnancy have been reported in the literature, but the

appearance of a TTP-like picture during the third trimester of pregnancy may actually be toxemia masquerading as TTP. [56] The pentad of TTP (fever, hemolytic anemia, thrombocytopenia, renal disease, and central nervous system disease) may all be present in toxemia except for fever. The management of a patient with this constellation during the last trimester of pregnancy is delivery of the infant and not the complex interventions used to treat classic TTP. When TTP appears earlier in pregnancy, steroids and plasma infusions [57] with and without plasmapheresis have been used successfully; uterine evacuation has also been used with successful reversal of the picture. [58]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DIC

The most frequent causes of bleeding in obstetric patients are the many pathologic precipitants of DIC. These have their origin in the entrance of the products of conception into the systemic circulation.[59] Slow DIC is now infrequently a problem because its cause, fetal death in utero, is easily recognized by ultrasound and can be corrected by induction of delivery with blood component support to correct any coagulation abnormalities; delivery of the dead fetus removes the source of the DIC, which is thought to be the tissue thromboplastin released from the decomposing fetus.[60]

A rapid and frequently fatal form of DIC accompanies clostridial sepsis; this unfortunate aftermath of illegal abortions is also characterized by severe intravascular hemolysis, attributable to the direct bacterial by-product attack of lecithinase on the lipid component of the RBC membrane.[61] Fast DIC also accompanies abruptio placentae[62] and amniotic fluid embolism.[63] The major complication of the former is hemorrhage, whereas the latter is usually complicated by cardiopulmonary collapse in addition to hemorrhage. Treatment of DIC associated with abruptio placentae consists of stabilization of the clotting disorder with the necessary blood component support, followed by delivery of the infant.

The epidemic of cocaine addiction has seen an increased incidence of abruptio placentae in which cocaine is thought to play a causal role. Amniotic fluid embolism is usually fatal (85% mortality), primarily as a result of cardiovascular collapse. This life-threatening entity occurs most frequently during a difficult delivery in a multiparous woman. Hypoxemia, shock, and hemorrhage in this setting should suggest the diagnosis, and aggressive cardiopulmonary support, blood component administration, and steroids have been recommended for its management.

Fast and slow DIC represent the most dramatic occurrences of DIC during pregnancy. However, evidence for DIC also exists in patients who have hypertonic saline- and urea-induced abortions.[64] This complication is usually fleeting and disappears shortly after the fetus is delivered. No therapeutic intervention is usually necessary. Heparin therapy is not indicated in this situation or in most other forms of DIC complicating pregnancy. Successful heparin treatment of DIC associated with a single fetal death in a twin pregnancy has been reported;[65] this may have implications for management of a multiple pregnancy now that selective destruction of some of the fetuses is performed.[66]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PREGNANCY AND THROMBOSIS

Pregnancy constitutes a hypercoagulable state with a progressive increase in the concentration of clotting factors and a decrease in the bodys fibrinolytic capacity. A specific plasminogen activator inhibitor is produced by the placenta. [67] This situation, when coupled with stasis due to obstruction of venous return by an enlarging uterus, explains the dramatically increased incidence of venous thrombosis that occurs during pregnancy and the puerperium. [68] Thrombosis of the pelvic and lower extremity vessels is common. Diagnosis and treatment are influenced by their potential for damage to the fetus (see box, Anticoagulation Therapy During Pregnancy).

ANTICOAGULATION THERAPY DURING PREGNANCY

No form of anticoagulation is without significant risk during pregnancy. [69] A firm diagnosis of thrombosis or embolism, or both, must be made before initiating any therapy. This may entail using the gold standard of venography, with shielding of the uterus, to document the thrombosis if impedance plethysmography is not available. The risk of the radiographic procedure is thought to be offset by the greater certainty that venography allows in dictating the need for anticoagulation. [70] The same is true for ventilation/perfusion scans or pulmonary angiography as a means of diagnosing pulmonary embolism in the same population.

The maternal and fetal morbity and mortality due to anticoagulation make family planning counseling essential for an individual who requires chronic anticoagulation. [71] Patients with artificial prosthetic valves require continuation of anticoagulation throughout pregnancy and must recognize that only one-third of pregnancies in which coumadin is administered during the first trimester result in normal live-born infants. [72] [73] Heparin administration is not clearly superior, although the risk of abnormalities in live-born infants is less. Heparin does not cross the placenta and is not associated with any specific embryopathy. Heparin, however, leads to bone demineralization in the mother and in about 10% of patients results in thrombocytopenia. Low-molecular-weight heparins appear to offer advantages over standard-dose heparin during pregnancy, both for prophylaxis and treatment of thrombotic disorders; bone demineralization and thrombocytopenia are not avoided by the use of this form of anticoagulation. [74] [75] [76] [77]

Because both coumadin and heparin pose serious risks during pregnancy, some clinicians use them sequentially to dampen the risk of one and capitalize on the convenience of the other. Standard heparin or low-molecular-weight heparin is used during the first trimester, with a subsequent switch to oral coumadin; close to the end of pregnancy, heparin or low-molecular-weight heparin is used and then stopped as described above at the time of delivery. Heparin or coumadin can be reintroduced postpartum because neither drug is a threat to nursing infants. Thrombolytic agents are contraindicated in pregnancy because of their risk of severe hemorrhage.

Because of the high incidence of recurrent thrombotic events with subsequent pregnancies, expectant mothers with a previous history of deep venous thrombosis or pulmonary embolism have usually been prophylactically anticoagulated. Low-molecular-weight heparin, with its once daily dosing, is an attractive option for this indication during pregnancy. [78] Anticoagulation is sometimes withheld as prophylaxis; dextran is administered at and around the time of delivery, and heparin is initiated in the postpartum period; a small series has demonstrated the safety and utility of this alternative management. [79]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PREGNANCY AND THE HEMOGLOBINOPATHIES

The vogue for prophylactic exchange transfusions in sickle cell anemia has waned and has given way to watchful anticipation

MANAGEMENT OF SICKLE CELL DISORDER

Management of the patient with sickle cell disorder during the delivery period remains controversial. Some would exchange transfuse such individuals if general anesthesia is required for delivery; the potential for an anesthetic accident with hypoxemia is the basis for this recommendation. Epidural anesthesia lessens this risk, but hypotension secondary to venous pooling may occur even with this modality; attention to fluid expansion, use of pressure leg wraps, and unweighting uterine compression of the vena cava by positioning the patient on the left lateral side lessen this risk.

of the patients course by the hematologist and obstetrician together. [80] Many series have demonstrated a high risk of stillbirths, abortions, and fetal growth retardation as the outcome of nontransfused sickle-cell pregnancies, but the contribution of poor prenatal care in this socioeconomically deprived group may have been the critical factor in these fetal losses. With good antenatal care and recognition of any backdrop of organ dysfunction, the usual patient with hemoglobin SS disease tolerates pregnancy without major morbidity for mother or child. Transfusions are reserved for any acceleration of the sickling disorder, worsening of anemia (hemoglobin <6 g%), or obstetric complications. [81] In light of the severe hemolytic component of this disease, folic acid must be adequately supplemented to guarantee that a hyporegenerative megaloblastic crisis does not occur. Iron therapy may also be needed because these young women frequently have meager iron stores even in the setting of hemolytic anemia (see box, Management of Sickle Cell Disorder).

The same concerns apply to individuals with other interacting hemoglobins (SC, S thal, and others) that participate in the sickling phenomenon. Sickle trait should pose no threat to pregnancy except for the need to recognize and treat properly the higher incidence of kidney infections. The probable contribution of infection to precipitation of premature labor makes such infection a more significant threat during pregnancy.

Thalassemia major is not a frequent problem for the obstetrician because such patients often suffer with failure of pubertal growth and delayed sexual development. Hypogonadotropic hypogonadism due to hemosiderin deposition in the hypothalamus makes these patients anovulatory and afertile. [82] However, there have been several reports of successful pregnancies in this patient population with a high risk of fetal loss. Cardiac iron disease may be present and may lead to heart failure during pregnancy; close attention to maintaining the hemoglobin at a level of 10 g/dl is important. Thalassemia intermedia and minor are not characterized by any special problems during pregnancy; ferritin levels in these groups may be adequate to permit dispensation from the need for iron supplementation during pregnancy. [83]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COAGULOPATHIES DURING PREGNANCY

The most common coagulopathy creating problems during pregnancy and delivery is von Willebrand disease (vWD). [84] Recommendations regarding the management of vWD must consider the spectrum of severity of the different subtypes of vWD and the relatively sparse experience in managing some of the more recently defined subtypes (see box, Therapy for von Willebrand Disease). Fortunately, in most of these patients, an increase in factor VIII coagulant and factor VIII antigen accompanying pregnancy frequently permits delivery without undue risk of bleeding. There remains the delayed risk of bleeding after delivery in these individuals because of the rapid return of coagulant levels to a nonpregnant deficient state. In such patients, the bleeding time is an important parameter to monitor and correct with desmopressin or concentrate as necessary.

Some individuals with vWD, especially those with the type III variant, have persisting very low to absent von Willebrand factor (vWF) levels throughout pregnancy and demonstrate a poor response to desmopressin infusions. Factor VIII concentrates that contain vWF should be administered to these patients if a cesarean section is performed; support should continue for 57 days after the delivery. The previous recommendation, that all such patients with severe vWD undergo cesarean section to protect the fetus, should be modified now that prenatal sampling of fetal blood allows identification of infants with the disorder.

The remainder of the inherited coagulopathies are not a major threat unless the coagulant levels are <25% of normal. [87] Fresh frozen plasma infusions or factor concentrates during and 45 days after delivery are the universal solution to these deficiencies, with monitoring of coagulant levels to gauge the adequacy of the replacement therapy. Factor XIII deficiency presents a special problem during pregnancy because of its association with spontaneous recurrent abortions and marked uterine bleeding; regular plasma infusions or factor XIII concentrates during pregnancy have sustained a normal pregnancy in the presence of factor XIII deficiency. [88]

Acquired inhibitors of coagulation factors may occur in the postpartum period with factor VIII antigen the most common target for these circulatory anticoagulants. Porcine factor VIII, factor VIII inhibitor bypass activity, and recombinant factor VII all are options to treat bleeding complications of this coagulopathy, although standard factor VIII concentrates are usually successful in neutralizing low levels of the inhibitor. The inhibitors often persist for months without any benefit from immunosuppression; fortunately, there is little risk for recurrence of the inhibitor in subsequent pregnancies. [89]

LUPUS ANTICOAGULANT AND PREGNANCY: ANTIPHOSPHOLIPID SYNDROME

The lupus anticoagulant (LA), an immunoglobulin of the IgG or IgM subclass, prolongs phospholipid-dependent coagulation tests by interfering with the essential phospholipid skeleton of

THERAPY FOR VON WILLEBRAND DISEASE TYPE IIB

The type IIB subtype presents an additional layer of complexity because a progressive diminution in platelet count accompanies the pregnancy-associated increased synthesis of this variant form of vWF. [85] The appearance of thrombocytopenia during pregnancy is, in fact, grounds for considering this diagnosis, wherein the interaction of the abnormal vWF and platelets results in thrombocytopenia.[86] Because of this interaction, administration of desmopressin to such patients has been proscribed, although there remains some question as to the appropriateness of this admonition. Patients with type IIB vWD have had normal vaginal deliveries without excessive bleeding even in the presence of significant thrombocytopenia. Factor VIII concentrate that contains vWF can successfully prevent bleeding in this condition when needed.

the coagulation cascade. [90] A positive test result for syphilis, a so-called biologic false-positive test, and anticardiolipin antibodies (both tests having phospholipids as their target antigens) are frequent accompaniments of the LA. Individuals possessing such antibodies often develop thrombocytopenia and thromboses involving both the arterial and venous circuits; [91] the antibodies may be a factor implicated in creating the thromboses because plasma from LA patients inhibits vessel wall generation of prostacyclin, a vasodilator and powerful inhibitor of platelet aggregation. The procoagulant role of LA plasma may not be restricted to prostacyclin inhibition because other investigators have demonstrated defective thrombomodulin activation of protein C in the presence of LA plasma; [92] reduction in levels of annexin V, a potent phospholipid anticoagulant protein on vascular endothelial cells, is another possible mechanism of thrombosis and pregnancy loss in the antiphospholipid-antibody syndrome. [93] Whatever the role of the phospholipid antibody in the process, the LA is paradoxically a marker for an increased risk of thrombotic episodes, including strokes.

Nowhere is this thrombotic tendency more threatening than in the association of the LA with first-trimester abortions and fetal deaths in the second and third trimesters.[94] The lesion in many of these women is a thrombotic process involving the decidual and placental vessels; the absence of such findings in other LA patients forces the conclusion that the pathogenetic mechanisms of the antiphospholipid antibodies must still be clarified. Because the fetal loss syndrome is well identified in mothers with anticardiolipin antibodies who lack LA, the phospholipid target of the antibody appears to have the most significance, especially when the target of the antibody includes the epitope $_2$ -globulin.[95]

Any mother with systemic lupus erythematosus (SLE) or a history of fetal loss should be screened for antiphospholipid antibodies. The LA is not restricted to women with SLE, and there is no relationship of the antibody to the activity of the disease or even to anti-DNA activity. [96] The activated partial thromboplastin time or the more sensitive Russells viper venom time[97] is a good screen for the presence of the LA; a low titer-positive serologic test result for syphilis is sometimes the clue that LA is complicating a pregnancy. Because the anticardiolipin antibody is only loosely associated with LA in patients with SLE, separate testing for this antibody should also be performed because it may be an earlier and more important predictor of fetal distress [98] (see box, Therapy for Lupus Anticoagulant).

THERAPY FOR LUPUS ANTICOAGULANT

Optimal treatment of the pregnant patient with the LA remains to be determined. The use of prednisone and aspirin as a means of reversing the poor outcome of such pregnancies has not been validated when compared with placebo controls. Therapeutic intervention with standard heparin has permitted successful pregnancies; thromboprophylaxis with low-molecular-weight heparin also appears to be efficacious in managing thromboembolic disease in these patients. [99] [100] [101] Doppler ultrasound monitoring of placental blood flow has been suggested as a means of charting the pathologic effects of the antibody on the vascular bed and helping define the need for infant delivery. [102] The complex clinical scenarios in these patients and the gaps in our knowledge regarding the pathophysiology of the disease make necessary a close collaboration among obstetricians, hematologists, and pediatricians in their care.

HYPERCOAGULABLE STATES AND PREGNANCY/MYELOPROLIFERATIVE DISORDERS

Primary or essential thrombocythemia in a pregnant woman may lead to the development of multiple placental infarcts, fetal loss, or fetal growth retardation. [103] [104] A combination of dipyridamole and aspirin has been administered with a successful outcome in such pregnancies; plateletpheresis has been performed immediately before delivery with effective lowering of the platelet counts. Interferon- has been used successfully during pregnancy in essential thrombocytosis without fetal complications.[105] Of note, essential thrombocytosis has also resolved during pregnancy with the disappearance of its threat of thrombosis. Monitoring of thrombocythemic pregnancies with Doppler ultrasound studies of placental blood flow has been recommended as a means of gauging the need for platelet reduction by pheresis earlier in the pregnancy.

Pregnancy complicated by polycythemia vera has been infrequently reported; the perinatal outcome has been poor, with significant fetal loss. [106] Attention must be paid to maintenance of a hematocrit in the 40% range with phlebotomy used to maintain that level. Iron supplementation needs careful monitoring and limitation to avoid erythrocytosis. Because of the frequent association of thrombocythemia with erythrocytosis in polycythemia vera, some clinicians recommend the use of low-dose heparin during and after delivery, although this approach is not without controversy. There is usually a rapid rebound in the hematocrit after delivery, requiring special vigilance to prevent threatening erythrocytosis at that time. Interferon- has been used successfully to control disease activity in myeloproliferative disorders during pregnancy without damage to the fetus; this agent may permit a smoother control of the blood counts, but experience with its use during pregnancy is still limited. [107]

Activated protein C resistance plays a prominent and threatening role in enhancing thrombosis during pregnancy and with oral contraceptive use. Because 5% of the white population is heterozygous for the gene and such heterozygotes are hypercoagulable, this mutation is the most common cause of a hypercoagulable state in the general population[108] and the most frequent cause of thrombophilia during pregnancy. Coinheritance of activated protein C resistance with other prothrombotic disorders such as protein C deficiency or homocysteinuria exaggerates the risk of thrombosis in the latter disorders. Identification of activated protein C resistance as a cause of thrombosis during pregnancy calls for standard anticoagulation administration and consideration of anticoagulant prophylaxis during subsequent pregnancies. Universal screening of pregnant women or oral contraceptive users is not recommended although any family or personal history of thrombosis would be an indication for such screening. [109] [110]

Deficiencies in proteins C and S and antithrombin III are all associated with an increased risk of venous thrombosis and fetal loss. Protein C deficiency dramatically increases the risk of deep venous thromboses during pregnancy; [111] [112] there is a 25% incidence of deep venous thrombosis in pregnancy and the puerperium in patients with this autosomal dominant inherited disorder. Therapy recommended for management of protein C deficiency is ambulatory full-dose subcutaneous heparin; protein C concentrates are also now available to correct this deficiency. [113] Protein S deficiency carries the same risks and implications for anticoagulation.

Antithrombin III deficiency is also a common inherited procoagulant state. Thrombotic events may occur during pregnancy or after delivery in 70% of such cases. [114] [115] Management of these patients has included heparin (20,000 U subcutaneously, twice a day) during the first 44.5 months and coumadin in the remainder of pregnancy to the 36th or 37th week; heparin is then introduced and withdrawn before delivery, at which time

a single infusion of antithrombin III (3,500 U) has been given. Low-molecular-weight heparin is an attractive alternative to this management. Heparin is again restarted in the postdelivery period until coumadin is introduced.

Approximately 50 cases of pregnancy in women with paroxysmal nocturnal hemoglobinuria have been reported; [116] these pregnancies have been complicated by venous thromboses involving the lower extremities and the hepatic and cerebral vasculatures. Anticoagulation with low-dose heparin or low-molecular-weight heparin is recommended for these patients if they are confined to bed during the pregnancy. This disease may also witness worsening of marrow aplasia during pregnancy and an increased number and severity of hemolytic crises. Transfusions with washed RBCs to maintain the hemoglobin at 10 g% is suggested, with particular attention toward preventing hemolytic crises after delivery. The fetus in such pregnancies needs monitoring for neonatal isoimmune hemolysis because of the risk of maternal sensitization after transfusions.

Chapter 150 - Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Charles W. Francis
Karen L. Kaplan

INTRODUCTION

Surgery represents a dual challenge to the hemostatic system. First, bleeding must be stopped rapidly at the operative site, but thrombosis must be prevented also. Hemostatic failure can result in a variety of bleeding complications that are well known to the surgeon. They may be mild with an increased transfusion requirement or excessive oozing at the operative site, or more severe, resulting in blood loss with shock in the postoperative period, internal hematomas that compromise organ function, or occasionally death from uncontrolled hemorrhage. On the other hand, thrombotic complications occur frequently in the postoperative period. They are related to hemostatic changes resulting from surgery, including local damage to vessels, venous stasis, and alterations in the fibrinolytic and coagulation systems. The prevention and treatment of thrombosis in surgical patients requires difficult choices and administration of drugs that interfere with hemostasis in the perioperative period when the risk of bleeding is high. Surgeons are well aware of the hemostatic requirements of operative procedures and manage most cases routinely and many that present with hemostatic problems without assistance. However, consultation is often requested for complex or difficult problems, including preoperative evaluation of hemostasis in patients with known hemostatic defects, treatment of unexpected intra- or postoperative bleeding, prophylaxis of deep vein thrombosis in high-risk patients, and treatment of thrombosis in the perioperative period.

PREOPERATIVE EVALUATION OF HEMOSTATIC RISK

Preoperative evaluation of hemostasis occurs at two levels. First is the routine evaluation needed in all patients before surgery to identify those with potential abnormalities of hemostasis. An adequate history is the most effective screening modality for adults and may be based on a questionnaire [1] (Chap. 105), whereas the need for routine laboratory testing is controversial. Those against routine testing [2] point to retrospective studies[3] [4] indicating that they rarely detect unexpected bleeding disorders and also emphasize the problems in evaluating false-positive abnormalities. The bleeding time is a poor predictor of abnormal surgical bleeding. [5] A recent retrospective study found that the bleeding time in asymptomatic individuals had only a 5% positive predictive value for postoperative bleeding, [6] and the poor correlation between surgical bleeding and the bleeding time has also been found in a prospective study of patients having cardiac surgery. [7] A number of recent prospective studies have also concluded that routine screening laboratory tests (bleeding time, prothrombin time [PT], partial thromboplastin time [PTT]) in asymptomatic patients are not predictive of peri- or postoperative bleeding. [8] [9] [10] [11] [12]

Screening programs that recommend laboratory testing point to the asymptomatic nature of some hemostatic abnormalities that may cause surgical bleeding and the occasional failure to obtain a detailed history. [1] [13] [14] A prospective study of preoperative screening in children before tonsillectomy found both history and laboratory screening to have high specificity but a low positive predictive value for perioperative bleeding. [14] Another study found that perioperative blood loss in adult cardiothoracic surgery patients could be predicted with a model, including the bleeding time, PT, and platelet count. [15] Given the variety of potential hemostatic defects, however, no simple screening system will identify all patients at increased risk of bleeding. The level of hemostatic risk for the proposed surgery (Table 150-1) forms the basis for an approach to preoperative evaluation (Table 150-2). A hemostatic history should be obtained in all patients, and in patients having low-risk surgery no laboratory tests are required. For moderate-to-high risk surgery additional screening would include a PTT, PT, and assessment of the platelet count.

In practice, a hematologist is rarely consulted for routine screening because surgeons have adopted approaches based on their training and local practice patterns. Rather, consultation is sought because of a history suggesting a bleeding disorder or an abnormal test that is found on screening. The approach of the consultant cannot be one of screening because the judgment of the referring physician that a bleeding disorder may be present indicates a greatly increased probability of finding an abnormality. If a referral is obtained as a result of an abnormal screening test result, this finding must be pursued and the abnormality fully explained. However, for all referrals the history is of central importance and must include a thorough review of any bleeding episodes, including hospital records and results of prior hemostatic testing, as well as careful attention to the family history. The physical examination should focus on evidence of bleeding and also identifying systemic disorders such as hepatic or renal disease. If the history of bleeding is negative or minimal, appropriate laboratory testing would include a PT and PTT and a biochemical profile to evaluate hepatic and renal function. A complete blood count and examination of the peripheral blood smear are useful to identify a myeloproliferative disorder or thrombocytopenia. If the history is suggestive of a hemostatic abnormality, then a full evaluation is indicated and additional specific testing is usually required because von Willebrand disease, mild factor VIII, factor IX, factor XI deficiencies, factor XIII deficiency, platelet functional defects, and fibrinolytic abnormalities are not identified by global screening tests.

TABLE 150-1 -- Risk of Bleeding with Surgical Procedures

Risk	Type of Surgery	Examples
Low	Nonvital organs involved, exposed surgical site, limited dissection	Lymph node biopsy, dental extraction
Moderate	Vital organs involved, deep or extensive dissection	Laparotomy, thoracotomy, mastectomy
High	Bleeding likely to compromise surgical result, bleeding complications frequent	Neurosurgery, ophthalmic surgery, cardiopulmonary bypass, prostatic surgery, surgery to stop bleeding

TABLE 150-2 -- Preoperative Hemostatic Evaluation

Routine Screening

Surgical Risk	Approach
Low	History only
Moderate or high	History, PTT, PT, platelet count

Consultation

History	Approach
Negative or minimal for bleeding	PT, PTT, platelet count, biochemical profile, complete blood count and differential, review of peripheral blood smear
Suggestive of bleeding disorder	Add to above as indicated: bleeding time, ristocetin cofactor, von Willebrand antigen, factor VIII, factor IX, factor XI, factor XIII assays

MANAGEMENT OF PATIENTS WITH HEMOSTATIC ABNORMALITIES

Patients with known hemostatic abnormalities are often referred in anticipation of surgery for assessment of bleeding risk and recommendations regarding perioperative management. Generally, operation in the presence of a hemostatic defect is associated with increased operative risk, and this should be adequately discussed with both patient and surgeon. Even when the diagnosis is clearly established and adequate replacement therapy available the operative risk is increased by the possibility of bleeding. Several general considerations affect evaluation of risk and planning management. First, the risk of bleeding with the specific surgery planned must be evaluated (Table 150-1). The support of hemostasis for an extensive procedure such as pneumonectomy will be much more difficult than that for a lymph node biopsy. Second, both the need for surgery and its urgency must be carefully considered. Greater risks are more warranted for correction of a life-threatening condition such as bowel perforation than for elective cosmetic surgery. Finally, the nature and severity of the hemostatic abnormality and the ability to correct it during the operative period are of fundamental importance. Consideration must also be given to the duration of replacement that will be required with appreciation of potential bleeding associated with events in the postoperative period such as removal of sutures and deep drains and the need for physical therapy, especially after orthopedic surgery.

The following sections discuss perioperative management of some of the more common acquired coagulation abnormalities; therapies for congenital factor deficiencies and von Willebrand disease are discussed elsewhere in this text.

Thrombocytopenia

Thrombocytopenia is one of the most common acquired hemostatic abnormalities in hospitalized patients, and the availability of platelet transfusion has made consideration of both emergency and elective surgery reasonable even in severely thrombocytopenic patients. The best index of the likelihood of bleeding in thrombocytopenic patients is the platelet count, with a minimal risk of bleeding if the platelet count is 80,000/l and significant likelihood of increased bleeding if the count is 20,000/l (Table 150-3). Differences in platelet function must also be considered in evaluating the risk of thrombocytopenic bleeding because large platelets usually seen in idiopathic thrombocytopenic purpura (ITP) are more effective than normal, whereas platelets in myeloproliferative disease or uremia, or after administration of drugs that affect platelet function (especially aspirin or other nonsteroidal anti-inflammatory drugs) will be less effective. Other critical considerations for surgery in thrombocytopenic patients include clinical conditions that reduce platelet recovery or life span after transfusion, including splenomegaly, fever, infection, active bleeding, and presence of auto- or alloantibodies.

In preparation for elective surgery, therapy for the disorder causing the thrombocytopenia is the most satisfactory approach. For example, steroid or intravenous -globulin therapy for ITP may increase the platelet count so that transfusion is not needed, and surgery in patients with leukemia should be scheduled, if possible, after achievement of hematologic remission. The platelet count required for safe performance of surgery is controversial. A National Institutes of Health Consensus Development Conference recommended transfusion at a platelet count <50,000/l; [16] others suggest transfusion at platelet counts <80,000/l for general surgery and <100,000/l for cardiopulmonary bypass.[17] A reasonable approach involves considering the bleeding risks associated with surgical intervention (Table 150-1) in deciding both the necessary platelet count to be achieved and the duration of required platelet support after surgery. For low-risk surgery, a single transfusion to increase the platelet count to >50,000/l followed by close observation may suffice. Transfusion to keep the platelet count >50,000/l for moderate-risk surgery and >100,000 l for high-risk surgery is appropriate. The duration of platelet support required has not been carefully studied, but for moderate- or high-risk surgery platelets may be needed for <1 week because platelets are principally

TABLE 150-3 -- Surgical Hemostasis in Common Clinical Problems

Thrombocytopenia		
Platelet count	80,000/l <80,000 and>20,000/l 20,000	Bleeding unlikely Platelet transfusion may be needed Bleeding likely, platelet transfusion indicated
Acquired platelet dysfunction		
Bleeding history or bleeding time	>15 min	DDAVP if bleeding time shortens Platelet transfusion if DDAVP ineffective
Liver disease		
Prothrombin time	3 sec over control	Bleeding unlikely
	>3 sec over control	FFP indicated, vitamin K may be helpful Prothrombin complex may be needed but has thrombotic risk
Fibrinogen	<100 mg/dl	Cryoprecipitate indicated
Thrombocytopenia, platelet dysfunction		As above, but platelet recovery poor because of short half-life
Accelerated fibrinolysis (short eublogulin clot lysis time)		Antifibrinolytic may be indicated

Abbreviations: DDAVP, desmopressin; FFP, fresh frozen plasma.

required for primary hemostasis. The platelet count should be monitored closely during the postoperative period with the expectation that platelet survival will be shortened by infection, fever, or bleeding. A special case is splenectomy for patients with ITP when the primary site of platelet destruction is being removed. Platelet transfusion in anticipation of splenectomy is not effective because of the short platelet survival, and transfusion, if necessary, after the splenic artery has been clamped, should be more effective.

Liver Disease

The hemostatic abnormality of liver disease is complex and may be due to one or more of several factors, including decreased synthesis of enzymes and inhibitors of the coagulation and fibrinolytic systems, synthesis of abnormal fibrinogen, decreased clearance of activated factors, abnormal platelet function, and thrombocytopenia.[18] [19] The severity of the hemostatic abnormality parallels the overall severity of the liver disease, which represents the greatest determinant of surgical risk. Patients with severe decompensated liver disease and markedly abnormal coagulation tests are at great risk of bleeding, and surgery should be avoided

except as a lifesaving measure. In evaluating hemostasis in patients with less severe disease, the PT provides a good measure of decreased synthesis of vitamin K-dependent coagulation factors and factor V. The PTT is less helpful because it is relatively shortened by a high factor VIII until late in liver disease. In addition, a platelet count is needed to identify thrombocytopenia (usually secondary to hypersplenism) and a bleeding time may be useful to determine whether platelet function is abnormal in the setting of a normal or near-normal platelet count. A fibrinogen assay should be performed, as should a thrombin time to test for dysfibrinogenemia. Tests for fibrinogen/fibrin degradation products, D dimer, and euglobulin clot lysis time are useful in evaluating disseminated intravascular coagulation (DIC) or accelerated fibrinolysis.

In patients with mild disease and a PT prolongation of <3 seconds, serious surgical bleeding is unlikely in the absence of other hemostatic abnormalities and prophylactic intervention is not necessary for low- or moderate-risk surgery. For high-risk surgery or greater degrees of hemostatic abnormality, transfusion of fresh frozen plasma is the most useful approach for correcting the coagulation abnormality. The volume needed is guided by the correction of the PT, and the success of this approach is limited by the volume required in patients with low factor levels. It should be noted that the PT of fresh frozen plasma is about 15 seconds, so complete correction of the patients PT cannot usually be achieved. Exchange transfusion may be of value in extreme circumstances. Administration of platelets should be considered for thrombocytopenia, although recovery will be decreased in the presence of splenomegaly. Administration of desmopressin acetate (DDAVP) is useful in correcting abnormal platelet function in some cases. [20] Prothrombin complex concentrates provide vitamin K-dependent factors in a smaller volume than plasma and have been used successfully before liver biopsy or surgery [21] [22] but cannot be generally recommended because of the occasional occurrence of severe thrombotic complications [23] [24] due to the presence of activated factors in available preparations. Vitamin K deficiency is a correctable abnormality in patients with associated bile duct obstruction or those taking broad-spectrum antibiotics, and administration of 10 mg vitamin K will usually shorten the PT if vitamin K deficiency is a contributory factor. Insertion of peritoneovenous shunts is frequently associated with development of a consumption coagulopathy [25] [26] due to entry into the circulation of procoagulants from ascitic fluid. Treatment with antithrombin III (AT III) replacement has not been successful, [27] but administration of heparin has led to decreased consumption of fibrinogen and platelets in this condition. [28] AT III replacement also failed to affect blood loss or transfusion in liver transplant recipients. [29]

Platelet Dysfunction

Patients with platelet dysfunction represent a large group in whom preoperative consultation is sought, usually because of finding a prolonged bleeding time with a normal platelet count. The etiology may be obvious in cases of renal or liver disease or myeloproliferative syndromes, but may also require evaluation for intrinsic platelet dysfunction (storage pool disease or platelet release defects) or von Willebrand disease. The most frequent cause of platelet dysfunction is administration of drugs such as aspirin. A careful drug history is therefore essential and drugs that interfere with platelet function should be discontinued before surgery and avoided in the perioperative period if possible. The bleeding time may be useful in assessing the efficacy of therapeutic modalities such as DDAVP.

Treatment of the underlying disease is the most effective approach in many acquired disorders of platelet function such as renal disease or myeloproliferative syndromes. Platelet transfusion is an effective treatment for intrinsic platelet dysfunction, but the dose required to achieve hemostasis is difficult to predict and depends in part on the severity of the underlying platelet abnormality. In these patients there is no need for prophylactic platelet transfusion for low- or moderate-risk surgery, but they do require close observation and treatment if abnormal bleeding occurs. Most hematologists would recommend prophylactic platelet transfusion for high-risk surgery if the bleeding time is prolonged to >15 minutes. Recently, DDAVP has been shown to shorten the bleeding time effectively in some patients with platelet dysfunction due to many but not all congenital or acquired abnormalities. [20] [30] [31] [32] [33] [34] [35] [36] [37] It is given in a dose of 0.3 g/kg intravenously and results in variable shortening of the bleeding time, noted within 1 hour and lasting 812 hours. Repeated doses can be given at approximately 24-hour intervals, but tachyphylaxis may restrict the effectiveness of subsequent doses. It has the advantage of decreasing transfusions, and its side effects are limited to occasional facial flushing, headache, mild tachycardia, and hypotension. The mechanism of DDAVP action is not well understood but is likely to be due at least in part to an increase in von Willebrand factor. [36] It may also increase the surface expression of the platelet von Willebrand factor receptor. [35]

Renal Disease

Patients with renal disease have platelet dysfunction disorders accompanied by increased bleeding times and abnormal in vitro platelet functional study results [38] [40] that may be related to defective platelet interaction with the vessel wall, [41] or as recently suggested, to increased nitric oxide synthesis by uremic platelets and endothelium. [42] The approach to therapy is given in Chapter 131 .

Antiplatelet, Anticoagulant, and Fibrinolytic Therapy

The most frequently encountered hemostatic abnormalities in patients before surgery are in those receiving antiplatelet, anticoagulant, or fibrinolytic drugs. Patients taking aspirin as antiplatelet therapy or for its anti-inflammatory or analgesic effects represent the largest such group. Some studies have shown a mild increase in surgical bleeding in patients taking aspirin [43] [44] [45] [46] [47] [48] although this has not been confirmed in other studies. [49] [50] [51] [52] Two reports concluded that aspirin should be stopped preoperatively only if the bleeding time on aspirin was outside the normal range. [53] [54] For elective surgery it is prudent to discontinue aspirin approximately 1 week before operation, although in the

absence of other hemostatic abnormalities, recent or current aspirin use should not represent a contraindication to surgery and requires no prophylactic therapy. The effect of aspirin may, however, seriously potentiate the bleeding tendency in the presence of other hemostatic abnormalities such as thrombocytopenia, uremia, or congenital factor deficiencies, and in such patients may contribute significantly to postoperative bleeding.

Subcutaneous heparin in low doses such as 5,000 U every 12 hours or low doses of low-molecular-weight heparin given subcutaneously daily are recommended as prophylaxis for postoperative venous thromboembolic disease in some patient groups (see later). This results in minimal prolongation of the PTT [55] [56] and only a slight increase in frequency of wound hematomas. [56] [57] [58] Higher doses of heparin given as treatment for acute thrombosis can increase in surgical bleeding, but the management of such patients is not difficult because the half-life of heparin is under 2 hours [59] (Table 150-4). Consequently, the heparin can be withheld 6 hours before anticipated surgery, and the PTT should return to control levels. [60] If more rapid neutralization is required for emergency surgery, heparin can be neutralized by protamine sulfate given intravenously in a dose of 1 mg for every 100 U heparin expected to be in the circulation. In patients receiving therapy for thrombosis, heparin should be interrupted for the minimum time consistent with obtaining good surgical hemostasis. In these patients, low-dose subcutaneous heparin or prophylactic doses of low-molecular-weight heparin can be substituted in the immediate preoperative period and continued in the early postoperative period. Therapeutic heparin can be restarted as early as 12 hours after surgery if there is no evidence of bleeding at the operative site; it should be restarted without a bolus at no more than the expected maintenance infusion rate. [60] The time at which full-dose heparin is resumed will depend on the type of surgery and the clinical course.

Low-molecular-weight heparin given subcutaneously has a longer half-life. [61] Consequently, if it has been given at therapeutic doses it should be discontinued 1224 hours before surgery.

Perioperative management of patients taking warfarin is more difficult because of the longer duration of its anticoagulant effect (Table 150-4). The risk of thrombosis or embolism during interruption of anticoagulant therapy must be balanced against the benefit of surgery, and this may be difficult in patients with recent venous thromboembolic disease, intracardiac thrombosis, or prosthetic heart valves. For elective surgery with low bleeding risk (Table 150-1), a reasonable approach is to reduce the dose preoperatively to achieve an International Normalized Ratio (INR) of <2.0 at which level surgery can be safely performed. For surgery with a moderate or high-risk for bleeding, this degree of anticoagulation is unacceptable, and warfarin should be held long enough before surgery to allow the INR to correct to <1.5, [60] and the patient switched to heparin, if continued antithrombotic therapy is needed. In most patients with steady-state INRs of 23, this will mean omission of four doses. [60] [62] Continuous intravenous heparin is convenient if there is reason for the patient to be hospitalized, or subcutaneous low-molecular-weight heparin can be administered on an outpatient basis. Anticoagulation can be reinstituted postoperatively with heparin. The patient should be started back on oral anticoagulants as soon as possible postoperatively because it generally takes 3 days for the INR to reach 2.0. [60] For emergency surgery in patients at moderate or high risk of bleeding, rapid reversal of the anticoagulant effect is required, and this can be achieved with vitamin K or fresh frozen plasma. Fresh frozen plasma contains all vitamin K-dependent coagulation factors, reliably and rapidly corrects the PT to near normal, and is the preferred approach in patients needing rapid correction. Its value is limited by the volume that must be administered, although 2 U of fresh frozen plasma usually corrects a therapeutic PT to within a level safe for surgery. Another limitation is that the half-life of factor VII is 5 hours, so that the PT should be monitored and additional fresh frozen plasma administered as needed. Parenteral administration of 510 mg of vitamin K will reverse the effect of warfarin with a delay of 612 hours, although its use is complicated by relative resistance to warfarin effect after its administration, so that reinstituting oral anticoagulation can be difficult. Administration of vitamin K intravenously in a low dose of 0.51.0 mg is also effective in reversing the anticoagulant effect and does not result in warfarin resistance. [63] Administration of both fresh frozen plasma and vitamin K is prudent in patients needing emergency surgery with high risk of bleeding. If the volume of plasma needed to correct the PT is too large, then prothrombin complex concentrates

can be substituted.

Fibrinolytic therapy results in pronounced hemostatic abnormalities including decreases in plasma plasminogen, $_2$ -plasmin inhibitor, fibrinogen, factor VIII, and factor V, and increases in fibrin(ogen) degradation products and abnormalities in platelet function. [64] [65] In combination with the capacity of fibrinolytic therapy to lyse needed hemostatic plugs, these abnormalities contribute to the bleeding complications seen with fibrinolytic therapy and make surgery hazardous. [66] Elective surgery should be postponed after fibrinolytic therapy until the hemostatic abnormalities are corrected. However, the need for emergency surgery is not uncommon, particularly with the increased use of fibrinolytic therapy for acute myocardial infarction and the occasional need for revascularization procedures soon after its administration. There are several reports [67] [68] [69] [70] [71] of successful coronary artery bypass graft surgery immediately after fibrinolytic therapy, although there was excessive bleeding and increased transfusion requirements were observed.

The two issues that must be considered in a patient receiving fibrinolytic therapy who requires emergency surgery are the presence of the plasminogen activator in the circulation and its effects on the hemostatic system. The effect of circulating plasminogen activator can be inhibited by administration of epsilon-aminocaproic acid (EACA), usually given in a loading dose of 6 g, administered either orally or intravenously, followed by a dose of 1 g/hr. This will have the unwanted effect of inhibiting

TABLE 150-4 -- Surgery in Patients Taking Anticoagulants

	Bleeding Risk	Elective Surgery	Emergency Surgery
Warfarin	Low	Adjust dose to INR 2.0	Discontinue warfarin
	Moderate	Adjust dose to INR 1.5	Discontinue warfarin; FFP to reduce INR to 1.5
	High	Substitute heparin if needed and hold heparin in perioperative period	Discontinue warfarin; FFP-vitamin K to reduce INR to <1.5
Heparin	Low or moderate	Discontinue high dose and give low-dose subcutaneous heparin or LMWH	Discontinue high-dose and give low-dose subcutaneous heparin or LMWH
	High	Discontinue 612 hr before surgery for unfractionated heparin or 1224 hr for LMWH	Discontinue; give protamine sulfate if needed

Abbreviations: FFP, fresh frozen plasma; INR, International Normalized Ratio; LMWH, low-molecular-weight heparin.

physiologic fibrinolysis and possibly increasing the chance of developing a thrombosis, a potentially serious problem in a patient with recent myocardial infarction. However, the half-life of fibrinolytic agents is short, varying from 6 minutes for tissue plasminogen activator (t-PA), to 23 minutes for streptokinase and 16 minutes for urokinase, although in the case of t-PA a low level of fibrinolytic activity can be identified for longer periods of time. [72] Because of the short half-life of fibrinolytic agents, administration of EACA should be required only if surgery is needed within 12 hours after discontinuing the fibrinolytic agent.

In cases in which surgery is delayed for longer periods of time, one must correct the hypocoagulable state resulting from fibrinolytic degradation of coagulation proteins. Cryoprecipitate, which is rich in fibrinogen, von Willebrand factor, and factor VIII, is the first approach to replacement. Ten bags can be given initially, along with 2 U fresh frozen plasma to help replete factor V. Monitoring improvement of coagulation abnormalities can be difficult in the emergency setting although the thrombin time is a useful guide to fibrinogen replacement. If operative bleeding occurs despite administration of cryoprecipitate and fresh frozen plasma, then EACA should be given, and platelet transfusion considered to correct potential platelet dysfunction. [73] [74]

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

Excessive bleeding during or after surgery is a serious and potentially life-threatening complication that requires immediate evaluation and a rapid approach to diagnosis and institution of treatment. The first consideration is to determine whether the bleeding is related to a hemostatic defect or to a local lesion that requires surgical intervention (Table 150-5). Failure to surgically control bleeding vessels at the operative site is the most frequent cause of postoperative bleeding. This results in excessive blood loss limited to the site of surgery that may be rapid if a large vessel is involved. Therefore, very rapid bleeding confined only to the operative site and seen as excessive blood in operative drains or the dressing is usually due to a surgical problem. This is in contrast to bleeding due to a hemostatic defect, which often causes a generalized and slower oozing at the operative site and frequently involves additional sites outside the operative field. The patient should, therefore, be examined for signs of petechiae or purpura particularly at venipuncture sites or indwelling catheters, and the urine, stool, and nasogastric aspirate should be examined for blood if they are available. Laboratory tests are an essential part of the evaluation,

TABLE 150-5 -- Approach to Intra- or Postoperative Bleeding

1. Decide whether the bleeding is due to a local cause or to hemostatic failure Local: single site of bleeding and rapid rate, minimal or no abnormalities of coagulation tests. Hemostatic failure: multiple sites of bleeding, unusual bleeding pattern, abnormal coagulation tests.
2. Causes of perioperative hemostatic failure Pre-existing hemostatic abnormality, DIC, primary fibrinolysis; also consider contribution of dilutional thrombocytopenia and drug effects. Special cases: cardiopulmonary bypass, platelet dysfunction, prostatic surgery.
3. Diagnosis of hemostatic failure Review preoperative coagulation tests and operative record; interview family members; obtain PT, PTT, thrombin clotting time, platelet count, peripheral blood smear; consider reptilase time, fibrinogen, fibrinogen degradation products, or D dimer, euglobulin lysis time, bleeding time.

and screening tests are nearly always ordered before consultation is requested. In addition to the PT, PTT, and platelet count, it may be useful to obtain a bleeding time to evaluate platelet function if the platelet count is normal. A fibrinogen level, a test for fibrin(ogen) degradation products or D dimer, and euglobulin lysis time are needed to search for evidence of DIC or fibrinolysis. Many patients are receiving therapeutic or prophylactic heparin or have heparin instilled into indwelling catheters from which blood is obtained. This results in heparin-induced prolongation of clotting tests, which complicates the evaluation. This possibility can be evaluated by mixing studies to identify a coagulation inhibitor and by comparing the results of a thrombin clotting time that will be prolonged by heparin with a reptilase time, which will be normal. The peripheral blood smear should be reviewed to examine platelet size and number and to identify possible red blood cell fragmentation that may occur in DIC.

When evaluating hemostatic tests in surgical patients, one must consider changes that normally occur in response to surgery. These vary depending on the extent of tissue dissection and duration of the procedure. Consumption of coagulation factors and hemodilution from crystalloid infusion both lead to acute reductions during surgery, and this is typically followed by changes resulting from the acute phase response in the subsequent days. In moderately extensive surgery such as abdominal aneurysm repair or total hip replacement, typical changes include decreases in platelet count, factor VIII, von Willebrand antigen, antithrombin III and protein C during and immediately after surgery. [75] [76] [77] [78] [79]

Increases in fibrinogen, platelet count, factor VIII, and plasminogen activator inhibitor-1 in the first postoperative week reflect changes due to the acute phase response.[80] If hemostatic failure is thought to contribute to bleeding, the potential causes should be considered quickly (Table 150-5). A pre-existing hemostatic abnormality may have been undetected before surgery, and the family history and patients past medical history should be reviewed. Results of preoperative coagulation tests should be checked and reinterpreted, realizing that mild deficiencies of factor VIII, factor IX, and factor XI may be present without prolongation of the PTT, and that platelet functional abnormalities will not be identified without a bleeding time. Diagnosis of factor XIII deficiency requires a specific test, and inherited fibrinolytic abnormalities including deficiency of $_2$ -plasmin inhibitor[81] [82] and of plasminogen activator inhibitor-1 [83] [84] can cause postoperative bleeding and are not identified by screening coagulation tests. Other diagnostic considerations include consumption coagulopathy, possibly due to a mismatched blood transfusion, a period of profound hypotension, fat embolism, or amniotic fluid embolization.

Massive transfusion is often considered as a cause of intraoperative coagulopathy but rarely causes bleeding by itself. Transfusion of more than one blood volume (5,000 ml in a 70-kg adult) of banked blood predictably decreases the platelet count, but the microvascular bleeding occasionally seen in patients receiving massive transfusion cannot be directly related to the thrombocytopenia. [85] [86] [87] Therefore, routine platelet transfusion in the absence of unusual bleeding has not been recommended even during massive transfusion.[88] However, in the presence of other hemostatic abnormalities such as drugs affecting platelet function, the dilutional thrombocytopenia may be a significant contributing factor to the development of bleeding, particularly if it is suggestive of a hemostatic defect. In the presence of excessive operative bleeding, aggressive platelet transfusion to a platelet count 100,000/l is indicated.

Certain surgical procedures induce unique hemostatic changes. Thus, perfusion through the extracorporeal membrane oxygenator results in hemostatic changes during cardiopulmonary bypass. Orthotopic liver transplantation is associated with major hemostatic problems due to preoperative deficiencies

caused by severe liver disease and hypersplenism and additional intraoperative problems during the anhepatic phase of the procedure requiring careful replacement with blood products.[89] [90] Excessive fibrinolysis may also occur during liver transplantation and treatment with antifibrinolytic agents may be needed in appropriate cases.[91] [92] Excessive fibrinolysis related to hepatic or mesenteric ischemia can also occur during aortic aneurysm repair, which requires clamping above the celiac axis.[79] Excessive urinary bleeding after prostatectomy can be caused by local fibrinolysis related to high concentrations of urokinase; therapy with EACA can be beneficial,[93] but care must be taken to avoid treatment of patients with upper urinary tract bleeding, in whom fibrinolytic inhibition can result in ureteral obstruction.

The hemostatic problems with cardiopulmonary bypass requires special consideration (Chap. 131). The platelet count, hematocrit, and levels of coagulation and fibrinolytic factors are reduced to 50% of baseline after starting bypass and are maintained throughout the procedure, with the exception of factor V, which shows further reduction to <20%.[94] [95] [96] [97] These changes may be caused in part by exposure to artificial surfaces and also by a tissue factor dependent pathway related to surgical trauma.[98] The bypass procedure results in significant platelet dysfunction reflected by release of -granule constituents, the generation of platelet microparticles, abnormal in vitro aggregation tests, and a prolonged bleeding time that usually corrects within 1 hour postoperatively. [94] [95] [96] [97] [98] [99] There are no apparent changes in platelet surface expression of the important receptors, GPIIb-IIIa and GPIb-IX. [100]

Several hemostatic abnormalities contribute to postoperative bleeding after cardiopulmonary bypass. Inadequate neutralization of heparin by protamine sulfate results in a prolonged PTT and thrombin time with a normal reptilase time and is treated by administration of additional protamine sulfate. The most significant contributor to post-bypass hemostatic failure is abnormal platelet function that can be detected by an excessively prolonged bleeding time with a normal platelet count. This abnormality usually corrects within several hours but may require treatment with platelet transfusion if associated with abnormal bleeding. [101] The appearance of the heparin effect several hours after adequate protamine sulfate neutralization, termed heparin rebound, has been suggested as a cause of post-bypass bleeding, [102] but is rare. Excessive fibrinolysis and DIC are uncommon causes of postoperative bleeding and should be well documented prior to instituting therapy with heparin or antifibrinolytic agents.

Desmopressin has been administered to patients undergoing surgery with cardiopulmonary bypass because of the frequent development of abnormal platelet function and the ability of DDAVP to improve hemostasis in a variety of conditions with abnormal platelet function. Salzman and colleagues [103] conducted a double-blind prospective randomized trial in 70 patients undergoing cardiopulmonary bypass. Patients that received DDAVP at the conclusion of bypass had reduced operative and early postoperative blood loss compared to those assigned to placebo. Reduced blood loss was related to an increase in plasma von Willebrand factor concentration.[104] Several subsequent studies, however, gave conflicting results,[105] [106] [107] [108] and recent meta-analysis of 17 randomized, double-blind, placebo controlled trials including 1,171 patients found that DDAVP reduced overall blood loss by 9%, but had no statistically significant effect on transfusion requirements. [109]

Evidence of fibrinolytic activation with cardiopulmonary bypass has led to trials examining the effects of antifibrinolytic agents on intra- and postoperative bleeding. Several prospective trials have found significant decreases in both bleeding and transfusion requirements [110] [111] [112] [113] and many centers are now routinely using aprotinin, EACA, or tranexamic acid. Despite reasonable concerns over increasing thrombotic risk with antifibrinolytic agents, clinical trials have shown little evidence of increased thrombotic complications.

PROPHYLAXIS OF DEEP VEIN THROMBOSIS

The clinical consequences of postoperative venous thromboembolic disease include acute symptomatic deep vein thrombosis (DVT) and the later development of the postphlebitic syndrome as well as pulmonary embolism, which may be fatal. Accurate epidemiologic information regarding postoperative DVT is available based on routine screening using sensitive objective imaging methods. The risk of developing venous thrombosis varies in different surgical groups, and the need for prophylaxis is greater in those with higher risk (Table 150-6). The risk is lowest in young patients undergoing surgical procedures lasting <30 minutes with minimal immobility. Patients at moderate risk include those over age 40 having general abdominal or thoracic surgery lasting >30 minutes, and they have an expected incidence of venous thrombosis of 2030%, proximal vein thrombosis 210%, and pulmonary embolism 13%. Within low- and moderate-risk groups, additional factors that contribute to a further increase in risk include malignant disease, congestive heart failure, prior venous thromboembolic disease, obesity, and inherited hypercoagulable states. In certain high-risk orthopedic groups, the overall incidence of venous thrombosis

TABLE 150-6 -- Recommendations for Prophylaxis of Deep Vein Thrombosis

Category	Patients	Approximate Risk[a]			
		Calf DVT	DVT	PE	Recommendation
Low	Surgical patients under 40, surgery lasting < 30 min, no additional risk factors	12%	0.51%	00.1%	Ambulation, leg exercises
Moderate	Surgical patients over age 40, having abdominal or thoracic surgery lasting >30 min	2030%	210%	13%	Low-dose heparin
	Neurosurgery or other patients with high bleeding risk				Pneumatic compression
High	Hip fracture	4080%	2040%	510%	Warfarin,[b] LMWH
	Hip replacement				Warfarin,[b] adjusted-dose heparin, LMWH
	Knee replacement				LMWH, external pneumatic compression
	Open prostatectomy				Pneumatic compression
	Gynecologic malignancy				Pneumatic compression

Abbreviations: DVT, deep vein thrombosis; PE, pulmonary embolism; LMWH, low-molecular-weight heparin.

[a]Without prophylaxis.
[b]Given in low-dose regimen.

is 4080%, with proximal vein thrombosis in 2040%, pulmonary embolism in 510%, and fatal pulmonary embolism in 15% of patients receiving no prophylaxis. [114]

The natural history of postoperative DVT indicates that thrombi are dynamic and may either resolve or extend. Thrombi begin forming during or soon after surgery, initially in the calf veins. Most clots are asymptomatic, and many spontaneously regress but approximately 20% extend into veins proximal to the knee in the absence of treatment.[1] Most pulmonary emboli originate from proximal leg vein thrombosis,[116] and many are asymptomatic or may be misdiagnosed.[117]

Strategies for management are based on the frequency of thromboembolic disease in different surgical groups, expected clinical outcomes, and cost effectiveness. The simplest approach relies on treatment of clinically diagnosed disease, but is unacceptable in moderate- or high-risk groups because post-operative DVT is frequently asymptomatic, and the initial presentation of pulmonary embolism may be sudden death. A second potential strategy is monitoring with noninvasive tests such as ultrasound or plethysmography and treatment of affected patients only. This approach would, however, be both expensive and cumbersome, and it also raises difficult problems in management of false-positive monitoring studies. The most effective approach is primary prophylaxis in moderate- or high-risk patients using anticoagulants or methods to reduce venous stasis.

Anesthesia, operative pain, bed rest, and lack of leg muscle activity reduce venous blood flow, and this predisposes to thrombosis. Simple measures to counteract venous stasis that are applicable to nearly all patients include leg and foot exercises while in bed and early ambulation. The use of elastic stockings is of little documented benefit, but graduated compression stockings that exert greater pressure at the ankles and less pressure proximally may be of value in low- or moderate-risk patients.[118] [119] [120] External pneumatic compression devices provide active leg compression with inflatable boots that rhythmically compress calf or both calf and thigh sequentially. Such compression increases venous blood flow [121] [122] and also increases blood fibrinolytic activity; [123] [124] both effects may contribute to its efficacy. The absence of side effects makes pneumatic compression an attractive prophylactic modality, particularly in patients at increased bleeding risk. External pneumatic compression has been effective in patients after general abdominal surgery, [125] [126] [127] urologic,[128] neurologic,[129] and gynecologic surgery including that for malignancy[130] and knee replacement.[131] A system that mechanically extends the foot to cause plantar venous compression has also been shown to be effective in limited studies.[132]

The greatest experience with anticoagulant prophylaxis of postoperative venous thromboembolic disease has been with low doses of heparin and is based on the rationale that lower concentrations are needed to prevent than to treat venous thrombosis. Heparin administered in a dose of 5,000 U subcutaneously results in a peak plasma level of 0.050.15 U/ml approximately 2 hours after injection[133] with a slight but detectable increase in the PTT. [55] Administration of this dose every 812 hours beginning 2 hours before surgery results in a risk reduction of approximately 70% as determined by meta-analysis of over 70 controlled trials. [58] Large prospective, randomized trials [57] [134] [135] also demonstrated significant reductions in both pulmonary embolism and fatal pulmonary embolism in patients over 40 years of age undergoing major surgery who receive low-dose heparin prophylaxis compared to controls. Analyses of the published experience suggests 5070% reduction in risk from postoperative pulmonary embolism with the use of low-dose heparin. [114] Side effects of this regimen include bruising at injection sites and a 2% increase in wound hematomas.[58] Monitoring of the PTT is not needed with prophylactic low-dose heparin. The effectiveness and safety of low-dose heparin makes it appropriate prophylaxis for most moderate-risk surgical patients. However, surveys indicate that many surgeons do not use low-dose heparin prophylaxis because of the perceived infrequency of clinically significant thromboembolic complications and fear of bleeding. [136] [137] [138]

Several approaches have been used to improve on the effectiveness of low-dose heparin, including the addition of ergot, a venoconstricting agent, to decrease venous capacitance.[139] This has not met with wide acceptance because of the occasional occurrence of vasospastic side effects and the limited evidence of the superiority of the combination compared to low-dose heparin alone. Other studies have suggested that adjusting the heparin dosage based on PTT may increase its

effectiveness and extend the usefulness of heparin prophylaxis to high-risk patients. [140] [141] Postoperatively, the plasma concentration of antithrombin declines, and this observation led to consideration that heparin prophylaxis could be improved by supplementation with antithrombin. This was tested in two prospective, randomized trials following total hip [142] and knee [143] replacement, demonstrating that the combination of antithrombin and heparin was safe and more effective than a standard regimen of dextran. Also, the risk of developing DVT was related to the extent of postoperative decline in plasma antithrombin concentration. [144]

Heparin preparations with a restricted low-molecular-weight (LMW) range have relatively greater activity in promoting inactivation of factor Xa by antithrombin than inactivation of thrombin. [61] In comparison with standard, unfractionated heparin, LMW heparin has greater bioavailability after subcutaneous injection and a longer plasma half-life, allowing for once daily injection rather than two or three times daily for unfractionated heparin. Data are conflicting regarding the relative effectiveness of LMW heparin in comparison with unfractionated heparin in prevention of venous thrombosis in moderate risk surgical patients. Meta-analysis suggests approximate equivalence to unfractionated heparin after general surgery. [145]

The protection afforded by low-dose, unfractionated heparin is insufficient in some surgical patients with a particularly high risk of developing venous thrombosis, especially following certain orthopedic procedures. For example, after hip fracture, total hip replacement, or total knee replacement, the risk of venous thrombosis without prophylaxis is 4080%, with the frequent development of proximal leg vein clots and an incidence of pulmonary embolism of 510% and fatal pulmonary embolism 15% without prophylaxis. [114] [146] Several alternative prophylactic modalities have been tested in these high-risk patients. Dextran has been shown to be effective after total hip replacement or fracture [147] [148] but is not widely used because of the need for intravenous administration and the occasional precipitation of congestive heart failure from the fluid load. External pneumatic compression was effective in a limited number of studies after total knee replacement [131] [149] [150] and also in high-risk patients after prostatectomy [128] and gynecologic surgery for malignancy. [130] It is more effective than no prophylaxis after total hip replacement [151] [152] but is less effective than warfarin in preventing proximal vein thrombosis. [153] Although the usual low-dose heparin regimen has not been sufficiently effective in high-risk patients, some evidence indicates that subcutaneous unfractionated heparin given in a dose to increase the PTT to the upper normal range may be more efficacious. [140]

Oral anticoagulants have been shown to be consistently effective in preventing venous thrombosis in high-risk patients. In a classic study, Sevitt and Gallagher [154] demonstrated a reduction in both clinical and autopsy evidence of pulmonary embolism and DVT with coumarin prophylaxis compared to a control group. Although the effectiveness of warfarin has been amply confirmed in subsequent studies, concern over bleeding complications has limited its general acceptance. Recent studies have, however, demonstrated that a lower intensity of

---

anticoagulation is effective without increasing the bleeding risk even in surgical patients. Low-dose warfarin regimens begun preoperatively were effective in patients undergoing joint replacement [155] or gynecologic surgery. [156] Paiement et al. [157] have also reported a low incidence of venous thrombosis and bleeding complications after hip replacement with the use of warfarin begun the night before surgery, and warfarin has also been effective when started postoperatively. [158] Francis et al. [159] reported no difference in outcomes comparing a warfarin regimen beginning 710 days preoperatively with one starting the night before surgery in patients undergoing knee replacement. With the use of warfarin in hip replacement, meta-analyses have identified rates of deep vein thrombosis of 24% [160] and 19%, [161] whereas large single studies have found rates between 14% and 23%. [153] [158] [162] [163] Warfarin has been less effective with knee replacement, with rates of DVT from 3855% in recent studies. [158] [159] [162]

Low-molecular-weight heparin is effective in high-risk patients, and meta-analyses have identified rates of postoperative DVT of between 12% and 17%, [145] [160] [161] similar to findings in recent large North American trials. [162] [164] [165] [166] [167] LMW heparin has also been compared directly with warfarin following hip replacement. In three studies, there was no significant difference in postoperative venous thrombosis rates, [152] [162] [163] whereas one showed a significantly lower rate with LMW heparin (15%) compared to warfarin (26%). [168] LMW heparin has also been compared with unfractionated heparin following hip replacement [97] [98] [99] and meta-analyses of published trials indicate that it is more effective. [145] [161] [162] Following knee replacement, LMW heparin has been shown superior to placebo, [169] graduated compression stockings, [170] or warfarin. [152] [162] [163] The optimum duration of prophylaxis after joint replacement surgery is not certain, and the period of risk may extend several weeks postoperatively. [171] [172] A recent double-blind study demonstrated a lower incidence of venous thrombosis 1 month after surgery when prophylaxis was extended postdischarge. [173]

Hip fracture is associated with a high risk of postoperative venous thrombosis similar to that with joint replacement. Low-intensity warfarin is effective in reducing risk [174] [175] [176] and LMW heparin [177] [178] or dermatan sulfate [179] achieves similar risk reduction. Patients suffering from multiple trauma are heterogeneous, but they also have a high risk of venous thrombosis. In one recent prospective study 58% of patients admitted to a regional trauma unit developed DVT [180] and a prospective randomized trial has demonstrated that LMW heparin is more effective than unfractionated heparin in preventing DVT in multiple trauma patients. [181]

Recommendations for prophylaxis in patients at low, moderate, or high risk are given in Table 150-6 . Early ambulation and leg exercises are recommended for patients in low-risk groups. If low-risk patients have additional factors predisposing to thrombosis, such as congestive heart failure, history of venous thromboembolic disease, severe obesity, or congenital hypercoagulable states, then low-dose heparin is indicated. Patients over age 40 having abdominal or thoracic surgery lasting >30 minutes represent a moderate-risk group, and the use of low-dose heparin (5,000 U twice daily) beginning 2 hours before surgery and continuing until the patient is fully ambulatory, is recommended. In patients with malignancy or additional risk factors the use of an every 8 hour regimen is preferable. External pneumatic compression is a good alternative in patients with an increased bleeding risk. Warfarin, LMW heparin, and adjusted-dose heparin are suitable in patients following hip fracture or hip replacement and LMW heparin and compression are recommended after knee replacement. Pneumatic compression or LMW heparin is appropriate in high-risk patients with surgery for gynecologic malignancy. Pneumatic compression is preferable following open prostatectomy because evidence indicates that heparin increases the risk of development of lymphoceles. [182] [183]

THERAPY FOR THROMBOSIS

The principles of treatment for established thrombotic disease following surgery do not differ from those in other settings except there must be a careful consideration of the risk of bleeding related to the specific surgical procedure (Chaps. 124 and 125). This often results in a difficult clinical decision, balancing the risks of worsening the thrombotic disease due to suboptimal anticoagulant therapy against the risk of bleeding with more intensive anticoagulation. Consideration of the bleeding risk associated with the specific surgical procedure (Table 150-1) is important in making these decisions. For patients at highest risk, such as those who have had intracranial or ophthalmologic surgery, anticoagulant therapy may not be appropriate until 57 days after surgery, and fibrinolytic therapy should be delayed for even longer. By contrast, after minor external procedures patients at low risk for bleeding can be treated aggressively with anticoagulants 12 days after surgery with close observation of the surgical site. Patients at moderate bleeding risk represent a difficult group because of the potentially serious consequences of bleeding at the operative site and into the thoracic cavity, abdomen, or retroperitoneum. Recent trauma or surgery is a significant predictor of bleeding complications during heparin therapy[184] [185] and even prophylactic low-dose heparin increases the risk of wound hematomas. [58] Therapeutic anticoagulation with heparin in the first week following total hip replacement may result in bleeding complications in up to 50% of patients. [186] Careful control of anticoagulant intensity will reduce bleeding risks as indicated by reports of successful abdominal or thoracic surgery [187] [188] or orthopedic surgery[153] [157] without undue bleeding in patients receiving oral anticoagulation with INRs of 22.5.

Both LMW heparin and unfractionated heparin are available for parenteral treatment of thrombosis (Chap. 122). LMW heparin offers advantages of subcutaneous administration and a longer half-life. In the postoperative period, however, unfractionated intravenous heparin may be preferred for treatment of thrombosis because its anticoagulant effect disappears more rapidly after the infusion is stopped if bleeding occurs. Each case must be individually considered, but experience suggests that heparin may be given in the early postoperative period by continuous infusion to keep the PTT in the low therapeutic range with close observation for evidence of bleeding. For fibrinolytic therapy, the risks of bleeding are higher. This is related primarily to the potential for dissolution of fibrin in hemostatic plugs at the surgical site. Clinical trials of fibrinolytic therapy have shown that most bleeding complications are related to prior invasive procedures such as arterial punctures [66] [189] and fibrinolytic therapy for venous thromboembolic disease should be delayed 710 days following surgery because heparin anticoagulation is an acceptable alternative treatment. For patients with acute myocardial infarction, however, the decision is more difficult because of the greater benefits of early treatment with fibrinolytic therapy. This must be carefully considered in the risk/benefit analysis in treating patients who develop myocardial infarction in the postoperative period.

Chapter 151 - Hematologic Manifestations of Childhood Illness

A. Kim Ritchey
Frank G. Keller

INTRODUCTION

The hematologic response to systemic illness in children is similar to that in adults. However, a number of disorders occur more frequently in children and some are unique to the pediatric population. In addition, interpretation of the hematologic response is predicated on knowledge of the normal developmental changes that occur within the hematopoietic system throughout childhood (Table 151-1). This chapter focuses on the hematologic manifestations of common or unique systemic diseases that occur in the neonate, child, or adolescent. Illnesses that often require hematologic consultation are emphasized. Systemic diseases that produce hematologic abnormalities that

INFECTIOUS DISEASE

Infection, especially viral infection, is the most common problem encountered by the pediatrician. Although most infections do not produce significant hematologic sequelae, all classes of microorganisms have been implicated in the pathogenesis of hematologic abnormalities that range from mild and clinically irrelevant to severe and life-threatening. In this section, we discuss the changes seen in red blood cells (RBCs), white blood cells (WBCs), platelets, or the coagulation system that are routinely encountered, are associated with a specific infection, or have a potentially serious clinical impact.

RBC

The anemia of chronic inflammation or infection in children is similar to that seen in adults in terms of both clinical and hematologic findings and pathogenesis. [2] However, anemia with acute infections occurs more commonly in children than in adults.

Anemia of Acute Infections

A mild to moderate anemia of uncertain etiology may occur in the setting of both acute viral infections or more serious bacterial infections. In a study of children with mild viral or bacterial infections in the outpatient setting, anemia was documented in 5% of children 412 years, 17% of children 6 months to 4 years, and 33% of infants 611 months of age.[3] In 14 of 15 young children the anemia resolved within 34 weeks. However, multiple mild infections may predispose the infant to develop a more chronic, mild anemia or low normal hemoglobin that may be due to iron deficiency, thus warranting a trial of iron. [4] In children hospitalized with moderately severe inflammatory processes, the incidence of mild anemia (hemoglobin 10.111.0 g/dl) is as high as 78%. [5] Specific acute bacterial infections associated with a high incidence of anemia (4474%) include bone and joint infection, [6] typhoid fever,[7] brucellosis,[8] and invasive*Hemophilus influenzae* infections.

The anemia associated with*H. influenzae* meningitis has been the most thoroughly studied of the anemias of acute infection. The majority of children with *H. influenzae* meningitis have mild anemia on admission with hemoglobin in the 911 g/dl range, and up to 90% become anemic during the course of the illness. [9] [10] This is in contrast to meningitis secondary to*Streptococcus pneumoniae* or*Neisseria meningitidis*, in which anemia is uncommon. The pathophysiology of the anemia of*H. influenzae* disease appears to be multifactorial. Shurin et al. [11] have shown that*H. influenzae* capsular polysaccharide, polyribosyl ribitol phosphate, binds to erythrocytes and in the presence of antibody and complement can result in intravascular and extravascular hemolysis. They further hypothesize that polyribosyl ribitol phosphate alone may induce more rapid clearance of RBC, perhaps on the basis of decreased RBC deformability. In addition, hypoferremia may limit bone marrow response to hemolysis.

Acute Hemolytic Anemia

Acute hemolysis has been observed with infections from all classes of microorganisms but is relatively uncommon. [12] [13] The anemia may be mild to severe and occurs in two clinical settings: (1) the child who presents predominantly with symptoms and signs of infection and is found to have anemia and (2) the child who presents with the manifestations of acute hemolytic anemia.

The mechanism of hemolysis in patients presenting with an infectious disorder depends on the infecting organism, but in most cases hemolysis is extravascular. [14] Reported mechanisms include:

1. Release of hemolysins (*Clostridium perfringens* sepsis)
2. Invasion of the RBC (malaria)
3. Alteration of RBC surface:
   a. Direct adherence by the organism (*Bartonella*)
   b. Alterations of antigenic phenotype by neuraminidase (influenza)
   c. Cold agglutinin (mycoplasma,*Listeria*, Epstein-Barr virus [EBV])
   d. Absorption of capsular polysaccharide (*H. influenzae*)
4. Mechanical mechanisms (microangiopathy associated with disseminated intravascular coagulation [DIC] or hemolytic-uremic syndrome)
5. Oxidation damage in individuals with congenital enzyme deficiencies (hepatitis and glucose-6-phosphate dehydrogenase [G6PD] deficiency, [15] *Campylobacter jejuni* in the neonate).[16]

Acute, infection-associated hemolytic anemia in one study lagged behind the clinical infection by 37 days. [17] Most children were shown to have adsorption of microbial antigens to the RBC surface suggesting an innocent bystander mechanism of erythrocyte sensitization, ultimately leading to hemolysis. The minority in this series had classic autoantibody-mediated hemolytic anemia.

Autoimmune hemolytic anemia in children is usually transient, is not associated with underlying systemic disease, and has a low mortality rate. [18] Children frequently have a history of concurrent or recently resolved infection, especially viral upper respiratory infection. In the typical acute, transient cases, 5968% of children have such a history, whereas 020% of those with the less common chronic course have a history of infection.

Aplastic Crisis

Temporary arrest of RBC production has been observed in children with infections, [19] but anemia is uncommon because of the long RBC life span. However, in two situations severe anemia has been linked with infection and cessation of erythropoiesis: (1) B19 parvovirus infection in patients with an underlying hemolytic anemia and (2) transient erythroblastopenia of childhood.

The B19 parvovirus has been a known pathogen in animals for years but has only recently been linked with human disease. [20] It is the etiologic agent of fifth disease (erythema infectiosum), a mild illness with a characteristic slapped cheek facial erythema and a generalized reticular rash. In normal volunteers infected with B19 parvovirus a mild, transient, and clinically irrelevant drop in the hemoglobin and reticulocyte count was observed. [22] In normal children this infection is not usually associated with hematologic abnormalities, although reports of both hematologic and nonhematologic effects are increasing. [21] [23] However, in children with sickle cell disease, spherocytosis, and other hemolytic anemias, B19 parvovirus infection can produce a severe anemia associated with peripheral reticulocytopenia and marrow erythroblastopenia, the aplastic crisis. Recovery within 12 weeks is the rule, but transfusion may be necessary. B19 parvovirus infection has also been associated

with prolonged anemia and reticulocytopenia in children with acute lymphoblastic leukemia in remission, [24] [25] children with solid tumors receiving chemotherapy, [26] immunodeficiency,[27] postrenal transplant,[28] autoimmune hemolytic anemia,[29] [30] and as the initial manifestation of human immunodeficiency virus infection. [31] Human parvovirus has also been identified as a cause of non-immune hydrops fetalis. [32]

Transient erythroblastopenia in childhood (TEC) is a syndrome characterized by temporary arrest of RBC production with moderate to severe anemia in previously normal infants and toddlers. Although no specific infectious agent has been proven to cause TEC, the frequency of a history of infection within 13 months, the seasonal clustering, and the similarity to childhood idiopathic thrombocytopenic purpura (ITP) all suggest a possible viral etiology. B19 parvovirus has not been associated with TEC.[33]

WBC

Children, as a rule, have the expected leukocyte response to infection. It should be remembered that infants and young children normally have a lymphocyte predominence (Table 151-1) and any leukocyte response to infection must be judged on the basis of age-related normal values.

The predictive value of the peripheral WBC and differential counts in suspected bacterial infections has been extensively evaluated in infants and children. [34] Todd has shown in hospitalized children that a neutrophil count >10,000/mm ^{3} or bands >500/mm^3 is associated with an 80% chance of having a bacterial infection. [35] In children undergoing evaluation for possible meningitis, Lembo et al. [36] found that a ratio of immature-to-total neutrophils of >0.12 was more strongly associated with, and more sensitive for, bacterial meningitis than were the total WBC or the total band count. Febrile children between the ages of 3 and 48 months are at increased risk for bacteremia, especially with *S. pneumoniae*. McCarthy et al.[37] demonstrated a threefold increase in risk of bacteremia in febrile (>40°C) children, <2 years old, who had a WBC count of 15,000/mm^3 . In this setting, the WBC count was a more sensitive indicator of the presence of pneumonia or bacteremia than was the absolute neutrophil or band count.

There are recognized exceptions to the anticipated leukocyte response to infection that may serve as a clue to the diagnosis. In typhoid fever and brucellosis, leukopenia and neutropenia are prominent early in the illness. Shigellosis is associated with a variable leukocyte count, but it is often normal, with a greater percentage of bands than neutrophils. Illnesses associated with lymphocytosis include pertussis (whooping cough), infectious lymphocytosis, infectious mononucleosis, and other viral infections. Neutropenia can be seen in bacterial sepsis from meningococcus, pneumococcus, staphylococcus, and other bacteriae and is associated with a poor prognosis. Black children (and adults) normally have lower WBC and neutrophil counts than whites and have less of a leukocytosis and neutrophilic response to serious infection. [38]

Neutropenia

The most common cause of neutropenia (neutrophil count <1,500/mm^3) in children is viral infection. A number of specific viruses are associated with neutropenia, including hepatitis, roseola, rubella, mumps, adenovirus, coxsackie A21, EBV, and influenza. [39] However, the most common clinical setting is the incidental discovery of neutropenia in the child with a nonspecific viral syndrome. Usually the neutropenia in this situation continues for <30 days and is rarely associated with infectious complications.[40] Neutropenia has also been associated with a number of bacterial, rickettsial, and fungal infections. [41]

Eosinophilia

The most common cause of eosinophilia worldwide is parasitic infection. In the United States, visceral larva migrans is the most common cause of exaggerated eosinophilia (WBC 30,000100,000/mm^3 with 5090% mature eosinophilis) in children. [42] Mild to moderate eosinophilia (400/mm^3) is most often seen in allergic children but is also characteristic of *Chlamydia* pneumonitis in infants.

Platelets/Coagulation

Thrombocytosis

Thrombocytosis (>500,000/mm^3) is known as an acute phase reaction to infection, but it has been infrequently identified in children in the past. [43] There is a particularly high incidence of thrombocytosis in patients with bacterial infections, especially pneumonia with empyema [44] and *H. influenzae* meningitis.[45] Inflammatory cytokines, such as interleukin (IL)-1, may play an etiologic role in the reactive thrombocytosis of infection. [46] Thrombocytosis may be more common in simple acute infections than previously recognized. Heath and Pearson documented a 13% incidence of thrombocytosis in ambulatory patients; children with an increased platelet count were more likely to have a diagnosis of infection. [47] There were no apparent sequelae to the thrombocytosis and antiplatelet therapy is not indicated. Although the most common cause of thrombocytosis in children is infection, [48] the differential diagnosis of an elevated

platelet count is extensive [49] and rarely includes underlying childhood malignancy. [50]

Thrombocytopenia

Thrombocytopenia can be seen in patients suffering from infections with all types of organisms. Common viral agents include varicella, EBV, rubella, mumps, measles (wild or vaccine strains), and cytomegalovirus (CMV). The primary mechanism of the thrombocytopenia is immune destruction, although a direct viral effect on the platelet or megakaryocyte has been demonstrated. Because childhood ITP is felt to be secondary to infection in most instances, the definitions of thrombocytopenia with infection and childhood ITP tend to merge. Children with thrombocytopenia from infection usually have a transient course, although instances of chronic thrombocytopenia from specific viral infections (e.g., varicella) have been documented. [51]

Thrombocytopenia is also associated with bacterial sepsis. The low platelet count may be an isolated finding or associated with DIC. Corrigan documented a 61% incidence of thrombocytopenia in 45 children with sepsis. [52] The degree of thrombocytopenia was mild to moderate (64% with >50,000/mm), but ranged as low as 8,000/mm^3 . There was no evidence of DIC in 39% of those with low platelet counts. Thrombocytopenia in the setting of bacterial sepsis is also probably mediated by an immune mechanism with elevated platelet-associated IgG. [53]

Petechial bleeding without thrombocytopenia can be seen in both bacterial and viral disease, especially with the meningococcus, streptococcus, and echoviruses. The explanation for the petechial rash in these infections is either vasculitis or platelet dysfunction.

DIC/Purpura Fulminans

Disseminated intravascular coagulation is uncommon after childhood infections and if present is usually accompanied by shock and at least a 50% mortality rate. The most common organisms producing DIC are bacterial, especially the gram-negative bacteria (meningococcus, *H. influenzae, Aerobacter*, and others) but also gram-positive organisms (*Staphylococcus aureus*, group B streptococcus, and *S. pneumoniae*, particularly in the asplenic host). DIC is also associated with disseminated viral (varicella, measles, rubella), rickettsial (Rocky Mountain spotted fever), fungal, mycoplasma, and parasitic infections.

Purpura fulminans is a rare syndrome, seen in extremely ill children with DIC. Purpura fulminans is characterized by the rapid progression of ecchymotic skin lesions, especially of the extremities, that may progress to gangrene and ultimately result in amputation. [54] This syndrome has been described as a postinfectious purpura with scarlet fever, upper respiratory tract infection, and varicella as the most common proceding illnesses with a latent period of 090 days following infection. [55] A similar clinical picture can be seen in children with DIC and acute bacterial sepsis, especially meningococcemia.

There is increasing evidence that DIC associated with purpura fulminans is associated with deficiency of the naturally occurring anticoagulants. Children with postvaricella purpura fulminans have been shown to have acquired protein S deficiency, antiprotein S antibody, and presence of a lupus anticoagulant. [56] Proteins C and S have been shown to be low in children with infectious purpura [57] and the severity of protein C deficiency has been associated with morbidity and mortality. [58]

The frequency of an inherited thrombophilia in children who develop purpura fulminans is unknown, although the association has been reported. [59]

Treatment of purpura fulminans consists of antibiotics for suspected bacterial infection, volume replacement for shock, and heparin. Although there is controversy regarding the routine use of heparin in DIC, its use in purpura fulminans has been associated with an improved outcome when started early in the course of the disease and continued for 23 weeks. [60] Theoretically to improve the efficacy of heparin, it is reasonable to infuse fresh frozen plasma or antithrombin III (AT III) concentrates[61] if the AT III level is low. There is anecdotal evidence that infusion of AT III concentrates without heparin or protein C concentrates may decrease morbidity and mortality.[62] [63] In addition, recombinant tissue plasminogen activator has been used in an attempt to restore organ perfusion by dissolution of diffuse microvascular thrombosis with apparent success.[64] Other treatments, such as regional sympathetic blockade, topical nitroglycerin, and local infusion of tissue plasminogen activator have been used to improve regional blood flow to the affected part. [65] [66] [67] The mortality of postinfectious purpura fulminans has declined from 90% in the past to 18%,[34] although patients with acute bacterial sepsis with purpura fulminans continue to have a high mortality rate.

Coagulation Inhibitors

Acquired inhibitors of coagulation in children with infection are uncommon, transient, and usually mild, [68] [69] but may be associated with severe bleeding.[70] They are usually detected after a viral illness, during penicillin therapy, [71] or incidentally. Both specific inhibitors of coagulation factors (especially factors VIII and IX) and lupus anticoagulants have been demonstrated. Significant bleeding is usually seen only in those children with specific factor inhibitors, although hemorrhage has also been described with lupus anticoagulants.[72] Treatment of symptomatic patients with prednisone has been associated with improvement in bleeding manifestations. Complete resolution without recurrence is the most common event.

Pancytopenia

Pancytopenia in a child should alert the clinician to disorders such as leukemia, aplastic anemia, or disseminated neuroblastoma. Infectious causes of pancytopenia are uncommon, and disseminated disease is most often present. Organisms implicated in patients with pancytopenia include *Mycobacterium tuberculosis*, atypical*Mycobacteria, Histoplasma capsulatum, Salmonella typhi, Mucor* species,*Brucella* species,*Fusobacterium necrophorum*, and*Erlichia canis*.[41] [73] Virus-associated or reactive hemophagocytic syndrome is an additional, though rare, cause of pancytopenia. [74] Children with human immunodeficiency virus (HIV) and concomitant infection with*mycobacterium avium intracellulare* or parvovirus B19 have been reported to have pancytopenia. [75] [76]

HIV Infection in Children/Adolescents

Infection with HIV is more common in adults but is now recognized as a leading cause of immunodeficiency in infants and children. [77] Acquisition of HIV in the majority of infected children (most of whom are <2 years old) is by vertical transmission from an infected mother to her infant. In children <13 years old with acquired immunodeficiency syndrome (AIDS), 80% have a parent with AIDS or AIDS-related complex (ARC), 13% have a history of blood transfusion, and 5% have hemophilia or another coagulation disorder.[78] Other adult routes of infection (homosexuality, intravenous needle use) are possible, especially in the adolescent and the sexually abused child.

The definition of AIDS in childhood differs from that for adults in two ways. [79] Multiple, serious bacterial infections and lymphocytic interstitial pneumonitis/pulmonary lymphoid hyperplasia are accepted as indicative of AIDS among children and not adults. In children <15 months old, because of the possibility of passively acquired maternal antibody, diagnosis of HIV infection is difficult and laboratory criteria are more stringent.

The Centers for Disease Control and Prevention (CDC) has published a revised classification of HIV infection in children <13 years of age based on infection status, clinical status, and immunologic status. [80]

The majority of children with AIDS present with oral thrush, chronic interstitial pneumonitis, hepatosplenomegaly, lymphadenopathy, or failure to thrive. Other clinical characteristics distinguishing pediatric HIV infection include a shorter incubation period, more pronounced hypergammaglobulinemia, more serious bacterial and CMV disease, and the rare occurrence of Kaposi sarcoma or other malignancies. However, as in adults, there is a broad spectrum of disease manifestations, with all organ systems potentially affected and progressive immune and clinical deterioration.

The hematologic manifestations of AIDS in children are similar to those in adults (Chap. 154) and depend on the state of the HIV infection and the presence of coexistent disease.[81] Anemia is by far the most common finding (>90%). Severe anemia (hematocrit <25%) in one study correlated with development of an opportunistic infection and death within 7 months. [82] Leukopenia and neutropenia are commonly seen in HIV-infected children (47% and 41%, respectively) with severe neutropenia associated with opportunistic infections. Immune neutropenia as well as circulating anticoagulants have been described. [83] [84] Lymphopenia is progressive but until late in the course less prominent in children than adults. Thrombocytopenia is present in 1330% of pediatric AIDS patients and can be associated with clinically significant and even fatal hemorrage. The mechanism of the thrombocytopenia in most cases is immune destruction with a high percentage of patients having antiplatelet antibodies or immune complexes, [85] although amegakaryocytic thrombocytopenia has been reported. [86] Variable therapeutic responses to both corticosteroids and intravenous IgG have been demonstrated; some children will have spontaneous remissions. [85] [87] The evaluation and treatment of hematologic abnormalities in HIV-infected children have been reviewed by Hilgartner. [88] Consensus guidelines for the diagnosis and overall management of children with HIV infection have also been published. [89]

Isolated thrombocytopenia as a presenting manifestation of HIV infection has been reported in a number of children, usually infants. [90] There have been no associated clinical stigmata of AIDS or ARC, and patients have been responsive to standard treatment (intravenous IgG or prednisone) often with sustained remissions. In a few patients with prolonged follow-up, no further manifestations of HIV infection were seen. Although it has been suggested that HIV testing may be indicated in all children with ITP, it seems most reasonable to check the HIV status of those with risk factors for AIDS and those outside the typical age group for ITP, especially infants. [91]

COLLAGEN VASCULAR DISEASE/ACUTE VASCULITIS

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) includes a group of disorders with a varied clinical presentation, course, and outcome. [92] Systemic JRA, which occurs in 30% of patients, is a multisystem disease characterized by fever, rash, polyarticular (often destructive) arthritis, hepatosplenomegaly, and lymphadenopathy. These patients commonly demonstrate hematologic abnormalities that are proportional to disease activity. In the polyarticular presentation, more than four joints are involved but the systemic findings are absent. This group, which makes up 25% of patients, may also exhibit hematologic findings. Pauciarticular JRA is characterized by involvement of fewer than four joints and is rarely associated with hematologic abnormalities.

The incidence of anemia is 5060% in patients with systemic or polyarticular JRA and 10% in pauciarticular arthritis. The anemia usually correlates well with disease activity, worsening during acute flare-ups, but there is no relationship to the duration of illness. [93] The RBC may be normochromic/normocytic or microcytic/hypochromic. The reticulocyte count is usually low. [94] Iron studies often show low serum iron, increased free erythrocyte protoporphyrin, low-normal or elevated total iron-binding capacity, and normal or low serum ferritin. Serum erythropoietin levels are usually mildly elevated (but not as high as in iron deficiency). [95] The bone marrow does not show erythroid hyperplasia in response to the anemia and has diminished (but not absent) iron stores. [96] The etiology of the anemia may be anemia of chronic disease, iron deficiency anemia, or both.

Although it is difficult to differentiate the anemia of chronic disease from iron deficiency, studies in patients with systemic-onset chronic JRA suggest defective iron supply as the primary cause.[97] Transferrin receptor levels are inversely related to hemoglobin levels in this population. Serum transferrin receptor levels have previously been shown to differentiate the anemia of chronic disease from iron deficiency. [98] Oral iron has been effective in raising the hemoglobin in anemic patients with JRA[94] and intravenous iron has been effective in raising the hemoglobin level in children unresponsive to oral iron. [97] [99] Excessive production of IL-6 has been documented in patients with JRA and may provide an explanation for the abnormalities in iron metabolism. IL-6 may enhance ferritin synthesis and increase hepatic uptake of serum iron. Increased ferritin results in reticuloendothelial iron blockage and diminished iron absorption. [97]

Less common causes of anemia in JRA include erythroid aplasia,[100] suppression of erythropoiesis by circulating inhibitors, [101] hemolysis, and a macrocytic anemia probably related to increased folate clearance and low plasma and RBC folate levels. [102] [103]

In systemic JRA, leukocytosis with mean WBC counts up to 30,000/mm^3 and neutrophilia with a left shift occur in 90% of patients, especially those with active disease. Leukocytosis is less common in polyarticular arthritis and usually absent in pauciarticular disease. [104] Leukocytosis is so prevalent in systemic JRA that the presence of neutropenia should alert the clinician to question the diagnosis and ensure that other possibilities such as systemic lupus erythematosus (SLE) and acute lymphocytic leukemia (ALL) are not overlooked.[105] [106] ALL in children may present with fever, joint pain, hepatosplenomegaly, and isolated cytopenias. Because about 4% of children with ALL are misdiagnosed as having JRA, [107] it is important to perform a bone marrow aspirate to rule out leukemia in any patient thought to have systemic JRA prior to starting corticosteroid therapy.

Nonetheless, neutropenia has been reported in several patients having JRA. [108] Other causes of neutropenia are bone marrow suppression due to therapy with gold or nonsteroidal anti-inflammatory drugs [109] and, in adults, Felty syndrome, the triad of rheumatoid arthritis, splenomegaly, and neutropenia. [110] Studies of neutrophil function have demonstrated mild defects in chemotaxis and phagocytosis. [111] [112] About 50% of patients with systemic JRA have >5% eosinophils on the peripheral smear.[113] Basophilia[114] and plasmacytoid lymphocytes[115] have also been reported. Studies of cellular immunity are conflicting, demonstrating normal or increased T- and B-lymphocyte number, increased immunoglobulin synthesis and secretion, and either impaired or normal delayed hypersensitivity and lymphoproliferative response to mitogens.[116] [117] [118] [119] Monocyte dysfunction with decreased Fc receptor expression, decreased nitroblue tetrazolium activity, and decreased complement-mediated phagocytosis has been described.[120]

The platelet count is elevated in 50% of patients with systemic JRA. [104] IL-6, a cytokine that stimulates thrombopoiesis, is

---

elevated in patients with active systemic JRA and increased levels of IL-6 are correlated with elevated platelet counts. [121] Thrombocytopenia may result from bone marrow suppression by gold therapy, [109] [122] the rare consumptive coagulopathy, [123] or platelet trapping in Felty syndrome. [93] Because thrombocytopenia is uncommon in JRA, an unexplained low platelet count should lead one to consider alternative diagnoses, such as SLE or ALL. [124] On the other hand, isolated thrombocytopenia may be the only presenting sign in a child who later develops JRA or another collagen vascular disease. Therefore, one should consider JRA and SLE in the differential diagnosis of ITP in the child who is older than 9 years and female. Appropriate screening tests for autoantibodies (e.g., antinuclear antibody, direct Coombs test) should be performed at diagnosis and periodically if new symptoms develop. [125] [126]

Disseminated intravascular coagulation may occur in children with systemic JRA after hepatic damage, from aspirin or gold therapy, or during disease flare-ups treated with nonsteroidal anti-inflammatory drugs when serum albumin is low. [127] These patients are often very ill and may require corticosteroid therapy as well as platelet and coagulation factor replacement to control the coagulopathy. [123] [128] The incidence of coagulation abnormalities in nonbleeding patients with systemic JRA is controversial. One study demonstrated prolonged prothrombin time (PT), partial thromboplastin time (PTT), and elevated fibrinogen, factor VIII, and fibrinopeptide A levels in up to 50% of these patients; [129] other reports have not confirmed such findings. [128] In addition, decreased fibrinolytic activity and increased plasminogen activator inhibitor are found in patients with active JRA, especially those with the systemic form. [130] Antibodies against factor VIII [131] and the lupus anticoagulant [132] are occasionally seen in children with JRA.

Kawasaki Syndrome

Kawasaki syndrome is an acute multisystem disorder characterized by abrupt onset of fever unresponsive to antibiotics; bilateral conjunctival injection, reddening of the lips, tongue, or oral mucosa, reddening, induration, or peeling of the hands or feet; polymorphous truncal rash; and cervical lymphadenopathy. This disorder occurs most commonly in children under the age of 2 years and has many features of a severe vasculitis; the most serious complication is development of coronary artery aneurysms, which occurs in 20% of children and is responsible for the 3% mortality rate associated with coronary artery thrombosis or rupture. The etiology of Kawasaki disease is unknown. The immunologic and clinical characteristics of this disorder are similar to diseases associated with superantigen production, of which toxic shock syndrome is a classic example.[133] [134]

Children with Kawasaki syndrome may have a mild normochromic, normocytic anemia with reticulocytopenia. [135] Rare patients with autoimmune hemolytic anemia

have been reported.[136] Leukocytosis is almost universal, with mean neutrophil counts of 21,000/mm^3 . Ninety-five percent of patients have neutrophilia, with a left shift persisting up to 3 weeks.[137] The finding of vacuoles and toxic granulation in neutrophils is a helpful adjunct in the diagnosis of Kawasaki disease. [138] The role of activated neutrophils and monocytes in aneurysm development is unclear because both impaired and enhanced phagocyte function are described. [139] [140] Studies of cellular immunity show normal total T-cell numbers but decreased suppressor T cells, causing relatively elevated T-helper cell levels during the first 4 weeks of disease.[141] The change of T-cell subsets plus B-lymphocyte stimulation may contribute to the exaggerated production of all major immunoglobulin classes during the first 8 weeks of the disease.[142] Circulating immune complexes and high C3 (but not C4) levels are found during weeks 13. During the acute phase increased levels of the cytokines IL-1, IL-6, IL-8, interferon-, and tumor necrosis factor are noted in the circulation and IL-1, IL-2, interferon-, and tumor necrosis factor in blood vessels and skin biopsies.[133] Impressive thrombocytosis occurs in 85% of patients by the second week, peaking during the third. [134] Platelet counts of up to 2 million are not uncommon and the mean platelet count is 700,000/mm^3 .[139] [143] However, 2% of patients may have thrombocytopenia caused by a consumptive coagulopathy. [144] Platelets demonstrate hyperaggregation on exposure to adenosine diphosphate, epinephrine, and collagen in vitro. These abnormalities may persist for as long as 9 months after diagnosis.[145] During the first month, levels of factor VIII, fibrinogen, thromboxane B_2 , and thromboglobulin are increased. AT III and fibrinolysis activity are decreased. The PT, PTT, and thrombin time are usually normal.[146]

Prevention and treatment of existing coronary aneurysms are the primary therapeutic goal. Aspirin suppresses platelet aggregation but does not affect aneurysm formation. Combining aspirin with high-dose intravenous immunoglobulin infusions reduces aneurysm formation, decreases fever, and normalizes laboratory signs of inflammation.[147] [148] Corticosteroid therapy increases aneurysm formation and should be avoided. [149] Guidelines for the treatment and long-term management of Kawasaki syndrome have been published.[150] [151]

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) (anaphylactoid purpura) is a systemic vasculitis characterized by unique purpuric skin lesions, transient arthralgias or arthritis, especially affecting the knees and ankles, colicky abdominal pain, and nephritis. [152] [153] [154] Recognition of HSP is important, not so much for its hematologic abnormalities (which are rare) as for the unusual nonthrombocytopenic purpuric lesions, which are frequently confused with the hemorrhagic rash of ITP.

This vasculitis occurs most commonly in children 37 years old, often 13 weeks after an upper respiratory illness. The presenting complaint in 50% of children is a characteristic rash, which may begin as urticaria. As these eruptions fade, they are replaced by brownish red maculopapular lesions and petechiae. The petechiae coalesce, forming areas of raised or palpable purpura on the buttocks, legs, and extensor surfaces of the arms, with a symmetric distribution. The rash may fade and can recur for months, especially with increased activity. Children <3 years of age often have painful soft tissue swellings of the scalp and face (especially periorbital areas) and dorsum of hands and feet.[152] Infantile acute hemorrhagic edema is an acute vasculitis in infants <2 years, which may be a benign form of HSP. [155]

Sixty-seven percent of patients experience colicky abdominal pain, often associated with vomiting, hematemesis, or melena from submucosal hemorrhage and edema of the small bowel wall. With severe edema, bowel wall may become a leading point for intussception. [152] [156]

Renal involvement occurs in 50% of patients, especially boys and older children. Hematuria, either microscopic or gross, may occur with proteinuria during the first 3 weeks of the illness. With progressive involvement, hypertension, impaired renal function, and, finally, renal failure in 15% of children may occur with an associated mortality rate of 3%.[152] [157]

Anemia occasionally develops as a result of gastrointestinal tract blood loss or decreased RBC production caused by renal failure. The leukocyte count is normal. Despite the impressive purpura, the platelet count is normal or increased with normal platelet function. [152] [158] Coagulation factor levels are usually normal, though transient decreases in factor XIII activity[159] and vitamin K deficiency from severe vasculitis-induced intestinal malabsorption [160] have been reported. Bleeding in the gastrointestinal tract, the lungs, or rarely, the central nervous system,

is due to a necrotizing vasculitis and not a hemostatic defect. [156] [158]

Henoch-Schönlein purpura is considered an IgA-mediated inflammation of small vessels. Biopsy of skin or other involved tissue reveals a leukocytoclastic vasculitis. Immune complexes of IgA with complement, IgG, or IgM have been found circulating in the serum[161] and deposited in blood vessel walls of kidney, and in intestinal and skin lesions.[162] The mechanism of production, accumulation, and deposition of IgA immune complexes in the blood vessel is unclear. [163] It has been suggested that HSP may be a systemic form of IgA nephropathy.[164] Both disorders have identical renal biopsy findings and are characterized by mesangial proliferation, occasional focal sclerosis, and crescent formation. [165] [166]

Treatment is mainly supportive, although corticosteroids have been used to provide symptomatic relief with severe joint or abdominal complaints. [167] They do not alter skin or renal involvement. The prognosis is good for full recovery, except in the children with renal failure.

CARDIOPULMONARY DISEASE

Congenital Heart Disease

Congenital heart disease occurs in about 1% of live births. [168] Structural heart malformation usually follows predictable patterns such that six defects account for 70% of all cardiac disorders: ventricular septal defect, atrial septal defect, tetralogy of Fallot, patent ductus arteriosus, pulmonary stenosis, or aortic stenosis. Children with cardiac abnormalities may be acyanotic or cyanotic, depending on the underlying lesion. Hematologic abnormalities occur most often in children with cyanotic congenital heart disease (CCHD).

Polycythemia, or an increased RBC mass for age, is the bone marrow response to chronic hypoxemia in patients with CCHD. The decreased arterial oxygen saturation stimulates erythropoietin production, which in turn increases erythropoiesis. The resultant increased RBC mass increases the oxygen-carrying capacity of the blood, resulting in improved tissue oxygenation. [169] With adequate compensation, erythropoietin levels fall to normal while higher RBC production is maintained.[170] A second compensatory mechanism is an increase in 2,3-diphosphoglycerate (2,3-DPG) levels in the RBC when the arterial oxygen tension is <70 mm Hg. The higher 2,3-DPG level causes a right shift of the oxyhemoglobin curve, resulting in greater oxygen release to the tissues.

Polycythemia in the cyanotic child is beneficial up to a point. Because the relationship between the hematocrit and blood viscosity is a hyperbolic curve, minor increases in the hematocrit above 70% cause marked increases in blood viscosity. [171] This higher viscosity results in impaired blood flow through the smaller veins with ultimately less tissue oxygen delivery. This impairment is magnified in severe polycythemia (hematocrit >75%) such that headache, irritability, dyspnea, and even pulmonary, renal, or central nervous system thrombi may occur. [172] To prevent these complications, the hematocrit should be maintained around 60% through the use of exchange transfusions. Small aliquots of the patients blood are slowly removed and replaced by equal volumes of plasma or 5% albumin. [187] Care should be taken to remove blood slowly as vascular collapse, cyanosis, stroke, and seizures have been reported with too rapid an exchange. [173] Apheresis (erythrocytopheresis) has also been shown to be an effective means of decreasing viscosity in polycythemic patients. [174]

Infants with CCHD are at risk of developing iron deficiency anemia. This may result from the combination of poor iron stores at birth (especially in premature infants), increased iron needed for enhanced erythropoiesis, poor iron intake due to poor feeding, and ongoing iron losses as a consequence of phlebotomy or exhange transfusion. These children may exhibit symptoms of iron deficiency (irritability, anorexia, poor weight gain) or worsening cyanosis. The hemoglobin may be normal for age but inappropriately low for the degree of hypoxemia. Low RBC indices and hypochromic microcytic RBC are better indices of iron deficiency in this setting. [175] Polycythemic children with iron deficiency anemia are at increased risk for cerebral vein thrombosis because of the poor deformability of the iron-deficient RBC, which further increases blood viscosity. [176] [177] To prevent this complication and to allow for maximal tissue oxygenation, all infants should be fed iron-rich infant formula and receive iron replacement therapy as needed. [178]

Routine screening of patients with congenital heart disease has demonstrated coagulation abnormalities in 2059% of children with acyanotic defects and 4050% of those with cyanotic heart disease[179] (Table 151-2). Only 11% of children with CCHD have any clinical evidence of bleeding preoperatively. However, children with underlying hemostatic defects have a greater frequency and severity of postoperative bleeding. [179] [180] Presurgical testing should include at least platelet count, bleeding time, PT, and PTT. Fibrinogen, fibrin split products, thrombin time, platelet function, and clot lysis time should be assessed with any history of bleeding or any abnormality revealed on the screening tests. Children with polycythemia have contracted plasma volumes; therefore, when collecting blood samples, extra care should be taken to ensure the proper 1:9 ratio of 3.8% sodium citrate to blood to prevent artificial abnormalities in coagulation tests.

The etiology of the coagulation abnormalities in CCHD is unclear. Earlier reports suggesting a role for consumptive coagulopathy have not been confirmed. [171] [181] [182] Protein C levels in 8 of 29 term infants with CCHD were significantly lower than controls with no evidence of familial deficiency. Of these, two had thrombotic complications, and four had consumptive coagulopathy. [183] Platelets have shortened survival times (even with normal counts), and normal to increased numbers of megakaryocytes in the bone marrow are reported.[184] This increased platelet destruction does not appear to be due to DIC. Both the platelet and coagulation abnormalities are directly proportional to the degree of hypoxemia and polycythemia. [182] For example, children with oxygen saturation >60% have mean platelet counts of 315,000/mm^3 , whereas those with saturation <60% have a mean of 185,000/mm^3 .[184] The mild platelet and coagulation abnormalities are usually improved or corrected after

TABLE 151-2 -- Coagulation Abnormalities in Congenital Heart Disease

	Acyanotic	Cyanotic
	(%)	(%)
Prolonged bleeding time	11	28
Prolonged PT		20
Prolonged PTT		19
Thrombocytopenia	1240	036
Abnormal platelet aggregation	14	3870
Increased fibrinolysis	12	010
Abnormal clot retraction	10	
Low fibrinogen	16	12
Increased fibrin split products		Occasionally
Decreased factors II,V,VII,VIII,IX,X,XI,XII		Occasionally
Decreased protein C		25[183]
Decreased large multimers of von Willebrand factor	100[a]

[a]Twelve patients studied; true prevalence unknown.

surgical repair of the heart defect. [179] [185] With bleeding or if surgery is not possible, the coagulopathy may be improved by correction of polycythemia to a hematocrit of 60% by using slow plasma exchange transfusion.[186] [187] [188]

Cystic Fibrosis

Cystic fibrosis (CF) is a multisystem disorder of exocrine gland dysfunction characterized by chronic pulmonary disease, pancreatic exocrine insufficiency, hepatic dysfunction, abnormal reproductive organ function, and intestinal obstruction associated with abnormally high sweat electrolyte levels. [189] It is an autosomal recessive disease with an incidence of 1/2,000 live births.

Severe hemolytic anemia due to vitamin E deficiency may be the presenting manifestation of CF. Dolan initially linked deficiency of vitamin E with severe hemolytic anemia in infants who presented with pallor, edema, hypoproteinemia, and thrombocytosis. [190] This complication can be seen as early as 6 weeks of age. [191]

Many children with CF are chronically hypoxic, yet they do not have the excepted augmented erythroid response. [192] In a study of 42 children with CF, Vichinsky et al.[193] showed that none had polycythemia and 30% (especially the boys and the older children) had a normochromic, normocytic, or hypochromic microcytic anemia with reticulocytopenia. Compared to children with congenital cyanotic heart disease, there was no appropriate increase in RBC 2,3-DPG levels, no right shift of oxyhemoglobin curve, and either a low or a normal erythropoietin level. In vitro assays showed normal erythroid progenitor cell numbers and no serum inhibitor of erythropoiesis. Up to 66% of 25 children studied had abnormalities consistent with iron deficiency, and all responded to oral or parenteral iron therapy. It appears that the etiology of anemia in CF is multifactorial. A blunted erythropoietic response to hypoxia plus iron deficiency secondary to iron malabsorption or poor dietary iron intake may each be partially responsible for the development of anemia. If iron deficiency persists despite adequate oral supplementation, one should consider the possibility of ongoing blood loss or iron malabsorption that may necessitate the use of parenteral iron replacement.

Studies of neutrophil function in children with CF are conflicting. Some reports indicate impaired chemotaxis, chemiluminesence, granule release, and superoxide production,[194] [195] [196] whereas others have demonstrated factors in patient sputum that actually enhance neutrophil and monocyte responses to stimulants. [197] [198] Although these sputum factors may improve neutrophil killing ability, they may also worsen neutrophil-mediated lung damage. Evaluation of immune function has revealed impaired lymphoproliferative responses to *Pseudomonas* and other gram-negative bacterial antigens, defective opsonization, increased levels of circulating immune complexes, and decreased numbers of T-helper cells in 30% of patients. [199] The contribution of these findings to frequent pulmonary infection is still under investigation.

Children with CF usually do not experience clinically significant bleeding due to impaired hemostasis despite the risk of liver disease and vitamin K deficiency from malabsorption. Routine coagulation tests usually yield normal results, with an occasional prolonged PTT reported. A study by Corrigan et al. [200] revealed that 60% of 24 patients had a more subtle deficiency of prothrombin activity thought to be due to vitamin K deficiency. However, Cornelissen et al., [201] using direct measurement of vitamin K and PIVKA-II, found only 1 of 24 patients to be deficient. Routine vitamin K supplementation is not recommended, although it may be indicated in individuals with severe liver disease and those with demonstrated coagulation abnormalities.

ANOREXIA NERVOSA

Anorexia nervosa is a psychiatric disorder occurring in about 1/800 adolescent girls; it is characterized by refusal to maintain a minimal normal body weight, intense fear of being fat, body image distortion, and amenorrhea. The profound weight loss is accompanied by hypothermia, hypotension, edema, lanugo, and metabolic changes, and has a mortality rate of 518%.[202]

A mild, normochromic, normocytic anemia with reticulocytopenia occurs in 30% of patients.[203] Acanthocytes or spur cells have been reported and may be due to low serum -lipoprotein levels. The causes of the anemia are most likely decreased RBC production and relative increase in plasma volume. A few patients have had slightly decreased RBC survival. Despite low serum iron and decreased marrow iron stores in 80% of patients, iron deficiency anemia is uncommon except during recovery when iron supplementation is necessary. Serum B_{12} and folate levels are usually normal.[204]

Fifty percent of patients have leukopenia, with an absolute decrease in numbers of neutrophils, lymphocytes, and monocytes.[203] [205] The neutropenia may be quite severe. An increased incidence of infection usually does not occur, although with increasing use of central venous catheters more serious bacterial infections are being reported.[206] Studies of neutrophil compartments have shown normal bone marrow reserves despite marrow hypoplasia and a normal to slightly decreased size of the marginal pool.[204] [205] Impaired neutrophil chemotaxis, intracellular killing of staphylococcus, and decreased complement levels have been demonstrated in patients with anorexia. These are associated with occasional skin abscess formation.[203] Lymphocytes may have impaired proliferative response to mitogens, poor or absent delayed hypersensitivity, decreased numbers of circulating T cells,[207] and a reduction in $CD8^+$ T cells.[208]

Patients with anorexia nervosa have no apparent bleeding diathesis. The platelet count is normal to slightly decreased [203] [209] and in vitro platelet aggregation to epinephrine, adenosine diphosphate, and collagen is exaggerated.[210] [211] Coagulation defects are uncommon except for vitamin K deficiency reported in bulimia.[212]

The hematologic changes in anorexia nervosa are directly correlated with total body fat mass depletion.[213] A bone marrow pattern on magnetic resonance imaging suggestive of gelatinous transformation of bone marrow (serous atrophy) is seen in patients with the lowest hematologic parameters. Direct examination of the bone marrow reveals hypoplasia with loss of fat stores and replacement by a gelatinous acid mucopolysaccharide ground substance.[214] Focal or extensive necrosis may be present.[215] Bone marrow histiocytes are relatively increased in number and have prominent blue-green granules.[204] With nutritional treatment, bone marrow hypoplasia reverses, the gelatinous material disappears, and the hematologic abnormalities, including neutrophil defects and low complement levels, resolve by 8 weeks.[203] [204]

HEMATOLOGIC ASPECTS OF POISONING

Poisoning is an important problem in children. [216] It has been estimated that 6 million children, most under the age of 5 years, ingest some toxin each year. The effects of toxins on the blood are diverse, usually nonspecific, and in most situations overshadowed by the nonhematologic manifestations of the exposure. [217] However, with certain toxins, bleeding, anemia, or change in the appearance of the blood may be an important component of the clinical sequelae of an acute exposure.

The abnormalities of hemostasis after poisoning are numerous and the mechanisms vary. Bleeding may be the only

---

manifestation of warfarin toxicity secondary to an overdose of the drug or ingestion of a rodenticide containing warfarin. Any hepatotoxic substance (e.g., iron or acetaminophen) may lead to decreased synthesis of clotting factors and resultant coagulopathy. Bleeding in these circumstances is delayed for at least 24 hours, although there appears to be an early coagulopathy in iron poisoning that may be due to a direct effect on clotting protein function and not hepatotoxicity. [218] DIC has been seen after ingestion of mushrooms of the*Amanita* genus[219] or a bite from the brown recluse spider (*Loxosceles reclusa*).[220] Poisonous snake bites can result in coagulation abnormalities characterized by hypofibrinogenemia with or without thrombocytopenia or a DIC-like syndrome. [217] Severe thrombocytopenia has been described with elemental mercury poisoning. [221]

Acute hemolytic anemia may be the presenting manifestation after exposure to drugs and toxins in children with G6PD deficiency or hemoglobin Zürich [222] [223] or (rarely) in normal children. [224] Severe hemolytic anemia has been seen after the bite of the brown recluse spider [220] [225] and after a wasp sting. [226]

Exposure to certain toxins may result in characteristic color change of the blood, which in turn may be reflected clinically in abnormal skin color. The child with methemoglobinemia (see following discussion) presents with a slate gray cyanosis unresponsive to 100% oxygen administration. On exposure to air, the blood retains a distinct brown color. Patients with toxic exposure to carbon monoxide or cyanide have increased levels of carboxyhemoglobin or cyanhemoglobin, respectively, resulting in a "cherry-red" color of the blood and skin, but only with high concentrations of the offending hemoglobin.

Infants (4 months of age) are at particular risk for developing methemoglobinemia because of a reduced amount (60% of normal) of cytochrome b_5 reductase present in neonatal RBC. Methemoglobinemia has been described in infants with diarrheal illness and in infants exposed to exogenous agents. [227]

Yano et al.[228] described 11 cases of transient methemoglobinemia in infants <1 month old who presented with vomiting, diarrhea, and acidosis. In prospective studies of infants <6 months of age with diarrheal disease, 64% had elevated levels of methemoglobin with a mean (± SD) of 10.5 ± 12.3%, 31% were cyanotic, most infants were small and/or failing to thrive, there was no association of methemoglobinemia and acidosis, and all recovered from their illness. [229] [230] Although most infants with endogenous methemoglobinemia can be managed with support and hydration, treatment with methylene-blue (1 mg/kg) is indicated in the symptomatic or more severely affected (methemoglobin >2030%) child.

Nursery epidemics of methemoglobinemia have been reported in normal newborns exposed to disinfectants or aniline dyes used to mark diapers. [231] Infants fed formulas made with well water containing a high concentration of nitrates have developed methemoglobinemia. EMLA cream, a eutectic mixture of the local anesthetics lidocaine and prilocaine, has been effective in decreasing pain in infants undergoing circumcision. [232] Methemoglobinemia has been reported with EMLA use in this situation, but only in overdose. [233] Other ingestions associated with methemoglobinemia include phenazopyridine (Pyridium), [234] dapsone,[235] metoclopramide,[236] and nitroethane (an artificial fingernail remover). [237] Although the list of oxidants reported to cause methemoglobinemia is long, [238] methemoglobinemia due to exogenous agents is uncommonly seen in infants and children.

Lead Poisoning

Lead poisoning in children has been a serious public health problem for decades. However, the most serious toxicities of lead (e.g., encephalopathy) commonly seen in the past are rarely encountered today, primarily because of measures instituted to decrease lead exposure (no-lead paint, no-lead gasoline) and screening programs in high-risk areas. Mean blood lead levels in the United States have declined from 15 g/dl between 1976 and 1982 to 3.6 g/dl between 1988 and 1991. [239] Nonetheless, lead toxicity remains a problem, especially in high-risk children. With increasing evidence that lower levels of lead exposure are associated with a significant decline in neurodevelopmental outcome, in 1991 the CDC lowered the intervention level of lead in the blood from 25 g/dl to 10 g/dl. [240] Reviews of the public health issues relating to lead poisoning in children have been published. [241] [242]

The primary hematologic effect of lead is interference at multiple points along the heme synthetic pathway. [243] The two most important effects are inhibition of -aminolevulinic acid (ALA) dehydratase [244] and ferrochelatase, [245] resulting in the accumulation of heme intermediates such as protoporphyrin. A shortened RBC survival accompanies lead poisoning and is probably due to decreased activity of pyrimidine 5-nucleotidase (also resulting in basophilic stippling of the RBC) and possibly inhibition of G6PD and the pentose shunt. [246]

The anemia of lead poisoning has classically been described as a hypochromic, microcytic anemia, as might be expected from the effects of lead on heme synthesis. Although anemia has been said to be a common finding in lead intoxication, in reality, anemia is uncommon unless the lead poisoning is severe or there is associated iron deficiency.

A strong association exists between lead poisoning and iron deficiency in children. Both tend to occur in the same population of predominantly lower socioeconomic status. Experimentally, iron deficiency has been shown to increase lead absorption, retention in tissues, and toxicity. [247] Iron deficiency also decreases lead excretion during chelation.[248] Lead may impede iron absorption and metabolism, thus leading to a vicious cycle of increasing lead toxicity and worsening iron deficiency. In a study of children with lead poisoning (blood lead 30 g/dl) 86% were found to have iron deficiency, and 100% of those with more severe lead poisoning (CDC risk classification III) [249] were iron deficient. [250]

There have now been a number of reports in children with lead toxicity documenting the infrequent occurrence of anemia without concomitant iron deficiency. Cohen et al.[251] found anemia in 12% and microcytosis in 21% of iron sufficient children with severe lead poisoning (CDC classes III and IV). The combination of anemia plus microcytosis, however, was found in only 1 of the 58 children. In less severely affected children (CDC classes I to III) Yip et al., [250] found a 30% incidence of anemia, but of those with either mild or no iron deficiency, only 6% were anemic. [250] Clark et al.[252] using multiple linear regression analysis, found transferrin saturation to be the most important predictor of mean corpuscular volume, hemoglobin, and zinc protoporphyin levels in children with lead poisoning. Two important points emerge from the foregoing information: (1) children with significant lead poisoning may have neither anemia nor microcytosis, and (2) children with documented lead

poisoning should be screened for underlying iron deficiency. The immediate treatment and long-term management of lead poisoning are beyond the scope of this chapter.[253]

HEMATOLOGIC ASPECTS OF DRUGS

Although hematologic effects of poisoning due to toxins or drug overdoses are well documented, iatrogenic adverse hematologic effects of prescribed medications are also an occasional reason for referral to a hematologist. The hematologic effects

of drugs are sometimes predictable and may be exploited for therapeutic benefit; however, rare or unexpected hematologic toxicity of drugs may cause considerable morbidity or even mortality, as well as pose diagnostic and therapeutic challenges to the clinician. Few data exist regarding the overall incidence of such adverse events in the pediatric population[254] and most are in the form of case reports. Table 151-3 lists peripheral blood cytopenias that have been associated with medications given to pediatric patients.

Drug-induced hematologic cytopenias have been reported in association with a large number of medications. A variety of mechanisms may apply to such cytopenias, including bone marrow suppression,[255] [256] aplasia,[257] [258] and nonimmune-[259] [260] [261] or immune-mediated[262] peripheral destruction. Antimicrobial and anticonvulsant medications are the most frequently reported classes of drugs implicated in hematologic toxicity in the pediatric age group, and valproate is the single most common drug reported in this context. Valproic acid has usually been associated with mild to moderate thrombocytopenia, occurring in 20% of children on long-term therapy.[263] [264] Severe and multilineage blood cytopenias have also been reported. [265] [266] The occurrence of macrocytosis and the Pelger-Huët anomaly are frequent manifestations of valproate hematopoietic toxicity.[263] The mechanisms by which cytopenias occur in valproate toxicity are not fully understood and may be multifactorial. Both immune-mediated effects and myelodysplasia have been reported. [265] [266] [267] The bone marrow findings may occasionally resemble acute leukemia.[267] Thrombocytopenia induced by valproate is frequently dose related [263] [264] and may respond to dose reduction, thereby allowing continued use of an agent effective in seizure control.

Adverse hemostatic effects from prescribed medications have also been reported in association with a wide range of drugs. Drug-induced bleeding diatheses may be secondary to hepatic failure[268] [269] or from impaired hepatic synthesis of procoagulant proteins.[270] Coagulopathy related to altered vitamin K metabolism may occur in the setting of broad-spectrum antibiotic use.[271] Consumptive coagulopathy has rarely been reported in association with various drugs. [272] [273] [274] A tendency to pathologic thrombosis has been described due to oral contraceptives [275] and L-asparaginase therapy.[276] The latter most closely corresponds to depletion of AT III, the major physiologic regulator of thrombin.[276]

HEMATOLOGIC ASPECTS OF METABOLIC DISEASES

A number of congenital disorders of metabolism may manifest hematologic abnormalities as part of the clinical presentation. Such global metabolic defects have diverse manifestations; especially prominent are neurologic findings, failure to thrive, and unexplained metabolic acidosis. Although the hematologic findings may be overshadowed by the systemic illness, the recognition of a characteristic pattern of signs and symptoms may lead expeditiously to the correct diagnosis. Table 151-4 is a compilation of inborn disorders of metabolism that may present in infancy or childhood with hematologic cytopenias.

SPLENOMEGALY IN CHILDREN

Splenomegaly is a problem frequently encountered by both the pediatrician and the pediatric hematologist. Although the spleen is rarely a site of primary disease, it may reflect systemic involvement with a variety of disorders. The spleen is the largest collection of lymphoid tissue in the body, with a unique association between the bloodstream and the reticuloendothelial compartment of the spleen. [343] Splenomegaly may result when there is antigenic stimulation of the lymphoid system (e.g., infection), obstruction of blood flow within or distal to the spleen (e.g., portal vein obstruction), exaggeration of one of the normal functions of the spleen due to an underlying abnormality (e.g., hemolytic anemia, splenic sequestration), or infiltration of the spleen by a foreign cell (e.g., leukemia, storage diseases).

The spleen tip is normally palpable in preterm infants; up to 30% of full-term neonates have a palpable spleen. [344] A spleen can be felt in up to 510% of normal children, but most of these are in the infant/toddler age group. As a general rule, a spleen easily palpable below the costal margin in any child over the age of 34 years must be considered abnormal until proven otherwise. That some palpable spleens may indeed be normal is attested to by the study of McIntyre and Ebaugh that 3% of healthy college freshmen have palpable spleens, of which about one-third persist. [345] Pretenders of splenomegaly include the left lobe of the liver, a left upper quadrant tumor such as Wilms tumor or neuroblastoma, the wandering spleen, [346] and the proptotic spleen (seen in children with depressed diaphragms from obstructive pulmonary disease, such as asthma or bronchiolitis).

A list of causes of splenomegaly in children is presented in Table 151-5 .[347] The most common cause of acute splenomegaly in children, especially young children, is a viral infection. Splenic enlargement in this setting is mild to moderate and usually transient. When history and physical examination suggest a viral etiology, a complete blood count with differential, platelet count, and reticulocyte count should be performed to rule out unsuspected leukemia or hemolytic anemia and to determine whether there is an atypical lymphocytosis. The child should be rechecked in 4 weeks (or sooner if symptoms persist). If splenomegaly persists beyond 46 weeks, the splenic enlargement may be considered chronic.

When evaluating the child with chronic splenomegaly, one must consider all of the possibilities noted in Table 151-5 . However, clues from the history and physical examination may suggest a specific etiology and direct a tailored approach to the diagnostic laboratory evaluation. If, on the other hand, there is no apparent cause of the enlarged spleen, a number of screening laboratory tests should be performed, including a complete blood count with differential, platelet count, and reticulocyte count; evaluation of the peripheral smear; sedimentation rate; liver function tests; antibody titers to EBV, CMV, and

TABLE 151-4 -- Hematologic Manifestations of Metabolic Disease with Onset in Infancy and Childhood

Finding	Category	Disease	Defect	Associated Findings	References
Anemia					
	Lysosomal enzyme defects	Gaucher disease, type 1	Glucocerebrosidase deficiency	Splenomegaly, thrombocytopenia, bone abnormalities, delayed puberty, lipid engorged macrophages (Gaucher cell) in bone marrow	[307]
		Niemann-Pick disease, type A	Acid sphingomyelinase deficiency	Feeding difficulties, hepatosplenomegaly developmental delay, neurodegenerative course, cherry-red macula, lipid laden macrophages (foam cell) in bone marrow	[308]
		Wolman disease	Acid lipase deficiency	Emesis, diarrhea, hepatosplenomegaly, thrombocytopenia, vacuolization of lymphocytes, lipid-laden macrophages in bone marrow, adrenal calcification	[309] [310]
	Defects of heme synthesis	Congenital erythropoietic porphyria	Uroporphyrinogen III cosynthase deficiency	Hemolysis, staining of diapers, photosensitivity, developmental delay, splenomegaly, thrombocytopenia, erythrodontia	[311]
		Erythropoietic protoporphyria	Ferrochelatase deficiency	Hemolysis, photosensitivity, neurologic findings, hepatobilliary dysfunction	[311]
	Defects of amino acid metabolism	Tyrosinemia, type 1	Fumarylacetoacetate hydrolase deficiency	Failure to thrive, emesis, hepatopathy, neurologic findings, thrombocytopenia, bleeding, cabbage-like odor, renal tubular dysfunction	[312]
	Defects of organic acid metabolism	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase deficiency	Acidosis, pancytopenia, emesis, neurologic findings, odor of sweaty feet	[313]
		Methylmalonic acidemia	Methylmalonyl-CoA mutase deficiency	Acidosis, leukopenia, thrombocytopenia, neurologic findings, failure to thrive, emesis	[314]
		Mevalonic aciduria	Mevalonate kinase deficiency	Acidosis, cataracts, neurologic findings, hepatosplenomegaly, thrombocytopenia	[315] [316]
		Propionic acidemia	Propionyl CoA carboxylase deficiency	Ketotic hyperglycinemia, acidosis, neurologic findings, pancytopenia	[317]
		Pyroglutamic aciduria	Glutathione synthetase deficiency	Hemolysis, neutropenia, neurologic findings, metabolic acidosis	[318] [320]
	Membrane transport defects	Lysinuric protein intolerance		Malabsorption, protein intolerance, hyperammonemia, neurologic findings, glomerulonephritis, pulmonary hemorrhage, thrombocytopenia, leukopenia	[321]

	Glycolytic pathway defects	Triosephosphate isomerase deficiency	Triosephosphate isomerase deficiency	Hemolysis, neurologic findings, myopathy	[322]
		Phosphoglycerate kinase deficiency	Phosphoglycerate kinase deficiency	Hemolysis, neurologic findings	[323]
	Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and utilization defects	Megaloblastosis, pancytopenia, failure to thrive, neurologic findings	[324]
		Folate metabolic defects	Folate transport and utilization defects	Megaloblastosis, ringed sideroblasts, thrombocytopenia, diarrhea, failure to thrive, neurologic findings	[325] [326] [327]
	Defects in metal metabolism	Wilson disease		Hemolysis, liver dysfunction, neurologic findings, Kayser-Fleischer rings, arthropathy	[328]
	Defects of purine and pyrimidine metabolism	Hereditary oroticaciduria	Uridine-5-monophosphate synthase deficiency	Megaloblastosis, leukopenia, orotic acid crystaluria, immunodeficiency	[329] [330]
		Lesch-Nyhan syndrome	Hypoxanthine-guanine phosphoribosyl-transferase deficiency	Megaloblastosis, hyperuricemia, nephrolithiasis, neurologic findings, self-mutilation	[331]
	Defects of carbohydrate metabolism	Galactosemia	Galactose-1-phosphate uridyltransferase deficiency	Hemolysis, failure to thrive, neurologic findings, jaundice, emesis, diarrhea, hepatic dysfunction, cataracts, gram-negative sepsis	[332]
		Glycogen storage disease type 1b	Deficient hepatic transport of glucose-6-phosphate	Neutropenia, hypoglycemia, acidosis, hepatomegaly, xanthomas, inflammatory bowel disease	[333] [334]
		Hereditary fructose intolerance	Aldolase b deficiency	Poor feeding, emesis, failure to thrive, neu-rologic findings, hypo-glycemia, liver dysfunc-tion, thrombocytopenia, ringed sideroblasts, coagulopathy, hemophagocytosis, shock	[335]
	Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletions	Megaloblastosis, ringed sideroblasts, neutropenia, thrombocytopenia, diabetes insipidus, diabetes mellitus, optic atrophy, deafness	[336]
		Pearsons syndrome	Mitochondrial DNA deletion	Ringed sideroblasts, vacuolization of marrow precursors, exocrine pancreatic dysfunction, metabolic acidosis, thrombocytopenia, neutropenia	[337] [338]
	Lipoprotein disorders	Abetalipoproteinemia		Hemolysis, acanthocytosis, bleeding, emesis, diarrhea, failure to thrive, neurologic findings	[339]

Neutropenia

	Lysosomal enzyme defects	Aspartylglucosaminuria	Aspartylglucosa minidase deficiency	Recurrent infections, diarrhea, hernias, lens opacities, neurologic findings, vacuolated lymphocytes	[340]
	Defects of organic acid metabolism	Barth syndrome (endocardial fibroelastosis-2)		Cardiomyopathy, endocardial fibroelastosis, skeletal myopathy, short stature, 3-methylglutaconicaciduria, abnormal mitochondria	[341]
		Isovaleric acidemia	Isovaleryl-CoA dehydrogenase deficiency	Acidosis, pancytopenia, emesis, neurologic findings, odor of "sweaty feet"	[313]
		Methylmalonic acidemia	Methylmalonyl-CoA mutase deficiency	Acidosis, anemia, leukopenia, neurologic findings, failure to thrive, emesis	[314]
		Propionic acidemia	Propionyl-CoA carboxylase deficiency	Ketotic hyperglycinemia, acidosis, neurologic findings, pancytopenia	[317]
		Pyroglutamic aciduria	Glutathione synthetase deficiency	Hemolysis, anemia, neurologic findings, metabolic acidosis	[318] [319] [320]
	Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and utilization defects	Megaloblastosis, pancytopenia, failure to thrive, neurologic findings	[324]
	Defects of carbohydrate metabolism	Glycogen storage disease type 1b	Deficient hepatic transport of glucose-6-phosphate	Anemia, hypoglycemia, acidosis, hepatomegaly, xanthomas, inflammatory bowel disease	[333] [334]
	Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletions	Megaloblastosis, anemia, ringed sideroblasts, thrombocytopenia, diabetes insipidus, diabetes mellitus, optic atrophy, deafness	[336]
	Mitochondrial disorders	Pearsons syndrome	Mitochondrial DNA deletion	Sideroblastic anemia, vacuolization of marrow precursors, exocrine pancreatic dysfunction, metabolic acidosis, thrombocytopenia	[337] [338]

Thrombocytopenia

	Lysosomal enzyme defects	Gaucher disease, type 1	Glucocerebrosidase deficiency	Splenomegaly, anemia, bone abnormalities, delayed puberty, lipid-engorged macrophages (Gaucher cell) in bone marrow	[307]
		Wolman disease	Acid lipase deficiency	Emesis, diarrhea, hepatosplenomegaly, anemia, vacuolization of lymphocytes, lipid-laden macrophages in bone marrow, adrenal calcification	[309] [310]
	Defects of heme synthesis	Congenital erythropoietic porphyria	Uroporphyrinogen III cosynthase deficiency	Hemolysis, staining of diapers, photosensitivity, developmental delay, splenomegaly, anemia, erythrodontia	[311]
	Defects of amino acid metabolism	Tyrosinemia type 1	Fumarylacetoacetate hydrolase deficiency	Failure to thrive, emesis, hepatopathy, neurologic findings, anemia, bleeding, cabbage-like odor, renal tubular dysfunction	[312]
	Defects of organic acid metabolism	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase deficiency	Acidosis, pancytopenia, emesis, neurologic findings, odor of sweaty feet	[313]
		Methylmalonic acidemia	Methylmalonyl-CoA mutase deficiency	Acidosis, leukopenia, anemia, neurologic findings, failure to thrive, emesis	[314]

		Mevalonic aciduria	Mevalonate kinase deficiency	Acidosis, cataracts, neurologic findings, hepatosplenomegaly, anemia	[315] [316]
		Propionic acidemia	Propionyl CoA carboxylase deficiency	Ketotic hyperglycinemia, acidosis, neurologic findings, pancytopenia	[317]
	Membrane transport defects	Lysinuric protein intolerance		Malabsorption, protein intolerance, hyperammonemia, neurologic findings, glomerulonephritis, pulmonary hemorrhage, anemia, leukopenia	[321]
	Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and utilization defects	Megaloblastosis, pancy-topenia, failure to thrive, neurologic findings	[324]
	Defects of vitamin metabolism	Folate metabolic defects	Folate transport and utilization defects	Megaloblastosis, ringed sideroblasts, anemia, diarrhea, failure to thrive, neurologic findings	[325] [326] [327]
		Holocarboxylase synthetase deficiency	Holocarboxylase synthetase deficiency	Acidosis, hyperammonemia, respiratory distress, neurologic findings, skin rash	[342]
	Defects of carbohydrate metabolism	Hereditary fructose intolerance	Aldolase B deficiency	Poor feeding, emesis, failure to thrive, neurologic findings, hypoglycemia, liver dysfunction, anemia, ringed sideroblasts, coagulopathy, hemophagocytosis, shock	[335]
	Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletions	Megaloblastosis, anemia, ringed sideroblasts, neutropenia, diabetes insipidus, diabetes mellitus, optic atrophy, deafness	[336]
		Pearsons syndrome	Mitochondrial DNA deletion	Sideroblastic anemia, vacuolization of marrow precursors, exocrine pancreatic dysfunction, metabolic acidosis	[337] [338]

toxoplasmosis; antinuclear antibody; and ultrasonic evaluation of the liver, spleen, and portal system (the latter with Doppler flow technique). Further evaluation, including bone marrow examination, may be necessary if the preceding screening tests do not reveal the cause of the splenic enlargement.

Symptoms from splenic enlargement are uncommon, although massive splenomegaly may cause abdominal discomfort and early satiety. If the spleen is sufficiently large, there may be increased destruction or sequestration of one or more of the formed elements of the blood (hypersplenism).

Management of splenomegaly is usually that of the underlying disease, where such treatment exits. Splenectomy may be indicated in selected conditions, but the potential benefits from splenectomy must be weighed against the risk of postsplenectomy sepsis, a rapidly progressive bacteremia, most commonly from *S. pneumoniae*, with a mortality rate of 50%.[348] The risk of postsplenectomy sepsis depends on the age of the patient and the nature of the underlying disorder. Patients <3 years old and those with a compromised immune or reticuloendothelial system are most susceptible. When elective splenectomy is indicated,

TABLE 151-5 -- Splenomegaly in Children

Disorders of the blood
Hemolytic anemia: congenital/acquired
Thalassemia
Sickle cell disease
Leukemia
Osteopetrosis
Myelofibrosis/myeloid metaplasia/thrombocythemia
Infections: acute and chronic
Viral
Congenital (TORCH)
Mononucleosis (EBV, CMV)
Virus-associated hemophagocytic syndrome
HIV
Bacterial
Sepsis/abscess
Brucellosis
Salmonella
Tularemia
Tuberculosis
Subacute bacterial endocarditis
Syphilis
Lyme disease
Fungal
Histoplasmosis (disseminated)
Rickettsial
Rocky Mountain spotted fever
Cat scratch disease
Parasitic
Toxoplasmosis
Malaria
Leishmaniasis (Kala-azar)
Schistosomiasis
Echinococcosis
Hepatic/portal system disorder
Acute/chronic active hepatitis
Cirrhosis/hepatic fibrosis/biliary atresia
Portal or splenic venous obstruction (Banti syndrome)
Autoimmune disease
Juvenile rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune lymphoproliferative syndrome (Canale-Smith syndrome)[349]

Neoplasms/cysts Lymphomas (Hodgkins and non-Hodgkins) Hemangiomas/lymphangiomas Hamartomas Congenital or acquired (post-traumatic) cysts
Storage diseases/inborn errors of metabolism Lipidoses: Gauchers disease, Niemann-Pick disease, etc. Mucopolysaccharidoses Defects in carbohydrate metabolism: galactosemia, fructose intolerance Sea blue histiocyte syndrome
Miscellaneous Histiocytoses Reactive Langerhans cell Malignant Sarcoidosis Congestive heart failure

it is advisable (1) to postpone surgery until the patient is at least 56 years of age, (2) to administer pneumococcal, meningococcal, and *H. influenza* (if not previously vaccinated) vaccines at least 12 weeks before splenectomy, (3) to consider prophylactic penicillin for at least 4 years, and (4) to manage significant febrile illnesses as possible postsplenectomy sepsis at all times.

Chapter 152 - Hematologic Problems in Patients with Cancer and Chronic Inflammatory Disorders

Irwin M. Weinstein
Barry E. Rosenbloom

HEMATOLOGIC PROBLEMS IN PATIENTS WITH CANCER

In patients with malignancy, hematologic abnormalities are encountered with considerable frequency. [1] [2] [3] [4] [5] [6] [7] [8] These abnormalities result directly from the malignancy or as a consequence of treatment.

Red Blood Cells

Anemia

Anemia is the most common hematologic abnormality seen in association with cancer, occurring in approximately 50% of patients during the course of their illness. [1] [2] Review of the red blood cell indices, reticulocyte count, peripheral smear, iron studies, hemolytic studies, and bone marrow examination usually delineate the etiology (Table 152-1).

Anemia of Chronic Disease

Anemia of chronic disease (ACD) is the most common type seen with nonhematologic malignancies. [9] [10] [11] It can manifest early in the course of disease in association with cancer, and the severity of anemia can parallel the extent of the underlying cancer. Although bone marrow involvement may be present, it is not required to cause this type of anemia. The etiology of ACD is unclear.

Treatment has until recently been limited to treatment of the underlying disease or blood transfusions. However, regular administration of human erythropoietin (EPO) can ameliorate the ACD associated with cancer. [12] [13] [14] [15] [16] [17]

Tumor Invasion of the Marrow

Marrow invasion by solid tumors can be seen most frequently with small-cell lung cancer, breast cancer, prostate cancer, and lymphoma. Anemia occurs as a direct result of replacement of the marrow with tumor. Peripheral smears may show a leukoerythroblastic pattern; with severe involvement, pancytopenia

TABLE 152-1 -- Causes of Anemia in Cancer

can occur. Extensive bone marrow fibrosis can accompany marrow invasion, further exacerbating the peripheral blood abnormalities. Treatment of the underlying malignancy, blood transfusions, and more recently EPO administration have been beneficial. [15]

Pure Red Blood Cell Aplasia

Although rare, pure red blood cell aplasia has been reported with neoplasms other than thymoma, including lymphoid tumors, nonsmall-cell lung cancer, breast cancer, and gastric cancer. The bone marrow typically shows a marked reduction of erythroid precursors, and plasma EPO levels are markedly increased. In approximately one-half the cases, an autoantibody directed against red blood cell progenitors can be observed. [18] [19] In T-cell chronic lymphocytic leukemia, T-lymphocyte suppression of erythropoiesis has been described, and this may be operative in patients with other types of malignancies. [20] [21] Treatment of pure red blood cell aplasia in patients with thymoma by thymectomy is successful in one-third of cases. Resection of the malignancy in patients with other types of tumors is also successful. However, most such patients need immunosuppressive therapy, including corticosteroids, high-dose immunoglobulin, antithymocyte globulin, danazol, and cytotoxic agents. Blood transfusion support is invariably required.

Anemia Due to Blood Loss

Iron deficiency is frequently the initial manifestation of patients with gastrointestinal malignancies. Renal carcinoma and bladder carcinoma may lead to blood loss through hematuria. Postgastrectomy patients may rebleed at sites of marginal ulcerations, and achlorhydria can impair iron absorption. The clinical distinction between iron deficiency and ACD may be difficult. Serum iron and transferrin levels can be low in both, but serum ferritin levels <10 mg/L are almost always due to iron deficiency. The presence of blood in the stools or urine is presumptive evidence for iron deficiency. Bone marrow iron stores are markedly reduced or absent.

Appropriate diagnostic studies to determine the site of blood loss should be the initial step. Treatment with oral iron preparations or parenteral iron dextran administration can improve the anemia. However, the hemoglobin level may not return to normal because, concomitantly, ACD may be present.

Therapy-Related Anemia

Treatment of solid tumors with cytotoxic agents usually leads to bone marrow depression, which can result in anemia. Although granulocytopenia and thrombocytopenia induced by such treatments reverse within 47 days after their onset, the anemia may be chronic and persist throughout the course of treatment secondary to depressed erythropoiesis. Macrocytic red cell indices and megaloblastic dysplasia of the bone marrow are frequently seen. [22] Blood transfusions may be needed, and EPO administration may benefit some patients and quality of life may improve. [23] [24]

Nutritional Causes of Anemia

Folic acid deficiency due to poor dietary intake can be seen as a result of anorexia associated with cancer. In addition, postgastrectomy patients with achlorhydria will develop vitamin B_{12} malabsorption, although anemia may take 35 years to develop. [25] Malnutrition per se can lead to ACD.

Hemolytic Anemias Associated with Cancer

Immunohemolytic Anemia.

Autoimmune hemolytic anemia is principally associated with lymphoid malignancies. Approximately 45% of patients with angioimmunoblastic lymphadenopathy will develop this type of hemolysis, and 2025% of patients with chronic lymphocytic leukemia will develop autoimmune hemolysis during the course of their illness. [26] [27] Additionally, patients with non-Hodgkin lymphoma can develop typical autoimmune hemolytic anemia. [28] With solid tumors, this is less frequent but is well documented with squamous carcinomas of the lung and cervix, adenocarcinomas of the breast, lung, ovaries, stomach, and colon, as well as others (Table 152-2). Most patients exhibit the warm antibody pattern with a positive direct antiglobulin test (Coombs test). However, cold agglutinins can be seen with non-Hodgkin lymphoma. When treatment directed at the underlying illness is successful, hemolysis can be ameliorated. However, more often other measures, including corticosteroids, cytotoxic agents, high-dose intravenous immunoglobulins, and splenectomy, are necessary.

Microangiopathic Hemolytic Anemia.

Mechanical intravascular destruction of red blood cells is relatively common with metastatic adenocarcinomas, especially those that secrete mucin. [29] [30] [31] Gastric cancer is the most frequently associated malignancy. The clinical laboratory findings associated with hemolysis are present, and, in addition, the peripheral smear will show schistocytes, helmet cells, and sometimes thrombocytopenia. In severe cases, nucleated red cells are seen in the peripheral blood along with hemoglobinemia, hemoglobinuria, and hemosiderinuria. The etiology appears, in part, to be due to low-grade disseminated intravascular coagulation (DIC) occurring in response to tumor products in the circulation that activate coagulation. Tumor products can also cause enhanced circulating platelet aggregates, which may also cause mechanical red blood cell destruction. [32] [33] Tumor products and platelet aggregates may cause endothelial cell damage leading to clinical manifestations of thrombotic microangiopathy. [34] Treatment is directed at the underlying tumor, but is usually incomplete because of the advanced state of the neoplasms associated with this complication.

Drug-Associated Hemolysis.

Mitomycin C has been associated with a syndrome of microangiopathic hemolytic anemia of a severe nature, with thrombocytopenia and renal insufficiency mimicking de novo hemolytic uremic syndrome. [35] [36] [37] Many of these patients have circulating immune complexes. This type of hemolytic uremic syndrome is usually refractory to treatment, with an almost invariably fatal course. However, recent reports suggest that plasma exchange, immuno-perfusion, and azothioprine may benefit some patients, especially when circulating immune complexes are etiologic. [38] A similar clinical picture has been reported with the bleomycin/ cisplatin-related Raynaud syndrome, and after exposure to

daunorubicin, cytosine arabinoside, methyl-CCNU, deoxycorfomycin, and tamoxifen. [34] [39] [40]

Some chemotherapeutic agents have caused a warm antibody type of hemolytic anemia. This has been reported with cisplatin, tenoposide, melphalan, and methotrexate. The mechanism appears similar to that seen with high-dose penicillin-associated hemolytic anemia. [41] Discontinuation of the drug usually leads to resolution of this hemolysis.

In patients with glucose-6-phosphate dehydrogenase deficiency, administration of doxorubicin can cause an oxidant stress, producing a hemolytic anemia. [42] Discontinuation of this drug leads to resolution.

Hemophagocytic Syndrome.

The hemophagocytic syndrome has rarely been reported with gastric cancer, lymphoma, and acute leukemia.[43] This syndrome is characterized by pancytopenia, fever, lymphadenopathy, and splenomegaly. The bone marrow resembles histiocytosis with hemophagocytosis by benign-appearing macrophages. This syndrome is unresponsive to treatment and is usually fatal within a few weeks.

Polycythemia

True erythrocytosis has been reported with certain neoplasms, including renal cell carcinoma, hepatocellular carcinoma, and cerebellar hemagioblastoma. [44] [45] [46] This phenomenon has been noted in approximately 13% of patients with renal cell carcinoma, and in many of these cases elevated serum EPO levels are found. Although tumor cells from these patients do contain immunoreactive EPO, erythrocytosis in patients with Wilms tumor is due to pressure-induced hypoxia of the adjacent normal renal parenchyma.[47] [48] Removal of the kidney in patients with renal cell carcinoma has frequently led to reversion of the red cell mass to normal, and recurrence of the polycythemia has occurred when metastatic disease develops.

The association of secondary polycythemia and hepatocellular carcinoma may be due to the production of extrarenal EPO. [49] [50] Other mechanisms such as diminished metabolism of androgenic-like substances have been postulated. [51] [52] Regardless of the etiology, if the tumor can be completely excised, reversal of this abnormality can ensue.

White Blood Cells

Leukocytosis

Mild-to-moderate leukocytosis can be seen with malignancies such as bronchogenic carcinoma, gastric carcinoma, and renal cell carcinoma. When the tumors are widespread and necrotic, a typical neutrophilic leukemoid reaction can be seen, with white cell counts of 50,000/mm ^{3} or more.[53] Counts as high as 200,000/mm^3 have been reported. The distinction between a leukemoid reaction and leukemia is sometimes confusing, but in the leukemoid reaction, immaturity is typically absent and the leukocyte alkaline phosphate score is high. The cause of this phenomenon may be tumor-elaborated colony-stimulating factors (CSFs). [54] [55] No specific therapy is warranted for this problem.

Leukopenia and Neutropenia

Leukopenia can be seen in association with marrow invasion due to malignancy and leukoerythroblastosis may be observed. More typically, leukopenia is a result of bone marrow depression due to chemotherapy. This is usually reversible within 47 days of onset. More rarely, prolonged leukopenia may be seen after a chemotherapeutic course with antileukemic therapy. The use of growth factors, including granulocyte-CSF and granulocyte/macrophage-CSF has led to an earlier recovery for these patients.[56] The use of these growth factors has become increasingly routine in treating infected neutropenic patients. [57] Furthermore, these agents are being increasingly used with high-dose chemotherapy regimens to ameliorate or prevent severe neutropenia. [58] [59] [60]

Neutropenia is frequently associated with the T--cell lymphoproliferative syndrome. [61] In this disorder, T-suppressor cells appear to inhibit granulopoiesis directly. This syndrome has responded to corticosteroids, cyclophosphamide, and granulocyte-CSF.

Platelets

Thrombocytosis

Thrombocytosis associated with malignancy probably represents a reactive response to the presence of malignancy and is seen with frequency in patients with cancer,[62] [63] with or without bone marrow hypercellularity and increased megakaryocytes. Whether thrombocytosis per se in part causes the hypercoagulable state seen in association with cancer is unclear. No specific treatment for this abnormality is available.

Thrombocytopenia

Modest thrombocytopenia is frequent after treatment of solid tumors with cytotoxic agents.[64] Severe life-threatening thrombocytopenia can occur in such patients, especially if they have had prior radiotherapy or incomplete recovery from prior bone marrow depressive treatment. The bleeding risk may be enhanced by concurrent infection as a result of treatment-induced granulocytopenia. In addition, the risk of gastrointestinal hemorrhage may be enhanced by breaks in mucosal integrity due to chemotherapy. Recovery from most chemotherapy occurs within 1 week after onset. However, some agents such as mitomycin C or the nitrosoureas may cause prolonged thrombocytopenia. Bone marrow invasion can also lead to thrombocytopenia, and bleomycin damage of pulmonary endothelium may lead to platelet destruction.[65]

Treatment for thrombocytopenia due to chemotherapeutic agents should follow the same guidelines established for leukemic patients. Although most patients have a spontaneous recovery of their platelets after chemotherapy, in those who have any bleeding or whose platelet counts fall too low, platelet transfusions may be necessary.

Autoimmune thrombocytopenia is most commonly seen in association with lymphoid malignancies, but also can be seen with lung cancer, breast cancer, and testicular carcinoma.[66] [67] Treatment with corticosteroids, cytotoxic agents, high-dose intravenous -globulin, and splenectomy may be necessary if treatment of the underlying neoplasm does not improve this condition.

Coagulation Abnormalities

Cancer-Related Thrombosis

Patients with cancer have a greater tendency to thrombosis as a result of a number of causal mechanisms. This hypercoagulable state has been characteristic of patients with various malignancies. In addition to cancer patients being debilitated and possibly requiring prolonged bed rest, tumors can compress or invade blood vessels, leading to stasis, and the normal hemostatic mechanisms may become disrupted.[68] [69] [70] [71] Also, release of tumor products into the circulation may be thrombogenic.

It has been demonstrated that many of the procoagulants are increased in patients with cancer. Fibrinogen and factors V, VII, VIII, IX, and XI have been found to be elevated.[72] [73] When DIC is present, antithrombin III, protein C, and protein S can be consumed, leading to an increased tendency to thrombosis. [74] Neoplastic

cells themselves can initiate clotting by releasing tissue factor, which complexes with factor VIIa in the blood to activate factor X. [75] Tissue factor has been described with lung, kidney, colon, and breast cancer. The migratory thrombotic syndrome known as Trousseau syndrome may be caused by this latter mechanism.[76] [77] This clinical syndrome has sometimes been called chronic DIC when a thrombotic tendency dominates the syndrome instead of a bleeding tendency. [78]

Mucinous adenocarcinomas of the lung, gastrointestinal tract, and ovary are associated with a high risk of thrombosis. In addition, systemic trypsin from pancreatic carcinoma can activate coagulation.[79]

Other mechanisms may be active, including monocytic production of procoagulant substances.[80] [81] [82] [83] The substances expressed include tissue factor, factor X activators, and prothrombinase complex. The lupus inhibitor and anticardiolipins are seen with some malignancies. They increase the thrombotic risk, although the actual mechanism is unknown. Increased platelet aggregation is seen in patients with cancer, which may add to the risk of thrombosis. [84] [85]

Treatment of cancer-related thrombosis starts with minimizing the conditions associated with thrombosis, such as prolonged bed rest and lower extremity edema. Although successful treatment of the underlying tumor can benefit these patients, many of these tumors are resistant to therapy and therefore anticoagulation should be considered. Some can be treated with warfarin, but heparin may also be useful. Anticoagulation in cancer patients can be fraught with difficulties, including heparin resistance and a greater bleeding risk. [86] [87] The use of thrombolytic agents is discouraged because the bleeding risk in cancer patients is high. [88]

Nonbacterial Thrombotic Endocarditis

Nonbacterial thrombotic endocarditis is a paraneoplastic thrombotic syndrome associated with predominantly neurologic complications and (less frequently) systemic embolization. [89] [90] Such patients can present with embolic strokes manifested by focal or generalized neurologic findings (or both). Cardiac findings are minimal, and fever is absent. Embolism to other sites such as the spleen, kidneys, gastrointestinal tract, and coronary arteries are detected at autopsy but are rarely clinically manifest. Additional findings at autopsy include fibrin-platelet vegetations on the mitral and aortic valves. Tumors most commonly associated with this complication include nonsmall-cell lung cancer, prostate cancer, and pancreatic cancer. Anticoagulants are of no benefit in this condition.

Cancer-Related Bleeding

Disseminated intravascular coagulation is a frequent cause of cancer-related bleeding. Although it is most frequently seen with prostate cancer, it has been reported with cancers of the gastrointestinal tract, ovary, and lung, as well as melanoma. Many of these patients bleed, usually mildly; bleeding can become massive after manipulating the tumor, as in prostate cancer surgery. Infections may exacerbate a compensated DIC and lead to bleeding. The treatment of DIC associated with cancer can be challenging. Treating the underlying disease is frequently inadequate. Judicious use of heparin may benefit some patients. [91]

Certain chemotherapeutic agents have been associated with hemostatic defects. L-Asparaginase can lead to the production of a functionally impaired fibrinogen, which may cause bleeding. [92] Mithramycin can cause platelet dysfunction and increased fibrinolysis, leading to an enhanced bleeding risk. [93] Suramin, which is used for refractory prostate cancer, has been associated with clinical bleeding. [94] Actinomycin D can antagonize vitamin K, and the anthracyclines have been reported to cause primary fibrinogenolysis. These effects will reverse with discontinuation of the agents.

HEMATOLOGIC PROBLEMS IN PATIENTS WITH CHRONIC INFLAMMATORY DISORDERS

Rheumatic Diseases

Inflammatory rheumatic disorders are commonly associated with hematologic abnormalities, especially anemia. The anemia of rheumatoid arthritis has been a classic model for studying ACD. Anemia and other hematopoietic dysfunctions also occur frequently in systemic lupus erythematosus (SLE). Other inflammatory states associated to a lesser degree with hematopoietic disorders include mixed connective tissue disease, polymyalgia rheumatica, dermatomyositis, scleroderma, and Sjögren syndrome.

Anemia of Rheumatic Disorders

Anemia of Chronic Disease

Anemia, usually ACD, is the most common hematologic abnormality found in rheumatic disorders.[95] The exact pathogenesis of ACD still remains a matter of debate. In 1966, Cartwright[10] postulated three basic abnormalities: impaired marrow response, possibly due to diminished production of EPO; impaired release of iron from the reticuloendothelial system; and a mild decrease in red cell survival. More recently, several studies have clarified the relationship of EPO to the anemia of rheumatoid arthritis.[96] [97] [98] [99] The EPO level is inversely correlated with the hemoglobin level. Although EPO levels rise in response to the anemia of rheumatoid arthritis, the rise is less than that found in patients with the same degree of anemia who have other illnesses. However, the blunted EPO effect is not the primary cause of the anemia of rheumatoid arthritis because the EPO levels are still greater than normal. [100] [101] Recent investigations have studied the failure of the bone marrow to respond to higher levels of EPO in chronic inflammatory disorders, particularly rheumatoid arthritis. Several cytokines involved in the inflammatory response are elevated in chronic inflammatory diseases.[102] [103] These include tumor necrosis factor-alpha (TNF-), interleukin (IL)-1, IL-6, interferon- and interferon-, and the pteridine neopterin, which is a marker of immune activation. IL-6, which is increased in patients with rheumatoid arthritis, produces anemia in animals and correlates with the other more common markers of inflammation such as the sedimentation rate. However, it is not clear in humans whether IL-6 is important in the pathogenesis of the anemia of rheumatoid arthritis or is merely a marker of disease activity. [104] [105] Cytokines may be involved in the impaired EPO response to anemia in rheumatic disorders. IL-1 and TNF- inhibit EPO production from a hepatoma cell line. This effect may occur at the level of EPO mRNA. [106] [107]

The pathogenesis of the disturbances of iron metabolism in rheumatoid disorders (decreased serum iron and iron-binding capacity, normal or increased tissue iron) has been extensively studied. Early studies demonstrating a block in the release of reticuloendothelial iron using [59] Fe-labeled iron have not been confirmed when smaller doses of radiolabeled iron were used.[108] [109] [110] [111] [112] These more recent studies also suggest that the disturbances of iron metabolism may be secondary to decreased erythropoiesis. The role of cytokines in the erythropoiesis of inflammatory disorders shows their involvement in the impairment of iron metabolism. [113] Recombinant TNF induces anemia and hypoferremia in animals.[114] [115] IL-1 increases ferritin production, and this additional ferritin may trap iron, making it unavailable for red cell production. [116]

Treatment options for the ACD associated with rheumatic

CONSIDERATIONS REGARDING THE USE OF EPO IN INFLAMMATORY DISORDERS

1. Pretreatment EPO level is not predictive of an optimal response.
2. Therapeutic dosage usually needs to be larger than that used in patients with renal failure.
3. It is prudent to delay therapy until the effects of treatment of the underlying disorder are evaluated.
4. Coexisting iron deficiency will blunt the response of EPO, and iron deficiency can develop during EPO treatment.
5. In most circumstances an EPO trial should be avoided in mild anemia (i.e., hematocrit >30 vol%).
6. An adequate response to EPO is an increase of the hematocrit l6 vol% in 68 weeks of therapy or relief of symptoms of anemia, or both.
7. A maintenance dose must be determined for each responder. A useful hint is to start by decreasing the dose by one-third.
8. Chronic administration of EPO is not justifiable for trivial improvement in the hematocrit or in the absence of an overall clinical improvement.

disorders have increased since the availability of EPO (see box). A recent randomized placebo-controlled double-blind study showed that EPO administered subcutaneously to active rheumatoid arthritis exerted a beneficial effect on disease activity. [117] Pharmacologic doses of EPO often ameliorate the anemia in patients with rheumatoid arthritis.[118] [119] [120] [121] EPO can also correct cytokine-induced inhibition of erythropoiesis in animals. [122] [123] EPO does not correct the anemia of chronic renal and inflammatory disorders in the presence of concomitant iron deficiency. Iron deficiency can develop during EPO treatment. [124] [125]

Iron Deficiency Anemia

Iron deficiency anemia commonly coexists with ACD in rheumatic disorders, especially in rheumatoid arthritis. If the serum ferritin level is <10 ng/L, the diagnosis of coexisting iron deficiency needs no further iron studies. When levels of ferritin are this low, gastrointestinal blood loss, particularly in patients taking anti-inflammatory drugs, is suggested.[126] When the serum ferritin level is >30 ng/L, the diagnosis of iron deficiency is more difficult and ultimately may depend on the finding of absent bone marrow iron.[127] In an attempt to avoid the need for a bone marrow study, various combinations of iron studies have been used. One recent study using a three-step algorithm measuring the serum ferritin, mean cell volume, and iron saturation, correctly classified 94% of rheumatoid arthritis patients with iron

deficiency.[128]

Hemolytic Anemia

Acquired hemolytic anemia, usually secondary to immune mechanisms, is frequently associated with rheumatic disorders, particularly SLE. The anemia may vary from mild to severe and is typically characterized by the presence of spherocytes on the peripheral blood film. Autoimmune hemolytic anemia associated with autoimmune thrombocytopenia is occasionally seen in SLE (Evan syndrome).

Therapy of autoimmune hemolytic anemia depends on the severity of the red cell destruction. Some patients have a compensated hemolytic state and need no therapy. More often, the anemia is severe enough that treatment should be instituted with corticosteroids. Large doses are usually required (prednisone 60100 mg/day orally). Beneficial responses occur in most patients, especially those with SLE. [129] Patients with severe anemia who have not responded to corticosteroids or in whom a large maintenance dose is required should be managed by splenectomy. However, poor-risk patients with SLE or other rheumatic syndromes may be treated first on immunosuppressive drugs, danazol, plasmapheresis, or high-dose intravenous -globulin. Reported results with these therapeutic modalities are contradictory.[130] [131] [132] [133] [134] [135]

Acquired Pure Red Cell Aplasia

Pure red cell aplasia is an uncommon immunologic disorder that has been reported in association with both rheumatoid arthritis and SLE. Pure red cell aplasia should not be mistaken for ACD. Distinctive features are moderate-to-severe anemia, marked reticulocytopenia, and the findings in the bone marrow of severe hypoplasia of the red cell series and normal production of the other marrow cell lines.

Spontaneous remission occurs in about 1015% of these patients. The management of this condition requires withdrawal of all medications. If there is no response to withdrawal nor any spontaneous remission occurring within a few weeks, corticosteroids, cytotoxic agents, antithymocyte globulin, danazol, cyclosporine, plasmapheresis, high-dose -globulin, and splenectomy may be considered. [136] [137] [138] [139] [140] [141] [142] [143] EPO therapy is not helpful. About two-thirds of patients in need of treatment will respond to one or more of the other modalities.

Neutropenia

With the exception of patients with SLE, neutropenia is seen infrequently in the inflammatory arthritides. In SLE, a neutropenia has been reported to occur in about one-half of patients.[144] The neutropenia in this setting is usually not severe and is not often associated with an infectious complication. Therefore, initiation of therapy is usually not indicated. Indeed, the neutropenia may worsen with cytotoxic therapy, even though the neutropenia is thought to be due to immune destruction of mature neutrophils or marrow progenitors.[145] Occasionally the neutropenia of SLE is secondary to hypersplenism.

Felty syndrome is an uncommon but important hematologic abnormality that occurs in 1% of patients with rheumatoid arthritis, developing about 15 years after the onset of the disease and usually when the arthritis is not active. [146] The characteristic triad of Felty syndrome is rheumatoid arthritis, splenomegaly, and neutropenia. The syndrome is also associated with recurrent infections, leg ulceration, rheumatoid nodules, and lymph node enlargement. The neutropenia is usually severe, ranging between 500 and 2,500/mm^3 . The mechanism of the neutropenia has been attributed to antineutrophil antibodies, increased occurrence of immune complexes, inhibition of neutrophil production mediated by T cells, altered neutrophil distribution, reduced neutrophil function, and hypersplenism. [147] [148] [149] Elevated levels of neutrophil-bound IgG and serum IgG neutrophil-binding activity are found in about one-half of these patients with Felty syndrome. [150]

Appropriate therapy for Felty syndrome is often difficult. If infections have been infrequent and mild in nature, no intervention is needed. Repeated and serious infections or chronic leg ulceration usually require treatment. In addition to the administration of appropriate antibiotics, other therapies are usually tried with mixed results. These include cytotoxic agents, corticosteroids, methotrexate, cyclosporine, penicillamine, plasmapheresis, gold salts, and splenic radiation. The role of splenectomy remains a matter of controversy. For decades, it has been known that splenectomy normalizes the neutrophil count in about one-half of patients with rheumatoid arthritis. Prior to the modern antibiotic era, mortality and morbidity were exceedingly high following splenectomy. Today, splenectomy is

still an increased risk and postoperative morbidity is frequent. Neutropenia recurs in about 20% of splenectomized patients. Splenectomy may be more effective in patients with high levels of serum granulocyte-binding IgG. [151] With the availability of leukocyte growth factors (granulocyte- or granulocyte/macrophage CSFs), the neutropenia of Felty syndrome has been ameliorated and the overall management of these patients has been improved. Although there have been complications, including reactivation of the arthritis, thrombocytopenia, vasculitis, and skin rash, sustained responses are commonly seen. [152] [153] [154] [155] [156] [157] [158] [159] [160] [161]

Certain similarities are apparent among Felty syndrome, the T- lymphoproliferative disorder, and hairy cell leukemia. Both hairy cell leukemia and the T-lymphoproliferative disorder are malignancies that have a known association with rheumatoid arthritis. [162] Patients with hairy cell leukemia may present with complaints of arthralgias or arthritis. [163] Table 152-3 summarizes some clinical and laboratory findings of these three syndromes.

Coagulation Disturbances

Thrombocytopenia

Thrombocytopenia, usually autoimmune in type, frequently occurs in the rheumatoid disorders, especially in patients with SLE. [164] It has also been reported in dermatomyoisitis, scleroderma, and mixed connective tissue disease. Thrombocytopenia is rare in rheumatoid arthritis, and its presence should alert the consultant to the possibility of a drug-related etiology or an unrelated primary bone marrow disorder. The therapy of autoimmune thrombocytopenic purpura in SLE is similar to that used in the management of idiopathic thrombocytopenic purpura, except that some evidence shows that splenectomy is less likely to be effective in patients with SLE.[165] Patients with SLE who fail corticosteroid therapy should be considered for alternative therapies other than splenectomy. These include cyclophosphamide, azothiaprine, vincristine, danazol, or high-dose intravenous -globulin. The prognostic significance of autoimmune thrombocytopenia in patients with SLE has been a matter of dispute. The platelet count is probably not a prognostic indicator in SLE. [166]

Although thrombotic thrombocytopenic purpura is associated with SLE, the relationship appears to be an example of distinct clinical entities occurring together in an immunologically compromised host, rather than a causal association. In patients with SLE who have neurologic symptoms along with thrombocytopenia, thrombotic thrombocytopenic purpura should be considered. Aggressive plasmapheresis is the treatment of choice and is usually effective. [167] [168]

Thrombocytosis

Thrombocytosis occurs in about one-half of patients with rheumatoid arthritis. The increased platelet count is an acute-phase reactant correlating positively with the sedimentation rate and the clinical activity of the disease. [169] This reactive thrombocytosis is almost never in excess of 1 million/mm^3 . Usually, the increased platelet count is 400,000700,000/mm^3 . The reactive thrombocytosis in these patients is only rarely associated with abnormal bleeding or clotting.

The Lupus Inhibitor

An elevated partial thromboplastin time is frequently found in patients with rheumatoid disorders, especially SLE. Typically, these patients have no history of bleeding nor any familial bleeding tendency. Most often, this elevation of the partial thromboplastin time is due to the presence of a lupus inhibitor. Although the reported case was of a hemorrhagic disorder,[170] this syndrome is generally not associated with bleeding but with an increase of both venous and arterial thrombotic events. In pregnancy, the lupus inhibitor is associated with increased spontaneous abortions, presumably secondary to placental infarctions. The correlation between the lupus inhibitor and an elevated anticardiolipin antibody titer is strong. Anticardiolipin antibody titers are found in about 40% of patients with SLE and 30% of patients with rheumatoid arthritis. Hughes[171] has described an antiphospholipid antibody syndrome in which these elevated antibodies are associated with thrombosis, recurrent fetal loss, and thrombocytopenia. The diagnosis of a lupus inhibitor is easily established.

Because the important clinical association is between the lupus inhibitor and thrombotic events, a program to prevent recurrent thrombosis is essential. Most patients do not have a history of thrombotic events even when their cardiolipin antibody level is quite high. Such patients should not be placed on an oral anticoagulant. However, if there is a history of thrombosis, warfarin should be administered. If thrombosis occurs in patients on warfarin, aspirin or immunosuppressive agents may be tried, although their effectiveness in this setting is not well defined. The management of pregnant patients with the lupus

TABLE 152-3 -- Differential Diagnosis of Syndromes Associated with Rheumatoid Arthritis

	Peripheral Blood	Bone Marrow	Spleen Size	Lymph Node Size	Tartaric Acid Phosphatase Activity	Renal Abnormalities	Cell Markers
Felty syndrome	Absolute neutropenia Cytopenias No characteristic cell	Normal Hypercellular Hypocellular	Splenomegaly prominent	Enlargement common	Negative	Usually absent	Normal or variable abnormalities
T- lymphoproliferative disorder	Lymphocytosis Cytopenias (neutropenia) Characteristic large granular lymphocyte	Lymphocytic infiltration	Splenomegaly present, not prominent	Enlargement rare	Rarely positive	Commonly present	Suppressor cytotoxic T cells $CD2^+$, $CD3^+$, $CD8^+$, $CD16^+$
Hairy cell leukemia	Cytopenias Characteristic hairy cell	Dry aspirate Hairy cells on biopsy	Splenomegaly present, not prominent	Enlargement rare	Positive Nearly pathognomonic	Usually absent	B-cell origin $CD11^+$, $CD19^+$, $CD20^+$, $CD22^+$

inhibitor is the subject of debate. The literature suggests that both aspirin and corticosteroids are useful. [172] [173] However, these agents may be dangerous in pregnancy.

Hematologic Malignancies

An increased incidence of lymphoproliferative disorders has been reported in patients with many of the rheumatoid disorders but most frequently with Sjögren syndrome. The incidence of eventual lymphoma in Sjögren syndrome is >40 times that expected in the general population. The incidence of leukemia and myeloma is two to eight times expected.[174] The association of hairy cell leukemia and the T- lymphoproliferative disorder with rheumatoid arthritis has been discussed previously.

Infectious Diseases

The hematologic consequences of viral, bacterial, and fungal infections are extremely common and protean in nature. A complete review of this relationship is beyond the scope of this discussion, which is restricted to hematologic manifestations of infectious diseases that might typically result in a hematologic consultation. Human immunodeficiency virus infection and hematologic disturbances are discussed elsewhere (Chap. 154).

Viral Infections

Neutropenia

Contrary to common perception, although neutropenia is frequently seen in viral infections, mild leukocytosis, both granulocytic and lymphocytic, is probably more frequent, particularly early in the course of the viral illness. [175] Certain viral illnesses are particularly apt to be associated with neutropenia. They include influenza, hepatitis, rubella, rubeola, adenovirus, coxsackie virus A21, dengue, and mumps. The specific cause(s) for neutropenia is still not well defined. [176] The neutropenia of common viral infections is almost never profound and is generally self-limiting. A hematology consultation is often requested when there is a severe neutropenia ($1,500/mm^3$) that has persisted for >1 or 2 weeks. This situation should be investigated further, including a bone marrow study to rule out a primary bone marrow disorder.

Lymphocytosis

Lymphocytosis occurs frequently in viral disorders. A childhood illness, acute infectious lymphocytosis, often occurs in outbreaks and is usually caused by the coxsackie virus.[177] [178]

Atypical lymphocytosis is characteristically seen in infectious mononucleosis as a result of an Epstein-Barr virus (EBV) infection. The primary cell target of EBV is the B lymphocyte. The response of activated suppressor CDA^+ T cells to the attack on B lymphocytes results in the characteristic large lymphocytes seen in this disorder. Atypical lymphocytosis may also be found in cytomegaloviral disease, hepatitis, mumps, varicella, rubeola, rubella, herpes simplex, herpes zoster, influenza, and roseola infantum. The appearance of infectious mononucleosis-like illness in an older adult may raise a concern about a lymphocytic leukemia, usually of the acute variety. In this uncommon setting, lymphocyte phenotyping and bone marrow evaluation will quickly resolve the concern. Some patients maintain the clinical and serologic manifestations of infectious mononucleosis for some period following the acute infection. [179] This sequela is rare but may especially be seen in families with a genetic disposition to disorders such as the X-linked lymphoproliferative syndrome. [180]

Thrombocytopenia

Mild-to-moderate thrombocytopenia is frequently seen in patients with measles, dengue, varicella, rubella, rubeola, mumps, EBV disease, and cytomegaloviral disease. Thrombocytopenia is rare in hepatitis B and in herpes simplex virus. Important bleeding events are rare in this viral-associated thrombocytopenia. Idiopathic thrombocytopenic purpura occurs in the aftermath of a viremia in children. Usually this complication is self-limited, but at times the thrombocytopenia is severe and prolonged, and intervention is necessary. In children, corticosteroid therapy is usually successful, and splenectomy is only rarely needed. DIC has occurred during the course of viral infections, especially rubella, rubeola, varicella, vaccinia, and variola. This is often a frightening complication unexpectedly accompanying a seemingly common childhood viral infection, but it is rarely fatal. [181] Hemorrhagic complications may also be alarming in other viral infections such as those caused by the arbovirus, the adenovirus, and the enterovirus. In these settings, fatal reactions have occurred and are attributed to DIC-like mechanisms. [182]

Virus-Related Bone Marrow Failure

Epstein-Barr virus and other viral infections have been reported to cause the hemophagocytic syndrome. This peculiar disorder is characterized by fever, hepatosplenomegaly, lymph node enlargement, rashes, and pancytopenia. Bone marrow study reveals hemophagocytosis and histocytic hyperplasia. It may be a self-limiting process, but death can occur.[183] A fatal outcome is frequent when this illness occurs in patients with malignancies.

Hematologic abnormalities have been associated with uncomplicated hepatitis, including leukopenia, thrombocytopenia, anemia with macrocytosis, and atypical lymphocytosis. Fatal aplastic anemia is a rare occurrence (0.22%) in patients with infectious hepatitis. [184] Conversely, patients with aplastic anemia may have an antecedent history of abnormal liver function tests, suggesting a subclinical hepatitis. Most cases of aplastic anemia, especially the fatal ones, occur within 6 months of the onset of the hepatitis and often when the illness is improving. Bone marrow transplantation after high-dose chemotherapy is effective in 7080% of these patients.[185] Transient aplastic crises due to infection with the parvovirus B19 has been described in patients with sickle cell disease and hereditary spherocytosis. In

hematologically healthy children, parvovirus B19 causes fifth disease. In adults, this virus causes arthralgias. Parvovirus B19 has been described as the causal agent for pure red cell anemia and transient aplastic anemia in immunodeficient patients. [186] The myriad of hematologic manifestations of human immunodeficiency virus positivity and the acquired immunodeficiency syndrome are discussed elsewhere (Chap. 154).

Bacterial and Fungal Infections

Neutrophilia

Neutrophilia is the hallmark of bacterial infection. Children have higher white counts in response to these infections than do adults. Neutrophil counts of 12,00015,000/mm^3 are usual in moderate and localized infections. Systemic infections are commonly associated with neutrophil counts of 15,00025,000/mm ^{3} , and in severe pyogenic infections neutrophil counts may reach 50,00075,000/mm ^{3} . Neutrophilic leukemoid reactions (>50,000/mm ^{3}) in adults can be confused with chronic myeloid leukemia. The presence of known infection and the finding of an elevated leukocyte alkaline phosphatase generally excludes chronic myeloid leukemia. Usual causes of leukemoid reactions include metastatic disease of the bone marrow, Hodgkin disease, and carcinoma of the stomach, breast, liver, and lung. When evaluating patients with neutrophilia of uncertain origin, a review of the morphologic changes in the peripheral blood film may be helpful. Infection as the etiology of the neutrophilia should be considered when findings such as toxic granulation, cytoplasmic vacuolization, Döhle bodies, and the Pelger-Huët

anomaly are found. However, these morphologic changes are more commonly seen when infection is obvious. They are also found in a diverse variety of noninfectious states, including myeloproliferative disorders, burns, pregnancy, and drug reactions. [187] Most fungal infections do not produce neutrophilia.

Neutropenia

Neutropenia is unusual in patients with bacterial infections. However, it is found with some frequency in patients who have salmonellosis, brucellosis, pertussis, rickettsial infections, disseminated tuberculosis, and disseminated histoplasmosis, as well as in the presence of overwhelming infection. Neutropenia in overwhelming infection is an indication of exhaustion of the bone marrow neutrophil reserve and is generally considered a poor prognostic sign. Usually the neutropenia associated with bacterial infections is modest and not clinically important. Severe neutropenia in patients with bacterial infection is more likely to occur in the elderly, in alcoholics and other drug abusers, and in patients who are myelosuppressed. The therapeutic value of granulocyte- and granulocyte/macrophage-CSF for the amelioration of severe neutropenia in these settings is under investigation. Most fungal infections do not produce neutropenia.

Lymphocytosis

Lymphocytosis >4,000/mm^3 is seen most often in pertussis. In this infection the lymphocytosis is usually 15,00025,000/mm ^{3} , but occasionally it may rise to 150,000/mm^3 . Other bacterial infections commonly associated with lymphocytosis are rickettsial illnesses, tuberculosis, syphilis, and burcellosis. Lymphocytosis is often seen as part of a neutrophilic leukemoid reaction. A lymphocytic leukemoid reaction has rarely been seen in patients with tuberculosis.

Lymphocytopenia

Lymphocyte counts <1,000/mm^3 are common in many acute infections, particularly when marked neutrophilia is present. Tuberculosis, brucellosis, and disseminated histoplasmosis infections frequently cause lymphocytopenia. Lymphocytopenia in elderly patients with a bacterial infection is a poor prognostic sign. [188]

Monocytosis

A low-grade monocytosis of >800/mm^3 often accompanies the recovery phase of acute infections. Of patients with disseminated tuberculosis and patients with subacute bacterial endocarditis, 1520% have a monocytosis. [189] [190] Persistent monocytosis following recovery from an infectious disorder suggests the possibility of an underlying primary marrow disorder and should be investigated.

Eosinophilia

Eosinophilia >350/mm^3 is rare in patients with bacterial or fungal diseases. Exceptions are bronchopulmonary aspergillosis, coccidiomycosis, and chlamydia pneumonitis of infancy. Fungal infections with eosinophilia appear to be related to immune responses, particularly high serum concentrations of IgE. The most common causes of infection-induced eosinophilia are parasites in the gastrointestinal tract. Occasionally eosinophilia from parasitic infections can be quite high and can mimic that degree of eosinophilia seen in the hypereosinophilic syndrome.

Thrombocytosis

Thrombocytosis (500,000700,000/mm^3) is fairly common in some chronic bacterial infections, including tuberculosis, subacute bacterial endocarditis, and osteomyelitis. However, thrombotic events accompanying this degree of platelet elevation are quite rare.

Thrombocytopenia

Any acute bacterial or fungus infection causing bacteremia or fungemia can cause thrombocytopenia. Several mechanisms are responsible for this development, but increased consumption is probably the most common. Tuberculosis, histoplasmosis, and rickettsial diseases may be associated with thrombocytopenia in the absence of bloodstream infection. The finding of thrombocytopenia in bacterial and fungal infections usually raises the specter of DIC. In the absence of this complication, severe bleeding from thrombocytopenia in acute bacterial and fungus infections is rare. However, severe infections are the most common cause of DIC, particularly in those caused by gram-negative bacilli. Fungal infections are only rarely associated with DIC. The prognosis of infection-induced DIC is relatively good because of the likelihood of control of the infection with appropriate antibiotic therapy. Platelet transfusions are valuable while the infectious etiology is being treated. Extreme forms of DIC, such as that seen with purpura fulminans, may prove fatal. [191]

Anemia

A significant anemia is uncommon in acute bacterial and fungal infections. An exception is the complication of a hemolytic anemia seen with a *Clostridium welchi*i or *Bartonella bacilliformis* infections. The anemia of chronic bacterial infection is usually the result of ACD.

Chapter 153 - Hematologic Manifestations of Infectious Disease

David S. Rosenthal

INTRODUCTION

Many catastrophic infections may affect the patient with hematologic-oncologic diseases. From the fungal lung infections of the acute leukemia patient to the *Salmonella*-associated osteomyelitis of the patient with sickle cell disease, the infectious disease consultant is of tremendous support in the overall management of hematologic diseases. Just as important is the role of the blood specialist in assisting the clinician in managing the various hematologic manifestations of infections. Some infectious diseases may cause a number of different, and occasionally opposite, blood dyscrasias. For example, tuberculosis, depending on its degree of severity, may present as pancytopenia with myelophthisis in one individual, but may mimic acute or chronic myeloid leukemia (AML, CML) in another. *Aspergillus* infection can cause disseminated intravascular coagulation (DIC) in one patient and thrombosis in another. A wide range of abnormalities and effects on primitive and adult hematopoietic cells occur with bacteria, viruses, fungi, and protozoa [1] and are discussed in this chapter. Infection with the human immunodeficiency virus (HIV) and the acquired immunodeficiency syndrome (AIDS) are discussed in Chapter 154; infectious mononucleosis is discussed in Chapter 58 .

ANEMIA

Anemia that results from infection can be categorized according to the same pathophysiologic mechanisms that apply to anemia in general: blood loss, decreased production, and increased destruction (Table 153-1). Anemia secondary to gastrointestinal (GI) blood loss can occur in patients with hookworm infestation and bowel involvement by shigellosis or typhoid. *Helicobacter pylori* has been implicated in gastric and duodenal

TABLE 153-1 -- Pathophysiology of Anemia

Blood loss
Gastrointestinal (hookworm)
Genitourinary (schistosomiasis)
Pulmonary (tuberculosis)
Decreased production
Aplasia
Anemia of chronic disease
Anemia of acute infection
Increased destruction
Intraerythrocyte parasitization
Immunohemolytic conditions
Autoimmune
"Innocent bystander"
Polyagglutination
Enzyme deficiency (G6PD)
Pathologic changes
Hemolytic-uremic syndrome
DIC
Hypersplenism

ulcer disease and may cause upper GI tract hemorrhage,[2] while blood loss can be significant when due to hematuria associated with bacterial cystitis, or with hemoptysis due to large cavitary pulmonary disease associated with tuberculosis or aspergillosis. Blood loss anemia, which is usually acute in these disorders, will be associated with iron deficiency anemia as well if it is chronic.

Most infections can cause some degree of marrow suppression or decreased production. In an acute or self-limited illness, the effect on blood cell counts may be imperceptible. If the illness is prolonged, the blood cell count changes will be more striking. Infection-induced myelosuppression can involve all three hematopoietic lines, resulting in aplastic or hypoplastic anemia, or the red cells alone, resulting in a number of acute and chronic infections.

Aplastic Anemia

Aplastic anemia is extremely uncommon but can result directly or indirectly from an infectious agent. Hepatitis, usually hepatitis C, has been shown to carry a significant risk for aplasia.[3] [4] Approximately 0.10.2% of all patients with hepatitis develop pancytopenia, while 5% of patients with aplastic anemia have a recent history of hepatitis. The incidence is unrelated to the severity of the infection, and the prognosis is grave. The marrow suppression generally occurs during the convalescent phase, and the mechanism is not clear. Certain viruses, among them hepatitis B, are known to be trophic for hematopoietic cells. [5] The ability to transplant compatible marrow cells into affected patients suggests that the virus does not cause damage to the marrow microenvironment. [6]

Other viral illnesses such as HIV infection, infectious mononucleosis, noncytopathic lymphocytic choriomeningitis virus (LCMV), and B19 parvovirus are also associated with aplastic anemia. Although anemia associated with parvovirus usually occurs in individuals with other underlying hematologic conditions, such as hemolytic anemia, immunodeficiency syndrome, or subsequent to transplantation, cases in previously normal individuals have been reported. [7] [8] [9] [10] [11] [12] Human parvovirus 19 is highly trophic to human bone marrow and can replicate in erythroid progenitor cells. It is believed that the occurrence of red cell aplasia is related to the fact that the B19 cellular receptor, globoside, is a blood group P antigen. Experimental studies with B19 parvovirus suggest an inhibitory effect of the organism on erythropoiesis.[7] The addition of infected sera to human marrow culture systems caused significant inhibition of erythropoiesis as measured by colony-forming unit-erythroid and burst-forming unit-erythroid growth. In the specific clinical conditions described previously, patients should be screened for B19 infection, because the viral-induced aplasia resolves quickly with immunoglobulin treatment. [13] [14] The aplasia caused by LCMV may be mediated by the interferon- (IFN-) or IFN-.[15] Replacement of the marrow by the granulomas of tuberculosis and histoplasmosis and the marrow necrosis caused by overwhelming gram-negative and gram-positive infections, mucor, dengue fever, rubella, *Brucella*, or *Salmonella typhi* may result in pancytopenia and marrow failure.[16] [17] [18] In these instances, possible mechanisms for pancytopenia include (1) a direct toxic effect causing marrow necrosis, (2) myelophthisis due to replacement by granulomas, (3) histiocytic hemophagocytosis, or (4) nutritional deficiencies as seen in anorexia nervosa. Indirectly, infectious organisms can interfere with hematopoiesis by activating macrophages or lymphocytes to release inhibitory mediators.[19] Whatever the mechanism of infection-related marrow failure, the incidence is greater in patients previously compromised by poor nutrition, alcohol abuse, or previous exposure to chemotherapy.

Pancytopenia may also result from persistence of congestive splenomegaly related to malaria, infectious mononucleosis, toxoplasmosis, hepatitis, salmonellosis, tularemia, syphilis, subacute bacterial endocarditis, tuberculosis, or schistosomiasis.

Anemia of Chronic Disease

The anemia of chronic disease (Table 153-2) is probably the most common blood dyscrasia to occur as a result of infection. [20] [21] [22] [23] The degree of anemia tends to correlate with the intensity of the fever or the degree of inflammation. The anemia may be normocytic, normochromic or microcytic, hypochromic and is characterized by a decreased reticulocyte count and low serum iron and serum transferrin levels with a slight to moderate decrease in percent saturation, and by decreased marrow sideroblasts but normal to increased body iron stores. The most common infectious diseases resulting in anemia of chronic disease are bacterial or fungal endocarditis, meningitis, empyema, cavitary pulmonary disease, abscess (especially intra-abdominal), chronic peritonitis, chronic osteomyelitis, and chronic

infectious arthritis (Table 153-2). In addition, any chronic infection such as tuberculosis, leprosy, typhoid, tularemia, brucellosis, or Lyme disease can be associated with anemia of chronic disease.

One mechanism for this anemia was initially proposed by Cartwright and Lee. [20] The reticuloendothelial system becomes activated by the chronic infection, resulting in a block in normal iron transfer. The result is that iron released by senescent red cells is picked up by stimulated macrophages and blocked from release to marrow erythropoietic precursors. Thus, marrow stores of iron (in macrophages) are sufficient, but sideroblasts are reduced to absent. Another theory relates to the effect of various cytokines whose activity is enhanced by infection. [21] Interleukin-1 (IL-1) and tumor necrosis factor- (TNF-) are two such proteins. [24] Bacteria and fungi, as well as certain endotoxins and other infectious agent by-products, are enhancers of IL-1 production and release. Among other biologic properties, IL-1 activates neutrophils to release lactoferrin and inhibits liver cells from synthesizing transferrin, thus resulting in decreased serum iron. [25] The IL-1-induced hypoferremia is thought to be a homeostatic mechanism to decrease the virulence of infection. Infusing iron into experimental animals increases the severity of infection, while reducing the iron level by chelation decreases the virulence. [26] [27] A similar mechanism involves the role of TNF in anemia of chronic disease.

TABLE 153-2 -- Anemia of Chronic Disease

Laboratory findings
Normochromic normocytic or microcytic hypochromic
Decreased reticulocyte count
Decreased serum iron
Decreased serum transferrin
Slight to moderate decrease in iron saturation
Slight to moderate decrease in sideroblasts
Normal to increased iron stores

Endocarditis (bacterial or fungal)
Meningitis
Emphysema
Cavitary pulmonary disease
Abscess
Chronic peritonitis
Chronic osteomyelitis
Chronic infectious arthritis
Agents
Tuberculosis
Leprosy
Typhoid
Tularemia
Brucellosis
Lyme disease

Anemia of Acute Infection

The anemia of acute infection has been described in children admitted for *Hemophilus influenzae* meningitis. [28] Although this infection is more commonly associated with hemolysis, the reticulocyte count has been reported to be low in some cases, implying marrow suppression. The anemia is usually mild and rebounds without hematinics when the infection is resolved. Other acute infections in children, such as osteomyelitis, arthritis, and pneumonia, can also cause a picture not too dissimilar from anemia of chronic disease.

Hemolytic Anemia

Hemolytic anemia, the rapid destruction of red cells, can occur as a result of infections and can involve many of the same mechanisms classically described for hemolysis in general, such as immune mechanisms, underlying red cell defects, or increased susceptibility to phagocytosis by macrophages in the spleen. [1] [29] Table 153-3 categorizes infection-induced hemolysis into that associated with normal red cells, that associated with an underlying red cell defect such as an enzyme deficiency, and that related to pathologic changes secondary to the infection. These anemias can be clinically quite dramatic, as well as demanding and exciting for the laboratory involved in their evaluation.

Parasitic and Bacterial Infection

Intraerythrocyte parasitization and red cell destruction occur with malaria and babesiosis as well as with *Bartonella bacilliformis* infection. In these disorders, the red cells are lysed, deformed, or removed by the spleen either directly or through immune mechanisms. Malaria-infected tissues release millions of merozoites into the circulation that adhere to erythrocytes through specific red-cell-surface antigens. [30] *Plasmodium falciparum* merozoites adhere to red cell glycophorin and then invade the membrane, creating a route of entry for the parasite. The cytoskeleton structure opens up to allow passage and then

reforms itself after the organism has entered the cytoplasm. Some red cells are lysed immediately by the resulting parasitization, while others, containing the characteristic Wright-Giemsa appearance (Fig. 153-1) and shapes, feed on hemoglobin and produce various proteins. These malaria by-products can protrude through the membrane and cause the cell to adhere to vascular endothelium or other red cells, or both. IgG is attracted to these abnormal proteins and prepares the cell for immune destruction by the splenic reticuloendothelial system. With continued splenic hemolysis, the spleen enlarges, causing increased red cell destruction by trapping and removing partially damaged or deformed erythrocytes. The most serious hemolytic complication is blackwater fever. In rare instances of *P. falciparum* infection, an overwhelming and acute intravascular hemolysis occurs as a result of a direct autoimmune reaction;the Coombs test is positive.

Babesiosis-induced hemolysis is similar to malaria. The disease occurs along the coast of New England, is caused by *Bacillus microti*, and is transmitted from infected deer mice by the tick from the *Ixodes* species. The parasite invades the red cell directly by a complement-mediated mechanism. The symptoms range from generalized malaise to a hectic fever and hemolytic anemia. [31] Infection in splenectomized patients can lead to catastrophic intravascular hemolysis and acute renal failure. [32]

Bartonellosis (Oroya fever) is transmitted by a sandfly, not uncommon in Peru. [33] Within 23 weeks of the bite, fever, chills, and hemolysis occur. The hemolysis is quite dramatic and severe. The organism attaches to the surface of the red cell and may or may not invade the membrane (Fig. 153-2). If untreated, the patient can die from the event.

Although it is well known that bacteria produce hemolytic toxins, rarely is there a direct effect in humans. An exception occurs in *Clostridium perfringens* infection, which can cause severe hemolysis through its -toxin, a lecithinase, which reacts with red cell membrane lipoproteins to release lysolecithin, a red cell-lysing agent. [34] [35] The resultant intravascular hemolysis can be quite sudden and dramatic. Suspicion of this infection is raised after septic abortion, biliary tract disease, traumatic wound infection, or with malignancy. A patient with CML developed a hemolytic crisis secondary to clostridial sepsis. She

Figure 153-2 (A) Wright-stained blood smear from Oroya fever (*Bartonella bacilliformis*). The parasites are pleomorphic, stain bright red, are usually spherical, and can form small chains (× 1,100). *(From Bogemann and Rastetter,[100] with permission.)* **(B)** Scanning electron microscopy showing *Bartonella* burrowing into and penetrating the membranes of red cells during hemolytic septicemia. *(From Benson et al.,[101] with permission.)*

was able to survive for almost 5 hours with a hematocrit of 0% on the oxygen-carrying capacity of free hemoglobin. [36]

Many other severe bacterial infections have been associated with hemolysis. [37] Rapidly falling hematocrits and increased reticulocyte counts without evidence of bleeding have been reported with septicemia and endocarditis due to gram-negative or gram-positive organisms. Intravascular hemolysis has been cited secondary to cholera, while hemoglobinuria has been observed in miliary tuberculosis and some spirochete infections such as those caused by *Borrelia*. The mechanism for these types of hemolysis is unclear, but evidence points to a direct effect of the infectious agent or its by-product.

Immunohemolytic Conditions

A large number of infection-related hemolytic anemias can be due to an immunohemolytic condition. The immunohemolytic conditions can be divided into three categories: (1) autoimmune, (2) antigen/antibody complexes or "innocent bystander" reactions, and (3) polyagglutination. [29] An infectious agent or its by-product can stimulate antibody production with an affinity for a red-cell-surface-specific protein and cause an autoimmune hemolytic anemia (AHA). The agent need not be present. The resultant hemolysis can be either intravascular, secondary to IgM or "cold" antibodies, or extravascular, secondary to IgG antibodies, which are usually of the "warm" type and are directed against one of the Rh antigens. Most of the infection-induced AHAs are of the cold antibody type and are referred to as cold hemagglutinin disease (CHAD). Two of the commonest infections causing CHAD are *Mycoplasma pneumoniae* and Epstein-Barr virus (EBV) associated with infectious mononucleosis. [38] [39] [40] Both infectious agents can result in IgM antibodies directed against the I, i red cell antigens: *Mycoplasma* with anti-I antibodies and infectious mononucleosis with anti-i antibodies. These cold agglutinin antibodies bind to the red cell at low temperatures, fix complement, and cause hemolysis. The incidence of CHAD with *M. pneumoniae* and EBV infections is low, but is aggravated by low external temperatures. Other

infections such as mumps, rubella, cytomegalovirus (CMV), and *Legionella* have also been known to produce CHAD. [41] [42] [43]

In secondary and congenital syphilis, an AHA can result from the production of Donath-Landsteiner antibodies. Even though these proteins are of the IgG class and react against the P antigen of red cells, they do so at cold temperatures, and the resultant clinical picture has been labeled paroxysmal cold hemoglobinuria. [44] In affected patients this can be a chronic illness and may require patients to live in warm climates. Paroxysmal cold hemoglobinuria can also occur as an acute illness following varicella, infectious mononucleosis, mumps, measles, MMR (measles, mumps, rubella) vaccination, parvovirus B19 infection, and *Mycoplasma* infection. [45] [46] During the convalescent stage of these infections or when the patient is exposed to low environmental temperatures, the individual suddenly develops pallor, jaundice, hemoglobinuria, and splenomegaly.

Rarely are infections associated with AHA secondary to warm antibodies. A case of *Chlamydia* pneumonia has been described with IgG antibodies. [47]

The "innocent bystander" mechanism for AHA is caused by the complex of the antigen with the antibody, in proximity to the red cell. An infectious agent or antibiotic medication, or both, can cause antibody formation. The resultant antigen/antibody complex in the bloodstream can nonspecifically attach to the red cell and lead to hemolysis, the red cell being the "innocent bystander." *H. influenzae* type b meningitis in children can cause this type of hemolysis. [48] The antigen of the bacteria and its resultant antibody are simultaneously present in the bloodstream of children with this infection. [49] The protein complex binds in some way to red cells, fixes complement, and causes intravascular hemolysis. Drugs that have been implicated in the "innocent bystander" type of hemolysis include antibiotics such as quinine, quinidine, sulfonamide, *p*-aminosalicylic acid, and sulfanilic acid derivatives.

The third mechanism for AHA has been termed polyagglutination. [29] Antigens that are normally hidden or masked from contact with the red cell membrane, called Thomson-Friedenreich cryptoantigens or T antigens, may become exposed by infectious agent enzyme digestion and make the red cell membrane more susceptible to normal plasma antibodies. [50] For example, neuraminidase, produced by enteric bacteria, can break down red cell surface glycoproteins, unmask the T antigen, and expose the red cell to natural blood IgM antibodies, resulting in cell agglutination or polyagglutination and eventual hemolysis. [51] AHA can be detected by the sudden clinical picture, and by a positive result on an antiglobulin or Coombs test.

Hemolysis Due to Infection in G6PD-Deficient Patients

Normal red cells cope with the oxidative stresses of infections and drugs with the help of reducing enzymes. [52] Four enzymes keep the red cell membrane and hemoglobin in the reduced state. Once oxidized, the membrane becomes rigid and susceptible to extravascular hemolysis within the spleen (Fig. 153-3). Oxidized hemoglobin or methemoglobin form inclusions within the cell (Heinz bodies) that cling to the surface of the membrane and further initiate extravascular hemolysis. The Heinz body-membrane interface is subject to splenic macrophage stimulation that causes the red cell to look as if a piece had been removed, a "bite cell." Of the four enzymes involved, glucose-6-phosphate dehydrogenase (G6PD) is most frequently deficient in various populations. Several common genetic variants such as G6PD ^{A} , G6PD^{Mediterranean} , and G6PD^{Canton} are associated with decreased enzyme activity. Historically, a higher incidence of infection-related hemolysis has been noted in blacks than in whites in the United States, which led to the hypothesis that infection causes hemolysis in G6PD-deficient patients. [53] [54] Infection-activated neutrophils produce superoxide, which converts

Figure 153-3 Pathophysiology of infection-induced hemolysis in G6PD-deficient patients. *(From Beck and Tepper,[102] with permission.)*

hemoglobin to methemoglobin. In the absence of the enzyme, methemoglobin interacts with hydrogen peroxide, Heinz bodies are formed, the red cell membrane becomes rigid, and hemolysis results. [55] [56] [57]

G6PD-deficient patients may not have had any prior clinically evident hemolysis when they first come to medical attention. Affected patients have sudden hemolysis, scleral icterus, and increased reticulocytes, with or without splenomegaly. The blood film may initially show bite cells along with polychromatophilia. Heinz body preparations may be positive if performed during the acute hemolytic episode. G6PD enzyme assays can be falsely normal during the hemolytic period, since enzyme activity is highest in young red cells, in some variants high enough to give a normal result. The cyanide-ascorbate test detects the red cells ability to prevent hemoglobin oxidation by ascorbate and can be sensitive enough to detect as few as 1015% deficient cells on a slide. [58]

The most frequent infectious organisms associated with hemoglobin oxidation are listed in Table 153-4 and include *Salmonella, Escherichia coli*, streptococci, various rickettsiae, and organisms causing viral hepatitis. In addition, influenza A virus has been shown to have a direct lytic effect in vitro on

G6PD-deficient cells. [59] Many antibiotics and medications used in managing infections are direct oxidants and cause hemolysis in enzyme-deficient patients during convalescence. Table 153-4 lists the more common agents implicated clinically.

Pathologic Changes

The final group of infection-induced hemolytic diseases can be categorized by tissue damage or hypertrophy. Pathologic changes in tissues created directly or indirectly by the infecting organism is the mechanism of hemolysis, as in the hemolytic-uremic syndrome, DIC, bacterial endocarditis, or hypersplenism. The hemolytic-uremic syndrome primarily affects young adults, children, and infants and follows a nonspecific infection. [60] For example, after an upper respiratory tract infection or bout of gastroenteritis, the child experiences the sudden development of hemolysis, thrombocytopenia, and renal failure. Pathologic changes noted in the renal glomeruli are consistent with a thrombotic microangiopathy. The blood film is characteristic of a microangiopathic hemolytic anemia, with fragmented cells, burr cells, helmet cells, and schistocytes. Whatever the inciting agent, endothelial injury occurs and leads to platelet aggregation, microthrombus formation, and the mechanical destruction of platelets and red cells. A direct toxic effect on the hematopoietic cells may occur as well. DIC and thrombotic thrombocytopenic purpura are in the differential diagnosis. Usually no organism can be identified, but documented relationships have been reported with *E. coli* (verotoxin-producing strains), *Shigella*, and *S. pneumoniae*. [61] The *E. coli* verotoxin is known to cause vascular injury, while *Shigella* infections may involve an endotoxin effect, and *Streptococcus*-associated disease may be mediated by the neuraminidase effect on cells through the organisms ability to unmask the T antigens (see previous discussion). [62]

Traumatic valvular hemolysis, a result of high blood flow through abnormal mitral and aortic valves, can occasionally be seen with rheumatic heart disease and in infective endocarditis due to organisms such as *Candida albicans*. [63] Hypersplenism and DIC, other causes of increased red cell destruction, are considered later in this chapter.

WHITE BLOOD CELL DISORDERS

Leukocyte disorders vary considerably from infection to infection and from individual to individual. A bacterial infection may cause neutrophilia in one instance and neutropenia in another. In addition to the absolute changes in numbers of lymphoid and myeloid cells, morphologic, immunologic, and functional alterations can result from infection.

Leukocytosis

The leukemoid blood picture is of great alarm to the clinician. It is most frequently caused by infection (Table 153-5). [64] [65] Although the definition varies, the basis for the entity is (1) no evidence of leukemia, (2) a white blood cell (WBC) count of >50 × 10^9 /L, with or without (3) the presence of immature cells. With some infections, the added complication of anemia and thrombocytopenia can create a difficult differential diagnostic problem that is solved only by a marrow examination, a leukocyte alkaline phosphatase determination, or cell marker studies.

Infections can mimic myeloid or lymphoid leukemia, acute or chronic. CML is probably the most common diagnosis with infection. A high WBC count with few or no immature cells can be seen with infections accompanying other disorders such as malignancy, inflammatory arthritis, or glomerulonephritis. More difficult to differentiate is the exaggerated response to disseminated

tuberculosis, with WBC counts as high as 200 × 10^9 /L, accompanied by a moderate left shift. [66] [67] [68] Similar blood pictures have been seen with staphylococcal septicemia and pneumonia, meningitis secondary to *H. influenzae* and *Neisseria meningitidis*, pneumococcal endocarditis, salmonellosis, diphtheria, and bubonic plague. [69] In the event of an elevated WBC count without a source of infection, it may be necessary to determine the leukocyte alkaline phosphatase concentration and in some instances to obtain a marrow sample for cytogenetic analysis.

An AML picture has also been described with tuberculosis, either in its disseminated form or when the organism invades lymphoid tissue and the spleen. [67] [70] A pseudoleukemic blood picture is not uncommon as a rebound phenomenon in antibiotic-induced agranulocytosis and after marrow suppression from severe bacterial and protozoan infections. This scenario may be extremely difficult to diagnose and requires careful follow-up observations after appropriate therapy.

Chronic lymphocytic (CLL) and acute lymphocytic (ALL) leukemias are less frequently confused with infections. In the pre-antibiotic era, potentially fatal cases of pertussis were reported to have WBC counts as high as 200 × 10^9 /L. [71] Similarly, chickenpox and the viral exanthems may be associated with extremely high mature lymphocyte counts. The age of the patient, associated symptoms, the clinical absence of adenopathy, and the presence of splenomegaly will often suffice to make the diagnosis. Rarely will it be necessary to obtain a bone marrow aspirate or analyze for lymphocyte clonality. Disseminated tuberculosis has also been reported to be associated with high WBC counts, with immature lymphoid cells resembling lymphoblasts and ALL. [68] [72] The blood findings of infectious mononucleosis (see Chap. 58) often instill the greatest fear of a diagnosis of ALL in young adults. The clinical picture, the "atypically atypical" lymphocytes (i.e., a nonuniform population of lymphocytes), in addition to abnormal liver function tests, serologic findings, and a normal marrow, will exclude ALL.

Disseminated tuberculosis may also mimic AML. [93] The recovery phase of many other infections may occasionally give rise to a high WBC count with monocytosis. Myelodysplastic

blood smears and marrow samples are being seen in greater frequency with infection and may be difficult to differentiate from the true myelodysplastic syndromes. HIV infection can cause marrow findings not greatly dissimilar from those of refractory anemia or refractory anemia with excess blasts (see Chap. 71). A leukoerythroblastic picture, immature myeloid cells, and nucleated red cells in the blood can be seen in septicemia, miliary tuberculosis, and histoplasmosis. [74] Less dramatic blood changes in the lymphoid, myeloid, and monocytic cell lineages caused by infection are considered in the following sections. Overall, the best approach

to diagnosing and excluding a primary hematologic problem is careful monitoring during the recovery phase of the infection to be sure of the causal relationship.

Lymphocytosis

Absolute increases in lymphocytes are rarely seen in acute bacterial infections (Table 153-6).[23] [75] Pertussis is the notable exception. Affected infants of <6 months of age have only minimal changes, whereas in >50% of older children the WBC count can rise to 1520 × 10^9 /L during the first 2 weeks of illness and, rarely, into the leukemoid range. *Bordetella pertussis* toxin, known as pertussigen or lymphocytosis-promoting factor, has been shown to increase the lymphocyte count in animal experiments.[76] It is suspected that pertussigen blocks the normal migration of lymphocytes out of the bloodstream and into the tissues. The cells are normal B and T cells.

Rickettsial infections such as scrub typhus, tuberculosis, syphilis, and brucellosis can also cause an absolute lymphocytosis. Acute infectious lymphocytosis varies from a very mild nonspecific illness to a more acute disorder characterized by fever, diarrhea, upper respiratory tract symptoms, central nervous system involvement, and dramatic, absolute lymphocyte counts of 30100 × 10^9 /L. Although no definite etiologic agent is known, an adenovirus and coxsackievirus A with incubation periods of 1221 days have been implicated.

Lymphocytopenia

Lymphocyte counts of <1 × 10^9 /L are quite common in acute hospitalized patients, in infections, sepsis, malaria, HIV infection, and in a number of chronic infections such as tuberculosis, histoplasmosis, and brucellosis. [77] [78] The decreased lymphocyte count (often in association with neutrophilia) probably results from elevated plasma cortisol levels. The degree of lymphocytopenia seems to correlate with the severity of the infection.

Morphologic and immunologic lymphoid changes may occur with disease. Atypical lymphoid cells characterized by an abnormal nuclear/cytoplasmic ratio with resultant increased cytoplasm are not uncommon in infectious mononucleosis, infectious hepatitis, and some chronic infections. Changes in the

numbers of B and T cells and in the ratio of T-cell subsets are hallmark findings in HIV infection (see Chap. 154) but have also been shown to occur in other viral infections and in bacterial and fungal disease. [79] [80] For example, in acute bacterial infections, T cells of all types can decline in number early in infection, while numbers of B cells rise. Prolonged T-cell lymphopenia in the face of active infection is more frequent in aging patients and is considered a poor prognostic finding. In leprosy and tuberculosis, T-cell subset ratios may change, and decreased cellular immunity has been associated with a decrease in T-helper cells and an increase in T-suppressor cells.[81]

Neutrophilia

Leukocytosis with neutrophilia and a left shift commonly accompanies bacterial infections. In addition, microscopy of blood smears to detect toxic granulation, Döhle bodies, and cytoplasmic vacuoles has a high sensitivity in predicting infectious disease. [82] Most bacteria produce a WBC count of 1214 × 10^9 /L, while systemic infections will have a WBC count as high as 1530 × 10^9 /L, and massive infections such as the leukemoid type are associated with counts of up to 150 × 10^9 /L.[76] Neutrophilia is most common with suppurative infections such as an abscess, empyema, or meningitis, and is usually associated with bacteria (e.g., *Staphylococcus, Streptococcus*). Over two-thirds of cases of infection-related neutrophilia are secondary to bacteria. [1] [83] The lack of an increased WBC count directs the clinician to a problem with the host, or to the type of infectious agent. Most healthy individuals respond with some degree of neutrophilia. Patients with alcohol-related problems may have a limited or no increase in WBC count, similar to the malnourished patient and a high percentage of the elderly. Infections with *Chlamydia*, fungi, *Mycoplasma*, and rickettsiae may have little effect on the WBC count. The neutrophilic response results from increased release from the marginal pool secondary to endogenous catecholamines and increased levels of IL-1. [84] Animal research has demonstrated an almost immediately accelerated egress of neutrophils from the storage pools into the blood after bacterial innoculation. [85]

Neutropenia/Agranulocytosis

Neutropenia, defined as absolute WBC counts of <1.5 × 10^9 /L, can occur paradoxically in almost any bacterial infection, but is more likely to occur in patients with compromised marrows as a result of chemotherapy, nutritional deficiency, or chronic debilitation. Certain viral, rickettsial, and protozoan infections may also be associated with low counts, whereas it would be unusual to find neutropenia in fungal infections (Table 153-7).[1] Were neutropenia to occur during the second week or recovery phase of the infection, it might be difficult to distinguish between a drug-related and an infection-related cause. Medications such as analgesics, sulfonamides, and other microbials can be implicated. Agranulocytosis is rare with infections and is more commonly caused by antibiotic therapy. In immunosuppressed patients, however, agranulocytosis (with or without red cell aplasia) and thrombocytopenia may occur with parvovirus B19 and other viral infections such as measles.[14] [86]

Bacterial infections such as typhoid, paratyphoid, and tularemia may cause an initial rise in neutrophils, and then a fall during the bacteremic phase of the disease. [87] Low counts are typical of many viral infections. Infectious hepatitis, HIV infection, yellow fever, influenza, measles, Colorado tick fever, and many others characteristically manifest with neutropenia. Well-documented instances of neutropenia have been shown to be caused by experimentally induced sandfly fever (Fig. 153-4)[88] and infectious hepatitis (Fig. 153-5). Almost 90% of patients with sandfly fever have neutropenia during the course of the disease.

The cause of infection-related neutropenia is either a direct

toxic effect on growth or increased utilization. With sepsis, neutrophils are mobilized, and the circulating pool decreases acutely before the accelerated marrow egress can compensate. Many individuals will overshoot, with a marrow rebound, producing a pseudoleukemic or leukemoid picture. There is some speculation that neutropenia is a result of inhibition of growth factors, a decrease in colony-stimulating factors, or lysis of WBCs through activation of the complement system. [19]

Neutrophil Morphologic Abnormalities

Some infected patients may show no change in the number of myeloid cells but, instead, either a shift to the left, with increased bands and metamyelocytes, or morphologic changes such as toxic granulations, cytoplasmic vacuolization, or the formation of Döhle bodies. Many elderly patients with infections such as community-acquired pneumonia may not have leukocytosis. Those individuals with neither fever nor a WBC response are at higher risk of death from the infection. With massive bacterial infection, organisms are rarely seen within the neutrophil cytoplasm, and nuclear changes can result, such as the Pelger-Huët anomaly. In patients with frequent infections, especially children, one should be alerted to the possibility of an inherited or acquired functional neutrophil abnormality. These are considered elsewhere (see Chap. 41) and include problems in phagocytosis, motility, chemotaxis and adherence, and bactericidal activity.

Monocytosis

Monocytosis, defined as WBC counts of >0.95 × 10^9 /L, may be seen with a subacute or chronic infection such as tuberculosis, subacute bacterial endocarditis, syphilis, and brucellosis, as well as with many rickettsial and protozoan infections such as malaria, typhus, trypanosomiasis, and kala-azar. [23] Varicella zoster virus infection can cause a striking monocytosis. Monocytosis may also develop transiently during the recovery phase of any infection. In tuberculosis, the monocytosis may reflect a high rate of turnover and new tubercle formation. The monocyte/lymphocyte ratio (M/L) may be a useful measure of the activity of the tuberculosis infection. [89] With activity, the M/L increases owing to an absolute increase in monocytes, and the ratio may exceed 1, (normal = 0.3). A ratio of >1 has been associated with active exudates and a poor overall prognosis. [90] The healing phase is characterized by an increase in lymphocyte count, a decrease in monocyte count, and a return to the normal M/L.

Cells resembling histiocytes or macrophages may accompany monocytes in chronic infections, and the monocytes may become vacuolated. A bedside diagnostic test for subacute bacterial endocarditis consisted of obtaining a blood smear from the ear lobe and demonstrating abundant macrophage-like cells. [91]

Eosinophilia

Eosinophilia, defined as a WBC count of >0.25 × 10^9 /L, is frequent in parasitic infections that invade tissues, such as trichinosis and spirochetal and echinococcal disease, but is rare in bacterial and fungal infections. [92] In schistosomiasis, filiariasis, gnathostomia, or invasion by the liver fluke *Clonorchis sinensis* or *Capillaria hepatica*, eosinophilia is frequently observed. Intestinal parasites are less likely to stimulate eosinophils if tissue invasion does not occur. In patients with bronchopulmonary aspergillosis, coccidioidomycosis, and *Chlamydia* pneumonitis of infancy, absolute eosinophil counts may range from 0.5 to 1.0 × 10^9 /L, with rare elevations to as high as 44 × 10^9 /L. A mild eosinophilia has also been seen in the early phases of scarlet fever.

Eosinopenia

Eosinopenia correlates with the severity of various infections. The absence of eosinophils in infection indicates a bad prognosis. The mechanism of eosinopenia is probably not corticosteroid related but due to other chemotactic factors such as C5a, which causes intravascular cell destruction, tissue margination, or intravascular margination.[93] Cytokine inhibition may also play a role in decreasing marrow production and release. Basophils are rarely affected by infection and in general are not part of the leukemoid blood picture. Basophilia should alert the clinician to a chronic myeloproliferative disorder.

PLATELET AND CLOTTING DISORDERS

Thrombocytopenia

Thrombocytopenia is a frequent complication of septicemia due to any bacterium, virus, or fungus and can be life-threatening. [1] [94] [95] Of patients with bacteremia, >65% have thrombocytopenia of some degree, while 33% will have a more significant drop to levels of $<50 \times 10^9$ /L. Despite the high incidence of abnormal counts, the thrombocytopenia is rarely associated with clinical bleeding unless simultaneous evidence of DIC is present. Occasionally a severe infection with bloodstream involvement (e.g., peritonitis, pneumonia, and abscess) can cause a drop in the platelet count.

The mechanism of thrombocytopenia without DIC may be due to (1) decreased production, (2) increased platelet utilization, (3) binding of platelets to exposed and infected subendothelial tissue, (4) clumping by endotoxin, or (5) an immune phenomenon. Infection-induced immune thrombocytopenia may be IgG mediated and caused by gram-positive and gram-negative septicemias or the development of platelet aggregates and subsequent lysis by complement or infection-related immune complexes.

Chronic infection with hepatitis C may produce a significant autoimmune reaction to platelets in up to 41% of affected patients. Elevated titers of platelet-associated IgG are usually detected and presumed to be the cause of the low platelet count.

Thrombocytosis

Thrombocytosis, with counts frequently as high as 500700×10^9 /L, is seen in chronic infections such as tuberculosis, osteomyelitis, and subacute bacterial endocarditis, as well as during recovery from a variety of fungal and bacterial infections. [96] [97] Despite reactive platelet counts as high as $9001{,}000 \times 10^9$ /L, thrombosis is rare, and no anticoagulation is necessary. The mechanism of reactive thrombocytosis is poorly understood. Some patients have impaired splenic function, which raises the possibility of a hyposplenic state with resultant increased platelets, Howell-Jolly bodies, and target cells.

DIC and Vascular Purpura

Up to 65% of all cases of DIC occur secondary to infections. [98] Serious infections often lead to the development of rapid and massive activation of the coagulation system. DIC can be caused by tissue necrosis, endothelial surface damage, and blood stagnation, all potential complications of infectious diseases. In Rocky Mountain spotted fever, for example, endothelial damage is the pathogenic mechanism. Many causative agents, bacterial, viral, parasitic, and fungal, are implicated in DIC (Table 153-8). Most impressive clinically are purpura fulminans and the Friderichsen-Waterhouse syndrome, comprising the trio in meningococcemia of vascular collapse, mucosal and cutaneous hemorrhage, and bleeding into the adrenal gland. In addition to the direct effect of the infecting agent, bacterial products and toxins such as meningococcal endotoxin can cause endothelial

TABLE 153-8 -- Infections That Cause DIC

Bacteria *Neisseria meningitidis* *Staphylococcus aureus* *Streptococcus pneumoniae* *Escherichia coli* *Neisseria gonorrhoeae* *Mycobacterium tuberculosis* *Salmonella typhimurium*
Rickettsia infection
Mycoplasmosis
Histoplasmosis
Aspergillosis
Malaria

destruction. [99] These endotoxins cause a necrotizing vasculitis, eventual vascular collapse, and a picture of DIC.

Thrombotic Complications

Thrombotic complications are infrequent results of usual and isolated infections, but the coexistence of infection and an endothelial injury can lead to platelet deposition and clot development. Endothelial injury can occur at an intravenous line or catheter site in a hospitalized patient or an intravenous drug abuser. A suppurative thrombophlebitis in the veins of the arm or leg or in the jugular, portal, or pelvic veins can result. An embolic phenomenon can result, but would be more likely in clinical situations such as fungal endocarditis with aspergillosis.

Chapter 154 - Hematologic Manifestations of HIV Infection

James A. Hoxie

INTRODUCTION

The acquired immunodeficiency syndrome (AIDS) is caused by infection with the human immunodeficiency virus (HIV). This retrovirus produces a slow and usually progressive deterioration in the host immune system that in its most advanced stage is complicated by particular opportunistic infections, neurologic disorders, and neoplasms. As will be described, hematologic abnormalities occur in the majority of individuals during the course of this infection, reflecting alterations in the host immune system as well as complications of secondary infections, malignancies, and therapy. Evidence has also implicated a direct role for HIV infection itself on some hematopoietic precursor cells and other cells in the bone marrow. This discussion presents a general overview of the basic epidemiologic, virologic, and immunologic aspects of HIV infection, followed by a more specific discussion of its hematologic complications.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DEFINITION AND EPIDEMIOLOGY

A diagnosis of AIDS is established when HIV infection is complicated by particular opportunistic infections, neoplasms, or neurologic disorders. The current definition of AIDS includes a number of clinical complications that are listed in Table 154-1 .[1] In addition, this surveillance case definition has been expanded to include individuals with laboratory evidence of severe immunodeficiency, as manifested by a reduction in the number of CD4+ T lymphocytes to <200/l or in the percentage of CD4+ T lymphocytes to <14.[1] It is clear, however, that AIDS is simply an advanced stage in a spectrum of clinical disorders that occur following HIV infection.

An earlier classification system defined a symptomatic state of HIV infection as AIDS-related complex (ARC), characterized most commonly by persisting generalized lymphadenopathy with or without a number of nonspecific complaints, including arthralgias, fatigue, intermittent diarrhea, or chronic sinusitis.

TABLE 154-1 -- CDC Classification of Clinical Categories for HIV Infection

Category A. Acute HIV infection, asymptomatic infection, persisting generalized lymphadenopathy
Category B. Symptomatic HIV infection (excluding conditions in Category C) complicated by conditions attributable to compromised cellular immunity (i.e., idiopathic thrombocytopenic purpura, thrush, listerosis, peripheral neuropathy)
Category C. AIDS (Any one of the following laboratory or clinical criteria)
Laboratory Criteria
CD4+ T-cell number <200 /l
CD4+ % of lymphocytes <14
Clinical criteria
Opportunistic infections
Candidiasis of bronchi, trachea, lungs, or esophagus
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal
Cytomegalovirus (other than liver, spleen, or nodes)
Herpes simplex (chronic ulcers, bronchitis, esophagitis)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis (chronic intestinal)
Mycobacterium avium complex or *kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, pulmonary or extrapulmonary
Mycobacterium, other species (disseminated or extrapulmonary)
Pneumocystis carinii pneumonia
Pneumonia, recurrent
Salmonella septicemia
Toxoplasmosis of brain
Neoplasms
Cervical cancer, invasive
Kaposis sarcoma
Lymphoma (non-Hodgkins)
Central nervous system
Encephalopathy, HIV-related
Progressive multifocal leukoencephalopathy
Wasting syndrome due to HIV
Modified from Centers for Disease Control.[1]

Although in the current revised definition, many of these individuals would now be defined as having AIDS if their CD4 cell number were <200/l, the term ARC has been used frequently in early studies of the symptomatic stages of HIV infection and will be used periodically in this review.

The pandemic of AIDS and HIV infection continues to be an international health crisis with, as of 1996, approximately 30 million people infected with HIV worldwide, including 5.8 million people infected in this year alone. [2] AIDS continues to devastate many countries in the developing world, including Southeast Asia, India, Latin America, and particularly sub-Saharan Africa, where it was estimated in 1996 that 7% of the adult population was infected by HIV. [2] [3] In the U.S. there have been >600,000 cumulative cases of AIDS diagnosed since the beginning of the epidemic in 1981 and >400,000 deaths. [4] Although the annual incidence of AIDS-related deaths has recently declined in the U.S., largely due to the beneficial effects of combination antiretroviral therapy, AIDS remains a leading cause of death for persons aged 2544.[4] Changes in the distribution of cases in the U.S. have continued to note an increase in the proportion of individuals who have become infected through

heterosexual contact, particularly adolescents and black and Hispanic women in urban areas. [4]

Although HIV has been cultured from a variety of body fluids, including blood, semen, saliva, urine, and tears, [5] infection occurs almost exclusively by sexual contact (homosexual and heterosexual), by parental inoculation of infected blood or blood products, and perinatally from mother to infant. [5] [6] [7] [8] Infection has also occurred as a result of skin and/or mucous membrane contact with blood from an infected individual, although this mode of transmission appears to be exceedingly uncommon.[9] Overall, the incidence of seroconversion to HIV following occupational exposure via a needle stick has been estimated to be approximately 0.3%. [10]

Two major groups of retroviruses have been associated with AIDS. HIV-1 is the cause of the AIDS pandemic in Europe, Central Africa, Asia, and the Americas, while a closely related but molecularly distinct virus, HIV-2, has been isolated from AIDS patients originating from West Africa, where this virus has been shown to be endemic.[11] Prospective epidemiologic studies have indicated that HIV-2 may be less pathogenic in vivo than HIV-1 with respect to the development of immunologic abnormalities and disease.[12] However, in view of the long time interval between infection and the development of AIDS, which for HIV-1 may average 10 years or more, longer periods of follow-up will be needed before the true pathologic potential of HIV-2 is known. Several different isolates of HIV-related simian immunodeficiency viruses (SIVs) have been obtained from a number of nonhuman primate species in Africa and have been particularly useful models for studies of AIDS-like illnesses in nonhuman primates and for attempts to develop an HIV vaccine. [13] Molecular studies of healthy humans in west Africa have identified variants of HIV-2 that are closely related to some SIVs, suggesting a zoogenic origin, at least for HIV-2. [14] The origin of HIV-1 is still unknown, but viruses related to HIV-1 have been isolated from chimpanzees and other nonhuman primates, strongly suggesting that HIV-1 also originated from nonhuman primates. [15] [16]

GENETIC ORGANIZATION OF HIV AND THE VIRAL LIFE CYCLE

The genetic organization of HIV-1 (Fig. 154-1) is remarkably complex compared to other retroviruses and contains 9 genes. Similar to other retroviruses, HIV-1 contains *gag*, *pol*, and *env* genes that encode viral core proteins, enzymes (reverse transcriptase, integrase, and a viral protease), and envelope glycoproteins, respectively. In addition, the viral *tat* and *rev* genes encode regulatory proteins that play critical roles in regulating the transcription and processing, respectively, of viral messenger RNA.[17] HIV-1 also contains a number of accessory genes (*nef, vif, vpr,* and *vpu*) that either mediate interactions with the host cell or affect the infectivity of the viral particle. [18] The viral Nef protein reduces expression of cellular CD4 and HLA class I molecules on the cell surface and also increases virus infectivity.[19] [20] [21] Vif appears to affect viral assembly in a way that is poorly defined and enhances viral infectivity on particular target cells. [22] Vpr is incorporated into the viral particle, facilitates the postentry targeting of viral RNA/DNA complexes to the nucleus, and induces cell-cycle arrest in infected cells. [23] [24] Finally, the viral Vpu protein induces CD4 degradation in the endoplasmic reticulum and enhances virus release from the cell surface. [18] [25]

The structure of the HIV virion and the viral life cycle at the cellular level are shown in Figures 154-2 and 154-3 . The mature virus particle contains two coding strands of RNA and the enzyme reverse transcriptase that are packaged in the viral core by the *gag* proteins, p24, p17, p9, and p7. This core is surrounded by a cell-derived lipid membrane into which trimers of the viral envelope glycoproteins gp120 and gp41 are inserted. Gp120 binds with high affinity to the CD4 molecule that is expressed on the surface of a number of cells that play essential roles in the function of the immune system. [26] In addition to the CD4+ subset of T lymphocytes, these cells include monocytes, follicular dendritic cells, and Langerhans cells, all of which have been shown to be infectable by HIV. [27] [28] [29] [30]

Figure 154-1 Genetic organization of HIV-1. The nine genes of HIV-1 are shown. Structural proteins of the virion and enzymes required for replication are encoded by Gag, Pol, and Env (darkly shaded regions); regulatory proteins (cross-hatched areas) are encoded by Tat and Rev, arising from doubly spliced messages, and Nef. The *vif*, *vpr*, and *vpu* genes are dispensable for viral replication in vitro but are essential for viral infection in vivo. Two identical long terminal repeats (LTRs) are present at the 5 and 3 end of the genome and contain sequences critical for viral transcription and activation by cellular and viral factors.

Although binding of gp120 to CD4 is required for attachment of the virion to the cell surface, it has been apparent for many years that interactions with other cellular molecules are required for HIV to traverse the plasma membrane.[31] [32] Recently members of the chemokine receptor family of proteins have been shown to associate with CD4 to form a functional receptor complex for this virus.[33] Chemokine receptors are seven membrane-spanning domain, G-protein-coupled receptors that are widely expressed on CD4-positive and -negative hematopoietic cells and that in conjunction with their physiologic ligands, the chemokines, induce chemotaxis, extravasation, and activation of a wide variety of leukocytes. [34] Binding of the viral envelope glycoprotein to CD4 is thought to induce conformational changes that facilitate a subsequent interaction of the envelope protein with a chemokine receptor, leading to a disruption of the cellular membrane and viral entry (Figure 154-3). Differences among HIVs in their ability to infect various CD4+ cell types have largely been explained by the particular type of chemokine receptor used by an HIV isolate.[33] Thus, HIVs that preferentially infect macrophages interact with the chemokine receptor CCR5, while viruses that use CXCR4 are able to infect CD4+ T-cell lines, which characteristically express high levels of this receptor. As described later, during the course

Figure 154-2 Structure of the HIV virion. Two coding strands of genomic RNA are packaged in a nucleoid core with the p7, p9, and p24 proteins and reverse transcriptase. The core is surrounded by the p17 matrix protein lining the inner surface of the envelope glycoprotein. The envelope consists of a lipid bilayer derived from the infected cell and glycoprotein spikes that consist of the outer gp120 molecule, which contains the binding site for the CD4 molecule, and gp41, which serves both to anchor the glycoprotein complex to the envelope and to mediate fusion of the viral membrane with the cell membrane during viral entry.

Figure 154-3 HIV life cycle. Binding of the virion to the cell surface is mediated by a specific interaction of the gp120 envelope glycoprotein with the cellular CD4 molecule and a member of the chemokine receptor family of proteins (usually CCR5 or CXCR4). Penetration occurs as the viral membrane fuses with the cellular membrane in a process that requires the gp41 envelope molecule. The viral capsid is uncoated and viral genomic RNA is reverse transcribed and duplicated by the viral reverse transcriptase to produce a double-stranded copy of viral DNA. The DNA duplex is translocated to the nucleus, where it circularizes and integrates into host chromosomes. Following appropriate activating signals, the provirus is transcribed by cellular RNA polymerase and transported to the cytoplasm. Proteins are translated and processed through biochemical steps that, depending on the protein, involve glycosylation (envelope), cleavage (envelope, Gag, Pol), myristoylation (p17), and phosphorylation (Rev, Nef). Packaging of genomic RNA with viral proteins occurs as envelope glycoproteins are inserted into the cell membrane, and a new virion subsequently buds.

of infection, HIV evolves in vivo to use different chemokine receptors, and the type of chemokine receptor used represents an important prognostic indicator. [35] [36] In addition, HIV has also been shown to be able to infect some CD4-negative cells, either by using alternative receptors such as the glycolipid galactosyl ceramide [37] or by interacting directly with a chemokine receptor in the absence of CD4. [38] [39] Although CD4-independent use of chemokine receptors can markedly expand the viral host range in vitro, the relevance of these findings to pathogenesis remains to be determined.

Following adsorption of the virion to the cell surface, HIV penetrates the cellular plasma membrane and is uncoated in the cytosol. Viral RNA is reverse transcribed to single- and then double-stranded DNA by reverse transcriptase and transported as a preintegration complex to the cell nucleus, where it circularizes and, through the action of the viral integrase, is inserted at random positions in host chromosomes. [40] [41] [42] Transcription of this provirus leads to the production of genomic RNA as well as viral proteins, and following an obligatory processing step in which the Gag and Pol precursor proteins are cleaved by the viral protease, the virion assembles at the inner surface of the plasma membrane, buds outward from the infected cell, and is released as an infectious particle. A number of factors have been shown to upregulate virus production markedly, including cellular activation, transacting factors of other viruses, and cytokines. [43] These cofactors, along with the balance of viral regulatory gene products Tat and Rev, could have relevance in vivo in determining the extent of virus production in an infected individual. [43] As described in a later section, combinations of antiretroviral drugs that target the viral reverse transcriptase and protease enzymes have recently been shown to have potent antiviral effects as a result of their synergistic inhibitory effects on viral replication. [44] [45]

PATHOGENESIS OF HIV

The mechanism by which HIV infection produces immunodeficiency in vivo remains under intense investigation and likely reflects a complex interplay of viral and host factors. Central to the evolution from asymptomatic HIV infection to full-blown AIDS is a gradual increase over time in the systemic viral load that leads to a progressive deterioration of cellular immunity. [46] In spite of active cellular and humoral immune responses, HIV continues to replicate actively throughout the course of infection, and virus is readily detectable in peripheral blood and lymph nodes at all stages of infection. [47] [48] Studies have shown that this persistent production of virus is a highly dynamic process that involves ongoing infection of new target cells and a rapid turnover of both viral particles and infected cells. [49] [50] It is estimated that 10^9 10^{10} virus particles are produced every day with a half-life of <6 hours. [49] [51] Although the vast majority of virus-producing cells have a half life of 1 day [51] and are likely killed by HIV infection itself, additional populations of infected cells, including macrophages and memory CD4+ cells, turn over more slowly and appear to represent long-term reservoirs of infected cells. [51] [52] [53] The steady-state level of viral RNA in plasma represents an important prognostic indicator and in addition to the CD4 cell number is highly predictive of the development of AIDS. [54] A transition from macrophage tropic to T-cell line tropic HIVs in an infected patient is also a poor prognostic finding, reflecting a change in chemokine receptor usage from viruses that use CCR5 to ones that use CXCR4. [35] [36]

Central to the immune abnormalities in AIDS are both quantitative and qualitative [55] [56] [57] [58] abnormalities in CD4+ lymphocytes. Proposed mechanisms for the depletion of these cells are listed in Table 154-2 and include direct effects of viral infection on mature and progenitor CD4 cells, as well as the destruction by cellular or humoral mechanisms of uninfected CD4 cells that display adsorbed or processed viral antigens on their surface. [59]

TABLE 154-2 -- Possible Mechanisms for Depletion of CD4 Lymphocytes During HIV Infection

1. Direct killing of CD4 cells by HIV
2. Syncytia formation between infected and uninfected cells
3. Cytotoxic humoral or cellular immune responses to gp120 adsorbed on uninfected CD4 cells
4. Induction of programmed cell death (apoptosis) by the interaction of gp120 with CD4 molecule
5. Defective maturation of CD4+ cells in the thymus
6. Infection and killing of lymphoid stem cells or supporting cells required for stem cell proliferation and/or differentiation
7. Antilymphocyte antibodies

Several reports have noted that the attachment of gp120 to CD4 on the surface of T lymphocytes can lead to programmed cell death or apoptosis when these cells are subsequently stimulated through their antigen receptor or when CD4 is crosslinked by anti-gp120 antibodies. [60] [61] Moreover, animal models have indicated that CD4+ cell depletion may also result from defective maturation of CD4+ T cells in the thymus. [62] In addition, immune defects are present prior to a severe depletion in CD4 lymphocytes and may reflect an imbalance of particular T-lymphocyte subsets resulting from a selective effect of HIV on memory as opposed to naive T cells. [56] [63] [64] Studies have suggested that memory but not naive CD4 cells express the chemokine receptor CCR5 and therefore might be particularly susceptible to infection by CCR5-utilizing viruses that are present in the early stages of infection. [65] Alternatively, an initial dysregulation in immunity may result from a depletion of CD4 cells involved in helping cellular immunity (TH1 cells) in contrast to those involved in promoting humoral immunity (TH2 cells). [66] One recent report noted a profound decrease in HIV-specific CD4+ T-helper lymphocyte response, suggesting that the loss of this cell population could contribute to the failure of the immune response to control viral replication. [58] In addition to the role of CD4+ lymphocyte depletion and dysfunction in the pathogenesis of AIDS, it is clear that monocytes, macrophages, and dendritic cells are targets for HIV infection and probably represent a major reservoir for virus production in vivo. [27] [30] [67] [68] [69] In view of the central role of monocytes and dendritic cells in processing and presenting antigens to T and B lymphocytes, it is likely that HIV infection of these cells plays a significant role in the development of immunodeficiency. [69]

As indicated by the current surveillance definition of AIDS (Table 154-1), neurologic abnormalities in both the central and peripheral nervous systems, as well as the development of Kaposis sarcoma (KS) and B-cell lymphomas, are common clinical manifestations of AIDS. [1] In the CNS, glial and other reticuloendothelial cells and possibly endothelial cells [70] [71] have been shown to be infected productively by HIV, raising the possibility that dementia and other neurologic defects could arise from the direct effects of viral infection, inflammatory responses, or the elaboration of toxic cytokines by infected cells. [70] [71] [72] Intense efforts are in progress to identify particular chemokine receptors that might be involved with CNS replication, with one recent report implicating the chemokine receptors CCR5 as well as CCR3 as candidates. [73]

Kaposis sarcoma is a proliferative disorder of endothelial cells that occurs predominantly in homosexual and bisexual men with HIV infection. [74] [75] This disorder has also been recognized as a classic form in older Mediterranean and Ashkenazic Jewish men, an endemic form in sub-Saharan Africa, and an iatrogenic form complicating immunosuppressive therapy for allografts. [75] In AIDS-associated KS, HIV is not detectable in the proliferating endothelial cells, suggesting an indirect role for HIV in pathogenesis. In addition, the finding that among HIV-infected people KS is largely restricted to homosexual men has

strongly implicated another transmissible agent. Recently a new human herpesvirus termed HHV-8 or KS-associated herpes virus (KSHV) has been shown to be detectable in KS lesions in AIDS-associated as well as classical, endemic, and iatrogenic forms of KS, strongly implicating a role for this infectious agent in pathogenesis. [76] [77] HHV-8 has also been detected in the semen of HIV-1-infected homosexual males, suggesting that this virus can be sexually transmitted. [78] Several studies have suggested that viral and cellular proteins are produced by HIV-infected cells that can promote angiogenesis and perhaps contribute to a dysregulation of endothelial cell growth. [74] [79] [80] [81] However, the finding that HHV-8 also encodes chemokine-like proteins that are potent angiogenic factors has further implicated a direct role for this virus in endothelial cell proliferation. [82] Although the factors responsible for dysregulation of endothelial cell growth in KS are not clear, it appears likely that a combination of HIV-induced immunosuppression and direct and indirect effects of HHV-8 are involved. In addition, given the apparent role of cytokines and chemokines in the endothelial cell growth in KS lesions, it is possible that KS does not represent a true neoplasm, and that it may ultimately be treatable by novel strategies that inhibit or modulate these angiogenic factors. [83]

A dramatic rise in the incidence of B-cell lymphomas has been reported in patients with HIV infection, [84] [85] [86] and in contrast to KS this complication has been observed in all HIV-infected patient groups, including children. [85] [86] [87] [88] The malignant B cells from these lymphomas are not infected by HIV, [85] [89] and are likely derived from a clonal outgrowth of polyclonal populations of proliferating B cells present in patients with HIV infection. [85] [86] [90] [91] Possible mechanisms for the B-cell stimulation observed in these individuals include a dysregulation in CD4 helper function, [66] or the direct mitogenic effects of Epstein-Barr virus (EBV) infection [85] [92] or HIV antigens. [93] [94] A recent study has also suggested that HIV infection of microvascular endothelial cells could promote B-cell attachment and activation, possibly contributing both to the increased incidence of lymphomas and to the peculiar predisposition of these neoplasms to involve extranodal sites. [95] Approximately 3070%

of lymphomas have been found to contain EBV DNA, strongly implicating this virus in at least some of these neoplasms. [85] [87] [89] [92] [96] Hodgkins disease has also been reported with increased frequency in HIV-infected patients, [97] [98] although the reason for this association is unclear. In at least a subset of non-AIDS and HIV-infected patients with Hodgkins disease, Reed-Sternberg cells have been shown to contain integrated copies of the EBV genome [99] [100] or to express EBV RNA,[96] raising the possibility that the reactivation of EBV that occurs in patients with HIV infection may be involved in the development of AIDS-associated Hodgkins disease. Although less common than B-cell lymphomas, peripheral as well as cutaneous T-cell lymphomas have also been reported in patients with HIV infection. [101] [102] In primary effusion lymphomas (previously termed body cavity-based lymphomas) seen in AIDS, HHV-8 has been identified in the malignant cells, implicating a direct role for this herpesvirus in these disorders. [103] [104] Unlike opportunistic infections, B-cell lymphomas may occur in individuals with only mild reductions in CD4 cell numbers. An additional discussion of AIDS-associated lymphomas is presented in Chapter 75 .

STAGES OF HIV INFECTION

A number of stages of HIV infection have been recognized, including an acute viral syndrome, an asymptomatic stage, a variety of symptomatic conditions frequently characterized by generalized lymphadenopathy, and full-blown AIDS (Table 154-1).[1] Patients with the acute viral syndrome typically present 26 weeks after exposure with fever, malaise, myalgias, maculopapular rash, diarrhea, lymphadenopathy, or aseptic meningitis. [105] Laboratory findings include lymphocytosis with atypical plasmacytoid lymphocytes, a negative heterophile, and mild thrombocytopenia. [105] Thrombocytopenia has been a frequent hematologic complication, along with leukopenia without lymphocytosis.[106] [107] Of importance in the diagnosis of acute HIV infection, individuals may be serologically negative during the viral prodrome but typically develop anti-HIV antibodies 12 months after the onset of this illness. Circulating viral p24 antigen in the absence of anti-HIV antibody may be detectable during this acute phase, [106] and individuals typically have high levels of plasma viremia, which subsequently decreases to low or undetectable levels as a consequence of the host immune response.[46] [108] [109] [110]

The majority of HIV-infected individuals in the United States are asymptomatic but exhibit serologic evidence of infection. That asymptomatic but seropositive patients are persistently infected with HIV has been clearly established by epidemiologic studies, positive viral cultures, and the presence of viral DNA and RNA in peripheral blood mononuclear cells and plasma, respectively, detected by the polymerase chain reaction. [47] [48] Studies evaluating lymph tissues of HIV-infected patients have shown that even in this asymptomatic period there is an abundance of replicating virus in these tissues, indicating that while these individuals may be clinically well, contrary to earlier views, HIV is clearly not latent during this period. [30] [48] This prolonged period of clinical latency may be complicated by persistent generalized lymphadenopathy with or without a number of nonspecific complaints, including arthralgias, fatigue, intermittent diarrhea, and chronic sinusitis. [1] In the final stage of full-blown AIDS, levels of viral RNA in plasma and lymph nodes are usually markedly elevated, and there is a disruption of lymph node architecture producing follicular involution. Prospective studies of HIV-infected patients indicate that the median duration between HIV infection and AIDS is 10 years or longer. [111] [112] As noted previously, factors that predict the impending development of full-blown AIDS include a high level of viral RNA in plasma and the presence of viruses that use the CXCR4 chemokine receptor and induce syncytia on laboratory derived T-cell lines. [35] [36] [54] The clinical course of HIV infection is summarized in Figure 154-4 . Clinical progression over time is associated with a progressive loss in CD4 lymphocytes as well as a gradual increase in a systemic viral load.

Interestingly, a subset of HIV-infected patients, termed long-term nonprogressors, who either fail to develop clinically significant immunodeficiency or do so at a much slower rate has been identified. [113] [114] [115] These individuals exhibit low levels of detectable HIV in plasma and lymph nodes. This important group of individuals is under intense investigation, and evidence has suggested that viral, [114] [116] immunologic,[58] [113] and other host factors may be contributing factors. Recently a naturally occurring mutation in the CCR5 chemokine receptor has been observed in 15% of North American and European Caucasians that results in a nonfunctional receptor. HIV-infected individuals who are heterozygous for this mutation progress to AIDS approximately 34 times more slowly than individuals who lack this allele. [117] Remarkably, individuals who are homozygous for this mutation exhibit a relative (though not absolute) resistance to HIV infection, likely indicating the importance of CCR5 in the transmission and/or the initial establishment of HIV infection. [118] [119] It is likely that additional host factors will be identified that also influence the course of HIV infection.[119] [120] [121]

HEMATOLOGIC ABNORMALITIES IN PATIENTS WITH HIV INFECTION

As described previously, it is clear that hematologic abnormalities in infected individuals may arise from a number of causes, including (1) direct infection by HIV of bone marrow cells or

Figure 154-4 Natural history of HIV infection in an infected individual. A typical course of HIV infection is shown. During primary infection there is active viral replication with viremia and widespread dissemination of virus to lymph organs, during which time a sharp decline in the number of CD4+ lymphocytes occurs. This is followed by a prolonged period of clinical latency, characterized by a slow but progressive decline in CD4+ lymphocytes. When the CD4+ cell number falls to <200/l, the clinical course is generally complicated by opportunistic infections. A quantitative increase in viremia occurs during this time, reflecting increased viral replication, an increasing viral load, and/or redistribution of virus from damaged lymph organs.

other supporting cells required for hematopoiesis, (2) dysregulation of the host immune system leading to destruction or inhibition of hematopoietic cells, and (3) secondary complications of opportunistic infections, malignancies, and/or therapy for these disorders. Not surprisingly, the principal hematologic problems encountered in patients with HIV infection include cytopenias of red cells, neutrophils, lymphocytes, and platelets, as well as a variety of polyclonal and oligoclonal gammopathies. Several general reviews of the hematologic complications in AIDS have been published. [122] [123] [124]

Abnormalities in Hematopoietic Cells

Anemia and Red Blood Cell Abnormalities

Anemia occurs in the majority of HIV-infected patients at some point in the course of their disease. [125] [126] [127] Both the incidence and degree of anemia have been shown to correlate with the severity of the clinical syndrome. [125] [128] When HIV infection is complicated by opportunistic infections, anemia has been seen in 7095% of patients with mean hemoglobin and hematocrit levels of 9.711.7 g/dl and 36%, respectively. [125] [129] However, even in asymptomatic patients with HIV infection or those with minimal symptoms, a mild but significant reduction in hematocrit has been reported in 1520% of patients. [125] Anemia and granulocytopenia tend to occur concurrently, with one series showing that 68% of patients with hematocrits <40 were also neutropenic, with white blood cell counts $<1.4 \times 10^3$ /l while 88% of patients with neutropenia were also anemic. [125]

Anemia in patients with HIV infection who are not undergoing antiretroviral therapy with zidovudine is typically normochromic normocytic, although a mild degree of anisocytosis and poikilocytosis is common. [130] [131] [132] [133] [134] Macrocytosis occurs in the majority of patients treated with zidovudine. [135] [136] Schistocytes are prominent in the setting of thrombotic thrombocytopenic purpura, which may complicate HIV infection, as described in a later section. [137] [138] [139] [140] [141] [142]

In addition to being a complication of the HIV infection itself, anemia is a frequent side effect of antiretroviral drugs, particularly zidovudine, as well as drugs used to treat or prevent opportunistic infections, including dapsone, primaquine, trimethoprim/sulfamethoxazole, and ganciclovir.

Depressed erythropoiesis in AIDS has been suggested by a low or inappropriately normal reticulocyte count, and in HIV-infected patients the reticulocyte count cannot be used as a reliable indicator of either hemolysis or bleeding. [123] [126] [134] Similar to the anemia of chronic disease, it is likely that inflammatory cytokines play a role in suppressing erythropoiesis in patients with HIV infection. Tumor necrosis factor and interleukin-1 have been shown to suppress erythropoiesis in vitro, and both of these cytokines can be increased in HIV-infected patients. [143] In addition, the finding on bone marrow examination of normal to increased numbers of erythroid progenitor cells, [125] [129] [144] along with a variable degree of dyserythropoiesis, [125] [133] [144] [145] has indicated that ineffective erythropoiesis may be an additional contributing factor. [122] [145] [146] A syndrome resembling paroxysmal nocturnal hemoglobinuria was described in a patient presenting with intravascular hemolytic anemia, markedly dysplastic erythroid hyperplasia on bone marrow examination, and abnormal HAM and sucrose-lysis tests. [147] Megaloblastic changes in erythroid precursors are uncommonly seen [133] [148] but have been described during therapy with trimethoprim/sulfamethoxazole, dapsone, and zidovudine. [133] [135] [136] [145] [146] [149] Several reports have noted profound erythroid hypoplasia as well as pure red cell aplasia in the setting of *Mycobacterium avium* complex (MAC) infection, [129] [130] [131] [133] [150] where suppression of erythroid progenitors due to soluble factors, including tumor necrosis factor , has been implicated. [150] [151] Pure red cell aplasia has also been reported in HIV-infected patients receiving zidovudine [152] and without any associated cause. [153] As described further in a later section, in both HIV-infected adults and children, a severe depression of erythropoiesis may occur due to chronic parvovirus B19 infection, where the presence of giant pronormoblasts in bone marrow may be diagnostic. [154] [155] [156] [157] Anemia in the setting of HIV infection can have

important prognostic significance. A low hematocrit (<25) has been shown to be a negative predictor for survival in patients with MAC infection, [158] and in one recent study HIV-associated anemia from any cause that did not resolve was highly correlated with a shortened survival. [128]

Serum erythropoietin levels in patients with HIV-associated anemia may be increased [136] [159] or reduced, [160] with one series finding reduced serum levels in 22 of 29 AIDS patients. [160] Although for untreated patients there is an inverse correlation between hematocrit and serum erythropoietin levels, the erythropoietin response to anemia is inappropriately low compared to patients with iron-deficiency anemia or bleeding. [159] [161] [162] Similar findings have been described in patients with the anemia of chronic disease. [163] Some experimental evidence has suggested that HIV infection itself may directly suppress erythropoietin. [164] Interestingly, for some patients treated with zidovudine, serum erythropoietin levels may increase dramatically in response to anemia, suggesting a restoration of the erythropoietin response. [159] [162] This finding could be related to the occasional reports of polycythemia following the initiation of zidovudine therapy. [165] [166] As described following, early clinical trials evaluating the role of recombinant erythropoietin in the treatment of anemia in patients receiving zidovudine found that patients with low pretreatment serum erythropoietin levels (500 IUL) are more likely to respond to erythropoietin therapy, as shown by an improvement in hematocrit and a decreased transfusion requirement. [160] [167]

Iron stores in anemic patients with HIV infection are typically adequate or increased, and iron indices are similar to those seen in chronic disease states, with a low serum iron and transferrin and an elevated serum ferritin. [131] [148] In both adults and children, the level of serum ferritin was found to be a marker for advanced or progressive disease. [168] [169] An elevated serum ferritin level has been shown to correlate with markers of immune activation (interferon , serum neopterin levels, and 2-microglobulin). [170] Bone marrow iron is usually adequate or increased in reticuloendothelial cells, [125] [133] although in one study reduced or absent bone marrow iron was found in 16 of 32 patients with AIDS. [130] Particularly in children with HIV infection, iron malabsorption has been implicated as a contributing factor to anemia. [171]

Sideroblasts, while uncommon, have been described in 5% of AIDS patients in some series.[125] [129] [133] [145]

Reduced serum B_{12} levels are seen in 730% of patients with AIDS, [172] [173] [174] [175] [176] although this typically occurs in the absence of neutrophilic hypersegmentation, red cell macrocytosis, or megaloblastic changes on bone marrow aspirate.[173] [174] [175] [177] When present, a low plasma B_{12} level in HIV-infected patients does not appear to be due to a reduction in the B_{12} binding proteins, transcobalamin or haptocorrin.[178] Malabsorption of B_{12} with an abnormal Schillings test has been found in AIDS patients both with[173] [179] and without[172] [174] [177] chronic diarrhea syndromes, suggesting that a true negative balance of B_{12} may exist in some patients. Correction of the Schillings test by intrinsic factor in these patients has been variable. [175] [177] In one study, patients with an abnormal Schillings test were noted to have chronic inflammatory changes on colonic and duodenal biopsy, as well as evidence by in situ hybridization of HIV-infected mononuclear cells within the lamina propria.[174] These findings have suggested that HIV infection within the gut mucosa could contribute directly to B_{12} malabsorption. However, normal Schillings tests in patients with low serum B_{12} levels have also been reported.[173] [176] [177] Although patients with reduced serum B_{12} levels are more likely to be anemic, the absence of megaloblastic changes and the lack of a hematologic response to B_{12} therapy have indicated that in most patients this reduction is not clinically significant. [123] [173] [175] Nonetheless, using a reduction in serum holo-transcobalamin II as a more sensitive indicator of negative B_{12} balance, reduced levels were reported in approximately half of patients with AIDS;[180] this has raised the possibility that subclinical B_{12} deficiency may be more significant than previously recognized. Clinically, a reduced serum B_{12} level may increase the hematologic toxicity associated with zidovudine therapy.[135] Although lower B_{12} levels have been noted more frequently in patients receiving zidovudine,[176] supplemental therapy with cobalamin and folate failed to prevent or reduce the myelosuppression associated with zidovudine. [181] Alterations in folate metabolism have also been reported in AIDS patients with reduced intestinal absorption of folate, [182] as well as increased serum and red cell folate levels, [183] [184] even in the absence of reduced serum B_{12} levels.[184] The underlying mechanism and clinical significance of these findings are unknown.

Positive direct antiglobulin tests have been reported in 2043% of hospitalized AIDS patients or patients undergoing transfusion therapy [122] [132] [185] [186] [187] and in 8% of asymptomatic individuals. [188] These reactions are usually weak, involve IgG and/or complement, and are likely due, at least in part, to the deposition of immune complexes on red blood cells, similar to that seen in non-AIDS patients with hypergammaglobulinemia. [185] Nonetheless, sensitive assays have documented the presence of true anti-red cell antibodies with anti-i and anti-U specificity in 64% and 32% of AIDS patients, respectively, [186] as well as anti-PI and anti-LEB antibodies in some patients.[122] [186] Anti-i antibodies are known to occur during acute EBV infection, and it is possible that the increased frequency of this antibody in patients with HIV infection results from active EBV or possibly cytomegalovirus (CMV) infection. [186] Cold agglutinins have been reported in up to 22% of HIV-infected patients, although no association between the presence of these antibodies and anemia has been found. [189] Although uncommon, severe autoimmune hemolytic anemia has been reported, with responses observed with steroids, intravenous gammaglobulin, splenectomy, or zidovudine. [156] [190] [191] [192] [193] [194] The relative reticulocytopenia frequently noted in patients with HIV infection may mask the diagnosis of autoimmune hemolytic anemia. [192]

Leukopenia and White Blood Cell Abnormalities

Leukopenia is common in HIV-infected individuals and, similar to anemia, occurs with a frequency that generally correlates with the severity of the clinical syndrome. Between 5785% of patients with AIDS[122] [131] and 1021% of patients with ARC[122] [129] are leukopenic, while <5% of asymptomatic seropositive patients present with leukopenia.[125] [129] Leukopenia typically involves both lymphocytes and granulocytes, although monocytopenia has also been reported in 875% of patients with AIDS.[129] [133] However, as noted previously, a reduction in the absolute number of CD4+ T cells occurs as one of the earliest immunologic abnormalities of HIV infection, and the number of these cells declines progressively over time (Figure 154-4). As noted previously, a low number of CD4+ lymphocytes is one of the most important prognostic indicators for the risk of developing opportunistic infections. [195]

A number of morphologic abnormalities have been described in peripheral blood and bone marrow white blood cells of patients with HIV infection; these are discussed in greater detail in a later section. Particularly in the setting of granulocytopenia, neutrophils may show nuclear hyposegmentation with an apparent left shift, along with the presence of monolobed or Pelger-Hüet forms[133] [134] (Fig. 154-5). In addition, other dysplastic changes of neutrophils have been described, including increased size, prominent granulation, and increased peroxidase activity. [122] [133] [134] Nonspecific morphologic findings include large vacuolated monocytes and atypical lymphocytes, particularly in patients who are lymphopenic. [133] Although myelodysplastic changes are common and do not represent a preleukemic syndrome,[123] [134] [196] rare cases of acute myeloblastic leukemia evolving from a pre-existing myelodysplastic state have been reported in HIV-infected individuals. [197] [198]

Figure 154-5 Peripheral blood and bone marrow morphologic abnormalities in AIDS. **(A)** Pelger-Hüet cell and macrocytes in a patient with AIDS-related complex undergoing therapy with zidovudine. The mean corpuscular volume on this blood sample was 118 ^{3} . **(B)** Loose granuloma formation from a bone marrow biopsy in a patient with disseminated MAC infection involving bone marrow. Acid-fast stains of this specimen showed numerous organisms within the granuloma. **(C)** Grocott stain showing cryptococcal involvement of bone marrow. Organisms in this panel are darkly stained. High magnification of this specimen in **(D)** shows numerous budding yeast forms. **(E)***Histoplasma* within a macrophage seen on Wright Geimsa stain of a bone marrow aspirate. **(F)** Non-Hodgkins lymphoma involvement of marrow (diffuse non-Burkitts type), showing a hypercellular marrow completely replaced by malignant cells. **(G)** Hodgkins disease involving mar-row, showing normal cellularity on the left portion of the panel and a pleomorphic desmoplastic reactive process on the right. High-magnification view of this specimen in **(H)** shows numerous Reed-Sternberg cells. **(I)** Giant pronormoblast in parvovirus B19 infection. **(J)** Pseudogaucher cell resulting from bone marrow histiocytes engorged with MAC organisms. **(K)** Condensed lobulated nucleus of a dysplastic megakaryocyte from a patient is shown adjacent to a normal megakaryocyte. *(Reprinted with permission from Bauer et al.[270])*

Granulocytopenia is a common complication of several drugs used in the therapy for AIDS-related infections, including trimethoprim/sulfamethoxozole and pentamidine for *Pneumocystis carinii* pneumonia (PCP), pyramethamine/sulfadiazine for CNS toxoplasmosis, flucytosine for cryptococcal and other fungal infections, and ganciclovir for CMV infection.[199] Between 1928% of patients receiving trimethoprim/sulfamethoxozole for PCP develop neutropenia, [200] [201] [202] often in the setting of fever, rash, and elevated liver transaminases.[202] As described in a later section, dose-dependent neutropenia in patients receiving zidovudine has been reported in 816% of patients during long-term therapy,[135] [203] but it may also occur in an apparently idiosyncratic manner with profound bone marrow hypoplasia [204] and agranulocytosis. [205] Although more commonly seen in the setting of advanced HIV infection, granulocytopenia has also been reported to complicate the viral prodrome of acute HIV infection.[107]

Not surprisingly, granulocytopenia complicating AIDS has been associated with an increased incidence of infection with bacterial and fungal pathogens similar to those seen in non-HIV neutropenic patients. These infections have included bacteremia (*Staphylococcus* species, *Pseudomonas aeruginosa*, and *Enterobacteriaceae*) and fungemia (*Cryptococcus* and *Candida* species) as well as pulmonary aspergillosis, pyomyositis malignant external otitis, neutropenic enterocolitis, and pseudomonal keratitis.[124] Risk factors for bacterial infections have included a granulocyte count <500/l and central venous access catheters. [206] [207]

Although the mechanism of granulocytopenia in AIDS remains under intense investigation, the role of HIV infection on bone marrow function is still controversial and has recently been reviewed.[208] Bone marrow biopsies in patients with AIDS and symptomatic HIV infection are either normocellular or hypercellular in 60100% [125] [129] [131] [133] [134] [144] [148] and are frequently associated with dysplastic changes,[129] [134] [144] suggesting that ineffective myelopoiesis may be occurring. In vitro culture of bone marrow from HIV-infected patients for granulocyte and macrophage (CFU-GM) and erythroid (BFU-E) colony-forming units (CFUs) or of CD34+ progenitor cells has been reported to be either normal[209] [210] [211] or reduced.[212] [213] [214] [215] [216] [217] [218] Infection of cultured bone marrow cells by HIV-1 has been demonstrated in vitro, and in some,[215] [219] [220] [221] but not all, studies[209] has been reported to inhibit colony formation. However, the direct evaluation of CD34+ cells or CFUs from patients with AIDS for HIV DNA by the polymerase chain reaction technique has in several, [209] [210] [214] [215] [222] [223] [224] but not all,[225] studies failed to show a significant degree of infection. A single study, however, using in situ hybridization of bone marrow from patients did report HIV genomes in a high proportion of patients, detectable in immature myeloid cells, histiocytes, endothelial cells, and nucleated red cells. [146] Nonetheless, the predominant view from most studies is that with the exception of

the megakaryocyte (discussed in a later section), few hematopoietic progenitor cells are directly infected by HIV.

A number of indirect mechanisms of HIV-mediated suppression of hematopoiesis have also been suggested. Suppressive effects and/or apoptosis induced by the viral envelope glycoprotein, gp120, on CFU formation have been observed in vitro in some, [221] [226] [227] but not all, studies.[209] In addition, earlier studies have implicated suppression of myelopoiesis by T lymphocytes, [212] anti-gp120 antibodies, [211] and a glycoprotein produced by cultured bone marrow cells of HIV-infected patients.[213] It is also likely that cytokines produced from HIV-infected cells, including transforming growth factor- [228] and tumor necrosis factor,[229] play a role in suppressing hematopoiesis. Viral gene products have also been implicated in suppressing myelopoiesis, including Tat, reported to suppress cultured bone marrow cells by inducing macrophages to produce transforming growth factor-, [228] and the *gag* gene product p24.[230] A possible autoimmune mechanism for the destruction of peripheral blood granulocytes has also been suggested by the presence of antineutrophil immunoglobulins in as high as 67% of patients with AIDS and ARC. [231] [232] [233] There is also some evidence that bone marrow stromal cells may be infectable by HIV, implying that hematopoiesis could be affected through viral-induced alterations in the bone marrow microenvironment.[234] Nonetheless, as discussed following, whatever the mechanism of AIDS-associated leukopenia, a dramatic rise in peripheral blood neutrophils is typically seen in AIDS patients following therapy with recombinant GM-CSF [235] or G-CSF,[236] clearly indicating that competent myeloid stem cells with the capacity for differentiation are present, even in patients with advanced immunodeficiency.

Thrombocytopenia

Thrombocytopenia is a frequently reported complication of HIV infection [237] [238] [239] and has been described in both adults and children. [240] [241] [242] [243] [244] Depending on the patient population analyzed, thrombocytopenia, defined as a platelet count <100,000/l, has been reported in 38% of seropositive individuals [132] [241] [245] [246] [247] and 3045% of patients with fully developed AIDS. [122] [246] In some studies an inverse correlation was found between the platelet count and the CD4+ lymphocyte number.[245] However, isolated and occasionally severe thrombocytopenia may occur even in asymptomatic individuals as the presenting manifestation of HIV infection. Thrombocytopenia has also been reported during acute HIV infection as part of the acute viral syndrome described earlier. [106] [248]

The degree of HIV-related thrombocytopenia is generally mild to moderate, with mean counts ranging from 43,000 to 57,000/l. [240] [249] However, a severe reduction to levels <10,000/l has also been described. [240] [249] [250] Roughly one-third of patients with thrombocytopenia present with a history of easy bruising, petechiae, or bleeding,[251] although in the majority, significant spontaneous clinical bleeding usually does not occur. [122] [237] Not surprisingly, life-threatening hemorrhagic complications, primarily due to CNS bleeding, may occur in HIV-infected hemophiliacs, particularly with platelet counts <50,000/l. [252] Unlike classic immune thrombocytopenic purpura (ITP), HIV-related thrombocytopenia frequently occurs with other hematologic abnormalities, usually neutropenia with or without anemia in 60% of cases.[122] [123] However, as noted previously, particularly in asymptomatic seropositive patients, it generally occurs as an isolated hematologic abnormality. [125] The presence or absence of thrombocytopenia in seropositive individuals appears not to be a prognostic indicator for the development of AIDS, [240] [242] [253] although one study of hemophiliacs noted an increased mortality in patients with thrombocytopenia independent of the CD4 lymphocyte count. [254] Interestingly, in as high as 1150% of patients, thrombocytopenia may regress spontaneously without therapy, [122] [240] [242] although these findings are not always observed.[255]

The mechanism of thrombocytopenia in HIV infection appears to involve both increased platelet destruction as well as ineffective platelet production. In one study, the survival of [111] Indium-labeled autologous platelets was found to be significantly reduced compared to normal controls in both untreated and zidovudine-treated patients with HIV-related thrombocytopenia.[256] Platelet survival was also decreased in HIV-infected patients without thrombocytopenia, although to a lesser extent. [256] Most but not all reports indicate that there is significant platelet sequestration and/or destruction in the spleen in HIV-associated thrombocytopenia. [256] [257] [258] One report indicated that platelet destruction was the predominant factor early in the course of disease, while decreased platelet production was the predominant factor later in the course of disease.[258] The high

response rate to splenectomy of HIV-associated thrombocytopenia, even in patients with advanced disease, certainly suggests that the spleen is probably a major site of platelet sequestration and/or destruction. [240] [259] [260] [261] [262] The observed decrease in platelet survival is most likely immunologically mediated. In HIV-related thrombocytopenia, there are marked increases in platelet-associated immunoglobulin and complement, and circulating immune complexes are increased 24 times that seen in classic ITP. [242] [249] [250] [258] Among HIV-infected patients, the presence of circulating immune complexes has been shown to correlate positively with the presence of thrombocytopenia.[258] An analysis of circulating as well as platelet-associated immune complexes has shown anti-idiotypic antibodies directed against antibodies to the HIV-1 envelope glycoprotein, gp120. [263] In at least some individuals, a true autoimmune process has been suggested by the detection of antiplatelet activity in IgG eluted from platelets;[231] [242] [249] [258] [264] one study suggested that at least some patients may exhibit antibodies to platelet glycoproteins IIb-IIIa [265] similar to that seen in classic ITP, although this has been somewhat controversial. [264] IgM rheumatoid factor containing IgG antiplatelet (anti-GPIIIa) antibodies has also been reported in HIV-infected patients and shown to correlate with thrombocytopenia. [266] Interestingly, two reports demonstrated that antibodies eluted from patient platelets could recognize both platelet glycoprotein IIIa and HIV envelope glycoproteins, suggesting that cross-reactive epitopes between viral envelope and platelet glycoproteins[267] [268] could potentially mediate a true autoimmune destruction of platelets in some patients.

Although megakaryocytes are typically increased in HIV-related thrombocytopenia, a kinetic analysis has shown a significant reduction in platelet production. [256] As described in a later section, megakaryocytes are characteristically dysplastic, [134] [144] [269] [270] and circulating platelets have been shown to exhibit an inappropriately low mean platelet volume, similar to that seen in myelosuppressive disorders. [271] A number of studies have strongly indicated that this dysplasia may be related to direct infection of the megakaryocyte by HIV.[258] [272] [273] [274] Megakaryocytes have been shown to express CD4 and to be able to bind HIV. [275] [276] [277] Megakaryocytic cell lines are susceptible in vitro to infection by particular isolates of HIV, [276] [278] and one report indicated that this infection could be markedly enhanced by tumor necrosis factor ,[279] similar to the effects of this cytokine on T-cell and monocytic cell lines. [280] [281] [282] [283] Finally, studies of megakaryocytes directly from HIV-infected patients have shown viral RNA (Fig. 154-6) and viral proteins, strongly suggesting that these cells are infected in vivo. [258] [284] [285] Interestingly, in one study HIV transcripts were not detected in CFUs for cultured megakaryocytes, suggesting that megakaryocytes may not be susceptible to infection until they are more differentiated or that infected megakaryocytes may be unable to proliferate or differentiate in vitro. [285] One study described an isolate of HIV-1 that was selectively cytopathic for megakaryocytic cell lines, indicating that viral factors could be involved in determining the extent to which megakaryocyte dysfunction and thrombocytopenia occur in infected patients. [286] Thus, unlike other hematopoietic precursors, there is clear evidence that HIV directly infects megakaryocytes, contributes to ineffective thrombopoiesis, and, coupled with antiviral immune responses, leads to thrombocytopenia in a subpopulation of patients. Future studies that evaluate chemokine receptor expression on megakaryocytes and the extent to which they are involved in viral infection will be of particular interest. [287]

A number of drugs frequently used in the setting of HIV infection may cause thrombocytopenia. These include trimethoprim/sulfamethoxazole, pentamidine, pyrimethamine, ganciclovir, fluconazole, -interferon, trimetrexate, eflornithine, rifabutin, and clarithromycin. [124] In addition, other secondary

Figure 154-6 Megakaryocyte infection by HIV. In situ hybridization with a ^{35}S-labeled HIV-specific probe in a bone marrow biopsy from an HIV-seropositive patient. In panels **(A)** and **(B)**, numerous grains are apparent, indicating the presence of HIV RNA within the megakaryocyte cytoplasm. In panel **(B)**, a dysplastic megakaryocyte largely denuded of cytoplasm is shown (arrow) that also is reactive with the HIV probe. *(Reprinted from Zucker-Franklin and Cao,[284] with permission.)*

causes of thrombocytopenia must also be considered in HIV-infected patients, including thrombotic thrombocytopenic purpura and bone marrow infiltration by lymphomas and opportunistic infections.

Abnormalities in Coagulation

Antiphospholipid antibodies detectable as lupus anticoagulants or anticardiolipin antibodies have been identified in 2282% of patients with HIV infection, including homosexual men, intravenous drug users, and hemophiliacs. [288] [289] [290] [291] [292] Interestingly, despite the association in non-HIV-infected patients between lupus anticoagulants, anticardiolipin antibodies, and a false-positive VDRL, the VDRL in HIV-infected patients without a history of syphilis is usually nonreactive, probably reflecting differences in specificity of the antiphospholipid antibodies in patients with and without HIV infection. [288]

Patients with a lupus anticoagulant typically present in the absence of a bleeding history with a prolonged activated partial

thromboplastin time (APTT) that does not correct after mixing with normal plasma and incubation at 37°C. A prolongation in the tissue thromboplastin time is also usually seen.[288] The Russell viper venom clotting time (RVVCT) that measures clot formation by the direct activation of factor X is the most specific indicator of a lupus anticoagulant.[122] [288] [293] In HIV-infected patients, lupus anticoagulants are typically IgMs [288] and can be partially adsorbed with phospholipids obtained from commercially available lipid extracts or platelet membranes.[122] [293] In one study of HIV-infected patients with prolonged APTTs, lupus anticoagulants were described that were not detectable by a mixing test. However, functional inhibitory activity was demonstrated by a prolonged RVVCT or by correction of the APTT with increasing concentrations of exogenous phospholipid.[294] Lupus inhibitors were initially described in 2073% of patients with AIDS [123] [288] [293] and in as high as 43% of asymptomatic seropositive patients,[295] although in another series this was found to be considerably less frequent, particularly in nonhospitalized patients, where it was not observed in 142 HIV-infected patients.[291]

Anticardiolipin antibodies (ACAs) that may or may not have activity as lupus inhibitors are detectable by enzyme-linked immunosorbent assays (ELISA) and in HIV-infected patients are usually IgG immunoglobulins.[289] [292] [295] In one study a higher frequency of ACAs in patients with AIDS compared to asymptomatic patients (84% vs. 50%) was found,[289] although another study of hemophiliacs found no difference in the frequency of ACAs among hemophiliacs with or without AIDS.[295] One study found that ACAs were detectable in 30% of hospitalized and 8% of nonhospitalized seropositive patients.[291] No correlation has been found between the presence of ACAs and the presence or absence of thrombocytopenia,[296] the CD4 cell number,[295] or the risk of progression to AIDS.[295] Despite the association of a positive ACA titer with antinuclear antibodies (ANAs) in >90% of patients with lupus, ANAs have rarely been reported in patients with AIDS,[289] although one study did note low-titer ANAs in 19 of 151 patients with AIDS or ARC.[297]

The presence of a lupus inhibitor or ACAs does not predispose to clinical bleeding, and in the absence of thrombocytopenia or an elevated prothrombin time is not, in and of itself, a contraindication to an invasive procedure.[122] [123] [288] [293] However, depending on the specificity of the antiphospholipid antibody, other coagulation defects may be present, including a reduced level of factor VII, resulting in a prolongation in the prothrombin time,[298] and abnormal platelet aggregation studies associated with an abnormal bleeding time.[288] Consequently, the decision to perform invasive procedures on an HIV-infected patient in whom a lupus anticoagulant is identified should be individualized; a careful bleeding history is required. In addition, the presence of a lupus inhibitor in hemophiliacs may complicate factor replacement therapy, where the resulting prolongation of the APTT may be misinterpreted as a factor VIII inhibitor and interfere with monitoring for factor VIII replacement therapy.[122] In contrast to patients without HIV infection, where the presence of a lupus inhibitor is associated with thrombotic events and fetal loss, a lupus inhibitor is rarely associated with thrombosis in patients with HIV infection.[288] [293] Nonetheless, HIV-infected patients who have lupus inhibitors and/or ACAs have been reported with avascular necrosis, skin necrosis, strokes, and other thrombotic events,[293] [299] [300] [301] and in some of these patients low-grade disseminated intravascular coagulation and depressed levels of protein C have also been implicated in thrombotic complications.[302]

The mechanism for the high frequency of antiphospholipid antibodies in HIV-infected patients is unclear but presumably involves the generation of phospholipids from either endogenous or exogenous sources. Destruction of immune or hematopoietic cells directly or indirectly by HIV could induce membrane damage and the liberation of phospholipids as immunogens. Alternatively, secondary infections could provide exogenous phospholipids or further contribute to the release of endogenous phospholipids from damaged tissues. The combined results of two studies noted a frequency of lupus anticoagulants or ACAs in 39 of 50 AIDS patients with PCP and in only 1 of 34 AIDS patients with other opportunistic infections, suggesting an association between *Pneumocystis carinii* and antiphospholipid antibodies.[303] Moreover, in both studies patients were described who developed these antibodies with the onset of the pneumonia and who subsequently lost the antibody with successful therapy for the infection. However, another study found no correlation between the presence of an opportunistic infection and a lupus inhibitor.[122] The high frequency of ACAs, even in asymptomatic individuals, however, indicates that other factors aside from PCP are likely involved.

Several reports have described a remarkably high frequency of acquired protein S deficiency in HIV-infected patients, with a reduction noted in 1773% of seropositive patients.[304] [305] [306] [307] [308] [309] Reduced protein S levels have also been reported in HIV-infected children.[310] This deficiency reflects a true reduction in both free and total protein S levels, with no alteration found in the level of C4b-binding protein, which binds 6070% of circulating protein S.[304] [305] Some studies have noted a correlation of reduced protein S levels with a diagnosis of AIDS and a low CD4 cell number,[306] [311] while another study found an association with an increasing duration of HIV infection and elevated levels of ACAs.[305] The mechanism of protein S deficiency in these patients is unclear and could involve decreased synthesis and/or abnormalities in endothelial cell function. Protein S is synthesized in liver and endothelial cells, and the presence of normal levels of other hepatic coagulation factors in patients studied does suggest that endothelial cell dysfunction could be involved.[305] [306] Increased levels of antigenic von Willebrand factor have been described in seropositive patients, possibly reflecting abnormal endothelial cell function.[305] [307] One study suggested that autoantibodies to protein S could also be playing a role.[309] Thromboembolic complications have been reported in HIV-infected patients with reduced protein S levels.[304] [305] [306] [312] [313] Thus, in contrast to the presence of a lupus anticoagulant, protein S deficiency may predispose to thrombosis in HIV-infected patients in certain settings.

Gammopathies

Polyclonal hypergammaglobulinemia was among the first immunologic abnormalities described in AIDS and is seen in both asymptomatic and symptomatic seropositive patients.[90] [314] [315] Elevated levels of IgG, IgA, and IgM are present in spite of depressed in vitro B-cell proliferative responses to mitogens.[90] [91] Interestingly, in 318% of HIV-infected patients, monoclonal or oligoclonal immunoglobulin bands can be demonstrated by serum protein electrophoresis or immunofixation.[316] [317] [318] [319] [320] This high frequency of monoclonal gammopathy in patients with a mean age of 35 is in marked contrast to a frequency of 0.09% for age-matched controls.[317] [321] Paraproteins can be either IgG or IgM and usually occur in the absence of a depression of other immunoglobulins and without Bence Jones proteinuria.[316] [317] In one study, an analysis of paraproteins in seven HIV-infected patients demonstrated five to represent a polyclonal response to HIV antigens, suggesting an exaggerated humoral immune response to particular viral components.[319]

Clinically, hypergammaglobulinemia may contribute to rouleaux formation of red cells on a peripheral blood smear,[129] the generation of circulating immune complexes,[322] [323] and the formation of a number of abnormal antibodies reactive with platelets,[231] [246] [249] [264] red cells,[122] [185] [186] lymphocytes,[324] [325] granulocytes,[231] [246] and phospholipids.[288] [289] [291] [293] Remarkable cases of a

hyperviscosity syndrome secondary to diffuse polyclonal hypergammaglobulinemia have also been described in HIV-infected patients presenting with visual blurring, characteristic changes on funduscopic examination, and epistaxis, with an elevated serum viscosity level.[326] [327] Hyperviscosity syndromes have also been reported in HIV-infected children during the administration of intravenous gammaglobulin.[328] Although uncommon, both multiple myeloma and isolated plasmacytomas have been described in HIV-infected patients,[146] [329] [330] including one case of myeloma in which the paraprotein was directed against the HIV p24 *gag* gene product.[331] Amyloidosis with AA-type fibrils has also been reported in a single patient with AIDS who presented with nephrotic syndrome and demonstrated characteristic green birefringence after Congo red staining of kidney, liver, spleen, and bone marrow.[332] Paradoxically, HIV-infected hemophiliacs with a history of acquired inhibitors to factor VIII frequently lose this activity during the course of their HIV infection, and may benefit from the reintroduction of factor VIII as part of their management.[333]

The mechanism of hypergammaglobulinemia in HIV-infected individuals appears to involve polyclonal activation of B cells in vivo. Although B cells obtained from patients are poorly responsive to mitogens in vitro, Lane et al.[90] demonstrated that cultured B cells from patients with HIV infection secrete immunoglobulin spontaneously, suggesting that circulating B cells in these patients were preactivated in vivo and, paradoxically, refractory to further stimulation in vitro. B cells from normal donors can be directly activated without T-cell help by EBV infection as well as CMV and HIV antigens, and one or more of these factors could be responsible for the apparent activation of B cells in HIV-infected patients. HIV gp120 has been implicated in functioning as a superantigen that can directly activate B-cell subsets that express particular immunoglobulin genes.[93] [94] [334] HIV has also been proposed to infect endothelial cells and stimulate B-cell proliferation indirectly by upregulating the costimulatory and adhesion molecules, CD40 and VCAM-1, respectively.[95] As noted previously, paraproteins in some patients may have anti-HIV activity,[319] [331] [335] indicating that one component of the hypergammaglobulinemia may be linked to the immune response to HIV antigens. Alternatively, as noted earlier, immune dysregulation may result from an imbalance of CD4 lymphocyte subsets that promote either cellular or humoral immune responses, resulting in sustained polyclonal B-cell activation.[66]

The profound stimulation of B cells present even in asymptomatic individuals with HIV infection is closely linked to the development of generalized lymphadenopathy[315] and likely plays a role in the pathogenesis of B-cell lymphomas observed in these patients.[336] [337] [338] Although the risk for developing B-cell lymphomas is greatest in patients with a severe depletion of CD4+ lymphocytes (<50/L),[339] unlike opportunistic infections, lymphomas may occur in the absence of clinically significant immunodeficiecy. It will be of great interest to determine if this sustained B-cell stimulation and the risk of lymphoma decrease following the

initiation of highly active antiretroviral therapy.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is an uncommon but well-described complication of HIV infection that has been described in both adults and children. [138] [139] [141] [142] [340] [341] [342] TTP can occur at any point in the natural history of HIV infection and has been described in patients with fully developed AIDS as well as the initial manifestation of HIV infection. [138] [139] [141] TTP has also been reported following and before a diagnosis of HIV-related ITP. [333] [344] Clinically, patients present with the typical TTP syndrome of fulminant microangiopathic hemolytic anemia and thrombocytopenia, with a variable proportion of individuals exhibiting fever, elevated creatinine, and neurologic abnormalities. [141] [345] More protracted cases of TTP have also been described. [346] Schistocytes and an elevated lactate dehydrogenase (LDH) level are typically present, although depending on the degree of bone marrow compromise by the underlying HIV infection, the reticulocyte count may be less than expected for the degree of anemia. Neurologic abnormalities have included mental status changes, seizures, transient focal neurologic defects, and coma. [138] [139] [141] Examinations of tissues from autopsy specimens, as well as lymph node and gingival biopsies, have documented characteristic histologic changes of fibrin deposition in the microvasculature. [138] [139] [347] Responses to therapy in HIV-associated TTP are similar to those seen for the classic syndrome, with 5085% of patients responding to regimens that included plasmapheresis with or without fresh-frozen plasma infusions, antiplatelet agents, corticosteroids, or vincristine. [138] [139] [140] [141] One case report of a patient with relapsing TTP suggested a response to zidovudine therapy. [348]

The mechanism for HIV-associated TTP and its relation to HIV infection itself are unclear. As with TTP in the absence of HIV infection, the pathogenesis of this disorder may involve primary endothelial cell damage [349] and/or factors that promote or inhibit platelet agglutination. [350] The hemolytic uremia syndrome has also been reported in HIV-infected patients presenting with renal failure and microangiopathic hemolytic anemia. [351] [352] Interestingly, TTP has also been reported in patients infected with a different human retrovirus, human T-cell lymphotropic virus (HTLV-I), [342] [353] which is closely associated with adult T-cell leukemia and a demyelinating neurologic disorder termed HTLV-associated myelopathy. [354] [355]

Porphyria Cutanea Tarda

Several recent reports have described acquired porphyria cutanea tarda (PCT) in HIV-seropositive patients. [356] [357] [358] [359] [360] [361] [362] Acquired PCT is a disorder of heme synthesis characterized by a reduction in uroporphyrin decarboxylase activity in liver cells with an elevation in heme precursors in plasma, primarily uroporphyrinogen. These metabolites are oxidized and excreted in the urine as uroporphyrin, causing an increased urinary uroporphyrin-to-coproporphyrin ratio (see Chap. 27). As in non-HIV-associated PCT, patients present with manifestations of delayed-type photosensitivity with increased skin fragility, vesicles, bullae, hyperpigmentation, and hypertrichosis, particularly on the face and dorsum of the hands. [356] However, in contrast to classic PCT, polycythemia and sclerodermoid changes are uncommon. [356] Hepatic dysfunction appears to be a common cofactor, since the majority of patients have abnormal liver function tests, serologic evidence of viral hepatitis, or a history of excessive alcohol consumption. [356] [357] [360] [361] [362] Therapeutic measures directed at avoiding sun exposure and removing precipitating agents (ethanol, estrogens, barbiturates) are generally successful, although additional measures including phlebotomy, antimalarials, [356] [358] and, in one case, therapy with zidovudine [358] may also be beneficial.

Diffuse Infiltrative CD8 Lymphocytosis Syndrome

A remarkable syndrome has been described in HIV-infected patients characterized clinically by bilateral parotid gland enlargement, xerostomia, and xeropthalmia. [363] [364] Biopsies of minor salivary or parotid glands have shown diffuse infiltration by benign CD8+ lymphocytes. Extraglandular infiltration by CD8+ cells is also common, with some patients presenting with lymphocytic interstitial pneumonitis, peripheral neuropathy, or lymphocytic infiltration of gastric mucosa, kidney, thymus, and

liver. [363] [365] Peripheral blood typically shows a normal total white cell count with a CD8+ T-cell lymphocytosis of approximately 50% and an elevated total CD8 count. CD4+ T cells in these patients are mildly to moderately depressed, indicating that this syndrome usually occurs in patients with minimal immune deficits. In contrast to patients with Sjögrens syndrome, serologic markers of rheumatologic disorders (rheumatoid factor, antinuclear antibodies, anti-Ro/SS-A, anti-La/SS-B) are negative, and HLA typing has shown an association with HLA DR5 or DR6. [365] [366] Complete responses in individual patients have been observed following treatment with zidovudine or chlorambucil. [363] However, numbers of treated patients are too small to permit general therapeutic recommendations. Phenotypic analysis of peripheral and infiltrating CD8+ lymphocytes, the detection of HIV antigens in salivary tissue, and the association of this syndrome with HLA DR5 suggest that this disorder results from a genetically determined and exuberant polyclonal cellular immune response to HIV itself, possibly correlated with an abnormal tissue expression of adhesion molecules. [364]

Morphology of Hematopoietic Cells in HIV Infection

Peripheral Smear

As noted previously, cytopenias of all peripheral blood cells have been observed in patients with HIV infection (Table 154-3). With the exception of thrombocytopenia, which can occur in asymptomatic individuals with relatively mild immune deficiency, anemia and leukopenia are both more frequent and severe in patients with advanced immunodeficiency. [122] [125] Peripheral red blood cells in patients with anemia are typically normochromic and normocytic and exhibit a varying degree of anisocytosis and poikilocytosis. [129] [132] [133] [134] The perturbation in red cell size and shape is reflected in an increased red cell distribution width. [123] Macrocytosis is rarely seen. [129] However, in patients receiving therapy with zidovudine, macrocytosis is present in the majority of patients, occasionally with mean corpuscular volumes as high as 120 or greater (Fig. 154-5). [135] [136] Rouleaux formation of red cells may also be seen; this likely reflects the presence of concomitant hypergammaglobulinemia. [129] [133] As noted previously, schistocytes and nucleated red cells are present in patients with HIV-associated TTP. [137] [138] [139] [141]

Peripheral blood neutrophils are typically left-shifted [129] and may exhibit a number of morphologic abnormalities, including enlarged size, hyposegmentation, and Pelger-Hüet anomalies (Fig. 154-5). [129] [134] Atypical plasmacytoid lymphocytes are occasionally seen in asymptomatic individuals but are particularly common in lymphopenic patients with AIDS [129] [133] and during acute HIV infection. [367] Large atypical monocytes have also been described with prominent vacuolization and fine nuclear chromatin. [129] [133]

Bone Marrow Histology

Bone marrow examinations in HIV-infected patients are usually performed to evaluate peripheral cytopenias or when systemic infections or malignancies are suspected. Thus, with the exception of patients with isolated thrombocytopenia, the majority of information available on bone marrow histology in patients with HIV infection is from individuals with advanced immunodeficiency. It is clear, however, that in this population, abnormalities are frequently seen in all marrow cellular elements, as well as in the marrow matrix itself (Table 154-3). With the possible exception of particular types of dysplastic changes in megakaryocytes [269] [270] (described further later), there appear to be no distinctive features of bone marrow histology in patients with HIV infection or AIDS. [122] [123] [368]

TABLE 154-3 -- Morphologic and Histologic Abnormalities of Peripheral Blood and Bone Marrow in Patients with ARC and AIDS

Peripheral Blood
Red cells
Normochromic normocytic anemia
Anisocytosis and poikilocytosis
Rouleaux
Schistocytes
Reticulocytopenia
Basophilic stippling

Macrocytosis (during zidovudine therapy)
Neutrophils
Enlarged
Left-shifted
Hyposegmented with Pelger-Hüet forms
Other
Plasmacytoid lymphocytes
Large vacuolated monocytes
Bone Marrow
Cytologic features
M/E ratio 25:1
Hypercellular, normocellular, or hypocellular
Erythroid dysplasia
Erythroid hypoplasia (MAC infection, zidovudine)
Myeloid dysplasia
Left-shifted, hyposegmented, maturation arrest at metamyelocyte stage
Megakaryocytes
Adequate to increased
Dysplastic (hyposegmented, micromegakaryocytes, denuded nuclei)
Plasmacytosis
Lymphoid aggregates/infiltrates
Histiocytes
Loose granulomas (aggregates of plasma cells, lymphocytes, histiocytes)
Erythrophagocytosis
Increased eosinophils
Iron adequate to increased (reticulo-endothelial cell distribution)
Marrow matrix
Increased reticulin
Necrosis
Serous atrophy

Adapted from reviews by Perkocha and Rodgers[123] and Zon and Goopman.[122]

Marrow cellularity is typically normocellular to hypercellular, even in the setting of peripheral cytopenias, although 525% of AIDS patients in some series have exhibited hypocellular marrows.[125] [130] [131] [144] [146] [148] In general, the peripheral blood counts do not correlate with the overall degree of marrow cellularity, and patients with granulocytopenia and anemia are more likely to have normocellular or hypercellular than hypocellular marrows. [125] The myeloid-to-erythroid ratio usually ranges from 27:1, reflecting the combined effects of myeloid hyperplasia seen even in patients with peripheral granulocytopenia, and erythroid hypoplasia. [123] [134] [144] [146] A higher degree of erythroid hypoplasia in some series likely reflects the increased use of zidovudine, which, as described in a later section, can suppress erythropoiesis.

A remarkable degree of dysplasia has been noted in the morphology of myeloid, erythroid, and platelet precursors. Myeloid maturation is in general left-shifted, [125] [144] with one series noting a relative maturation arrest at the metamyelocyte stage. [129] A number of myelodysplastic changes in the myeloid lineage have been described, including the presence of abnormal myeloblasts with high nuclear/cytoplasmic ratios and abnormal folded or cleaved nuclei, [134] as well as large myelocytes, metamyelocytes,

and bands with megaloblastic-appearing nuclei. [129] [134] [144] [145] In contrast to the megaloblastic changes of myeloid cells seen in B_{12} deficiency, granulocytes in patients with AIDS are often hyposegmented rather than hypersegmented.[129] [134]

Dyserythropoiesis, although initially reported less often than myelodysplasia, has been increasingly recognized. [145] [146] Abnormalities have included erythroblasts with lobulated, binucleated, and fragmented nuclei, as well as basophilic stippling in more mature red blood cells. [129] [134] [144] In one series, all patients with dysplastic changes were found to be anemic and exhibited marked anisocytosis and poikilocytosis on peripheral smear. [125] Frank megaloblastic changes in erythroid precursors have been reported but appear to be less common than megaloblastic features of myeloid cells. [134] However, erythroid megaloblastic changes have been described and are likely more common in patients receiving folate antagonists or zidovudine. [133] [135] [136] [145] [146] [149] Erythroid hypoplasia that may be severe has been reported in some patients with AIDS or ARC,[148] in patients receiving zidovudine,[136] [152] [204] and in the setting of systemic MAC infection. [129] [133] [150] [158] Pure red cell aplasia or severe hypoplasia secondary to persistent parvovirus B19 infection has also been described in immunocompromised patients with [154] [156] [157] [369] [370] [371] and without[369] [372] [373] [374] HIV infection. Remarkable responses have been observed with intravenous gammaglobulin therapy due to the presence of neutralizing immunoglobulin in commercial gammaglobulin preparations.[154] [157] [369] [372] [375] Chronic parvovirus B19 infection should be suspected if characteristic vacuolated giant pronormoblasts are seen on marrow aspirates or biopsies[154] [156] [157] [372] [376] (Fig. 154-5), but this may warrant consideration in any patient in whom a profound depression in erythropoiesis occurs out of proportion to other marrow elements. In general, marrow morphology is a poor predictor of parvovirus infection, and more sensitive assays are often required, including polymerase chain reaction analysis of viral DNA in plasma and immunoperoxidase stains or in situ hybridization analysis of marrow samples.[375] [377]

Megakaryocytic dysplasia has become increasingly recognized in patients with fully developed AIDS as well as in those with isolated thrombocytopenia. [146] [231] [270] Dysplastic changes that have been described have included micromegakaryocytes with denuded nuclei and megakaryocytes with hyposegmented or fragmented nuclei [134] [144] [145] [146] [269] [270] (Fig. 154-5). Ultrastructural analysis of megakaryocytes from AIDS patients with thrombocytopenia has demonstrated marked ballooning or blebbing of the peripheral zone, a finding not encountered in megakaryocytes from individuals with non-HIV ITP. [269] In addition, abnormal clustering of megakaryocytes on bone marrow biopsy sections, similar to that seen in myeloproliferative syndromes, has also been described. [134] As noted previously, dysplastic changes observed in megakaryocytes (Fig. 154-6), the detection of HIV RNA in megakaryocytes from infected patients, and the clinical response of 5068% of patients with HIV-related thrombocytopenia to zidovudine are all consistent with the view that the megakaryocyte itself is a target for HIV infection in vivo. [284] [285]

Although several of the dysplastic changes noted in HIV-infected patients resemble those seen in preleukemia syndromes, myeloid leukemia in AIDS, though reported, is very uncommon.[197] [198] [378] Thus, it appears that the significance and the etiology of dysplasia in patients with HIV infection are different than those described for patients without HIV infection who present with peripheral cytopenias and marrow dysplasia. [123] [134] As noted previously, direct infection of marrow

precursors by HIV may contribute to these defects, although this issue remains controversial. [209] [210] [211] [215] [219] [220] [221] [284] [379]

Lymphoid aggregates are common and have been reported in 1050% of patients with AIDS and ARC. [125] [130] [131] [132] [134] [144] [145] [146] [148] Lymphoid aggregates may be either small, well circumscribed, and composed of small round lymphocytes, or large, poorly defined, and mixed with histiocytes. [133] [145] Infiltrating lymphocytes have also been described that are atypical or cleaved and located in paratrabecular areas. [144] [148] However, when paratrabecular localization of lymphocytes is seen, it is important to rule out the possibility of a non-Hodgkins lymphoma, since lymphomas in AIDS patients involve bone marrow in up to 50% of cases. Bone marrow has also been described as the initial or only site of involvement for both non-Hodgkins and Hodgkins lymphomas complicating HIV infection [380] [381] (Fig. 154-5).

Plasmacytosis is also extremely common in bone marrow and has been seen in 3185% of patients. [125] [130] [145] [146] In individual patients, plasma cells may represent as high as 40% of bone marrow cells in the absence of a neoplastic disorder. [382] The morphology of plasma cells has varied from being normal to moderately dysplastic with large bi- or trinucleated cells. Russell bodies with multiple globules have also been described. [382] Although myeloma has clearly been reported in AIDS, patients may present with monoclonal spikes on serum protein electrophoresis and marrow plasmacytosis with plasma cell aggregates and atypical forms, but without a clonal proliferation of plasma cells. [383] Thus, in the absence of lytic bone lesions or other clinical evidence of a plasma cell neoplasm, a diagnosis of myeloma should be made with caution.

Additional cellular abnormalities of bone marrow include increased numbers of histiocytes, noncaseating granulomas, and the presence of loose granulomas consisting of aggregated histiocytes, lymphocytes, and plasma cells [130] [131] [134] [144] [146] [148] [382] (Fig. 154-5). Pseudogaucher cells have also been described from a patient with MAC infection in which large foamy histiocytes on Wright Geimsa stain were shown to contain numerous mycobacterial organisms by periodic acid-Schiff and Ziehl-Nielsen stains. [384] An additional case of this morphologic manifestation of MAC is shown in Figure 154-5 . Histiocytic phagocytosis of erythroid cells and occasionally granulocytes and platelets has been described, [133] [385] but this is a nonspecific finding that may also occur in a variety of viral, fungal, and bacterial infections. Severe hemophagocytic syndromes have been reported in HIV-infected patients presenting with pancytopenia. [386] [387] [388] Although peripheral blood eosinophilia is rarely seen, [129] marrow eosinophilia is common and has been reported in 961% of patients with AIDS. [125] [144] [148] [382]

In most series, bone marrow iron stores are adequate to increased [125] [131] [133] [134] [148] in reticuloendothelial cells, indicating a defect in iron utilization similar to that seen in other chronic disease states. [163] Interestingly, one study in children described decreased iron stores in 27 of 78 patients (44%). [368] Sideroblasts with or without the presence of ringed forms have been described but are uncommon. [125] [129] [131]

Abnormalities in the bone marrow matrix are frequently seen and include increased reticulin or fibrosis, [125] [129] [131] [134] [144] [146] [148] [382] and serous atrophy or gelatinous transformation. [130] [144] [146] [148] [382] The increase in marrow reticulin may be focal or diffuse and may be increased in areas of granuloma formation [131] [148] or lymphoid aggregates. [148] In the majority of patients in some series, bone marrow aspiration is difficult or not uncommonly dry, [129] [131] [133] probably as a result of one or more of these abnormalities. While atypical proliferation of endothelial cells has been noted on histologic sections of marrow, [148] KS involving bone marrow is rarely seen. [389] [390]

Bone marrow histology or culture may be particularly useful in documenting opportunistic infection and should be performed in HIV-infected patients with undiagnosed fevers or constitutional symptoms, especially those with low CD4 cell numbers. [391] [392] [393] In one series of 47 patients with AIDS in whom a bone marrow aspiration or biopsy was performed to evaluate unexplained fever, pathogens were detected in 20 patients

TABLE 154-4 -- Infections Involving the Bone Marrow in Patients with AIDS

(42.5%). [394] Although it has been argued in the diagnosis of mycobacterial infection that blood cultures have a sensitivity comparable to that of bone marrow cultures in diagnosing disseminated infection, [395] bone marrow examination with special histologic staining can certainly provide a more rapid method of diagnosis for both opportunistic mycobacterial and fungal infections. [396] Infectious agents reported to involve the bone marrow in patients with AIDS are listed in Table 154-4 and include MAC, [129] [130] [131] [133] [393] [394] [396] *Mycobacterium tuberculosis*, [393] [394] [396] *Mycobacterium xenopi*, and *kansasii*, [396] *Histoplasma* [130] [396] (Fig. 154-5), *Cryptococcus* [394] [396] [397] (Fig. 154-5), *Toxoplasma,* [131] CMV, [144] *Leishmania,* [398] disseminated cat-scratch disease, [399] and *Pneumocystis carinii.* [400] [401] [402] Marrow granuloma in patients with mycobacterial infection may be either loosely formed or absent despite the presence of abundant organisms on acid-fast stains [130] [394] (Fig. 154-5). As noted previously, parvovirus B19 infection should be suspected in the setting of profound erythroid hypoplasia if giant pronormoblasts are present (Fig. 154-5). [154] [156] [157] [369] [370]

Extralymphatic presentation of non-Hodgkins lymphomas occurs in up to 90% of patients with HIV infection and has been reported to involve the bone marrow in 50% of cases. [403] As noted previously, bone marrow involvement may be the presenting site of lymphoma. [337] [403] The lymphomas are typically high-grade Burkitts or non-Burkitts lymphomas (Fig. 154-5), although more well-differentiated types have also been described. [337] [403] Lymphomas should be suspected in the clinical setting of constitutional symptoms, an elevated LDH, and the presence of teardrops or nucleated red blood cells on peripheral blood smear. Hodgkins disease, also noted with increased frequency in HIV-infected patients, is, in comparison to patients without HIV infection, more likely to involve extralymphatic sites, including the bone marrow (Fig. 154-5). [337] [381]

HEMATOLOGIC COMPLICATIONS AND EFFICACY OF ANTIRETROVIRAL THERAPY

Zidovudine (AZT)

3azido-2,3-dideoxythymidine (AZT), or zidovudine, was the first antiretroviral drug shown to improve the survival of patients with AIDS. [404] [405] This thymidine analogue contains an azido group in place of the 3 hydroxyl group of the nucleoside sugar moiety. Zidovudine is phosphorylated by cellular kinases, and following incorporation into an elongating strand of viral DNA by reverse transcriptase, AZT-triphosphate prevents subsequent 5 to 3 phosphodiester linkages from forming, resulting in premature termination of the viral DNA chain.[404] [405] [406] An increased sensitivity of reverse transcriptase to zidovudine compared to cellular DNA polymerases confers greater activity on viral rather than cellular DNA synthesis. [404] [406] [407] The antiviral effects of zidovudine are dependent on its phosphorylation by cellular kinases. [406] In addition to its activity as a chain terminator, AZT-monophosphate competitively inhibits thymidine kinase, resulting in a reduced level of intracellular thymidine-5-triphosphate (dTTP) and an inhibition of DNA synthesis. [404] [405]

Early studies demonstrated that zidovudine could prolong survival in patients with fully developed AIDS [160] and delay the progression to AIDS in asymptomatic patients with HIV infection whose CD4 cell numbers were <500/l. [408] [409] Zidovudine can also improve HIV-related dementia and other neurologic defects [410] [411] [412] and has been shown to reduce maternal-to-fetal transmission of HIV when administered to the mother before and to the fetus after birth. [413]

Hematologic toxicities associated with zidovudine are, in general, dose-related and are more likely to develop in patients with pre-existing neutropenia and anemia, low serum B_{12} levels, and CD4 cell numbers <100/l. [135] [414] However, severe pancytopenia occurring within 46 weeks of starting zidovudine has also been reported as an apparently idiosyncratic reaction and may persist several months after discontinuation of therapy. [204] Patients on chronic zidovudine therapy typically develop macrocytic red cell indices, although generally without hypersegmentation of neutrophils. [135] [415] The incidence of anemia has decreased considerably with the lower doses of zidovudine used in current protocols. [127] Unlike thrombocytopenia (discussed further later), HIV-related anemia and neutropenia usually do not respond to zidovudine therapy. As noted previously, bone marrow examinations of patients receiving zidovudine have demonstrated a number of abnormalities in the erythroid lineage, including erythroid hypoplasia, aplasia, or maturation arrest. [136] Interestingly, among patients who develop severe pancytopenia and marrow hypoplasia as an early complication of zidovudine therapy, macrocytosis is not seen. [204] Zidovudine is metabolized primarily by glucuronidation in the liver, and drugs that are also glucuronidated, particularly probenecid, [405] [416] may prolong the half-life of zidovudine and potentiate its toxicity. The effects of myelosuppressive drugs such as chemotheraputic agents will be worsened by concomitant therapy with zidovudine. [417]

The hematologic toxicity of zidovudine is likely related to inhibition of cellular DNA polymerases as well as a depletion of intracellular thymidine pools. [404] [405] [418] Studies on the effects of zidovudine on bone marrow cultures have demonstrated a time- and dose-dependent inhibition of marrow erythroid and granulocyte/macrophage precursors, with the BFU-Es exhibiting 5- to 8-fold more sensitivity to zidovudine than CFU-Es, CFU-GMs, and CFU-GEMMs. [418] As discussed further in the following sections, the concurrent administration of recombinant erythropoietin or myeloid colony-stimulating factors (GM- or G-CSF) can ameliorate the anemia and leukopenia that may complicate zidovudine therapy. [167] [236] [419] [420] [421]

Other Reverse Transcriptase Inhibitors and Protease Inhibitors

A number of other nucleoside analogs are now available to treat HIV-infected patients, including DDI, DDC, D4T, and 3TC, as well as nonnucleoside analogs such as navaripine. In general, these compounds have little hematologic toxicity and can be used in patients who cannot tolerate zidovudine. [405] In one retrospective study of patients receiving DDI, a significant improvement in hemoglobin level, granulocyte number, and platelet count was observed and found to persist for up to 1 year following therapy.[422] Macrocytosis has not been observed with either DDC or DDI. [423] [424] However, nonhematologic toxicities are

TREATMENT OF ANEMIA IN HIV INFECTION

As in any patient with a low hematocrit, the diagnostic evaluation of anemia in a patient with HIV infection requires a careful consideration of factors that contribute to decreased or ineffective red cell production, increased peripheral destruction, and blood loss. In addition to direct effects of HIV and/or chronic disease states on hematopoietic precursors, other important etiologies include marrow involvement by lymphomas and opportunistic infections (particularly MAC or fungal pathogens) and blood loss due to gastrointestinal involvement by lymphomas and CMV infection. As noted previously, pure red cell aplasia secondary to persisting parvovirus B19 infection has been well described in HIV- infected patients and typically responds to intravenous gammaglobulin therapy. [154] [156] [157] [369] [370] [377] Available evidence does not indicate that decreased iron, B_{12}, or folate levels contribute to the chronic anemia that is typically seen in HIV-infected patients, although consideration of these potentially reversible etiologies is always warranted. [123] [181] Immune hemolytic anemia, although reported, is similarly rare [190] [192] [193] [194] [404] [434] despite the frequency of positive anti-red cell immunoglobulin tests, [122] [185] [186] but when present has been reported to respond to corticosteroids, splenectomy, and, in a single case, zidovudine. [192] [193] [434] Microangiopathic hemolytic anemia secondary to TTP, although uncommon, may be fulminant but has responded to regimens that included plasmapheresis with or without antiplatelet agents and plasma infusion. [137] [138] [139] [140] [141]

Potentially reversible drug etiologies of anemia include zidovudine, trimethoprim/sulfamethoxazole, dapsone, and, in the setting of antimycobacterial therapy, isoniazid. Reversible megaloblastic panhypoplasia has been reported secondary to trimethoprim and dapsone therapy for PCP, and folinic acid has been recommended, particularly with suspected vitamin B_{12} deficiency, to ameliorate the hematopoietic toxicity of these and other folate antagonists. [149] Although patients receiving dapsone frequently exhibit manifestations of low-grade hemolysis with an increase in LDH, severe hemolysis may also occur, particularly in the setting of G6PD deficiency. [435] [436]

As noted previously, therapy with zidovudine is frequently complicated by anemia and occurs more commonly in patients with advanced immunodeficiency and low serum vitamin B_{12} levels. [135] [176] Although the anemia secondary to zidovudine therapy is generally dose-related and typically responds to dose reduction, apparently idiosyncratic reactions have been reported and may cause profound and prolonged marrow hypoplasia even after zidovudine is discontinued. [204] The long-term administration of zidovudine to some patients may require transfusion support, although, as described following, in some patients this may be ameliorated by the use of recombinant erythropoietin. [167] [419] [420]

Chronic transfusion support was initially a common practice in the treatment of AIDS patients. However, transfusion requirements have decreased in recent years due to the use of lower doses of zidovudine, the availability of alternative antiretroviral drugs, particularly protease inhibitors, and the use of erythropoietin. In general, the indications, benefits, and complications of transfusion support of patients with HIV-associated anemia are similar to those of the non-HIV-infected patient. [437] [438] There is some evidence that hepatitis C infection as a complication of transfusion therapy can have a more aggressive clinical course in the setting of HIV infection. [439] As with non-HIV-infected patients, chronic transfusion therapy may cause clinically significant iron overload complicated by hepatic fibrosis. [440] Interestingly, although transfusion-associated graft-versus-host disease has been observed in immunosuppressed patients, this complication has not been reported in patients with HIV infection, perhaps as a result of cytopathic effects of HIV on CD4 lymphocytes that are likely required to initiate or sustain the graft-versus-host reaction. [441] [442]

Several clinical trials have evaluated the effects of recombinant human erythropoietin in treating anemia in patients with HIV infection receiving zidovudine. [167] [419] [420] Erythropoietin has been shown to improve the hematocrit and decrease transfusion requirement in patients whose levels of endogenous erythropoietin levels were <500 IU/L (Fig. 154-7). No benefit was seen in patients with pretreatment erythropoietin levels >500 IU/L, who made up approximately one-third of the zidovudine-treated patients. [167] [419] A similar clinical benefit was also seen in zidovudine-treated patients who received erythropoietin in combination with recombinant granulocyte colony-stimulating factor (G-CSF). [420] Similar results have been described in HIV-infected patients not receiving zidovudine. [443] [444] Quality of life assessments have demonstrated that patients receiving erythropoietin for anemia experienced a greater energy level and an improvement in their activity level. [445] Although studies in AIDS patients did not demonstrate significant side effects from erythropoietin therapy, toxicities are well described in other patient groups and include rash, fatigue, and headache, as well as more severe cerebrovascular and cardiovascular complications, including stroke, seizure, hypertension, and myocardial infarction. Finally, an additional study demonstrated that G-CSF in the absence of erythropoietin treatment may also increase red cell production and the number of circulating BFU-Es, raising the possibility that additional therapeutic approaches using combinations of hematopoietic growth factors may be useful in the treatment of HIV-associated anemia. [446]

In patients with endogenous erythropoietin levels <500 IU/L, the recommended starting dose of erythropoietin is 100 Ukg subcutaneously or intravenously three times a week for 8 weeks. Doses are then increased by 50 Ukg every 4 weeks until a rise in hematocrit of 5% is observed or a hematocrit of 36% is achieved. The dose should not exceed 300 Ukg. [124]

Figure 154-7 Response to recombinant erythropoietin in patients on zidovudine therapy. Mean hematocrit concentrations are shown for zidovudine-treated patients with endogenous erythropoietin levels of 500 mU/ml who were treated with either recombinant erythropoietin (r-HuEPO) or placebo. r-HuEPO dose in the treated group was 100200 U/kg IV or SC three times per week. Bars represent 95% confidence intervals. No benefit was seen in patients with endogenous erythropoietin levels >500 mU/ml. *(Reprinted from Henry et al.,[167] with permission.)*

common, particularly for the nucleoside analogs, and include peripheral neuropathy and gastrointestinal toxicity, particularly acute pancreatitis. [414] [422] [423] [424] [425]

For both nucleoside analog and nonnucleoside-based reverse transcriptase inhibitors, drug-resistant strains of HIV characteristically emerge due to the selection of viral mutants with specific amino acid changes in the viral reverse transcriptase. [426] [427] These drug-resistant variants have been seen even when reverse transcriptase inhibitors are used in combination. [405] [428] [429] Recently, a number of compounds that inhibit the viral protease have become available, including saquinavir, indinavir, and ritonavir. When used in combination with one or more reverse transcriptase inhibitors, these regimens have been highly effective in reducing the levels of circulating viral RNA to low or even undetectable levels, [44] [430] a finding that is expected to have substantial clinical benefit. Although these complex drug regimens can be difficult to administer and may be poorly tolerated in some patients, in general combination antiretroviral regimens that do not include zidovudine have little hematologic toxicity. [44] [430] In protocols that incorporate interferon, leukopenia can be a significant dose-limiting toxicity. [431] [432] [433]

TREATMENT OF HEMATOLOGIC COMPLICATIONS OF HIV INFECTION

The evaluation and treatment of cytopenias in patients with HIV infection must take into account a number of possible contributing factors, including (1) the effects of drugs used to treat HIV infection itself or complicating opportunistic infections, (2) direct marrow involvement by pathogens or neoplasms (particularly lymphomas), (3) generalized suppressive effects of chronic disease states on myelo- and erythropoiesis, (4) possible nutritional deficiencies, (5) immune-mediated destruction of mature or immature hematopoietic cells, and (6) direct effects of the underlying HIV infection on bone marrow stem cells (Table 154-5). Consequently, the approach to the treatment of cytopenias in patients with HIV infection requires a careful consideration of multiple iatrogenic, infectious, neoplastic, and immune etiologies, many of which are potentially reversible.

Neutropenia

A number of drugs as well as infectious and neoplastic complications of AIDS can produce leukopenia, although reversible iatrogenic or secondary etiologies are often not found. Commonly used medications whose use is frequently complicated

TABLE 154-5 -- General Approach to the Differential Diagnosis of Cytopenias in Patients with HIV Infection

1. Hematologic toxicity of drugs disseminated intravascular coagulation
Antiretroviral therapy (i.e., zidovudine, interferon)
Antibiotics (i.e., trimethoprim/sulfamethoxazole, dapsone, pentamidine, ganciclovir, flucytosine)
2. Direct marrow involvement by infections (i.e., MAC, parvovirus B19)
3. Marrow involvement by malignancies (i.e., non-Hodgkins and Hodgkins lymphomas)
4. Autoimmune destruction of hematopoietic cells
5. Nutritional deficiencies (B_{12} , folate)
6. Generalized myelosuppressive effects of chronic disease states
7. Direct effects of HIV infection of marrow stem cells (i.e., megakaryocytes)
8. Miscellaneous (i.e., blood loss, TTP, disseminated intravascular coagulation)

by neutropenia include zidovudine, interferons, trimethoprim/sulfamethoxazole, sulfadiazine, ganciclovir, pentamidine, rifabutin, flucytosine, and chemotherapeutic agents (for lymphomas or KS).[199] [200] [202] [414] [433] However, even when drugs can be implicated as the cause of neutopenia, management decisions are frequently complicated by risks associated with discontinuing or reducing the dose of drugs required for treating infections or neoplasms. Some reports have noted an improvement of HIV-related neutropenia following the initiation of antiretroviral therapy, [422] and it is likely that further improvements will be reported with the use of combinations of antiretroviral agents (i.e., reverse transcriptase inhibitors and protease inhibitors).

The early observation that AIDS-related neutropenia could respond dramatically to therapy with GM-CSF provided a rationale for using hematopoietic growth factors in a number of clinical settings in which neutropenia is common. Groopman et al. [235] initially described responses in 16 of 16 AIDS patients treated with intravenous recombinant GM-CSF. A remarkably rapid and dose-dependent increase in peripheral blood neutrophils, monocytes, and eosinophils was observed (Fig. 154-8). Increased marrow cellularity was seen even in patients who had hypocellular marrows prior to therapy. Toxicities were mild and included fever, myalgias, headache, and flushing. Similar responses were subsequently described for patients treated with G-CSF. [236] Although responses to intravenous GM-CSF or G-CSF were transient, subsequent studies have demonstrated that long-term subcutaneous therapy with these growth factors can produce a sustained increase in granulocyte counts from weeks to months without an apparent depletion in marrow stem cell activity.[420] [421] [447] This effect has been observed in a variety of clinical settings in which neutropenia is common, including (1) patients receiving zidovudine either with [431] [432] or without[236] [420] [421] [447] interferon, (2) patients with CMV infection receiving ganciclovir, [448] (3) patients with HIV-related lymphomas receiving chemotherapy, [449] and (4) patients with HIV-associated neutropenia complicated by bacterial infections.[450] These studies demonstrated that GM-CSF or G-CSF, given at low doses, could elevate the granulocyte count and allow continuation of myelosuppressive therapy.[451] [452] In one study of patients with AIDS-associated non-Hodgkins lymphomas, GM-CSF therapy reduced the number of febrile episodes and days of hospitalization.[449] Further studies will be needed to determine the ultimate impact of hematopoietic growth factors on quality of life and survival.

Although some in vitro studies have shown that GM-CSF but not G-CSF could stimulate replication of particular HIV isolates, [283] with one exception,[421] clinical trials to date have not demonstrated laboratory evidence of a sustained enhancement of viral replication in vivo. [431] [432] [447] [449] [453] Interestingly, GM-CSF has been shown to augment markedly the antiretroviral effects of zidovudine in vitro, apparently by increasing intracellular levels of the biologically active triphosphate form. [454] [455] In addition, several reports have, depending on the assay used, described functional defects in neutrophils from patients with HIV infection, although no consensus exists as to specific defects involved. [456] [457] [458] [459] [460] In two studies, neutrophil function was observed to be enhanced following GM-CSF therapy. [460] [461] Neutrophils from patients treated with GM-CSF have also exhibited enhanced killing of HIV-infected target cells in the presence of antibodies to the HIV envelope glycoprotein. [462] Thus, myeloid growth factors may have a number of therapeutic roles both in promoting antiviral effects and in augmenting host immunity. However, the significance of these findings in terms of clinical benefit to patients remains to be demonstrated.

The usual starting dose of G-CSF for HIV-associated neutropenia is 5 g/kg/day given subcutaneously; it may be increased to 7.5 g/kg/day and then 10 g/kg/day. [124] Depending on the clinical setting, attempts may be made to reduce

TREATMENT OF THROMBOCYTOPENIA IN HIV INFECTION

As noted previously, studies on the mechanism of thrombocytopenia in HIV-infected patients have demonstrated decreased platelet survival [256] and the presence of circulating and platelet-associated immune complexes, [242] [322] [323] as well as the presence of true antiplatelet antibodies in some patients. [231] [242] [246] [249] [264] A number of medical approaches that have been successfully used to treat classic ITP have also been used in HIV-related thrombocytopenia with varying degrees of success, including corticosteroids, [240] [241] [251] intravenous gammaglobulin, [463] [464] and danazol. [251] Although responses are seen in as high as 6085% of patients receiving prednisone, usually in 4-week courses of 1 mg/kg/d followed by a rapid taper, these responses are sustained in only 10-20% of patients. [240] [241] [251] However, the long-term or repetitive use of an immunosuppressive agent in the setting of HIV infection is a major concern. Intravenous gammaglobulin may produce a rapid improvement in the platelet count, as seen in classic ITP, in approximately 90% of patients and represents the treatment of choice in the setting of a medical emergency or as a supportive measure for an invasive procedure. [463] [465] Responses typically last several days or occasionally weeks, but as with corticosteroids are usually transient. Encouraging results with anti-Rh(D) immunoglobulin [466] [467] [468] [469] and even dapsone [470] have been reported, presumably as a result of reticuloendothelial modulation from IgG-coated or hemolyzed red blood cells. Vincristine has also been reported to improve the platelet count in small numbers of AIDS patients with thrombocytopenia. [241] [471] In a more investigational approach, long-term correction of the platelet count was observed in a single AIDS patient following treatment with an anti-CD16 monoclonal antibody, reactive with the low-affinity Fc gamma receptor, again indicating that therapeutic measures to induce reticuloendothelial blockade may improve platelet survival. [472]

In contrast to the typically transient improvement following medical management of HIV-related ITP, splenectomy has been highly effective in producing a sustained increase in platelet counts in approximately 90% of patients. [240] [259] [260] [261] [262] Improvement has been seen even in patients who are refractory to steroids and gammaglobulin before splenectomy and those with severe thrombocytopenia with platelet counts <10,000/l. [260] Although in most reported series there has been no increase in the morbidity of splenectomy in HIV-infected patients, [260] the use of this procedure, while effective, clearly must be individualized. Among hemophiliacs, in whom relatively mild thrombocytopenia can lead to life-threatening hemorrhagic complications, [252] complete and last- ing responses were seen following splenectomy in four of four patients studied. [473] Most reported series have shown that splenectomy does not accelerate the clinical progression to AIDS. [240] [251] [262] As a possible alternative to splenectomy, some benefit with low dose splenic irradiation has also been reported, including patients who have failed to respond to zidovudine or gammaglobulin. [474] [475] [476]

Several reports have shown responses to zidovudine in approximately 50% of patients with HIV-related thrombocytopenia. [238] [477] [478] [479] [480] [481] [482] In one blinded placebo-controlled trial of 10 patients with platelet counts ranging from 20,000 to 100,000/l (mean 53,000/l), zidovudine therapy (250 mg q6h) resulted in a mean increase of 53,000/l in all patients during 8 weeks of treatment, while no patients receiving placebo showed improvement. [477] Relapses occurred in three of five patients on discontinuation of drug. Another prospective trial showed that the response to zidovudine was dose-dependent and durable. [482] In spite of concern that the well-documented myelosuppressive effects of zidovudine could pose risks for thrombocytopenic patients, thrombocytopenia, in contrast to neutropenia and anemia, is a rare complication of zidovudine. [135] [160] The mechanism for the beneficial effects of zidovudine on HIV-related thrombocytopenia is unclear, but in view of the evidence for HIV infection of megakaryocytes, as noted previously, it is likely that the antiviral activity of this agent acts to promote more effective thrombopoiesis. One kinetic analysis of platelet production demonstrated a significant improvement following zidovudine treatment. [256] Successful therapy of HIV-related thrombocytopenia has also been described for another antiretroviral drug, DDI, in both children [483] and adults. [484] [485] One large series of patients receiving long-term DDI therapy showed a general improvement in hemoglobin, granulocyte, and platelet counts. [422] Interestingly, in one report a beneficial effect on HIV-related thrombocytopenia was seen for zidovudine but not DDI. [486] Alpha-interferon has been reported to produce an increase in the platelet count in thrombocytopenic patients with HIV infection, [487] [488] [489] [490] [491] although it is unclear if this benefit is mediated by its antiviral, cytotoxic, or immunosuppressive effects. [237] Future studies using thrombopoietin to treat HIV-associated thrombocytopenia will be of interest, given the evidence for impaired platelet production. In view of the progress that has been made in reducing HIV replication with combinations of antiretroviral drugs, it is likely that there will be a decline in the incidence of HIV-related thrombocytopenia in the coming years.

Figure 154-8 Response to recombinant GM-CSF in an AIDS patient with neutropenia. Total leukocyte counts and differentials are shown for an AIDS patient treated with intravenous recombi-nant GM-CSF (1.0×10^4 U/kg/d) from days 117. *(Reprinted from Groopman et al., [235] with permission.)*

therapy to alternate-day treatments with a goal of maintaining the granulocyte count between 5001,000/l.

FUTURE DIRECTIONS

The pandemic of AIDS and HIV infection will continue well into the next decade and will continue to pose major health care problems throughout the world. Many of the advances in therapy described in this review are unavailable or too expensive to be used in the populations of the world most affected. Although studies with a simian immunodeficiency virus model have shown that protective immunity can be generated by infection with an attenuated virus, [492] [493] the prospect for an effective vaccine for HIV in the near future is remote. [494] [495] [496] The treatment of HIV-infected patients with combinations of antiretroviral drugs has shown a dramatic reduction in the level of replicating virus, a result that is likely to have substantial clinical benefit. [497] [498] However, given that HIV remains detectable in long-lived populations of CD4 cells, [52] [53] the likelihood that HIV infection can be cured is small. Nonetheless, the prospects for controlling HIV infection are very encouraging. Newer drugs with fewer side effects and improved pharmacokinetic properties are clearly needed to simplify therapeutic regimens that are often too difficult or toxic for patients to tolerate. Research areas in the years ahead will also be focusing on new approaches, such as chemokine receptor antagonists to prevent viral entry as well as inhibitors of other viral proteins, such as the viral integrase. In addition, several studies have shown that hematopoietic cells can be engineered to become resistant to HIV infection and/or replication. [499] [500] [501] [502] [503] [504] These approaches may hold some promise as ways to reconstitute the immune system in patients once HIV replication has been suppressed. [504]

As has been the case with pharmacologic approaches to antimicrobial and antineoplastic therapy, improvements in controlling HIV infection have resulted from synergistic effects of effective agents that have different mechanisms of action. With a better understanding of HIV pathogenesis and the effects of this virus on the hematopoietic system, the use of antiretroviral agents and supportive modalities such as hematopoietic growth factors may be able to control or even reverse many of the problems discussed in this review. Clearly, hematologic complications of HIV infection will remain an active area for basic research and a challenge to clinicians in the years ahead.

Chapter 155 - Bone Marrow Aspiration and Morphology

Daniel H. Ryan
Harvey J. Cohen

BACKGROUND

History and Ontogeny of the Bone Marrow

After the blood itself, the bone marrow is the largest and most widely distributed organ in the body. Our bone marrow contains about 1 trillion cells and releases approximately 200 billion red blood cells, 100 billion white blood cells, and 400 billion platelets each day. [1]

For centuries, the marrow was considered a source of warmth and energy. Before its discovery as a blood-forming organ, it was believed to be the source of bone nutrition. It was not until the work of Neumann and Bizzozero that a relationship between the blood and bone marrow was established. In 1868, Neumann noted that bone marrow was an important organ for blood formation and was involved in de novo formation of red blood cells. [2] Bizzozero independently concluded that non-nucleated cells form from bone marrow nucleated cells and that white blood cells are also made in the bone marrow. [3] [4] Neumann continued to investigate bone marrow and was the first to identify leukemia as a disease of the marrow. [5] He also coined the term myelogenous leukemia. [6] Neumann was also the first individual to recognize that at birth, all bones that contain marrow contain red marrow. As the individual ages, the peripheral marrow becomes more fatty and develops into yellow marrow. [7]

Bone marrow is the last site of hematopoiesis during the prenatal period. In humans, bone marrow hematopoiesis becomes apparent at approximately 20 weeks of gestation. [8] However, some observers have found evidence for bone marrow activity as early as 1215 weeks of gestation. [9] At the time of birth, almost all hematopoiesis, under normal conditions, occurs in the bone marrow. Extramedullary hematopoiesis is sometimes observed in stressed situations, such as severe hemolytic anemia.

Anatomy of the Bone Marrow

The marrow is a richly cellular and highly vascular tissue. It consists of two components: the hematopoietic cell compartment and a highly organized stromal component that supports the proliferation of these hematopoietic cells. Whereas the hematopoietic cells are transient in the marrow, the stroma remains and serves as a backbone upon which the hematopoietic cells grow and differentiate. Within the hematopoietic areas of the bone marrow, hematopoiesis appears to be highly compartmentalized. Erythropoiesis takes place in distinct anatomic units surrounding a central macrophage, known as erythroid islands. [10] Granulopoiesis also appears to take place in somewhat less appreciable morphologic foci and is often associated with a stromal cell. [11] [12] Megakaryopoiesis occurs adjacent to the sinus endothelium with cytoplasmic processes of the megakaryocytes appearing to penetrate the endothelial wall. [13] [14] Both the hematopoietic cells and the stromal cells of the bone marrow are separated from the blood by a vascular wall that is of a large caliber and is relatively thin-walled. It is through these vessel walls that the mature cells of bone marrow migrate. This appears to occur as a transendothelial process, with the exiting cells appearing to make pores within the endothelial cells. [15]

At birth, all bone cavities are completely filled with hematopoietic cells and hence appear red, but with advancing age the hematopoietic elements are gradually replaced by adipose tissue. By adolescence, hematopoietic marrow is found only in the cavities of the centrally located bones, such as the sternum, ribs, vertebrae, clavicles, scapulae, skull, pelvis, and proximal ends of the femurs and humeri. A slow reduction in the red marrow mass then continues throughout life. This phenomenon has implications for using age to determine where bone marrow aspirations and biopsies might be performed. Thus, for the tibia and femur, approximately half of the hematopoietic cells are replaced by fatty material after the first decade of life, whereas for the vertebral column and iliac crest, half of the bone marrow remains hematopoietic for up to 60 or more years of life.

Historical Perspective of Bone Marrow Examinations

The first bone marrow biopsy was reported in 1905 by Pianese. [16] [17] It was performed in an infant with leishmaniasis. In 1909, Pianese trephined the tibia and femur, aspirating the marrow with a needle attached to a syringe. [18] In 1923, Seyfarth used a surgical trephine to obtain marrow from the ribs and the sternum. [19] Because trephination resulted in excessive bleeding and infection, it was not a generally well-accepted procedure. Airinkin, in 1927, eliminated the trephine complications by using a short lumbar needle to puncture the manubrium and sternum. [20] He obtained a marrow aspiration by placing a syringe on the needle hub. In 1945, Vandenberghe and Blitstein were the first to use the iliac crest to obtain bone marrow, [21] and Heidenreich obtained marrow from the spinous processes. [22] In 1952, Bierman used the posterior iliac crest as the site for bone marrow aspiration, claiming it to be a safe site. [23]

PERFORMANCE OF THE BONE MARROW ASPIRATION AND BIOPSY

Criteria for Aspiration and Biopsy

The bone marrow aspiration and biopsy are now well-accepted procedures for evaluating both the cellularity of the marrow and the nature of the cells present. Before deciding whether, or what kind of, bone marrow examination is necessary, it is important to obtain a clinical history and to clarify what information is needed. Although in most instances, both aspiration and biopsy are necessary to evaluate the clinical situation fully, there are instances in which an aspiration, by itself, will give the information required. In the evaluation of a patient who is felt to have immune thrombocytopenia, a bone marrow aspiration, appropriately handled as discussed later in this chapter, allows the hematologist to determine whether the thrombocytopenia is associated with increased numbers of megakaryocytes. In pediatric practice, the hematologist is sometimes consulted to perform a bone marrow biopsy to determine whether the individual has a constitutional chromosomal abnormality. This

not infrequently occurs in the neonatal intensive care unit. For such an analysis, a bone marrow aspiration is adequate and often gives results regarding potential chromosomal abnormalities within 12 days. The only other instance in which an aspiration alone is indicated is in the follow-up of individuals with leukemia, when the only question being asked is, Are these patients still in remission? Otherwise, it is the norm to have a bone marrow biopsy accompany a bone marrow aspiration. This is especially true in assessing the cellularity of the bone marrow (for example, in patients with cytopenias) and in looking for evidence of infiltration associated with either malignancies or storage diseases.

Bone marrow cytologic examination may also be obtained by an incisional biopsy. This is usually performed by the surgeon at the time of a staging laparotomy for Hodgkin disease. Occasionally the site at which the bone marrow aspiration and biopsy are performed is determined by prior examination of the patient. For example, when looking for metastatic cancer or multiple myeloma, it is of value, if possible, to aspirate an area where there is tenderness or where there is radiologic evidence of potential infiltration.

The only contraindication to performing a bone marrow biopsy is the presence of hemophilia or other related disorders. Thrombocytopenia, no matter how severe, is not a contraindication. There are, however, complications of a bone marrow aspiration or biopsy. Fatalities, although rare, have been reported, especially with sternal aspirations and biopsies.

Rarely, a bone marrow needle may break. If this occurs, an attempt to extract the distal segment with a hemostat should be made. If it is unsuccessful, a surgeon should be consulted. Hemorrhage from bone marrow aspiration can occur at any site, especially in the thrombocytopenic individual. This can usually be prevented by applying a pressure bandage at the site. Other rare complications include pulmonary emboli following sternal aspiration and infected bone marrow aspiration sites, especially in immunocompromised patients.

Although it has been traditional to utilize the sternum for bone marrow aspiration but not for biopsy, our preferred site for both aspiration and biopsy in the adult as well as the child and infant is the posterior iliac crest and spine. In many premature infants and some full-term infants, the iliac bone has not completely ossified, and therefore an alternative bone, such as the anterior tibia, should be utilized. It is still worthwhile, because of both ease and safety, to attempt to use the iliac bone initially, even in neonates.

Aspiration of the posterior iliac bone marrow is usually quite cellular, even in the elderly. However, if an individual has had total nodal radiation therapy for Hodgkin disease, this bone may be permanently altered. In obese patients, it is necessary to use a long needle if the posterior iliac crest is aspirated.

Bone Marrow Aspiration and Biopsy

Before performing the examination, the patient should be reassured that the study is safe and that although some pain will occur, analgesic agents will be used, and pain will terminate at the end of the procedure. For the overly anxious patient, the use of a tranquilizer can be helpful. In children, especially those with procedure phobias, the use of lorazepam under carefully controlled conditions has been very beneficial. This drug produces both relaxation and an antegrade amnesia that many children prefer. A safe, conscious sedation policy should be in place prior to using drugs such as lorazepam in children.

Adults and some older or heavier children are asked to lie on one side after removing their clothing. In young or thin patients, it may be easier to perform the aspiration with the patient lying prone or with a pillow under the abdomen and pelvis. Since this procedure is performed without the patients seeing it, it is important to tell the patient what will be and is being done. The iliac crest and spine are felt with the fingers and a small mark is made in the appropriate area with the fingernail. After double gloving, the area is swabbed with an antiseptic solution. After cleansing the area, the outer pair of gloves is removed. Lidocaine or some other anesthetic agent is then injected where the mark was made. We utilize an air gun to give the initial anesthetic agent and follow it with a needle long enough to anesthetize the periosteum directly. It is worthwhile then to allow 12 minutes for the anesthetic to produce a maximum effect.

The kinds of needles used for aspiration are quite numerous. We prefer using a needle with a stylet fixed by a Luer-Lok or some other locking device. It is important to use a sharp needle, one long enough to penetrate the bone easily. In order to be sure that the needle is entering correctly, the second and third fingers on the hand not being used to insert the needle should be placed on the iliac crest or spine and the needle inserted between them. The needle and stylet are pushed into the bone with a slight rotary motion. When it is felt that the needle is firmly in place, the stylet is removed and a 10- or 20-ml plastic syringe is attached. The patient is then told that he/she may feel an unpleasant sensation, and the plunger of the syringe is pulled back vigorously with no more than 0.5 ml of bone marrow and blood aspirated. The smaller the volume, the less the contamination with peripheral blood. The sample is then given to an assistant, who prepares it as described later in this chapter. If additional samples are needed, another syringe may then be placed on the needle. When the procedure is completed, the stylet is reinserted, the needle removed, and pressure applied to the area.

If a biopsy is performed, a small incision with a #11 scalpel blade is made before insertion of the biopsy needle and stylet. A different site should be chosen for the biopsy, if it is performed after the aspiration. After insertion of the biopsy needle into the bone, the stylet is removed. The needle is then advanced between 1 and 2 cm, depending on the size of the patient. This is performed with very little rotation of the needle. After advancing the needle, the hub is rotated a few times in one direction, followed by a few times in the other direction. The needle is inserted a small additional amount to break the attachment, and the rotations are repeated. The thumb is then placed on the hub of the needle, and the needle is extracted with slight lateral movements accompanying the removal. The bone marrow biopsy is then placed on a slide, where imprints are made before processing for cytologic investigations.

Morphologic Preparation of Bone Marrow

A complete diagnostic evaluation of a bone marrow sample may involve any or all of the following techniques: morphologic examination of stained smears, cytochemistry, culture for microorganisms, histologic examination of stained sections, immunocytochemistry, cell marker analysis by flow cytometery, cell culture assays, cytogenetics, and molecular biologic studies of gene rearrangements or translocations. It is important that the sample is prepared in a fashion that allows the maximal use of as many of these techniques as is necessary to answer the clinical question.

Several morphologic preparations can be made from the bone marrow sample obtained by aspiration or biopsy. [24] Each has its advantages and limitations, as listed in Table 155-1 . The sample considered to have the best morphology and most representative distribution of cell types is the direct smear, since its preparation involves the least manipulation of the sample and no anticoagulant is present. This is the preparation that should preferably be used for a bone marrow differential count. In some cases, the marrow is too hypocellular to allow

TABLE 155-1 -- Morphologic Preparations Made from the Bone Marrow Sample

Preparation	Major Purpose	Limitations
Direct smear	Relative percentage of marrow elements; best morphology	Too few cells to evaluate in some hypocellular marrows
Particle	Marrow cellularity	Parts of smear (near particles) may be too thick for best morphology
Concentrate	Concentrates nucleated cells, especially megakaryocytes and tumor clumps	Relative proportions of cells may be distorted; morphologic changes due to EDTA
Mixed layer	Enriched for macrophages; evaluation of iron stores	Similar to particle
Biopsy imprint	Tumor cells; useful in case of a dry tap	Similar to particle

an adequate number of cells to be examined on the direct smear. Here, the bone marrow concentrate (essentially a buffy coat preparation) is useful since the leukocytes are enriched relative to red blood cells. Megakaryocytes and tumor cell clumps are also enriched, particularly at the feathered and side edges of the smear. However, because the buffy coat layer is not sharply demarcated and merges imperceptably with the red cell layer, there is some variability in the degree of enrichment of nucleated cell types of differing densities. Often, erythroid precursors are significantly enriched relative to granulocyte precursors. Furthermore, the exposure to an anticoagulant such as ethylene-diamenetetracetic acid (EDTA) required during the preparation of the buffy coat may result in artifactual nuclear clefting and cytoplasmic vacuolation, particularly of abnormal cells. [25] The bone marrow particle preparation is useful for estimation of overall cellularity, since large spicules are concentrated in this specimen. However, the morphology is often not as good as in the direct smear, since portions of the smear near the particles may be relatively thick. Macrophages are frequently enriched in the particles found in the mixed layer and are useful in evaluating iron stores. The bone marrow biopsy imprint is important to detect metastatic tumor in cases in which the aspirate is uninformative and to allow immediate morphologic examination of the marrow in case of a dry tap, which occurs in about 4% of marrow aspirations. [26] This is useful in view of the high incidence of pathologic changes (93%) in these cases. [26] There is considerable evidence also that metastatic malignancy, lymphoma, or multiple myeloma is missed more frequently on the aspirate than the biopsy. [27] [28] [29] However, the sensitivity of bone marrow aspirate for detection of metastatic tumor is dependent on the thoroughness of examination of all smear preparations. A recent study, in which the presence of tumor cells on each aspirate smear was examined separately, showed that tumor cell clumps are found in only one of eight smears in 5% of cases with positive aspirates. [30]

Technical Considerations in Smear Preparation

Preparation of good quality peripheral blood and bone marrow smears on a consistent basis is more difficult than it would appear. There is no substitute for practice in blood smear preparation under the guidance of an experienced technologist. The pusher slide used to make the smear should be narrower than the glass slide on which the drop of blood/marrow is placed, to ensure that the side edge of the smear can be examined. Important variables affecting smear quality are the size of the blood/marrow drop, angle at which the spreader slide is held, speed at which the smear is made, and hematocrit of the sample. High pusher slide angle, rapid movement of the pusher slide, and high hematocrit all tend to produce thicker smears. The ideal smear should be about two-thirds the length of the glass slide, with an even transition from thick to thin areas, terminating in a feathered edge.

Preparation of Bone Marrow Smears at the Bedside

In addition to the syringes and needles required for the actual aspiration, it is important to have the following materials ready for the preparation of the sample:

Glass slides, coverslips

Gauze

Forceps

Sample collection tube with EDTA (liquid EDTA for best morphology)

Heparinized tubes with culture medium for special studies

Pusher device (forceps with hemacytometer cover glass)

The glass slides should be placed in a convenient location before the procedure so that no time is lost in the preparation of the direct smears. About 0.5 ml of marrow is placed on a glass slide and the remainder immediately added to the EDTA anticoagulated sample collection tube and mixed well. The marrow placed on the glass slide is examined to determine whether bone marrow has been obtained, as indicated by the presence of spicules, which appear as fatty droplets, granules, or small chunks of bone. These concentrate at the feathered edge when a smear of the bone marrow is made.

Nine bone marrow direct smears are made from the pool of marrow by placing a tiny drop on a clean glass slide and making a smear in the same fashion as a blood smear. Alternatively, the pusher may be dipped directly into the pool of marrow and then the smear quickly pushed out on a fresh glass slide. This step should be done quickly, as the marrow pool is not anticoagulated. Four bone marrow direct particle coverslips are made by placing a small drop of the spicule-containing marrow pool on a coverslip or the end of a glass slide, placing another coverslip/slide on top, allowing the marrow to spread, and quickly pulling apart. It is very important to get spicules on this preparation so that the cellularity of the particles can be assessed. In addition, two direct squash particle slides are made by draining the marrow pool on a gauze (leaving behind the particles), placing a slide on top, and slowly pulling apart.

When a biopsy is performed, the bone is pushed out onto the slide. Several touch preparations (usually five) are made without damaging the bone (by lightly touching the bone on different sites on the slide). The bone is placed into 10% formalin for fixation and histologic sectioning. Several blood smears should also be prepared.

Preparation of Bone Marrow Concentrate

The EDTA tube containing marrow is mixed and pipetted into Wintrobe tubes as would be done for a buffy coat. The Wintrobe tube is spun at 1,500 g for 10 minutes. The layers of the Wintrobe tube are shown in Figure 155-1 , with approximate normal ranges for the nucleated cell containing layers (the plasma and red cell layers are variable and reflect the amount of blood aspirated with the marrow).

The fat layer is discarded. The mixed layer is placed on a slide to make a squash particle slide as described previously. A drop of plasma is placed on a parafilm watchglass. The myeloid-erythroid (M-E) layer is removed (if there is not much of an M-E layer, the top of the RBC layer is taken also) and mixed with an equal amount of plasma. Several (1015) push

Figure 155-1 Layers of the Wintrobe tube: the fatty layer is on top and is yellow or milky in color (12%); the mixed layer is second, and is not always present. It contains particles with a high content of fat cells (<1%). The plasma layer is next, followed by the myeloid-erythroid layer. This layer appears as a buffy coat and contains nucleated cells not associated with fat cells (38%). At the bottom of the tube are the red blood cells (i.e., the hematocrit of the marrow sample).

smears of this concentrated bone marrow sample are made in the usual fashion. Smears containing any particles that are seen in the concentrated sample can also be made.

It is important to retain several unstained smears from each preparation for special stains. Unstained slides are labeled before storage at room temperature on the side opposite the smear with an identifying number using a marker. When special stains are performed, the slides should be marked on the edge with a diamond point pencil to prevent sample mixup. The finished bone marrow slide folder should contain Wright-Giemsa stained smears of blood, direct marrow smear, marrow particle, marrow concentrate, and marrow biopsy imprint, as well as unstained smears of the mixed layer. Marked iron accumulation in macrophages can be seen on the unstained mixed layer smear as a golden-brown pigment.

Preparation of Bone Marrow Sample for Special Studies

At the time of bone marrow aspiration, it is important to consider whether cell marker studies, cell culture assays, cytogenetic analysis, or molecular biologic assays are likely to be required for clinical diagnosis. Fortunately, the initial sample preparation at the bedside is similar for most special studies, so that an extra sample may be obtained to be used if preliminary morphologic examination suggests the need for additional testing of the bone marrow aspirate.

The general rule is to obtain a viable, sterile, anticoagulated marrow specimen sufficient for the required assays. It is essential to determine the sample preparation and storage requirements of the individual laboratory performing each test, since assay procedures may vary. The most commonly used procedures are outlined in the following sections.

Preparation of Bone Marrow Sample for Cell Marker Studies

Bone marrow may be collected in EDTA or heparinized for cell marker studies. Bone marrow samples are stable at room temperature for 24 hours prior to staining, allowing shipment to a reference laboratory for analysis if necessary. Either EDTA or heparin is suitable for cell marker analysis, but EDTA may be preferable because of the possible interference of heparin with some molecular studies, as discussed later. EDTA has also become the standard anticoagulant for T-cell phenotyping in peripheral blood. In cases of inadequate aspirate in which phenotypic data is critical, mechanical or collagenase disaggregation of the biopsy preparation may permit cell marker analysis. [31] [32]

Long-term storage of interesting or complex samples is often desired, in order to allow later testing with additional antibodies or molecular biology techniques. The best way to accomplish this is to freeze aliquots of the marrow sample for storage in liquid nitrogen. The standard technique of freezing cells in DMSO using a controlled rate (1°C/minute) liquid nitrogen freezer, followed by rapid rewarming from liquid nitrogen storage, has been shown to preserve lymphocyte markers. [33] If a controlled-rate freezer is not available, a modification of the two-step method published by McGann and Farrant [34] [35] can be used. Ficoll/Hypaque separated cells (10^7 /ml in RPMI 1640, 10% fetal calf serum, and 5% DMSO) are held in 1-ml vials at 30°C for 5 minutes (in methanol cooled with dry ice), then quickly plunged into liquid nitrogen. Cells are thawed by rapid rewarming at 40°C and gradual addition, over 5 minutes, of five volumes of tissue culture medium with 10% fetal calf serum before centrifugation to remove the DMSO. Cell viability should be determined after thawing, as this may be variable, especially if the sample contains many myeloid cells.

Preparation of Bone Marrow Sample for Cytogenetic and Cell Culture Studies

In order to maintain cells in an optimal condition for assays requiring cell proliferation, it is advisable to collect marrow at room temperature in a sterile tube containing tissue culture medium (RPMI 1640 with 10% fetal calf serum) with anticoagulant as described previously. The shorter the storage period the better, although overnight storage in general does not significantly affect the validity of cytogenetic results. However, it is necessary to test proposed storage conditions to be sure that they will yield valid results with the specific assay being performed.

Preparation of Bone Marrow Sample for Molecular Analysis

Preparation and storage of marrow cells for molecular diagnostic tests is similar to cell marker studies, although sample requirements should be checked with the specific laboratory before obtaining the marrow sample. Heparin may contaminate DNA preparations and interfere with endonuclease digestion or PCR reactions. DNA is relatively stable, so any sample suitable for cell marker or cytogenetic analysis should yield DNA suitable for Southern blot or PCR, if enough cells are present. Even paraffin-embedded tissue can be used for PCR of genomic DNA sequences. In contrast, mRNA is very liable to digestion by ubiquitous nucleases, once cell membranes are disrupted. If RT-PCR assays are required or samples are to be stored for future RT-PCR analysis (e.g., bcr/abl, RAR/PML translocations), RNA preparations should be made from buffy coat or Ficoll/Hypaque density gradient separated mononuclear cells as soon as possible after preparation. Alternatively, RNA can be isolated from aliquots of cells frozen and stored under viable conditions (e.g., in liquid nitrogen).

INTERPRETATION OF THE BONE MARROW ASPIRATION AND BIOPSY

Overview

Careful formulation of the clinical question being asked is the starting point for evaluation of the bone marrow aspiration and biopsy. Clarifying what information is needed ensures that appropriate samples for special studies to address all relevant diagnostic possibilities are obtained. Morphologic evaluation of the bone marrow as well as interpretation of special procedures, such as cell marker studies, is dependent on an assessment of the patients history, physical exam, and results of laboratory studies already performed.

The evaluation of bone marrow aspiration and biopsy involves at least two phases. The first is immediate examination of a Wright-Giemsa stained bone marrow aspirate preparation, typically the direct smear, to arrive at a preliminary diagnosis. This allows the physician to take appropriate clinical action or order additional special studies based on unexpected findings.

The final diagnosis should be based on the complete picture provided by clinical history, peripheral blood smear examination, laboratory tests, bone marrow biopsy and aspiration, and all special studies (cytochemical stains, cell marker studies, cytogenetics, molecular diagnostic assays, etc.) performed on the bone marrow sample. Given the complexity and variety of these diagnostic assays, the challenge for the clinical laboratory, pathologist, and hematologist is to organize these activities so that the diagnostic picture is clearly evaluated and reported with a minimum of redundant effort and inconsistent interpretations. This necessitates a close working relationship between the involved laboratories, or establishment of a hematopathology laboratory which has as its mission the coordination of all these activities to provide a complete diagnostic evaluation.

Morphologic Examination of Blood and Bone Marrow Smears

Accurate evaluation of blood or bone marrow smears is dependent on adequate smear preparation and staining. Short smears, overly thick or thin smears, or those without feathered or side edges, are inadequate and repeat smears should be made.

At medium power (20× objective), the smear should be examined for distribution of leukocytes (excess leukocytes at the feathered or side edges may bias the leukocyte differential). Platelet clumps at the feathered edge or platelet satellitism (Plate 155-1 are suggestive of EDTA-induced platelet aggregation, which may affect the platelet count. The smear should also

SOME CONSIDERATIONS IN BONE MARROW INTERPRETATION

1. Formulate clinical question prompting the bone marrow examination on the basis of clinical history, blood counts, and peripheral smear.
2. Determine need for aspirate only or aspirate plus biopsy.
3. Immediately review direct marrow aspirate smear for provisional diagnosis and to make sure appropriate special studies are ordered while sample is fresh.
4. Interpret bone marrow in light of clinical information, laboratory studies, peripheral smear examination, review of all bone marrow preparations including marrow biopsy, and evaluation of all special studies.
5. Examine bone marrow for nonhematopoietic or tumor cell infiltration (biopsy is most sensitive, but marrow concentrate may reveal tumor clumps in the side or feathered edges).
6. Examine marrow aspirate smears for intracellular organisms or abnormal storage products.
7. Estimate overall bone marrow cellularity and adequacy of each hematopoietic lineage from the biopsy and particle preparation, and confirm by examination of direct aspirate smear. Bone marrow concentrate is useful in evaluating megakaryocyte adequacy.
8. Assess adequacy of differentiation in each hematopoietic lineage.

be scanned for abnormal cells, smudge cells, nucleated red cells, red cell agglutination (Plate 155-2) or rouleaux (Plate 155-3), fibrin strands (Plate 155-4 ; these may indicate partial clotting of the sample and falsely low platelet count), parasites (plasmodia, Plate 155-5), and background staining suggestive of paraproteinemia.

Blood cell morphology is examined under oil immersion at 50× or 100×. The higher magnification is required for accurate evaluation of cytologic detail, while examination at 50× is most useful for the leukocyte differential. The most important variable affecting interpretation of blood cell morphology is selection of the appropriate part of the smear to examine. As shown in Figure 155-2 , the optimal area to examine is the transitional area between the thick part of the smear and the feathered edge, where there are only a few overlapping red cells and central pallor of normal red cells is evident. Skilled technique in preparing

Figure 155-2 Optimal area for examination of the blood smear is indicated by the box. Red cells are separate, with only a few overlapping cells per oil immersion field. Leukocytes are sufficiently spread to view their cytoplasmic contents. In the thin part of the smear, near the feathered edge, red cells are flattened and appear as large spherocytes (right), whereas in the thick part of the smear (left), red cells are rounded up and overlapping. Leukocytes also round up in this area of the smear, hindering proper identification of abnormal cells.

the smear is necessary to ensure that this transitional area is in fact represented on the smear. The most common error in blood smear interpretation results from drawing inappropriate diagnostic conclusions based on morphology of cells examined in nonoptimal portions of the blood smear. In the thin portion of the smear, red

cells are large and flattened, losing their central pallor and appearing as unusually large spherocytes. Leukocytes are flattened and often show nuclear degeneration or cellular disruption due to excessive shear forces during smear preparation. In thick areas, red cells are overlapping and stacks of erythrocytes (rouleaux) are normally present, obscuring erythroid morphology. Leukocytes are rounded and appear to have a high N/C ratio, potentially causing serious diagnostic confusion. The thick portion of the blood smear, however, may be useful for identifying microfilariae and malaria parasites. The side edges of the smear should be examined, since large cells, such as malignant cells and immature precursors, tend to accumulate in this area. These large cells are also disproportionately found in the feathered edge, but here their morphology is often distorted.

At high power, leukocyte subpopulations can be assesed either qualitatively or quantitatively by performing a 100 cell leukocyte differential (Plates 155-6 , 155-7 , 155-8 , and 155-9). Leukocytes are examined for degree and type of granulation (Plates 155-10 and 155-11) as well as abnormal nuclear structure (Plates 155-12). Red cells are systematically examined for average size, presence of polychromatophilia, inclusions and hemoglobin crystals (Plates 155-13). Some common red cell morphologic variants are shown in Plates 155-14 , 155-15 , 155-16 , 155-17 , 155-18 , 155-19 , 155-20 , 155-21 , 155-22 , 155-23 , 155-24 , 155-25 , 155-26 . Platelet number is estimated and abnormalities in platelet size (Plate 155-27) noted. A rough estimate of platelet number can be obtained by multiplying the average number of platelets per 100× oil immersion field (based on 10 fields) by 20,000 (this varies somewhat depending on the optics of the microscope).

The observer should be aware of some common artifacts that complicate interpretation of blood and bone marrow smears. These include artifactual loss of central pallor in red cells at the thin edge of the smear, rouleaux (occuring normally in the thick portion of the smear), crenated red cells (a uniform spiny shape that can occur upon prolonged storage), and a sharply demarcated hypochromic central pallor with refractile borders (Plate 155-28 , resulting from excessive ambient humidity at the time of smear preparation, or from low hematocrit). Cryoglobulin aggregates may resemble platelets (Plate 155-29). Granulocytes undergo apoptosis in samples stored for long periods prior to smear preparationthe pyknotic nucleus often resembles that of a nucleated red cell. Lymphoid cells, particularly abnormal ones, are subject to nuclear lobulation upon storage. This phenomenon is also observed in cytocentrifuged cells (for instance, in a body fluid preparation).

Adequacy of Bone Marrow Specimens

Before any specimen can be interpreted, a judgment must be made as to its adequacy for the diagnostic purpose. Biopsies that consist mostly of cortical bone, cartilage, or muscle and little or no medullary cavity are clearly inadequate for evaluation of hematopoiesis. Typically, at least a 0.5 cm core of marrow should be present, especially when looking for nonuniform abnormalities such as metastatic tumors. A recent survey found the incidence of inadequate pediatric biopsies submitted as part of a multicenter clinical trial to be about 17%. [36] Extensive crush artifact or hemorrhage may also obscure diagnostic findings in biopsy specimens that do include hematopoietic marrow. Morphologic interpretation may be adversely affected by excessively thick (>5 m) sections. It should also be recognized that even an adequate biopsy is only a sampling of the bone marrow, and interpretation could be affected by local factors, such as radiation-induced fibrosis and the nonuniform pattern of tumor metastasis.[37]

Adequacy of the bone marrow aspirate is sometimes difficult to assess, since the characteristic tissue architecture is not as readily evaluated as on the biopsy. Here the best indicator is the appearance of particles, or fragments of intact marrow, which are observed on the particle preparation. These are recognized by their characteristic mixture of fat and cellular elements, the proportion of which varies depending on marrow cellularity. Presence of marrow particles reassures the observer that the marrow space was entered and marrow was successfully aspirated. It does not assure, however, that all types of cells in the marrow space were aspirated effectively as single cells. If no particles are found, and no hematopoietic progenitors characteristic of the bone marrow (i.e., megakaryocytes, myeloid, or erythroid progenitors) are present, the possibility exists that the marrow cavity was not entered, or the marrow elements were not effectively aspirated (dry tap). The cells that do appear in the aspirate specimen in such cases likely originate from the peripheral blood. Adult aspirates containing >30% small lymphocytes and monocytes (in the absence of lymphoproliferative disease) are likely to be significantly contaminated with peripheral blood, as suggested by studies comparing proliferative activity of cells in simultaneously obtained aspirate and biopsy specimens. [38]

Assessment of Bone Marrow Cellularity

A major purpose of the bone marrow examination is to evaluate the adequacy of bone marrow development in each hematopoietic lineage. The most reliable assessment of overall hematopoietic cellularity is based on the biopsy specimen. [39] [40] A visual estimation of the percentage of marrow space occupied by hematopoietic elements plus stroma is the typical parameter used to assess cellularity (Plates 155-30 and 155-31). The reference range for marrow cellularity decreases with age (from 90% in infants to 50% in the elderly for the iliac crest), and so this value must be interpreted in light of the patients age. Erythroid cellularity can be estimated visually by looking for erythroid aggregates, which are clusters of darkly staining cells scattered throughout the marrow cavity. Adequacy of megakaryocyte numbers is also fairly readily evident at low power by the frequency of these large multilobulated cells.

Cellularity is less reliably assessed in aspirate preparations, because the tissue architecture has been disrupted and the sample is inevitably mixed to a varying degree with peripheral blood. Furthermore, cells that are abundant in the bone marrow, but tightly adherent to supportive elements in the tissue, may be grossly underrepresented in the aspirate.

In spite of these caveats, the density of cellular elements in particles appearing in the aspirate smear is usually a reasonable indicator of bone marrow cellularity (Plate 155-32). These particles are most easily observed in the particle preparation and direct smear. Somewhat less reliable, but nevertheless useful, is the overall density of hematopoietic precursors in the body of the bone marrow aspirate preparations. The most common interpretive problem is a falsely low estimate of cellularity based on the aspirate [40] resulting from dilution with peripheral blood during aspiration. A cellular aspirate specimen with good marrow particles nearly always indicates good cellularity of the biopsy as well.

The myeloid:erythroid (M/E) ratio can be derived from marrow differential counts or estimated, and is a rough indicator of significant alterations in cellularity of either myeloid or erythroid lineages. This value can be adequately interpreted, however, only in the context of overall cellularity. Otherwise, it is not clear whether a lowered M/E ratio represents erythroid hyperplasia or myeloid hypoplasia. The relative number of myeloid and erythroid cells is best evaluated on the direct smear or particle preparation, because the concentrate is often enriched in erythroid elements. Megakaryocyte number is not as easily estimated as in the biopsy. The best approach is to look

for megakaryoctes in particles (most particles should contain one or more megakaryocytes), in the direct smear (there should be at least 510 megakaryocytes in the readable portion of the slide), and in the feathered edge of the marrow concentrate (in a properly prepared concentrate, this should contain numerous megakaryocytes).

Infiltration of the Bone Marrow

One of the first questions to be addressed in examination of the bone marrow is whether the marrow cavity is infiltrated with cells other than the precursors of the major hematopoietic lineages and other accessory cells that should normally be present. This information is critical because it may provide clues to diagnoses other than those of primary hematologic disorders. If the differential diagnosis includes disorders that result in infiltration of the bone marrow, a bone marrow biopsy should be obtained if possible. The biopsy is clearly superior to the aspirate in sensitivity of detection of most types of infiltrative diseases of the bone marrow, although in many cases, the diagnostic cells will also appear on the aspirate preparation. [41]

Metastatic Tumor

Nonhematopoietic tumors are usually recognizable as such on the biopsy (Plate 155-33), although the tissue of origin may not be obvious if the tumor is anaplastic. The differential diagnosis should be pursued with special studies (e.g., immunocytochemistry) as dictated by the histologic appearance of the tumor and the patients history. Nonhematopoietic tumors are recognizable on aspirate preparations primarily by their tendency to form three-dimensional clumps (Plate 155-34). These are sometimes preferentially found in the feathered or side edges of the smears, and may be so infrequent that they are found only on the concentrate smear. A common interpretive problem is in distinguishing tumor clumps from the frequent clumps of damaged hematopoietic cells typically observed, particularly in the concentrate smear (Plate 155-35). Nucleic acid released from damaged cells (often found in manipulated samples, such as the concentrate) is very sticky, and so entraps hematopoietic cells in sizeable clumps. The best strategy is to examine cells at the periphery of clumps, where their morphology can best be evaluated. Nonhematopoietic tumor cells may also be observed as single cells with typically dense nuclear chromatin, high N/C ratio, abnormal nucleoli, and vacuolated

cytoplasm (Plate 155-36), but such isolated cells are not always present, since nonhematopoietic tumors are typically very adherent to each other and the supportive structures in the bone marrow.

Lymphoma cells infiltrating the marrow space are relatively adherent to underlying marrow structures and therefore better represented in the biopsy than the aspirate preparations. The biopsy is more sensitive in detection of lymphomatous involvement, even in small-cell lymphomas, which would be expected to be most easily aspirated.[42] In the biopsy, differentiation of malignant lymphoma (Plate 155-37) from lymphoid aggregates (Plate 155-38), common in the elderly and in autoimmune disorders,[43] is sometimes difficult. The best diagnostic indicators of malignant lymphoma are atypical cytologic features of the lymphoid cells themselves, a monomorphous appearance of the infiltrate, and location immediately adjacent to bony trabeculae (Plate 155-37). The aspirate preparations are useful in that lymphoid morphology may be more easily seen on the smears than in the biopsy sections. In contrast to solid tumors, lymphoma cells do not appear as adherent clusters in the aspirate. In some cases, special studies (e.g., immunocytochemistry, flow cytometry) may be required to distinguish a malignant lymphoma involving the bone marrow from an atypical lymphoid reactive process. Examples of immunohistochemical markers include cyclin D1 for mantle cell lymphoma and bcl-2 for follicular lymphoma. Of particular interest is the adaptation of in situ hybridization techniques for routine immunohistochemistry laboratories to allow detection of monoclonal kappa or lambda mRNA expression in bone marrow biopsy specimens.[44] This circumvents the limited sensitivity of immunohistochemical detection of surface monoclonal Ig light chain. Hairy cell lymphoma is characterized by a rather distinctive pattern of monomorphous infiltrate of cells with abundant cytoplasm, giving rise to a fried egg appearance to the tissue. The aspirate often fails to yield any of these adherent cells, and when the marrow is replaced by lymphoma, the result is a dry tap.

Multiple myeloma primarily involves the bone marrow, reflecting the normal migratory pattern of plasma cells to the bone marrow. The proportion of myeloma cells as estimated from the biopsy is often higher than it would appear from the aspirate, probably related to the adhesive properties of these malignant cells. In both biopsy and aspirate, atypical cytologic features (high N/C ratio, fine nuclear chromatin, and atypical nucleoli) should be looked for, as these indicate a more aggressive biologic behavior. Binuclearity on its own does not represent an atypical feature.

Fibrosis

Bone marrow fibrosis is a feature of some primary hematologic disorders (e.g., myelofibrosis) and may accompany infiltrative disorders of the bone marrow. A bone marrow biopsy is necessary to assess the presence and degree of fibrosis. To reliably detect early fibrosis, a reticulin stain of the biopsy specimen should be performed (Plate 155-39). The effect of fibrosis on the bone marrow aspirate is typically to reduce the number of cells obtained, resulting in a dry tap if the fibrosis is severe.

Storage Disorders

Accumulation of lipid or other storage products in bone marrow macrophages can be a diagnostic clue to storage disorders, such as Gaucher (Plate 155-40) or Niemann-Pick (Plate 155-41) disease. Macrophages are most readily found in the feathered edge of bone marrow direct smear or concentrate preparations. The detailed morphologic appearance of the cytoplasm can best be identified on the aspirate, although abnormal macrophages can be identified on both biopsy and aspirate preparations.

Infectious Diseases

A frequent indication for bone marrow aspiration is identification of infectious organisms by culture or histologic examination. The biopsy section is better suited for identification of granulomas (Plate 155-42), which can be infrequent, underlining the need for an adequate biopsy size. The presence of granulomas is an indication for staining for mycobacterial or fungal organisms, since granulomas are almost always present when mycobacterial organisms are identified by special stains. [45] [46] However, the differential diagnosis of bone marrow granulomas is extensive. [47] Intracellular organisms, such as leishmania[48] (Plate 155-43), histoplasma (Plate 155-44), and toxoplasma, [49] or viruses (cytomegalovirus) can be identified on bone marrow aspirate smears. Bone marrow examination may be particularly useful in the rapid diagnosis of infectious disorders in high-risk populations, such as AIDS patients. [46] [50] Erythrophagocytosis by bone marrow macrophages is associated with severe viral infections (Plate 155-45).

Assessment of Differentiation in the Hematopoietic Lineages

The cytologic features associated with differentiation in the major hematopoietic lineages are central to the evaluation of the

bone marrow in hematologic disorders. Bone marrow biopsies prepared according to standard procedures are fixed in formalin or mercury based fixatives (B5, Zenker) and decalcified prior to paraffin embedding and sectioning. The preservation of cytologic detail is dependent on fixation, sectioning, and staining techniques, so that consistency in these protocols is essential for reliable interpretation. Plastic embedding of undecalcified biopsies allows thin (2 m) sections to be produced, which can result in superior preservation of cytologic detail. [51] Antigen preservation in these sections for immunohistochemistry may be unreliable, but modified protocols have been described which improve the retention of antigenic epitopes. [52] [53]

Myeloid

Maturation of myeloid precursors can be assessed on both biopsy and aspirate preparations. [41] The biopsy provides a good overall assessment of maturation. Abnormally large clusters of immature myeloid precursors (abnormal localization of immature precursors) observed in biopsies of patients with myelodysplasia have been associated with a poor prognosis. [54] Fine cytologic detail is often more easily identified on the aspirate preparations. The direct smear is the best starting point, since these cells are not exposed to EDTA anticoagulant, which can induce vacuolation and subtle nuclear changes in abnormal cells. Myelocytes and later precursors are normally nearly as abundant as mature neutrophils; promyelocytes are infrequent (<10% of myeloid elements), and blasts should number <5% of nonlymphoid hematopoietic cells in the marrow. Abnormally large precursors, hypogranulation of late neutrophilic precursors, and nuclear hyposegmentation of neutrophils (pseudo-Pelger-Huet anomaly; Plate 155-46) suggest myelodysplasia if observed in a significant proportion of neutrophilic cells. It should be recognized that these features are not specific for primary hematopoietic disorders, and may particularly be seen in AIDS patients. Abnormally large precursors and hypersegmentation of neutrophils suggest folate or vitamin B_{12} deficiency.

Erythroid

Like myeloid maturation, erythroid maturation can be assessed in both aspirate and biopsy preparations, although cytologic detail is usually more easily seen on the aspirate and adequacy of numbers is more reliably assessed on the biopsy. Delay in nuclear maturation relative to cytoplasmic hemoglobinization, abnormal nuclear shape, or binuclearity are observed in myelodysplasia (Plate 155-47). These features are also associated with megaloblastic anemia, but the nuclear maturation delay is much more severe and is accompanied by a more significant increase in cell size. The marked hypercellularity and nuclear immaturity of erythroid precursors in megaloblastic anemia can suggest acute leukemia on initial evaluation of the bone marrow biopsy. Erythroid precursors containing abnormal iron deposits are observed in certain types of myelodysplastic syndromes (RARS), with the iron-laden mitochondria frequently forming a ring around the nucleus (Plate 155-48).

Megakaryocytic

The most common question involving the megakaryocytic lineage is a numeric one: is there sufficient megakaryopoiesis to support the diagnosis of peripheral platelet destruction in a case of thrombocytopenia? This is addressed by examination of either biopsy or aspirate specimen. Normal megakaryocytes must be distinguished from osteoclasts, which are large, multinucleated, and have similar-appearing cytoplasmic granulation, but whose nuclei are separate. Lymphocytes and other hematopoietic cells may sometimes be normally observed within the cytoplasm of megakaryocytes, a phenomenon known as emperipolesis. Mature megakaryocytes in conditions accompanied by increased peripheral platelet destruction often have reduced cytoplasm, suggesting exhaustion by premature release of platelets, but this is not a definitive diagnostic finding. An important feature of myelodysplastic syndromes is the appearance of abnormally small but mature megakaryocytes (as identified by cytoplasmic platelet-like purple granulation or histochemical staining for gpIIb/IIIa) [55] with 12 round unlobulated nuclei. These micromegakaryocytes (Plate 155-49), although not specific, are suggestive of myelodysplasia [56] if found frequently in the marrow, typically in the feathered edge of the concentrate

preparation. In myelodysplastic and myeloproliferative syndromes, these cells can be small enough to be confused with lymphocytes in the marrow or peripheral blood.

Lymphoid

The bone marrow is the primary site of the antigen-independent (precursor) phase of B-cell development. Therefore, variable numbers of B-cell precursors are normally found in the marrow. This number is highest in infants, in whom they may be nearly as frequent as the myeloid and erythroid elements, and decreases with age. Normal B-cell precursors (termed hematogones by some observers[57] [58]) show some immature features (moderately fine chromatin, larger cell size, fairly high N/C ratio), and may be confused with recurrent leukemia, especially after cessation of chemotherapy in children with lymphoblastic leukemia, [59] when a rebound of these normal cells is typically seen.

Macrophage

Macrophages are typically indistinct on both biopsy and aspirate preparations, with small nuclei and indistinct cytoplasmic borders. Easily found macrophages suggest an increase in their numbers, which may occur as a consequence of chemotherapy or secondary to infectious, inflammatory, or storage disorders. Phagocytosis of cellular debris by macrophages is a common event secondary to high cellular turnover, but prominent erythrophagocytosis suggests familial or virus-induced hemophagocytic syndromes.

INTERPRETIVE CONSIDERATIONS IN RELATION TO SPECIAL STUDIES

Often the hematologist or pathologist must reconcile seemingly conflicting information from bone marrow aspirate, biopsy, and multiple special studies. In some cases, the apparent conflict is explainable based on the underlying biology and the different information provided by these tests.

In interpreting cell marker studies by flow cytometry, the reported percentage of lymphocytes or abnormal cells is typically based on analysis of a population defined by light scatter that excludes myeloid precursors and most erythroid cells. Because this is a selected population, the proportions of abnormal cells thus obtained may differ from that observed in unmanipulated bone marrow aspirate smears. Certain types of lymphoma may be difficult to aspirate and may therefore be undetected in the cell marker study even though the marrow biopsy is positive. Another limitation of flow cytometry is that the abnormal cells cannot be morphologically identified on the instrument, and so if they do not possess a distinctive marker, a small subset of abnormal cells, although easily identified in the aspirate, may be difficult if not impossible to definitively distinguish from normal precursors on the flow cytometer. Immunohistochemical staining circumvents many of these problems, but not all antibodies are capable of reacting with antigenic determinants in fixed deparaffinized tissue.

Southern blot for clonal gene rearrangements or translocations is sensitive to about a 510% abnormal population. Typically, an abnormal population large enough to be identified at a molecular level by Southern blot is likely to be recognizable on morphologic examination if the cells possess distinctive morphologic features. Polymerase chain-reaction-based assays are much more sensitive than visual observation, and are designed to identify residual abnormal cells in bone marrow samples that appear morphologically to be in remission.

Chapter 156 - Automated Analysis of Blood Cells

Daniel H. Ryan

Automated blood cell analysis and manual morphologic examination of blood cells each offer significant advantages and disadvantages. It is unlikely that either approach will totally supplant the other. Without the speed and walk-away capabilities of modern automated instruments, clinical laboratories would be unable to handle a large volume of samples efficiently. Automated instruments also provide superior accuracy and precision in quantitative blood cell measurements. However, the complexity and remarkable variation of the formed blood elements should be recognized as a formidable challenge for any automated instrument. A large number of samples screened on automated instruments still require manual examination of the blood smear for definitive diagnosis of morphologic abnormalities.

A current trend in instrument design is to incorporate as many analysis parameters as possible into one instrument platform, in order to reduce the need for manual review of problem samples and to minimize the need to run a single sample on multiple instruments. Automated blood cell counts, leukocyte differentials, smear preparation, reticulocyte counts, and even CD4 counts are being performed on an integrated set of automated instruments. [1] Increasingly, laboratories are planning to incorporate such instruments into a highly automated combined chemistry/hematology laboratory setting where samples are automatically sorted, aliquoted, and brought to the appropriate instrument for analysis by a robotic track system. [2] [3] [4] The goal is to provide cost-effective automated analysis and reporting for the majority of samples, selecting those that need manual review, and automatically preparing stained smears from those selected samples.

COMMON TECHNIQUES USED IN BLOOD CELL ANALYSIS

Packed Cell Volume

The oldest method of quantitative measurement of blood cells is the measurement of packed volume of formed elements of the blood after centrifugation. The best example is the spun hematocrit, but instruments have also been devised to estimate leukocyte and platelet count from a blood sample centrifuged in a special device.[5]

Image Analysis

Computerized image analysis for leukocyte differential counts[6] has been largely superseded by blood counters that analyze cells in flow, offering increased throughput and versatility.

Impedance Particle Counting: The Coulter Principle

This is the basis for cell count and volume measurements on most automated clinical hematology instruments. Cells can be counted and their size estimated by measuring change in electrical resistance as cells in solution flow through a narrow aperture across which a DC current is maintained. [7] The magnitude of the voltage change is directly proportional to cell size, but is affected by the shape of the cell as it passes through the aperture, thus necessitating separate calibration for cells with different deformability parameters, such as red cells[8] and leukocytes.[9]

Light Scatter

A focused light beam striking a cell will be scattered in all directions. The amount of light scattered at a relatively low angle from the incident light path is primarily dependent on cell size. The amount of light scattered at a wide angle is primarily affected by structural complexity within the cell (granules, nuclear shape). Although there is some overlap, simultaneous measurement of light scattered at different angles allows certain leukocyte types to be distinguished. Because of overlap, an unanticipated excess of any one cell type (for instance, incompletely lysed red cells in a leukocyte analysis) may invalidate the quantitative results.

Light Absorption

Absorption of incident light by cells as a result of accumulation of a cytochemical dye for detection of peroxidase activity is used by some instruments in conjunction with light scatter measurements to identify the five major leukocyte populations. [10] This method is generally less sensitive than fluorescence labeling, but has been used for immunophenotyping with alkaline-phosphatase conjugated antibodies. [11]

Conductivity

A relatively new technique in clinical instruments is measurement of conductivity of cells to high frequency alternating current to identify granulocytes.

Fluorescence

Measurement of emission of fluorescent light is sensitive and broadly applicable to analysis of multiple cellular characteristics, such as immunophenotype (using labeled antibodies), DNA content, RNA content, and other cellular characteristics.

Blood analyzers increasingly combine analytical principles, such as light scatter and fluorescence (flow cytometers), impedance, conductivity, and light scatter (automated blood cell counters), progressively blurring distinctions between flow cytometers and automated cell counters. These instruments represent significant clinical advances, but require an increasing degree of interpretive sophistication on the part of the laboratory technologist.

INTERPRETATION OF AUTOMATED BLOOD CELL ANALYSIS

In a typical automated blood cell counter, a portion of the aspirated sample is lysed for hemoglobin and leukocyte analysis. A separate aliquot is diluted without lysis for red cell and platelet analysis. Some parameters are calculated from the primary data, including hematocrit (= RBC count × MCV), MCHC (= hemoglobin/hematocrit), MCH (= hemoglobin/

RBC count), and RDW or PDW (= estimate of variance in the red cell or platelet volume distribution).

Hemoglobin and Hematocrit

All hemoglobins in the lysed aliquot, including oxy-, carboxy-, carbonmonoxy-, and methemoglobin are converted by potassium ferricyanide to cyanmethemoglobin, which has a broad and easily measured absorbance peak at 540 nm.[12] The hemoglobin is preferable to the hematocrit (Hct) for clinical use, since it is directly measured, and not subject to some of the infrequent artifacts that affect the Hct measurement. Lipemia may falsely elevate the hemoglobin measurement, but this artifact is usually detectable by examination of the sample and comparison of the hemoglobin and (independently calculated) Hct. Hematocrit measured as packed cell volume (spun Hct) is slightly higher than the automated Hct, due to the inclusion of trapped plasma in the packed red cell column. [13] The amount of this trapped plasma, typically about 23% of the packed red cell volume,[13] varies depending on red cell morphology and technical factors, and may be as high as 6% in microcytic anemias.[14] Although blood counters are typically calibrated to yield a hematocrit equivalent to the packed cell volume for normal blood, the spun Hct is likely to be higher than the automated Hct in patients with hypochromic or poorly deformable (i.e., sickled) red cells, due to increased plasma trapping, or in patients with high Hct (e.g., newborns). Hemoglobin can be accurately measured by recently available point of care instruments, in particular those using a photometric measurement similar to the larger automated instruments.[15] This approach may be of particular value in critical care settings. [16]

Erythrocyte Count and Indices

The MCV is directly derived from the mean red cell volume determined by impedance or light scatter, whereas the other indices are calculated as described previously. The MCV is the most clinically useful red cell index. [17] [18] Although the MCV has been widely used to direct the evaluation of anemias, its diagnostic sensitivity in both iron-deficiency anemia and megaloblastic anemia has been questioned. [19] [20] The MCH closely parallels the MCV, and provides little additional diagnostic information.[18] The MCHC is more frequently reduced in iron-deficiency anemia than other causes of microcytosis, [21] but the drop in MCHC occurs relatively late, [22] and the diagnostic utility of the parameter is poor. [23] An elevated MCHC is associated with hereditary spherocytosis, [24] but this finding is not always present. Numerous discriminant functions based on red cell indices have been proposed to differentiate iron deficiency from thalassemia trait, but cannot substitute for definitive tests in diagnosing individual patients. [21] [25]

The MCV and red cell count are subject to several artifacts. The most common of these is autoreactive red cell antibodies active at room temperature, which aggregate red cells in the instrument, lowering the red cell count, while increasing the MCV. [26] Typically, the red cell count is lowered to a greater degree than the MCV is increased (since large aggregates are not counted), causing a falsely elevated MCHC. Warming or prediluting the sample usually reverses this effect, which may occur in healthy subjects. Artifactually low MCV measurements resulting from osmotic effects have been infrequently reported in extreme hyperglycemia. [27]

Red Cell Distribution Width (RDW)

The RDW is a quantitative estimation of anisocytosis, and is typically computed as the coefficient of variation of red cell size distribution. Anemic disorders can be classified on the basis of RDW. [28] In particular, the RDW is more frequently elevated in iron-deficiency anemia than in thalassemia or anemia of chronic disease. [28] [29] However, there is significant overlap among these patient groups, even when only clear-cut presentations are considered, [21] complicating interpretation of the results in individual patients. [30] This parameter may be useful in screening high-prevalence populations or in conjunction with other more specific tests, such as serum ferritin.[31] The RDW is used in the clinical laboratory as an indicator of anisocytosis in order to select samples from the automated blood counter for morphologic red cell analysis.

Reticulocyte Count

In the standard manual reticulocyte count, new methylene blue is used to stain residual RNA and aggregate the RNA to make it easily visible. Automated reticulocyte analysis relies on detection by staining with either methylene blue [32] or fluorescent RNA-binding dyes in single cells. [33] This methodology has been adapted to flow cytometers and automated blood cell counters,[32] as well as dedicated reticulocyte counters. [33] Leukocytes and large platelets or platelet aggregates must be carefully excluded, as these cells will contain variable amounts of RNA. [34] A major advantage of automated reticulocyte counting is improved precision,[33] especially in the low-normal range, where manual methods are imprecise as a result of the small number of reticulocytes counted. [35] Reference ranges should be re-evaluated when introducing an automated reticulocyte method, as methodology-dependent variations in reticulocyte counts have been observed. [36] Recovery after bone marrow transplant may be detectable slightly earlier by the automated reticulocyte count as compared with the standard reticulocyte count, platelet, or neutrophil counts. [37] [38] Standardization of staining procedures, data analysis, [39] and quality control[40] [41] are important, since the reticulocyte RNA content is a continuous variable without clearly separated positive and negative populations (this is also a problem with manual reticulocyte counting). [42]

Reticulocyte Maturity Index

Immature or shift reticulocytes with increased RNA can be recognized by increased staining with precipitating RNA dyes [43] or as polychromatophilic cells on a blood smear.[44] Increased RNA content by flow cytometry may be an indicator of reticulocyte immaturity. Increased reticulocyte RNA content is an early sign of erythroid recovery following bone marrow transplant, [38] [45] [46] and varies in anemic states in accordance with the expected degree of erythropoietic stimulus. [47] [48]

Platelet Count

Counting of platelets in whole blood has traditionally been difficult because of their small size, wide size range, tendency to aggregate, and potential overlap with more numerous red cells or debris.[49] Current instruments deal with these problems by mathematical analysis of the platelet volume distribution to insure that it represents the log-normal distribution (skewed to the higher volumes) expected in both normal and diseased subjects. If the volume distribution does not conform to this shape, the presence of cell fragments, debris or microcytic red cells is suspected, and manual techniques must be used. Similar to the MCV and RDW, a mean

platelet volume (MPV) and platelet distribution width (PDW) is calculated from the platelet volume distribution.

Even with automated instruments, the platelet count is measured less precisely than the other components of the blood count (expected analytic variability of about 22%).[50] Variability tends to be higher in the markedly thrombocytopenic range, where there may be the greatest need to accurately measure small changes in platelet number. The lower limit of linearity

is an important limiting factor in automated instruments,[51] because of the difficulty in distinguishing platelets from cellular debris and other particles. In the markedly thrombocytopenic range, the platelet count may be flagged by the instrument as suspect, necessitating a time-consuming manual confirmation. In spite of these limitations, current automated instruments provide accurate information for clinical decision-making in thrombocytopenic patients.[52] Flow methods using specific platelet-associated markers have been shown to increase accuracy at low platelet concentrations,[53] but these are not yet adapted for routine clinical use.

The most important cause of a falsely low platelet count is inadequate anticoagulation of the specimen (indicated by small clots or fibrin strands visible on smear). Some individuals possess autoreactive antibodies that recognize platelet surface epitopes, which are exposed under divalent cation-free conditions (i.e., EDTA- or citrate-anticoagulated blood).[54] The resulting platelet clumps show up as an abnormal peak in the leukocyte volume histogram (the aggregated platelets are incompletely lysed by detergent), and can also be observed in the feathered edge of the smear. Platelet adequacy can be estimated from a heparinized sample or fingerstick smear (both of which typically show some platelet clumping resulting from incomplete inhibition of platelet activation). Falsely high platelet counts can be caused by cytoplasmic fragments of degenerated leukocytes, microcytic red cells, cryoglobulins, or debris. In all these instances, the platelet volume distribution would be expected to demonstrate a significant deviation from the expected log-normal relationship, and would be flagged as abnormal.

Platelet Analysis

MPV

The MPV is inversely correlated with platelet count,[55] and must therefore be interpreted in conjunction with the platelet count using a nomogram of reference ranges.[56] An elevated MPV has been associated with destructive thrombocytopenia,[57] and a decreased MPV with hypoproliferative thrombocytopenia.[56] Increased MPV may be a result of stimulation of megakaryopoiesis,[58] rather than simply decreased platelet age.[57] [59] MPV is increased in several clinical settings associated with cardiovascular risk,[60] and may be a risk factor for recurrent myocardial infarction[61] and restenosis after coronary angioplasty.[62] Interpretation of MPV is complicated by the continuously changing MPV observed in patients recovering from destructive thrombocytopenia[57] and the instability of MPV in blood collected in EDTA[63] (but not citrate[64]). The platelet distribution width (PDW), when interpreted in combination with the platelet count and MPV, may help to distinguish reactive from primary thrombocytosis.[65] Routine clinical use of either of these parameters awaits further definition of diagnostic utility.

Reticulated Platelets

The RNA content of platelets can be quantitated by flow cytometry using the RNA-binding dye thiazole orange.[66] Recent studies in animals suggest that reticulated platelets are in fact young platelets, analogous to reticulocytes.[67] An increased percentage, but not absolute number, of reticulated or RNA-containing platelets is observed in destructive thrombocytopenia, suggesting that young platelets are also subject to destruction.[66] [68] [69] A subset of patients with clinically defined ITP do not show increased RNA-containing platelets;[68] it is not known whether these patients represent a subgroup complicated by deficient thrombopoiesis.[70] In contrast, patients with hypoproliferative thrombocytopenia have a normal percentage, but markedly decreased absolute numbers, of RNA-containing platelets.[66] As is the case with reticulocytes, appearance of reticulated platelets precedes platelet recovery after stem cell transplantation.[71] [72] Platelets must be carefully distinguished from RNA-containing cellular fragments and other debris using light scatter parameters, platelet-specific markers,[73] or by physical separation of platelets.[74] These technical issues as well as difficulty in standardization limit widespread routine clinical application of this assay.[75]

Platelet Function

Flow cytometry analysis can detect decreased surface expression of platelet surface integrin adhesion molecules in congenital platelet function disorders.[76] Platelet activation results in conformational changes in surface gpIIb/IIIa, and exposure of granule membrane proteins, such as P-selectin (CD62P) and CD63. Binding of specific antibodies to determinants on these molecules can therefore serve as an estimate of the degree of platelet activation in a clinical sample.[77] [78] Platelet CD63 expression in early pregnancy may indicate increased risk factor of preeclampsia.[79] [80] Platelet activation is observed in acute coronary syndromes[81] and after coronary angioplasty,[82] but its prognostic value in cardiovascular disease and prothrombotic states remains to be established.

Leukocyte Count and Differential

Three major normal leukocyte populations (lymphocytes, monocytes, and neutrophils; the three-part differential), can be distinguished by electrical impedance volume measurement of leukocytes in which the cytoplasmic contents have been partially removed by detergent lysis of the cell membrane. Eosinophils and basophils are not sufficiently distinctive to be enumerated using this single-parameter approach. Analysis of the volume histograms is used to indicate the presence of increased numbers of eosinophils, basophils, reactive lymphocytes, or abnormal cells, whose volume tends to fall between the three major normal cell types. If present in sufficient quantity, nucleated red cells, clumped platelets, fibrin strands, malaria parasites, and cryoglobulins will show up on the leukocyte volume histogram. Samples are flagged by the instrument for manual review if any of these abnormalities are found.

Five normal leukocyte populations (the five-part differential), can be distinguished by several different techniques. One approach is to use a combination of light scatter and absorption to identify stained leukocytes in flow (Technicon[83]). A peroxidase stain is used to detect neutrophils and eosinophils. Eosinophils have very high peroxidase staining but relatively low forward light scatter, because their large granules scatter most of the incident light at high angles rather than low angles. Basophils are identified by resistance to lysis using a different detergent. Leukemic cells are typically large but lack peroxidase positivity (large unstained cells).

A commonly used instrument (Coulter) identifies the five major blood leukocyte types by electrical impedance, light scatter, and electrical conductivity, as shown in Figure 156-1 . Other approaches to the five-part leukocyte differential include differential resistance to lysis of eosinophils and basophils in specific detergents at different temperatures (Sysmex), or patterns of light scatter determined by measurements at four different angles, using a polarized light source (Abbott Cell-Dyn). These instruments are being successfully used in clinical laboratory settings.[1] [84]

A significant proportion of samples submitted for automated blood count and differential (about 2050% depending on patient population and instrument type) are flagged by the instrument for manual review.[85] [86] [87] The correlation of automated and manual differential counts in samples not flagged for manual review is excellent with instruments reporting either three-part[88] or five-part[89] differential. The automated differential has

Figure 156-1 Automated five-part leukocyte differential. **(A)** Simultaneously measured volume, electrical conductivity and light scatter in lysed whole blood analyzed by the Coulter STKS automated blood counter. As shown, each parameter distinguishes different groups of leukocytes, allowing numerical estimation of the five major leukocyte subgroups by comparing data from each measurement. Abnormal cells typically lie in between these normal populations. **(B)** Two-parameter histogram of discriminant function (DF) 1 (derived from scatter data) vs. volume, showing the cell populations identified. Basophils are indistinguishable from lymphocytes on the basis of scatter and volume alone. **(C)** Two-parameter histogram of DF2 (derived from conductivity data) vs. volume. Basophils have higher conductivity than lymphocytes, but are not separable from other granulocytes. **(D)** Two-parameter histogram of DF3 (conductivity, gated on scatter to eliminate cells with high light scatter) vs. volume. Basophils can now be seen as a separate population, since they have lower light scatter than other granulocytes, but higher conductivity than lymphocytes or monocytes.

an advantage in precision over the standard differential, because thousands, rather than 100, cells are counted.[90] However, in practice the substantial physiologic variation in the differential leukocyte count may complicate interpretation of small changes in percentages.[91]

The false negative rate (i.e., failure to detect significant numbers [typically 5%] of abnormal cells) in the newer instruments which report a five-part differential varies from 120%.[85] [92] [93] [94] Circulating lymphoma cells and reactive lymphocytes are among the more common causes of false negative results. [85] The false negative rate for significant red cell or platelet abnormalities is about 2.5%. [95] Reliable detection of infrequent abnormal cells is a problem for both automated counters and conventional microscopy. The best approach is to use all available clinical and laboratory information to identify patients in whom careful morphologic examination of the blood smear for a specific abnormality is of diagnostic relevance. [96] The data generated by automated blood counters can be used to direct attention to those blood films most likely to contain diagnostic information. [97]

The blood count[98] and leukocyte differential count [95] are considered by many observers to be overutilized as screening tests relative to their diagnostic utility. Given the current ordering patterns for these tests, automated differential counters offer a rapid and cost-effective means for screening blood for significant quantitative and qualitative leukocyte abnormalities, but definitive characterization of any cell populations flagged by these instruments as atypical still requires visual examination of the blood smear by a trained observer.

CELL MARKER ANALYSIS BY FLOW CYTOMETRY

Principles of Flow Cytometry

Flow cytometers use the general principles of automated cell analysis mentioned previously, particularly light scatter, but are especially designed for sensitive and quantitative fluorescence measurements of single cells. A very brief overview of technical aspects of flow cytometry is presented here. Excellent reviews and textbooks covering this subject in detail are available. [100]

Cell Preparation and Staining

For accurate surface labeling and flow cytometric analysis, cells must be viable and available as a single cell suspension. Bone marrow and blood cells are easily kept in suspension as single cells, but solid tissue samples must be mechanically or enzymatically disaggregated, sometimes resulting in loss of the cells of interest and a false negative result. This is not an infrequent occurrence in some lymphomas, praticularly large cell lymphoma, where the cells are fragile and highly adherent.

Fluorescence Measurement

The fluorescence emitted by each cell as it passes through the light beam is optically focused and amplified. Discrimination of up to four fluorescent dyes is possible on most standard clinical flow cytometers, using optical filters placed in front of separate light detectors.

Selecting the Right Population to Analyze

The flow cytometer senses particles passing through the light beam by detecting pulses of scattered light. It cannot identify cells morphologically, and thus the operater must set decision criteria (gates) to tell the flow cytometer which are the populations of interest for display of the fluorescence data. Modern flow cytometers store all of the correlated light scatter and fluorescence data, so that if the operator has selected the wrong population, the data can be replayed on the computer, selecting a different population for analysis. The major subpopulations of hematopoietic cells can be recognized (albeit with some overlap) by analysis of light scatter and expression of common leukocyte antigen CD45 (Fig. 156-2). Because monocytes and myeloid cells may nonspecifically bind antibodies, it is critical to select the proper cell population for analysis. Leukemic populations can be distinguished from most normal cells and therefore more readily phenotyped by selecting a population with weak CD45 expression and low wide angle light scatter (cell granularity). [101] [102] By including CD45 with each marker combination, this same population can be selected for each analysis performed on the sample.

Principles of Cell Marker Analysis

Flow cytometry is broadly applicable beyond the field of hematology. [103] The most common applications in hematology are detection of differentiation or maturation-related cellular proteins using labeled monoclonal antibodies, or DNA content using DNA binding dyes. Numerous cellular proteins have been recognized using monoclonal antibodies (termed CD for cluster designation referring to a cluster of antibodies identifying the same antigen; the designations are regularly updated).[103] Some clinically useful lineage-associated markers are listed in Table 156-1 , and the pattern of expression of selected markers in the major hematopoietic lineages is shown in Figure 156-3 .

Rationale for Immunophenotyping of Hematologic Neoplasms

The clinical relevance of immunophenotyping is based on the assumptions that the phenotype of the abnormal cell is an interpretable pattern and not a random collection of markers and that the phenotype of a cell reflects important biologic characteristics (i.e., clinical aggressiveness, drug sensitivity). In view of their markedly altered genotype and clinical behavior, it is remarkable that leukemic cells usually phenotypically resemble some normal stage of differentiation. However, our understanding of the biologic role of most cell markers is extremely incomplete. Therefore, these markers are likely to be mere surrogates for the actual factors that determine response to chemotherapy and clinical aggressiveness. For this reason, diagnostic interpretation of phenotypic data must always be verified empirically by careful clinical studies. Based upon the recent expansion of knowledge linking morphologically, immunophenotypically, and cytogenetically defined disorders with molecular mechanisms (recently reviewed in detail[104]), we now have an unprecedented opportunity to determine the most clinically relevant approach to classification of hematologic neoplasms.

Pattern Recognition in Immunophenotyping of Hematologic Malignancies

A pattern of marker expression is more convincing and more likely to be clinically relevant than expression of any single marker. The diagnostic importance of recognizing characteristic combinations of surface markers in lymphoid malignancies is illustrated in Figure 156-4 . Flow cytometry analysis of neoplasms requires pattern recognition; it has been stated that flow cytometric diagnosis is more analogous to reading a bone marrow aspirate than determining a serum sodium level. [105] The recognition of populations of cells with distinctive

Figure 156-2 Selection of cells for flow cytometry analysis using light scatter. Proper selection of the cell population of interest is the first and most important step in data analysis of flow cytometry studies. Several normal cell populations are recognizable by their CD45 expression and light scattering properties, as shown in **(A)**. The boxed area includes cells with weak CD45 expression and low wide angle light scatter, which is a fraction enriched in early precursor and progenitor cells. Acute leukemia cells typically show these features **(B, C)**, making it possible to select a cell population relatively enriched in abnormal cells and depleted of normal cells on which to analyze surface marker expression. Panel **(D)** illustrates the need to look at all cell subpop-ulations to be sure malignant cells are not being excluded from the analysis. The population with high CD45 expression above the boxed area represents lymphoma cells, which are similar in their CD45 expression and light scatter properties to normal lymphocytes, but show monoclonal surface immunoglobulin expression and B cell markers on further study.

TABLE 156-1 -- Lineage Association of Diagnostically Useful Hematopoietic Markers

Marker	Lineage Association
B cell	
Immunoglobin	B[a]
CD22	B
CD20	B
CD21	B
CD19	B
T cell	
CD3/TcR	T
CD2	T, NK
CD5	T, B subset
CD4	T, Mo, eos, MK
CD7	T, myeloid progenitor
CD1	Thymocyte, Langerhans
Progenitors	
CD34	All progenitors
TdT	Lymphoid progenitors
CD10	Pre-B, activated B, PMN
Myeloid/monocyte	
MPO	My, Mo
CD33	My, Mo
CD13	My, Mo
CD14	Mo
CD15	My, Mo
CD11c	My, Mo
Megakaryocyte	
CD41a	MK, endothelium
CD61	MK, endothelium
Erythroid	
Glycophorin	Erythroid
Spectrin	Erythroid
NK/cytotoxic T	
CD56	NK, plasma cell
CD16	NK, PMN
CD57	Cytotoxic T

B, B cell; T, T cell; AMoL, acute monocytic leukemia; NK, natural killer cell; Mo, monocyte; TdT, terminal transferase; MPO, myeloperoxidase; My, myeloid cells; MK, megakaryocytes.

[a]Commonly used markers are grouped according to their major lineage association. Lineage associations of each marker are shown to the right of the CD designation. The more specific markers are at the top of the list in each lineage category.

immunophenotype and correlation of these populations with morphologically relevant cells is the key skill of flow cytometric interpretation. The major steps in cell marker analysis and interpretation by flow cytometry are summarized in Table 156-2 . A recent study has emphasized the importance of pattern recognition over numerical analysis in the diagnosis of hematologic neoplasia. [106] The importance of visual analysis of histograms to recognize abnormal expression density or coexpression of markers is often obscured by the standard practice of reporting percentage of positive cells for each marker, which may be misleading when a weakly staining population of neoplastic cells is present. [107] [108]

Lineage Specificity of Markers

Although terms such as myeloid marker are convenient and commonly used, the functional role of any surface protein is seldom restricted to cells of a given lineage. For instance, the neutral endopeptidase CD10, initially identified as a marker of immature B cells, is expressed by other cell types including neutrophils and renal tubular epithelium. Although neoplastic cells do tend to resemble normal cells in a particular lineage at a particular stage of differentiation, upon close examination neoplastic cells often display an incorrect phenotype when compared with any known normal cell. This can take the form of asynchronous (lineage-correct markers appearing in the wrong order) or mixed lineage (markers associated with different lineages appearing in one cell) differentiation. It should be recognized that aberrant marker expression may also reflect leukemic expansion of a rare normal population that is difficult to detect by standard techniques. [109] Careful study of acute leukemia cells at diagnosis with multicolor antibody panels reveals such unusual marker combinations in a majority of cases. These can be used to allow detection of small numbers of residual leukemia cells after initiation of treatment. [110]

Demonstration of Monoclonality

Monoclonal origin can be detected in immunoglobulin-expressing B-cell malignancies by light chain restriction (i.e., a population expressing only kappa or lambda light chain).[111] There is no comparable phenotypic marker for monoclonality in T cells. Light chain analysis is more sensitive in identifying B-cell lymphoma than the percent of total B cells, with a / ratio of >3:1 or <1:2 strongly suggesting the presence of a monoclonal population. [112] Quantitatively restricted expression of surface Ig by monoclonal B cells has been used to detect small monoclonal B cell populations undetectable by analysis of / ratio. [113] Nonspecific binding should be excluded by simultaneous staining with anti- and anti- antibodies or combining the anti-light chain antibody with a B-cell marker [114] (Fig. 156-5).

Cell Marker Analysis in Acute Leukemia

Classification of Acute Leukemia

In diagnosis of a hematologic malignancy, cell marker studies are most useful if a morphologically recognizable abnormal population is present. This is because of phenotypic overlap between leukemic and normal progenitors and the relative lack of leukemia-specific markers. Once the diagnostic sample is carefully analyzed, it

may then be possible to detect minimal residual disease based on expression of unusual marker combinations as mentioned previously.

Immunophenotyping allows reproducible lineage assignment of some leukemias which would otherwise be difficult to classify, [115] [116] particularly in differentiating lymphoid from immature myeloid leukemias (Table 156-1). Cytoplasmic markers (peroxidase, cCD13[117] [myeloid], cCD22[118] [B lineage], cCD3[119] [T lineage]) may be more specific indicators of lineage commitment in acute leukemia. [118] There is significant immunophenotypic overlap among the different FAB categories, [120] but important associations exist between immunophenotype and some morphologic or molecular entities, as recently reviewed. [104] In myeloid leukemia, these include CD14 expression in M4/ M5;[121] aberrant expression of CD2 (a lymphoid-associated marker) in M3 [122] and M4eo;[123] lack of HLA-DR in M3;[124] aberrant CD19 expression in t(8;21) M2[125] and monocytic leukemias;[126] CD34 expression and chromosome 5 or 7 abnormalities in M0;[127] [128] [129] and CD61 or CD41 (platelet-associated glycoproteins) expression in megakaryoblastic leukemia (but false-positive results due to platelet adherence to monoblasts must be avoided [130]). Acute lymphoblastic leukemia can be classified into B-cell precursor (CD19+, usually CD10+), pre-B (cytoplasmic Igm+), B cell/Burkitt (surface IgM+), or T cell (CD7+/CD2+) based on immunophenotype.[104] In some studies, the B-cell precursor phenotype is associated with the best overall prognosis in childhood ALL. [131] A characteristic mixed lineage phenotype (CD19+/CD10+/CD15+) in infants is associated with chromosome 11q23 translocations involving the HRX gene and an adverse prognosis.[132] A fairly characteristic

Figure 156-3 Differentiation based expression of cell markers (lineage maps). Expression of clinically useful surface markers during differentiation in the **(A)** B cell, **(B)** T cell, **(C)** myeloid,[162] [163] and **(D)** monocytic lineages. A general idea of the variation of expression intensity of a specific marker is indicated by the height of the line corresponding to each marker. CD5 is expressed on a subset of normal B cells and on B-CLL. The phenotype of activated B cells and corresponding lymphomas is complex and varied. While most normal pre-B cells are TdT, pre-B ALL is TdT+, an example of asyncronous differentiation. Asynchronous differentiation is also seen in myeloid leukemias; they often express late markers such as CD11b, CD14 and CD15 along with earlier markers CD34 and HLA-DR, so that leukemia phenotypes do not always match a normal differentiation stage.

Figure 156-4 Diagnostic importance of multiparameter analysis. **(A)** Fluorescence histogram of CD20 vs. CD5 in normal lymph node. Only a small number of CD20+/CD5+ cells are typically observed in normal tissues. **(B)** Fluorescence histogram of CD20 vs. CD5 in B-cell CLL. The characteristic co-expression of CD5 by the malignant B cells is clearly demonstrated by two-color analysis. Note that expression of both CD20 and CD5 is quantitatively lower in the malignant cells than the normal B (CD20+) or T (CD5+) cells. **(C)** Fluorescence histogram of CD8 vs. CD4 in normal blood mononuclear cells. Note virtually exclusive expression of the two markers on different subsets (T-suppresser/cytotoxic and T-helper/inducer). **(D)** Fluorescence histogram of CD8 vs. CD4 in T-cell lymphoblastic lymphoma, showing co-expression of CD4 and CD8, a common thymocyte phenotype that is typical of T-ALL and T cell lymphoblastic lymphoma. **(E)** Fluorescence histogram of CD10 vs. CD45 in remission bone marrow after chemotherapy. Although 60% of the lymphoid cells are CD10+, they show a sequence of loss of CD10 correlated with increasing CD45 expression characteristic of normal B-cell maturation, as indicated in the histogram. **(F)** Fluorescence histogram of CD10 vs. CD45 in B-cell precursor ALL. Note the high CD10 expression, CD45 negativity, and lack of evidence of progressive maturation of the cells.

TABLE 156-2 -- Practical Considerations in Hematopoietic Immunophenotyping

1. Morphologically identify cells of interest
2. Formulate the clinical question
3. Select appropriate antibody panel
4. Identify light scatter/CD45 population likely to contain cells of interest
5. Are the other populations consistent with expected normal cell types?
6. What is the overall phenotype of the cells of interest?
Level of confidence (from phenotype, morphology, surface Ig clonality) that population is abnormal
Best fit for lineage identity
Look for atypical or mixed-lineage markers (used to detect residual disease)
Assess differentiation stage and look for specific phenotypes associated with clinical and molecular leukemia/lymphoma subtypes
7. Restain with additional markers if needed based on initial data.

CD10+/CD19+/CD34 phenotype is found in a subset of pre-B ALL patients and is strongly associated with the t(1;19) translocation (E2A-PBX1). [133]

It is becoming increasingly evident that immunophenotypic patterns are most useful not as separate independent prognostic indicators, but as clues to the existence of more specific molecular abnormalities underlying malignant transformation and clinical behavior. For instance, expression of myeloid antigens in childhood ALL is not associated with an adverse prognosis in the overall patient population. [134] However, the group of patients with a true bilineage phenotype [135] does include a subset of patients with t(9;22) and 11q23 translocations, which definitely indicate a poor prognosis.

Phenotypic changes are generally not sufficiently characteristic to allow diagnosis of myelodysplastic syndromes or to differentiate the various subgroups.

Minimal Residual Disease

Highly sensitive molecular assays such as RT-PCR have recently made it possible to detect residual leukemic cells at concentrations of 10^{5} 10^{6} . These assays are applicable to patients whose leukemic cells contain a clonal genomic rearrangement amenable to PCR amplification. An alternative approach is to detect residual leukemic cells by virtue of their expression of combinations of cell markers found infrequently (<10^{3} 10^{4}) in normal bone marrow or blood.[136] Such combinations are surprisingly frequent, if a thorough investigation is made. Common aberrant phenotypes include cross-lineage marker expression (CD2, CD19 in AML), asynchronous marker expression (i.e., an early plus a late marker expressed together), over- or under-expression of a marker relative to normal cells, [137] and abnormal light scatter profile (i.e., a big CD2+ cell, or a small CD13+ cell). [138] Such unusual marker combinations are found in 87% of AML, [138] with a high proportion having more than one aberrant phenotype suitable for follow-up studies. [139] Phenotypic shifts occur in relapsed cells, but the diagnostic aberrant phenotypes are infrequently altered. [140] Although the sensitivity of PCR-based assays is inherently higher, flow cytometry offers the advantage of simple and reliable quantitation, and the ability to sort cells of interest for studies.

Recent results using immunophenotypic approaches to detection of minimal residual disease suggest that even though flow cytometry assays may be intrinsically less sensitive than molecular assays, the detection of residual cells in the range of

Figure 156-5 Detection of monoclonality by flow cytometry. Fluorescence histograms of: anti-kappa vs. anti-lambda **(A,B),** CD20 vs. anti-kappa **(C,D),** and CD20 vs. anti-lambda **(E,F)** in a reactive lymph node **(A,C,E)** or a lymph node replaced by B-cell lymphoma **(B,D,F).** Note the separate +/ (15%) and /+ (12%) populations in the benign reactive node **(A)**, each of which is identified as a true B-cell population by co-expression of CD20 **(C,E)**. Note the +/ (81%) population without a corresponding /+ (<1%) population in B-cell lymphoma, consistent with a B-cell monoclonal proliferation.

25 × 10^{3} at the time of completion of induction or intensification chemotherapy is highly predictive of clinical outcome. [138]

Cell Marker Analysis in Lymphoproliferative Disorders

B-Cell Neoplasms

B-cell chronic lymphoproliferative disorders are identified by expression of B-cell associated markers and monotypic surface immunoglobulin. Some lymphomas, particularly large cell lymphomas, may lack detectable surface immunoglobulin expression. [104] A number of clinically important lymphoproliferative disorders express a fairly characteristic immunophenotype, while others are not clearly distinguishable on the basis of cell marker studies. [141] Clinical presentation, morphology, and histopathologic appearance are critical in drawing optimal diagnostic conclusions in all instances. The most distinctive phenotypes are found in hairy cell leukemia (CD103+/CD11cbright+/CD25+), CLL (CD5+/CD23+/FMC7) and mantle cell lymphoma (CD5+/CD23/FMC7+). Monoclonal light chain expression and an expanded CD20+/CD5+ population may permit diagnosis of early CLL in patients with relative lymphocytosis, but with normal absolute lymphocyte counts. [142] The hairy cell phenotype is sufficiently distinctive to allow detection of small numbers of residual leukemic cells. [143] Quantitative expression of surface markers is a useful parameter, particularly in CLL, where CD20 and surface Ig are weakly expressed relative to normal B cells and most other lymphoproliferative disorders. CLL is distinguishable from prolymphocytic leukemia by these features and by the lack of CD5 expression in prolymphocytic leukemia. Interestingly prolymphocytic transformation of CLL usually retains a typical CLL phenotype. Follicular lymphomas are distinguishable from CLL by intensity of surface Ig expression, CD10 positivity (in most cases), and by lack of CD5 expression. Multiple myeloma (in common with normal plasma cells) lacks many of the characteristic B-cell markers (CD19, CD20, surface Ig). Diagnosis may be more easily accomplished by immunohistochemical staining for cytoplasmic immunoglobulin light chain. Interestingly, both normal [144] and neoplastic[145] plasma cells co-express several myeloid-associated markers. Diagnosis of Hodgkin lymphoma by flow cytometry is seldom practical due to the infrequency of the abnormal cells.

T-Cell Neoplasms

Immunophenotypic diagnosis of T-cell lymphoproliferative disorders is more difficult, since these cells usually express markers found normally in mature T cells. However, on careful analysis, the majority of both mature and immature T-cell lymphomas show either loss of an expected T-cell marker (typically CD7 or CD5), loss or co-expression of CD4 and CD8, or expression of CD1, suggesting aberrant or asynchronous differentiation. [146] Because the mixture of cells making up the normal T-cell population is phenotypically complex, detection of small malignant T-cell populations (i.e., 2% Sezary cells) on this basis is generally not feasible. Most instances of large granular cell (LGL) lymphoproliferative disease display a characteristic cytotoxic T-cell phenotype [147] (CD3+/CD57+/CD56/CD16±), although a minority resemble true natural killer cells (CD3/CD57±/CD56+/CD16+). Only the former type can be identified by T-cell antigen receptor gene rearrangement.

Other Flow Cytometry Applications in Hematology

Enumeration of CD34+ Progenitors

Adequacy of peripheral blood stem cell harvests can now be rapidly assessed by flow cytometric measurement of CD34+ cell concentration. [148] CD34+ cell measurement is as effective as CFU-GM assays in predicting successful engraftment,[149] but is more rapid and is easier to perform. This assay is increasingly utilized by bone marrow transplant centers, but technical aspects of the assay (for instance, gating strategy for cell selection [150] and choice of red cell lysis methods[151]) that affect the quantitative results have not yet been adequately standardized. [150] [152] [153]

Paroxysmal Nocturnal Hemoglobinuria (PNH)

The diagnosis of PNH has entered a new era with the ability to directly measure expression of phosphatidylinositolglycan

(PIG)-anchored surface molecules in different hematopoietic lineages by flow cytometry. [154] Consistent with detailed studies of complement lysis sensitivity, flow cytometry analysis reveals subpopulations of Type I, II, and III erythrocytes with progressively decreasing expression of PIG-linked proteins. [155] The flow cytometry assay is more sensitive than standard complement lysis sensitivity tests, [156] and offers the ability to analyze blood neutrophils and monocytes, which are usually more severely deficient in PIG-linked protein expression than red cells. [156] [157] Lymphocytes are typically least affected.[158] Recommended surface markers for sensitive and reliable PNH diagnosis are CD59 (all lineages), CD55 (neutrophils, monocytes, lymphoid cells), and CD14 (monocytes) (Fig. 156-6).[156]

DNA Content

Staining of fixed cells with dyes that bind stoichiometrically to DNA permits direct analysis of DNA content in individual cells.

Figure 156-6 Quantitative flow cytometry for diagnosis of PNH. Single-parameter histograms of fluorescence intensity vs. cell number in blood cells from a patient with paroxysmal nocturnal hemoglobinuria (color tracing) and a normal control (black tracing). Each peak represents a population of cells; position on the x-axis corresponds to fluorescence intensity on a log scale. Preparations of red cells, neutrophils, and mononuclear cells were stained with the indicated monoclonal antibodies and the appropriate cell population selected for analysis by light scatter gating. Fluorescence of cells stained with control irrelevant antibodies was lower than 1 unit on the log scale. **(A)** Red cells. There is only a small subpopulation in the PNH patient with decreased CD59 expression, and no reduction in CD55 expression. **(B)** Neutrophils. Note the clearly defined subpopulation showing weak expression of CD55, CD59, and CD24, consistent with type II PNH cells. The diagnosis of PNH is more evident on examination of the neutrophils than red cells, perhaps as a result of preferential destruction of the most severely affected red cells in the circulation. **(C)** Monocytes. A population of very weakly staining (type II) PNH monocytes is evident on the CD14 histogram. Note that surface expression of PIG-linked surface molecules (CD59 and CD14) is not equally affected in this lineage. This study is an example of the ability to quantitate surface molecule expression using flow cytometry.

Flow cytometry can detect a gain or loss of 520% (depending on instrument precision and percentage of aneuploid cells) in DNA content of G0/1 cells. B-precursor ALL patients with a DNA index (DNA content relative to normal cells) of >1.16 have significantly better relapse-free survival regardless of age or white count than those with DNA index of 1.16.[159] DNA content is of limited diagnostic value in chronic lymphoproliferative disorders and myeloid leukemia. Cells in the S phase of cell cycle can be recognized by DNA content between G0/1 and G2. Estimated percentage of S phase cells (using DNA content analysis) in lymphomas is correlated with morphologic risk categories, and may provide additional prognostic information. [160] Reproducible estimation of the percentage of S phase cells presents considerably more technical challenges than measurement of DNA content, because of the greater complexity in modeling the S phase to account for variability in G0/1 and G2 peaks, as well as the presence of nuclear fragments and debris.

Leukocyte Adhesion Deficiency (LAD)

A congenital defect in production of the common 2 chain of the leukocyte integrin adhesion molecule family causes defective migration of neutrophils and an increased susceptibility to recurrent infections, and is detectable by loss of surface expression of the beta-2 integrin family on leukocytes. [161]

Chapter 157 - Laboratory Detection of Hemoglobinopathies and Thalassemias

Martin H. Steinberg
Junius G. Adams III

INTRODUCTION

Hemoglobinopathies are a result of the production of globin polypeptides with an abnormal primary structure. Sickle cell anemia is an example. In thalassemia, the primary structure of globin is usually normal, but there is an abnormal distribution of normal hemoglobins. For example, in -thalassemia, hemoglobin (Hb) A_2 and fetal hemoglobin (Hb F) are increased. The diagnosis of inherited disorders of hemoglobin requires the ability both to find abnormal hemoglobins and to detect increased or decreased amounts of normal hemoglobins. Finding these disorders in neonates and in adults is important clinically. When clinical or laboratory findings suggest common or rare hemoglobin disorders, a definitive diagnosis must be established before counseling and treatment planning are started. Population screening is directed at finding heterozygotes for the most common hemoglobin disorders. These include sickle cell disease, Hb E disease, and the - and -thalassemias. In pregnancies at risk for these disorders, antenatal diagnosis is possible. Newborn screening can detect homozygotes for hemoglobin disorders at birth, providing affected individuals the benefits of early treatment. Although tests used for definitive diagnosis and screening can be similar, each rationale requires a different approach (Tables 157-1 , 157-2 , and 157-3).

Testing for hemoglobin disorders ranges from detection of the globin proteins produced by the affected genes by isoelectric focusing (IEF), electrophoresis, high-performance liquid chromatography (HPLC), and mass spectroscopy, to gene analysis by restriction endonuclease cleavage, specific oligonucleotide hybridization, and DNA sequencing. Some methods provide a preliminary diagnosis and others a definitive diagnosis of disorders of hemoglobin structure or synthesis. These methods have been reviewed.[1] [2] [3] [4] [5] [6] [7] No single laboratory test alone is adequate for the detection of all hemoglobinopathies and thalassemias. The various techniques used currently and their pitfalls are discussed below. Blood counts and erythrocyte indices can modulate the interpretation of more definitive studies and will first be reviewed briefly.

MEASUREMENT OF HEMATOLOGIC PARAMETERS

Hematologic indices, measured by electronic cell counting, play an important role in the differential diagnosis of hemoglobinopathies

TABLE 157-1 -- Screening Protocols for Heterozygote Detection in Adults

For -thalassemia trait
Microcytosis detected by electronic cell counters.
Hb A_2 determination. If elevated, probable -thalassemia trait.
Provide counseling. If Hb A_2 normal, consider iron deficiency, -thalassemia, or rare types of -thalassemia.
For -thalassemia
Microcytosis in the absence of -thalassemia or iron deficiency [a]
For initial screening of sickle cell trait, Hb C trait, Hb E trait
Isoelectric focusing, or electrophoresis at pH 8.6 and 6.1, or high-performance liquid chromatography
If AS, AC, or AE pattern (Hb A concentration >Hbs S, C, E),[b] a carrier state is likely; provide counseling.

[a] Simple means are not generally available to detect mild forms of -thalassemia whose diagnosis still requires the detection of -globin gene deletions. Definitive diagnosis is only required for genetic counseling. Otherwise, a presumptive diagnosis by exclusion is usually sufficient.
[b] By convention, the hemoglobin fraction of the greatest concentration is listed first.

and the thalassemia syndromes, but they are nonspecific. [1] [7] The peripheral blood film also provides important clues to the nature of these disorders. In thalassemia, microcytosis is usually, but not always, present. The Hb E syndromes and, to a lesser extent, the Hb C disorders are also associated with a decreased mean corpuscular volume (MCV). A normal value for the MCV generally excludes the possibility of Hb E or -thalassemia trait. Some milder types of -thalassemia may have normal MCV. In sickling hemoglobinopathies without associated thalassemia or iron deficiency, the erythrocytes are usually normocytic. [8] [9] [10] [11] [12] [13] [14] Cell counters that measure the electrical resistance of cells (Coulter principle) may overestimate the volume of the poorly deformable sickle cell. Analyzers using the light scattering (Mie) principle are more accurate for this determination. [15] With this method, determining the distribution of red blood cell (RBC) density that may be useful for evaluating certain treatments and the clinical course of sickle cell anemia is also possible. RBC distribution width (RDW) may help differentiate thalassemia carriers from people with iron deficiency. In iron deficiency, the RDW is high; in most other conditions with microcytosis RDW is normal. Many different discriminant functions using blood counts and RBC indices have been proposed to allow easy differentiation between thalassemia and iron deficiency. None are sufficiently robust to be recommended for diagnostic purposes.

TABLE 157-2 -- Newborn Screening for Hemoglobinopathies

It is recommended that pretest education be given to prospective parents so that they can better understand the implications of disease detection or the presence of a carrier state.
Hemoglobin separation by isoelectric focusing, high-performance liquid chromatography, or cellulose acetate electrophoresis (pH 8.6).
If a normal result (FA) is obtained, notify the patients that the results appear normal. If clinically or hematologically indicated, the analysis should be repeated at 6 months.
If the study shows an FS or FSC pattern indicating possible sickle cell anemia or Hb SC disease, confirm by citrate agar gel electrophoresis (pH 6.1) and refer the patient for hematologic evaluation, family studies, parental counseling, long-term care, and prophylactic penicillin therapy. Perform confirmatory studies as outlined in the adult protocol at 6 months of age.
If the study shows an FSA, FCA (indicating possible Hb S- or Hb C- $^{+}$ thalassemia) or FE, FC pattern (indicating possible Hb E disease, Hb C disease, or Hb E or Hb C with ^{0} thalassemia, (Hb A_2 is not easily measured in the presence of Hb C or Hb E), confirm by citrate agar gel electrophoresis (pH 6.1) and refer the patient for hematologic evaluation, family studies, parent counseling, and long-term care. Perform confirmatory studies as outlined in Table 157-3 .
If the study shows Hb Barts and Hb H, suspect Hb H disease.
If the study shows an FAS, FAC, or FAE pattern, perform citrate agar gel electrophoresis (pH 6.1). If the results confirm sickle cell trait, Hb C trait, or Hb E trait, the parents should be provided counseling.
If the results indicate the presence of another variant, obtain another sample at 6 months of age and refer to reference laboratory.
If another pattern is obtained, obtain sample at 6 months of age and refer to reference laboratory.
In patients with a presumptive diagnosis of sickle cell disease, Hb E- ^{0} thalassemia, -thalassemia, or Hb H disease, perform confirmatory testing as in Table 157-3 or by DNA analysis that can provide definitive results much earlier than hemoglobin-based studies.

TABLE 157-3 -- Primary Evaluation of Suspected Hemoglobin Disorders

Initial laboratory determinations
Measurement of hemoglobin concentration and packed cell volume (PCV), red blood cell indices (mean corpuscular volume and RDW)
Hemoglobin separation by either isoelectric focusing, cellulose acetate electrophoresis (pH 8.6), or high-performance liquid chromatography, measurement of Hb F
Evaluation
Hemoglobin concentration and PCV measurement

If a normal value is obtained, proceed with other initial studies as clinically indicated.
If a decreased value is obtained, complete the initial studies and if indicated, obtain hematologic evaluation.
If an abnormally high value is obtained, measure hemoglobin-oxygen affinity and complete other studies as clinically indicated.
Measurement of the mean corpuscular volume
If a normal value is obtained, proceed with the other initial studies.
If a decreased value is obtained, quantify Hb A_2 and Hb F and determine the iron and iron-binding capacity or serum ferritin level.
If the findings indicate -thalassemia trait (elevated Hb A_2) obtain appropriate family studies and counseling.
If the findings indicate iron deficiency, complete medical evaluation and treatment.
If normal Hb A_2 and iron values are obtained, if indicated, obtain family studies and specialized laboratory determinations for the detection of -thalassemia or other abnormalities. Refer if needed for counseling or treatment.
Hemoglobin separation studies
If a normal pattern is seen and the other determinations are normal, notify the patient that all results appear normal.
If the hemoglobin separation study shows SS, SA, SC, do confirmatory testing and then refer if needed for hematologic evaluation, family studies, counseling, and long-term care.
If Hb F is elevated and Hb A reduced or absent, consider thalassemia or hereditary persistence of fetal hemoglobin and provide counseling and treatment.
If Hb H is present, provide counseling and treatment.
If an AS pattern is obtained, confirm by citrate agar gel electrophoresis (pH 6.1), and perform sickle solubility test.
If sickle cell trait is confirmed, provide counseling.
If sickle cell trait is not confirmed, refer to reference laboratory to determine the hemoglobin abnormality and provide counseling.
If an AC, CC, AE, or EE pattern is obtained, perform citrate agar gel electrophoresis (pH 6.1) to confirm presence of Hb E or Hb C. Do sickle solubility test.
If solubility test is negative, counsel or treat as needed.
If solubility test is positive, refer to reference laboratory to determine the hemoglobin abnormality and provide counseling.
If another pattern is obtained, refer to reference laboratory to determine the hemoglobin abnormality and counsel.

HEMOGLOBIN DIAGNOSIS BASED ON PROTEIN DETECTION

The following methods all detect abnormal hemoglobin protein or abnormal quantities of normal hemoglobin. Some can be adapted to measure the concentration of hemoglobin fractions.

Commonly Used Techniques

IEF

Hemoglobin is a charged molecule. When a hemoglobin solution, or hemolysate, is applied to a supporting medium like a cast polyacrylamide gel and placed in an electrical field, it migrates to the anode or cathode from its point of application.

Some, but not all, hemoglobin variants have charge differences from normal hemoglobin and migrate differently in an electrical field. For example, sickle hemoglobin (Hb S) has two more positive charges than Hb A per hemoglobin tetramer, Hb C has four more positive charges, and Hb J has two less positive charges. Thus, Hb S migrates more slowly than Hb A toward the anode, Hb C migrates more slowly than Hb S, and Hb J migrates more rapidly than Hb A. Isoelectric focusing uses a pH gradient in a polyacrylamide gel. [16] [17] [18] The electric field also focuses the hemoglobin fractions into sharp, distinct bands at their isoelectric points. As can be seen in Figure 157-1 (bottom), hemoglobin variants that are resolved poorly by electrophoresis are clearly differentiated by this technique. Although more costly than electrophoresis, the resolving power of this technique and the ability to separate Hb C and Hb E has made it the method of choice for initial screening in many laboratories, especially for neonatal screening. However, gels must be evaluated visually and considerable skill is required to interpret isoelectric focusing gels because many extraneous minor hemoglobin bands are often present. Also, quantitation of hemoglobin fractions is difficult and only qualitative information is obtained.

Hemoglobin Electrophoresis at Alkaline pH

Hemoglobin electrophoresis has used various solid support media, but cellulose acetate membranes are now the material of choice. They are inexpensive, can be prepared quickly and easily, provide sharp resolution of hemoglobin bands, allow measurement of the relative quantities of the major hemoglobin bands by densitometry or elution and spectroscopy, and furnish a permanent record after the membranes are fixed and cleared. [19]

However, when applied to newborn screening, Hb A and Hb S are poorly resolved from Hb F, which makes up about 80% of the newborn hemolysate. It is imperative that in newborns another method, such as citrate agar gel electrophoresis, is used with cellulose acetate. Cellulose acetate electrophoresis of some common hemoglobin variants is shown in Figure 157-1 (top) and more complex patterns are diagrammatically depicted in Figure 157-2 .

Citrate Agar Gel Electrophoresis at Acid pH

To more definitively identify abnormal hemoglobins by electrophoresis, examining their mobility using more than one support medium, buffer, and pH is useful. Electrophoresis on agar gels

Figure 157-1 (Top) Cellulose acetate electrophoresis (TRIS-EDTA, borate buffer, pH 8.6) of some common hemoglobinopathies. Migration is from cathode to anode. The samples are: (1) Hb AA (adult, normal); (2) Hb AS (adult, sickle cell trait); (3) Hb SS (adult, sickle cell anemia); (4) Hb SC (adult, Hb SC disease); (5) Hb FA (newborn, normal); (6) Hb FAS (newborn, sickle cell trait); (7) Hb FS (newborn, sickle cell anemia); and (8) Hb FSC (newborn, Hb SC disease). When high concentrations of Hb A and Hb F are present, their resolution is poor. Hb A_2 is a very faint band and does not show up well in all samples. **(Middle)** Citrate agar gel electrophoresis, pH 6.1. The samples are arranged as in the top panel. Note the excellent resolution of Hb F from all other hemoglobin types. The migrations of Hb C and, to a lesser extent, Hb S depend on their concentrations. Thus, there are differences in the mobilities in samples 4 and 8. Controls of appropriate concentrations eliminate any confusion in this regard. **(Bottom)** IEF using pH 59 ampholines in polyacrylamide gel. The samples are arranged as in the top panel. Note that Hb Fis more clearly resolved from Hb A anf Hb S than on cellulose acetate. The high resolving power of this technique leads to the resolution of several minor hemoglobin bands that are not seen by other methods. These bands represent glycosylated and acetylated hemoglobins as well as various methemoglobin hybrids. *(Electrophoretograms courtesy of Robert L. Barlow.)*

Figure 157-2 Diagrammatic representation of some common electrophoretic patterns on cellulose acetate (pH 8.6) and citrate agar gel (pH 6.1). The electrophoretic mobilities of the common variants are listed above the electrophoretograms. The numbers beneath the cellulose acetate electrophoretic patterns indicate the positions of hybrid hemoglobins formed with Hb G Philadelphia (an -globin mutant). Position 1 can be occupied by $_2{}^G{}_2$ (e.g., see Hb AG) or by this hybrid and $_2{}^G{}_2{}^C$ (e.g., see Hb AC/G). Position 2 can be occupied by $_2{}^G{}_2{}^S$ (e.g., see Hb AS/G) or by this hybrid and Hb C (e.g., see Hb SC/G). Position 3 is occupied by $^G{}_2{}_2$ (e.g., see Hb FA/G). Position 4 can be occupied by Hb G (e.g., see Hb AG) or by Hb S and Hb G (e.g., see Hb AS/G).

with citrate buffers at pH 6.1 is the complementary electrophoretic method most often used. In this technique, most hemoglobins move cathodically from their point of origin and with different relative mobilities than seen with cellulose acetate electrophoresis at alkaline pH. [19] [20] Citrate agar electrophoresis can detect some variants that do not separate from Hb A, S, or C by cellulose acetate electrophoresis and should be used with cellulose acetate electrophoresis to resolve confusion in the identification of many common variants. It is especially useful for detecting hemoglobinopathies in the newborn owing to the distinct separation of Hb F from Hb A and the major common variants. The migration patterns of some common hemoglobin variants on citrate agar gels at pH 6.1 are shown in Figures 157-1 (middle) and 157-2 . Hb D and Hb G, which comigrate with Hb S on cellulose acetate, migrate with Hb A on citrate agar (boxes). Citrate agar gel electrophoresis is extremely helpful for differentiating between Hb E, Hb C, and Hb O Arab that all comigrate on alkaline electrophoresis (Fig. 157-2). Thus, citrate agar gel electrophoresis remains one of the few methods that unambiguously distinguishes Hb S and Hb C from other common variants, and it is an important adjunct to cellulose acetate electrophoresis.

HPLC

Hemoglobins can also be separated by HPLC[21] (Fig. 157-3). The advantages of this technique are:

1. The resolution of various hemoglobins, including Hb F, is excellent.
2. The procedure is usually automated by an interface to a microcomputer, which can produce a reliable interpretation of the chromatogram.
3. The various hemoglobin fractions are quantified by this method.

This technique is used as the primary screening procedure in some newborn screening programs. Its limitation is that it cannot always resolve Hb S or Hb C from other variants with the same charge. Also, the equipment is expensive to purchase and maintain and greater technical skills are required with some systems. Reversed-phase HPLC is useful for globin chain separation but is not used for primary diagnosis and is restricted to specialized laboratories. [22]

Figure 157-3 HPLC on a CS-300 cation exchange column (Brownlee Labs). The samples are the same as those in Figure 157-1 .

INTERPRETATION OF COMMONLY USED METHODS OF HEMOGLOBIN SEPARATION

Isoelectric focusing, electrophoresis, and HPLC of hemoglobin are usually done for limited clinical indications: (1) heterozygote screening; (2) neonatal screening for disease carriers; (3) evaluation of anemia, microcytosis, erythrocytosis, syndromes suggesting a sickling disorder; or (4) quantitation of the percentage of normal and abnormal hemoglobin components to monitor chronic transfusion programs. Except for chronic transfusion monitoring and neonatal screening, there is rarely an indication for repeat studies once a diagnosis has been established because after the neonatal period, the vast majority of patients will have a stable distribution of normal and abnormal hemoglobins.

The major clinical questions to resolve when ordering these studies are:

1. Is an abnormal variant present?
2. What is (are) the abnormal variant(s)?
3. How abundant is (are) the variant(s)?
4. Is (are) the variant hemoglobin(s) relevant to the clinical picture that prompted the electrophoresis in the first place?
5. Is a normal hemoglobin present in abnormal quantities?

Most studies will be ordered to evaluate the possibility of a sickle cell syndrome, a thalassemia syndrome, or the presence of common hemoglobin variants such as Hbs C, E, D, O, and G, which often accompany these conditions.

The use of IEF or electrophoresis to detect an unstable hemoglobin as a cause of an unexplained hemolytic anemia, a hemoglobin with altered oxygen affinity as the cause of erythrocytosis or cyanosis, or the presence of methemoglobinemia must be approached with a proper appreciation of the actual diagnostic value of protein-based studies. For these rare abnormal hemoglobins, such studies are usually reliable only for confirmation and further characterization of variants causing these clinical syndromes. Functional tests to establish the presence of an abnormal hemoglobin that is likely to be relevant to these clinical syndromes should be the primary diagnostic maneuvers. A heat or isopropanol stability test and a search for Heinz bodies are obtained when evaluating the possibility of hemolysis from unstable hemoglobins. The P_{50} should be measured when a variant with high- or low-affinity hemoglobin oxygen affinity is suspected. Spectrophotometric analysis for methemoglobin best detects this oxidized form of hemoglobin. As discussed in Chapters 22 and 31 , one should also search for characteristic clinical and hematologic features of these syndromes. Many variants that are unstable or have altered oxygen affinity are silent electrophoretically so that normal electrophoresis will not rule these out. Only if an abnormal band or peak is present will IEF, electrophoresis, or HPLC be informative; the mobility of the abnormal band may also provide clues to the likely identity of the hemoglobin.

Although there are >800 known mutants of hemoglobin, the bulk of abnormal results will arise from a handful of variants like Hbs S, C, D, E, G- Philadelphia, and Lepore. This reflects the fact that sickling syndromes, thalassemias, and a few other hemoglobinopathies account for >99% of the abnormal hemoglobins encountered. Most remaining variants occur rarely and sporadically among human populations and the bulk of them are irrelevant clinically. [23]

Interpreting IEF or electrophoresis results is not always simple because several common variants have identical charge differences and comigrate (Figs. 157-1 and 157-2). For example, on cellulose acetate electrophoresis, Hb D and Hb G comigrate with Hb S, and Hbs E, C, O, and A_2 have identical mobilities. Hb C and Hb A_2 are well separated, however, on citrate agar where Hb A_2 travels with Hb A. Both Hb D and Hb E comigrate with Hb A on citrate agar electrophoresis. By using both techniques of electrophoretic separation distinguishing these

A VARIANT MIMICKING Hb S

A 24-year-old African-American woman with sickle cell disease was referred for further testing because of conflicting results of hemoglobin studies. One child was told at a health fair that she had only normal hemoglobin. But she knew from recent studies in her science class, that if her mother had sickle cell anemia she must have the sickle cell trait. An older sibling had sickle cell trait. The mother had symptoms of sickle cell disease and was anemic.

The pedigree and the results of hemoglobin electrophoresis in the reference laboratory are shown in Figure 157-4 . The mother, (I 2) is a mixed heterozygote for Hb S and the -globin variant, Hb D Los Angeles. This combination results in sickle cell disease because Hb D Los Angeles, present in 0.10.4% of African-Americans, polymerizes with Hb S. Cellulose acetate electrophoresis does not resolve Hb D from Hb S. If this is the sole method of diagnosis, the single major band of Hb S seen in the mother will be misinterpreted as homozygosity for the sickle hemoglobin gene when, in fact, it represents both Hb S and Hb D. Agar gel electrophoresis at pH 6.1 causes Hb D to migrate with Hb A, permitting its distinction from Hb S and producing in I 2 a pattern appearing like sickle cell trait. At the health fair, hemoglobin screening was done by solubility testing only. This method is incapable of detecting variants that do not contain the Hb S mutation and is an ill-advised screening test. Hence the report that this child was normal. When his blood was examined by electrophoresis, (II 2) the pattern on cellulose acetate membranes at alkaline pH, like his sister (II 1), resembled sickle cell trait. But, agar gel electrophoresis, showed only a Hb A band that actually contained both Hb A and Hb D.

Of the several Hb D variants, only Hb D Los Angeles causes severe sickle cell disease when it coexists with Hb S. Hb D should be suspected when a sickle cell trait pattern is accompanied by a negative solubility test. Hb D trait is innocuous.

Figure 157-4 Electrophoretic results and pedigree of a family with the -globin variants Hb D Los Angeles and Hb S. Figure 157-4

A VARIANT MIMICKING Hb D

An African-American couple was planning a family and sought genetic counseling for hemoglobinopathies. After performing both cellulose acetate electrophoresis and citrate agar gel electrophoresis, the mother was diagnosed with sickle cell trait and the father was diagnosed with Hb D Los Angeles trait. The pedigree is shown in Figure 157-5 and the electrophoretic results are included in Figure 157-2 . The couple was told that there was a 25% chance with each pregnancy that the child would have Hb S/D Los Angeles disease (see previous box).

After discussion, the couple decided that the risk was worth taking. When the first child was born, the electrophoretic pattern on cellulose acetate at alkaline pH was confusing because Hb A was present with multiple variant bands and was not consistent with any of the outcomes discussed by the genetic counselor. When specimens of the childs blood and the fathers blood were sent to a reference laboratory, the child was shown to have Hb S trait with Hb G Philadelphia trait, and the father was shown to be a simple heterozygote for Hb G Philadelphia. Hb G Philadelphia is an -globin chain variant that is relatively common in African-Americans. Because it is an -globin chain variant, it affects the electrophoretic mobility of Hb A_2 and Hb F as well as Hb A. Thus, it should have been picked up in the father because of the minor variant Hb A_2 band cathodic to nor al Hb A_2 (Fig. 157-2 , AG). In addition, as an -globin variant, Hb G Philadelphia usually comprises 20% of the total hemolysate whereas Hb D Los Angeles, a -globin variant usually comprises 40%. The quantitative differences between the two hemoglobins, however, is not always reliable because the percentage of Hb D Los Angeles may be reduced in the presence of -thalassemia. Conversely, Hb G Philadelphia is usually linked to a deletion of the other -globin gene in *cis*, and when in *trans* to a chromosome that also has an -globin gene deleted, can comprise up to 45% of the total hemolysate. The multiple bands in the newborn are explained in Figure 157-2 (FAS/G).

The distinction between Hb G Philadelphia and Hb D Los Angeles is not trivial. Unlike Hb D Los Angeles, Hb G Philadelphia does not participate in the polymerization of Hb S. Thus, it would be impossible for these parents to have a child with a clinically significant hemoglobinopathy.

Figure 157-5 Pedigree of a family with Hb S and Hb G Philadelphia. Figure 157-5 .

variants from Hb A is possible. IEF and HPLC used alone can differentiate some of these variants.

The fractional percent of each hemoglobin is an important factor in abnormal hemoglobin identification and in the diagnosis of certain types of thalassemia. For example, Hb A_2 rarely accounts for >6% and is never >12% of the total hemoglobin. A band in the position of Hb A_2 on cellulose acetate that comprises 2550% of the total hemoglobin is probably Hb C or Hb E. Hb Lepore comigrates with Hb S on cellulose acetate but is never >1015% of the total hemoglobin; Hb S, on the other hand, is rarely <2530% of the total hemoglobin.

For most common hemoglobinopathies, IEF or hemoglobin electrophoresis results can usually be interpreted by considering (1) the number of abnormal bands seen and their mobility compared with Hb A; (2) the amount of each hemoglobin found, expressed as percentage of the total; and (3) this information related to the clinical context of the case by considering the patients age, hematologic parameters, and RBC morphology.

In adults, three hemoglobin bands or peaks are present on IEF, cellulose acetate electrophoresis, and HPLC: Hb A ($_2$ $_2$), forming 95% of the total; Hb A_2 ($_2$ $_2$), constituting 23% of the total; and Hb F ($_2$ $_2$), barely visible if at all, and accounting for 0.51% of the total. These components should be used as a frame of reference when evaluating abnormalities; one should focus not simply on the abnormal bands but also on the deviations of the overall pattern from the normal. For example, are the Hb A_2 and Hb F bands present at the appropriate positions but in altered amounts? Are any normal bands missing from their usual positions? **S**pecific globin gene mutations will have very different impacts on this pattern. The hemoglobin profile of a patient represents the complex interaction of products of several globin genes: four loci, two loci, four loci, and two loci. The following principles should be remembered:

1. Mutations affecting the -globin locus will tend to change only *one* band and this will usually be a major band, in terms of the quantity of hemoglobin. This reflects the fact that there is only one copy of the -globin gene per haploid cell and that -globin is a constituent of only Hb A. Two -globin genes are expressed in the diploid erythroid cell, and this accounts for 95% percent or more of the total non-globin chains. Based on gene dosage and this level of output, one would expect, as a first approximation, heterozygosity for a -globin variant to yield a single new band that would account for about half the total hemoglobin. As a corollary, Hb A levels would be reduced nearly half. The actual quantity of normal and abnormal hemoglobins may deviate somewhat from 50% for complex reasons (Chap. 31).
2. In contrast, -globin variants should produce altered Hb A, A_2 , and F bands because each of these hemoglobins contains -globin. Four functioning -globin genes exist in the diploid erythroid cell. Therefore, a mutation of one globin gene might then be expected to create variants forming 25% of the total Hb A, 25% of the total Hb A_2 , and 25% of the Hb F. This approximation is reasonable in practice, but not precise, because the two -globin alleles are not equally expressed. Moreover, the frequent occurrence of -globin variants in areas of the world where -thalassemia is extremely common often results in complex linkages of structural variants to thalassemic alleles, a feature that complicates predictions of the quantity of hemoglobin types based on gene dosage alone. Consequently, -globin variants usually, but not always, amount to 25% or less of the total hemoglobin and tend to produce multiple new hemoglobin bands.
3. -Globin variants will alter a single major hemoglobin band during fetal and neonatal life but, after the first year of life, will alter only the faint Hb F band and are rarely detected.
4. Mutants of the -globin gene will alter only the Hb A_2 band

and are never clinically significant. However, an elevation of the amounts of normal Hb A_2 suggests the probable presence of -thalassemia trait.

The actual amounts of different hemoglobin types that accumulate in vivo depend on the output from individual globin genes, the stability of the globin and hemoglobin products, and on the post-translational assembly of -dimers. From a practical viewpoint, this is most relevant to sickle cell disease.

The more positively charged the -variant, the lower its affinity for -chains. This usually has little impact on the steady-state accumulation of hemoglobin tetramers because a slight excess of -chains is always available to bind non-chains. However, mild forms of -thalassemia are extraordinarily common in the same populations in which sickle cell anemia and other -chain variants are often found. Individuals heterozygous for -chain variants who also carry -thalassemia genes exhibit altered ratios of the individual hemoglobin components. For example, the positively charged ^{S} -globin chain binds -chain less well than does ^{A} -chain. Because -thalassemia limits the number of -chains, normal ^{A} and abnormal ^{S} compete for the limited -globin pool and more Hb A than Hb S forms. Therefore, a typical Hb A/Hb S ratio in individuals with sickle cell trait and -thalassemia is 70:30 compared to 60:40 in uncomplicated sickle cell trait. [24] In contrast, Hb S is *less* positively charged than Hb C. In patients inheriting both ^{S} and ^{C} genes (Hb SC disease), the Hb S/Hb C ratio is 50:50, reflecting a similar affinity of each variant for -globin chains.

Heterozygosity for both Hb S and $^+$ thalassemia causes higher amounts of Hb S than Hb A because the output of the -thalassemia locus is usually reduced to <30% of normal. Typical Hb S/Hb A ratios in Hb S-$^+$ thalassemia are 70:30 to 90:10.[25] [26] [27] Hb E is a very common variant in southeast Asians and is inefficiently expressed (Chap. 29). It rarely forms >2530% of the total hemoglobin. Because it is highly positively charged, its percentage drops dramatically to 1015% in patients who also inherit -thalassemia. Hb C and Hb O, in contrast, usually accumulate in amounts closer to those of Hb S in sickle cell trait. Individuals with Hb E will have a thalassemic phenotype and a lower percentage of the abnormal hemoglobin, which provides strong evidence for the diagnosis.

Hemoglobin Lepore is moderately common among southern Europeans. As noted in Chapter 29 , Hb Lepore arises from fusion of the and genes, eliminating the normal - and -globin loci from that chromosome and replacing them with a poorly expressed thalassemic gene. Therefore, heterozygous Hb Lepore should be suspected if a hemoglobin band migrates like Hb S but comprises only 510% of the hemolysate. Homozygotes for Hb Lepore have no Hb A. The cells of these patients are also profoundly microcytic, like those of patients with classic forms of -thalassemia.

By using these principles, interpretation of the most common types of hemoglobinopathies should be possible. To summarize:

1. -Globin variants affect multiple bands and are usually <25% of total hemoglobin in heterozygotes.
2. -Globin variants affect one band and form 50% of total hemoglobin.
3. -Globin and -globin variants affect only the minor Hb F and A_2 bands in adult life.
4. The fractional percent of the variant can be as informative as its point of migration in the hemoglobin separation system.

ADDITIONAL PROTEIN-BASED METHODS FOR CHARACTERIZING HEMOGLOBINS

The Sickle Solubility Test

Sickle hemoglobin has unique properties that allow its chemical detection. It is insoluble and precipitates in high-molarity phosphate buffer at neutral pH when reduced with sodium dithionite. This observation forms the basis for the sickle solubility tests. [28] The sickle solubility test has no role as a primary screening test or as the sole means of detecting Hb S. It identifies only the presence of Hb S and not its quantity and so cannot distinguish among sickle cell trait, sickle cell anemia, and Hb S-$^{+}$ thalassemia. It cannot detect other nonsickling variants. The solubility test is not applicable in neonates who have a large amount of fetal hemoglobin and fails to detect low concentrations of Hb S. A reliable solubility test is a useful adjunct to the IEF, electrophoretic, or HPLC identification of Hb S in adults. This test is quite specific for Hb S and will help distinguish it from variants that may mimic it electrophoretically. This test is also useful for the identification of the rare variants with two amino acid substitutions, one of which is the sickle mutation (Hb C Harlem, C Ziguinchor, S Antilles, S Travis, S Providence, and S Oman). Solubility tests sometimes give false-positive results but, with reliable reagents, this problem is rare.

SICKLE CELL ^{0} THALASSEMIA

A 34-year-old African-American woman (I 2), early in her third pregnancy, was referred to clarify the possibility of her carrying a fetus at risk for sickle cell disease. Her first child (Fig. 157-6 , II 1) with her first husband (I 1) had sickle cell anemia and was ill. Her second child (II 2) by her present husband (I 3) was also ill. Yet, the referring laboratory told her that because her husband had no abnormal hemoglobin present on IEF, it was not possible for the child to have any type of sickle cell disease.

On IEF, I 1 and I 2 had typical findings of sickle cell trait. II 1 and II 2 had 90% and 80% Hb S, respectively. Their Hb F levels were 7% and 14% with Hb A_2 of 3% and 6%. I 3 had Hb A, 94%, Hb F, 1%, and Hb A_2 , 5%. He was not anemic but had an MCV of 70 fl. A blood film showed microcytosis, target cells, and basophillic stippling.

II 3 is not normal. He has ^{0} thalassemia trait. Therefore, each pregnancy with his current wife has a 25% chance of resulting in a fetus with Hb S-^{0} thalassemia. Hb S-^{0} thalassemia is a phenocopy of sickle cell anemia and patients can have all of the complications of this disease. Although an abnormal hemoglobin is not found in carriers of -thalassemia, microcytosis and elevated Hb A_2 suggest this diagnosis.

Figure 157-6 Pedigree of family with Hb S-^{0} thalassemia. Figure 157-6

Quantitation of Hemoglobin and Globin Chain Fractions

Measuring the fractional percentages of the hemoglobin components present can be important. Quantitation of Hb S and Hb A levels help distinguish Hb S-$^{+}$ thalassemia from sickle cell trait; the proportion of Hb S in sickle cell trait is often reduced in the presence of -thalassemia; the quantitation of Hb A_2 in adults is important because it is so often elevated in -thalassemia carriers. [29]

Several reliable procedures for hemoglobin quantitation exist and include elution from cellulose acetate strips and spectrophotometric analysis of the eluted fraction, densitometry of stained and cleared cellulose acetate strips, chromatography on minicolumns, and HPLC. [30] The elution method is highly reliable for measuring Hb A_2 and variant hemoglobin levels in adults. Because Hb F migrates between Hb A and Hb S, this method is not used for newborn samples. Densitometry is unreliable for measuring Hb A_2 and Hb F.[31] [32] The minicolumn method is reliable but has been largely supplanted by HPLC, [33] which is probably the method of choice for quantitation of the major hemoglobins in the newborn.

The quantitation of Hb F is extremely important in the diagnosis of the thalassemias, sickle cell disease, the Hb E syndromes, and the hereditary persistence of fetal hemoglobin (HPFH) syndromes in adults. Most human hemoglobins rapidly denature at alkaline pH and can then be precipitated with ammonium sulfate. Fetal hemoglobin, however, is not denatured and remains soluble under these conditions. The alkali resistance of Hb F provides a rapid and simple technique for quantifying Hb F in human blood samples.[34] Fetal hemoglobin can also be quantified by HPLC and immunologic methods.[33] [35] The analysis of the distribution of Hb F in the RBC is useful in distinguishing among various forms of -thalassemia and HPFH. [36] The ^{A} - and ^{G} -globin chains of Hb F can be separated and quantified by reversed-phase HPLC, and this is useful for differentiating among the types of HPFH. [37] Hb F-specific antibodies can measure the number of F cells and the amount of Hb F per F cell.[38] [39]

Mass Spectroscopy

Replacing the laborious methods of tryptic peptide separation and amino acid analysis by HPLC, mass spectrometric methods allow the protein-based detection of uncommon or unique globin structural variants. Using electrospray ionization mass spectrometry, differences among most abnormal globins may be detected. [40] When this method is insufficiently sensitive, other forms of mass spectrometry, like liquid secondary ion, fast atom bombardment, and tandem mass spectrometry are used to

distinguish among abnormal tryptic fragments of globin and analyze the sequence of their amino acids. [1] These analyses have limited applications and are restricted to a few specialized laboratories.

Capillary Isoelectric Focusing

In this recent modification of thin-layer IEF discussed above, hemoglobins are separated by their isoelectric points in pH gradients established in fine capillary tubes. Available commercial systems allow automated data analysis, require small sample size, are rapid and sensitive, conserve expensive reagents, and provide quantitative information.[41] These advantages argue for the more widespread application of this procedure as a primary screening technique.

Immunologic Detection

Specific antibodies can be raised to normal hemoglobin and some hemoglobin variants. [35] [42] The major applications of immunologic detection of hemoglobin are for the measurement of Hb F by radial immunodiffusion[43] and for quantifying the -globin chain of Hb Barts, a technique of value in the detection of carriers of the common type of severe thalassemia in Asians.[44] [45]

Hemoglobin Functional Studies

Some variant hemoglobins are characterized by abnormal functional properties. Variants with abnormal oxygen affinity may be recognized by abnormal oxygen dissociation curves or determination of the P_{50}. Several automatic methods of obtaining oxyhemoglobin dissociation curves have been described. [46] Most unstable hemoglobins have been found to precipitate more readily than Hb A when exposed to heat or when incubated at 37°C in a buffer containing isopropyl alcohol. [47] The Hb M variants may be identified by their spectral changes although often their detection is very difficult.

DNA-BASED METHODS

DNA-based methods of detecting hemoglobin abnormalities have the advantage of specificity and the current disadvantage of cost and availability. Most often they are limited to reference laboratories. They are limited in that they do not provide important ancillary information that may come with the protein-based techniques, like levels of Hb F, which are prognostically useful in sickle cell anemia.

A mutation that causes a hemoglobinopathy or a thalassemia can be precisely identified in material as limited as a single cell or blastocyst, enabling preimplantation diagnosis.[48] In principle, hemoglobin disorders can be detected by analyzing fetal cells that find their way into maternal blood, [49] but, more practically, DNA-based methods lend themselves to antenatal diagnosis. Here, different methods, covered elsewhere in this volume, like single-strand conformation polymorphism, denaturing gradient gel electrophoresis, restriction endonuclease analysis of mutations, detection of mutations by allele-specific oligonucleotide probes, and mutation detection by DNA sequencing, have all been used. [4]

-Thalassemia gene identification using specific oligonucleotides is available commercially and is useful for heterozygote detection in selected populations, often as an antecedent to antenatal diagnosis. Rapid methodologic advances coupled with price decreases may soon see DNA-based techniques used in neonatal screening programs.

LABORATORY PROTOCOLS

Laboratory methods should be based on the reason for abnormal hemoglobin detection. Table 157-1 illustrates useful protocols for heterozygote detection, Table 157-2 provides an approach to neonatal disease detection, and Table 157-3 illustrates the evaluation of suspected hemoglobin abnormalities in patients.

Chapter 158 - Antenatal Diagnosis of Hematologic Disorders

Kim Kramer
Harvey J. Cohen

INTRODUCTION

The past three decades have taken the concept of antenatal diagnosis from a blind needle uterine insertion for the acquisition of amniotic cells to a refined ultrasound-guided transcervical swab for villus sampling. In the past, karyotyping was performed in 4 weeks; today, single gene defects can be detected in a matter of hours. What once necessitated 50 ml of amniotic fluid in the 20th week of gestation now routinely requires as little as 20 mg from chorionic villus sampling at 6 weeks of gestation.[1] Indeed, we are now able to detect single DNA base pair alterations in one blastomere from an extracorporeal embryo.

With this explosive surge in methods to diagnose molecular defects earlier, more quickly, and more effectively comes the need for earlier, safer, and more effective interventional and therapeutic techniques. The practice of antenatal diagnosis once served only for elective termination of fetuses affected by a known genetic

disorder. It is now possible to provide in utero treatments that can alter the natural history of many genetic disorders. This is of particular relevance for the hematologist, who is often involved in an entire array of clinical conditions that can be detected and treated in the antenatal period.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

METHODS OF ANTENATAL DIAGNOSIS

Prenatal diagnostic techniques differ in their indications, invasiveness, diagnostic accuracy, and risks. The choice of technique depends on the gestational age, indications for the procedure, safety considerations, turnaround time, and maternal and fetal risks. Before choosing a procedure, thorough consideration must be given to the potential use of the information obtained.

Amniocentesis

The concept of obtaining amniotic fluid cells shed from fetal skin, lung, and gastrointestinal tract for diagnostic purposes had its origin in 1930 in the setting of amniography.[2] It was not until the 1950s, however, that amniocentesis was introduced as a method for the diagnosis and management of erythroblastosis fetalis [3] and sex chromatin analysis.[4] In 1966, Steele and Breg[5] cultured amniotic fluid cells in sufficient quantity to be karyotyped, leading to the first in utero diagnosis of Down syndrome by Valenti et al. in 1968.[6] By 1970, an estimated 10,000 procedures had been performed in high-risk pregnancies, with a fetal morbidity and mortality rate of <1%.[7]

Although routine amniocentesis is often performed at 1620 weeks gestation, the clinical and laboratory experience with first-trimester procedures is encouraging. [8] After a thorough ultrasound examination of the fetus, placenta, and uterus, a 22-gauge spinal needle is inserted transabdominally or transvaginally. [8] Approximately 1 ml/week of gestation is withdrawn; successful fluid acquisition approaches 99.8% and can be used for cytogenetic and biochemical studies. [8] With enhanced cell growth, prenatal diagnosis for some disorders is possible as early as 5 days; [9] reliable karyotyping is completed by approximately 14 days. [10] The procedure boasts an extremely high diagnostic reliability, with an estimate of 1 miskaryotype per 5,000 procedures and a culture failure rate of <1%. [11] Procedure-related fetal loss rate is approximately 0.5%.[12] Complications are rare and usually minor; they include amniotic fluid leakage, vaginal cramping, fetal trauma, blood-stained amniotic fluid, and infection.[13] Concerns over the possibility of positional deformities and pulmonary hypoplasia due to removal of amniotic fluid early in gestation have been raised, although no conclusive evidence for such associations exists. [14]

Chorionic Villus Sampling

Fetal chorionic villi were successfully sampled using a transvaginal hysteroscope as early as 1968, [15] although chromosome analysis from chorionic villus sampling (CVS) in the first trimester became possible only in the early 1980s. Since that time, CVS has emerged as a means of making earlier, quicker, and more reliable prenatal diagnoses. The test, commonly performed under ultrasound guidance at 912 weeks gestation, involves the aspiration of 2030 mg of villi from the placenta via a transabdominal or (more conventionally) a transcervical approach (Fig. 158-1).[16] Chorionic villi may be analyzed directly for a rapid karyotype or cultured for DNA and enzyme analysis.[17] The polymerase chain reaction (PCR) has shortened the diagnostic time to a few hours. In general, CVS permits earlier detection of a genetic defect and provides a greater number of cells for genetic studies. These advantages need to be weighed against a slightly poorer performance with respect to fetal loss rate and diagnostic accuracy. Unlike amniocentesis, CVS does not allow the diagnosis of structural problems such as neural tube defects. Other complications with CVS exist, including fetal hemorrhagic lesions, [18] [19] post-CVS amnionitis,[20] and reported limb and

Figure 158-1 Chorionic villus sampling depicting the transabdominal and transcervical approach.

oromandibular malformations. [21] No clear proof of limb-reduction abnormalities exists, although the risk appears greatest in CVS obtained prior to 9 weeks gestation.[17] Fetomaternal hemorrhage occurs in up to 50% of women and appears to be independent of technical approach. [22] Maternal contamination is a potential pitfall that can be avoided with experience in the dissection and preparation of the samples for assay. [23] Currently, CVS remains the optimal procedure for diagnosing many metabolic disorders and single gene defects.

Fetal Blood Sampling

In utero blood sampling was introduced in 1973 via fetoscopy. A fiberoptic endoscope is passed transabdominally into the amniotic cavity, followed by the passage of a needle through the fetoscope into the umbilical vessels for blood acquisition. [24] Although it is a reliable method of obtaining pure fetal blood, procedure-related fetal deaths approach 25%.[25] Other methods of fetal blood acquisition include embryoscopy, placental aspiration, hepatic vein sampling, and cardiac puncture. Since 1983, fetal blood sampling (FBS), also called cordocentesis, has become a safe and reliable means of accessing the fetal circulation. [26] It is generally performed from 15 weeks gestation until the last trimester of pregnancy but may be performed earlier. [27] Under direct high-resolution ultrasound guidance, a spinal needle is inserted transabdominally through the uterus and into the umbilical vessel. Approximately 13 ml of blood is aspirated, and the purity of the sample is assessed to determine if there is maternal blood or amniotic fluid contamination. [28] Difficulty in obtaining the sample occurs if fetal movements are frequent and strong enough to dislodge the needle, if the placenta is placed posteriorly, if the umbilical cord is small, and in the case of oligohydramnios and maternal obesity, causing poor ultrasound visualization.[29] Indications for FBS continue to decrease as more congenital disorders are diagnosed earlier with molecular techniques by CVS and amniocentesis. The most common indications for FBS in the 1990s include the assessment and management of alloimmunization disorders, intrauterine growth retardation, nonimmune hydrops, fetal blood pH and acidbase status, neural tube defects, and congenital infections. [30] FBS is also used for rapid karyotyping, and if DNA studies are not informative. Serious complications, although

unusual, include bleeding from the umbilical puncture site, fetal bradycardia, [31] irregular uterine contractions, chorioamnionitis, cord hematoma, premature rupture of membranes,[26] and fetomaternal hemorrhage. [32] The procedure-related fetal loss rate is approximately 12%. [31] [33] Gestational age and duration of the procedure appear related to fetal loss within 48 hours of FBS. [34] Evidence suggests that the risk of FBS is increased in abnormal pregnancies, most likely due to underlying pathology.[35] The success of FBS, in part, requires a highly capable clinical laboratory aware of the most commonly requested fetal serologic, hematologic, and serum chemistry studies. FBS remains the most desirable way of accessing the fetal circulation for both the diagnosis and therapeutic management of numerous congenital hematologic disorders.

Noninvasive Prenatal Diagnosis

Every known invasive prenatal procedure carries the risk of fetal death. Retrieval of trophoblasts from the lower uterine cavity has been proposed as a minimally invasive method of obtaining fetal DNA.[36] [37] It remains to be established whether trophoblasts are present in most or only a few transcervical samplings. The

reliability of transcervical sampling has been questioned by several investigators [38] but may ultimately be improved with refinements in technique.

Several attempts have been made to detect fetal cells in the maternal circulation for the noninvasive diagnosis of selected inherited disorders. More than a century has elapsed since Schmorl, a German pathologist, identified trophoblasts in lung tissue of women dying of eclampsia. [39] In the 1950s, trophoblasts were detected in the uterine vein,[40] and Kleihauer found fetal cells in maternal blood by using a stain for fetal hemoglobin. [41] Nearly three decades have passed since Walknowska et al.[42] cultured fetal lymphocytes from maternal blood for karyotyping. Recent efforts have focused on defining the cell types to be retrieved, the quantity of fetal cells in maternal blood, fetal cell enrichment techniques, and the feasibility of clinical applications.

Target fetal cell types from maternal blood include trophoblasts, lymphocytes, granulocytes, nucleated erythrocytes, and platelets (Table 158-1). Currently, the fetal nucleated erythrocyte appears to be the most desirable target cell. The frequency of fetal erythrocytes and CD34+ hematopoietic progenitor cells in sorted subpopulations from maternal blood was recently determined by Little et al. [43]

Techniques of fetal cell separation include fluorescent flow cytometry, fluorescence-activated cell sorting, and the use of immunomagnetic beads. Improved fetal nucleated erythrocyte sorting has recently been reported using intracellular antifetal hemoglobin antibodies [44] and fetal thymidine kinase assays.[45] Genetic analysis has been accomplished by PCR amplification of fetal Y chromosome and paternal-specific sequences, and by fluorescent in situ hybridization.

The retrieval of fetal cells from maternal blood currently remains in the investigational phase because of low sensitivity and low specificity. Success has been met where a known unique paternal mutation or polymorphism exists. Fetal inheritance of a paternal beta-globin mutation, Hb Lepore-Boston, has been detected in maternal blood,[46] as has paternally inherited -thalassemia mutations.[47] Limited experience exists for the diagnosis of other genetic disorders, such as sickle cell anemia,[48] and for the determination of fetal Rh(D) status.[49] The possibility of diagnosing X-linked inherited diseases in maternal blood was recently reported by Sekizawa et al.,[50] who diagnosed Duchenne muscular dystrophy using a single fetal erythrocyte in maternal blood. Successful efforts have been reported for the diagnosis of fetal aneuploidy and fetal sex determination. [51] It remains to be determined if there is an ideal gestational age for sampling, whether ABO incompatibility limits the availability of fetal cells, and whether abnormal pregnancies affect the fetal cell yield. [52] Although techniques to improve diagnostic accuracy are needed, the future of noninvasive prenatal testing is optimistic.

WHITE BLOOD CELL DISORDERS

Severe inherited immunodeficiency states encompass a wide spectrum of disorders involving absent or abhorrent components of the lymphoid or phagocytic system. Although rare, many of these disorders are life-threatening (Table 158-2). The issue of prenatal diagnosis arises in families that already have a severely affected child. A prerequisite for antenatal diagnosis includes extensive phenotypic or genotypic analysis of the index patient.

The relatively late development of the fetal immune system largely restricts confident phenotypic antenatal diagnosis to fetal blood analysis during the second trimester of pregnancy. The most primitive lymphoid stem cell arises in the fetal liver by 7 weeks gestation and is detectable in the developing thymus by 89 weeks. [53] Phenotypically mature T lymphocytes can be detected in the fetal circulation and peripheral lymphoid tissues by 1213 weeks. [54] Synthesis of IgM, IgG, and IgA has been demonstrated by B lymphocytes at this stage.[55] Likewise, the synthesis of fetal liver complement components C2, C3, C4, C5, and Clq inhibitor takes place in the first trimester.[53] Insufficient numbers of neutrophils in the fetal circulation before 7 weeks

TABLE 158-1 -- Target Fetal Cells in the Maternal Circulation

Cell Type	Advantage	Disadvantage
Trophoblasts	Unique morphology Uniquely fetal	Possible mosaicism, often filtered in the pulmonary circulation Difficult to analyze by fluorescent in situ hybridization [291] Specificity of antibodies unclear
Lymphocytes	May be sorted by HLA status in selected cases	Persistence in maternal circulation as long as 27 years [292] Not inherently different from maternal cells Produced late in gestation
Granulocytes	Functional assessment of single cells	Least studied Frequency of fetal cells not consistent
Nucleated red cells	Common in fetal blood, rare in adult blood Amenable to cytogenetic analysis Express unique antigens and unique fetal hemoglobin for positive identification	Increased number in preeclampsia of maternal vs. fetal origin [293]
Platelets		Lack genomic DNA

TABLE 158-2 -- Hematologic Disorders Diagnosed Antenatally

White blood cell disorders
Chronic granulomatous disease
Chédiak-Higashi syndrome
Wiskott-Aldrich syndrome
Leukocyte adhesion deficiency
X-linked agammaglobulinemia
X-linked lymphoproliferative disorder
Ataxia-telangiectasia
Severe combined immunodeficiency (SCID)
X-linked SCID
ADA-deficient SCID
Hyper-IgM immunodeficiency
Bare lymphocyte syndrome
Human immunodeficiency disease (HIV)
Platelet disorders
Alloimmune thrombocytopenia
Autoimmune thrombocytopenia
Glanzmanns thrombasthenia
Bernard-Soulier syndrome
Thrombocytopeniaabsent radii syndrome
Gray platelet syndrome
May-Hegglin syndrome
Congenital amegakaryocytic thrombocytopenia
Red blood cell disorders
Hemoglobinopathies
Sickle cell anemia
-thalassemia
-thalassemia
HbE, HbC, HbD, HbH, Hb Lepore, HbO-Arab
Alloimmunization
Rh disease
Kell incompatibility
RBC enzyme deficiency (G6PD, PK)
Congenital anemias
Fanconi anemia
Diamond-Blackfan anemia
Nonimmune hydrops fetalis

Coagulopathies
- von Willebrand disease
- Hemophilia A
- Hemophilia B
- Isolated factor deficiencies
- Hypo- or A-fibrinogenemia
- Thrombophilia
- Protein C deficiency
- Protein S deficiency
- Antithrombin deficiency

gestation restrict phenotypic identification of phagocytic disorders until the second trimester. [56] Entertaining earlier antenatal diagnosis of the congenital white blood cell disorders has only recently become possible with molecular techniques and a greater understanding of the associated genetic defects.

Chronic Granulomatous Disease

Granulocyte function in chronic granulomatous disease (CGD) has been evaluated by demonstrating the inability of neutrophils to reduce nitroblue tetrazolium (NBT) dye to blue formazan particles, as well as absent superoxide anion production and NADPH oxidase activity. [57] Prenatal diagnosis of CGD was first performed by Newberger et al.[58] in 1979; they adapted the NBT test on blood samples obtained by placental vessel puncture visualized by fetoscopy. Unsuccessful attempts were made at performing NBT reduction on cultured amniotic fluid cells. [59] No consistent differences have been observed between normal cultured amniotic cells and those from CGD patients.[60] Matthay et al.[61] adapted the luminol-enhanced chemiluminescence method on pure fetal blood samples to exclude the diagnosis in one fetus at risk. Recently, CGD has been diagnosed postnatally by a single cell granulocyte oxidative burst activity by flow cytometry. [62] Routine flow cytometric diagnosis appears reliable.[63] Analysis at the DNA level became possible as our understanding of the genetic heterogeneity of the disease improved. CGD is caused by a diversity of mutations that may affect multiple genes.[64] Using closely linked flanking markers to a part of the NADPH oxidase complex, Lindof et al. [65] performed the antenatal diagnosis of X-linked CGD on cultured amniotic fluid cells. In 1990, Nakamura et al. [66] demonstrated monoclonal antibody staining against cytochrome b558 villus macrophages in an unaffected fetus at 8 weeks gestation. More specifically, direct sequence analysis of amplified fetal DNA may demonstrate a single base pair substitution of a known genetic defect in question. [67] [68]

Chédiak-Higashi Syndrome

Antenatal assessment of Chédiak-Higashi syndrome has primarily relied on the secondary manifestations of the disorder, including the identification of characteristic abnormally large acid-phosphatase-positive lysozomes present in neutrophils, eosinophils, basophils, lymphocytes, and fibroblasts. [69] Identification of peroxidase-positive granules in neutrophils from midgestation FBS has led to the positive phenotypic identification of affected fetuses. [69] [70] Phenotypic expression has also been tested in cultured amniotic fluid cells in the feline model [71] and in human chorionic villi.[69] Recent identification and mutation analysis of the complete Chédiak-Higashi gene on chromosome lq42-43 will allow more precise genotypic diagnosis. [72]

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency is a rare autosomal recessive disease caused by deficient leukocyte surface glycoproteins (integrins) that leads to severe and often fatal infections. Prenatal diagnosis is possible by FBS at 2022 weeks gestation by demonstrating integrin expression on fetal leukocytes. [73] Distinct mutations of the gene encoding the common subunit CD11/CD18 shared by three leukocyte surface glycoproteins (integrins) have been identified and mapped to chromosome 21, [74] [75] suggesting the potential of using PCR-amplified DNA from CVS or amniocentesis for antenatal diagnosis.

Severe Combined Immunodeficiency Syndromes

The severe combined immune deficiency (SCID) syndromes include a heterogeneous group of disorders resulting in profound impairment of both cellular and humoral immune function. The inherited defect is largely X-linked, caused by mutations in the IL-2R chain gene. [76] About 20% of SCID lesions are associated with adenosine deaminase (ADA) deficiency and purine nucleoside phosphorylase deficiency, resulting in a virtual absence or functional deficiency of T and B lymphocytes. [77] The high lethality of the disorder makes prenatal diagnosis and identification of the carrier states desirable. Prenatal diagnosis is possible by immunophenotypic, functional, and molecular analysis.[78] The value of FBS in the diagnosis of various forms of SCID has been recognized by many investigators. [79] [80] [81] [82] As reference ranges of fetal leukocyte and lymphoid subpopulations have been established, monoclonal antibodies and flow cytometry may be used to determine cell subsets in fetuses at risk and to assess IL-2R expression.[78] [83] T- and B-lymphocyte HLA-DR and $_2$ microglobulin can also be detected by immunofluorescence.[84] A profound lymphopenia and an absence of T- and B-cell markers in pure fetal blood confirm the diagnosis of SCID. [84] Where ADA deficiency is the known defect, ADA and dATP measurements in chorionic villi, fetal red cells, and cultured amniotic fluid cells may be used to perform rapid prenatal diagnosis. [85] [86] [87] The most

promising method is the genotypic analysis of SCID by identification of the IL-2R mutation [78] [88] or direct mutation analysis of the ADA gene.[89]

The bare lymphocyte syndrome is a SCID variant in which T and B lymphocytes lack expression of HLA antigens. [90] Demonstrating HLA antigen expression on fetal blood lymphocytes using immunofluorescent monoclonal antibodies and flow cytometry may exclude the diagnosis in infants at risk. [90] Recently, a restriction fragment length polymorphism (RFLP) has been identified, allowing rapid genotypic analysis for a subgroup of patients with HLA class II-deficient immunodeficiency. [91]

Wiskott-Aldrich Syndrome

The X-linked recessively inherited Wiskott-Aldrich syndrome (WAS) is characterized by eczematoid dermatitis, thrombocytopenia, and reduced cellular and humoral immunity. The absence of a defined lymphocyte population or a constant immunologic abnormality has made phenotypic antenatal diagnosis difficult. Normal mean platelet volumes and platelet counts by FBS have been used to exclude the diagnosis, [92] but these measurements are unreliable where abnormal hematologic parameters progress after birth.[93] Kenney et al.[94] found that patients with WAS have structurally abnormal lymphocytes with short blunted microvilli under electron microscopy; they used this morphologic marker to correctly identify an affected fetus. Progress in genotypic diagnosis was made by indirect DNA analysis combined with studies of X-chromosome inactivation patterns as early as 9 weeks gestation. [95] [96] [97] [98] The WAS gene is mapped to the proximal arm of the X chromosome between Xp11.22-11.3.[99] [100] Several mutations and DNA flanking markers have been found in the WAS gene that facilitate reliable diagnosis of both carriers and affected fetuses.[101]

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia is a congenital antibody deficiency disease caused by defective B-lymphocyte differentiation due to a defective cytoplasmic tyrosine kinase (BTK). In families seeking genetic counseling, carrier status can be identified by assessing nonrandom X-chromosome inactivation patterns in the maternal B-lymphocyte population.[102] [103] [104] [105] [106] Because of the variability in the number of B cells in the midtrimester fetus, prenatal diagnosis using lymphocyte subpopulations is helpful in excluding the disease only if a normal number of cells are seen. [103] The BTK gene has recently been cloned and the genomic organization determined.[107] Several flanking markers surround the locus and have been used to diagnose the disorder as early as 10 weeks gestation using CVS. [104] Nonallelic genetic heterogeneity with RFLPs may complicate the diagnosis, although a method of calculating this risk has been developed. [105] [106] An ordered approach to diagnosis includes adequate tests for primary carrier status, linkage analysis using RFLPs where applicable, direct mutational analysis when possible, and confirmational immunologic studies later in gestation.

Hyper-IgM Syndrome

Patients with the hyper-IgM syndrome have a primary underlying immune disorder caused by the inability to initiate switching from one immunoglobulin subtype to another. The disease is inherited in an X-linked or autosomal recessive manner. Prenatal diagnosis by immunophenotypic analysis was limited due to the absence of

immunologic abnormalities during fetal development and the random pattern of X inactivation in lymphoid cells of obligate carriers. [108] Recently, X-linked hyper-IgM immunodeficiency was diagnosed at 12 weeks gestation using a highly polymorphic dinucleotide repeat in the CD40 ligand gene of fetal DNA isolated from CVS. [109]

X-Linked Lymphoproliferative Disorder

The X-linked lymphoproliferative disorder is characterized by a selective severe or fatal immunodeficiency to the Epstein-Barr virus. [110] The X-linked lymphoproliferative mutation has been mapped to the distal arm of the X chromosome at Xq25-q26. [111] [112] Prenatal diagnosis has been reported using multiplex PCR with highly polymorphic markers on CVS-obtained fetal DNA. [113]

Immunodeficiency with Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an autosomal recessive disorder characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, immunodeficiency, increased incidence of malignancy, and a 23 times increased sensitivity to ionizing radiation. The underlying molecular abnormalities all result in defective DNA replication and repair. Prenatal diagnosis is possible by demonstrating spontaneous chromosome breakage and radioresistant DNA synthesis in cultured villus cells and/or amniotic fluid cells, and by analyzing the response of amniocytes to x-ray stress. [114] [115] The presence of a clastogenic factor, a low-molecular-weight protein in the serum of affected patients, has also been identified in the amniotic fluid of an affected fetus. [115] The first prenatal diagnostic testing for AT by genetic analysis was performed by Gatti et al.[116] in 1993. The entire coding sequence of the AT gene has recently been characterized, making possible mutation screening in carriers and fetuses at risk.[117] A high frequency of distinct AT gene mutations has been identified. [118]

Human Immunodeficiency Virus Infection

Until recently, no treatment could reduce the risk of maternalfetal human immunodeficiency virus (HIV) transmission. In the last 5 years much knowledge concerning the transmission of HIV in the perinatal period has been gained. Efforts have focused on effective screening programs for HIV infection in pregnant women, patient education, and interruption of the transmission cycle.

The United States Centers for Disease Control and Prevention has published guidelines urging health care providers to offer HIV counseling and antenatal HIV testing to all women.[119] Voluntary universal antenatal HIV screening programs in pregnant women appear to result in a higher percentage of women accepting testing and a subsequent increase in the detection of previously unrecognized infections. [120] Reasons for declining testing have included poor patient knowledge about vertical transmission, the assumption of no risk, being in a stable relationship, not wanting to think about HIV when pregnant, and not wanting to know if one is HIV-positive.[121] Culturally and linguistically appropriate efforts have improved womens knowledge regarding vertical transmission and treatment options. [122]

The risk of vertical transmission is reduced by the administration of maternal and neonatal zidovudine therapy [123] and the use of bottle feeding.[124] This has contributed to practical and ethical arguments concerning mandatory prenatal HIV screening for all pregnant women. Prenatal testing for fetal HIV infection has emerged as a challenging task. Fetal HIV infection probably occurs after 13 weeks gestation, and concerns have been raised about the small but serious risk of fetal exposure to maternal HIV due to fetomaternal hemorrhage with amniocentesis, FBS, or CVS.[125] Routine fetal serologic studies are of limited use, given that almost all children of HIV-infected mothers have normal immunologic findings, even at birth. [126] HIV reverse transcriptase activity and viral antigens have been demonstrated in amniotic fluid as early as 15 weeks gestation, although it is unknown if such a finding invariably means fetal infection. [127] [128] More diagnostic is the finding of HIV antigens or

genome in fetal cells obtained by FBS. Given the infrequent early in utero HIV transmission rate, midtrimester FBS is currently of limited value to women in making reproductive decisions.[129]

RED BLOOD CELL DISORDERS

Hemoglobinopathies

The hemoglobinopathies are the most commonly inherited recessive diseases in humans, with an estimated 240 million heterozygotes worldwide and 200,000 homozygotes or compound heterozygotes born each year.[130] The global nature of these conditions, coupled with the desire for disease prevention and prediction, has propelled molecular biology research. Application to antenatal assessment has progressed at a comparable rate, leading to the International Registry for Prenatal Monitoring of Hereditary Anemias, a documentation of the thousands of individuals examined to date. [131] Initial methods of testing involved determining the relative rates of fetal , , and chain synthesis. This has gradually been replaced by DNA analysis of fetal amniocytes or chorionic villi. The combination of heterozygote screening, counseling, and prenatal testing has dramatically reduced the number of affected infants born in many countries throughout the world. [130]

Sickle Cell Anemia

Hollenberg et al.[131] first predicted that the detection of sickle cell hemoglobin in utero could identify affected fetuses. In 1972, Kan et al. [132] detected sickle cell trait in a 15-week-old fetus by incubating umbilical cord blood with radioactive leucine, followed by separation of the globin chains using carboxymethyl cellulose chromatography (CMC). Other methods for globin chain analysis include electrophoresis on polyacrylamide gels containing urea, acetic acid, Triton X-100, and hemoglobin immunofluorescence.[133] [134] High-pressure liquid chromatography (HPLC) by ion exchange correlates highly with CMC and can separate globin chains to provide an answer in 15 minutes. [135] Isoelectric focusing is an alternative method for analyzing hemoglobin tetramers instead of globin chain synthesis in pure fetal blood samples.[136] [137] Maternal blood contamination is a potential source of error in any of the above methods, skewing globin chain percentages. [138]

Kan and Dozy[139] first performed antenatal diagnosis of sickle cell disease at the DNA level by indirect molecular techniques. Polymorphism of the DNA sequence adjacent to the -globin gene was established, and the normal HbA fragment was differentiated from the HbS allele of a different length. Several altered restriction endonuclease sites have been found using the enzymes HpaI, DdeI, MstII, CvnI, and OxaNI. [140] [141] PCR allows restriction digestion and direct visualization of DNA fragments more rapidly and without the need for radioisotopes. [142] Direct assays detecting the HbS mutation in enzymatically amplified fetal DNA are possible using allele-specific oligonucleotide probes. [143] [144] The sickle cell base alteration has also been detected by the color complementation methods with allele-specific oligonucleotide primers conjugated to fluorescein, described by Chehab and Kan. [145]

Thalassemias

In contrast to the structural variant of HbS, the thalassemias are characterized by a decreased production of - or -globin chain synthesis. Screening programs and elective reproduction cessation were the initial methods of preventing the birth of an affected child. More precise methods were devised using second-trimester FBS and evaluation of globin chain synthesis. Knowing that a rise in the / ratio occurs normally throughout gestation, CMC was used to calculate the / ratio. Quantitative analysis of -chain production was used to suggest the presence of the homozygous state. Diagnostic errors were known to occur in patients having high -producing + thalassemia major and low -producing -thalassemia trait.[131] CMC was gradually replaced by HPLC, [146] isoelectric focusing,[147] and gel electrophoresis.[148] Other mutant -globin chain variants such as HbE, Hb Lepore, HbC, and Hb O-Arab have been detected by CMC using fetal blood. [131] As the molecular defects in the -globin gene producing thalassemia were characterized, restriction enzymes, gene mapping, and oligonucleotide probes specific for point mutations of interest have been more commonly used for antenatal diagnosis.[130] [149] A rapid and simple modified PCR-based method has been developed for the detection of the most common -thalassemia and HbE mutations in target populations. [150] Although rarer alleles are expected to be identified in the future, it is estimated that the 54 known alleles account for 99% of -thalassemia gene defects in the world.[149] The combination of PCR and specific restriction enzymes or probes is currently the most commonly used method of antenatal assessment and continues to revolutionize programs aimed at disease prevention.

Detecting -thalassemia by gene deletion assessment was performed in 1976 by Kan et al. [151] A quantitated reduced amount of fibroblast DNA hybridization could indicate -thalassemia trait, Hb H disease, or -thalassemia fetal hydrops syndrome. [151] [152] Hybridization techniques can detect rarer forms of thalassemia caused by gene deletions,[153] as can the lack of amplified globin gene DNA.[154] Recently, a simple monoclonal antibody test was described as having a high sensitivity and specificity in Southeast Asian populations carrying the (- ^{SEA}) deletion.[155] This test may be applied to the screening of pregnancies at risk for hydrops fetalis due to homozygous (- ^{SEA}) deletions.

Rh Disease

In the 1950s, severe hemolytic disease due to red blood cell alloimmunization accounted for >1,000 deaths per year. [156] Since the introduction of anti-D immunoglobulin prophylaxis in the 1970s, a dramatic decrease to 34 deaths per year has occurred. [157] Nevertheless, maternal Rh sensitization and fetal hemolytic disease due to other blood group antibodies remain significant problems that may lead to anasarca, fetal cardiac failure, and death. [158] Diagnostic and therapeutic advances were made in the late 1950s by Liley et al.; an indirect index of fetal erythrocyte destruction was estimated by amniotic fluid bilirubin spectrophotometric measurement.[159] Intraperitoneal infusion, introduced in 1963, was the first method used to treat seemingly severely affected fetuses. [160] Gaining access to the fetal circulation allowed more direct measurement of fetal hematocrit, reticulocyte count, and Coombs test, and has provided a more direct route for transfusion therapy. [158] Fetal Rh phenotyping is firmly established by obtaining a pure fetal blood sample. Bennett et al. [161] described the use of PCR to determine the RhD genotype of both amniotic cells and fetal blood samples in 15 fetuses, with complete correlation. Such a method of fetal RhD typing permits accurate first-trimester identification of infants at risk without invading the fetomaternal circulation, and appears accurate and reliable. [162] Similar PCR-based determinations of Rhc, Rhe, and Kell blood group typing of fetuses at risk for hemolytic disease have been described. [163] [164] [165]

Nonimmune hydrops fetalis may occur in a number of conditions, including the fetal aplastic anemia associated with parvovirus B19 infection. The gestational age with the greatest risk for fetal hydrops appears to be the second trimester. [166] Parvovirus B19 DNA has been obtained from fetal blood using PCR and parvovirus B19 specific primers, and has been used with fetal ultrasound to diagnose fetuses at risk for severe disease.

Reversal of parvovirus B19 hydrops has occurred with antenatal transfusion therapy. [167]

Enzymopathies

Inherited red blood cell enzyme defects may result in clinically undetectable altered erythrocyte survival or function, intermittent hemolytic crises, or a state of chronic

hemolytic anemia. The most common enzyme defects involve glucose-6 phosphate dehydrogenase and pyruvate kinase. The diagnosis often relies on demonstrating decreased erythrocyte enzyme activity. Normal enzymatic activities are available for >12 glycolytic enzymes in fetal erythrocytes at 1724 weeks gestation. [168] Two other disorders in the heme synthetic pathway, acute intermittent porphyria and protoporphyria, can also be detected by assays of uroporphyrinogen I synthetase and heme synthetase, respectively.[169] [170] Analysis at the molecular level will likely prove to be a more reliable means of antenatal diagnosis of these disorders in the future.

Other Congenital Anemias

Two other rare fetal congenital anemias, Fanconi anemia and Diamond-Blackfan anemia, may be diagnosed in utero. [171] [172] Fetal blood counts and the number of circulating erythroid progenitor cells can be compared with normal values for gestational age. [173] Ultrasound demonstrating abnormalities of the radii or thumbs support these diagnoses.[171] A more definitive test for Fanconi anemia is based on demonstrating hypersensitivity of chorionic villi and amniocytes to clastogen-induced chromosomal breakage.[174] The characterization of the Fanconi anemia gene for complementation group C now permits the detection of affected pregnancies by molecular identification of specific mutations. [175] [176]

PLATELET DISORDERS

The antenatal diagnosis of platelet disorders is aimed at identifying and treating fetuses at risk for hemorrhagic complications. Early detection may identify infants likely to benefit from in utero treatment, delivery by cesarean section, or treatment in the immediate neonatal period (see Table 158-2).

Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is a potentially severe disease caused by fetomaternal incompatibility for platelet-specific antigens, most commonly the PlA antigen system. As many as 1 in 2,000 fetuses may be affected,[177] with a mortality rate as high as 13%.[178] Half the cases of NAIT occur in a first-born child.[179] Although the risk of intracranial hemorrhage appears to be highest during delivery, 2550% of such hemorrhages appear to occur earlier in gestation. [180] Prenatal diagnosis is generally indicated in families with a previously affected neonate, since the risk of subsequent affected pregnancies is as high as 7585%, with a tendency to increasing disease severity. [181] Parental platelet phenotyping is first performed to determine pregnancies at risk. PlA1-negative women who are HLA-B8, DR3 appear to be most at risk for having an affected infant. [182] Maternal anti-PlA1 antibody levels have not been useful in predicting the severity of fetal thrombocytopenia.[183] Rapid genotype assays for PlA haplotypes may aid in predicting fetal risk. [184] FBS at 2022 weeks gestation is the most reliable method of assessing fetal platelet phenotype and platelet count. [185] Fetuses with platelet counts severely depressed early in gestation (i.e., by 20 weeks) appear to be at greatest risk of developing intracranial hemorrhage. [186] Early therapeutic interventions with in utero transfusions of PlA1-negative platelets, together with frequent ultrasound examinations, have been shown to increase the fetal platelet count and decrease the complication rate. [183] [187] Fetal scalp vein platelet count estimations have been used at the time of delivery to determine which infants should be delivered by cesarean section. This procedure, however, is associated with a high frequency of falsely low fetal platelet counts in the setting of amniotic fluid contamination, and does not address the risk of early gestational intracranial hemorrhage.

Advances in the diagnosis of PlA1-associated NAIT using allele-specific oligonucleotide probes have been made by McFarland et al. [188] A single nucleic acid base substitution in the gene encoding glycoprotein IIIa of the PlA1 antigen differentiates it from PlA2 and accounts for the alloantigenic polymorphism in the PlA system. [189] DNA-based phenotyping has been used on fetal leukocytes and amniocytes and is applicable to CVS obtained earlier in pregnancy. [188] [190] Its greatest advantage lies in the potential for earlier, more accurate diagnoses, and it eliminates the problems and risks associated with platelet serologic typing from FBS.

Autoimmune Thrombocytopenia

Autoimmune thrombocytopenia in the neonate can occur by passive placental transfer of maternal IgG, resulting in the destruction of fetal platelets. For unclear reasons, the morbidity and mortality of fetal autoimmune thrombocytopenia is much lower than that associated with alloimmune thrombocytopenia. [191] Indeed, the nadir platelet count in affected infants often occurs after delivery. [192] Given that idiopathic thrombocytopenic purpura (ITP) is a fairly common disease in childhood and in women of childbearing years, it is important to determine which fetuses may be at greatest risk for severe thrombocytopenia and thus would benefit from a cesarean section with postnatal observation. Little correlation exists between maternal and fetal platelet counts. The observation that maternal platelet-associated IgG levels were predictive of neonatal thrombocytopenia has not been confirmed, [192] nor has the measurement of amniotic fluid or cord blood antibody levels. [193] Likewise, the platelet count of a previous baby is not a reliable predictor. [194] Fetal thrombocytopenia does appear to be more frequent when maternal thrombocytopenia is present at the time of delivery.[195] The only reliable way to establish the presence of fetal thrombocytopenia is by FBS. Given the low risk of antenatal fetal morbidity, the benefit of an invasive procedure such as FBS has not been proven. FBS prior to delivery is recommended by some investigators as a reliable means of detecting fetal thrombocytopenia to aid in perinatal planning. [196] Avoidance of fetal head trauma and delivery by cesarean section is generally reserved for pregnant patients with ITP and documented fetal platelet counts <5070,000/mm^3 .[192] [197]

Many pregnant women have platelet counts in the range of 80150,000/mm^3 , especially in the second half of gestation. [198] This benign thrombocytopenia of pregnancy, also called pseudo-ITP, poses no maternal or fetal risk and is not associated with neonatal thrombocytopenia. In the absence of an associated bleeding tendency, no specific antenatal or perinatal precautions need be taken. At times, this incidentally detected condition may be difficult to distinguish from chronic ITP. [192]

Glanzmanns Thrombasthenia

Patients with Glanzmanns thrombasthenia have a normal circulating number and appearance of platelets, but platelets fail to aggregate in response to normal agonists. Absence or deficiency of glycoprotein IIb/IIIa, the fibrinogen receptor needed for normal platelet aggregation, causes a variable hemorrhagic tendency. [199] The GP IIb/IIIa complex is immunologically detectable as early as 19 weeks gestation, allowing radiolabeled anti-GP IIb/IIIa antibodies to be used in the assessment of fetuses at risk.[185] [200] The risk of fetal death due to post-FBS hemorrhage

appears to be particularly high with this disorder, thereby limiting antenatal diagnosis to parents who have decided on terminating an affected pregnancy. [201] This risk may be removed by diagnosis at the gene level with CVS. Several mutant alleles all purported to cause Glanzmanns thrombasthenia have been described. [202] The use of gene markers, however, is limited because the Glanzmanns phenotype corresponds to different genetic mutations. [203]

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is a rare autosomal recessive inherited bleeding disorder characterized by mild thrombocytopenia, giant platelets, and absent ristocetin-induced von Willebrand factor (vWF) binding. The platelet membranes of affected individuals have absent or deficient GP Ib/IX and GP V. [204] Mutant alleles in the genes encoding these proteins have been described. [205] Antenatal diagnosis is theoretically possible by FBS at 1822 weeks for membrane assessment of GP Ib/IX content.[206] Affected women who have had multiple blood and platelet transfusions have an increased risk of fetal thrombocytopenia or immune hydrops fetalis.[207]

Other Inherited Platelet Disorders

Several other inherited platelet disorders may be detected in utero. Thrombocytopenia-absent radii syndrome is initially suspected by characteristic radiographic or ultrasonographic abnormalities and may be confirmed by FBS documenting thrombocytopenia. [208] This syndrome is differentiated from amegakaryocytic thrombocytopenia, in which neonatal thrombocytopenia is followed by pancytopenia later in childhood. The latter disorder had been diagnosed in utero by detecting thrombocytopenia in one infant at risk.[209] Gray platelet syndrome, a rare platelet disorder caused by defective platelet -granules, may be assessed antenatally by demonstrating the presence or absence of -granules by electron microscopy. [201] [203] Similarly, the demonstration of a normal platelet count and volume in the absence

of abnormal spindle-shaped leukocyte inclusion bodies excluded the May-Hegglin anomaly in an infant at risk. [201]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COAGULOPATHIES

Components of the fetal hemostatic system begin to appear at approximately 1011 weeks gestation.[210] Reference values for numerous coagulation factors have been obtained from fetal blood samples.[211] Important insights into the genetics of inherited coagulopathies have enabled prenatal diagnosis by direct defect detection or by DNA polymorphism-based gene tracking.

von Willebrand Disease

One of the most commonly inherited bleeding disorders, von Willebrand disease (vWD) is a heterogeneous autosomally inherited disease caused by a qualitative and/or quantitative deficiency of vWF. More than 20 distinct clinical and laboratory subtypes of vWD have been described. [212] Variability of levels in the heterozygous state make the phenotypic diagnosis difficult. vWF behaves as an acute-phase reactant, and levels are often markedly elevated in the neonate. [213] Prenatal diagnosis of vWD has been reported using assays detecting factor VIII-related antigen and activity in fetal blood samples. [209] [214] [215] Advances in vWD molecular biology have led to both prenatal diagnosis and rapid neonatal diagnosis of certain subtypes. Peake et al. [216] used PCR to amplify DNA from CVS at 10 weeks gestation to identify a fetus with type 3 disease. The diagnosis was confirmed at 18 weeks by demonstrating undetectable levels of VIIIc, vWF Ag, and vWFRiCo in fetal blood. Cord blood leukocyte DNA testing of this sequence has been reported in the rapid diagnosis of types 1 and 2B in the neonatal period. [217] [218] Characterization of molecular defects by single point mutations or RFLP analysis is now possible in the majority of type 2A, 2B, and 2N cases and some type 3 cases. [219]

Hemophilia

Deficiency or abnormality of human factor VIII or IX results in the inherited bleeding disorder hemophilia A or B, respectively. The diseases are X-linked recessive, with an incidence of 1 in 5,000 males. In the era prior to antenatal diagnosis, presumed carriers of severe hemophilia were advised not to conceive children. [220] With the technology offered by amniocentesis for prenatal sex determination, others practiced the termination of all male fetuses. Because measurements of fetal clotting factors may provide a method of detecting affected fetuses,[221] FBS at 1820 weeks offered hemophilia carriers the chance to give birth to a known unaffected son. [222] Since factor levels may vary widely with inflammation, stress, exercise, and pregnancy, ambiguous results at a fairly late stage of pregnancy were occasionally obtained.[223] Fetal plasma assays have since been surpassed by analysis at the DNA level. Today, CVS is the most widely used method, although analysis by amniocentesis, FBS, and preimplantation genetic studies have been used in selected cases. [224] Direct DNA analysis has identified large numbers of point mutations, deletions, and insertions.[225] Most families carry a unique mutation, enabling RFLPs to be widely used in DNA analysis for fetuses at risk. [226] RFLPs within or closely linked to the factor VIII gene can establish carrier status and enable rapid prenatal diagnosis by detecting a mutant factor VIII allele. In the United States and Italy, St14, BclI, and XbAI markers have been the most useful in diagnosing hemophilia A; St14 is informative in 90% of cases. [227] The combined use of the enzymes TaqI, XmnI, MspI, BamHI, SstI, MnlI, DdeI, and HhaI can ensure definitive diagnosis of hemophilia B in up to 90% of people of European descent. [225] Such technology is limited when mothers are not heterozygous for the mutant or marker gene and when linkage disequilibrium exists. [228]

Other Factor Deficiencies

Congenital deficiencies of prothrombin, [229] and factors V,[230] VII,[231] X,[232] XI,[233] XII,[234] and XIII,[235] and familial multiple factor deficiencies [236] have all been described. Prenatal diagnosis by conventional specific functional and antigenic assays on fetal blood samples has been performed. [237] Awareness of the diagnosis antenatally is important in providing parents with desired information and in reducing the potential morbidity associated with vaginal delivery, scalp electrodes, vacuum extractions, forceps, and long labor.[237] Factor concentrate given just prior to delivery may benefit infants most at risk.

Hypercoagulable States

Severe thromboembolic disease may occur as a result of moderate to severe deficiency of the coagulation cascade inhibitory protein S or C, or antithrombin III. Disseminated intravascular coagulation and purpura fulminans have been documented hours to days after birth in infants with homozygous or compound heterozygous protein S or C deficiency.[238] [239] Protein S and C levels in newborns are 2040% normal adult levels; [240] thus, detecting levels <1% by FBS may identify infants most at risk for purpura fulminans. More reliable methods are now possible with molecular techniques that can identify affected fetuses earlier in gestation. The gene for protein C has been localized to chromosome 2. [241] Family diagnosis in a pedigree of protein C deficiency has been performed using DNA

ETHICAL ISSUES IN ANTENATAL DIAGNOSIS

The value of advances in antenatal assessment can be assessed only by also examining the personal, cultural, legal, religious, social, political, and economic factors. Ethical arguments encountered in prenatal diagnosis largely focus on the right of reproductive choice and on maternal rights versus fetal rights. Multiple and often contradictory values and belief systems influence reproductive choice decisions. Arguably, the foremost ethical justification for prenatal diagnosis lies in its potential to prevent the suffering of a future child affected by a serious and untreatable genetic disorder by selective abortion. [279] This in turn may prevent the inevitable suffering otherwise forced on a family and society. Such a premise would require clear distinctions as to what is a serious and untreatable disorder. Potential decisions about termination are often focused on the severity of the disorder and only marginally influenced about when in gestation the decision is made.[280] In a study of womens opinions on the use of prenatal diagnosis, strong positive attitudes toward diagnostic procedures were found, particularly if treatable abnormalities were detected.[281] In some instances, the availability of prenatal diagnosis has increased the birth rate, as in the Greek Cypriot population at risk for homozygous -thalassemia. This group previously had a low birth rate or terminated pregnancies without a diagnosis because of the risk involved. [282] The >90% termination rate for fetuses having thalassemia major in Europe further emphasizes the cultural variations in the need for antenatal assessment. [283] For other diseases, however, prenatal diagnosis is not widely accepted, as is evident by its exceedingly low practice in pregnancies at risk for sickle cell anemia in the United States.[284] The unpredictability of the severity of sickle cell anemia contributes to its infrequent antenatal assessment.

The influence on reproductive genetics by political parties, civil liberty groups, and religious forces is enormous. Political intervention has influenced the access to new technologies (e.g., RU486, the gag rule prohibiting physicians in federally funded clinics from engaging in abortion counseling), the availability of private insurance and federal funds for prenatal procedures, and the availability of research resources (i.e., fetal tissue research). [285] The prospect of malpractice litigation under certain circumstances has induced physician anxiety: there are physicians in France jailed for purportedly delaying HIV testing. [286]

Many questions are raised regarding the purpose of pre- natal diagnosis. A serious and controversial issue concerns assessment for fetal sex selection, a practice reportedly rare in industrialized countries but relatively common in developing countries. [287] Prenatal testing of the fetus conceived for the purpose of benefiting another sibling is another issue reviewed by legal and ethical advisory committees. [279] In one instance, a family sought prenatal diagnosis to bear a healthy child to serve as an HLA-identical bone marrow donor for their son affected by Wiskott-Aldrich syndrome. The physicians involved concluded prenatal testing should not be used to benefit a third party.[279] Here, the concept of parental reproductive autonomy is a strong rebuttal. Prenatal diagnosis for the purpose of the prevention of late-onset genetic disorders is another issue arising with advanced antenatal technology. Our ability to detect offspring who have genes rendering them more susceptible to cancer, diabetes, heart disease, and depression further clouds the picture.

Although it is an arduous and yet to be perfected procedure, preimplantation genetic screening is now technically feasible. The genetic structure of the embryo formed by in vitro fertilization may be assessed, followed by uterine transfer of the genetically unaffected embryo. Preconceptive testing of oocytes is yet another possibility, whereby biopsy of the first polar body permits knowledge of the DNA content remaining in the ovum. [288] Although strong ethical objections to such practices are raised, preimplantation genetic screening may appeal to those opposed to selective termination but who are at risk for a genetically affected offspring.

More universal acceptance of antenatal assessment can be expected with the development of intrauterine therapies, although procedures such as in utero fetal stem cell transplantation, fetal liver cell transplantation and germ line genetic therapy have posed ethical questions in and of themselves. Selective termination is no longer the common conclusion in prenatal diagnosis. Genetic counseling has been shown to reduce anxiety and depression [289] and may serve to prepare a couple for parenting a child with special needs. [290] Physicians devoid of provider prejudice have legal and ethical duties to inform parents of tests widely accepted in the medical community as standard prenatal care. Health care providers are obligated to communicate fully in helping families make the most informed reproductive choices. This will ultimately improve perinatal care, allay parental anxiety where possible, and provide psychosocial support for those involved.

polymorphism of the gene.[242] Several RFLP sites within or near the protein C gene have been discovered, implying the potential for early diagnosis and improvement in carrier detection. Prenatal diagnosis of compound heterozygous deficiency of protein C by direct detection of the mutation sites has been reported. [243] Two protein S genes have been identified and localized near the centromere of chromosome 3. [244] [245] Several protein S gene mutations in patients with phenotypic protein S deficiency and thrombosis have been identified. [246] Further research is needed to reveal genetic alterations in affected individuals and the RFLPs that may be useful in prenatal diagnosis and carrier detection.

Deficiency of antithrombin predisposes affected individuals to repeated thrombotic events. Inherited in an autosomal dominant pattern, homozygosity has been reported in children of consanguineous families. [247] [248] Undetectable antithrombin levels obtained by FBS in the second trimester may detect severely affected infants. Recently, prenatal diagnosis of combined antithrombin and factor V deficiency by genotypic analysis from CVS at 12 weeks gestation in a fetus at risk was successfully performed.[249] The diagnosis of the heterozygote form is best deferred until later in the postnatal period. [249]

FUTURE DIRECTIONS

Considerable progress has been achieved in our understanding of the molecular basis of several congenital hematologic disorders. The future of antenatal assessment relies on the refinement of prenatal diagnostic procedures that do not endanger fetal or maternal well-being and on improving available therapeutic options. Reliable, noninvasive screening techniques applicable to all pregnant women may one day be realized.

Preimplantation genetic analysis of aspirated blastomeres has become possible and is a valuable asset to in vitro fertilization programs. The genetic indications for preimplantation diagnosis

are largely the same as those for prenatal diagnosis. Thus far, approximately 40 healthy children have been born worldwide after preimplantation diagnosis excluded genetic disease.[250] Defects must be detectable by PCR or, for X-linked diseases, by fluorescent in situ hybridization. Experience has been gained with preimplantation sex determination[251] and in the diagnosis of hematologic conditions, including -thalassemia, [252] RhD blood typing,[253] and sex-linked diseases. [254] Preimplantation diagnosis is currently hindered by the limited quantity of material available for genetic analysis and the potential for misdiagnosis by allele dropout. [255] Recently, simultaneous detection of multiple gene expression in human preimplantation embryos was described. [256] This novel RT-PCR method permits the comparison of gene expression at different stages of development and may further our understanding of gene activation and regulation.

Advances for the correction of selected hematologic disorders with in utero therapy continue to be made. The immaturity of the fetal immune system and the presence of marrow space makes the fetus an ideal transplantation host, requiring neither extensive preconditioning regimens nor HLA-identical transfusions. [257] Hematopoietic stem cell transplantation, first demonstrated in mice,[258] sheep, and nonhuman primates[259] led to several attempts in human fetuses.[257] [260] [261] The source of hematopoietic stem cells appears critical to engraftment. [260] [261] [262] Fetal liver cells, alone or with syngeneic fetal thymus and skin cells, have engrafted following umbilical vein and intraperitoneal transfusions. [260] [261] [262] Full immunologic reconstitution of human fetuses with SCID has occurred following in utero stem cell transplantation.[261] [263] In 1996, Flake et al.[264] reported the successful treatment of X-linked SCID by in utero transplantation of haploidentical paternal enriched hematopoietic progenitors that resulted in split chimerism in which T cells were of donor origin. Complete cure or significant improvements have been demonstrated in conditions associated with severe aplastic anemia, thalassemia, bare lymphocyte syndrome, and inborn errors of metabolism. [260] [261] In utero stem cell transplantation offers the advantages of increased probability of engraftment and chimerism, [265] decreased risk of acute graft-versus-host disease, [257] [266] a more sterile environment,[266] and a selective growth benefit for normal hematopoietic cells. [264] Early gestational age improves the chance for full, rapid development of transplanted stem cells. This exciting therapeutic modality has the potential to eliminate or ameliorate many inherited hematologic disorders before the onset of clinical manifestations of the disease. Permanent engraftment will likely be limited to hereditary disorders with a growth advantage of donor cells over recipient cells (i.e., immune deficiency syndromes, Fanconi anemia).[267] A concern with in utero stem cell transplantation is the possibility of transmission of viral infections to immunocompromised fetuses.

An alternative method of in utero treatment may be seen with gene transfer techniques. When incorporated into a retroviral vector, foreign genes have been successfully incorporated into murine hematopoietic stem cells, hepatocytes, skin cells, and endothelial cells. [268] [269] [270] [271] [272] Phenotypic correction of Fanconi anemia in human hematopoietic cells with a recombinant adeno-associated viral vector has been reported; the corrected cells have a selective advantage over defective hematopoietic stem cells.[273] In utero gene transfer and expression of neomycin-resistance genes in fetal sheep hematopoietic cells have been demonstrated.[274] Cord blood cells as a target for genetic modification have been increasingly studied. The in vivo proliferation of retrovirally marked cord blood cells has been evaluated in the ovine system[274] and is actively being studied in infants diagnosed prenatally with ADA deficiency. [275] Thus far, it remains to be proven that transduction in primary cells is permanent and that the viral vector is fully integrated. [276] Improvements in the gene transfer efficiency of cord blood cells may permit effective treatments for a variety of inherited hematopoietic disorders.

The future is likely to find prenatal testing increasingly used to assess fetal donor prospects. One unit of umbilical cord blood contains sufficient hematopoietic stem cells to fully reconstitute a child and in some cases an adult with a disease treatable by bone marrow transplantation. [277] [278] Predictive genetic testing and HLA typing of cultured fetal cells enable one to know early in pregnancy if a fetus is genetically normal and a possible allogeneic bone marrow donor for an affected family member. Cord blood cells may become an increasingly valuable source of progenitor cells for transplantation, immunotherapy, and gene therapy. [267]

Chapter 159 - Electrophoretic and Immunochemical Analysis of Human Immunoglobulins

John P. Leddy

INTRODUCTION

Human immunoglobulins occur in five classes, based on amino acid sequence differences in the constant regions of their heavy polypeptide chains. A given immunoglobulin molecule may have either type or type light chains, a distinction determined by primary structural differences in the constant regions of the molecule. The various immunoglobulin heavy chain classes and subclasses (Table 159-1), termed isotypes, are encoded by immunoglobulin genes on chromosome 14. and light chain genes are encoded on chromosomes 2 and 22, respectively. Detailed information on immunoglobulin genes, on B-cell development and activation, and on molecular structure and biologic functions of immunoglobulins is given in Chapter 36 . The availability of heavy chain-specific antisera that identify human , , , , or chains, and light chain-specific antisera that recognize human or chains, is central to two of the

TABLE 159-1 -- Selected Properties of Immunoglobulins in Human Serum

Class (Isotypes)	Heavy Chain Type	Light Chain Type	Molecular Weight	Normal Adult Serum Concentration[a]	Subclasses (%)	Normal Electrophoretic Mobility (range)	Half-life (days)	Other Comments
IgG		or	150,000	565 1,765 mg/dl[b]	IgG1 (6270)[e] IgG2 (1133) IgG3 (36) IgG4 (0.56)	From most cathodal portion of -globulin area to $_2$ -globulin region	23	Crosses placenta; neonatal levels approximate adult concentration; some IgG myelomas are euglobulins[f]
IgA		or	170,000 (monomer)	85385 mg/dl[b]	IgA1 IgA2	From fast - to $_1$ -globulin area	6	In IgA myeloma a portion of paraprotein may form higher molecular weight polymers that differ from monomer in electrophoretic mobility
IgM		or	900,000 (Pentamer)	45250 mg/dl[b]	None recognized	From fast - to $_2$ -globulin area	5	In Waldenström macroglobulinemia significant IgM monomer may be present; IgM paraproteins often are euglobulins[f]
IgD		or	185,000	0trace[c]	None recognized	Similar to IgM and IgA	2	Concentration in normal serum too low to be detected by zone electrophoresis, IEP, or IFE; rare myeloma; very rare HCD
IgE		or	200,000	10200 IU/ml[d]	None recognized	Similar to IgM and IgA	2	Concentration in normal serum too low to be detected by zone electrophoresis, IEP, or IFE; very rare myeloma; elevated levels in allergic or parasitic diseases

Abbreviations: IEP, immunoelectrophoresis; IFE, immunofixation electrophoresis; HCD, heavy chain disease.

principal methods for analysis of human immunoglobulins. [1] Of greatest utility in clinical diagnostic laboratories are polyclonal antisera, usually prepared in goats or rabbits. At this time, monoclonal antibodies have a more limited role because they precipitate poorly with the proteins to which they are directed, and their use therefore requires additional steps to immobilize the protein(s) of interest.

Most pathologic immunoglobulin disorders involve IgG, IgA, and IgM, and these are emphasized in this chapter. IgD and IgE occur only in trace amounts in normal human sera (Table 159-1) and cannot be detected by the standard electrophoretic methods currently in use, unless the concentration of these proteins is abnormally elevated, as in the rare IgD or IgE myelomas.

CONCEPTS OF MONOCLONAL AND POLYCLONAL IMMUNOGLOBULINS

One of the most striking features of the immunoglobulins synthesized by normal individuals is their heterogeneity, not only with respect to class, subclass, and light chain type, but also as reflected by an enormous diversity in antibody specificity. The latter property is related to amino acid differences in the variable regions of the heavy and light chains making up the immunoglobulin molecule. Within this extremely diverse array of circulating immunoglobulins are the products of individual cells of the B-lymphocyte lineage. Each antibody with its unique primary structure arises from a unique B cell and its progeny (i.e., a clone). However, so many clones contribute to the immunoglobulin pool in normal serum that the immunoglobulin molecules produced by an individual clone cannot be detected within the collective background of immunoglobulins synthesized by all the other clones. Thus, the great heterogeneity of immunoglobulins in normal serum reflects their highly polyclonal origin.

All of the immunoglobulins synthesized by a clone of antibody-forming cells share identical amino acid sequences in both constant and variable regions and therefore are identical in class, subclass, and light chain type. Post-synthetic glycosylation of heavy chain constant regions varies among the immunoglobulin classes, but is generally similar for immunoglobulin molecules formed by a given clone. It follows from these principles that the immunoglobulin proteins arising from a single clone typically have the same net electrical charge, and therefore the same electrophoretic mobility. Such monoclonal immunoglobulin proteins migrate electrophoretically as a very sharp, dense band. This is in contrast to the broader, polydisperse migration of normal serum immunoglobulins that reflects synthesis by a vast number of clones, resulting in a polyclonal pattern. At the molecular level, this electrophoretic (charge) heterogeneity of normal immunoglobulins is thought to be determined mainly by primary sequence differences in the immunoglobulin variable regions, with some contributions from their class and subclass. Thus, antibodies with specificity for a given antigenic epitope may have a monoclonal origin and, if so, would be expected to exhibit a sharply restricted electrophoretic mobility.

However, the quantity of immunoglobulin synthesized by each clone of antibody-forming cells is normally modulated in such a way that its immunoglobulin products are not in sufficient concentration to be distinguished from immunoglobulins contributed by all the other clones.

In contrast, in myeloma, Waldenström macroglobulinemia, some B-cell lymphomas, heavy chain diseases, or primary amyloidosis, a single clone of plasma cells or immunoglobulin-synthesizing B lymphocytes emerges from the general B-cell population, expands in an unregulated fashion, and synthesizes a homogenous immunoglobulin product at a high enough rate to be detectable against the background of polyclonal immunoglobulins.

In this chapter, the historical term paraprotein is sometimes used to designate such a monoclonal immunoglobulin, even though the original concept that all monoclonal proteins represent intrinsically defective molecules, having no counterpart in the normal host, is no longer accepted. On the other hand, heavy chain disease, in which only portions of an immunoglobulin heavy chain are synthesized, and light chain disease (Bence Jones myeloma), in which qualitatively normal light chains are synthesized and secreted without heavy chains, do represent disordered synthesis beyond the abnormality of uncontrolled clonal expansion.

METHODS FOR CLINICAL EVALUATION OF HUMAN IMMUNOGLOBULINS

Assessments of abnormalities of human immunoglobulins in serum, urine, or other body fluids utilize zone electrophoresis, immunoelectrophoresis (IEP), and immunofixation electrophoresis (IFE) for qualitative and semiquantitative analysis. Nephelometry or radial immunodiffusion are used for quantitative measurement of immunoglobulins. Other specialized procedures are employed for evaluation of anomalous proteins such as cryoglobulins.

Zone Electrophoresis

All electrophoretic methods separate proteins within a complex mixture by virtue of differences in their net electrochemical charges. Zone electrophoresis is a general term for procedures that subject proteins to an electrical field in, or on, a supporting matrix that permits subsequent fixation of the separated proteins and their detection by staining with protein-binding dyes. The supporting medium for the most familiar form of zone electrophoresis consists of strips of cellulose acetate. Agarose gels, supported on a clear plastic film sheet, are now more widely used than cellulose acetate because of their capacity to resolve serum into a greater number of discrete bands.[2] After fixation and drying, stained zone electrophoretic patterns (on cellulose acetate or dried agarose gels) can be scanned by a densitometer to produce a tracing in which each band in the stained pattern is translated into an inscribed peak whose height and width reflect the intensity and electrophoretic dispersity, respectively, of the band being scanned. When this is applied to serum separated on cellulose acetate, the traditional serum protein electrophoresis (SPEP) profile results (Fig. 159-1A). By determining the total protein concentration in the sample, each main peak (e.g., albumin, $_1$ - or $_2$ -globulins, -globulin, or -globulin) can be assigned an approximate protein concentration (by mathematical integration). Similar SPEP analyses are performed with stained protein patterns obtained by zone electrophoresis in agarose gel. Such patterns are shown in the uppermost sections of each of the immunofixation electrophoresis figures (Figs. 159-4 , 159-5 , 159-6 , and 159-7).

It must be remembered that the classical -globulin peak does not encompass the full range of immunoglobulin mobilities. Some human immunoglobulins migrate as -globulins and occasionally into the $_2$ -globulin area. By convention, an immunoglobulin population (with a negative net charge) that migrates more strongly toward the positive pole (anode) is said to have fast electrophoretic mobility, and immunoglobulin molecules found close to the cathode are said to be slow.

Figure 159-1 Zone electrophoresis on cellulose acetate with densitometric scans. **(A)** Normal human serum. **(B)** Serum with large monoclonal spike in the mid -globulin area. Note that background of normal polyclonal -globulin on either side of the spike is severely diminished. Further evaluation by IEP revealed that the monoclonal spike was IgG-.

Zone electrophoresis (SPEP) has been widely employed for many years as a first screening test for evaluation of serum immunoglobulins. This technique can establish the presence of moderate to large monoclonal spikes (Fig. 159-1B), polyclonal hypergammaglobulinemia, or generalized (pan-) hypogammaglobulinemia. By itself, this method has significant shortcomings: (1) it cannot identify the class or light chain type of a monoclonal protein; (2) it may be too insensitive to detect a low

concentration of monoclonal immunoglobulins or free light chains in serum, especially if the background immunoglobulins are normal or increased; and (3) it is incapable of detecting selective IgA or IgM deficiency. SPEP performed in agarose gel is more sensitive than SPEP in cellulose acetate in detecting small monoclonal immunoglobulin populations, although shortcomings (1) and (3) above still apply.

The use of SPEP in combination with quantitative assays of IgG, IgA, and IgM (e.g., by nephelometry or radial immunodiffusion) can greatly add to the power of this evaluation. Some clinical laboratories offer quantitation of total or molecules by rate nephelometry. This provides a / ratio (normally about 70:30). A patient with a sizable spike by SPEP might be found to have very high serum IgA and light chain values by nephelometry, not infrequently with a depression of IgG, IgM, and total molecules, making the diagnosis of an IgA myeloma very likely.

Evaluation of a paraprotein disorder should also include IEP or IFE analysis of both serum and concentrated urine because the greater sensitivity of the latter procedures would permit a more complete analysis. This includes the detection of a second, lesser paraprotein (aside from a major serum spike seen in SPEP), such as free monoclonal light chains in serum or urine (Bence Jones protein), occasional biclonal paraproteins or the presence of multimers of the main paraprotein that have slightly different electrophoretic mobility. Formation of such multimers (e.g., dimers and tetramers) occurs quite often in IgA myeloma and can result in a falsely polyclonal appearance of an abnormal peak seen in SPEP.

Urine electrophoresis on cellulose acetate or agarose gel (UPEP), usually performed after the urine has been concentrated 50- to 200-fold, can reveal (1) a restricted band representing a Bence Jones protein (BJP); (2) an intact immunoglobulin paraprotein that has entered the urine from the plasma; (3) both of the above; or rarely (4) immunoglobulin fragments, as in heavy chain disease. However, the precise identity of such urinary proteins will not be determined by this procedure, and subtle monoclonal bands, such as those due to low concentrations of BJP, may be missed. Thus, evaluation of urine for paraproteins is optimally done by IEP or IFE on 50- to 200-fold concentrated urine. (The extent to which the urine is concentrated is largely determined by the overall concentration of protein in the sample.) For the clinician, the accurate detection of BJP is more than academic, since the presence of BJP is associated with a greater risk of amyloidosis and renal disease (myeloma kidney). In some patients who eventually prove to have primary amyloidosis, a low concentration of monoclonal light chains in the urine may be a decisive clue. Thus, evaluation for a paraprotein disorder should always include appropriate studies of urine as well as serum. A 24-hour collection of urine is not necessary for this diagnostic study; the current, highly sensitive IEP or IFE analysis of concentrated urine requires only 100 mL of a random voiding. In contrast, serial quantitative assay of urinary light chains has been used in some centers for judging the efficacy of therapy. This type of assay does require a 24-hour collection.

Immunoelectrophoresis

IEP is a versatile and broadly effective procedure for the detection of pathologic proteins in serum and urine. [1] In this method, a thin (22.5 mm) layer of agar gel dissolved in 50 mM barbital buffer (pH 8.2) is formed on the surface of glass slides or on 85 × 100 mm clear, flexible plastic film sheets (Gel Bond). (Agar, rather than its purified constituent, agarose, is commonly used in IEP because its higher endosmotic [reverse] flow advantageously positions the immunoglobulins for analysis.) The patients serum or concentrated urine is placed in a small well punched into the agar, and a similar well on the same gel receives normal human serum (NHS) as a control. The slides (or film sheets) are placed in the electrophoresis apparatus, connected to the buffer wells by wicks, and then subjected to an electrical field at room temperature. After a predetermined period, or based on movement of a marker dye, the current is stopped, the agar-containing slides are removed from the

electrophoresis apparatus, and narrow troughs are cut parallel to, and on either side of, the path of protein migration (Fig. 159-2). Each trough is filled with selected polyclonal antisera to human immunoglobulins and the slides are kept in a moist environment overnight at room temperature. The antibodies diffuse from the trough into the neutral agar, where they meet their corresponding antigens (i.e., human immunoglobulins or other serum proteins) that have migrated to various points in the agar during the electrophoretic phase of the procedure. When antigen and antibody meet, a smooth curvilinear arc of precipitation is formed (Fig. 159-2). This arc of precipitation demonstrates both the presence and the electrophoretic dispersion of the protein recognized by the antiserum. The intensity and position of the arc also provide a semiquantitative estimate of the concentration of that protein present in the patients serum. Thus, IEP is a two-phase procedure: electrophoretic separation and immunoprecipitation. In common laboratory practice, the chief diagnostic interest concerns the immunoglobulins; accordingly, polyclonal anti-, anti-, anti-, anti-, and anti- antibodies are routinely employed to develop such precipitin arcs.

Figure 159-2 displays an IEP pattern of a serum with a large monoclonal IgG spike (lower patterns in Fig. 159-2A and Fig. 159-2B).

Figure 159-2 IEP analysis of a serum containing a large IgG- myeloma protein. For the initial electrophoretic separation in the agar gel, the upper small wells in each pairing received normal serum and the lower wells received the patients serum. At the conclusion of the electrophoretic separation, monospecific antisera to **(A)** human -chains (IgG-specific), **(B)** -chains, and **(C)** -chains were added to the longitudinal troughs. For ease of illustration, results with antisera of other specificities are not shown. Arrowheads point to the abnormal bowing in the IgG and -arcs that indicates the presence of an IgG- monoclonal protein.

The key diagnostic feature is the localized bulge or bowing in both the IgG arc and the arc. Note that these two arcs show bowing in precisely the same electrophoretic position, i.e., the abnormality in the IgG arc and in the arc is attributable to the same molecule. The bulge or bowing in these IgG and arcs results from an extremely high concentration of identical molecules having the same net charge migrating to one highly localized point during the electrophoretic separation; they then diffuse as a molecular cohort into the oncoming anti- or anti- antibodies from the troughs. The bowing or displacement of the IgG and arcs toward the antibody source (lower patterns in Fig. 159-2A and Fig. 159-2B) results from the shift in the equilibrium point for antigen-antibody precipitation. Antigen excess (i.e., the high concentration of monoclonal IgG) drives the region of optimal precipitation toward the antibody trough. In contrast, the IgG and precipitin arcs produced by normal serum are smooth, continuous curves without localized bowing or displacement (Fig. 159-2 , upper patterns). Note that the polydisperse precipitin arc produced by anti- antibody with this myeloma serum is significantly weaker than that obtained with normal serum (Fig. 159-2C). This indicates a depressed level of type polyclonal immunoglobulins in the serum containing the IgG spike. Such reciprocal depression of normal immunoglobulin concentrations is common in advanced myeloma.

IgA paraproteins typically have a fast - or -globulin mobility. This is also true of some IgM paraproteins, as well as the rarely encountered IgD or IgE paraproteins. However, some IgG paraproteins also migrate in this area.

The use of IEP to demonstrate type Bence Jones protein in concentrated urine is demonstrated in Figure 159-3 . It should

Figure 159-3 IEP of 50-fold concentrated urine. Each of the upper wells contained normal serum; each lower well contained the concentrated urine of the patient. Trough **(A)** received polyspecific antiserum to whole human serum; trough **(B)**, anti-; trough **(C)**, anti-. Note the clear bowing or deviation of the precipitin arc formed by anti- but the smooth, polydisperse appearance of the arc formed by anti-. This urine sample contains -type BJP.

be borne in mind that 50- to 200-fold concentrated urine from healthy individuals often displays free polyclonal light chains (both type and type) by either IEP or IFE. Some myeloma patients have both a serum paraprotein and urinary BJP. In such cases, the BJP often has a greater net negative charge (faster mobility) than the intact monoclonal immunoglobulin.

IEP (or IFE) also provides information on whether the normal immunoglobulins are depressed. In advanced myeloma, with a large monoclonal spike or with urinary BJP alone, it is common to observe depression of normal background immunoglobulin. When severe, this depression of normal polyclonal immunoglobulin may be associated with an increased clinical risk of bacterial infection. Moreover, in the absence of a detectable serum paraprotein, hypogammaglobulinemia in an older patient may be an important clue to the presence of Bence Jones myeloma, in which case IEP or IFE of urine should provide decisive evidence.

Immunofixation Electrophoresis (IFE)

Although IEP has been a major asset for the detection and isotyping of monoclonal proteins, the more recently developed technique of IFE [3] is even more sensitive in identifying monoclonal immunoglobulins or light chains in very low concentrations in serum or urine. Thus, IFE has emerged in many clinical laboratories as the dominant immunospecific electrophoretic procedure employed. Two situations in which IFE surpasses IEP warrant comment. In the presence of a normal or increased background of polyclonal immunoglobulins, IEP may fail to detect a very small monoclonal immunoglobulin, because the background immunoglobulins form unusually strong precipitin arcs within which it is difficult for a small quantity of paraprotein to produce a clear-cut deviation or bulge. Another problem occasionally encountered with IEP in this same setting is unsuccessful light chain typing of a monoclonal IgM protein, because lower molecular weight and faster diffusing IgG and IgA molecules may preemptively bind the available anti- or anti- antibodies before the more slowly diffusing, high molecular weight IgM proteins can make contact. IFE is usually successful in these situations. IFE is, however, technically more demanding and labor-intensive than IEP. IFE has the added advantage of being ready for interpretation on the same day as the electrophoretic run, and it requires less experience to interpret than IEP.

Like IEP, IFE employs a combination of zone electrophoresis and immunoprecipitation with specific antisera. IFE begins with electrophoretic separation of suitably diluted serum or urine in 1 percent agarose gel (in 50 mM barbital buffer, pH 8.6). The agarose gel is applied to the surface of the same 85 × 100 mm Gel Bond clear plastic film sheets described in the discussion of IEP. The electrophoretic separation is performed on a cooling plate connected to a recirculating, temperature-controlled water bath at 515°C (we favor 13°C). Immediately after the electrophoretic run, precut strips of cellulose acetate or lens paper, each soaked in a monospecific antiserum (e.g., anti-, anti-, anti-, anti-, or anti-), are applied to the gel surface overlying individual electrophoretic lanes. The antibodies are allowed to diffuse (for approximately 10 min.) from the strips into the gel, where they encounter and precipitate with their respective immunoglobulin antigens. The strips are removed and the agarose gel (on its plastic support) is then washed to remove all proteins that were not precipitated by a specific antibody. The final steps involve drying the gel on the plastic sheet, and staining with a protein dye, such as Coomassie blue or amido black, to reveal the bands of antibody-precipitated immunoglobulins.

Figure 159-4 , demonstrates an IFE pattern for normal serum, including both a Coomassie blue stained agarose zone electrophoresis

Figure 159-4 IFE applied to normal serum. The upper pattern (track 1) represents zone electrophoresis in which Coomassie blue dye was applied to a strip cut from the plate after electrophoresis, without addition of antiserum. The major bands (from right to left) are albumin, $_1$ -antitrypsin, haptoglobin, transferrin, C3, and -globulin (with its normal polydisperse pattern). Below the zone electrophoresis strip, each horizontal track represents concurrently assayed immunoprecipitation (IFE) after overlay with antisera as follows: track 2, anti-IgG; track 3, anti-IgA; track 4, anti-IgM; track 5, anti-; track 6, anti-. The small daggers indicate the point of application of the serum sample; this process commonly leaves a narrow stripe that must not be confused with a monoclonal band.

with no antiserum added (lane 1) and the immunofixation patterns produced by each of five specific antisera (lanes 26). All such patterns are polydisperse. Figures 159-5 and 159-6 depict sera with small monoclonal IgG or IgM bands, respectively, which were not clearly resolved by IEP. Fig. 159-7 presents the serum IFE of a patient with IgD myeloma that had been classified, at another hospital, as Bence Jones myeloma because anti-IgD had not been tested. The patient has both an intact IgD paraprotein and free type light chains. (Virtually all IgD myelomas are type .) Similarly, IFE is even more sensitive than IEP in detecting very low concentrations of monoclonal light chains in concentrated urine.

Despite its superior sensitivity for detecting monoclonal immunoglobulins at low concentrations, IFE does have some pitfalls. Optimal dilution of the serum or urine sample is essential. Too heavy a protein input can result in obscuring monoclonal bands within the darkly staining background. Overdilution may result in loss of a potentially detectable monoclonal immunoglobulin. If the patients serum concentrations of IgG, IgA, and IgM are known, that is helpful.

IFE is so sensitive that one must be concerned about overdiagnosis of monoclonal disorders and the potential to set in motion an expensive, anxiety-producing clinical workup. For example, monoclonal gammopathies of undetermined significance (MGUS), [4] which are increasingly encountered in the seventh, eighth, and ninth decades of life, are detected by IFE with far greater frequency than by more traditional SPEP or IEP. Clonally restricted light chains may also be detected in urine in the absence of other evidence for a plasma cell dyscrasia. [5] Moreover, using IFE, one, or even several, faint but reproducible electrophoretically restricted bands are sometimes found in a strongly polyclonal hypergammaglobulinemic serum. Such oligoclonal bands are often undetectable by conventional SPEP or even by repeated careful IEP. This type of oligoclonal pattern in serum has been seen in acute and chronic infections, in rheumatologic diseases, in acquired immunodeficiency syndrome or asymptomatic human immunodeficiency virus infection, in chronic liver disease, in carcinoma, or in severe drug hypersensitivity. [6] [7] [8] [9] These oligoclonal bands may be undetectable when the patients serum is reexamined several months later, and thus may represent transient, accelerated immunoglobulin synthesis by vigorously expanded but nonmalignant clone(s) of antibody-forming cells stimulated by the acute illness or active flare. In other instances, such very weak monoclonal bands persist without change over time, and should be considered a variant

Figure 159-5 IFE demonstrating a very small IgG- monoclonal protein. The upper segment is a stained zone electrophoresis of the patients serum (no antibody was added). The other tracks, in descending order, were developed as follows: track 2, anti-IgG; track 3, anti-IgA; track 4, anti-IgM; tracks 5 and 6, two different anti-- sera; track 7, anti-; track 8, anti-IgG. The arrowhead indicates the position of the monoclonal IgG- band. The small daggers mark the point of serum application.

Figure 159-6 IFE demonstrating a subtle IgM- monoclonal protein (arrowhead). Upper track: agarose zone electrophoresis. Other tracks, in descending order, were developed with anti-IgG (track 2), anti-IgA (track 3), anti-IgM (track 4), anti- (track 5), anti- (track 6), repeat anti-IgM (track 7), and repeat anti- (track 8).

form of monoclonal gammopathy of undetermined significance.

OVERVIEW OF ELECTROPHORETIC PROCEDURES

The complete characterization of immunoglobulins often requires several different laboratory assays. A single method that will cover all situations does not exist. [1] A gradation, or hierarchy, of progressively more sensitive, and usually more expensive, methods has evolved. Some authors do not recommend the very sensitive IFE as an initial screening procedure. [10] We employ zone electrophoresis in agarose, IEP, and IFE in our laboratory. Increasingly, referring physicians, now aware of the greater sensitivity of IFE in detecting monoclonal immunoglobulins, are specifically requesting this procedure as the first-line assay. As a result, a combination of SPEP in agarose and IFE has gradually become the norm of serum or urine evaluation.

This review highlights the relative strengths and shortcomings of these diagnostic tools, thus diminishing some of the mystery in their usage. Good communication between the clinician and diagnostic laboratory personnel should solve most problems.

QUANTITATIVE ASSAY OF IMMUNOGLOBULINS

Concentration ranges for immunoglobulins in adult human serum are included in Table 159-1; age-adjusted values are shown

Figure 159-7 IgD myeloma. Zone electrophoresis of undiluted and 1/3 dilution of patient serum (tracks 1 and 2) revealed two abnormal, restricted bands (arrowheads). Concurrent IFE (tracks 310) was set up as follows: anti-IgG (lane 3), anti-IgA (lane 4), anti-IgM (lane 5), anti- (vs. undiluted serum, lane 6), anti- (vs. 1/3 serum, lane 7), anti-IgD (vs. undiluted serum, lane 8), anti-IgD (vs. 1/3 serum, lane 9), anti- (lane 10). The IFE results demonstrate that the more cathodal paraprotein (seen in lane 1) is IgD- and the more anodal band contains free- light chains (BJP).

in Table 159-2 . The technique of radial immunodiffusion [11] was the dominant assay procedure for quantitative measurement of immunoglobulins for many years. In this technique, polyclonal antiserum specific for IgG, IgA, or IgM is incorporated into melted agarose and the mixture is then allowed to gel on a glass or plastic slide, thus creating an anti-IgG slide,

TABLE 159-2 -- Age-Adjusted Serum Immunoglobulin Levels (mg/dl)[a]

	IgG	IgA	IgM
Birth-4 months	7001,480	02.2	530
46 months	3001,000	382	15109
6 months16 years	5001,550	14232	43240

[a] Adult concentrations are shown in Table 159-1 .

an anti-IgA slide, and an anti-IgM slide. Multiple wells are punched into the gels. The wells are filled with serum from each patient to be assayed, and some wells receive serial dilutions of a standard serum or other preparation containing known concentrations of IgG, IgA, and IgM. From each well, the immunoglobulins diffuse into the surrounding antibody-impregnated agarose. Because excess antigen solubilizes antigen-antibody complexes, the point of equilibrium for maximum immunoprecipitation keeps moving outward as long as there is excess immunoglobulin antigen to solubilize the inner ring of precipitate. Ultimately, at about 24 hours, the system reaches equilibrium and each well shows a halo of surrounding precipitate. The diameter of the halo, measured accurately by special optical magnifiers, is proportional to the quantity of that immunoglobulin in a patients serum. The diameter of the halo is converted to concentration by constructing a standard curve relating halo diameter to several known concentrations of the respective immunoglobulin.

Nephelometry has recently emerged as the dominant technique for immunoglobulin quantitation in large laboratories because the procedure can be automated. [11] This method is possible because an extremely fine suspension of antigen-antibody complexes results when diluted antiserum (e.g., anti-, anti-, or anti-) is added to a diluted human serum. Although invisible to the eye, these complexes produce scattering of a beam of laser light that is passed through the mixture. Such light scattering is readily detected and quantified by a photoelectric sensor. Moreover, either the amount of light scattering (endpoint nephelometry) or the speed at which it develops (rate nephelometry) is proportional to the amount of the specific protein in the serum sample. A standard curve is again constructed (by computer) from the readings given by multiple dilutions of a serum standard whose concentration of each immunoglobulin is known.

CRYOGLOBULINS

Cryoglobulins are immunoglobulins that form insoluble aggregates at temperatures <37°C. [12] Type I cryoglobulins are of one immunoglobulin class, most commonly IgM or IgG (rarely IgA or free light chains), and are monoclonal. Many examples are associated with myeloma, Waldenströms macroglobulinemia, or lymphoma. In some instances, there is no recognizable underlying disorder (primary or essential type I cryoglobulinemia); such patients may, in time, develop an overt lymphoproliferative disease. The physical form of the type I cryoprecipitation may be amorphous, gelatinous, or crystalline.

Types II and III cryoglobulins are termed mixed in that their formation involves the interaction of two or more classes of immunoglobulin. At least one of the components is a cold-reactive anti-IgG (rheumatoid factor) that combines with the patients polyclonal IgG (or any source of normal human IgG) to form a cryoprecipitate. This cryoprecipitate is a special type of immune complex possessing a definite capacity to activate and consume complement, both in vivo and in the venipuncture tube if cooling occurs. The anti-IgG antibody appears to be the critical component mediating cryoprecipitation. The essential immunochemical difference between types II and III cryoglobulinemia is that in type II the anti-IgG component is monoclonal, most commonly IgM, but in some cases it is IgG or IgA. In type III cryoglobulinemia, the anti-IgG component is polyclonal; it may be polyclonal IgM alone or IgM in combination with IgG or IgA anti-IgG antibodies. Both type II and type III cryoglobulinemia have been associated with hepatitis C infection (i.e., detection of anti-hepatitis C antibody or viral RNA in the serum or cryoprecipitate). [13] Distinguishing between type II and type III is important because patients with type II, but apparently not type III, cryoglobulinemia are at increased risk of concurrent or subsequently developing B-cell lymphoma. Many other instances of type II cryoglobulinemia, in which an underlying disorder is not evident, are termed essential or primary, but B-cell lymphomas have developed in a substantial proportion of such patients. Patients with type III cryoglobulinemia may have a collagen-vascular disease such as systemic lupus erythematosus or a systemic viral infection, but this disorder also occurs in an essential or primary form.

Blood drawn for cryoglobulin assay is ideally transported to the laboratory in a container of warm water, permitted to clot in a 37°C bath, and subjected to centrifugation in a warmed centrifuge. This 37°C serum is placed in the refrigerator in a graduated conical tube for 7296 hours to permit complete precipitation. Many cryoglobulins, especially type I, precipitate far more rapidly. At the end of 7296 hours, the tubes are spun and the packed precipitate volume (cryocrit) is measured in the same way as a hematocrit. Normal sera show no visible precipitate under these conditions.

If the test result is positive, the supernatant serum is removed and the cryoprecipitate is washed thoroughly in cold saline and re-dissolved in a small volume of 0.15 M NaCl for analysis of its composition. For large cryoprecipitates, IEP is effective. For small cryoprecipitates and for distinction between type II and type III cryoglobulins, IFE has been highly effective.

Chapter 160 - Use of Molecular Techniques in the Analysis of Hematologic Diseases

Nancy Berliner

The dramatic advances in recombinant DNA technology since the late 1970s have yielded crucial insights into the processes involved in hematopoietic cell ontogeny. Equally impressive is the effect this technology has had on the diagnostic capabilities for defining, diagnosing, and predicting the natural history of hematologic diseases. The same techniques that have allowed the elucidation of the molecular mechanisms of hematologic abnormalities have provided powerful diagnostic tools, bringing our understanding of basic science into sharply relevant clinical focus. An exhaustive review of the application of these techniques is beyond the scope of this chapter; however, a brief summary of the areas outlined in Table 160-1 provides some insight into the current and evolving uses of DNA technology in clinical hematologic practice.

PRENATAL DIAGNOSIS

The interplay of basic science and clinical diagnostics has been well demonstrated in the analysis of hemoglobinopathies. The increasing precision with which the molecular lesions of thalassemia and sickle cell disease have been defined is paralleled by the increasing sensitivity and specificity of techniques for antenatal diagnosis of these disorders[1] (see Chap. 157). For the purposes of this discussion, the range of molecular techniques

TABLE 160-1 -- Use of Molecular Techniques for Hematologic Diagnosis

Prenatal diagnosis
Analysis of restriction fragment length polymorphisms linked to diseases of known genetic loci
Direct oligonucleotide screening to detect single base changes defined as the basis of disease
Use of PCR to amplify regions of DNA for further analysis for known or suspected molecular abnormalities in the gene of interest
Diagnosis of lymphoproliferative disease
Defining clonality of poorly defined lymphoproliferative lesions lacking classic histologic features or lymphoid surface markers
Determining extent of disease in patients with lymphoproliferative lesions
Monitoring disease activity in patients undergoing treatment for lymphoproliferative disease
Human leukocyte antigen (HLA) typing for bone marrow transplantation
Analysis of cell origins in bone marrow transplantation recipients
Documentation of engraftment after marrow transplantation
Identification of chimeric states and prediction of graft rejection
Determination of cell implicated in relapse after bone marrow transplantation
Diagnosis of follow-up of diseases associated with known cytogenetic abnormalities
Documenting aberrant translocations (e.g., Philadelphia chromosome-negative chronic myelogenous leukemia
Detection of minimal residual disease by PCR across known chromosomal breakpoints

PCR, polymerase chain reaction.

for antenatal diagnosis of sickle cell disease is described as a paradigm for these developing concepts.

With the exception of lymphocytes, as described later, the DNA content of all cells in a given individual is identical. Consequently, prenatal diagnosis by DNA analysis can be performed on DNA derived from any fetal tissue. The usual source of fetal DNA has been amniotic fluid cells. Obtaining adequate tissue for diagnosis requires 2030 ml of amniotic fluid with growth of the cells in tissue culture before DNA isolation. Amniocentesis is performed at 16 weeks gestation, and analysis may not be completed until 4 weeks later. Chorionic villus sampling has begun to supplant amniocentesis as a source of fetal tissue, because it can be performed at 812 weeks of gestation.[2] [3] With the development of more sensitive methods of DNA diagnosis, notably the polymerase chain reaction (PCR), the cellular material necessary for genetic analysis has been reduced to a very few cells; consequently, it is likely that progressively less invasive procedures for obtaining fetal cells will evolve.

Analysis of Restriction Fragment Length Polymorphisms

Restriction fragment length polymorphisms (RFLPs) have been described in detail in Chapter 1 . Briefly, RFLPs reflect DNA mutations that alter the recognition sites for restriction endonucleases and persist as detectable polymorphisms on Southern blot analysis of genomic DNA. [4] These mutations are usually phenotypically silent, in that they usually lie within introns and do not affect the protein encoded by the gene locus in which they are found. The exception to this rule is discussed in the following paragraph.

Restriction fragment length polymorphisms can be related to diseases caused by single gene defects in several ways (Fig. 160-1). A single base change causing a disease may itself give rise to an altered restriction site. Such a chance occurrence represents the exception to the usual rule that RFLPs arise from phenotypically silent mutations in intron regions; in this instance, finding the RFLP is diagnostic of the mutant allele. It allows the direct identification of both carriers and homozygous people with the disease and is not seen in any person who does not carry the mutant allele. In such a situation, a person can be diagnosed without knowing family inheritance patterns. With respect to the mutation in sickle cell anemia, the single A-to-T change at the DNA level that causes the conversion of glutamic acid to valine at position 6 of the -chain can be detected directly using several restriction enzymes. [5] [6] [7]

In most instances, however, single-base-pair changes do not give rise to convenient restriction enzyme site alterations that allow direct detection of the mutation. Alternatively, RFLPs may arise within the gene of interest independently from the mutation that causes the disease. These reflect common mutations associated with, but not responsible for, the less frequent mutations that alter gene expression and cause disease. In these instances, the RFLP does not directly identify affected people in the general population but is diagnostic in a family known to carry a mutant gene in association with a given RFLP. The informativeness of such an RFLP depends on the origin of the

Figure 160-1 Two different types of restriction fragment length polymorphisms used in the prenatal diagnosis of sickle cell disease. **(A)** The point mutation in the globin gene that gives rise to the sickle mutation alters the recognition site for the restriction endonuclease *Mst*II, giving rise to an altered restriction fragment when DNA containing the sickle gene is digested with that enzyme. **(B)** The sickle cell gene is associated with a DNA polymorphism in the 3 flanking DNA of the globin gene. This polymorphism is clinically silent but can aid in the antenatal diagnosis of sickle cell disease. If carrier parents are heterozygous for the polymorphism in association with the sickle gene (AS in the Southern diagram), fetuses at risk can be identified by homozygous presence of the same band (SS in diagram). M, *Mst*II; H, *Hpa*I; SS, sickle cell disease; AS, sickle trait; AA, normal.

disease-related mutation as a single event within a population at a time after the RFLP arose. Thus, it requires the selection for persistence of the original disease allele in the population rather than its continued renewal by new mutations. Both sickle cell disease and the thalassemias have been shown to have arisen in selected populations in association with such polymorphisms. [8] [9] [10] In stable populations, several such polymorphisms together have been used to define a haplotype with which a given disease is associated. This has been documented by Orkin and associates [11] for several specific -thalassemia mutations.

Finally, an RFLP may not lie within the locus of the gene of interest at all, but may lie close enough to the gene that the two loci rarely, if ever, become separated by recombination. The diagnostic value of the RFLP then depends on statistical analysis of the proximity of the polymorphism to the gene of interest. Diagnosis is based on the analysis of the RFLP patterns of a given affected family to ascertain whether the distribution of alleles allows identification of the RFLP associated with the disease within that individual pedigree. Although this kind of linkage analysis is the least direct application of RFLPs to disease diagnosis, it is the most generalizable to a wide range of diseases. Because the globin gene locus has been fully sequenced and the mutant alleles extensively analyzed, most diagnoses can be made by direct diagnosis using RFLP analysis based on either altered restriction sites at the site of mutation or haplotype analysis, as described earlier. However, this more general application of RFLPs is the basis for gene mapping efforts that promise to allow diagnosis of diseases for which the mutations, and indeed the affected genes themselves, are yet to be identified.

The use of RFLPs for antenatal diagnosis was first undertaken for the diagnosis of hemoglobinopathies. The application of these techniques to the diagnosis of sickle cell disease is diagrammed in Figure 160-1 . Similar techniques have been used in parallel fashion for the prenatal diagnosis of thalassemia. The earliest studies of sickle cell disease were based on a polymorphic site for the enzyme *Hpa*I, which was located 4 kilobases (kb) downstream of the -globin gene. [3] Absence of the restriction site was seen in 87% of sickle genes in the population studied. [8] Consequently, if parents carrying the sickle gene were heterozygous for the absent restriction site, affected fetuses could be identified by homozygous absence of the same site (Fig. 160-1B). Subsequent techniques for diagnosing sickle cell disease exploited the fact that sickle cell disease, unlike thalassemia, arises from a single defined mutation, namely a single A-to-T base substitution. This allowed the identification of restriction enzyme sites that were altered by the mutation, as well as direct analysis of mutant alleles without family studies. Two enzymes that can be used to identify the sickle mutation have been identified. [5] [6] [7] One of these, *Mst*II, results in an easily distinguishable pattern diagnostic of the disease (Fig. 160-1A). This technique has also been used to diagnose other single-base mutations resulting in hemoglobins S, O-Arab, and others. [12] [13] As previously suggested, thalassemia is not readily amenable to this approach because of the heterogeneous lesions giving rise to the disease; however, certain predominant mutations within defined populations have been diagnosed in this manner. [14]

All of these studies are performed using Southern blotting techniques. [15] Genomic DNA from the fetus (and appropriate family members as needed) is digested with a diagnostic restriction enzyme, size fractionated by agarose gel electrophoresis, blotted on nitrocellulose, and hybridized to a radiolabeled probe for the -globin gene. Hybridization techniques are described in Chapter 1 .

Direct Oligonucleotide Screening for Known Point Mutations

The full sequence of the -globin gene is known, and the single base change responsible for the sickle mutation has been established. This knowledge allows more refined techniques for prenatal diagnosis of sickle cell disease, as well as for other hemoglobinopathies in which the responsible mutation is known at the level of the DNA sequence. Molecular hybridization techniques have been developed that can pinpoint single base changes in DNA sequence using short probes of 1520 nucleotides. Under stringent washing conditions, hybridization between such a short probe and the DNA in question requires that the base pairing between the two be exact. Technology for the synthesis of such oligonucleotide probes now exists. Oligonucleotide sequences that are identical to either the native or the mutant gene can be synthesized and the oligonucleotides radiolabeled and hybridized to DNA from the fetus at risk (Fig. 160-2). This DNA can be spotted directly onto nitrocellulose because the hybridization does not require restriction enzyme digestion of the DNA. The consequent rapidity of diagnosis gives this technique its primary advantage over RFLP analysis by Southern blot hybridization. The method has been used successfully for prenatal diagnosis of both sickle cell disease and thalassemias associated with known single-base changes. [16] [17] [18]

Use of PCR in Prenatal Diagnosis

The development of PCR represents one of the most important technical advances in molecular diagnostics. [19] The technique is described elsewhere (see Chap. 1) and is summarized again in Figure 160-3 . Using PCR, prenatal diagnosis is possible with as little as 1 g of DNA. Diagnosis is performed by using oligonucleotides flanking the gene to amplify the DNA of interest from minute quantities of total cellular DNA. The amplified sequences can then be analyzed by any of the techniques described. A common means of diagnosis is to hybridize the amplified DNA to oligonucleotide probes. This is currently the most rapid means of diagnosis of sickle cell disease[20] [21] and thalassemias with known mutations.[22] These techniques can also be invaluable in the rapid analysis of unknown mutations. [22] Alternatively, if a mutation alters a known restriction enzyme site, PCR-amplified DNA can be digested and analyzed by agarose gel electrophoresis.

A fluorescence amplification technique has been developed that permits direct PCR analysis of DNA for known single-base mutations. Oligonucleotide primers containing the normal and mutant sequence are synthesized, and the two primers are differentially labeled with red and green fluorescent tags. These primers are mixed with a common antisense primer, which is left unlabeled. PCR is then performed, and the reaction products are then directly analyzed in a fluorometer for differential fluorescence. [23]

Although the primary focus of this discussion has been on the prenatal diagnosis of hemoglobinopathies, similar techniques are also being used in the diagnosis of hemophilia and other congenital hematopoietic disorders as their molecular origins become better understood. [24] These techniques are not restricted to prenatal diagnosis. For example, PCR for the diagnosis of factor V Leiden has become a routine part of the evaluation of patients with suspected hypercoaguable states. [25]

DIAGNOSIS OF LYMPHOPROLIFERATIVE DISEASE

As mentioned previously, lymphocytes are a unique exception to the rule that all somatic cells carry identical DNA. Lymphocyte ontogeny is marked by a series of DNA rearrangements and deletions by which the immunoglobulin and T-cell receptor (TCR) gene loci become functional units capable of expression. The details of gene rearrangement and the role it plays in the generation of antigen specificity and immunologic diversity are described in Chapter 15 . The discussion here is limited to a

Figure 160-2 Use of oligonucleotide probes to screen for sickle cell disease. Specific oligonucleotide probes that are homologous to the sequence of the ^{A} and the ^{S} -globin genes are synthesized. Because the oligonucleotides are only 19 nucleotides long, hybridization under appropriately stringent conditions will yield stable hybrids only if the DNA sequence is identical to the probe sequence. The single base change that gives rise to the sickle mutation is sufficient to destabilize the DNA-oligonucleotide duplex and allows the distinction of normal (AA), sickle trait (AS), and sickle cell disease (SS) DNA. After isolation, the DNA is blotted directly onto nitrocellulose without the necessity of restriction enzyme digestion and hybridized to the radiolabeled oligonucleotide probes. The blots are washed at high stringency and autoradiographed. Predicted results are as diagrammed in the lower panel.

description of the direct clinical applications of molecular probes to the investigation of the characteristics and natural history of lymphoproliferative disease.

The use of the Southern blotting technique to elucidate the clonal rearrangements of the immunoglobulin light chain genes is outlined in Figure 160-4 . Similar general principles apply to the rearrangement of the heavy chain genes and the light chain loci, as well as the TCR gene loci. In nonlymphoid cells, all the immunoglobulin and TCR genes are in the germline (unrearranged) state. Southern blot analysis of DNA derived from nonlymphoid cells using a probe for the immunoglobulin heavy chain gene reveals a single band.

The immunoglobulin genes in all B cells, and the TCR genes in all T cells, have undergone somatic rearrangement. Because there is flexibility of the precise site at which the rearrangement of these genes takes place, not all the recombinations maintain a reading frame that allows for successful translation of the mRNA into a functional protein. If a nonfunctional rearrangement takes place on one chromosome, a further rearrangement takes place on the homologous chromosome. Because of the large deletions that take place in the course of recombination, it is not possible for two rearrangements to take place on the same chromosome. Consequently, every lymphoid cell has either one or two rearranged heavy chain genes, and one or two rearranged light chain genes. If Southern blot analysis could be performed on a single cell, each lymphocyte would show either one or two rearranged bands. However, because the DNA from >10,000 cells is required to detect a single-copy gene by Southern blot analysis, these bands will be undetectable in a polyclonal proliferation of lymphocytes. The only detectable band is the germline band contributed by the unrearranged heavy chain genes in the lymphocytes that have rearranged only one of the two heavy chain loci.

In a monoclonal proliferation of B cells, however, all the cells contain an identical pattern of heavy chain rearrangement. Southern blot analysis thus reveals one or two rearranged bands, corresponding to one or two rearranged heavy chain loci.

Defining Clonality of Lymphoproliferative Lesions

The process of malignant transformation freezes a tumor cell population at a given stage of differentiation and gives rise to a proliferation of cells manifesting an identical pattern of DNA rearrangement. Southern blot analysis consequently offers a sensitive means of establishing the clonality and lymphoid origin of cells showing somatic rearrangement of their immunoglobulin or TCR gene loci. Southern blot analysis of DNA from a range of tissues, including lymph nodes, pleural fluid, and peripheral blood, has been used to establish the diagnosis of lymphoma in lesions that lack either definitive histology or surface markers. [25] It has also been used to examine the clonality of poorly defined lymphoid lesions such as T-cell lymphocytosis, [26] [27] [28] angioimmunoblastic lymphadenopathy,[29] and

Figure 160-3 Use of PCR to amplify a portion of DNA for analysis. One microgram of total genomic DNA is denatured at high temperature and annealed to oligonucleotide primers flanking the DNA of interest. By using the temperature-stable *taq* polymerase, the primers are extended to synthesize a copy of the DNA between the two primers. The temperature is then raised to denature the products, and the process is repeated for 30 cycles. The primary product of this reaction is a fragment of DNA bounded by the two oligonucleotide primers (short-short hybrids). By this means, a minute quantity of total DNA may be used to generate specific DNA in large quantity for analysis.

Figure 160-4 Southern blot analysis of light chain rearrangement to establish clonality of populations of B lymphocytes. **(A)** The Southern technique and its predicted results in different cell populations. **(B)** The molecular configuration of the -locus. **(Left)** Genomic DNA, as represented in peripheral blood granulocytes, is analyzed. Because all of these cells retain their immunoglobulin genes in the germline configuration, a single band on Southern blot analysis corresponds to the germline -locus. **(Middle)** Polyclonal lymphocytes also show only a germline band on Southern analysis. However, as shown in part B, this does not show that the cells do not have rearrangement of the -locus. Instead, it demonstrates that there are insufficient cells of any one clone to be detectable as a discrete band on Southern analysis. Because a significant fraction of the cells retain one -locus that is unrearranged, a germline band is detectable. (In normal peripheral lymphocytes, this band also partly reflects T cells, which do not rearrange their immunoglobulin gene loci.) **(Right)** The Southern pattern produced by monoclonal tumor cells bearing a light chain. All the cells of the population have an identical rearrangement of the -genes that will be apparent as a rearranged band on Southern blot analysis. The figure demonstrates the pattern of cells in which one -locus has rearranged. If both chromosomes are rearranged, there will be two rearranged bands, and the germline band will no longer be present.

lymphoproliferative lesions related to the acquired immunodeficiency syndrome. [30]

Gene rearrangement studies must be interpreted in light of the genetic events tied to lymphocyte ontogeny that they reflect. Because a chromosomal locus can rearrange only one time, only one band corresponding to the DNA should be seen on each chromosome. More than two rearranged bands is indicative of an oligoclonal population of cells. In addition, there is a strict hierarchy of recombinatorial events. The immunoglobulin heavy chain locus rearranges before the light chains, and light chains rearrange before the -chains. [31] Similarly, the -chain of the TCR is the first of the TCR loci to rearrange. [32] If a functional rearrangement does not occur in either -locus, and the -locus rearranges successfully, the -regions are often subsequently deleted altogether. Finally, in some lymphoid tumors, immunoglobulin heavy chain rearrangements are found in the company of T-cell -chain rearrangements. Such lineage infidelity has never involved light chain rearrangement and is thought to be a marker of malignant derangement of a very early lymphoid cell.

The sensitivity of gene rearrangement studies allows the detection of very small clonal populations amounting to as little as 1% of the total cellular population studied.[33] The significance of small clonal populations has been debated, and the equation of monoclonality with malignancy has been challenged. [32] For example, patients with angioimmunoblastic lymphadenopathy have been observed to have small clonal populations of B and T cells in lymph nodes and peripheral blood that are frequently transient. It seems likely that this represents temporary overgrowth of small clones of cells secondary to defective immunoregulatory control rather than malignancy.[29]

Determining Extent of Lymphoproliferative Disease

Immunoglobulin and TCR gene rearrangements have been used in the staging of patients with lymphoproliferative disease. Southern blot analysis using probes for these loci has been shown to be sensitive enough to detect clonal populations of approximately 1% of the total cell population studied. This translates to detection of the DNA represented by 10^4 cells.[32] [33] Consequently, it is a highly sensitive means of detecting peripheral blood or bone marrow involvement with lymphoma in patients with known lymphoproliferative disease in whom marrow involvement is insufficient for histologic diagnosis.

Gene rearrangement studies have also been used to validate the use of flow cytometry as a means of detecting peripheral blood involvement with B-cell lymphoma. [34] The test allows cytofluorometric identification of small populations of clonal B lymphocytes by detection of an imbalance in the normal distribution of surface immunofluorescent staining for and light chains. Peripheral blood mononuclear cells are labeled with fluorescent-tagged rabbit heteroantisera to and light chains and then analyzed in a flow cytometer. The success of the technique is based on the empiric observation that a given clone of B cells has a uniform expression of surface light chains, and that the histograms of and light chain distribution in normal polyclonal B cells are identical. The presence of a predominant clone distorts the histogram of the light chain expressed and causes the shift of one curve relative to the other. The difference between the curves may then be analyzed by computer.[35] [36] The sensitivity of the flow cytometric technique allows detection of clonal populations in the 510% range. Gene rearrangement studies have confirmed that the finding of a positive test result correlates with the finding of a circulating population of cells with the same DNA rearrangement as that found in the primary tumor.[32] Although Southern blot analysis is more sensitive than flow cytometry, it appears that the latter, simpler, technique is an extremely effective means of detecting minimal bone marrow involvement with lymphoma.

Monitoring Disease Activity in Treated Patients

The sensitivity of immunoglobulin and TCR gene rearrangement studies makes them an excellent method for detecting minimal residual involvement of the bone marrow in patients undergoing chemotherapy or bone marrow transplantation for the treatment of lymphoid malignancy. In a study of children treated with chemotherapy for acute lymphocytic leukemia, this technique allowed detection of an estimated 1 in 5001,000 leukemic cells in remission marrows. [37] [38] Subsequent studies have suggested that detection of any number of residual leukemic cells by this technique is highly predictive of relapse, although negative studies do not guarantee long-term remission.[38] [39]

Use of PCR Analysis of Immunoglobulin and TCR Loci in Lymphoproliferative Disease

Because PCR can potentially amplify the DNA of a single gene from a single cell to a detectable level, it can detect minimal involvement with cells carrying a characteristic gene rearrangement well below the limits of detectability by any other technique. However, PCR for diagnosis of lymphoproliferative disease is hampered because the sequence of rearranged immunoglobulin or TCR loci in a given lymphoma is specific to that patients tumor and theoretically requires design of patient-specific primers to amplify tumor DNA. Modifications of the PCR technique have allowed for the design of primers that can monitor minimal residual disease by PCR. Two major techniques have been used. The first is to design two consensus primers, one to conserved sequences within the flanking DNA of the V region, and the other to a similarly conserved sequence flanking the J region; these regions lie too far apart in unrearranged DNA to allow efficient PCR. Only rearranged immunoglobulin or TCR loci will allow amplification of a distinct fragment; clonal populations yield an amplified species by this technique. PCR is then used to detect a characteristic footprint of the rearranged DNA within the tumor that can then be followed as a marker for residual disease. [40] [41] [42]

A more sensitive technique has been developed by which PCR fragments generated using consensus sequences are then subcloned and sequenced, with subsequent synthesis of patient-specific oligonucleotide probes, termed *allele-specific oligonucleotides.* PCR is then performed using one consensus primer and one allele-specific oligonucleotide; this has in fact resulted in the detection of malignant cells at the theoretic detection limits of PCR, namely 1 in 10 ^{5} 10^6 cells.[43]

Use of PCR of the immunoglobulin and TCR loci for detection of residual lymphoproliferative disease has proved highly predictive of relapse in patients with acute lymphocytic leukemia.[44] [45] However, absence of detectable diagnostic fragments by either Southern blot analysis or PCR has not been shown to guarantee ongoing remission. In some patients with previously normal results, positive PCR studies were seen to develop before relapse. [46]

The negative prognostic significance of detection of residual disease by these techniques contrasts with the results found for detection of residual *bcr-abl* transcripts after bone marrow transplantation for chronic myelogenous leukemia (CML), as is discussed in greater detail later.

HUMAN LEUKOCYTE ANTIGEN TYPING FOR BONE MARROW TRANSPLANTATION

Molecular techniques are of growing importance in the analysis of potential donors for bone marrow transplantation. Serologic human leukocyte antigen (HLA) testing identifies large groups of cross-reactive antigens. It has been found that genotypic incompatibility results in acute graft-versus-host disease, despite

serologic identity.[47] When evaluating sibling donors, serologic testing and mixed lymphocyte culture (MLC) assays are usually adequate to confirm the haplotype identity of the donor and recipient. However, with the advent of unrelated donor transplantation, it has become increasingly important to guarantee genotypic identity by molecular techniques. In unrelated donor transplantation, MLC reactivity has been shown to be a very poor predictor of graft-versus-host-disease. [48] Most laboratories have abandoned MLC testing and are routinely using PCR amplification of DNA followed by hybridization to sequence-specific oligonucleotide probes to establish specific HLA-DR antigen typing.[49] [50] [51] Similar assays of HLA class I loci are also being developed and are anticipated to replace serologic testing in the future.[52]

ANALYSIS OF CELL ORIGINS IN BONE MARROW TRANSPLANT RECIPIENTS

Restriction fragment length polymorphism analysis is a powerful technique for analyzing the engraftment of patients from their donors after bone marrow transplantation. Southern blot analysis allows the laboratorian to distinguish virtually any two individuals by the use of any of the growing panel of defined DNA polymorphisms.[53] Peripheral blood from the patient and the donor can be analyzed before transplantation to define polymorphic sites at which they differ. Alternatively, after transplantation, DNA from a nonhematopoietic tissue from the patient (i.e., skin) can be compared with DNA from the donor.

This approach has been used to document engraftment, graft failure, and graft loss. It has also been used to document hematopoietic chimerism in a patient with severe combined immunodeficiency, in whom the T cells were shown to be of donor origin and the B cells and granulocytes were shown to be of patient origin. [54] [55] Similar studies can also be used to determine the cell implicated in the relapse of leukemia after transplantation. [56] [57]

DIAGNOSIS AND FOLLOW-UP OF DISEASES ASSOCIATED WITH KNOWN CYTOGENETIC ABNORMALITIES

Several hematologic malignancies are associated with characteristic chromosomal translocations that mark the abnormal cell population. The Philadelphia chromosome in CML and the t(14;18) translocation in follicular lymphoma are two examples of such translocations in which the genes involved in the chromosomal breakpoint have been defined. Southern blot analysis, using probes for the genes involved in the translocation event, permits the detection of a rearranged band in DNA from cells carrying the translation. In a manner similar to that used for the detection of small populations of lymphoma cells, this method can be used to detect small residual populations of malignant cells after treatment with chemotherapy or bone marrow transplantation.

The advent of PCR has rendered this methodology much more powerful. By means of probes for the *bcr-abl* translocation, this technique has been used to demonstrate residual CML cells in patients after chemotherapy and bone marrow transplantation. [58] [59] Similarly, probes of t(14;18) have been used to detect residual follicular lymphoma cells in patients apparently in remission in terms of histologic and conventional Southern blot analysis. [60] With respect to t(14;18), detection of residual disease was highly predictive of relapse in one study. [61] However, in CML, *bcr-abl* transcripts were detectable by PCR in almost all patients within the first 6 months after bone marrow transplantation. This finding does not appear to be predictive of imminent cytogenetic or hematologic relapse and may support the hypothesis that the cure of CML depends on the graft-versus-leukemia effect, at least in some patients. [62] The long-term prognostic significance of repeated amplifiable *bcr-abl* transcripts in patients in remission remains to be determined. Similarly, in M2 acute myelogenous leukemia (AML) associated with the t(8;21) translocation, there is a high rate of detectable fusion *AML1/ETO* transcripts from the translocation seen in patients in long-term remission. [63] [64] This is not associated with a threat of imminent relapse. In one study, patients after allogeneic transplantation for AML associated with this cytogenetic abnormality did not have detectable transcripts.[64] However, because most patients with this subtype of AML do not require bone marrow transplantation, [65] it is important to note that there is no established predictive value for detectable *AML1/ETO* fusion transcripts after successful chemotherapy for this disease. With this caveat in mind, PCR promises to be an extremely important tool for following the natural history and predicting the course of these diseases.

TABLE 5 -- Red Cell Enzyme Activity in Adults and Term Infants[a]

Enzyme	Adults (n = 20)	Infants (n = 10)
Hexokinase	12.9 ± 2.1	34.0 ± 6.0
Phosphoglucose isomerase	406 ± 37	560 ± 112
Phosphofructokinase	148 ± 24.5	84.5 ± 24
Aldolase	24.5 ± 3.7	42.0 ± 10.0
Glyceraldehyde-3-phosphate dehydrogenase	885 ± 127	884 ± 245

Triosephosphate isomerase	26,323 ± 3,240	29,111 ± 4,100
Phosphoglycerate kinase	2,795 ± 144	3,926 ± 528
Phosphoglycerate mutase	751 ± 99	1,049 ± 160
Enolase	252 ± 54	517 ± 121
Pyruvate kinase	179 ± 16	256 ± 50
Lactic dehydrogenase	2,033 ± 287	2,756 ± 425
Glucose-6-phosphate dehydrogenase	215 ± 18	328 ± 40

Reproduced with permission from Oski FA: Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes. Pediatrics 44:84, 1969.

[a]Infant samples were obtained from newborns weighing more than 2,800 g whose gestational age was 39 weeks or greater. Blood was drawn within 24 hours of birth. All the newborns were clinically healthy. Adult samples were obtained from healthy, normal volunteers. Units per 100 ml of RBCs.

TABLE 6 -- Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants[a]

Metabolite	Normal Adults (n = 10)	Term Infants (n = 10)	Premature Infants (n = 11)
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9
Fructose-1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15
2,3-Diphosphoglycerate	4,423 ± 1,907	3,609 ± 800	3,152 ± 2,133

Reproduced with permission from Oski FA: Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes. Pediatrics 44:84, 1969.

[a]Premature infants had birth weight below 2,200 g and gestational age of <37 weeks, and were clinically healthy at the time of investigation.

From Andrew M, Vegh P et al: Maturation of the hemostatic system during childhood. Blood 80:1998, 1992, with permission.

[a]All factors except fibrinogen are expressed as units per milliliter, where pooled plasma contains 1.0 U/ml. All data are expressed as the mean, followed by the upper and lower boundary encompassing 95% of the population. Between 20 and 50 samples were assayed for each value for each age group. Some measurements were skewed due to disproportionate number of high values. The lower limit, which excludes the lower 2.5% of the population, is given. PT, prothrombin time; APTT, activated partial thromboplastin time; VII, factor VII procoagulant; vWF, von Willebrand factor; PK, prekallikrein; HMWK, high molecular weight kininogen.
[b]Values that are significantly different from values in adults.

TABLE 16 -- Reference Values for the Inhibitors of Coagulation in Fetuses, Full-term Infants, and Adults[a]

Parameter	Fetuses (Weeks Gestation)			Newborns (n = 60)	Adults (n = 40)
	19 23 (n = 20)	24 29 (n = 22)	30 38 (n = 22)		
ATII (%)	20.2 (1231) [c]	30.0 (2039)	37.1 (2455) [d]	59.4 (4280) [d]	99.8 (65130)
HCII (%)	10.3 (616)	12.9 (5.520)	21.1 (1133) [d]	52.1 (1999) [d]	101.4 (70128)
TFPI (ng/ml) [b]	21.0 (16.029.2)	20.6 (13.433.2)	20.7 (10.431.5) [d]	38.1 (22.755.8) [d]	73.0 (50.990.1)
PC Ag (%)	9.5 (614)	12.1 (816)	15.9 (830) [d]	32.5 (2147) [d]	100.8 (68125)
PC Act (%)	9.6 (713)	10.4 (813)	14.1 (818) [c]	28.2 (1442) [d]	98.8 (68129)
Total PS (%)	15.1 (1121)	17.4 (1425)	21.0 (1530) [d]	38.5 (2255) [d]	99.6 (72118)
Free PS (%)	21.7 (1332)	27.9 (1940)	27.1 (1840) [d]	49.3 (3367) [d]	98.7 (72128)
Ratio of free PS to total PS	0.82 (0.750.92)	0.83 (0.760.95)	0.79 (0.700.89) [d]	0.64 (0.590.98) [d]	0.41 (0.380.43)
C4b-BP (%)	1.8 (0.6)	6.1 (012.5)	9.3 (514)	18.6 (340) [d]	100.3 (70124)

From Reverdiau-Moalic P, Delahousse B et al: Evolution of blood coagulation activators and inhibitors in the healthy human fetus. Blood 88:900, 1996, with permission.

[a]Values are the mean, followed in parentheses by the lower and upper boundaries including 95% of the population. Abbreviations: Ag, antigen; Act, activity.
[c]$P < 0.05$.
[d]$P < .01$.
[b]Twenty samples were assayed for each group, but only 10 for 19- to 23-week-old fetuses.
