Mathé and colleagues in the 1970s observed unexpected improvement of pancytopenia after failed marrow transplantation. They speculated that the immunosuppressive conditioning regimen, intended to allow engraftment of the donor marrow, might instead have promoted the recovery of host marrow function. [67] Purposeful targeting of the immune system followed these observations. The known mechanisms of action of these medical treatments, the effectiveness of diverse therapies that reduce lymphocyte number or block T-cell function, and the superior results obtained when agents are combined strongly suggest that such therapeutic success is due to the immunosuppressive effects of the drugs employed. In addition, AA shares numerous clinical and pathophysiologic features with other autoimmune disorders, including multiple sclerosis, type I diabetes, autoimmune thyroiditis, uveitis, and idiopathic myocarditis. Each of these disorders is characterized by T-cell-mediated, tissue-specific organ destruction. Like AA, these disorders

Figure 19-4 Possible etiologies of direct and indirect bone marrow failure in aplastic anemia.

tend to occur in younger persons and may occur in greater numbers in specific geographic locales. The late immune events that dominate at the time of clinical presentationcytotoxic lymphocyte activation, cytokine production, and specific target cell eliminationare common to all of these disorders. In AA, chemical and viral antigens are thought to initiate the immune process, whereas in other T-cell-mediated diseases, specific antigens like myelin basic protein in multiple sclerosis or insulin in diabetes have been identified.

Immune system destruction of marrow occurs in animal models of graft-versus-host disease (GvHD) and in humans with transfusion-associated GvHD, in which marrow destruction is the invariable cause of death.[68] Very small numbers of effector cells, which have been conveyed by residual lymphocytes contained within the transfusion product[69] or with solid organ transplants,[70] are sufficient to mediate GvHD under these conditions. Extremely limited antigenic differences in HLA molecules (even single amino acid substitution) are sufficient to induce GvHD. AA is associated with rheumatologic syndromes, such as eosinophilic fasciitis,[71] and with systemic lupus erythematosus, which may appear or worsen with pregnancy.[72] AA occasionally occurs in individuals with hypogammaglobulinemia[73] [74] or congenital immunodeficiency syndrome.[75] This combination of AA and congenital immunodeficiency syndrome is associated with thymoma, thymic hyperplasia,[76] and thymic carcinoma.[77] In one case, suppressor T cells, already implicated in B-cell inhibition, were shown to suppress erythropoietic colony formation.[78] Reduced serum immunoglobulins and thymic dysplasia have also been observed with marrow aplasia in patients with the congenital dyskeratosis congenital syndrome,[79] which may manifest late in life with bone marrow failure.

Laboratory support for the immune hypothesis first came from co-culture experiments in which mononuclear cells from AA patients blood or bone marrow were shown to suppress in vitro hematopoietic colony formation by hematopoietic progenitor cells. Removal of T cells from the patient samples sometimes improved colony formation in vitro.[80] Peripheral blood and bone marrow samples from patients were shown to produce a soluble factor that inhibited hematopoiesis; normal lymphocytes could be stimulated to release a similar activity.[81] [82] [83] This soluble inhibitory activity was ultimately identified as interferon- (IFN-).[84] Patients T cells, in bulk culture[85] [86] or when cloned,[87] overproduced both IFN- and tumor necrosis factor (TNF). These two cytokines inhibit hematopoietic proliferation at all stages of differentiation.[88] Marrow IFN- mRNA was detected in samples from most patients but not in samples from normal control subjects or from patients with other hematologic diseases.[89] [90] Patients blood and marrow also contained elevated numbers of activated cytotoxic lymphocytes.[91] The activity and levels of these cytotoxic cells fell appropriately with antithymocyte globulin (ATG) therapy.[92] [93] It appears that both secretion of cytokines and accumulation of activated cytotoxic lymphocytes are specifically localized to the affected target tissuethe bone marrow.

The lymphokines IFN- and TNF suppress proliferation of early and late hematopoietic progenitor and stem cells.[88] These effects are far more potent when these lymphokines are secreted into the marrow microenvironment than when they are simply added to the cultures.[94] Such findings are consistent with their localization in the marrow of patients. Although IFN- and TNF can suppress hematopoiesis by effects on cell proliferation, an important component of their inhibitory activity is cell death by induction of apoptosis. Both lymphokines also induce expression of the Fas receptor on CD34+ progenitor cells; triggering of the Fas receptor by its ligand initiates a fatal process of apoptosis.[95] [96] Apoptosis of hematopoietic cells in AA is suggested by the findings of high Fas receptor expression[97] and increased numbers of apoptotic cells[98] in patients bone marrow. Apparently, immune-mediated cell cycle blockade and apoptosis can lead to the dramatic elimination of hematopoietic progenitor and stem cells in AA.

The early immune system events that must precede the global destruction of hematopoietic cells are much less clear. Involvement of CD4+ lymphocytes has been suggested. HLA-DR2 is overrepresented among European and American patients with AA,[32] [99] and a more specific class II haplotype has been identified among Japanese patients.[40] Several HLA antigens may be much more common in certain subsets of AA (B8, Cw7, Dr7, DQ2, and Drw53 in marrow failure after hepatitis[38] [100]). The frequency of HLA-DR2 and HLA-DRw51 were both increased in the idiopathic form AA but were decreased in hepatitis-associated AA, whereas the frequencies of HLA-DQ and HLA-DRw53 appeared to be specifically increased.[38] Clones of HLA-DR-restricted T cells derived from a few patients have been shown to proliferate in response to marrow cells.[101] [102] A V21+CD4 T-cell clone has been isolated from an AA patient and shown to lyse DRB1*0405 target cells, including enriched CD34+ cells.[103] Although it has been suggested that an endogenous antigen (heat shock protein 70) could serve as a putative target for these autoreactive clones, the initial antigen recognition event that leads to breached tolerance and the subsequent process of spreading autoimmunity remains undetermined.

Radiation

Marrow aplasia is a major acute toxic effect of radiation:[104] [105] both stem and progenitor cells are damaged (Fig. 19-5). Bone marrow cells are most affected by high-energy -rays, and secondarily by - and -particles. With the exception of lymphocytes, which are directly killed, a round of replication is required for radiation damage to become manifest. Mitotically active hematopoietic tissue is exquisitely sensitive to irradiation, with a rough correlation between mitotic cycling status and radiation sensitivity. The dose-related occurrence of pancytopenia 24 weeks after exposure to radiation is due to injury of actively replicating progenitor cells. Mortality from hematologic toxicity is a function of the marrows ability to tolerate both depletion of hematopoietic cells and damage to the stem cell. The capacity for recovery of hematopoietic function after even massive single irradiation exposures is considerable, reflecting the resistance of the quiescent stem cell to damage and the enormous marrow repopulating potential of even a greatly reduced stem cell pool. At intermediate radiation doses around LD_{50}, where marrow toxicity limits survival, supportive efforts can drastically alter outcome. Autopsies of atomic bomb victims in Japan showed acellular bone marrows in the first weeks of the explosion, but there frequently was regenerating bone marrow in those who survived longer.[106] The histologic picture of radiation-mediated aplasia includes necrosis, nuclear pyknosis and karyorrhexia, nuclear lysis, and ultimately cytolysis; the associated phagocytosis, marked congestion, and hemorrhage are rapidly followed by fatty replacement.[107] Bone marrow hypoplasia occurs with radiation doses above 1.52 Gy to the whole body. Precise LD_{50} figures for humans do not exist, and estimates are based on the limited direct human data and extrapolation from animal experiments. The LD_{50} is highly dependent on the quality of medical care: improved support may double the tolerated radiation dose.[108] From assessment of the outcome of radiation accidents and high-dose therapeutic irradiation, the LD_{50} has been estimated at about 4.5 Gy,[109] [110] an almost mythical figure sometimes termed the Shields Warren number (Fig. 19-5).

The hematologist might be required to care for a patient who has received a dose sufficient to suppress hematopoiesis but not so overwhelming that death from other causes is inevitable. Although the principles of management of pancytopenia after a single large dose of irradiation are similar to those for treating

Figure 19-5 Scale of whole body radiation doses. A Gray (Gy) is a measure of absorbed dose equivalent to 1 J/kg unit mass; 1 Gy = 100 rads. Radiation represents radiant energy. When absorbed by biologic tissue, radiant energy causes release of electrons and molecular ionization, which in turn result in further energy release. Radiant energy can directly break chemical bonds and indirectly damage macromolecules through generation of high-energy free radical forms. The relationship between increased mutation rate and radiation dose is very approximate (hatched bars). Measurement of the phenotype of an autosomal recessive gene like glycophorin would be expected to be a very sensitive indicator. Since malignant transformation is almost certainly a two-step process, increased leukemogenesis is probably an underestimation of the effect of radiation on a single gene. In addition, even the extensive data from the atomic bomb survivors of Hiroshima are subject to statistical error because of the small number of cases; a linear or exponential curve fit gives varying results, and very high doses of irradiation may not be associated with as high a risk of leukemia because of stem cell death. Other data that may bear on mutation frequency lie outside the range shown: in a patient with ankylosing spondylitis who underwent irradiation of the spine, leukemogenesis was observed at relatively low doses (doubling of the leukemia rate can be extrapolated to about 7 mGy), but such individuals may be predisposed to leukemia. On the other hand, an increased risk of thyroid cancer after irradiation of the mediastinum in childhood occurred at about 4 Gy.

AA in general, some unique points should be made concerning immediate evaluation and long-term prognosis. The type and intensity of the source of radiation and the distance and shielding of the subject are the major determinants of radiation injury; owing to the nature of the exposure, these factors are often difficult to assess. Early recognition of the nature of the accident provides the best opportunity for dosimetry by accident reconstruction and may allow employment of blocking, displacement, or chelation agents. Exposure correlates well with the degree of pancytopenia.[111] Because lymphocytes are particularly sensitive to radiation, their rate of decline can be used to estimate the dose of total body exposure to a level of about 3 Gy.[111] At higher doses, the fall in granulocytes and the severity of thrombocytopenia and reticulocytopenia can be used as gauges.[112] After the Chernobyl radiation accident, measurements of dicentric chromosomes were utilized to estimate dose, which correlated better with neutrophil than with lymphocyte kinetics. The cytogenetic alterations in stem cells are dose related, irreversible, and probably cumulative in increasing the probability of leukemic transformation.[113] The survival of some patients who received doses >9 Gy suggests in retrospect that autologous marrow reconstitution may occur in most persons who survive the immediate consequences of radiation exposure.[114]

Pancytopenia may be a late consequence of a single radiation dose, [115] but AA is not well documented as a delayed event following radiation exposure. Out of 156 cases of AA in Japan in the 20 years following the atomic bomb explosions, only 13 individuals had received more than a 1-rad dose, and of the three individuals who had been heavily irradiated, only one had typical AA. [116]

A variety of hematologic abnormalities are associated with chronic low-level radiation exposure, most commonly lymphocytosis, neutropenia, immature or dysmorphic white cells, and giant platelets (Fig. 19-5). Cytogenetic abnormalities accumulate with time following chronic exposure, but they may not be reliably related to dose.[117] Repeated low doses of radiation can damage bone marrow and have been associated with AA under special circumstances, [118] but even under these circumstances only a small proportion of exposed individuals developed hematologic disease. [119] AA does not appear to be especially frequent among nuclear power plant or thorium processing factory workers or residents living in close proximity to the plants. [120] Excessive numbers of deaths from AA were reported after therapeutic irradiation of the spine for ankylosing spondylitis, [121] although later analysis has suggested that the risk may have been overestimated. [122] Despite occasional instances in which marrow failure developed years after radiation therapy

and chemotherapy,[123] AA was not found in unexpected numbers in a large population of cancer patients who had received therapeutic irradiation. [124] Bone marrow failure has not been observed with abnormally high frequency among persons exposed to higher natural background radiation. [125] Excessive deaths from AA did occur among American radiologists who died between 1948 and 1961;[126] AA deaths were estimated to be 43-fold higher in radiologists between 1920 and 1929 but were not elevated among later cohorts. With radiation as with benzene exposure, late marrow failure referred to in the older literature as aplastic might in fact be classified now as myelodysplasia.

Drugs and Chemicals

Medical drug use is frequently associated with AA (Table 19-3). [127] At the end of the 19th century, chemicals were linked to marrow function through observations of benzene effects on workers. Establishment of a relationship between the analgesic amidopyrine and agranulocytosis in the early 20th century, and an apparent epidemic of AA following the introduction of chloramphenicol in the 1960s, also supported this concept. Initially suggested by the accumulation of case reports, drug associations have been established in formal case-control population-based epidemiologic studies. In the IAAAS study, relative risks were established for individual drugs and large classes of pharmaceutical agents, including NSAIDs, drugs affecting thyroid function, certain cardiovascular agents, some psychotropics, and sulfa-based antibiotics (Table 19-4).[5] Approximately 25% of the cases of AA identified in the IAAAS study could be blamed on drug use. Drug use as a risk factor was also assessed by similar methods in Thailand, [128] where the incidence of AA is higher than in the West. [20] Surprisingly, chloramphenicol was not shown to be a risk factor; only sulfonamide exposure reached statistical significance, and the etiologic fraction for drugs in AA was only about 15%. [128]

Associations between drug exposure and AA are conveniently divided into two classes. Drugs used in cancer chemotherapy are selected for their cytotoxicity, and their regular, dose-dependent induction of marrow aplasia is an expected effect. Most AA associated with medical drug use in the community is described as idiosyncratic, meaning that its occurrences are unexpectedly rare. Many of the drugs implicated in AA also appear to cause other, milder forms of marrow suppression like neutropenia. Although difficult to prove, some dose relationship probably does exist even for idiosyncratic reactions. In most case reports, patients received normal or high doses of the agent, usually for a period of weeks to months. As

TABLE 19-3 -- Classification of Drugs and Chemicals Associated with Aplastic Anemia

I.	Agents that regularly produce marrow depression as a major toxic effect when used in commonly employed doses or normal exposures Cytotoxic drugs used in cancer chemotherapy Alkylating agents (busulfan, melphalan, cyclophosphamide) Antimetabolites (antifolic compounds, nucleotide analogs) antimitotics (vincristine, vinblastine, colchicine) Some antibiotics (daunorubicin, adriamycin) Benzene (and less often benzene-containing chemicals: kerosene, carbon tetrachloride, Stoddards solvent, chlorophenols)
II.	Agents probably associated with aplastic anemia but with a relatively low probability relative to their use Chloramphenicol (see text) Insecticides (see text) Antiprotozoals (quinacrine and chloroquine) >Nonsteroidal antiinflammatory drugs (including phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, naproxen, piroxicam, fenoprofen, fenbufen, aspirin) Anticonvulsants (hydantoins, carbamazepine, phenacemide, ethosuximide) Gold and arsenic (and other heavy metals, like bismuth, mercury) Sulfonamides as a class Antithyroid medications (methimazole, methylthiouracil, propylthiouracil) Antidiabetes drugs (tolbutamide, carbutamide, chlorpropamide) Carbonic anhydrase inhibitors (acetazolamide and methazolamide, mesalazine) D-Penicillamine 2-Chlorodeoxyadenosine
III.	Agents more rarely associated with aplastic anemia Antibiotics (streptomycin, tetracycline, methicillin, ampicillin, mebendazole and albendazole, sulfonamides, flucytosine, mefloquine, dapsone) Antihistamines (cimetidine, ranitidine, chlorpheniramine) Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon, remoxipride) Anti-arrhythmics (tocainide, amiodarone) >Allopurinol (may potentiate marrow suppression by cytotoxic drugs) Ticlopidine Methyldopa Quinidine Lithium Guanidine Canthaxanin Thiocyanate Carbimazole Cyanamide Deferoxamine Amphetamines

TABLE 19-4 -- Drugs Associated with Aplastic Anemia in the International Aplastic Anemia and Agranulocytosis Study[a]

Drug	Stratified Risk Estimate (95% CI)	Multivariate Relative Risk Estimate (95% CI)
Nonsteroidal analgesics		
Butazones	3.7 (1.97.2)	5.1 (2.112)
Indomethacin	7.1 (3.415)	8.2 (3.320)

Piroxicam	9.8 (3.329)	7.4 (2.126)
Diclofenac	4.6 (2.011)	4.2 (1.611)
Antibiotics		
Sulfonamides[b]	2.8 (1.17.3)	2.2 (0.67.4)
Antithyroid drugs	16 (4.854)	11 (2.056)
Cardiovascular drugs		
Furosemide	3.3 (1.67.0)	3.1 (1.28.0)
Psychotropic drugs		
Phenothiazines	3.0 (1.18.2)	1.6 (0.47.4)
Corticosteroids	5.0 (2.88.9)	3.5 (1.67.7)
Penicillamine		
Allopurinol	7.3 (3.017)	5.9 (1.819)
Gold	29 (9.789)	

From Kaufman DW, Kelly JP, Levy M, Shapiro S: The Drug Etiology of Agranulocytosis and Aplastic Anemia. Oxford University Press, New York, 1991, with permission of Oxford University Press.

[a]Extracted from the IAAAS monograph.[5] The multivariate model included the following factors: age, sex, geographic area, date of interview, reliability of the patient, person interviewed, transfer from another hospital, history of blood disorder or tuberculosis, exposure to benzene and related chemicals, and use of other suspected drugs.
[b]Other than trimethoprim-sulfonamide combination.

for agranulocytosis, most marrow failure complications occurred after a few weeks of initiation and within the first 6 months of treatment.

The mechanisms that lead to the development of AA after drug exposure include direct chemical toxicity and immune-mediated destruction. These pathophysiologic pathways have been best described for agranulocytosis. Unfortunately, drug-induced hematopoietic failure is difficult to study. AA is a rare rather than a common outcome, precluding development of an animal model, and the diversity of implicated drugs and the problem of confidently assigning causation in an individual case make clinical studies impractical. Drug-induced aplasia cannot be distinguished by history from idiopathic forms of the disease; the clinical course, including the favorable response to immunosuppressive therapy, of patients with histories of drug exposure is the same as in idiopathic disease. [129] Serum assays are also unhelpful because antibodies to either drugs or cells have only occasionally been identified in AA. [130]

The low probability of developing AA following a course of drug may be a reflection of the gene frequency for metabolic enzymes (for direct chemical effects) or immune response genes (for immune-mediated marrow failure) in the population. The rarity of idiosyncratic drug reactions would then arise from the infrequent combination of unusual circumstances: exposure, genetic variations in drug metabolism, the physical properties of the agent, enzymatic pathways that chemically alter the drug, and the susceptibility of the host to the action of a toxic compound. Many drugs and chemicals, especially if they have limited water solubility, must be enzymatically degraded before conjugation and excretion. Degradative pathways for xenobiotics are complex, specific, redundant, and interrelated. Intermediate metabolites in complex degradation pathways may be toxic, highly reactive, and responsible for some adverse effects of the primary agents. Examples of detoxifying enzyme systems directly applicable to bone marrow failure and that also demonstrate genetic variability include arylhydrocarbon hydroxylase (benzene toxicity), epoxide hydrolases (phenytoin toxicity), S-methylation (6-mercaptopurine, 6-thioguanine, azathioprine) and N-acetylation (sulfa drugs). The role of genetic background was shown in experiments using cells of a patient with carbamazapine-associated AA: only after generation of reactive metabolites from the incriminated agent by rat microsomes were the patients lymphocytes killed in a dose-dependent, drug-specific pattern. [131] These metabolites were not toxic for normal donors cells and displayed intermediate toxicity toward cells of the patients mother.

An immune basis for agranulocytosis was initially established with the identification of leukoagglutinating antibodies and, quite dramatically, by the rapid reproduction of the syndrome on drug challenge of affected patients or with infusions of plasma from affected patients into normal volunteers. Strong HLA class II linkage of clozapine[41] and thiouracil[132] agranulocytosis in certain ethnic groups suggests early involvement of CD4+T cells in drug-induced marrow failure. The absence of serum antibodies in AA suggests that drugs do not serve as simple haptens in the induction of this type of marrow failure. Possible mechanisms include binding to cellular proteins, leading to the loss of self-tolerance or disturbance of regulatory immune system networks with the same effect. The rarity of idiosyncratic drug reactions could be a function of genetic variation in drug metabolism systems, differences in major histocompatibility antigens and their peptide-binding properties, and the repertoire of potentially self-reactive circulating lymphocytes during the period of drug exposure.

Cytotoxic Agents

AA is predictably produced by the chemotherapeutic agents used in the treatment of cancer. Some agents, like busulfan, can cause profound delayed depression of bone marrow function and reduce marrow regenerative capacity. By contrast, 5-fluorouracil, cyclophosphamide, 6-mercaptopurine, methotrexate, and vinblastine appear to spare the regenerating cell population.

Benzene

Benzene is a ubiquitous chemical most convincingly linked to AA. [133] [134] [135] Benzene myelotoxicity can be placed between the predictable effects of chemotherapeutic agents and idiosyncratic drug reactions. Industrial emissions add greatly to the biologic sources of ambient benzene. Significant benzene exposure can also occur outside of industry. However, the concentrations of benzene to which consumers are exposed are orders of magnitude lower than those observed in industrial workers. The effect of chronic exposure to low doses of benzene is unknown.

Water-soluble products of benzene metabolism such as phenols, hydroquinones, and catechols mediate the toxicity to the marrow. Benzene and its intermediate metabolites covalently and irreversibly bind to bone marrow DNA, inhibit DNA synthesis, and introduce DNA strand breaks. Benzene thus acts both as a mitotic poison and as a mutagen. Acutely, the more mature, actively cycling marrow precursor cells are preferentially damaged over the more primitive progenitors. [136] Intermittent exposure may be more damaging to the stem cell compartment than continuous exposure[136] and suggests stem cell depletion. Marrow stroma can also be damaged by benzene.[137]

The range of hematologic disease attributable to benzene is quite broad, from relatively frequent mild alterations in blood counts to AA or leukemia. Studies of exposed American workers earlier in the 20th century suggested that the risk of AA was 34% in men exposed to concentrations >300 ppm, and that 50% of individuals exposed to 100 ppm showed some blood cell count depression.[138] The prevalence of some form of marrow suppression with heavy exposure can be high: >10% of workers developed leukopenia; with improved hygiene the figure was lowered to 0.5%. [139] Leukopenia, anemia, thrombocytopenia, and lymphocytopenia are common consequences of benzene; other

manifestations include macrocytosis, acquired Pelger-Huet anomaly, eosinophilia, basophilia, and, more unusually, polycythemia, leukocytosis, thrombocytosis, or splenomegaly. The marrow is usually normocellular but may show hypo- or hypercellularity; [138] a hypercellular phase may precede complete aplasia. In addition to hypocellularity, chronically exposed workers may have marrow necrosis, fibrosis, edema, and hemorrhage. [140] Chronic benzene exposure clearly increases the risk of a variety of lymphohematopoietic malignancies. AA and AML have occurred in the same person, [141] and pancytopenia preceded acute leukemia in one-fourth of industrial workers. [142] Both marrow failure and leukemia in benzene workers may manifest decades after exposure, but malignancy may be the more frequent late consequence.

Aromatic Hydrocarbons

The common perception that other molecules resembling benzene or containing a benzene ring may also cause marrow suppression is not well supported. Not all aromatic hydrocarbons share the same biologic activities. Neither the closely related alkylbenzenes nor pure toluene or xylene are established marrow toxins. Often an aromatic hydrocarbon has been implicated by the clinician as a causative agent for AA for lack of another apparent etiology. For some substances, toxicity may be due to the presence of benzene itself, either as a contaminant of the synthesis of the molecule or in the petroleum distillates used to dissolve the compound. Yet the total number of AA cases reported with aromatic hydrocarbon exposures is small when the large populations exposed to this heterogeneous group of chemicals are considered. For example, surveys of AA patients found that only 26% of cases were associated with insecticide exposure. [143] [144] The significance of a handful of case reports associated with insecticide exposure in the context of the vast use of these compounds is questionable. Of course, the very high prevalence of aromatic hydrocarbons in daily life would greatly amplify even a small individual risk. Pesticides and insecticides have been associated with AA for decades, with almost 300 medical case reports appearing in the medical literature. [145] The most frequently cited insecticides are chlordane and lindane or DDT. For the miscellaneous aromatic hydrocarbons, case reports also greatly outnumber series of patients, and systematic epidemiologic surveys have shown mixed results. Significant excesses of cases of AA were found in workers in the printing industry (odds ratio [OR] = 6.2), in lumber and wood products industries (OR = 3.7), in agriculture workers (OR = 2.4), and in construction workers (OR = 2.0).

Chloramphenicol

Structural similarity of chloramphenicol to amidopyrine, a drug known to cause agranulocytosis, led to early prediction of possible hematotoxicity. [146] [147] During the period of its unrestrained use, chloramphenicol was considered the commonest cause of AA in the United States, [148] accounting for 2030% of total cases and 50% of drug-associated cases.[149] [150] [151] Estimates of the risk of AA after a course of chloramphenicol ranged from 1/20,000 [150] to 1/800,000.[152] Based on these figures, a course of chloramphenicol was estimated to increase the risk of AA 13-fold. Although the introduction of chloramphenicol into the American market was perceived as having increased the total number of cases of AA,[148] [153] this assumption was only weakly supported by epidemiologic data, and the mortality from AA remained essentially constant during the period of chloramphenicols introduction and extensive use and following the withdrawal of chloramphenicol from the market. In recent series reported from the United States and Europe, of a total of 394 patients, only one was found to have ingested the drug. [25] [154] Chloramphenicol has not been associated with AA in Thailand, despite its high rate of use there. In Hong Kong, where utilization of chloramphenicol is almost 100 times higher than in the West, drug-associated AA is infrequent.[155] [156] The early epidemiologic surveys stressed excessive dosage, high blood levels, repeated or intermittent courses, young age, and oral route of administration as particular risks for chloramphenicol marrow toxicity. However, in a series of 600 cases, most patients had received a dose of <10 g.[157]

At ordinary doses, a pattern of reversible alterations in erythropoiesis occurs in most patients treated with chloramphenicol. [158] In vitro, chloramphenicol can decrease hematopoietic colony formation[159] or diminish colony size,[160] but usually at doses greater than those achieved in patients. Inhibition of marrow stromal cell proliferation[161] and the production of growth factors[162] have also been reported. There is no consistent evidence of abnormal marrow sensitivity to the drug in affected individuals. Chloramphenicol was also claimed to produce marked chromosomal abnormalities in white blood cells (WBCs). [163] Others have proposed that chloramphenicol toxicity is the result of covalent binding of the drug to reactive oxidative metabolites, such as an oxalic acid derivative produced by P-450 cytochrome-mediated oxidative dehalogenation to produce a chloramphenicol free radical and hydroxylamine intermediate, all capable of acylating proteins.

NSAIDs

In comparison to chloramphenicol, it took far longer to associate phenylbutazone with AA. [164] Mortality estimates have ranged from $1/10^5$ to $1/10^6$ treatment courses.[165] Usage of other NSAIDs is associated with case reports of AA. The large case-control investigation in Europe not only confirmed the risk of AA with phenylbutazone but identified even higher probabilities with other NSAIDs. [166] There was a suggestion of increased risk with drugs taken regularly for a prolonged period at very high doses, and in some cases hematologic reactions were reproduced on re-exposure.

Neuroleptics and Psychotropic Drugs

A variety of drugs used to treat disorders of the central nervous system have been associated with AA: the hydantoins and carbamazapine, anti-depressants, tranquilizers, and most recently Felbamate. The marketing of Felbamate was severely affected by the occurrence of aplasia in more than 30 patients. [167] Monitoring of drug blood levels and peripheral blood counts in patients receiving carbamazepine was recommended despite fewer than two dozen AA cases reported by 1982. [168] Doubt about the validity of many cases reported in the literature, as well as several large series of patients who did not develop hematologic toxicity [169] and an estimated AA case rate of about 1 in 200,000 treated patients,[170] have led many to question the relationship between carbamazepine and AA.

Gold and Other Heavy Metals

Gold salts have an extraordinarily high frequency of fatal adverse reactions, estimated at $1.6/10^4$ prescriptions. Dose-dependent leukopenia is common, but several dozen cases of AA have been reported.[171] In the IAAAS study, exposure to gold salts was the most significant drug association with AA, with an RR of 29 and an excess risk of 23 cases/10^6 users in 1 week.[5] Spontaneous recovery rarely occurs.[172] Other patients have been successfully treated with stem cell transplant or immunosuppressive therapy; chelation therapy has not been generally helpful. [173] High concentrations of gold salts inhibit hematopoietic colony formation in vitro. [174] There is some evidence for a dose relationship in patients, as high doses have been associated with the development of fatal pancytopenia, as opposed to transient neutropenia or thrombocytopenia.[175]

Arsenic poisoning can result in neutropenia, anemia, and thrombocytopenia. [176] Red cell basophilic stippling such as occurs in lead poisoning is a characteristic finding. Organic arsenicals, originally used in the treatment of syphilis (arsphenamine)

and now as antihelminthics (arseneamide), have also been associated with AA. [177] The quality of the older reports of both arsenic and other heavy metal effects do not allow the exclusion of myelodysplasia as a cause of the marrow failure.

Antithyroid Drugs

Antithyroid drugs have been more closely associated with the development of agranulocytosis than with AA. Thiouracil was reported to cause agranulocytosis in about 2% of treated patients;[178] estimates for propylthiouracil and methimazole ranged widely, from 0 to about 10%. [179] [180] In a Japanese series of over 19,000 cases, only 70 patients developed agranulocytosis. [181] Agranulocytosis was also significantly associated with antithyroid drugs in the IAAAS study, where the RR for agranulocytosis with a history of recent use was >100. In comparison, the risk of AA was about 10-fold lower. [182]

Antibiotics

Trimethoprim-sulfamethoxazole (TMX/SM) is associated with a variety of hematologic toxicities. Of cases reported in Sweden over a decade, leukopenia was most common, followed by bicytopenia, pancytopenia, thrombocytopenia, agranulocytosis, and anemia. The overall probability of developing a hematologic disorder with this treatment was estimated to be $5.3/10^6$ defined daily doses.[183] TMX/SM-associated agranulocytosis is the most common reported complication. As a class, antibiotics may be the commonest agents associated with hospital-acquired neutropenia. [184] Virtually every antibiotic has been associated with the development of agranulocytosis. In the IAAAS, exposure to TMX/SM during the 2 weeks prior to onset of agranulocytosis carried an RR of 12 (CI: 3.940). [154] The association of agranulocytosis with the use of sulfonamides, -lactams, tetracyclines, and other antibiotics, however, did not achieve statistical significance, nor was the use of any antibiotic significantly associated with the development of AA. [154]

Viruses

Viral infections are frequently associated with limited marrow suppression, typically neutropenia and less commonly thrombocytopenia. Epidemiologic studies of AA indirectly suggest an infectious agent. In Thailand, poverty [26] and grain farming (with its attendant water and insect exposure) [185] are associated with the development of AA. Viruses can damage bone marrow directly, by infection and cytolysis of hematopoietic cells, or indirectly, through induction of secondary immune pathways, initiation of autoimmune processes leading to depletion of progenitor and stem cells, or destuction of supporting stroma. Under specific circumstances known viruses can also cause bone marrow failure. AA rarely follows an Epstein-Barr virus (EBV) infection. The classic hepatitis/aplasia syndrome appears to be of viral origin but has not been linked to any known hepatitis agent. Other viruses, including a variety of herpesviruses, retroviruses such as human immunodeficiency virus (HIV), and B19 parvovirus, have not been convincingly implicated as general causes of AA. An interesting parallel exists between AA and the hemophagocytic syndrome, in which immune-mediated pancytopenia develops during convalescence from a wide variety of viral infections. [186] The clinical syndromes in which AA is associated with viral infections are discussed later.

TYPICAL AND ATYPICAL PRESENTATIONS

Classic Aplastic Anemia

History and Physical Examination

Most patients with AA seek medical attention for symptoms that occur as a result of low blood counts (Table 19-5; Plate 19-2AC). All of the blood elements may be depressed, or a

TABLE 19-5 -- Presenting Symptoms of Aplastic Anemia

Symptom(s)	Number of Patients

decrease in a single lineage may dominate the clinical picture. It should be remembered that the differential diagnosis of pancytopenia includes a variety of diseases (see Table 19-1). Bleeding is the most alarming manifestation of pancytopenia and most frequently sends the patient to a doctor. Thrombocytopenia is usually not associated with massive bleeding. Instead, the patient reports easy bruisability and the appearance of red spots, especially over dependent surfaces; gum bleeding with tooth brushing and episodic nosebleeds are also common complaints. Heavy menstrual flow or irregular vaginal bleeding can occur in younger women. In classic cases of paroxysmal nocturnal hemoglobinuria there are reports of red or dark urine that is due to free hemoglobin, but visible bleeding from the genitourinary and gastrointestinal tracts is rare on presentation in AA. Massive hemorrhage from any organ may occur but usually late in the course of the disease and almost always associated with infections, drug therapy (corticosteroids), or invasive procedures.

The ability to adapt to a gradual reduction in hemoglobin concentration is remarkable. The patient with insidious onset of anemia may relate fatigue, lassitude, shortness of breath, or ringing in the ears, but some individuals will tolerate astonishingly low hemoglobin levels without complaint. Angina precipitated by anemia may be a presenting symptom in the older patient. Even abrupt cessation of erythropoiesis will lead to only a slow decline in hemoglobin (about 1 g/dl/week). The presence, absence, or severity of anemia is not useful in judging the time of onset of disease as blood counts do not necessarily fall (or rise) concurrently.

Infection is an infrequent presentation of patients with AA. The sore throat of agranulocytosis is not often observed, presumably because other alarming symptoms appear earlier.

Except for complaints referable to the blood counts, most patients do not have systemic symptoms. Weight loss, persistent fever, and loss of appetite point to an alternative diagnosis. Pain is unusual.

Retrospective studies of AA associated with drugs and viruses and the observation of the occasional patient with serially monitored blood counts suggest a latent period of 68 weeks between the inciting event and the onset of pancytopenia. [187] The interval may be more prolonged when pancytopenia is well tolerated or moderate. Performing a careful, persistent, and reiterative history will often reveal exposure to drugs or chemicals or a preceding viral infection. For purposes of management, a history of blood diseases in other family members is important.

The findings on physical examination usually reflect the severity of the pancytopenia (Table 19-6). However, patients with severe disease may look remarkably well. The patient may present with subtle variations from normal or with a dramatic, even toxic appearance. Petechiae are often present over dependent areas, especially the pretibial surface of the lower leg and the dorsal aspects of the forearm and wrist; a few petechiae may be seen in the oropharynx and on the palate. Scattered ecchymoses of various sizes and shades may be seen, typically on areas

TABLE 19-6 -- Aplastic Anemia: Severity Defined by Laboratory Studies

Severe AA

Platelets <20,000/mm^3
Reticulocytes <40,000/mm^3
No other hematologic disease
Moderate AA
Patients with pancytopenia who do not fulfill the criteria of severe disease

exposed to minor trauma. With severe thrombocytopenia, retinal hemorrhages may be present on funduscopic examination, there may be gingival oozing or blood in

the nares, and hemorrhage may be apparent at the uterine cervical os. The stool may contain traces of heme. Pallor is common and is best appreciated on the mucosal membranes and palmar surfaces. The new patient may be febrile, but specific or localizing signs of infection are uncommon on presentation. Cachexia, splenomegaly, and lymphadenopathy are not associated with AA, and these findings should strongly suggest another diagnosis. The examiner should look carefully for café-au-lait spots and other physical anomalies of Fanconi anemia in adults as well as children. Acquired AA is usually a solitary diagnosis, and evidence from the history or physical examination of another major disease suggests secondary pancytopenia; an exception is drug-associated aplasia, as in the patient with chronic rheumatoid arthritis.

Several atypical presentations of the AA should be pointed out. A physician may encounter an elderly patient with pancytopenia in whom subsequent bone marrow examination reveals dysplastic features. This patient may represent a diagnostic challenge to the physician, who must discriminate AA from hypoplastic myelodysplasia (Fig. 19-6 ; Table 19-7 (Table Not Available)). Although the history of the present illness in a newly diagnosed patient will be short, in the range of months, occasional patients recall a long history of bruisability, anemia, and low blood cell counts reported to them by previous physicians during routine examinations.

Figure 19-6 Diagnostic algorithm in aplastic anemia. PB, peripheral blood; BM, bone marrow; AA, aplastic anemia; MDS, myelodysplastic syndrome; AML, acute myelogenous leukemia; AMM, agnogenic myeloid metaplasia; DEB, diepoxybutane; MMC, mitomycin C.

CLINICAL ASSOCIATIONS

A number of clinical syndromes, usually revealed through a careful history and physical examination, are associated with AA (Fig. 19-6 ; Tables 19-2 and 19-3).

Post-transfusion Graft-versus-Host Disease

Almost uniformly fatal AA is a constant feature of transfusion-associated GvHD, a syndrome produced by the transfusion of competent lymphocytes into immune-deficient hosts, including children with congenital syndromes, cancer patients receiving high-dose chemotherapy, and, more recently, with adoptive cellular immunotherapy for leukemia.[68] [188] Rarely, post-transfusion GvHD occurs in an apparently immunocompetent recipient in the special circumstance in which the donor is homozygous for an HLA haplotype also shared by the recipient, as may occur among first-degree family members. Small numbers of lymphocytes are sufficient to produce the syndrome, which is surprisingly resistant to immunosuppressive therapy. Pancytopenia with marrow hypoplasia is an almost constant feature of post-transfusion GvHD. Runt disease in animals is a model of this immune-mediated marrow failure syndrome.

Pregnancy

Pregnancy is common in the age groups most susceptible to marrow failure, and in many cases its association is probably only coincidental. The true frequency of AA in pregnancy is not known, but from the number of cases reported it appears rare, [189] [190] [191] although bone marrow hypoplasia may be relatively common during pregnancy.[192] A causal relationship is suggested by the temporal relationship between the onset of pancytopenia and that of pregnancy, and by resolution following delivery and spontaneous or induced abortion; [193] [194] occasional patients have developed AA that remitted after each delivery. [195] Survival rates for AA in pregnancy have been relatively high for the mother (83%) and baby (75%), with most pregnancies successful (69%). [191] When death occurs during pregnancy or delivery, hemorrhage usually is responsible. The published data

are insufficient to guide the management of the pregnant woman with AA, especially since it is clear that AA in some cases is serendipitously diagnosed and can persist beyond parturition. A woman who desires a child can be maintained with transfusions, with the understanding that any clinical deterioration is a criterion for interruption or termination of the pregnancy. The risk of pregnancy to the woman who has recovered from idiopathic AA is similarly unknown.

Hepatitis/Aplasia Syndrome

The association of AA and acute, apparently viral hepatitis is not rare. Several hundred cases have been reported. [100] [196] [197] A prior history of hepatitis is recognized in 29% of AA patients in Western series [198] [199] and in perhaps a larger proportion of patients in the Far East. [200] [201] Uncomplicated viral hepatitis is frequently associated with mild blood cell count depression, but severe pancytopenia with marrow aplasia is a rare sequela, estimated at <0.07% of total pediatric hepatitis cases[202] and 2% of patients with non-A, non-B hepatitis.[203] [204] However, in patients, usually children, who develop hepatic failure after fulminant seronegative hepatitis, about one-third develop AA at the time of liver transplantation. [205] [206]

Hepatitis-associated AA has several peculiar features. [100] [197] [207] Typically, an uneventful episode of apparent viral hepatitis in a young man is followed in 12 months, during convalescence from the liver inflammation, by severe pancytopenia. Depression of blood cell counts during the course of hepatitis is, of course, common: leukopenia, atypical lymphocytosis, erythroid macrocytosis, and thrombocytopenia mimic in milder forms the hematologic changes of AA. However, posthepatitis AA has a very poor prognosis, with early estimates of mortality at 90% at 1 year, [197] so that a history of hepatitis in AA has been considered an indication for early marrow transplantation.[208] Patients with posthepatitis AA can successfully undergo marrow transplantation without an increased risk of venoocclusive disease. [209] Patients with hepatitis-associated aplasia have markers of immune system activation and also respond well to intensive immunosuppressive therapy. [100] [210]

The putative viral agent in posthepatitis AA is unknown. Almost all well-studied cases have been non-A, non-B, non-C, [211] [212] and most recently non-G.[100] Both hepatitis C and G viruses are common in patients with AA, but usually as a result of their heavy transfusion load. [100] [211] [213] Posthepatitis AA is linked to both fulminant hepatitis of childhood and acute seronegative hepatitis. Acute viral hepatitis that is seronegative differs clinically from hepatitis C disease: parenteral exposure is not a risk factor, liver functions abnormalities are more severe during the acute phase, and late complications are more common. [214]

Postmononucleosis Aplastic Anemia

Acute infection with EBV causes infectious mononucleosis that is commonly associated with neutropenia and other hematologic abnormalities [215] [216] [217] but, like acute hepatitis, is only rarely complicated by AA. [218] [219] [220] However, EBV may be involved in the etiology of AA more frequently than originally appreciated, since a large number of primary EBV infections are unrecognized. [219] [221] [222] Pancytopenia can be first observed during the acute mononucleosis syndrome or shortly after disappearence of symptoms. Some patients have recovered spontaneously; others after therapy with corticosteroids or ATG. EBV can occasionally be demonstrated in the bone marrow cells of patients with apparently idiopathic AA, in association with serologic evidence of a primary or reactivated viral infection. Some patients with EBV-associated AA may respond to antiviral therapy.[219] [223] [224] [225] For those with severe disease, conventional therapeutic interventions should be implemented early.

Hemophagocytic Syndrome/Aplasia Syndrome

The marrow is hypocellular in about a third of cases with hemophagocytic syndrome. In this disorder there may be progression from marrow hypercellularity to aplasia; myelofibrosis is also common. Pancytopenia occurs in 74% of cases. Anemia is a universal finding; thrombocytopenia (91%) and neutropenia (65%) are also frequent.[226] In contrast to typical AA, patients appear systemically ill, with fever and constitutional symptoms, and peripheral blood cell count depression is often associated with abnormalities of other organ systems: hepatosplenomegaly, lymphadenopathy, cutaneous eruptions, and pulmonary infiltrates. [226] [227] [228] Hemophagocytic syndrome is associated with a large variety of diseases, including immunodeficiency, malignancy, and infections. In the infectious category, viral infections are commonest, often with herpesviruses, including especially EBV, and also cytomegalovirus, herpes simplex, or herpes zoster. [226] [229] B19 parvovirus, HIV-1, and bacterial and parasitic infections also have been associated with hemophagocytosis. Hemophagocytosis is often observed on supravital [230] or Wright-Giemsa staining [187] of the marrow of patients with idiopathic AA, and it is also a morphologic feature of graft rejection after marrow transplantation. [231] In virus-associated hemophagocytosis, there is evidence of immune system activation. The sera of patients contain high levels of IFN-, TNF-, and IL-6, soluble CD8 and soluble IL-2 receptor, and T cells overproduce IFN- in vitro. [186] The clinical response to cyclosporin A (CsA) is consistent with a T-cell-mediated pathophysiology of

hematopoietic failure.[232]

Paroxysmal Nocturnal Hemoglobinuria/Aplasia Syndrome

There is a strong association between AA and paroxysmal nocturnal hemoglobinuria (PNH). These diseases frequently are diagnosed concurrently or sequentially in the same individual, and they share similar clinical and pathologic features (pancytopenia and marrow hypocellularity), a striking geographic variation in rate (higher frequency in Asia), and similar responsiveness to immunosuppressive therapy.[233] [234] [235] [236] PNH is characterized by the triad of intravascular hemolysis, venous thrombosis, and marrow failure. More patients, however, appear to die of thrombotic than of bleeding complications.[237] PNH is due to a somatic mutation in the X-chromosome gene termed *PIG-A*; the product of this gene is responsible for an early step in the biosynthesis of the proteoglycan anchor of the class of glycophosphatidylinositol-linked cell-surface membrane proteins.[235] [238] These proteins can now be measured easily and quantitatively using flow cytometric methods, extending and replacing the classic Ham test. The role of CD59 in inactivating complement on the RBC surface adquately explains the intravascular hemolysis of PNH, but the role of the absence of glycophosphoinositol-linked proteins in the pathophysiology of marrow failure is unknown.

Marrow failure may be present at the onset of PNH or may develop after diagnosis. In a retrospective review, marrow failure was especially prevalent among young patients, occurring in 58%.[239] In a cooperative study from France of 220 patients with PNH (defined by a positive Ham test), there was a previous history of AA in 30%, and in the remainder the actuarial risk of developing pancytopenia was estimated at 14% at 4 years.[240] Conversely, AA may evolve into PNH months or years after successful immunosuppressive treatment; many patients will have only a positive Ham test or a population of granulocytes lacking glycophosphoinositol-linked proteins. In one study a presumptive diagnosis of PNH based on flow cytometry was made in a large proportion, nearly 50%, of AA cases at presentation,[241] but this figure is likely an overestimate.[242] [243] On the other hand, flow cytometric analysis of marrow from patients with

AA suggested that PNH clones may be detectable in the marrow even when absent from the circulation.[244] Longitudinal studies of patients with de novo PNH[237] as well as PNH developing from AA[245] indicate a significant probability of spontaneous disappearance of serologic or flow cytometric evidence of disease.

In the setting of marrow failure, PNH could develop as a result of an intrinsic growth or survival advantage for the somatically mutated cell or because of extrinsic selection of cells bearing the *PIG-A* defect, most current evidence favors the latter possibility. Supporting an extrinsic mechanism are the presence of multiple genetically different *PIG-A* mutations in a single patient;[246] apparent in vivo selection for the development of PNH-like lymphocytes in lymphoma patients treated with CAMPATH-1, a monoclonal antibody that incidentally recognizes a glycophosphoinositol-linked protein;[247] lack of a growth advantage for *PIG-A* knockout cells in vitro[248] and in vivo;[249] and similar in vitro growth characteristics of normal and deficient progenitor cells.[242] Evidence for an intrinsic effect comes from experiments demonstrating that PNH cells proliferate better in immunodeficient mice[250] and from the implication of a glycophosphoinositol-linked protein in the interaction between stromal and progenitor cells.[251] A generalized resistance to apoptosis that was initially proposed has not been confirmed.[252] [253] [254] One likely pathophysiology is relative resistance to attack by the immune system of PNH stem cells due to lack of a required recognition protein on the hematopoietic target cell.[255]

Collagen Vascular Diseases

AA is a component of the collagen vascular syndrome called eosinophilic fasciitis.[256] [257] [258] This severe, scleroderma-like disease is characterized by fibrosis of subcutaneous and fascial tissue, localized skin induration, eosinophilia, hypergammaglobulinemia, and an elevated erythrocyte sedimentation rate. The rheumatologic symptoms of fasciitis respond to corticosteroids, but the associated AA has a very poor prognosis. A few patients have survived after bone marrow transplantation or immunosuppressive therapy. More unusually, AA has complicated systemic lupus erythematosus and rheumatoid arthritis, but in many cases the role of concomitant drug therapy is confounding.[259] Also rarely, AA may complicate Sjögrens syndrome,[260] multiple sclerosis,[261] and immune thyroid disease.[261] AA occasionally occurs in individuals with hypogammaglobulinemia[73] or congenital immunodeficiency syndrome,[75] thymoma, or thymic hyperplasia.[76] [77]

LABORATORY EVALUATION

Peripheral Blood

In typical cases of AA, all the blood cell counts are depressed. From the half-life in the circulation of granulocytes, platelets, and erythrocytes, most patients would be predicted to develop neutropenia and thrombocytopenia, but in fact anemia is common and the granulocyte count may fall further during observation. The blood smear usually shows an obvious paucity of platelets and leukocytes but with normal RBC morphology; toxic granulations may be present in neutrophils. Automated cell counting frequently shows erythrocyte macrocytosis and a normal red cell distribution of width indicating little variation in RBC size. Platelet size is normal and not increased as in immune peripheral destruction, but the low number may cause greater heterogeneity of size. Low numbers of reticulocytes may be accurately quantified with automated counting. Inexplicably, a few patients with otherwise typical AA have been reported to have circulating erythroblasts; [262] similar cells have been detected by flow cytometry.[263] Prior transfusions will alter platelet numbers, relative reticulocyte counts, and hemoglobin values. Although relative lymphocytosis is very common, most patients also have decreased absolute numbers of monocytes[264]

DIAGNOSIS OF APLASTIC ANEMIA

While the ultimate diagnosis of aplastic anemia rests on the interpretation of an adequate bone marrow biopsy specimen, important clues to the etiology of pancytopenia can be obtained from the history, physical examination, and laboratory data. Pancytopenia that is not primarily hematologic in origin but secondary to other disease processes is usually an obvious diagnosis. Patients with severe liver disease and splenomegaly, systemic lupus erythematosus, or overwhelming sepsis may all have low blood cell counts, but their clinical presentation is not subtle. Similarly, bone marrow aplasia follows cytotoxic drug therapy for cancers and, in more recent practice, for a variety of nonmalignant diseases, but this is an anticipated and transient toxic effect. In the challenging case, obvious medical causes of pancytopenia usually have already been excluded. Pancytopenia is almost never due to peripheral blood cell destruction alone. In AA, the blood smear will not show reticulocytes, band forms, or the large platelets typical of increased compensatory bone marrow efforts. Acquired AA is a disease of the young, but so is constitutional aplasia. Patients with Fanconi anemia often have physical anomalies or look funny, but the distinction between acquired and constitutional disease depends on the results of a clastogenic-stress culture of peripheral lymphocytes and the appearance of typical chromosomal abnormalities in vitro. Fanconi anemia has been diagnosed in patients in late middle age! However, in most older patients the major differential diagnosis is between aplastic anemia and myelodysplasia. There is a true gray zone between hypocellular myelodysplasia and moderate aplastic anemia in which competent hematologists may not agree on the final diagnosis. Bone marrow cytogenetics should be performed to help in establishing the proper diagnosis. Myelofibrosis can also produce pancytopenia, but the bone marrow is not aspirable, the spleen is often enlarged, and the peripheral blood smear shows characteristic abnormalities. Acute leukemia in both children and the elderly may manifest with bone marrow hypocellularity requiring a careful search for lymphoblasts or myeloblasts, including phenotypic analysis by flow cytometry. Peripheral blood flow cytometry for glycophosphoinositol-anchored proteins should be performed to diagnose PNH. The patients history may have interesting clues: benzene exposure for myelodysplasia and acute leukemia or a suspicious drug history for AA. Discontinuation of exposure to incriminated drugs or chemicals is mandatory, and in some instances patients may then recover. However, given the difficulty of assigning blame with absolute certainty to environmental agents, we treat all patients similarly and do not advocate protracted observation for possible spontaneous recovery. In patients with severe disease (Table 19-6), suitable and early preparation for bone marrow transplant should be undertaken or immunosuppression begun, whereas in those with moderate disease, clinical status should be evaluated and serial blood cell counts are required to assess progression of the disease.

and lymphocytes. The severity of AA can be graded based on the peripheral blood cell counts (Table 19-6).

There is no characteristic pattern of other findings on routine hematologic and clinical chemistry tests. Serum transaminase levels may be mildly elevated in patients with hepatitis-associated AA. The Ham test and the sucrose hemolysis test may be positive. Patients with AA generally have normal immunoglobulin levels and normal antibody titers to common viral antigens. About one-half of patients were reported to be anergic to a common panel of antigens with normal lymphocyte proliferation in vitro.[265]

Bone Marrow

The marrow must be assessed quantitatively and qualitatively, for cellularity and the morphology of residual cells (Plates 19-1A and B , 19-3AF , and 19-4AD). Both marrow aspiration and biopsy should always be performed, with the core specimen at least 1 cm in length. There should be no compromise in obtaining adequate specimens and no hesitation in requesting and performing a second procedure if required.

Bone marrow cellularity is best estimated from the core biopsy. Point counting under microscopic cross hairs in many parts of a histologic section [266] is the most accurate method of determining cellularity, but hematologists commonly rely on visual estimation only; [267] a crude eyeball approximation is almost always adequate in severe aplasia, as the hematopoietic content of the marrow specimen is usually close to zero. Estimates of marrow cellularity based on examination of the aspirate smear and biopsy specimen are correlated, but dilution of the aspirate by sinusoidal blood often occurs, and the aspirate may be hypocellular when the biopsy specimen is hypercellular[268] or may show focal areas of active hematopoiesis.[269] Normal marrow cellularity decreases considerably with age, a variation that is of some importance in assessing the older patient with aplasia or myelodysplasia. In autopsy samples from normal young children, about 80% of the marrow space of the iliac crest is cellular (range, 60100% [270]); marrow from the sternum, vertebrae, and long bones is more usually 100% cellular in infants; [271] for sternal aspirates, cellularity ranges from 35% to 80%.[272] Marrow cellularity gradually falls from age 20 to 70 years and more precipitously in the very elderly, to about 30% in the eighth decade of life.[270] Although for practical purposes, the lower limit of normal marrow cellularity in adults is accepted at about 30%, the differences at the extremes of life should be recalled when evaluating infants and the elderly. In most patients with AA total marrow cellularity is extremely low, but there may be significant residual lymphocytosis. The increase in marrow fat in aplasia is due to an increase in both the size and number of individual fat cells. Hot pockets of hematopoiesis may be present in a minority of patients.[273] The marrow tends to contract centripetally with age, and a similar process can be observed in pathologic states, so the sternal bone marrow may be more cellular than iliac crest samples.

Examination of the bone marrow (Plates 19-1 , 19-3 , and 19-4) is basic for the diagnosis of most primary hematologic causes of pancytopenia. (Table 19-1 ; Fig. 19-6). Information may be gained by observing the marrow aspirate itself. A fatty, even watery specimen can usually be aspirated without difficulty from an aplastic patient, whereas a truly dry tap is more typical of a packed or fibrotic bone marrow. The morphology of individual cells is best seen in the Wright-Giemsa-stained aspirate smear, the architecture of the marrow in the biopsy section. In acellular specimens, the only cells visible are usually lymphocytes, plasma cells, and stromal

elementsfibroblastoid and histiocytic cells. Some degree of dyserythropoiesis is frequent, usually the megaloblastoid features of macrocytosis and some nuclear-cytoplasmic maturation asynchrony, but sometimes more complex degenerative changes in nuclei and cytoplasm can be observed by light [274] and electron [275] microscopy (Plate 19-3). These features are common to AA and myelodysplasia (Table 19-7 (Table Not Available)), which may be very difficult to distinguish prospectively. [276] Hemophagocytosis of RBCs can also be seen in AA. Examination of the cells close to the spicules of a sparse aspirate smear may disclose a distinctive population of leukemic blasts, or the dysmorphic appearance of residual erythroid cells, which will more strongly suggest dysplasia than aplasia. Increased numbers of myeloblasts are not seen in AA and are evidence of aleukemic leukemia or herald the evolution of leukemia from pancytopenia. [277] Lymphoid aggregates, nests of tumor cells, granulomas, and infectious particles may be apparent on examination of the fixed biopsy specimen. Karyotyping of marrow cells is diagnostically important. Unfortunately, the yield of cells from a hypocellular marrow may be inadequate to perform cytogenetic analysis. Chromosome analysis is usually normal in AA [276] but frequently reveals a clonal abnormality in myelodysplasia. [278] [279]

Radiographic Measures of Bone Marrow Function

Ferrokinetic studies of patients with AA are characterized by high plasma iron concentrations, transferrin saturation, and prolonged clearance of radioactively labeled iron. [280] Binding of labeled ^{59}Fe to transferrin prior to injection more specifically distinguishes iron uptake by erythroid cells. [281] ^{111}Indium, which also binds to transferrin, has been employed for bone marrow scintigraphy. Studies of AA patients almost always show markedly decreased ^{111}In uptake; [282] however, the technique has been limited by the lack of availability of the isotope and imperfect correlation with blood cell counts. Myelopoiesis has been mapped in experimental studies using ^{99m}Tc-conjugated monoclonal antibodies to leukocyte antigens (CD67 [283] and a nonspecific cross-reacting antigen [284]), with good correlation with results of ^{59}Fe scanning. Magnetic resonance imaging (MRI) with spin-echo sequences has proved to be most useful in the study of bone marrow disease. On T1-weighted spin-echo images, fatty marrow appears bright and cellular marrow exhibits a lower-density signal (Fig. 19-7). The high fat content of aplastic bone marrow can be readily appreciated on MRI. MR spectroscopy, which detects the type of fat signal, has shown diverse patterns among AA patients. [285] MRI is complementary to tissue sampling, allowing a large area of marrow to be visualized and fat content to be roughly quantified. The technique appears to be worthwhile in diagnosis, because the patterns of fat and cell distribution appear to differ between aplasia and hypocellular myelodysplasia, and in prognosis, to monitor improvements in hematopoiesis after treatment. [286]

DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA

AA is not the most common cause of pancytopenia (see Table 19-1). In one study, of 100 pancytopenic cases, a diagnosis of AA could be made in only 19, despite prescreening for systemic or malignant diseases. [287] A rational diagnostic algorithm may be very helpful in establishing a correct diagnosis (Fig. 19-6). An uncertain diagnosis jeopardizes the patient, who may be directed to an improper treatment. Pancytopenia can result from peripheral blood processes with relatively normal bone marrow function, but such syndromes usually occur in an obvious context as complications of nonhematologic primary disease. Pancytopenia is unlikely to be the presenting feature of hypersplenism in cirrhosis or of Evan syndrome in systemic lupus erythematosus. Findings on physical examination may point strongly toward another diagnosis. For example, the patient with myelofibrosis usually has splenomegaly, but a large spleen is very unusual in AA. While B_{12} and folate deficiency have been reported to be associated with erythroid hypoplasia, [288] this must be an exceedingly rare event. Well before a bone marrow aspiration

Figure 19-7 Magnetic resonance imaging of bone marrow in **(A)** severe aplastic anemia in a young man, **(B)** severe aplastic anemia in a middle-aged woman, and **(C)** myelodsyplasia in a middle-aged woman.

is performed, the list of possible diagnoses should be shortened by reasoning from the patients history, physical examination findings, and knowledge of the probability of alternative disorders.

For the practicing hematologist, the most important and difficult choice of diagnoses in pancytopenic patients is among primary bone marrow disorders. An empty bone marrow is usually obvious, but several complicating factors should be recognized. Most diagnostic confusion arises from (1) the equivocal character of moderate AA; (2) alterations in marrow appearance in patients with chronic disease; and (3) real overlap between AA, myelodysplasia, and leukemia.

In moderate AA the modest depression of marrow cellularity can muddle the single most reliable diagnostic criterion. Bone marrow cellularity is imprecisely quantitated at best, and further uncertainty is introduced by large sampling errors. Hot spots of hematopoietic activity in an otherwise acellular specimen reflect biologic heterogeneity in the pattern of cell loss. In addition, a syndrome of transient pancytopenia has been recognized in which spontaneous recovery occurs within a few months; although the blood cell counts can be severely depressed, the marrow is much more commonly normal or hypercellular than hypoplastic. [289] In patients with chronic bone marrow failure, serial bone marrow specimens may not be identical, either because of sampling error or because the original disease was misdiagnosed or has changed its character. Occasional patients with AA are not pancytopenic; they do not have uniform depression of red cell, white cell, and platelet production, despite an empty bone marrow, and their clinical course will be dominated by failure in two or a single hematopoietic lineage. Related conditions such as pure red cell aplasia, amegakaryocytic thrombocytopenia, and agranulocytosis, while usually distinctive in their clinical presentation, may evolve into more generalized marrow failure. In the absence of better markers, sometimes the only accurate diagnosis is a description of the clinical features and the specific marrow morphology.

A hypocellular bone marrow often precludes the proper morphologic diagnosis. This problem may be especially evident in the case of a myelodysplastic syndrome with hypoplastic bone marrow (Table 19-7 (Table Not Available)). In addition to the clinical features, more sophisticated laboratory studies may be helpful. Bone marrow cytogenetics, if positive for chromosomal abnormalities, facilitate the diagnosis of leukemia or myelodysplastic syndrome. Conventional bone marrow examination is not helpful in differentiating AA from Fanconi anemia. Fanconi anemia is diagnosed by a positive mitomycin-C resistance test (see Chap. 18).

TREATMENT

AA should be considered a medical emergency. Lives are lost, mainly because the grave consequences of severe pancytopenia go unrecognized. The ultimate benefits of definitive therapies such as transplantation or immunosuppression will be unrealized if the patient succumbs to early clinical catastrophe. A haphazard transfusion policy increases the risk of graft rejection after a marrow transplant, but too conservative an approach to transfusion can jeopardize the patients life and increase morbidity. Supportive management therefore requires both meticulous attention to the daily problems that occur as a consequence of pancytopenia and appreciation of their impact on the ultimate possibilities for cure or amelioration of AA. AA can be cured by replacement of stem cells, by bone marrow transplantation, and by immunosuppressive therapy. Androgens and hematopoietic growth factors have secondary roles (Fig. 19-8).

Supportive Management

Bleeding

Bleeding was historically a common symptom in AA, and death from hemorrhage was frequent in the premodern era. The effective use of platelet transfusions has substantially improved survival in this disease. Measurable correction of the platelet count by transfusion almost always alleviates the minor mucocutaneous

Figure 19-8 Algorithm-based selection of treatment for patients with aplastic anemia. BMT, bone marrow transplantation; ATG, antithymocyte globulin; CSA, cyclosporine A; IS, immunosuppression.

bleeding common in thrombocytopenic patients. Major bleeding usually is not due to thrombocytopenia alone, and ancillary explanations for massive hemorrhage should be sought. The bleeding time improves after erythrocyte transfusion in patients with anemia, and there is a strong inverse correlation between the hematocrit and bleeding.[290] Therefore, the treatment of serious hemorrhage should include correction of severe anemia and red cell transfusions.

Modern transfusion practice has made platelets readily available and safe to administer. Other than cost and convenience, the major problem related to platelet transfusions is the development of alloimmunization in the recipient. [291] [292] The life span of the transfused platelet in the circulation is dramatically shortened by host antibodies, almost always directed to HLA-A and B antigens. Alloimmunization is suggested by poor recovery of the 1-hour-post-transfusion platelet count and confirmed by finding specific HLA antibodies in serum. [293] [294] Refractoriness can often be overcome by selection of HLA-matched donors, but 639% of perfectly HLA-matched transfusions fail.[294] Alloimmunization can be prevented or delayed by the use of single-donor platelets rather than pooled platelets. [295] Physical leukocyte depletion by filtration or ultraviolet treatment of blood products [296] [297] has been successfully piloted in AA patients. [298] Avoidance of platelet transfusions except when there is active bleeding is another alternative to prevent alloimmunization, but the dose relationship between exposure to different donors platelets and the probability of developing refractoriness is not clearly established, [294] and only after >40 units have been administered does the risk of alloimmunization clearly increase.[299]

Prophylactic transfusion of platelets is controversial. [300] [301] The primary indication for platelet prophylaxis is to prevent intracranial hemorrhage, but the risk of this complication in the chronically thrombocytopenic patient, while real, is low. Prophylactic platelet transfusions have not been shown to alter survival. [300] [301] [302] Nevertheless, the beneficial effects of avoiding bleeding complications and improving the quality of life have been used to justify their routine continuation. [303] Maintenance of platelet counts >20,000/l will decrease bleeding episodes, [304] [305] but the threshold of 20,000/l is based on a very old study showing reduction in days of bleeding and serious hemorrhage among children with acute leukemia. [306] Although the 20,000/l value has long been used to trigger transfusion, several reports have suggested little difference in the risk of bleeding over a wide range of platelet counts between 5,000 and 100,000/l. [307] [308] Until recently, tradition has resisted attempts to lower the transfusion threshold.[309] In one study, a rigorous transfusion policy during induction therapy was proposed: platelets were administered to every patient with a count less than 5,000/l, for patients with 6,00010,000/l platelet count if fresh minor hemorrhages or fever were present, for patients with platelet counts of 11,00020,000/l if a coagulation disorder was present or before a minor procedure, and for patients with 20,000/l platelet counts if major bleeding complications

occurred or surgery was planned. Fatal or severe bleeding episodes were rare and did not occur in patients with platelet counts >10,000/l. The worst bleeding episodes in these cases were associated with refractoriness to platelet transfusions. [310] In a recent randomized trial of patients with AML, the risk of major bleeding was no different when 10,000 or 20,000/l was chosen as the threshold, while the lower value led to a 20% reduction in platelet use. [311] Any prophylaxis program must be modified to address the individual patient, but a goal of maintaining platelet counts >5,000/l is reasonable.

Bone marrow aspirates and biopsy specimens can be obtained without platelet transfusion support. Major surgery can be accomplished in the setting of thrombocytopenia; in one study, blood loss and morbidity were low even at platelet counts <30,000/l. [312]

Anemia

Other than to reduce the risk of graft rejection after allogeneic transplant, there is no reason to allow a patient to suffer the symptoms of anemia. Once equilibrium is achieved, a constant amount of blood will be required to maintain a given hemoglobin concentration. Physically fit individuals are usually not symptomatic at hemoglobin concentrations >7 g/dl; patients with underlying cardiovascular disease should be maintained at a higher level (9 g/dl). Perhaps in contrast to alloimmunization by platelet transfusions, AA patients show a relatively low frequency (about 11%) of alloimmunization due to packed red cell transfusions. [313] In patients with acquired anemia who are likely to remain dependent on erythrocyte transfusions, deferoxamine therapy is effective in chelating iron. Iron chelation should be used in patients with unresponsive chronic anemia who have a reasonable expectation of survival.

Alloimmunization as a result of blood product administration increases the probability of graft rejection and the mortality following marrow transplantation. Blood products from a potential marrow donor such as a sibling or a parent (who will share histocompatability antigens) should be avoided. Small numbers of transfusions do not have a major deleterious effect on survival. The 5% risk of graft rejection following transplantation in entirely untransfused patients was increased to 15% with receipt of 140 units and to >25% only in more heavily transfused patients. [314] An increased rate of graft rejection was observed in patients who had received >10 units of erythrocytes or 40 units of platelets.[315] Speed in arranging tissue typing and transfer to an appropriate center has a greater impact on the survival of the patient

than the judicious transfusion of a few units of RBCs to a severely anemic patient or platelets to a bleeding patient. Transfusions should not be withheld in an older patient in whom immunosuppressive therapy will be first therapy.

Infection

There are very few specific reports of infections and their therapy in patients with AA. [264] [316] The duration of neutropenia is the major difference between the neutropenia of bone marrow failure and that induced by cytotoxic chemotherapy. With longer periods of neutropenia, the probability of serious bacterial or fungal infection increases. A second major difference is that neutropenia is part of a complex of problems associated with malignant disease and its therapy. In AA, the immune system is activated and, with the exception of intravenous catheter placement, the integument is preserved. Studies of cancer patients have usually identified a low-risk category of neutropenia, determined by the relatively brief period of neutropenia; by this criterion, almost all unresponsive patients with AA are high risk.

In classic studies of leukemic children, neutropenia was shown to increase susceptibility to bacterial infections and the number of infectious episodes was quantitatively correlated with the degree and duration of neutropenia: 910% of days at granulocyte levels above 1,500/l was associated with proved infection, but this figure rose to 20% at granulocyte counts of 5001,000/l, to 36% at 100500/l, and to 53% at <100 neutrophils/l. [317] Extreme neutropenia (neutrophils <100/l) was associated with the most serious infections and a very high mortality. [318] Susceptibility to infection is extremely high with an absolute neutrophil count <200/l, and this value has been used to define a category of very severe AA. [319] As severe granulocytopenia becomes prolonged, infection is inevitable.

Similar recommendations for initiation of empiric antibiotic therapy apply to AA patients as to other patients with neutropenia. The cardinal rule is, if the absolute neutrophil count is <500/l and infection is suspected, immediately begin broad-spectrum parenteral antibiotic therapy. Any regimen may need modification based on results of cultures, new symptoms or signs, or a deteriorating clinical course. Bacteremia is present in only 20% of febrile neutropenic episodes, and in only about 40% of those can a microbiologic cause or localizing physical findings be identified. [320] [321] Thus, early discontinuation of antibiotics in instances where cultures are unrevealing in persistently neutropenic patients is dangerous. Sometimes patients remain febrile despite antibiotic therapy; fever may also reappear after a few days or weeks. In the absence of additional microbiologic data or clinical clues from the patients complaints or physical examination, we routinely institute antifungal therapy with amphotericin B in patients who have remained febrile despite adequate antibacterial therapy for more than 3 days. Fungemia during an initial febrile episode is rare, but fungal infection becomes more likely with repeated courses of antibiotics, and ultimately is the major cause of death in AA patients in whom definitive therapy fails. [322] *Candida* and *Asperqillus* species account for almost all fungal disease in AA. [322] Early aggressive treatment of neutropenic patients can reverse fungal disease, as demonstrated in individual cases [323] and by comparison of autopsy series. [324]

Polymorphonuclear cells have a relatively brief life span in the circulation and their major activity is in infected tissue. There are no simple measures of the therapeutic efficacy of WBC transfusions. The absolute neutrophil count is not measurably increased by standard transfusions. Nonetheless, several controlled trials performed in the 1970s reported significantly improved survival in patients who received granulocyte transfusions; the negative studies were criticized because of the relatively low numbers of granulocytes transfused ($<10^{10}$ /m^2 /day). [325] [326] [327] As granulocyte transfusions have fallen out of favor, they have tended to be used solely in desperate clinical circumstances, making them appear even less efficacious. Granulocyte transfusions are expensive and associated with serious toxicity: severe febrile reactions, pulmonary capillary leak syndrome (especially when amphotericin is being concurrently administered), an increased risk of infection, and inevitable alloimmunization. Alloimmunization leads to an inability of infused leukocytes to localize to sites of infection. However, a meta-analysis of published studies suggested that granulocyte transfusions are beneficial in patients with sepsis unresponsive to antibiotics if (1) adequate cell numbers were administered (23×10^{10} /day), (2) donor and recipient compatibility was present, and (3) the patients treated were unlikely to have imminent improvement in marrow function. [328]

Cytokines offer a new strategy for increasing the efficiency of donor harvests. Administration of G-CSF to normal donors greatly increases the yield of leukapheresis without adverse effects on the volunteers. Such large numbers of neutrophils can be obtained as to allow dramatic increases in the absolute granulocyte level in neutropenic recipients. Case reports have suggested that G-CSF-mobilized granulocyte transfusions may be

helpful in the treatment of life-threatening fungal infections in severely neutropenic patients. [329] [330] A randomized trial to test the efficacy of these preparations is needed.

Infections can be prevented. Most important are measures directed toward increasing general hygiene. [331] The physical surroundings of the patient should be well maintained to reduce the risk of nosocomial infection. Dental hygiene is important and sources of infection should be removed under antibiotic and platelet coverage. Nystatin oral rinses prevent thrush. [332] Routine rectal examinations are more likely to be harmful than helpful. Blood should not be taken from fingertips and ear lobes. Early attention to the signs of infection, especially after hospital discharge, can avert many of the complications of initially minor infectious episodes.

Total protective environments, often in combination with nonabsorbable antibiotics or selective gut decontamination to preserve some anaerobic bacteria, [333] have had strong advocates. Laminar flow rooms with gut sterilization are not obviously superior to simpler methods of isolation. [334] Simple reverse isolation accomplishes little more than compulsive hand washing. [335] Sterile diets, avoidance of fresh fruit and vegetables, and no flowers in the room similarly are practices of unproven value.

Definitive Therapy

Bone Marrow Transplantation

Allogeneic bone marrow transplantation from an HLA-matched sibling donor provides curative therapy for AA patients (Figs. 19-9A and B ; Table 19-8). Bone marrow transplantation in AA is the subject of a large number of reports and reviews. [336] [337] [338] [339] [340] [341] Recently, cytokine-primed peripheral blood has been used successfully as a stem cell graft. [342] [343] [344] The convenience of this method likely will lead to its substitution for marrow harvesting as the major method of stem cell collection. [345] Conclusions drawn from marrow transplant studies should be broadly applicable to peripheral blood transplants.

The first studies of allogeneic marrow transplants conclusively demonstrated their value in comparison to conventional supportive therapy. In a controlled trial reported by the International Aplastic Anemia Study Group, patients with severe

THERAPY FOR APLASTIC ANEMIA

After the diagnosis of acquired aplastic anemia has been established, treatment options must be identified, considered carefully, and chosen with alacrity. In patients with moderate disease (Table 19-6) either an expectant approach can be chosen based on stable course and adequate blood counts, or, in patients dependent upon transfusion support, ATG (40 mg/kg/day × 4 days) should be given. Intradermal sensitivity testing with 50 ng/ml ATG solution should be performed and patients showing immediate reaction should be desensitized. After assessment of the response, patients who improve should be monitored for hematologic signs of relapse and non-responders can be offered alternative therapy, such as androgens or CsA (12 mg/kg for adults or 15 mg/kg for children) for 36 months. For severe disease in which the prognosis with blood transfusion and antibiotic support alone is very poor, bone marrow transplantation from a histocompatible sibling or immunosuppression are accepted and effective therapies. Although large retrospective analyses have shown that long-term survival rates from either transplantation or immune therapy are equivalent, each has its own advantages and disadvantages. For children, bone marrow transplantation remains the treatment of choice if an appropriate family donor is available because they have a low rate of GvHD and the marrow disease is cured by stem cell replacement. The risk of later cancers may be increased, especially in children, after marrow transplantation. Adults with aplastic anemia also successfully receive transplants, although both the risk and severity of chronic GvHD and other treatment-related complications increase with age. Bone marrow transplantation has been performed in patients over 50 years of age, and it is certainly a reasonable approach to a younger adult, especially with more severe degrees of neutropenia.

Most patients with aplastic anemia do not have an HLA-matched sibling donor, and immunosuppression is the treatment of choice in these cases. Such patients with severe disease should receive a combination of ATG and CsA. We recommend a regimen consisting of 40 mg/kg/day of ATG at days 14, followed by CsA for 6 months at a dose of 12 mg/kg. Corticosteroids are added in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate serum sickness. Improvement should be expected within 6 months. This regimen has produced hematologic responses in about 70% of treated patients, who then have an excellent 5-year survival rate.

Although immunosuppressive therapy is relatively nontoxic, patients frequently relapse and require further treatment; however, relapse is not associated with poor prognosis. A more serious problem is the development of late-onset clonal diseases, PNH (which may not be clinically significant), but also MDS, and more rarely AML. Immunosuppression can be considered ameliorative therapy in which bone marrow destruction may continue and abnormal stem cell clones develop. For patients in whom immunosuppressive therapy fails, there are a number of options. For children, alternative donor bone marrow transplantation should be seriously considered; at the best centers, survival rates almost as good as from sibling donors have been achieved. Adults do less well, primarily owing to transplant-related mortality from the intensive conditioning regimen. Some patients will respond to androgen therapy, others to combinations of growth factors. There is no accepted practice for repeated immunosuppression in a patient in whom a first course of ATG and CsA has failed, and perhaps these patients are best served by enrollment in research protocols for refractory disease. High-dose cyclophosphamide may also be effective therapy for both AA at presentation and in patients with disease refractory to more modest immunosuppression in the form of ATG and CsA.

For general management, a few comments are necessary. First, patients with severe AA should not be subjected to useless early trials of corticosteroids or hematopoietic growth factors as primary treatment. Second, for the occasional patient who must decide between bone marrow transplantation and immunosuppression, the advice of experts familiar with this disease and careful counseling of the patient are advisable. Age and severity of neutropenia are decisive factors. A limited number of transfusions may be necessary to optimize the patients condition prior to definitive therapy and are acceptable. Single-donor platelets should be given and may be obtained from HLA-compatible donors. In severely neutropenic patients, G-CSF or GM-CSF therapy may decrease the risk of life-threatening infections. In the absence of overt bleeding, platelet counts as low as 5,000/l appear to be safe.

Figure 19-9 Actuarial survival in aplastic anemia. **(A)** Bone marrow transplantation (data from the University of Washington). **(B)** Bone marrow transplantation versus immunosuppression with ALG. *(Data from the European Group for Bone Marrow Transplantation).* **(C)** Natural history, survival with supportive and other treatments. Two groups are illustrated. Extrapolated survival curves for patients with severe disease are derived from retrospective reviews from the University of Utah of 101 records collected from the late 1940s to early 1970s; patients received blood transfusions and later in this period also platelets. Almost all were treated with corticosteroids and half with androgens as well. Data for patients who did not receive transplants come from a multicenter study of the efficacy of marrow transplantation, performed in the early 1970s; this control group was variably treated with androgens.

disease who received transplants early had an actuarial survival of >60%, compared to about 20% in patients who received androgens and blood transfusions only.[346] Results with marrow transplantation have improved over time, owing to a combination of factors: progressive modification of conditioning regimens and lower procedure-related early mortality, improved transfusion support and antibiotic regimens, and the introduction of CsA as prophylactic therapy for GvHD. Analysis of the International Bone Marrow Transplant Registry data showed that 5-year survival rates climbed from 48% in the years 19761980 to 66% for 19881992. [347] Some hospitals now report very high rates of survival: 89% in Seattle at 8 years, [348] [349] 79% in Baltimore,[350] 89% and 95% at Viennese centers.[351] [352] Registry data support lower survival values as the general experience for the same period, with 64% of patients who received transplants during the period 19851991 being alive at 5 years.[353] For the period 19901994, the European Group for Bone Marrow Transplant (EGBMT) reported 72% survival at 3.5 years. [354] The explanation for these differences is not obvious. Patient selection and reporting bias may be as important as modest differences among conditioning programs or the experience of the transplant team.[340] In the most favorable subgroupuntransfused or minimally transfused, young, uninfected patientsa survival rate of 8090% should be routinely achieved (Fig. 19-9A).[355]

Graft rejection and GvHD are the major complications of allogeneic transplantation in AA. Graft rejection may be a unique problem for transplantation in AA because of the diseases underlying immune pathophysiology as well as the use of more intensive conditioning preparative chemotherapy for malignant diseases like leukemia. Graft rejection is a major predictor of post-transplantation survival. In one study of transplants performed between 1981 and 1986, 29% of deaths were secondary to graft rejection, the single most common cause of mortality.[356] The rate of graft rejection fell with intensification of the immunosuppressive conditioning regimen, from 15% to 4% in Europe[356] and from 35% to 1015% in Seattle,[357] and remained stable in the last decade.[358] Graft rejection might be due to the pathophysiology of AA, a finding supported by the unexpectedly high proportion of failure in unprepared patients receiving syngeneic transplants [359] [360] [361] [362] and even in adequately preconditioned patients receiving syngeneic transplants. [363] [364] In a group of untransfused patients who received allogeneic stem cells, the incidence of graft rejection was 10%, indicating that AA patients may be particularly sensitive to alloimmunization. [365] Nevertheless, the influence of the number of transfusions on graft rejection is relative, and modest numbers of blood donations (<40 units in the International Bone Marrow Transplant Registry experience [314] and <10 units of erythrocytes or 40 units of platelets in Seattle [315]) do not greatly increase the risk of graft rejection.

Intensification of immunosuppressive conditioning regimens with the use of total body [314] [366] [367] or lymphoid irradiation,[368] [369] CsA,[314] [350] or ATG[348] reduces the risk of graft rejection. Such measures, however, have not been shown to influence long-term survival. [314] [370] [371] The effect of the conditioning program on graft rejection is probably through elimination of the recipients lymphocytes and of subsequent mixed hematologic chimerism, which is associated with rejection. [372] [373] More rapid regeneration of bone marrow grafts has been observed when CsA[3] was used,[374] and second transplants have been successful when ATG was added to the conditioning regimen.[375] The effect of ATG or CsA in the conditioning regimen on the rate of graft rejection [348] [376] [377] is currently being tested in randomized studies.

Rates of chronic GvHD vary and are related to patient selection and treatment regimens. Historically, age has been a major risk factor for the development of chronic GvHD. The incidence of chronic GvHD ranges from 19% for patients 010 years old to 46% for those 1130 years old, and to 90% in patients over 31 years old in an older Seattle series.[378] With improved treatment regimens, patients have fared better, but even recent studies

confirm a higher incidence and more serious consequences of GvHD in older patients. [379] [380] Children have a lower probability of suffering and dying from chronic GvHD.[381] The major difference in survival figures between patients 2030 years old is almost certainly due to the chronic GvHD. In an EGBMT analysis, a significant survival difference was observed between those less than 20 years old (65%) and those more than 20 years old (56%), but there was no survival difference between patients 2130 years old and those 3155 years old. [370] Young adults have fared better in other series, [382] [383] although morbidity from severe GvHD disease was far more prevalent in the young adults than in children (43% vs. 10%). [382] [383]

Very late complications also occur after transplantation. These include effects on growth and development as well as on the function of endocrine, neurologic, and other organ systems.[384] [385] A high rate of secondary malignancies has been recorded after transplantation. In a National Cancer Institute retrospective analysis of almost 20,000 transplants, the risk of late-onset cancer was eightfold higher at 10 years than in the general population and even higher for young patients, in whom the risk of malignancy was increased about 40-fold. [386] The risk was greatest for the development of malignant melanoma, buccal cavity tumors, and cancer of the liver, brain, CNS, thyroid, bone, and connective tissues. Multivariate analysis suggested that high-dose irradiation was a risk factor for the development of malignancies. For AA, among 320 patients who received transplants in Seattle, four developed cancer, leading to a calculated risk seven times higher than in normal controls.[387] In a French survey, four of 147 AA patients developed solid tumors, an 8-year cumulative incidence rate of 22%, equivalent to an RR of 41. [388] Secondary solid tumors developed in the radiation field of five of 147 AA patients whose conditioning regimen included the thorax and abdomen. [389] Immune events such as acute GvHD, treatment with ATG or monoclonal antibodies, and total-body irradiation have been related to the development of secondary malignancies. [387] Patients with these secondary cancers have a poor prognosis. [390]

The risk of cancer after bone marrow transplantation must be evaluated in the context of other therapeutic options, especially immunosuppression, because a significant risk of late malignancy exists in AA patients independent of transplant therapy. The risk of malignancy in the large registry of the EGBMT was equivalent for patients who received immunosuppression and those who underwent transplantation. Compared to the general European population, the RR of malignancy was calculated at 5.15 for AA patients treated with immunosuppression (confidence interval 3.267.94) and at 6.67 (3.0512.65) for patients receiving transplants. [391]

In summary, excellent survival rates and low morbidity in younger patients make allogeneic bone marrow transplantation the treatment of choice for children and adolescents. Patients older than about 40 years have a higher risk of transplant-related morbidity and mortality. Young adults in the intermediate age group have a reasonable opportunity for cure with bone marrow transplantation but also face more complications than children. In addition to age, a prolonged interval between diagnosis and transplantation, multiple transfusions, and serious infections before transplantation are poor risk factors.

Matched Unrelated and Nonhistocompatible Family Donors

Until recently, the lack of an HLA genotypically identical sibling donor precluded marrow transplantation, thus excluding about 70% of patients with AA from access to this therapeutic option. Alternative potential donors include either relatives who are phenotypically matched or partially matched and HLA phenotypically matched but unrelated volunteers. Although phenotypically identical family donors are available in only 12% of cases, mismatched family members and matched but unrelated donors represent a much larger pool.[392]

Haplotype sharing between parents occasionally has allowed identification and successful transplantation between phenotypically matched relatives. [393] [394] Long-term survival after even one-locus-mismatched family donations is inferior to genotypically matched transplants, mainly because of problems with graft rejection and GvHD. In the large European experience, for phenotypically identical family matches the actuarial survival was 45%, for patients with a single-locus mismatch it 25%, and for those with two to three loci mismatched 11%.[395] [396] In a recent report from Seattle, although all patients who received fully HLA-matched transplants survived, those with mismatches at one or more loci had a much poorer outcome, and even with total body irradiation added to the conditioning regimen, survival was only 50%. [394]

Most large studies of unrelated donors have shown inferior long-term survival and higher rates of complications such as graft rejection, [397] GvHD,[398] [399] and delayed immune system reconstitution.[400] Even more than in standard sibling transplants, age is a crucial risk factor in unrelated transplants and probably more important than the level of match, conditioning regimen, or use of T-cell depletion. [392] [396] [401] [402] [403] For patients with AA who received unrelated transplants and who were enrolled in the National Marrow Donor Program, survival at 2 years was 29%. [404] In the EGBMTs 1994 report, survival in 110 recipients of marrow grafts from other than a matched sibling was 34%, about half the rate of standard transplantation. [354] Superior

results were obtained at Childrens Hospital in Milwaukee, where T-cell depletion of the donor graft was combined with a rigorous conditioning program of cytosine arabinoside, cyclophosphamide, and total body irradiation: in 28 transfused and previously treated children with severe AA, a survival rate of 54% was reported at a median follow-up of almost 3 years, with no incidence of chronic GvHD. [405]

In summary, alternative donor transplantation is feasible; the rare phenotypic match from within the family may be equivalent to a sibling donor, but with other family members or unrelated donors there is a high risk of transplant-related mortality. Because unrelated donor transplantation takes months to arrange, it should be considered early. At the best centers, alternative donor transplantation represents an option, especially for the young patient with very severe pancytopenia in whom immunosuppressive therapy has failed.

Immunosuppression

Antithymocyte and Antilymphocyte Globulins

Immunosuppressive therapy is an effective alternative treatment for patients who are not candidates for bone marrow transplantation (Fig. 19-9 , Table 19-9). Immunoglobulin preparations made from the sera of horses (less frequently rabbits) immunized against human lymphocytes are the mainstays of current regimens. In Europe, thoracic duct lymphocytes are the antigens for antilymphocyte globulin (ALG), and in the United States, thymocytes (from children undergoing cardiac surgery) are the immunogen used for production of ATG; ALG dosages are often expressed in lytic units for lymphocytes in vitro and ATG dosages are expressed in milligrams.[340] [406] [407] [408] [409] [410] Only ATG is licensed for use in the United States. Both ATG and ALG are used in clinics elsewhere in the world.

The efficacy of ALG in marrow failure was discovered serendipitously in the late 1960s, when Mathé observed recovery of autologous hematopoietic function in patients who received antilymphocyte serum as conditioning for marrow transplantation. [67] In a collection of European cases from Basel, Paris, and Leiden in which patients were treated with different serum preparations and with a variety of dose regimens, sustained hematologic improvement occurred in 12 (41%) of 29 patients with severe AA, and the 1-year survival of the entire group was 55%. [411] In a multicenter study, Swiss ALG was clearly superior to androgen treatment, with a significantly better response rate (70% vs. 18%) and 1-year survival (76% vs. 22%). [412] Similar results were also obtained in a randomized study of ATG versus supportive care.[413] In a large multicenter American trial, 47% of patients improved. [414] Review of published results from Europe and North America suggests that overall, about half of patients treated with either ATG and ALG will show hematologic improvement, broadly defined as an end to transfusion dependence and an improvement in a neutrophil number to a level protective against infection. [406] Response rates may vary from 20% to 85%.[406] The putative etiology of AA is not a factor that predicts response. Both virus-associated [100] [219] and drug-induced[415] [416] aplasia respond similarly to idiopathic disease. Cytogenetic abnormalities do not preclude a response since both AA with chromosomal abnormalities[417] [418] [419] as well as some cases of frank myleodysplasia[420] may be responsive to immunosuppressive therapy. The response rate to ATG or ALG is not improved by the addition of androgens [421] or very high doses of corticosteroids.[422]

A hematologic response to ATG is usually apparent within several months of therapy; in some cases, all blood counts rise dramatically, in others, increases in platelets or red cells may be delayed (Fig. 19-10). The average time to improvement in

Figure 19-10 Time to response after treatment with ATG. **(A)** Distribution of patients with severe aplastic anemia by time to achieve an increase in the absolute neutrophil count of 1,000/mm ^{3} . **(B)** Distribution of patients with an initial absolute neutrophil count <200/mm ^{3} by time to achieve an absolute neutrophil count of 1,000/mm ^{3} .

neutrophil number is 12 months.[414] Transfusion independence occurs about 23 months after initiatiation of treatment. [423] [424] Continued improvement without further therapy not uncommonly occurs after 3 months; nevertheless, clinical status by 3 months is strongly correlated with long-term survival. [414] [425] Patient selection is important, as the likelihood of response to ALG has been inversely correlated with disease severity, [426] [427] and in particular with a low neutrophil count. [319] [370]

The administration of antilymphocyte sera is associated with three major toxic effects: immediate allergic phenomena, serum sickness, and transient blood cell count depression (Plate 19-5A and B). Fever, rigors, and an urticarial cutaneous eruption are common on the first day or two of ATG or ALG therapy, and these symptoms respond to antihistamines and meperidine therapy. Anaphylaxis is rare, but its occurrence has been fatal. [428] A positive immediate wheal-and-flare reaction to the cutaneous application of a 50 mg/ml stock solution of ATG may be predictive of massive histamine release on systemic infusion, and desensitization with gradually increasing doses of ATG administered intradermally, subcutaneously, and then intravenously has permitted ATG use in allergic individuals. [428] Corticosteroids are usually administered in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate the symptoms of serum sickness. Doses of ATG and ALG have varied from 5 to 50 mg/kg and the duration of administration has varied from 4 to 28 days. It is more rational to administer equivalent doses of ATG or ALG by the schedule originally employed in Europe, 40 mg/kg/day for 4 days; antiserum will then have reached low levels in the circulation by the time host antibody appears.[429] A short course of therapy is easier to administer, associated with less serum sickness, and equally effective as the same dose given over a more prolonged course.

Antilymphocyte globulins are immunosuppressive. ATG and ALG contain a heterogeneous mix of antibody specificities for lymphocytes, including reactivity to antigens such as CD2, CD3, CD4, CD8, CD25 (the receptor for IL-2), and HLA-DR. [430] [431] [432] [433] Horse sera fix human complement efficiently, and all preparations are T-cell cytotoxic in vitro, with little difference between ATG and ALG or among lots for lymphocyte killing in vitro. [431] In vitro, antilymphocyte globulins efficiently inhibit T-cell proliferation and block IL-2 and IFN- production and IL-2 receptor expression; [434] ATG induces Fas-mediated apoptosis of T cells, especially after activation.[435] In monkeys, ATG and ALG suppress cutaneous allograft rejection.[433] Studies of rabbit ATG in rhesus monkeys undergoing kidney transplantation have indicated that persistence of specific antibodies may be responsible for a chronic anergic state and tolerance induction. [436] In patients, administration of ATG and ALG results in rapid reduction in the number of circulating lymphocytes, usually to <10% of starting values, and lymphocytopenia persists for several days after discontinuing therapy. Although lymphocyte numbers return to pretreatment values by 3 months, reductions in activated lymphocyte numbers in recovered patients persist.[92] [437] [438] [439] It seems likely that these inhibitory effects on T cells are responsible for the efficacy of antilymphocyte globulins in AA. Nevertheless, the ability of ATG and ALG to also stimulate lymphocyte function by acting as a mitogen may also have a role in their therapeutic efficacy. ATG and ALG provoked both IL-2 and hematopoietic growth factor production by peripheral blood mononuclear cells, [440] later identified as GM-CSF[87] [441] [442] and IL-3.[441] T cells cloned after ALG stimulation produced GM-CSF and/or IL-3, and, less frequently, IL-2 and IFN-. [443] Acutely, ALG administration was accompanied by reduced serum GM-CSF levels in one study.[444] In a mouse model, ATG administration was associated with increased circulating levels of colony-stimulating factors. [445] Administration of ATG after human marrow transplantation is associated with increased serum levels of IL-3. [446] ATG also binds to bone marrow precursor[447] and progenitor[448] cells and might modestly directly enhance hematopoiesis, possibly through binding to CD45RO, a molecule capable of promoting tyrosine phosphatase signaling. [449]

Reliable methods to predict which patients will respond to ATG are lacking. In some cases, inhibitory activity of lymphocytes on hematopoiesis is no longer detected after successful ATG therapy.[450] [451] In one recent study, CD8 T cells obtained from patients before treatment inhibited autologous hematopoietic colony formation, whereas CD8 lymphocytes isolated from the same patients after recovery were not active.[452] Good correlations were reported between clinical response to immunosuppression and improvement in hematopoietic colony formation in vitro after T-cell depletion. [82] [450] These promising findings have not been confirmed by others.[230] [425] [456] [457] [458] The lymphocyte stimulatory effects of ATG and ALG have been associated with positive clinical outcomes by some [459] but not by other[441] studies.

Cyclosporin A

Shahidis group[460] and others[461] [462] [463] [464] [465] [466] [467] reported success with cyclosporine therapy combined with androgens in individual patients with AA, in many of whom other therapies had failed. Several studies suggested efficacy of cyclosporine in patients refractory to ALG or ATG alone, with salvage rates of about 50%. [468] [469] [470] [471] [472] [473] The use of CsA as initial therapy was promoted by a large French cooperative randomized study in which low but equivalent response rates were observed in comparison with standard ALG therapy.[474] However, in a recent randomized German trial, cyclosporine was clearly inferior to ALG as measured by response and survival rates.[435]

The optimal regimen has not been determined. In the United States, CsA has usually been employed in high doses, 12 mg/kg/day for adults and 15 mg/kg/day for children, with doses adjusted according to plasma drug concentrations and serum creatinine levels. In Europe, lower doses, 37 mg/kg/day, have been reported to be equally efficacious.[475] [476] Hematologic improvement may occur in a few weeks or months. A 6-month trial is warranted. Remissions, when achieved, usually have been durable, but some patients experience relapse when CsA is discontinued. Most patients who relapse will then respond to the reinstitution of cyclosporine. [475] [476] [477] [478] Some patients require maintenance treatment. [465] [468]

The toxicity associated with cyclosporine therapy is considerable. Hypertension and azotemia are the most common serious side effects; hirsutism and gingival hypertrophy are also frequent complaints. Increasing serum creatinine levels are an indication for dose reduction. Chronic nephropathy characterized by interstitial fibrosis and tubular atrophy due to cyclosporine can be irreversible. The risk of nephropathy is increased by high doses and longer duration of therapy, and occurs more commonly in older than in younger patients. CsA, especially in combination with corticosteroids, converts patients with AA to a temporary immunodeficiency state and puts them at high risk for opportunistic infections. Monthly aerosolized pentamidine prophylaxis will prevent *Pneumocystis* pneumonia in patients receiving

CsA. Convulsions, possibly related to hypomagnesemia, are another serious complication of cyclosporine therapy.

Combined or Intensive Immunosuppressive Therapy

The combination for the treatment of AA of an agent that lyses lymphocytes (ATG or ALG) with a drug that blocks lymphocyte function is rational (Table 19-9). The strategy resulted in a striking increase in the response rate to immunosuppressive therapy observed in a German randomized trial in which patients were treated initially with a combination of ALG and CsA or ALG only. The addition of CsA led to higher hematologic response rates and more complete responses than were observed with

ALG alone: 65% versus 39% and 70% versus 46% at 3 and 6 months, respectively. [479] In an NIH study of combination ATG and CsA therapy[480] and in a multicenter European study of ALG and CsA,[481] the hematologic response rates at 1 year were about 80%. In all the trials, 5-year survival rates for responding patients have been reported to be between 80% and 90%. Intensive immunosuppression has been beneficial to two groups in particular: patients with extreme neutropenia (<200 neutrophils/l) and children. Both of these groups respond poorly to ATG therapy alone but have nearly equivalent response and survival rates with combined treatment.

Immunosuppressive therapy has been intensified in other regimens. In Europe, repeated courses of ALG are commonly given in an effort to induce hematologic improvement.[426] [482] [483] [484] A longer course of ATG (28 days versus 10 days) appeared to produce more complete responses in an American multicenter trial. [414] The addition of high-dose methylprednisolone to ALG has been associated with very high response rates in some trials. [482] [485] [486] Most recently, the experience with 11 patients who received high doses of cyclophosphamide, 45 mg/kg/day for 4 days without stem cell rescue, was reported, with an overall response rate similar to that reported with ATG therapy. Remarkably, following cyclophosphamide therapy, blood cell counts were normal and there was no evidence of relapse or late complications.[487] However, the period of pancytopenia, especially neutropenia, was prolonged after cyclophosphamide therapy. High-dose cyclophosphamide therapy for AA is of great interest and is being tested in several experimental trials.

Corticosteroids

Methylprednisolone in modest doses, usually 1 mg/kg/day, is usually administered during ATG and ALG therapy to ameliorate symptoms due to serum sickness. Low-dose corticosteroids are not effective treatment for AA. Very highindustrial strengthsteroids have been administered as boluses of 6-methylprednisolone given intravenously in dosages of 20 mg/kg/day on days 13, 10 mg/kg/day on days 47, 5 mg/kg/day on days 811, 2 mg/kg/day on days 1220, and 1 mgkg/ day until day 30, followed by maintenance. Such high-dose regimens may be effective, especially in recently diagnosed patients. [230] [484] [488] As reviewed above, high-dose methylprednisolone has also been added to ALG therapy, with inconsistent results. ATG and ALG therapy is associated with better response rates and many fewer associated toxic effects than high-dose steroid therapy and is generally preferable as initial therapy. Modest doses of corticosteroids do not have a role in the treatment of aplastic anemia except in combination with antilymphocyte globulins. Not only is there little evidence of their effectiveness in reversing marrow failure or improving hemostasis, but even limited courses of steroids may contribute to the development of aseptic vascular necrosis, a troubling complication in the pancytopenic patient.[489]

Late Complications of Immunosuppressive Therapy

Relapse following immunosuppressive therapy is common. In the European experience, in 719 patients treated with immunosuppressive therapy, the actuarial rate of relapse among 358 responders was 35% at 14 years; relapse was more common among patients who had shown initial rapid responses.[490] About half the patients who relapsed responded to a second course of immunosuppression, but survival was lower in patients who experienced relapse than in those who did not. In the large NIH cohort of 112 patients, relapse, defined as a need for treatment, was even more common, with a risk estimated at 87% at 7 years; however, survival was unaffected by the occurrence of relapse, and most patients responded to further therapy, usually reinstitution of cyclosporine. [245] These observations are consistent with a view of AA as a chronic immunologic disease that may not be cured by a single course of immunosuppressive therapy.

A much more serious complication is the development of late clonal hematologic disease, often years after apparently successful immunosuppressive therapy. The syndromes include PNH, myelodysplasia, and AML.[491] [492] [493] These events may represent part of the natural history of AA. Before the recent improvements in treatment, leukemia was considered an unusual complication,[494] but late-onset clonal disorders do not appear to simply be the result of the introduction of immunosuppressive therapy. In a series of 156 patients treated with androgens, there was a 10% actuarial probability of developing PNH; in addition, five cases of late-onset myelodysplasia and one of non-Hodgkin lymphoma were observed.[495] For patients in the modern era who undergo immunosuppression, the most accurate figures concerning the risk of developing myelodysplasia or PNH are derived from retrospective analyses performed by the EGBMT. Of 223 long-term survivors after immunosuppression, 19 developed PNH (13% risk at 7 years) and 11 developed myelodysplastic syndrome, which in five later evolved to AML (combined risk 15% at 7 years).[496] In single-center series, estimated rates of late-onset clonal disease have ranged from 9% (at 6 years) [422] to 57% (at 8 years).[497] In our series of NIH patients, the actuarial risk was about 16% at 7 years, PNH almost invariably appeared early, within the first year of diagnosis, whereas myelodysplastic syndrome occurred late and usually in patients in whom treatment had failed and who remained pancytopenic. PNH may be without clinical manifestations and only diagnosed by a positive Ham test or by means of flow cytometric studies. Myelodysplastic syndrome after AA may transform to acute leukemia[491] but may also be surprisingly indolent.[498]

Immunosuppression versus Bone Marrow Transplantation

Both immunosuppression and bone marrow transplantation are effective therapy for AA (Figs. 19-8 and 19-10). [340] Lack of a matched sibling donor, the expense and availability of transplantation, and risk factors such as active infections, advanced age, or a heavy transfusion burden lead most patients to automatically undergo treatment with ALG and CsA.[499] For a few patients with AA, a choice does exist between transplantation and immunosuppressive therapy. Marrow transplantation offers the possibility of permanent cure. Its disadvantages are cost, procedure-related morbidity and mortality, especially GvHD in older patients, and an increased incidence of solid organ malignancies. Immunosuppressive therapy is easier and initially cheaper. However, many patients do not achieve normal blood cell counts and remain at high risk for relapse and the more serious complications of late clonal disease, especially myelodysplasia.

Retrospective analyses of the large number of European patients reported to the EGBMT show consistently improved results with both therapies but have repeatedly failed to demonstrate a survival advantage for transplantation over immunosuppression: [370] [500] [501] [502] the most recent 5-year survival figures were 75% for immunosuppression and 77% for transplantation (A. Bacigalupo, personal communication). Single-center studies are similar. Certain categories of patients, defined by neutrophil number and age, likely benefit from one therapy or the other. In the EGBMT analyses, marrow transplantation yielded superior results in children less than 10 years old and in younger patients with a neutrophil count of <400/l, whereas immunosuppressive therapy was superior for adults 40 years old and older. For patients of intermediate age and a neutrophil count of <300/l, transplantation results in a favorable outcome when compared with immunosuppressive therapy [356] (A. Bacigalupo, personal communication). Superior results with matched sibling transplantation

in children have been reported by others. [319] [503] [504] [505] [506] In contrast, older individuals fare less well than children with transplantation. In a compilation of results of transplantation for AA performed from 1970 to 1989 in Seattle, long-term survival in patients more than 40 years old was only about 10%, and in patients 3039 years old it was 35%.[507] Even its enthusiasts do not recommend transplantation as first-line therapy for patients more than 50 years old; [508] 40 years was adopted as a cutoff for consideration of transplantation in one recent review. [509] In some cases, an unsuccessful trial of immunosuppression may be followed by transplantation of marrow from a sibling donor.[510]

Androgens

Testosterone and synthetic anabolic steroids appeared to be a major advance in the treatment of AA when they were introduced in the 1960s. [511] [512] The high response rates that were reported in some early series may be retrospectively attributed to the inclusion of patients with moderate acquired and constitutional AA. For

severe AA, controlled trials in general have failed to demonstrate efficacy, as measured by survival rates [513] or hematologic improvement.[414] When added to immunosuppressive therapies, androgens failed to result in any increase in response rates. [421] In Europe, a modest survival advantage was observed only in women with severe neutropenia who received combined therapy. [514]

Although marrow transplantation or immunosuppressive therapy is generally preferred, certain androgen regimens have their advocates. These investigators have reported response rates and prolonged survivals [495] similar to those observed with ATG.[515] Androgens continue to be helpful in some patients when used as second-line therapy. Most hematologists have observed patients who appeared to respond or even to develop hormone dependence. [516] [517] Androgen therapy is popular in Asia[518] [519] [520] [521] and Mexico[522] because it is inexpensive and seemingly effective. Various preparations of androgens in different doses have resulted in virtually identical response rates of 3560% after 6 months of therapy. [523]

Popular androgens include nandralone decanoate, oxymetholone, and danazol. The hemoglobin response will frequently be more impressive than improvements in granulocyte or platelet levels. An adequate trial of full doses given for at least 3 months and possibly as long as 6 months is required before interrupting therapy. Despite the multiple toxic effects of androgens, complications are infrequent, although some are serious and may limit effective therapy, especially in the elderly. [524] The associated liver cholestasis is usually reversible. Hepatotoxicity (bile duct proliferation, peliosis, atypical hepatocyte hyperplasia, tumors) can occur but is less frequent with parenteral formulations.[525] Children appear to tolerate high doses of androgens without lasting effects on growth or maturation. [526]

The mechanism of action by which male hormones improve failed hematopoiesis remains unclear.[527] [528] Increased secretion of erythropoietin, the most definitive effect, is probably not a significant factor in mediating hematopoietic recovery in AA. Modest direct effects on progenitor cells [529] [530] [531] are of uncertain clinical significance. In in vitro and in vivo models of autoimmune disease, androgens appear to act as immunomodulators. [532]

Hematopoietic Growth Factors

Although hematopoietic growth factor production is normal or increased in most patients with AA, pharmacologic stimulation with very high doses of cytokines might be effective, either through a direct effect on residual stem cells, promoting marrow recovery, or by increasing progenitor cell activity and allowing patients to survive long enough to respond to other, more definitive therapy. [533] [534]

Neutropenia most often leads to serious and life-threatening infections. Both G-CSF and GM-CSF are capable of increasing neutrophil counts in patients with AA. [535] [536] [537] Controlled trials with these agents have not been performed, so that data demonstrating that growth factor administration either decreases the incidence of serious infections or improves survival are lacking. In general, neutrophil responses to growth factors are transient, dependent on their continuous administration, and usually restricted to patients with quantitatively less severe forms of AA. Nevertheless, occasional bilineage and trilineage responses have been observed. [538] Children may be more sensitive to the effects of prolonged administration of G-CSF. [536] [539]

G-CSF and GM-CSF have some immediate toxic effects, including bone pain and cytokine flu symptoms. GM-CSF may increase eosinophil and monocyte counts, while G-CSF and GM-CSF can cause a concurrent reduction in platelet numbers. Of concern has been the possibility that prolonged administration of G-CSF may increase the probability of late clonal disease, especially monosomy 7. In retrospective analyses of Japanese children [540] [541] and adults[542] with severe AA, this syndrome appeared to occur only among patients who had received growth factor. This experience has not yet been confirmed in Europe or the United States (where long-term use of growth factors may be less frequent). Regardless of toxic or late effects, growth factors, perhaps because of their recent availability, often are inappropriately employed as first-line therapy in AA, where they have not been shown to be useful. Such practices lead to unfortunate delays in the institution of definitive therapy.[340] [543]

IL-1, IL-3, IL-6, and stem cell factor have been tested in small pilot trials, usually in patients with refractory AA. IL-1, the monocyte production of which is deficient in severe AA, is not effective and is highly toxic. [544] [545] IL-3 can increase neutrophil numbers and less frequently platelet levels. IL-3 use is associated with significant side effects.[546] [547] [548] [549] A trial of IL-6 in AA was discontinued prematurely because of an increased incidence of bleeding episodes and worsening of anemia. [550] Anemia[65] [551] and pancytopenia[552] in rare patients have responded to prolonged administration of high doses of erythropoietin.

Clinically meaningful hematologic responses to the administration of single cytokines have been limited in marrow failure syndromes, but combinations of growth factors might be more effective because of physiologic or pharmacologic synergism. Some complete remissions have been reported with GM-CSF and erythropoietin [418] [553] [554] [555] and with IL-3 and G-CSF.[556] In a large randomized protocol, the combination of G-CSF and high doses of erythropoietin improved hemoglobin values, mainly in patients with moderate disease.[557] Although neither was very effective alone, the combination of stem cell factor and G-CSF has led to improvement in blood cell counts, including trilineage recovery, in some patients with refractory AA. [558]

Growth factors have also been combined with definitive medical therapy for the purpose of improving neutrophil counts during the early phase of immunosuppression. Often, therapy with G-CSF or GM-CSF is instituted because the neutropenic patient is febrile and unresponsive to antibiotics; its value under these circumstances is unknown. A brief course of GM-CSF before or concurrent with ALG has not added appreciable benefit in two small trials. [559] [560] A few case reports have suggested that the combination of a growth factor with CsA might rescue patients with refractory disease, [561] [562] [563] but, as noted above, a randomized trial showed G-CSF and cyclosporine to be inferior to ALG and CsA as first-line therapy for AA. [564] Prolonged G-CSF was part of the EGBMTs trial of intensive immunosuppression, [481] but whether the excellent hematologic responses and survival rates were due to the use of growth factor or to the sequential courses of immunosuppression is unclear. A randomized trial to determine the efficacy of G-CSF

therapy has recently been completed and should determine the value of the cytokine in this setting.

In the absence of convincing evidence of benefit, either short or long term, growth factor use in AA will be dictated by the individual physicians judgment. Most severely neutropenic patients who are persistently or seriously infected undergo a therapeutic trial in the hope of achieving clinical benefit. G-CSF may be preferred to GM-CSF because of its more favorable toxicity profile. Some patients with disease refractory to other forms of treatment may also receive prolonged courses of cytokines in the hope of either raising the low neutrophil count or, less likely, of inducing clinical remission or a reduction in transfusion requirements. Preferably, the use of growth factors over long treatment periods, especially in patients who are not severely neutropenic, should be in the context of a formal study. Both physicians and patients should be aware of possibly significant risks associated with such treatment.

PROGNOSIS

The initial blood cell counts of a patient with AA are the most important indicators of prognosis. The most popular criteria used to define severe disease are the presence of two of the following three: neutrophil count <500/l; platelet count <20,000/l; corrected reticulocytes <1% (<40,000/l). [346] More complicated formulas are less easy to use and often only quantitate the obvious. [565] In a comparative study of prognostic indices, decreasing blood cell counts during the first 3 months of therapy were uniformly associated with death within 5 years, while stable or improved blood cell counts correctly predicted long-term survival in 75% of patients. Of the prognostic indices, the simple criteria noted above were most accurate at 6 months, correctly predicting poor survival in 85% of patients with 100% sensitivity after 6 months.[566] One modification to the standard criteria is useful. Although bleeding was a major cause of death in the past, infection kills the overwhelming proportion of patients today. Accordingly, in the large European cooperative trials, the category of supersevere AA has recently been defined by an extremely low absolute neutrophil count (<200/l).[319]

In contrast to blood cell counts, bone marrow examination is subject to sampling error, and cellularity is not usually quantitated. For these reasons, in pancytopenic states in general, blood cell counts have been more readily correlated with survival than has the gross marrow appearance. [567] A predominance of lymphoid cells in the bone marrow has been associated with a bad prognosis in some studies, [274] the presence of residual hematopoiesis, particularly erythropoiesis, with a good outlook in others.[568] [569] The permanence of marrow depression after an insult may also be predicted by continued diminished marrow cellularity despite blood cell count recovery.[289] Correlations that were initially found between clinical response to immunosuppression and pretreatment improvement in hematopoietic colony formation after in vitro immune cell manipulation have not proved reproducible or practical.

The rate of spontaneous recovery is difficult to estimate, and most current observers believe it to be low. Untreated severe disease is almost invariably fatal. By contrast, moderate AA has a good prognosis, and some patients with minimal blood cell count depression will recover normal blood cell counts with limited or no therapy.[570] Nevertheless, in an older series of pediatric patients treated mainly with transfusions, only 3% of 334 were judged to be cured, [153] and among more recently reported African patients who received transfusions, corticosteroids, and androgens, mortality at 1 year was 56%, and 72% after 18 months. [24] Interpretation of older publications is complicated by uncertainties concerning diagnosis and the inclusion of a large proportion of patients with moderate disease. In a randomized study from the contemporary era, none of 21 patients assigned to supportive care improved during 3 months of observation. [413]

Improved survival after effective treatment has brought with it a series of problems that affect prognosis, especially late-onset clonal hematologic diseases when bone marrow failure is reversed without stem cell replacement and the late development of malignancies after the aggressive conditioning regimens used in bone marrow transplantation.

Chapter 20 - Paroxysmal Nocturnal Hemoglobinuria

Wendell F. Rosse

INTRODUCTION

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal disorder of the hematopoietic stem cell that results in the production of blood cells with characteristic defects.[1] The first defect detected was the unusual susceptibility of erythrocytes to the hemolytic action of complement; [2] this characteristic was first definitively demonstrated by Ham and his associates in 1938 and has been used as the principle indicator in laboratory diagnosis of this disorder.

The first descriptions of PNH emphasized the hemoglobinuria, which characteristically occurs at night and often in paroxysms, at times initiated by infections. [3] [4] The recognition that hemosiderinuria is perpetual suggested that more hemolysis occurred than was demonstrated by the dark urine. [5] With the advent of diagnostic tests, it became apparent that the disease was much more complex than first realized. In addition to hemolytic anemia, patients often have venous thromboses in unusual places such as the sagittal sinus, the hepatic veins, and the dermal veins. [6] Many patients have granulocytopenia or thrombocytopenia, or both, in addition to the hemolytic anemia.[7] Although most patients have erythroid hyperplasia of the marrow, many have relative or absolute hypoplasia. In addition, a small proportion of patients develop acute myeloid leukemia. [8] [9]

These nonerythrocytic manifestations led to the hypothesis that the other blood elements are also abnormal and showed abnormalities similar to those found in red cells were found in cells of other hematopoietic lineages. [10] These findings suggested that the disorder originated at the level of the hematopoietic stem cell. [11] The finding that most patients have a normal as well as an abnormal population of erythrocytes and that the abnormal cells appeared to be clonal gave rise to the hypothesis that the disorder is the result of a clonal proliferation of an abnormal hematopoietic stem cell. [12]

More recently, the nature of the abnormality has been described. The abnormal cells in PNH lack a number of membrane proteins that have in common fixation to the plasma membrane by a complex glycolipid anchor.[13] In the abnormal cells in PNH, this anchor cannot be synthesized because of a defect early in the biosynthetic pathway,[14] [15] [16] [17] and since the anchor cannot be made, the proteins cannot be affixed to the membrane. Many of the manifestations of PNH can be traced to the lack of these proteins on the abnormal cells.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PATHOBIOLOGY

In PNH, normal and abnormal erythrocytes, granulocytes, monocytes, and platelets are present in the peripheral blood at the same time, suggesting that the abnormal cells arose as a clone within the marrow. The clonal origin of the abnormal population was supported by the finding in women heterozygous for variants of the enzyme glucose-6-phosphate dehydrogenase that the abnormal PNH erythrocytes were all of one isoenzyme. [18] Because the gene for this enzyme is located on the X chromosome, the assumption is that the abnormal cells are derived from a single precursor that possessed that isoenzyme after meiotic suppression of the other X chromosome.

More recent studies have confirmed this hypothesis. Using probes for detecting polymorphisms in genes located on the X chromosome, a monoclonal pattern was found in the marrow cells in five of five PNH patients, strongly indicating that the abnormal cells had arisen from a single precursor. [19]

Defect in Glycosylphosphatidylinositol Anchor

The nature of the defect in the abnormal cells in PNH was difficult to understand, as evidence of missing membrane proteins accumulated. The observation by Low and colleagues[20] [21] that

Figure 20-1 Structure of the glycosylphosphatidylinositol (GPI) anchor. Phosphatidylinositol (with unusual fatty acids and an extra fatty acid attachment to the inositol) is inserted into the lipid core of the membrane. The glycan core consists of four sugars: one molecule of *N*-glucosamine and three molecules of mannose. Ethanolamine is attached to these sugars; the one on the terminal mannose is attached by an amide bond to the carboxyl terminus of the protein.

acetylcholinesterase (one of the proteins missing on the abnormal cells [22]) could be removed from the membrane by an enzyme, phosphatidylinositol-specific phospholipase C, without injury to its enzymatic activity, suggested that this protein was attached to the membrane in the same way as the variable surface glycoproteins of trypanosomes (i.e., by a glycosylphosphatidylinositol (GPI) anchor rather than by a transmembrane sequence of hydrophobic amino acids). [21] [22] When decay accelerating factor (DAF) was also found to be attached by this anchor, a defect in this anchoring mechanism was proposed as the fundamental defect in PNH.[23]

The structure of the GPI anchor has remained fundamentally unchanged from the simplest life forms (e.g., trypanosomes) to mammals, including humans (Fig. 20-1).[24] [25] It consists of a molecule of phosphatidylinositol to which are attached four sugars (a molecule of *N*-glucosamine and three molecules of mannose); the last mannose is attached to the carboxyl end of the protein through phosphoethanolamine. Phosphoethanolamine molecules may be attached to each of the other two mannose residues but do not attach to the protein. A palmitoyl moiety is added to the inositol but may later be removed. The *N*-glucosamine is derived from *N*-acetylglucosamine that is added and then deacetylated.[26] The source of the mannose residues is dolichyl phosphoryl mannose, which is synthesized from GDP-mannose and dolichol phosphate (a long-chain polymer of isoprene) by a specific enzyme. [27] The source of the phosphoethanolamines is not entirely clear, but they are probably derived from phosphatidylethanolamine.

When the synthesis of the anchor is complete, it is attached to the protein in the cisterna of the endoplasmic reticulum by transamidation of the amino group of the terminal phosphoethanolamine to the carboxyl group in the protein. [28] When the protein is attached to the anchor, it proceeds through the Golgi apparatus and on to the membrane surface.

Evidence for a Biosynthetic Defect

The absence of all GPI-linked proteins on the abnormal cells in PNH results from a defect in the biosynthesis of the GPI anchor at a step prior to the addition of *N*-acetylglucosamine to the phosphatidylinositol moiety. This was shown in two ways: (1) the abnormal cells synthesize little or no biosynthetic intermediates containing *N*-glucosamine or mannose, [14] [16] and (2) when the abnormal cells were fused with mouse cell lines defective in the synthesis of the anchor, those fused with cells of the class A phenotype did not complement (i.e., exhibit GPI-linked proteins

on the surface), whereas those fused with lines of the other phenotypes did complement. [15] [16] [29] This means that the PNH cells were defective at the same step as the class A murine cells. Although the enzyme mediating this step has not been identified, the gene responsible for it has been found and is called the *pig-a*.[30] [31] [32] [33] The defect in this gene has been identified in nearly 100 patients with PNH. [33] In most patients, the defect results in no gene product; this results in PNH III cells. [33] In some patients, the defect results in a missense message and the product is presumably defective in performing the glycosylation necessary for the synthesis of the GPI anchor; this results in cells with small amounts of the anchored proteins on their surface (PNH II cells). Some patients have two or more clones of abnormal cells.[33]

The *pig-a* gene is located on the X chromosome[17] at Xp.22 (at the end of the short arm) near the gene for the glycine receptor; [34] this means that a disabling acquired abnormality cannot be complemented by an allelic chromosome. Thus, it appears likely that the abnormalities in PNH result from a single hit to this gene in a hematopoietic stem cell.

Effects of the Deficiency of the Membrane Proteins

To date, about 15 proteins have been found to be lacking on the abnormal cells of patients with PNH (Table 20-1). [45] Not surprisingly, the deficiency, whether partial or complete, of so many proteins has profound effects on the function of the abnormal cells. These proteins can be divided into several functional groups.

Complement Defense Proteins

The indicator used to define PNH is the unusual sensitivity of the red cells to the hemolytic action of complement. This results from reduced control of the activation of

complement on the cell surface because of the lack of two (perhaps three) membrane proteins.

Complement consists of a group of proteins that circulate in the plasma in an inactive form; these proteins are sequentially activated on cellular sites to mediate some of the cellular destruction of the immune system (Fig. 20-2).[45] [46] [47] Inactivation mechanisms are in place to control the reactions. Several fluid-phase proteins inhibit the enzymatic activity of some of the complexes;[48] other proteins cleave the cell-bound components, thus inactivating them. Membrane proteins on the cell surface

TABLE 20-1 -- Membrane Proteins Missing from the Blood Cells in PNH

Complement defense proteins
Decay accelerating factor (DAF, CD55)[32]
Membrane inhibitor of reactive lysis (MIRL, CD59, protectin) [33]
C8-binding protein[34] (homologous restriction factor)[35]
Immunologic proteins
Fc receptor IIIa[36]
Lymphocyte function-associated antigen-3 (LFA-3, CD58) [37]
Endotoxin-binding protein receptor (CD14) [38A]
CDw52[38B] (Campath-1)
Enzymes
Acetylcholinesterase[22]
Leukocyte alkaline phosphatase[39]
Receptors
Urokinase (plasminogen activator) receptor[40]
Folate receptor
Granulocyte proteins of unknown function
CD14[41] [a]
CD48[42A]
CD66[42B]
Dombrock-Holley/Gregory-bearing protein [42C]

[a]Rothenberg S, personal communication.

Figure 20-2 Activation complexes of complement and their down-regulation by membrane proteins. Activation can take place by three pathways: the classic pathway involving antibody, the alternative pathway involving surface-bound C3b, and the reactive pathway involving the elements of the terminal complex C5b-7, which has been activated elsewhere (not on the target surface). Initiation complexes localize the reaction, amplification complexes amplify the effect by bimolecular enzymes (convertases), and cytotoxicity complexes insert protein into the lipid of the membrane to breach it. Decay accelerating factor inhibits the amplification complexes; membrane inhibitor of reactive lysis inhibits the formation of the membrane attack complex.

are more important for the protection of homologous cells against the attack by activated complement. Such proteins include DAF (CD55), [35] membrane inhibitor of reactive lysis (MIRL, CD59, protectin,[33] and perhaps C8-binding protein [homologous restriction factor]). [37] [38A]

Decay Accelerating Factor

Decay accelerating factor (DAF), a glycoprotein of 68,000 molecular weight, increases the rate at which the convertase complexes (the enzyme complexes responsible for the activation of C3 and C5 C4b2a of the classic pathway and C3bBb of the alternative pathway) are dissociated or decayed. In disrupting the convertase complexes, it reduces the amount of C3 that is cleaved and thus reduces, ultimately, the number of membrane attack complexes that are formed.

The deficiency of CD55 on the abnormal PNH cells results in a greater activity of the convertases; hence, much more C3 is deposited on the membrane when either the classic or alternative pathway is activated.[49] The deficiency of this activity was thought at first to account for the greater sensitivity of PNH red cells to complement, but in fact this deficiency plays a relatively minor role in that phenomenon.

The platelets in PNH also lack DAF but compensate with the release of factor H from internal granules; [50] factor H is a fluid-phase regulatory molecule with the same molecular action as DAF. This release is stimulated by activation of complement on the platelet surface and results in the local down-regulation of the convertase complexes.

Membrane Inhibitor of Reactive Lysis

Membrane inhibitor of reactive lysis (MIRL) (CD59), a glycoprotein of 19,000 molecular weight, is more important than DAF in the cellular regulation of complement action.[51] It prevents the interaction between C8 and C9 in the final steps of complement activation. [52] Lysis of the cell is caused by the insertion of C9 into the membrane after it has been amphipathic by interaction with C8 of the C5b/8 complex that is situated at the membrane surface; CD59 prevents this interaction. [47] The absence of CD59 on PNH red cells is primarily responsible for their increased susceptibility to complement lysis. [53]

Figure 20-3 Effect of polymeric C9 on the platelet membrane. **(A and Inset)** When the membrane attack complex is assembled on the membrane, aggregates of polymeric C9 result. **(B)** These polymeric C9 complexes are gathered into a region of the membrane and are removed by vesiculation. **(C)** The vesicles that result are not able to maintain phosphatidylserine on the internal leaflet of the bilayer. **(D)** The phosphatidylserine molecules become binding sites for the components of the prothrombinase complex, which is able to activate prothrombin.

The absence of CD59 on the abnormal platelets of PNH does not result in their lysis in vivo but may play a role in a serious complication of PNH, venous thrombosis. The response of the normal and PNH platelet to the insertion of the polymeric C9 into the membrane is to gather the offending complexes and remove them by exovesiculation (Fig. 20-3).[54] The vesicles that are thus generated cannot maintain the acidic phospholipids on the internal leaflet and hence externalized phosphotidylserine serves as a site for prothrombinase complexes. These complexes generate thrombin. Because the formation of polymeric C9 complexes is not regulated on the PNH platelet, many more are inserted into the membrane, resulting in many more vesicles, which generate more thrombin.

The abnormal platelets in PNH appear to be specifically sensitive to the aggregating activity of thrombin. Much smaller amounts of thrombin than are needed to aggregate normal platelets cause aggregation of these abnormal platelets. The combination of these two reactionsincreased production of thrombin and increased

sensitivity to thrombins aggregating activity probably accounts in large part for the markedly increased incidence of thrombosis in these patients.

Fc Receptor IIIa (CD16a)

The Fc receptors on phagocytic cells bind to immunoglobulin, which is attached to antigens of the target cell. Several types exist, but only one is linked to the membrane by the GPI anchor Fc receptor IIIa, the primary IgG receptor present on granulocytes. Its absence on PNH granulocytes [39] may contribute to the propensity of these patients to infections, especially blood-borne ones (septicemia, bacterial endocarditis, etc).

Other Proteins Missing from PNH Cells

A number of other proteins are known to be missing from the blood cells in PNH (Table 20-1). Some are enzymes that have no known function in the biology of the cells. Some are related to immunologic function; their absence may play a role in the pathogenesis of the syndrome, but data for this hypothesis are not available. Lack of the folate receptor and urokinase receptor [43] may alter the way in which those molecules are metabolized, but associated pathophysiology has not been identified.

CLINICAL MANIFESTATIONS

Because of the variety of missing proteins on the hematopoietic cells, PNH is a highly protean syndrome with different manifestations in different patients. In addition, because it is clonal and the size of the abnormal clone is different in different patients, the severity of a given manifestation varies greatly from patient to patient. For these reasons, PNH must be considered in a number of hematologic clinical settings.

Hemolytic Anemia

All patients with PNH have some intravascular hemolysis, which can range from barely detectable to massive, requiring repeated transfusions. The hemoglobin concentration of the blood may range from normal to very low levels, and the reticulocyte count is usually elevated but may be lower than expected for the degree of anemia.[7] The red cells are usually quite normal in appearance, although some variation in shape may occur in some patients with more dysplastic hematopoiesis.

The amount of hemolysis depends on a number of factors:

1. The size of the abnormal clone(s): the proportion of complement-sensitive red cells in the circulation can vary from 1 to 90%. Because these are the cells at risk for hemolysis,[55] the amount of hemolysis will be greater according to the number of abnormal cells, all other things being equal.
2. The abnormality of the red cells: the red cells may vary greatly in their abnormality because of differences in the content of the complement defense proteins on the surface. The most abnormal (the so-called PNH III) cells completely lack these proteins and thus are very readily lysed in the circulation by minimal activation of complement. Cells of intermediate sensitivity (PNH II cells) display limited expression of the proteins on the surface and are not as readily lysed by complement activated in vivo.[56]
3. The degree of complement activation: the abnormal cells in PNH can be lysed by complement even when it is activated on other cells or in the plasma. Thus, situations in which complement is activated (infections, transfusion reactions, etc.) result in increased lysis of these red cells. The characteristic nocturnal hemolysis may be due to the activation of complement by the absorption of endotoxin (a potent activator of the alternative pathway) from the gut, resulting in

C5b/7 complexes that initiate attack through the reactive pathway (Fig. 20-2); normal cells are protected against this attack, whereas the defective PNH cells are not. Paroxysms of hemolysis often occur in conjunction with infections that activate complement.

In addition to contributing to the anemia of the patient, the intravascular hemolysis has several other effects, the severity of which is largely related to the degree of hemolysis:

1. Most patients have excessive iron loss both because of the hemoglobinuria as well as the perpetual hemosiderinuria; 20 mg/day of iron (10 times the normal amount) may be lost without evident hemoglobinuria. [57] In the kidney, hemoglobin permeates the glomerulus as a dimer and is actively transported into the cells of the proximal tubule; when the T_{max} is exceeded, hemoglobinuria results. In the proximal tubule, hemoglobin is broken down, but the iron remains and is excreted as hemosiderin.
2. In acute and massive hemolytic episodes, the kidneys may undergo acute tubular necrosis because of the large amount of hemoglobin being passed; this occurs most readily if the patient is also dehydrated, and can be prevented by adequate hydration. [58]
3. In patients with long-lasting hemoglobinuria, defects in kidney function may occur. These may be as mild as renal Fanconi syndrome (excretion of other molecules normally reabsorbed by the proximal tubule). Rarely, mild renal tubular acidosis of the proximal tubular type may be seen. [59] [60] In a few patients, renal failure may intervene after many years of hemoglobinuria.

Hemoglobinemia may also account for two manifestations of PNHesophageal spasm and impotence. Many patients will have achalasia-like esophageal symptoms when they are having hemoglobinuria, and most men are impotent at those times. This may result from the adsorption of nitric oxide (NO) by free hemoglobin; a reduction in NO results in smooth muscle contraction.

Relative and Absolute Bone Marrow Failure

In all patients with PNH, an element of diminished hematopoiesis is present. In its most severe form, it manifests as aplastic anemia with the virtual absence of bone marrow precursors; in these cases, relatively few red cells are being made, so little hemolysis is evident. In many patients, the bone marrow is actively producing cells, particularly erythrocyte precursors, and in fact may be hyperplastic, yet a hematopoietic defect can be demonstrated.

At least two-thirds of all PNH patients have thrombocytopenia or granulocytopenia during the course of the illness. [61] Because the survival of platelets [62] and granulocytes [63] in the circulation in PNH is normal, these diminished numbers are due to deficient or ineffective production of these cells. These cytopenias may be important aspects of the patients clinical syndrome.

The hematopoietic defect can be detected in most if not all patients on the bone marrow culture. Even when the bone marrow is hyperplastic, many fewer hematopoietic colonies result when PNH progenitor cells are assayed in vitro than when normal marrow progenitor cells are assayed. [64] [65] [66] It is this characteristic that places the syndrome in the class of myelodysplastic rather than myeloproliferative syndromes.

The cause of the relative or absolute hematopoietic defect is not clear. It may have to do with missing GPI-anchored proteins on the abnormal stem cells or on the lymphocytes and monocytes that may control hematopoiesis. The presence of the defect is all the more perplexing because the abnormal stem cell must have some proliferative advantage over the normal clones of cells in order to be able to dominate the marrow in most patients.

An alternative theory has been proposed, suggesting that PNH is the result of two processes: the abnormal stem cells are generated from a somatic mutation but are not able to proliferate in a normal marrow environment; clinical PNH arises when the marrow is suppressed by an aplastic process, most likely immunological in nature.[64] The abnormal PNH cells are less suppressed by this process than the normal cells are and hence can come to dominate the marrow. [66B] Although much data are compatible with this theory, more data are needed to confirm it.

The effects of the diminution in hematopoiesis can be dramatic. It magnifies the effects of the hemolysis, since the response to anemia is inadequate. The granulocytopenia and thrombocytopenia may be severe enough to result in infections and bleeding. Bone marrow aplasia may intervene, with fatal results.

Thrombotic Events

Venous thrombosis, one of the most feared complications of PNH, was described in earlier reports and recognized as part of the syndrome by Crosby in 1952. [6] About 20% of patients with PNH from Europe and the United States experience thrombotic episodes; this fraction appears to be much less in Asian populations, which have symptoms related to such events that are difficult to document. These thromboses commonly occur at several specific sites, as described in the following sections.

Hepatic Vein Thrombosis (Budd-Chiari Syndrome)

The hepatic veins are one of the most common sites of venous thrombosis in PNH.[67] Onset may be acute and dramatic, causing severe right upper quadrant pain, jaundice, hepatomegaly, and ascites;[68] this often occurs during a hemolytic crisis, suggesting that the activation of complement is responsible for both. In other instances, the onset is more gradual and insidious. [69] In either case, serum levels of enzymes indicative of hepatic injury (SGPT, AST) are elevated; this elevation must not be confused with the marked elevation of lactate dehydrogenase and significant elevation of SGOT, which are indicative of hemolysis of the red cells. The serum alkaline phosphatase level may also be elevated. The most direct diagnostic test is the demonstration of the clots in the hepatic veins by computed tomography scan, magnetic resonance imaging (MRI), or ultrasound, particularly with Doppler flow measurements. [70] Sometimes the clots may not be demonstrable, but characteristic abnormalities in flow may indicate clots in the smaller vessels. Contrast injection into the hepatic veins may demonstrate the clots but should be done with caution. Imaging of the liver with colloid ^{99m}Tc may show a relative enhancement of the caudal lobe, which is spared the effects of hepatic vein thrombosis because the veins that drain this part of the liver go directly to the inferior vena cava and are not involved. [71] The thrombosis in the hepatic veins may extend to the inferior vena cava in extreme cases.[72]

The process, once initiated, tends to persist, with periodic exacerbations and remissions. Although patients may live for some years with chronic Budd-Chiari syndrome, it is usually ultimately fatal.

Cerebral Vein Thrombosis

The cerebral veins and sinuses are also prone to thrombosis, particularly the sagittal sinus and the veins covering the parietal lobes. [73] [74] [75] This results in severe headache, focal and nonfocal neurologic symptoms (depending on the location of the thrombosis), and, if sufficiently severe, coma and death. The spinal fluid is often xanthochromic or bloody. Careful examination of the flow of the cerebral veins with MRI or Doppler flow ultrasound may be needed to demonstrate the presence of the thrombosed veins. Although less common than hepatic vein

thrombosis, cerebral venous thrombosis also tends to be chronic and does not portend a good prognosis.

Abdominal Vein Thrombosis

The large and small veins of the abdomen may be thrombosed, resulting in a variety of syndromes. The most common is severe abdominal pain, often recurrent, usually lasting 35 days, with or without signs of intestinal obstruction. The symptoms tend to occur in the same part of the abdomen with each attack. The thromboses are difficult to demonstrate radiologically. In some patients, the problem is so severe that intestinal infarction requiring resection occurs. In other patients with recurrent pain, evidence of scarring and thrombosis may be found at operation; removal of the area may relieve the symptoms. [76]

The larger veins of the abdomen may be thrombosed, resulting in symptoms related to their site. Splenic venous thrombosis may result in splenomegaly and even splenic rupture. Portal venous thrombosis may result in ascites, esophageal varices, and other indications of rerouted venous circulation. Thrombosis of veins of the stomach and duodenum may result in lesions that are detectable with gastroduodenalendoscopy.

Dermal Vein Thrombosis

Thrombosis of the veins of the skin may occur in two clinical patterns. [77] [78] Areas of thrombosis may appear as painful, swollen, discolored lesions, usually measuring 510 cm, over various parts of the body. These usually resolve but on occasion may ulcerate. These dermal thromboses are recurrent but do not necessarily occur at the same site. Alternatively, patients may have localized lesions resembling purpura fulminans, with purple discoloration of larger areas of skin, demarcation, and often necrosis. If the lesions are sufficiently extensive, death may result.

Thrombosis at Other Sites

Thromboses may occur at other sites. Thrombosis of the veins of the lower extremity occurs with greater frequency than is common in the general population, but death by pulmonary embolism is rare. Thrombosis of the epididymal veins leads to a syndrome much like acute orchitis. Arterial thrombosis is rare.

Other Symptoms and Complications

Patients with PNH may have other symptoms that are probably related to their disease but for which there is no current explanation.

1. Many patients complain of dysphagia during episodes of intravascular hemolysis; this appears to be due to the generation in the esophagus of very strong peristaltic waves. When the hemolysis is nocturnal, the dysphagia is present in the morning but disappears by noon.
2. Many men with PNH note impotence during the periods of hemoglobinuria. In some cases, this impotence lasts beyond the hemoglobinuric period and becomes permanent. This and the symptoms of esophageal contraction may result from the fact that free hemoglobin binds nitric oxide, causing increased contractility of smooth muscle.
3. Many patients note a feeling of fatigue that may be disabling during periods of hemoglobinuria. This is not related to hemoglobin level, as it disappears when the hemoglobinuria stops.
4. Rarely, patients may have severe low back pain. Blood chemistries done at the time of pain suggest that there may be muscle destruction, and this symptom has been ascribed to small and undetectable thromboses in the muscles.

DIAGNOSIS

Until recently, the abnormal sensitivity of the red cells to the hemolytic action of complement has been the basis of the diagnostic tests for PNH. In the original Ham test, complement is activated by acidification of the serum to a pH of 6.2; PNH cells will lyse in such serum, whereas normal cells will not. [2] The test is specific (there is no other cause for a positive test other than the very different syndrome hereditary erythroblastic multinuclearity with positive acidified serum test (HEMPAS, congenital dyserythropoietic anemia type II). [79] The sensitivity of this test is dependent on the concentration of Mg^{2+} in serum. The test becomes more sensitive if the Mg^{2+} concentration is raised to 0.005 M; [80] even then, the test may not detect small populations of abnormal cells and cells of intermediate sensitivity. Furthermore, the test seems to be technically difficult, since many false-positive and false-negative reactions occur during routine laboratory practice.

Complement is also activated when the serum is mixed with a medium of low ionic strength; sucrose is the solute usually used to replace the salt solution in maintaining isosmotic conditions, and the test is often called the sugar water test. [81] [82] This test is quite sensitive and usually does not fail to lyse the abnormal PNH cells; however, it is less specific because cells in other conditions (autoimmune hemolytic anemia, leukemia, etc.) may be lysed. [83] Many tests have been proposed in which complement is activated by antibody to red cell antigens. The most quantitative of these is the complement lysis sensitivity test in which limiting amounts of complement are activated by antibody. [12] By careful titration, both the proportion of abnormal cells and their abnormality can be demonstrated.

Tests Based on Detection of GPI-Linked Proteins

Since the finding that the abnormal cells lack the GPI-linked proteins, the demonstration that these proteins are deficient on the blood cells has been used as a diagnostic test for PNH. In general, monoclonal antibodies to CD59 or CD55 (DAF) are used with flow cytometric analysis (Fig. 20-4). [5] [84] [85] These tests have the advantage of being readily performed on granulocytes and platelets; the proportion of abnormal cells in these populations is greater than that of red cells, because the abnormal granulocytes and platelets have a normal survival time in the circulation.

In patients whose cells are partially deficient, some proteins are more deficient than others; in general, CD59 is the most deficient and (on granulocytes) CD16 (the FC receptor IIIa) is the least deficient. [86]

The results of the examination of CD55 and CD59 on lymphocytes obtained from PNH patients are less clear. In some patients, a population of abnormal cells could be detected in all three lymphocyte cell lineages (T cell, B cell, and natural killer cells) [6] [87] [88] [89] (often in surprisingly small numbers), whereas in others, they could not. [85]

At the present time, the demonstration of red cells and/or granulocytes lacking one or more of the GPI-linked proteins by the use of monoclonal antibodies and flow cytometry provides the best means of diagnosing PNH; this method is both sensitive and specific and can readily provide information on the relative proportion of the abnormal populations. [5]

Differential Diagnosis

Hemoglobinuria is a relatively unusual symptom in clinical medicine and is easily confused with two other symptoms, myoglobinuria and hematuria. Myoglobinuria can be identified by examination of the serum (which is without red pigment), differential solubility of the two pigments (hemoglobin is more easily precipitated by ammonium sulfate), or reaction with

Figure 20-4 Demonstration of the abnormal cells of PNH by flow cytometry, using fluorescein-labeled CD59. In each case, the relative fluorescence intensity, a measure of the CD59 content per cell, is described on the abscissa using a logarithmic scale. The relative number of cells with that intensity is shown on the ordinate. The populations of PNH cells (PNH Inormal, PNH IImoderately abnormal, PNH III markedly abnormal) are indicated. Panels A and Berythrocytes; panels CFgranulocytes.

AN APPROACH TO PNH

DIAGNOSIS

The diagnosis of PNH is ultimately made by the laboratory tests demonstrating complement sensitivity of the red cells by the Ham or other test or (preferably) deficiency of the GPI-linked proteins by flow cytometry. Diagnostic tests should be obtained in patients with (1) hemolytic anemia, with or without hemoglobinuria, with normal-appearing red cells, and without other hemolytic diagnosis; (2) signs of marrow dysfunction including aplastic anemia, granulocytopenia, or thrombocytopenia not otherwise explained, or myelodysplastic disease (if the test is initially negative, it should be repeated at intervals as it may become positive); (3) unexplained thromboses, particularly venous thromboses in unusual places; and (4) recurrent bouts of abdominal pain, or neurologic symptoms and headaches.

TREATMENT

The appropriate treatment depends on the symptoms. All patients should receive iron supplements unless they are receiving transfusions.

Anemia

For anemic patients with signs of hemolysis, prednisone should be tried at a dose of 2040 mg every other day; if this is successful, it may be tapered, but not below a dose of about 20 mg every other day. If it is not helpful (the hemoglobin does not rise after 1 month or so), it should be discontinued unless the patient is having thrombotic complications. Some patients respond to androgens; danazol (400 mg/day) is best tolerated. Again, if no response is seen within 2 months, it should be discontinued. Prednisone and danazol may be given simultaneously. Some patients respond to very high doses of recombinant erythropoietin (20,000 U 23 times a week). Transfusions should be given as needed.

Thrombosis

Patients with acute thrombosis should be given thrombolytic agents (streptokinase, urokinase, or tissue plasminogen activator) as rapidly as possible. Full-dose heparin therapy should be instituted for 710 days, followed by appropriate treatment with Coumadin. Patients with documented thrombosis should be maintained on Coumadin for long periods. Antiplatelet agents (aspirin, ibuprofen, etc.) may be useful but their action is unproved.

Deficient Hematopoiesis

If the patient has an identical twin, syngeneic transplantation should be done. If the patient has a histocompatibility antigen-compatible sibling, transplantation should be considered if any complications due to the PNH are present; this is particularly true for children. Transplantation with the marrow of an antigen-compatible unrelated donor should be reserved only for patients with major complications.

Patients with marrow hypofunction (manifested by low reticulocyte count, thrombocytopenia, and/or granulocytopenia) may be candidates for antithymocyte globulin. The usual dose is 15 mg/kg/day for 10 days or 45 mg/kg/day for 4 days; this must be given with high doses of prednisone and usually results in worsening of the platelet count during and shortly after administration. The use of cyclosporine is also being explored. Granulocytic patients may respond to G-CSF (150300 g 12 times per week).

GENERAL COMMENTS

PNH is a chronic disease, and most patients are quickly tired of having it. Careful follow-up and good patient education are important parts of their care. The hope can be held out that patients who do not have serious complications may eventually be rid of their disease.

specific antibodies against myoglobin and hemoglobin. In hematuria, red cells are present in the freshly collected urine and the supernatant does not contain heme-reactive pigments after centrifugation.

Several other hemolytic diseases may cause hemoglobinuria. Severe autoimmune hemolytic anemia, particularly paroxysmal cold hemoglobinuria, may result in enough intravascular lysis to produce hemoglobinuria. Severe traumatic hemolytic anemia from prosthetic cardiac devices or from microangiopathic causes may also lead to hemoglobinuria; schistocytes are always evident on examination of the peripheral blood film. Rarely, toxic hemolytic anemia (such as that occuring during clostridial infection, copper poisoning, oxidant ingestion in a patient deficient in glucose-6-phosphate dehydrogenase, etc.) may result in hemoglobinuria. Other more common and more subtle symptoms of PNH are more readily missed and may only be identified as part of the clinical constellation of PNH by doing the diagnostic tests for PNH. The abdominal pain that patients with PNH experience can be confused with ileitis. Budd-Chiari syndrome can be confused with cirrhosis or other parenchymal liver disease; the elevation of the enzymes (SGOT and lactate dehydrogenase) usually seen in PNH may add to the confusion. The effects of sagittal venous thrombosis (headaches, edema of the optic nerve, etc.) may resemble pseudotumor cerebri or other cerebrovascular events.

Most commonly, PNH is confused with other hematologic syndromes, particularly other stem cell disorders. The relationship to aplastic anemia has been described. In recent surveys,[90] [91] [92] an average of 6.8% (4.120.8%) of untransplanted patients with aplastic anemia evolve to PNH. Most of these patients have clinical symptoms attributable to PNH, but some have only cells with the defects characteristic of PNH. The occurrence of PNH in other stem cell disorders is more rare but too common to be due to chance alone. Erythroleukemia, chronic myeloid leukemia, and myelofibrosis are the most common accompanying diseases, [93] but patients with refractory anemia with excess blasts,[94] myelofibrosis,[93] and polycythemia vera (personal observation) have been associated with cells expressing the PNH defect. Rotoli and Luzzatto[93] have determined that 11 of 113 patients with myelodysplastic syndrome had a positive Ham test, suggesting the presence of the PNH defect in 112% of the cells. In one series, PNH developed before the documentation of an identifiable myelodysplastic syndrome (5 of 47 patients) and after the development of agnogenic myeloid metaplasia (4 patients). [95] The incidence of the defect in this population might be even higher if granulocytes and platelets were examined for the deficiency of GPI-linked cells.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COURSE AND PROGNOSIS

The clinical outcome in PNH is extremely variable. Estimates of mean life span from the time of diagnosis have varied from

810 years,[96A] to 15 years or more,[96B] [96C] in a Chinese study, the mean life span was 25 years, probably because of the decreased morbidity caused by thrombosis in this population. The most common causes of death are the consequences of thrombosis (particularly of the hepatic and other intraabdominal veins) or of the effects of hypoproliferation of the bone marrow (infections, bleeding).

The population of abnormal cells may decrease with time in patients surviving for prolonged periods (1520 years). [97] The abnormal erythrocytes and granulocytes may disappear completely but a small population of lymphocytes may persist for many years;[1] commonly, a small population of erythrocytes may remain, but the patient is asymptomatic.

Progression to Acute Leukemia

In about 35% of patients with PNH, the illness progresses to acute leukemia. [8] [9] This is usually of myeloid origin but occasionally the leukemic cells are positive for terminal deoxynucleotidyl transferase, suggesting a lymphocytic origin. [98] The onset is typically about 5 years after the onset of symptoms related to PNH. As the leukemic cells appear, the abnormal red cells disappear but will reappear if (in the rare case) the leukemia is successful treated. [99] The leukemic cells have the PNH phenotype of deficient GPI-linked proteins [100] [101] and may show cytogenetic changes suggestive of subclonal evolution. [102]

THERAPY

Treatment in PNH depends on the symptoms of the patient. In general, several modalities are available:

1. Correction of the anemia by
   a. Interruption of complement activation
   b. Replacement of missing nutrients
   c. Transfusion
2. Treatment and prevention of thrombosis
3. Modification of the bone marrow by transplantation or stimulation

Each of these modalities of therapy may be applied as needed and as circumstances permit.

Correction of the Anemia

Since the hemolytic component of the disorder is ultimately a result of the activation of complement, measures that prevent this event lead to amelioration of the hemolysis. At present, the only agents that do so are glucocorticoids; the dose required is relatively large (0.30.5 mg/kg/day). The action of the steroids is very rapid. Because the dose required is so high, the drug is generally given every other day; on the intervening day, the patient may have hemoglobinuria and its accompanying symptoms. During an acute episode of hemoglobinuria, the dose may be increased to 1 mg/kg/day and be administered every day until the bout is over. Only about 60% of patients with hemolysis respond to this treatment.

Patients with hemolysis in PNH waste large amounts of iron as hemosiderin and hemoglobin in the urine. Unless they are getting iron from other sources (e.g., blood transfusions), most of these patients need to receive iron supplements. Usually, oral iron administration is sufficient, but occasionally the parenteral route is used. When iron is first administered to an anemic and iron-deficient patient, a hemolytic episode may result when the stimulated marrow begins to pour out abnormal cells that are then hemolysed.[103] [104] This can be prevented by the simultaneous administration of prednisone or by suppression of erythropoiesis by transfusion.

Because patients with hemolysis have increased erythropoiesis, they may theoretically become deficient in folic acid. This deficiency seems to be rare; it may be that the intravascular hemolysis releases red cell folate into the serum, where it again becomes available for metabolism.

Some patients require transfusion to maintain an adequate oxygen-carrying capacity, which may result in the lysis of a small number of the patients own cells and resulting hemoglobinuria. Such lysis is probably rarer than commonly thought and may be due to minor sensitization either to red cells or to other blood elements. [104] [105] When it occurs, it is confused with a hemolytic transfusion reaction resulting from incompatibility. The reaction can be prevented by washing the donor cells before transfusion.[106]

Therapy for and Prevention of Thrombosis

When acute thrombosis occurs, it should be treated as an emergency. Thrombolytic agents (streptokinase, urokinase, or tissue plasminogen activator) should be administered at once unless otherwise contraindicated.[3] [107] [108] [108] The results may be dramatic; the enlarged, swollen liver of a patient with acute Budd-Chiari syndrome may reduce in size over a period of a few minutes to a few hours. Although thrombolytic agents are less effective if not used quickly after the clot has formed, they may be of some use even days later and should be tried.

Once it is safe, the patient suffering acute thrombosis should be given heparin in the usual fashion (a bolus of 5,000 U followed by an infusion of 25,000 U/day followed by careful monitoring of appropriate parameters of anticoagulation). Although hemolytic reactions after heparin administration have been reported, [6] [109] they are rare. As the acute episode passes, the patient should be anticoagulated with warfarin derivatives and should be maintained on anticoagulation therapy for 6 months.

These measures for preventing and treating thrombosis are inadequate. Most patients with Budd-Chiari syndrome never entirely eliminate the problem. With the development of better antithrombin agents (e.g., recombinant hirudin) and better ways of controlling the activation of platelets by thrombin, more successful ways of dealing with this complication may be found.

Modification of Hematopoiesis

Until recently, alteration of hematopoietic function was difficult and ineffective. Androgens and modified cogeners may, in some patients, stimulate erythropoiesis. [110] More recently, recombinant cytokines have been used, particularly erythropoietin and colony-stimulating factor-granulocyte (G-CSF) these are usually only moderately effective and are difficult to administer.

Antithymocyte Globulin

Based on the assumption that T lymphocytes modify hematopoiesis and may play a role in its diminution, patients with aplastic anemia were given equine antiserum to human thoracic duct lymphocytes (antithymocyte globulin); remission of the aplastic anemia was seen in about 60% of patients, although the reason for this response is not entirely clear.[111] [112] On the basis of the similarities of PNH and aplastic anemia, antithymocyte globulin was given to patients with evidence of deficient hematopoiesis.[113] About 70% of these patients had correction of their cytopenia; reversal of thrombocytopenia was the most common. In most cases, the increase in the proportion of complement-sensitive cells was not great, and the amount of hemolysis did not usually increase.

Allogeneic Bone Marrow Transplantation

PNH can be cured by replacement of the abnormal cells of the bone marrow with normal bone marrow.[114] [115] In the past, such

replacement has been limited to patients with bone marrow failure who have histocompatible sibling donors, either (optimally) identical twins or HLA-A, -B, and -D

matched siblings. As bone marrow transplantation has become safer, patients with other complications of PNH have undergone bone marrow transplantation, particularly children, in whom transplantation is safer and in whom the prognosis of the disease is known to be relatively poor. [116]

Syngeneic transplantation is easier to perform than allogeneic. In at least one instance, the syngeneic marrow (from an identical twin) was infused without prior conditioning (treatment of the patient with immunosuppressive and marrow-ablative drugs); disappearance of the abnormal PNH cells resulted. [117] In other instances, this has not been the case. In a recent personal case, a patient with severe Budd-Chiari syndrome was successfully given a syngeneic transplant, following which the liver disease improved. [118]

Allogeneic marrow transplantation still carries a considerable risk of complications, including graft-versus-host disease, intercurrent infections, and failure of engraftment. However, when faced with the poor prognosis of the complicated patient, the benefits are worth the risks in many cases. To date, few patients have been given allogeneic transplants from unrelated donors; although some of these transplants are successful, the complications are even greater than those of allogeneic transplantation from a sibling.

Gene Therapy

With the identification of the gene that is abnormal in PNH, treatment by reinsertion of the gene becomes possible. Experiments are currently under way to ascertain the appropriate conditions for this treatment.

Chapter 21 - Pure Red Cell Aplasia

Emmanuel N. Dessypris

Pure red cell aplasia (PRCA) is a syndrome characterized by normochromic normocytic anemia, reticulocytopenia (reticulocyte count <1%), and an almost complete absence of erythroblasts from the bone marrow (erythroblasts <0.5%). [1] In contrast to aplastic anemia, in which the aplasia involves all three cell lines, in PRCA the aplasia is selective for the erythroid cell line, resulting in severe anemia with normal leucocyte and platelet counts. After its initial description by Kaznelson in 1922, [2] this syndrome has appeared in the literature under different terms, including pure aplastic anemia, erythrophthisis, chronic hypoplastic anemia, aplastic crisis, erythroblastopenia, erythrogenesis imperfecta, Blackfan-Diamond syndrome, pure red cell agenesis, and primary red cell anemia. [1] Today, the term PRCA is used to describe this disorder in adults; congenital hypoplastic anemia (CHA) or Diamond-Blackfan anemia, and transient erythroblastopenia of childhood (TEC) are used for the congenital and acquired forms that occur in infants and children.

Pure red cell aplasia is a relatively uncommon disorder, the exact incidence of which is not known. It may affect any age group and occurs with almost the same frequency in men and women. It has been described in all parts of the world, and there seems to be no ethnic or racial predisposition.

ETIOLOGY AND PATHOGENESIS

Pure red cell aplasia may present as a congenital disorder early in life or later as an acquired anemia that may be primary or secondary to a variety of neoplastic, autoimmune, or infectious diseases. A classification of PRCA is presented in Table 21-1 . Congenital hypoplastic anemia is a form of erythroid aplasia that manifests itself during the first year of life.[3] It is considered to be an inherited disorder that is frequently associated with a variety of congenital malformations. In approximately 10% of cases, more than one member of the family has been affected, and in a small number of cases, members in successive generations were affected, indicating an inheritance pattern that has been defined in different families as either autosomal dominant or recessive. [1] [3] [4]

Primary acquired PRCA affects people of any age in the absence of any underlying disorder. It may run an acute and usually self-limited course or may persist chronically as a form of refractory anemia. In children, this condition is referred to as TEC, which is usually of limited duration. [101] In contrast, in adults, the acute form of primary PRCA is unusual and the chronic form of this disorder predominates. It is conceivable that many cases of acute PRCA in adults escape diagnosis because acute arrest of erythropoiesis of short duration is not expected to lead to symptoms of anemia because of the long life span of the red cells. Children, however, are quite frequently seen for minor illnesses during which an anemia may be found, the work-up of which leads to the diagnosis of TEC. A large number of cases of both PRCA and TEC have been shown to have an immune pathogenesis and are classified as autoimmune. However, there is a significant number of cases in which no immune pathogenetic mechanism can be established, and they are classified as idiopathic. The failure to demonstrate an immune mechanism, however, does not mean that the case may be of a nonimmune pathogenesis, because the outcome of treatment seems to be the same among autoimmune and idiopathic cases.[1] A small percentage of cases of idiopathic PRCA, usually refractory to treatment, may evolve into acute leukemia, and these cases are classified as preleukemic/myelodysplastic.[102]

Pure red cell aplasia may develop as a hematologic complication in the course of a variety of diseases (Table 211). Among

them, thymic neoplasms were the first to be associated with erythroid aplasia.[1] [5] [6] The incidence of PRCA among patients with thymoma was initially estimated to be as high as 15%; however, in more recent series, the incidence was found to be close to 4%.[1] [5] The presence of a thymoma among patients presenting with PRCA was initially reported to be as high as 50%, but in more recent series it was estimated to be close to 9%.[1] [5] [6] [103] PRCA may precede the development of thymoma, coexist with thymoma, or develop even years after the surgical removal of a thymoma.

Various hematologic malignancies have been associated with severe erythroid aplasia [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] and with chronic lymphocytic leukemia (CLL), with the B-cell, T-cell, or large granular lymphocyte (LGL) types being the most frequently seen.[7] [13] It has been estimated that the incidence of severe erythroid aplasia among patients with CLL may be as high as 6%, with many cases being missed because severe normochromic anemia and reticulocytopenia are frequent manifestations of advanced-stage CLL and are usually attributed to the myelophthisic process in the marrow. The development of erythroid aplasia may depend on the stage of CLL,[104] but this does not affect its prognosis, and in most cases does not seem to be related to previous cytotoxic chemotherapy.[1] [7] PRCA has been also described in association with Hodgkins and non-Hodgkins lymphomas,[18] [19] [20] [21] [22] [23] [24] multiple myeloma and Waldenströms macroglobulinemia,[23] [24] [25] chronic myelocytic leukemia, idiopathic myelofibrosis and essential thrombocythemia,[26] [27] [28] [29] [30] [31] and acute lymphoblastic leukemia.[32] [33] [34]

Pure red cell aplasia has been reported in association with a variety of nonhematopoietic, nonthymic neoplasms.[35] [36] [37] [38] [39] [40] [41] [42] [43] [44] [45] [46] [47] Considering the rarity of reports and the high incidence of malignant neoplasms, it seems obvious that such an association is very rare. On the other hand, it may be that PRCA is underdiagnosed in patients with advanced cancer in whom anemia is such a frequent finding that bone marrow examination is not routinely performed. In both hematopoietic malignancies and solid tumors, PRCA may appear before or after the diagnosis of malignancy and follows a chronic course independent of the evolution of the underlying disease.[1] In those cases in which a real association exists, successful treatment of the underlying malignant disease leads to remission of PRCA.

In a number of infections, acute, self-limited PRCA may develop.[48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] [66] [67] [68] [69] [70] [71] [72] Infection with human B19 parvovirus is responsible for the aplastic crisis seen in children and young adults with chronic hemolytic anemia [48] [52] [53] [54] [55] [58] and for chronic PRCA in immunocompromised patients (i.e., acquired immunodeficiency syndrome, post-transplantation, chemotherapy, or immunosuppressive treatment).[56] [57] Viral hepatitis and infectious mononucleosis are two other viral infections that have been reported in frequent association with PRCA.[62] [63] [64] [65] [66] [67] [68] In general, PRCA remits with treatment or resolution of the underlying infection.

Pure red cell aplasia may appear as a hematologic complication in a number of autoimmune diseases, including collagen vascular diseases, such as systemic lupus erythematosus,[73] [74] rheumatoid arthritis,[75] [76] mixed connective tissue disease,[77] and Sjögrens syndrome,[78] [79] in autoimmune hemolytic anemia,[1] [105] [106] [107] multiple endocrine gland insufficiency,[93] [94] autoimmune hypothyroidism,[95] [96] ulcerative colitis,[97] autoimmune hepatitis,[97] [98] angioimmunoblastic lymphadenopathy,[91] [92] postABO-incompatible bone marrow transplantation,[89] [90] and in very rare cases of patients with end-stage renal disease treated with recombinant erythropoietin in whom antibodies to the hormone developed.[99] In many of these conditions, PRCA may appear as the presenting manifestation of the underlying disease.

A continuously increasing number of drugs and chemicals have been reported as causes of PRCA [108] [109] [110] [111] [112] [113] [114] [115] [116] [117] [118] [119] (Table 21-2). Drug-induced PRCA is usually an acute form of erythroblastopenia that remits soon after discontinuation of the drug or cessation of exposure to the chemical. It may appear after the first exposure to the drug or a significant time after its initiation. In most instances, the association of a drug with PRCA is circumstantial and is based on the evidence that PRCA remits after discontinuation of the drug.[1] [109] Diphenylhydantoin, azathioprine, chlorpropamide, and isoniazid have been repeatedly implicated as causes of PRCA, and in certain instances their association with

PRCA has been proven by recurrence of anemia on reinstitution of therapy. [1]

Pregnancy also has been associated with PRCA, which usually remits after delivery. [80] [81] [82] [83] Development of PRCA during pregnancy does not necessarily predict recurrence of the disease in subsequent pregnancies. Only in a unique case did PRCA develop in three successive pregnancies in the same person, and two of the fetuses were born with hydrops fetalis and found to have erythroid aplasia on autopsy, whereas the third one, treated with intrauterine red cell transfusions, was born with red cell aplasia that remitted after 3 months. [83]

In rare cases, PRCA has been associated with renal failure, [84] severe malnutrition such as marasmus and kwashiorkor,[85] and riboflavin,[85] [120] vitamin B_{12} ,[86] [87] [88] and folic acid deficiency. [86]

BIOLOGIC AND MOLECULAR ASPECTS

The erythropoietic failure in red cell aplasia is characterized by absence of mature marrow erythroid precursor cells despite the presence of normal or nearly normal numbers of erythroid progenitor cells. The failure of the erythroid progenitors to mature, differentiate, and give rise to erythroblasts may be due to an intrinsic defect in these cells, to the presence of humoral or cellular inhibitors of erythropoiesis, or to an abnormal bone marrow microenvironment. Different mechanisms seem to operate in each of the various forms of PRCA.

Congenital Hypoplastic Anemia

The pathogenesis of CHA is not yet fully understood. The basic abnormality seems to be an intrinsic defect in the erythroid cells that prevents their development and differentiation into mature erythroblasts. Earlier reports that the arrest of erythropoiesis is due to a microenvironmental defect, [121] to IgG inhibitors,[122] or to cytotoxic lymphocytes/monocytes[123] [124] have not been confirmed in subsequent larger studies. [125] [126] [127] [128] Serum erythropoietin levels are appropriately elevated [129] and the numbers of erythroid progenitors (burst-forming unitserythrocyte [BFU-E] or colony-forming unitserythrocyte [CFU-E]) in the bone marrow of patients with CHA are either normal or decreased. [125] [127] [128] [130] Earlier studies have suggested a block in erythroid differentiation preceding the BFU-E. [128] In more recent studies, however, a normal or near-normal number of BFU-E was reported.[130] In addition, there is evidence for decreased responsiveness of erythroid progenitors to erythropoietin, which is partially correctable by addition of glucocorticosteroids, [131] [132] but this does not seem to be a constant finding among all examined cases. Erythroid progenitors in CHA seem to exhibit an accelerated rate of programmed cell death on withdrawal of erythropoietin compared with normal erythroid cells. [133] In addition, the response of early erythroid progenitors to interleukin-3, granulocytemacrophage colony-stimulating factor, and stem cell factor in vitro may be either normal or diminished.[134] [135] [136] [137] [138] A repetitive theme in all in vitro studies is the fact that both the numbers of marrow erythroid progenitors and their sensitivity to various hematopoietic factors vary from patient to patient, indicating that what is morphologically recognized as CHA may be pathogenetically a number of diverse but clinically indistinguishable disorders.

The observation that decreased erythroid growth in vitro can be restored to normal in a number of cases of CHA by factors affecting early erythroid progenitor cell growth (BFU-E) led to studies for identification of possible defects in the receptors of these factors. In particular, molecular studies on the stem cell factor gene and its receptor failed to show any abnormalities. [139] [140] Thus, in CHA the intrinsic defect detectable in vitro in erythroid cell cultures seems to be variable from case to case. By the use of linkage analysis with chromosome 19 markers, however, a consistent abnormality was detected in 19q13 among patients with CHA of diverse ethnic origin, indicating that the genetic abnormality for this disease may be homogeneous despite its clinical and phenotypic variability. [141]

Primary Acquired PRCA

Primary acquired PRCA and TEC have been studied extensively for the last 30 years, and repeated studies have indicated that the arrest of erythropoiesis is caused by the presence in the patients plasma of an erythropoietic inhibitor. Earlier studies in animals have shown that injection of patients plasma leads to a significant suppression of in vivo erythropoiesis as measured by [59] Fe incorporation into newly formed red cells. [1] [18] [142] [143] [144] Assessment of the response of patients marrow cells to erythropoietin by measuring the amount of heme synthesized in vitro showed that in the presence of normal serum, PRCA marrow responds normally to erythropoietin, but in the presence of the patients autologous plasma, a significant decline in the heme synthesis is observed, suggesting the presence in the patients plasma of an inhibitor acting on erythroid cells. [145] [146] In about 60% of cases, patients marrow cells respond to erythropoietin in a normal way by increasing the rate of the heme synthesis by two- to ninefold, and in approximately 40%, an inhibitor of erythropoiesis can be detected in their plasma. This inhibitor has been localized to the IgG fraction, and it disappears from the plasma after remission of PRCA. [145] [146] [147] [148]

The stage of erythropoiesis at which the arrest occurs can be assessed by assaying PRCA marrow cells in semisolid media for erythroid progenitors. Despite a conspicuous absence of erythroblasts from the PRCA marrow, in at least 60% of patients normal numbers of early and late erythroid progenitors can be detected, indicating that the arrest occurs at any level between CFU-E and basophilic erythroblasts. In the remaining patients, the erythroid cell compartment is affected at a stage earlier than the CFU-E, so that the CFU-E and/or BFU-E marrow pools are significantly reduced. [1] [28] [149] [150] The presence of normal numbers of erythroid progenitors has been associated with a favorable outcome of immunosuppressive therapy. [28] [150] Maturation and differentiation of erythroid progenitors into erythroblasts in vitro is inhibited by the patients serum IgG. The inhibition is dose dependent and is no longer present in the IgG fraction

of the patients plasma collected after remission. The inhibitory effect of the IgG is specific for erythroid cells because no effect on myeloid progenitor cell growth is detected.[149] [151] [152]

The mode of action of the PRCA IgG inhibitor of erythropoiesis has been studied in a number of cases of primary PRCA and TEC. In some cases, the IgG seems to be cytotoxic to CFU-E in the presence of complement; in others, its inhibitory activity is independent of the presence of complement, but its presence is continuously required during the 7-day period of maturation of CFU-E to erythroblasts. [1] [151] [153] In another cohort of patients, the IgG is cytotoxic to mature recognizable erythroblasts,[130] [154] [155] [156] and in rare cases, the inhibitory IgG has the properties of an anti-erythropoietin antibody. [157] [158] [159] In most cases, the target for the IgG antibody is an erythroid cell at a stage of differentiation between BFU-E and mature erythroblast. The nature of the molecule(s) on the erythroid cell membrane with which the PRCA IgG inhibitor interacts has not yet been defined.

Secondary PRCA

Thymoma and PRCA

A number of studies have demonstrated the presence of an inhibitor of erythroid cell development in the plasma of patients with thymoma and PRCA. [1] [15] [18] [46] [141] [142] [143] These studies, however, were performed on either mice in vivo or allogeneic human marrow cells in vitro, and the significance of these findings is unknown because the possibility of detection of heterophile antibodies or antibodies developed as a consequence of alloimmunization secondary to multiple red cell transfusions cannot be excluded.[1] A possible role for T-cell-mediated suppression of erythropoiesis has been suggested by more recent studies. [160] [161] [162] The exact incidence of antibody- or T-cell-induced erythropoietic arrest in PRCA associated with thymoma remains unknown.

Chronic Lymphocytic Leukemia and PRCA

In B-cell CLL, the frequency of PRCA is 6%, and in T-cell as well as in LGL types it may be even higher. [7] [8] [9] [10] [11] [12] [13] All attempts to detect an inhibitor in the

plasma of these patients have provided negative results. [10] [148] [163] Various studies have demonstrated that in T-cell CLL (including the LGL type), the T lymphocytes are responsible for the suppression of erythropoiesis. [10] [11] [12] [61] [164] The suppression is mediated by direct cell-to-cell interaction, mainly between a subset of T cells expressing receptors for the -chain of IgG (T cells) and erythroid progenitors, and it is human leukocyte antigen (HLA)-DR restricted. [12] The suppression is selective for the erythroid cells, and is not detectable after remission of the PRCA. [11] Similar findings have been reported in B-cell CLL, in which there seems to be a progressive increase in the marrow of T cells, which, when they reach a critical concentration, suppress erythropoiesis and cause red cell aplasia. [8] [104] [163]

Viral Infections and PRCA

Human B19 parvovirus, the agent responsible for exanthema infectiosum/fifth disease is the cause of acute PRCA (aplastic crisis) in children and young adults with chronic hemolytic anemias[48] [49] [50] [51] [52] [53] [54] [55] and of chronic PRCA in immunocompromised patients.[56] [57] [165] [166] [167] [168] [169] Human B19 parvovirus infection is not associated with TEC that affects hematologically normal children. [49] [170]

This DNA virus can infect erythroid cells by binding to the P antigen on erythroid cell membrane, [171] is directly cytotoxic to erythroid progenitors and inhibits preferentially normal CFU-E growth and development, but has no significant effects on myeloid cells. [49] [50] The effects of the virus on erythroid cells in vitro can be abolished by the presence of antibodies to the virus. [49]

APPROACH TO THE DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ACQUIRED PRCA

In a patient with moderate to severe normochromic normocytic anemia with a low reticulocyte count, the diagnosis of PRCA is established by examination of the bone marrow. The peripheral blood smear is examined first for presence of red cells with abnormal morphology, monocytosis, leftward shift, bilobed granulocytes, or lymphocytosis with increased large granular lymphocytes. If there is any finding suspect of myelodysplasia, a sample of the bone marrow aspirate is submitted for cytogenetic studies. If there is a suspicion for a B- or T-cell lymphoid malignancy (B, T, or LGL CLL), the blood is submitted for immunophenotyping of lymphocytes by flow cytometry or for T-cell receptor gene rearrangement. The LGL type of CLL may be difficult to diagnose in early phases, when PRCA is the predominant hematologic abnormality. In the bone marrow, the almost complete absence of erythroblasts with normal myeloid and megakaryocytic cells exhibiting normal maturation is sufficient to confirm the diagnosis. The presence of a small number of large, vacuolated proerythroblasts frequently indicates active infection by B19 parvovirus. Special attention is paid during examination of the bone marrow smear to morphologic abnormalities suggesting possible myelodysplasia or an underlying primary bone marrow disorder. Erythroid hypoplasia with megaloblastoid changes in erythroid cells, mononuclear megakaryocytes, shift of the myeloid cell line to the left, hypogranular myelocytes, lymphocytosis, or increased mast cells are not common features of acquired PRCA, and other coexisting marrow disorders should be excluded by appropriate tests. High or low cellularity on bone marrow biopsy, presence of a small number of erythroblastic islands, and focal infiltration by lymphoid or immature cells are considered findings inconsistent with the diagnosis of primary acquired PRCA. Once the diagnosis is established, the clinical history may provide adequate information for the presence of a disease with which PRCA may be associated. If symptoms suggest an autoimmune disorder, appropriate testing is performed to confirm or rule out such a possibility. In all patients diagnosed with primary acquired PRCA, a computed tomography scan of the chest is obtained to rule out the presence of thymoma. In patients considered to be potentially immunocompromised, active B19 parvovirus infection should be excluded by obtaining IgM and IgG antibody titers for B19 parvovirus or using the polymerase chain reaction to detect the virus.

In normal people, infection by B19 parvovirus does not lead to symptomatic anemia because the arrest of erythropoiesis is transient and the survival of red cells normal. However, in the presence of hemolysis (short red cell survival), even transient arrest of erythropoiesis leads to an acute and precipitous decline of the hemoglobin concentration, resulting in clinically symptomatic anemia. Erythropoiesis is usually restored within 515 days with development of immunity to the virus and elimination of the viral infection. In immunocompromised patients, because of their inability to clear the virus, the infection becomes chronic and the arrest of erythropoiesis persists for as long as the infection is active, leading to a chronic form of PRCA. [56] [57] [165] [166] [167] [168] [169] In these patients, administration of high-dose, pooled human IgG provides adequate amounts of specific antibodies to eliminate the chronic infection, thus allowing the restoration

of erythropoiesis. In view of the primary therapeutic role of human IgG in chronic parvovirus infection, all immunocompromised patients with PRCA should be tested for evidence of active parvovirus infection.

Studies on the pathogenesis of PRCA in the course of viral hepatitis, infectious mononucleosis, and human T-lymphotropic virus type 1 infection have suggested that the suppression of erythropoiesis is mediated by cytotoxic T lymphocytes. [61] [64] [67] The pathogenesis of erythroid aplasia in the course of other infections has received limited attention and remains basically unknown.

Autoimmune Hemolytic Anemia and PRCA

It has been suggested that antibodies directed against red cells may in certain cases attack the erythroid precursors and/or progenitors, leading to erythroid aplasia.[105] This hypothesis was confirmed in two cases of autoimmune hemolytic anemia and PRCA in which the IgG antibody eluted from the red cells inhibited in vitro normal and autologous CFU-E growth. [1] [73] In another two cases, two separate autoantibodies, one directed against the erythrocytes and another one inhibiting autologous CFU-E growth in vitro, were detected.[106] [107]

Collagen Vascular Diseases and PRCA

A serum IgG inhibitor of autologous erythroid progenitor cell growth in vitro has been demonstrated in a case of systemic lupus erythematosus and in a case of rheumatoid arthritis.[74] [75]

Drug-Induced PRCA

Limited numbers of studies have addressed the pathogenesis of drug-induced PRCA. A serum IgG inhibitor was detected in a case of diphenylhydantoin-induced PRCA that inhibited erythroid but not myeloid cell growth in vitro in the presence but not in the absence of subtherapeutic concentrations of diphenylhydantoin. Diphenylhydantoin alone in the same concentration had no effect on autologous erythroid progenitor cell growth in vitro. [108] A similar mechanism was shown in a case of rifampicin-induced PRCA.[172] In both cases, the plasma inhibitor disappeared from the patients plasma after remission of PRCA. However, studies performed in cases of isoniazid- and procainamide-induced PRCA failed to demonstrate a similar mechanism. [112] [114] [173] It seems that various drugs can cause erythroid aplasia

through different mechanisms. Studies on direct drug effects on erythroid cell growth in vitro should be interpreted with caution because a large number of drugs may affect hematopoietic colony formation in vitro in a nonspecific way. The pathogenesis of acquired PRCA is summarized in Figure 21-1 . PRCA may result from either injury of erythroid progenitor cells in vivo by IgG antibodies, cytotoxic T lymphocytes, or parvovirus B19, or by an IgG antibody cytotoxic to mature erythroblasts, or an antibody to erythropoietin.

Figure 21-1 Different mechanisms by which erythropoiesis may be inhibited in pure red cell aplasia. *(From Krantz and Dessypris,[70] with permission.)*

CLINICAL MANIFESTATIONS

Most adult patients present with symptoms of anemia that at the time of diagnosis may be quite severe. With complete arrest of erythropoiesis, the drop in red cell count averages approximately 1% a day, so the development of anemia is slow and progressive, allowing for physiologic compensatory changes. Children with CHA or TEC are most frequently diagnosed during a routine follow-up visit or a visit to the pediatrician for a febrile illness. Physical examination in primary PRCA is usually negative except for pallor and signs of anemia. Hepatosplenomegaly or lymphadenopathy are not findings consistent with primary PRCA. In secondary cases, physical findings consistent with the underlying disease may be present. In children with CHA, physical examination may reveal the presence of one or more congenital abnormalities described in association with this disorder. [174] [175] [176] In patients with long-standing red cell aplasia who have been supported chronically with red cell transfusions, chronic hepatitis or transfusional hemosiderosis may develop with physical findings secondary to iron overload.

LABORATORY EVALUATION

In acquired PRCA, the erythrocytes are normochromic and normocytic, whereas in CHA they tend to be either normocytic or macrocytic with a mean corpuscular volume of 95 fl or higher.[4] [174] [175] [176] There is a complete absence of polychromatophilic red cells on the smear, and the reticulocyte count is between 0% and 1%. In CHA, the reticulocyte count may be occasionally as high as 5%. [4] [174] [175] [176] In adults, a reticulocyte count greater than 2% should raise serious doubt about the correctness of the diagnosis. The white cell count and the differential count are normal. Occasionally, mild leukopenia, lymphocytosis, or eosinophilia may be present. The platelet count is usually normal. Mild thrombocytopenia of 100,000150,000 platelets per microliter is occasionally seen, and a number of patients may have a thrombocytosis reactive to anemia.

The hallmark of PRCA is the absence of erythroblasts from an otherwise normal marrow. The cellularity of the marrow is normal or slightly increased. Marrow hypercellularity with elimination of fat spaces is not usually seen in PRCA. In classic cases, the erythroblasts are either totally absent, or they constitute <1% on the marrow differential count. In a small number of cases, a few proerythroblasts or basophilic erythroblasts may be seen, not exceeding 5% of the differential count. [101] [105] [146] [176] In TEC, but not in adult PRCA, such a finding may be a sign of early recovery that becomes apparent a few days later by a rise in the reticulocyte count. [174] The presence of a small number of proerythroblasts with vacuolated cytoplasm and pseudopod formation may raise the suspicion of an active B19 parvovirus infection or of severe malnutrition.[50] [85] In CHA presenting during the first few months of life, the erythroblastopenia may not be as severe as later in life, and erythroblasts, mainly proerythroblasts and basophilic erythroblasts, may constitute up to 10% of marrow cells. [176] In 510% of cases of CHA, erythroid hyperplasia with maturation arrest at the proerythroblast stage or megaloblastic changes have been described. [176]

In unusual cases, a period of ineffective erythropoiesis characterized by erythroid hyperplasia with maturation arrest at the stage of proerythroblasts or basophilic erythroblasts in the marrow and reticulocytopenia in the blood may precede the development of PRCA, develop during the course of PRCA, or develop after a partial response to treatment and before the return of erythropoiesis to normal. [177] [178] [179] Although this picture is not diagnostic of PRCA, it is a phase in the natural course of this disease, and in the absence of any dysplastic features in any of the three marrow cell lines or of any bone marrow karyotypic abnormality, it should raise the suspicion of developing PRCA,

and the marrow should be re-evaluated at a later time or the patient managed as a case of PRCA.

The myeloid cells and the megakaryocytes in the marrow are normal and exhibit full maturation. An increased number of lymphocytes on marrow smear, or on marrow biopsy, an increased number of lymphoid aggregates or a mild increase in plasma cells, eosinophils, or mast cells may be seen. [1] Iron stores are increased and normally distributed, but during recovery or the phase of ineffective erythropoiesis an occasional ring sideroblast may be noticed. [1]

Cytogenetic studies on marrow cells in PRCA reveal a normal karyotype with the exception of preleukemic cases, where chromosomal abnormalities may be detected.[13] [102] [150] The presence of an abnormal karyotype in a patient with morphologically classic PRCA carries a poor prognosis regarding response to treatment and may be a harbinger of leukemic transformation.[13] [102] [150] In CHA, chromosomal studies on peripheral blood lymphocytes in the presence of a DNA clastogenic agent (mitomycincardiepoxybutane) are normal and they clearly distinguish this disorder from Fanconis anemia. The demonstration in a patient with CHA of a translocation involving chromosome 19q has led to the identification of the CHA gene. [141]

Vitamin B_{12} , folic acid, ferritin, serum iron, and saturation of transferrin are normal or elevated. Serum erythropoietin levels are increased in proportion to the severity of the anemia.[145] [155] Ferrokinetic studies show a prolonged clearance of[59] Fe, no accumulation of iron in the sacral bone, and almost undetectable iron incorporation into red cells, findings consistent with an almost complete arrest of erythropoiesis. Ferrokinetic parameters return to normal after full hematologic recovery except in adult patients in partial remission, in whom ineffective erythropoiesis may be present. [179] Bone marrow imaging using[59] Fe or[111] In shows little or no uptake, but this returns to normal on remission. In both children and adults with PRCA, [51] Cr red cell survival is mildly shortened to a degree inadequate to explain the severity of the anemia.[175] [179] [180] Patients refractory to treatment who are supported by regular red cell transfusions may acquire a significant hemolytic component after alloimmunization or development of hypersplenism.[1]

In children with CHA, the erythrocytes maintain fetal-like characteristics, such as i antigen, increased fetal hemoglobin, and increased levels of enzymes in red cell glycolysis and the hexose monophosphate shunt pathways.[175] [176] [181] The distribution of fetal hemoglobin among the red cells is uneven and the ratio of glycine to alanine at position 136 of the -chain indicates that the hemoglobin is of fetal and not adult type. [175] The fetal-like erythropoiesis persists during phases of remission. [176] In addition, erythrocytes in CHA have elevated levels of adenosine deaminase (ADA), an enzyme not elevated in cord blood. [182] The increase in red cell ADA is not specific for CHA because it has been noted in cases of acute lymphoblastic leukemia, in some myeloproliferative disorders, in dyskeratosis with pancytopenia, and in megaloblastic anemia.[183] The fetal-like erythropoiesis and the elevated ADA activity are findings helpful in distinguishing CHA from TEC. During recovery from TEC, a transient phase of fetal-like erythropoiesis has been described, but ADA levels remain normal. [184] [185]

A variety of abnormalities of the immune system have been reported in patients with chronic PRCA, [1] including hypogammaglobulinemia, [162] [186] monoclonal gammopathies,[146] pyroproteins,[146] decreased complement,[187] antinuclear antibodies, [188] [189] decreased or increased B cells, and impaired phytohemagglutinin-induced lymphocyte cytotoxicity.[190] More recently, in a number of patients the presence of lymphocytes with the or T-cell receptor gene rearrangement has been described;[161] [191] [192] [193] [194] however, it is not yet clear whether these were cases associated with T-cell CLL or lymphoproliferative syndrome, frequently having very subtle morphologic abnormalities, [13] or cases of primary acquired PRCA. Immunologic abnormalities have also been described in children with CHA, suggesting that in this disorder the defect may not be restricted to the erythroid cells, but may include lymphocytes. [195]

DIFFERENTIAL DIAGNOSIS

Pure red cell aplasia in adults can be easily diagnosed when isolated anemia with a normal white cell and platelet count is associated with a marrow of normal cellularity in which there is almost a complete absence of erythroblasts but normal myeloid cells and megakaryocytes. It can be easily differentiated from aplastic anemia, where pancytopenia is present and the marrow cellularity is severely decreased, with hypoplasia or aplasia of all three cell lines. The most frequent hematologic disorders from which PRCA has to be differentiated are refractory anemia/myelodysplastic syndromes. In myelodysplastic syndromes presenting with isolated anemia, the reticulocyte count is rarely <1%, the red cells tend to be slightly macrocytic, and there may be some white cell dysplasia. Careful examination of the blood smear may reveal the presence of monocytosis or Pelger-Huët anomaly. In addition, the marrow is hypercellular with dysplastic myelopoiesis, with a shift of the myeloid cells to the left and a possible increase in blasts and the presence of mononuclear megakaryocytes. Erythroblasts may be present in small numbers, but only rarely are they absent or comprise <5% of the marrow cells, and they usually exhibit megaloblastoid features. Cytogenetic abnormalities are frequent and their presence is helpful in differentiating preleukemic/myelodysplastic erythroid hypoplasia from primary autoimmune PRCA. [1] [13] [102] [150]

In children, TEC must be differentiated from CHA/Blackfan-Diamond syndrome. Table 21-3 presents the major clinical and laboratory findings useful in the differential diagnosis of these two types of erythroblastopenia.

TREATMENT

Acquired PRCA

Once the diagnosis of PRCA is confirmed by bone marrow examination, all drugs should be discontinued and any infection present be treated with the appropriate antibiotics. In the presence of laboratory findings indicative of an active or recent B19 parvovirus infection, administration of normal pooled serum

TABLE 21-3 -- Differential Diagnosis of Pure Red Cell Aplasia in Childhood

	Congenital Hypoplastic Anemia	Transient Erythroblastopenia
Pure red cell aplasia	Present	Present
Age	Younger than 1 y	Older than 1 y
Inheritance	Dominant or recessive	Not inherited
Congenital anomalies	Present	Absent
Mean corpuscular volume	Elevated	Normal
Fetal hemoglobin	Elevated	Normal
RBC i antigen	Present	Absent
RBC glycolytic and hexose monophosphate shunt exzymes	Elevated	Normal
RBC adenosine deaminase activity	Elevated	Normal

RBC, red blood cell.

All RBC characteristics except adenosine deaminase activity are helpful only when tested in a reticulocytopenic child. During recovery from transient erythroblastopenia of childhood, a transient wave of fetal-like erythropoiesis may be detected.

IgG provides specific antibodies capable of controlling the viral infection and allowing the recovery of erythropoiesis. [56] [57] [165] [166] [167] [168] [169] If laboratory evidence exists for B_{12} or folate deficiency, these vitamins should be given in adequate doses. In the presence of a malignant tumor, appropriate treatment should be instituted. PRCA associated with drugs or infection usually remits within 13 weeks after elimination of the responsible drug or treatment of the infection. [1]

In the presence of thymoma, thymectomy should be performed before the initiation of any immunosuppressive treatment. In approximately 3040% of patients with thymoma, erythropoiesis returns to normal within 48 weeks after thymectomy.[5] [6] [196] Patients not responding to thymectomy should be treated as having primary acquired PRCA. Removal of the thymoma seems to increase the effectiveness of immunosuppressive therapy.[6] Patients with severe contraindications to surgery or with malignant thymomas may benefit from chemotherapy or radiation.[196] [197] Thymectomy in the absence of thymoma is not recommended.[1]

For primary PRCA as well as secondary PRCA not responding to the treatment of the underlying disease, the therapeutic plan should focus on sequential use of various immunosuppressive therapies until remission is obtained. Corticosteroids are the immunosuppressive drugs of choice and should be tried before any other form of immunosuppressive treatment. Prednisone is administered orally at a dose of 1 mg/kg/day until a remission is induced. In approximately 40% of patients remission usually occurs within 4 weeks, so that continuation of treatment with prednisone longer than 12 weeks is not recommended. [13] [150] [198] The effect of treatment can be assessed by biweekly reticulocyte count and measurement of hemoglobin concentration. A rising reticulocyte count or stabilization of the hematocrit are the first laboratory findings indicating response to treatment. Once the hematocrit reaches 35%, the dose of prednisone can be tapered very slowly and the drug eventually can be discontinued, preferably after 34 months. Rapid tapering of prednisone can result in recurrence of anemia. A number of responders may be prednisone dependent, requiring small doses of the drug for maintaining a normal hematocrit. [199] [200] The dependence of the response on low-dose prednisone can be assessed during the period of slow tapering and the minimum dose required can easily be determined.

In patients not responding to prednisone after a trial of 23 months, the dose should be rapidly decreased to 2030 mg/day because responses seen after this period of treatment are extremely rare.[198] These patients should be considered candidates for an alternate immunosuppressive treatment, including administration of cyclophosphamide or azathioprine, cyclosporine, antithymocyte globulin (ATG), or high-dose -globulin. No data exist favoring one type of treatment over the other. The physician should take into consideration any coexisting systemic disease, the age of the patient, the potential short- and long-term side effects, and the cost of treatment. The advantage of cytotoxic agents is their low cost, but they have long-term potential leukemogenic and carcinogenic effects. [201] [202] [203] [204] Cyclosporine therapy is more expensive and requires monitoring of renal function, but it seems that the average time to induce remission is shorter than with cytotoxic drugs. In most cases, ATG administration requires hospitalization, which increases its cost significantly, but it lacks the leukemogenic potential of cytostatic agents. High-dose intravenous -globulin is the most expensive form of therapy, but lacks any significant side effects.

Cyclophosphamide or azathioprine may be given alone or, preferably, with small doses of prednisone, which seems to increase the effectiveness of treatment. These drugs are given orally at an initial dose of 50 mg/day. If the white blood and platelet counts allow it, the dose is increased by 50 mg weekly or biweekly to a maximum of 150 mg/day until

APPROACH TO THE TREATMENT OF ACQUIRED PRCA

After establishing the diagnosis, all medicines are discontinued and any infection present is treated appropriately. If no return of erythropoiesis occurs within 4 weeks, the patient is considered to have primary acquired PRCA. Patients with thymoma are treated by thymectomy and immunocompromised patients by high-dose intravenous IgG. Patients with PRCA and cytogenetic abnormalities or myelodysplastic features are treated on a trial-and-error basis with a course of corticosteroids. If they do not respond, as is usually the case, no further immunosuppressive therapy is given. Corticosteroids are the first choice of treatment for primary acquired disease. For PRCA associated with an indolent lymphoid malignancy, the combination of corticosteroids and a cytotoxic agent, cyclophosphamide or azathioprine, is preferred. In patients with PRCA not responding to initial therapy, immunosuppression continues by sequential use of low-dose corticosteroids combined with cyclosporine, ATG, high-dose intravenous IgG, cytotoxic agents, plasmapheresis, and, finally, splenectomy, followed, if necessary, by another round of immunosuppressive therapy. Plasmapheresis is used in those patients unresponsive to sequential immunosuppression in whom an IgG inhibitor of autologous erythroid progenitor cell growth in vitro can be demonstrated and in whom no evidence exists for T-cellmediated suppression of erythropoiesis. In primary PRCA, because of their potential leukemogenic and carcinogenic effects, the use of cytotoxic agents is avoided until other means of immunosuppression are found ineffective. Patients are followed biweekly by a reticulocyte count and a complete blood cell count, and are instructed to return to the clinic with any symptom suggestive of an infection. Relapses are treated with the same regimen that induced the first remission. After a second relapse, patients are given maintenance therapy for a period of 2 years. Patients refractory to all forms of treatment receive regular red cell transfusions and iron chelation therapy with deferoxamine, which is usually initiated after the number of transfused red cell units exceeds 50.

remission occurs or bone marrow toxicity develops. The mean time to response is approximately 1112 weeks, with a broad range of 226 weeks and an overall response rate of 4060%.[13] [145] [146] [147] [150] [155] [198] [205] [206] If response occurs, prednisone is tapered and then the dose of cytotoxic agent is progressively decreased and eventually discontinued. If bone marrow toxicity develops, the drug is discontinued and the marrow is allowed to recover. If, after 3 months of treatment, no response and no marrow toxicity is seen, the dose may be increased progressively (by 50 mg biweekly) to a maximum tolerated or to a maximum of 250 mg/day under close monitoring of the white blood cell and platelet count. If reticulocytosis or stabilization of the hematocrit is noticed, the dose is gradually reduced. If the absolute neutrophil count decreases below 1,000/l or the platelet count drops below 100,000/l, the cytotoxic drug is discontinued. In a number of cases, with the return of granulocytes and platelets to normal, a reticulocytosis may be seen followed by a return of erythropoiesis to normal (Fig. 21-2). If no response occurs, another type of immunosuppressive treatment should be initiated.

Cyclosporine is frequently used as a second or third line treatment at a dose of 1012 mg/kg/day in two divided doses,

Figure 21-2 Response of pure red cell aplasia to cyclophosphamide and prednisone simultaneous with the appearance of marrow toxicity. This 38-year-old man did not respond to initial treatment with prednisone. Cyclophosphamide was added and its dose gradually increased until leukopenia developed (white blood cell count = 2,000/l) when reticulocytes first appeared. The dose of cyclophosphamide was reduced. The patient maintained a normal hematocrit despite phlebotomies initiated for reduction of transfusional iron overload. *(From Krantz SB: Implications of studies on pure red cell aplasia for the study of aplastic anemia. In Hibino S [ed]: Aplastic Anemia. University Park Press, Baltimore, 1978, p. 305, with permission.)*

preferably with 2030 mg of prednisone daily, with monitoring of renal function. Remission occurs usually at an average time of 24 weeks. A response to cyclosporine is seen in 6580% of patients receiving this drug as a second- or third-line treatment. [1] [13] [150] [207] [208] [209] [210] [211] [212] [213] Once remission occurs, the dose of prednisone is tapered, followed by tapering of the dose of cyclosporine. If no remission occurs after 34 months of treatment with cyclosporine, the drug should be discontinued and an alternate mode of immunosuppression initiated.

Antithymocyte -globulin is used as another therapeutic modality, usually in patients who have failed other means of immunosuppression. It is given as an intravenous infusion at a dose of 20 mg of horse IgG per kilogram of body weight daily for 7 days, preferably in combination with 2030 mg prednisone orally per day that is tapered within 2 weeks after completion of ATG therapy. The overall response rate to ATG seems to be approximately 50%. [13] [46] [150] [187] [198] [214] [215]

High-dose intravenous -globulin is the treatment of choice for immunosuppressed patients with PRCA in whom the disease may be the result of infection with B19 parvovirus.[56] [57] [165] [166] [167] [168] [169] Responses have been reported, however, in nonimmunosuppressed patients with primary as well as various secondary types of PRCA.[9] [216] [217] [218]

Plasmapheresis is considered in patients having failed all the previously mentioned immunosuppressive therapies. [152] [219] [220] [221] [222] [223] It is performed at least thrice weekly for a minimum of 23 weeks, and occasionally much longer until a response is noted. Considering the fact that IgG is distributed in both intravascular and extravascular space, plasmapheresis should be performed intensively and for a long period of time before any response is seen.

Splenectomy is considered as a final therapeutic maneuver in patients refractory to all other forms of treatment. Responses to splenectomy have been reported in approximately 17% of such cases recalcitrant to treatment within the first 23 postoperative months. [1] [69] [105] [198] [224] [225] Nonresponders to splenectomy should receive another trial of immunosuppression following the same approach used for initial therapy of PRCA. A number of refractory cases have been reported to have responded to immunosuppressive therapy after splenectomy.[69] [198] [226] Sequential, prolonged immunosuppressive therapy should be administered carefully because, although it induces remission in two thirds of patients, it is associated with a high frequency of infection in one third of patients. [198]

Patients unresponsive to all forms of treatment should be maintained on regular red cell transfusions. They usually require approximately 1 unit of packed red cells per week. Because of the frequency of red cell transfusions, after a period of time iron overload, with its detrimental effects on various organs, develops in these patients. Thus, in this patient population institution of iron chelation with deferoxamine should be considered within the first 6 months after the disease is declared refractory to treatment.[1] [227]

Evaluation of the relative effectiveness of each immunosuppressive treatment of PRCA is very difficult because of the infrequency of the disease and its unpredictable clinical course, with spontaneous remissions occurring in approximately 510% of cases of primary PRCA within 4 months to 14 years after the diagnosis. [1] [13] [150] [198] In addition, there is no clinical or laboratory criterion other than observation by which to distinguish between chronic and acute disease. A number of cases treated immediately after diagnosis may represent acute and self-limited PRCA secondary to a viral infection or drugs that the patient did not mention. Comparative studies of different immunosuppressive modalities are not available. The experience with various forms of treatment of 133 patients at three different institutions is presented in Table 21-4 .

Congenital Hypoplastic Anemia

After excluding TEC as the cause of anemia and establishing the diagnosis of CHA, patients should be treated with prednisone

TABLE 21-4 -- Response of Pure Red Cell Aplasia to Various Immunosuppressive Therapies

Study	Dessypris[1]	Lacy et al.[13]	Charles et al. [150]	Total
Number of patients	49	47	37	133
Primary PRCA	32	25	18	75
Secondary PRCA	17	22	19	58
Corticosteroids	18/41[a]	9/29	9/36	36/106 (34%)
Cytotoxic agents[b]	24/54	14/29	8/27	46/110 (42%)
Antithymocyte globulin	2/6	0/1	8/12	10/19 (53%)
Cyclosporine	3/4	4/5	2/3	9/12 (70%)
Intravenous IgG		5/10	2/8	3/10 (30%)
Plasmapheresis			0/2	
Splenectomy	4/23	0/1	0/1	4/25 (16%)
Multiple treatments	35/49	28/47	28/37	91/133 (68%)

Many patients did not respond to treatment or had relapses, so one patient may be included in more than one treatment modality.

[a] Number of responders/number of patients treated.
[b] Includes cyclophosphamide, azathioprine, or methotrexate given alone or in combination with prednisone.

at a dose of 2 mg/kg in three divided doses per day. Treatment continues until the hemoglobin concentration reaches 10 g/dl, at which point the dose is gradually decreased to a single small dose per day, followed by an attempt to switch to an alternate-day schedule. Approximately 70% of patients respond to corticosteroids with reticulocytosis and an increase in the hemoglobin concentration, usually within 46 weeks; however, the pattern of response may vary from patient to patient. [175] [176] A number of patients respond with a rapid rise of the hematocrit and enter a steroid-independent remission, another group shows only intermittent response, others respond but become dependent on low- or high-dose corticosteroids to maintain their remission, and others respond to initial treatment but later acquire a steroid-resistant disease. Approximately 3040% of patients do not respond to steroids. A trial of treatment with high-dose prednisone (46 mg/kg/day) should be given before a patient is declared unresponsive to corticosteroids. Responses seem to be more frequent in patients in whom treatment is initiated a short period after diagnosis who have been transfused to a limited extent. [228] Approximately 25% of patients with corticosteroid-resistant disease may respond to high-dose intravenous methylprednisolone. [229] In contrast to acquired PRCA, CHA is rarely responsive to immunosuppressive therapy. Only isolated cases have been reported in which a response was seen after 6-mercaptopurine, cyclophosphamide, ATG, or plasmapheresis. [129] [230] [231] [232] [233] [234] Treatment with recombinant human erythropoietin has not induced remissions. [235] Treatment with interleukin-3 may induce a response in 25% of patients. [236] Patients with refractory disease may be considered candidates for HLA-matched allogeneic bone marrow transplantation. [237] [238] [239] Patients refractory to all forms of treatment should be maintained on regular red cell transfusions and chronic iron chelation therapy with deferoxamine.

PROGNOSIS

With sequential immunosuppressive therapy, approximately 68% of patients enter remission. In addition, approximately 510% of patients may remit spontaneously. Relapses are not uncommon, and in one study 80% of patients were found to be at risk for relapse during the 24 months after remission. [198] However, relapses are treated as successfully as the initial disease. [150] [198] A number of patients may require low-dose maintenance immunosuppressive therapy, which, if deemed necessary, should be continued for 12 years. [1] [75] [150] [199] [200] Even after repeated relapses, approximately 60% of patients become transfusion independent for many years. The median survival of patients with primary acquired PRCA has been estimated to be approximately 14 years. [198] Overall, patients with bone marrow cytogenetic abnormalities or low growth of erythroid progenitor cells in vitro have a much worse prognosis because of very low or no response to immunosuppressive agents, and in these patients the persistent use of sequential immunosuppressive therapies is not indicated. [1] [13] [28] [150] [198] Evolution of PRCA into aplastic anemia has been described, but is exceedingly rare. [6] [180] Approximately 35% of patients with refractory disease will develop acute nonlymphocytic leukemia. [1] [151] [198] [240] The prognosis of patients with secondary PRCA depends on the nature of their primary disease.

In CHA, the use of corticosteroids induces a remission in approximately half of the patients , 80% of whom are expected to reach the age of 50 years. Patients unresponsive to corticosteroids and maintained on chronic red cell transfusions and iron chelation therapy may have a shorter long-term survival, primarily related to iron overload over many decades. The overall median survival among 436 patients reported during the period 19361990 was estimated to be 38 years. [176] Acute nonlymphoblastic leukemia and development of myelodysplastic syndrome have been reported in no more than 2% of cases. [176]

Chapter 22 - Pathobiology of the Human Erythrocyte and Its Hemoglobins

Martin H. Steinberg
Edward J. Benz Jr.

INTRODUCTION/OVERVIEW

The anemias, polycythemias, and functional derangements of the human erythrocyte together represent a particularly important group of human disorders. The relevance of these conditions to general medicine extends beyond their individual clinical severities or the number of patients affected. A critical added dimension of erythrocyte disorders is the extraordinarily detailed knowledge available about the basic biochemistry, physiology, and molecular biology of the human red cell and its membrane, enzymes, and its major component, hemoglobin. Red cells are especially abundant, relatively simple, and readily accessible for repeated testing in individual patients. These features have facilitated rapid application of the techniques of cellular and molecular biology to studies of the red cell, its component molecules and structures, and syndromes resulting from abnormalities of these entities. Thus, taken as a group, erythrocyte disorders are better understood at the molecular and cellular level than disorders of any other cell or tissue. It is for this reason that these conditions merit particularly thorough and careful scrutiny by students of hematology.

This chapter attempts to introduce concepts about normal red cell homeostasis that form the essential knowledge base for understanding anemias, polycythemias, and functional erythrocyte disorders. The primary focus and object for detailed discussion of this chapter is hemoglobin, the major component, both quantitatively and qualitatively, of the erythrocyte. Hemoglobin molecules dominate the pathophysiology of many red cell disorders and modulate most of the others, in part because of their sheer quantitative predominance in red cell cytoplasm. The other major relevant aspects of human red cellsthe red cell membrane, red cell enzymes used for intermediary metabolism, red cell differentiation and development, and the process of red cell destructionare discussed in detail in the introductory portions of other chapters. This chapter shall survey these areas only briefly. The reader can find detailed descriptions of the red cell membrane in Chapter 4 and Chapter 33 . Red cell enzymes and enzymopathies are described in Chapter 32 ; red cell differentiation and development in Chapter 15 ; regulation of red cell mass by erythropoietin in Chapter 25 ; and the necessary aspects of red cell destruction in Chapters 34 and 35 .

ESSENTIAL FEATURES OF RED CELL HOMEOSTASIS

As discussed in considerable detail in Chapter 15 , the mature red cell is the product of a complex and orderly set of differentiation and maturation steps beginning with the pluripotent stem cell. By incompletely understood mechanisms involving hierarchic networks of cytokines, a portion of these cells becomes committed to differentiate along the erythroid pathway. Commitment provokes a progressively increasing sensitivity to the stimulatory actions of the hormone erythropoietin as differentiation proceeds, and also involves preprogramming of certain genes whose expression at high levels will be required during the maturation phase of erythropoiesis. Genes coding for molecules defining the red cell phenotype (e.g., globin) are thus poised for activation at later maturation steps.

Intermediate progenitor cells arising during differentiation have been characterized experimentally, including the burst-forming unit erythroid (BFU-E) and the colony-forming unit erythroid (CFU-E) stages. BFU-Es are progenitor cells that produce bursts or clusters of erythroid colonies, are relatively less sensitive to erythropoietin, and are more plastic with respect to important gene expression parameters, such as the synthesis of adult or fetal hemoglobin by their descendants. CFU-Es produce single colonies, exhibit considerably higher sensitivity to erythropoietin, and appear to be more fixed in their potential to express genes, at least among the globin family. As discussed in Chapter 15 , CFU-Es appear to give rise to the first morphologically recognizable erythroid cells, the proerythroblasts. At this primitive morphologic stage, the program of erythroid cell expression has already been essentially predetermined, and the cell is predestined to undergo only a limited additional number of cell divisions, culminating in formation of the enucleate reticulocyte. The terminal maturation stages are morphologically recognizable as erythroblasts exhibiting progressive hemoglobinization of the cytoplasm, condensation and eventual ejection of the nucleus, and remodeling of the plasma membrane. Actual expression of the preprogrammed genes occurs during the 5- to 7-day period of erythroblast maturation.

As discussed in Chapter 15 , both the actual reconfiguration of chromatin for activation of the genes and activation itself appear to require the concerted and complex interaction of a diverse but limited group of transcription factors. These recognize a specific array of promoter and enhancer sequences that are embedded as recurrent motifs in and around the appropriate target genes. Even though an enormous amount of information has been gathered about sequences such as the GATA enhancers and their cognate transcription factors, the precise means by which these sequences and factors cause erythroid differentiation remains largely mysterious. At this time, this information is of limited clinical relevance to anemias or polycythemias; thus, we shall not consider these aspects in additional detail in this chapter. The orderly 14- to 21-day sequence of differentiation and maturation becomes progressively influenced by the levels of erythropoietin available to the progenitor cells, possibly due to increasing density and affinity of erythropoietin receptors on their cell surfaces.

Within 24 hours after enucleation, the reticulocyte is released into the circulation as an immature erythrocyte, the reticulocyte. These cells retain remnants of nucleated precursors in the form of a relatively small number of polyribosomes actively translating messenger RNA (>90% of which is globin messenger RNA), a cell membrane that retains some molecules and structures reminiscent of its earlier stages of differentiation, and the only complement of enzymes, phospholipids, and cytoskeletal proteins that the cell will possess throughout its remaining life span.

During its first 24 hours in the circulation, the reticulocyte spends considerable amounts of time in the spleen, during which its membrane is polished. This is a poorly understood remodeling process by which some proteins, including adhesive molecules such as fibronectin, are removed. The content of polyribosomes and other nucleic acids progressively declines

---

so that stainability with methylene blue, until recently the standard method used for clinical enumeration of reticulocytes, is lost by the end of the first day. At this time, the red cell is regarded as a mature erythrocyte, and it circulates largely unchanged for the remainder of its 120-day life span in the circulation.

Perhaps the most remarkable feature of the human red cell is its durability, given that it is an enucleate cell devoid of organelles that appear to be critical for the survival and function of most other cell types. Thus, the red cell has no mitochondria available for efficient oxidative metabolism, no ribosomes for regeneration of lost or damaged proteins, a very limited metabolic repertoire that largely precludes de novo synthesis of lipids, and no nucleus to direct regenerative processes, adaptation to circulatory stresses, or cell division to replenish itself. The 120-day survival of these cells is even more striking when one considers that, given these handicaps, erythrocytes live their life span in an exceedingly hostile environment. Mechanical stresses of the circulation include high hydrostatic pressure and turbulence and the shear stresses inherent in a microcirculation networked with many capillaries having diameters only one-third to one-half that of the normal red cell; biochemical stresses include osmotic and redox fluxes associated with travel through the collecting system of the kidney, the sluggish vascular beds of the spleen, muscle, and bone, and the rapid changes in ambient oxygen pressures occurring in the lungs. All conspire to damage red cells. Their 4-month survival is thus truly remarkable.

The ability of the red cell to persist in the circulation depends on its simple but exquisitely adaptive membrane structures, its pathways of intermediary energy metabolism and redox regulation, and its ability to maintain its largest cytoplasmic component, hemoglobin, in a soluble and nonoxidized state. Indeed, the membrane and enzymes of the red cell appear to be exquisitely crafted to protect the cell from not only the external ravages of the circulation but also the potential internal assaults of the massive amount of iron-rich and potentially oxidizing protein represented by its complement of hemoglobin molecules. For these reasons, a few basic features of these membrane and enzyme systems merit comment before considering the hemoglobin molecule itself.

MAJOR FEATURES OF THE RED CELL MEMBRANE

Chapter 4 describes the red cell membrane in considerable detail, using it as a model for understanding membrane structure in general. Only a few major aspects of that discussion bear repeating for the purposes of this chapter. See also Figure 4-2 , which shows a schematic diagram of the red cell membrane organization, and will facilitate understanding of the discussion in this section. The red cell membrane and its underlying cytoskeleton have evolved to provide both mechanical strength and the necessary pliability and resilience to withstand the mechanical, osmotic, and chemical stresses of the circulation. Since the lipid bilayer membrane has the physical properties, essentially, of a soap bubble, it would rapidly be emulsified in the circulation. Strength and order are provided to the lipid bilayer by the hexagonal arrays of the highly helical protein spectrin, which forms a latticework underlying the membrane.

As shown in Figure 4-2 , this spectrin meshwork is held together by adaptor molecules, such as protein 4.1, adducin, p55, and ankyrin, arrayed at defined points along the highly coiled, rodlike structure of the spectrin oligomers. These proteinprotein interactions appear to be critical for holding the latticework together in what has been described as the horizontal dimension that permits resistance to shear stress (see Chap. 33). The involvement of intermediate-length actin fibers and the variability of binding affinities by phosphorylation state appear to provide some flexibility and pliability at these points of interaction. Strength in the vertical dimension is provided by additional molecules, or additional binding functions of the same molecule, whereby the latticework is attached to the lipid bilayer. For the most part, the physiologically important attachments appear to be indirect. Linkage is mediated through the interaction of the adaptor proteins, such as ankyrin and protein 4.1, with the cytoplasmic domains of abundant transmembrane proteins. These traverse and are embedded in the lipid bilayer, providing a firm anchor. The two most critical of these molecules appear to be band 3 (the anion transport channel) and a glycophorin, probably glycophorin C/D. The construction of these attachments by multiple hinge or coupling molecules appears to provide for the flexibility and distensibility of the red cell membrane, a property essential to its ability to flow through small capillaries.

As described in Chapters 30 and 33 , the complex structure of the red cell membrane is exquisitely sensitive to perturbations impinging on any of its components. In particular, the membrane cytoskeleton and phospholipid structures are each highly susceptible to oxidation, particularly by partially proteolized molecules of hemoglobin, which denature to form highly toxic compounds called hemipyrroles. This interaction of denatured hemoglobin with the red cell membrane is clinically important, as illustrated by its impact on the pathophysiology of sickle cell anemia (see Chap. 30), or of oxidized and precipitated globin inclusion bodies in thalassemia (see Chap. 29). For present purposes it is sufficient to note that alterations of proteins of the red cell membrane can contribute to shortening of the red cell life span. Damage may result from direct defects in the cytoskeletal proteins themselves or from susceptibility of these proteins to direct oxidation or attack by oxidized or denatured hemoglobin molecules. The reader is referred to the aforementioned chapters for detailed descriptions of the relevant phenomena.

ENZYMES OF RED CELL INTERMEDIARY METABOLISM

Mammalian erythrocytes possess the highly specialized yet remarkably simplified set of metabolic pathways. As discussed in Chapter 32 and illustrated in Figure 32-1 , there are essentially three relevant sets of pathways. The first two are interconnected by the enzyme glucose-6-phosphate dehydrogenase (G6PD). Glucose entering the red cell is metabolized by an anaerobic pathway, the Embden-Meyerhof pathway, which terminates with the enzyme lactic dehydrogenase, forming lactate. Despite its inefficiency (a net of only 2 adenosine triphosphate [ATP]/glucose molecule), this pathway is the sole source of usable ATP in the cell. Moreover, the pathway generates reduced NADH, a molecule necessary for driving the reduction of methemoglobin to hemoglobin (see Chap. 32). A shunt within this pathway, the Rapopport-Luebreing shunt, generates the compound 2,3-bis(phosphoglyceric acid) (2,3-BPG), an important cofactor that, when bound to hemoglobin, reduces the affinity of hemoglobin for oxygen, as described later. The ATP generated is necessary for kinase reactions controlling phosphorylation of membrane and signaling components, for fueling ion pumps and channels, and for maintaining phospholipid levels.

The anaerobic metabolic pathway generates, as one of its intermediates, glucose-6 phosphate, which is the substrate for G6PD. G6PD, in turn, appears to be the rate-limiting enzyme for a linked pathway called the oxidative hexosemonophosphate shunt. As shown in Figure 32-1 , this pathway involves a cascade of reactions culminating in the reduction of oxidized glutathione to reduced glutathione. Reduced glutathione is utilized to reverse oxidation of critical structures, including hemoglobin, cytoskeletal proteins, and membrane lipids. Anaerobic glycolysis generates NADH for methemoglobin reduction, 2,3-BPG for modulation of hemoglobin oxygen affinity, and ATP for metabolic

energy requirements. Its end product is lactate. The oxidative glycolysis pathway generates NADPH and reduced glutathione for use as the major erythrocyte antioxidant.

The third set of red cell enzymes is involved in interconversions that maintain a balanced nucleotide pool within the erythrocyte. This pool is essential for the synthesis of ATP and other high-energy nucleotides.

During the past decade, most of the enzymes (or at least the erythroid isoforms of these enzymes) involved in red cell intermediary metabolism have been characterized at the molecular level by cloning of their cDNAs and/or genomic loci. Some of the more relevant information arising from this progress is discussed in Chapter 32 . For our purposes, however, a discussion of this information is not appropriate.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

RED CELL SENESCENCE AND DESTRUCTION

As discussed in several of the chapters already mentioned, erythrocytes, despite their impressive adaptations to circulatory stresses, eventually wear out and are destroyed. Red cell survival in humans appears to be remarkably uniform under normal circumstances, spanning 115120 days from release of the reticulocyte into the circulation to sequestration of the senescent red cell in the reticuloendothelial cells of the liver and spleen. The precise signal, or signals, marking red cells for destruction remain unknown, as does the underlying pathophysiology within the red cell or on its surface. However, several interrelated theories have emerged; these will be noted only briefly because they are mentioned in other chapters.

It is well established that red cells accumulate surface blemishes during their lives in the circulation. These appear to result in part from the accumulation of small amounts of oxygen damage to membrane structures. The altered regions are sensed by the reticuloendothelial (RE) cells during passage of the erythrocytes through the liver and spleen. Removal or pitting of these damaged regions from red cell membranes can be documented microscopically; small amounts of normal membrane are also lost during the process.

As noted in other chapters, the biconcave disk shape of the red cell, so important to its distensibility, depends on a high ratio of surface area to surface volume. This requires redundant membrane surface area. Thus, the membrane surface area of the normal biconcave disk is about 140 microns ^{2} ; to enclose a sphere containing a normal red cell volume (about 90 fl), only about 95 microns ^{2} would be needed. Progressive loss of membrane surface via the pitting phenomenon should ultimately cause the aging erythrocyte to assume a more rigid spherical shape that would inevitably be far less distensible and far less capable of passing through small apertures, especially in the sluggish and torturous circulation of the spleen. This geometric mechanism might, then, lead to the eventual destruction of the red cell.

It is also well documented that red cells progressively lose some of the critical enzymes needed for intermediary metabolism and antioxidant capacity. G6PD levels, for example, progressively decline during the circulating life span, as do levels of several other enzymes. Indeed, the decline of certain red cell enzymes can be used as a crude means of estimating the relative age of different red cell populations. The biochemical or oxidative mechanism for red cell destruction postulates that aged red cells are eventually depleted of critical enzymes needed for maintenance of redox status. Oxidation of critical membrane proteins, lipids, and hemoglobin would then ensue, causing distortion and rigidity of the red cell membrane, with accelerated loss as described above. The end product, once again, would be spherocytes incapable of traversing the splenic vascular bed and escaping engulfment by the RE cell.

More recently, it has been proposed that an immune mechanism may contribute to normal and pathologic red cell senescence. This hypothesis is based on the observation that oxygen damage, regardless of cause, promotes a clustering or capping of oligomers of band 3 on the red cell surface. Under normal circumstances, band 3 molecules form monomers, dimers, or tetramers. Higher-order aggregates appear to be recognized by an endogenous iso-antibody possessed by all of us. Any red cell accumulating oxidative damage, from wear and tear in the circulation, from depletion of enzymes, or from internal pathologic processes, such as denaturation of hemoglobin in sickle cell disease or unstable hemoglobin disorders, might accumulate these aggregates, be bound by antibody, and be removed by the RE cells as antigenantibody complexes, employing the same means used by RE cells to recognize any immune complex. This mechanism could also provide for the pitting or polishing of damaged red cell membranes mentioned earlier. Note that all three of the proposed mechanisms are interrelated by their inception with oxidative damage.

Regardless of the mechanism fostering eventual senescence and destruction of red cells, the process itself involves components clinically useful for assessment of anemias associated with accelerated red cell destruction. Chief among these is the generation of indirect or unconjugated bilirubin, the byproduct of heme catabolism occurring within the RE cells. In markedly accelerated states of red cell destruction, hypertrophy of the liver and spleen can also occur, providing a useful physical indicator of hemolytic anemia. Indeed, these indirect clinical features, coupled with the reticulocyte count, remain more useful for detecting clinical hemolysis than complicated studies of red cell kinetics.

HEMOGLOBIN SYNTHESIS, STRUCTURE, AND FUNCTION

Basic Features

Hemoglobins are the major oxygen-carrying pigments of the body. They are packaged into red cells in quantities sufficient to carry enough oxygen from the lungs to the tissues to meet the needs of those cells for oxidative metabolism. These quantities are enormousnearly two pounds of hemoglobin is present in the body of a reasonably sized man at any given time. Since free hemoglobin in the bloodstream is catabolized and excreted renally in a matter of minutes, packaging in erythrocytes is essential to preserve the newly synthesized molecules for the entire 4-month life span of the red cell. Otherwise, the caloric and biosynthetic resources needed to replace daily losses of hemoglobin would be prohibitive. The red cells major function is to encase hemoglobin and protect it so it can function as an oxygen transporter for a prolonged period.

The cellular content of blood influences its viscosity; in particular, hemodynamics are adversely compromised by the presence of too many circulating erythrocytes, because blood viscosity correlates especially with hematocrit. To provide for adequate oxygen transport (i.e., enough hemoglobin molecules) in a number of red cells compatible with tolerable viscosity, each red cell must enclose a high concentration of hemoglobin (about 3234 gr per 100 ml cytoplasm). This concentration is close to the solubility limit of hemoglobin in physiologic solutions. It follows that even minor perturbations within these molecules (e.g., oxidation) or in the milieu (e.g., changes in pH or ionic strength) can have potentially devastating effects on the solubility of hemoglobin. Since polymerized or precipitated hemoglobins derange intracellular viscosity, trigger proteolytic reactions that lead to oxidative damage of erythrocytes (see Chap. 31), and compromise oxygen transport, it is hardly surprising that the fate of the red cell is inextricably interwoven with the state of its enormous complement of hemoglobin molecules.

Hemoglobin Structure

The hemoglobin tetramer consists of two pairs of unlike globin polypeptide chains, each associated with a heme group. The behavior of hemoglobin is determined by its primary structure, the covalent linking of amino acids to form the polypeptide globin. The higher-order structures of hemoglobin are dependent on the sequence of amino acid residues that make up the globin chain. The -globin chains contain 141 residues, while the -like chains are 146 amino acids long (Fig. 22-1). There is considerable homology among these globins, especially among the non- chains. While the -globin chains result from a very ancient gene duplication, the non--globin chains are the result of more recent gene duplications and thus are more akin to each other than they are to the -like globin genes. Gene conversion events also ensure the similarity of duplicated genes.

Elements of the secondary structure of globin are shown in Figure 22-3 (Figure Not Available) . About 75% of the globin polypeptide chain forms an helix. There are eight helical segments, A through H, separated by short stretches from which the helix is absent. These nonhelical segments permit folding of the polypeptide upon itself and are often dictated by the presence of prolyl residues, which are generally unable to participate in the formation of helices. While the helical segments of the and non- globin chains do not exactly correspond, it is possible to align amino

Figure 22-1 The -globin chain, showing helical and nonhelical segments. The helical segments are labeled AH, while nonhelical segments are designated NA for those residues between the N terminus and the A helix, CD for residues between the C and D helices, and so forth. *(From Huisman THJ, Schroeder WA: New Aspects of the Structure, Function, and Synthesis of Hemoglobin. CRC Press, Boca Raton, FL, 1971, with permission.)*

Figure 22-2 Tertiary structure of a globin chain. Globin folds into a tertiary structure such that polar or charged amino acids are located on the exterior of the molecule and the heme ring resides in a hydrophobic niche between the E and F helices. Linked to the heme are the proximal (F8) histidine and the distal (E7) histidine. *(From Perutz MF: Molecular anatomy, physiology, and pathology of hemoglobin. In Stammatoyannopoulos G, Neinhuis AW, Leder P, Majerus PW (eds): The Molecular Basis of Blood Diseases. WB Saunders, Philadelphia, 1987, p. 127, with permission.)*

acid residues in all globin peptides by their helical and nonhelical residue number, as indicated in Figure 22-3 (Figure Not Available) . This permits greater appreciation of the homology among globins. Some of the amino acids of globin are invariant, or conserved, in the sense that they are preserved during phylogeny. These residues occur at portions of the molecule that are critical for its stability and functionfor example, heme binding residues, hydrophobic amino acids of the interior of the molecule, and certain subunit contacts at the $_{1\,2}$ interface. The introduction of prolyl residues into helical segments by mutation leads to interruption of the helix and instability of the resulting hemoglobin molecule.

The poorly understood laws that govern the folding of proteins are responsible for the tertiary structure of globin, shown in Figure 22-2 . This folding pattern places polar residues exteriorly and provides a hydrophobic niche for the heme ring between the E and F helices. Numerous noncovalent bonds are formed between the heme and surrounding amino acid residues of globin. An iron atom in the center of the porphyrin ring forms an important bond with the F8 or proximal histidine and via the linked oxygen with the E7 or distal histidine residue. Oxygenation and deoxygenation of hemoglobin occur at the heme iron.

Two -globin chains and two non--globin chains fit together specifically to form a hemoglobin tetramer with a molecular weight of about 64,000 and with the quaternary structure shown in Figure 22-3 (Figure Not Available) . The motion of individual globin chains, as well as the movement of globin chains relative to each other during oxygenation and deoxygenation, gives hemoglobin its unique utility as a respiratory protein.

Figure 22-3 (Figure Not Available) Quaternary structure of hemoglobin. The contacts between subunits are shown as circled amino acids. In the front view **(A)** $_{1\,2}$ contacts are shown, while in the side view **(B)** $_{1\,1}$ contacts are depicted. *(From Dickerson RE, Geis I: Hemoglobin: Structure, Function, and Evolution Pathology. Hemoglobin Function

Evolution has honed the hemoglobin tetramer into a molecule ideally suited for its tasks. Since human hemoglobin must behave differently from that of altitude

dwellers or inhabitants of hypoxic locales, many different variants of the same basic molecular design have evolved. Owing to the exigencies of molecular evolution, we can find in the genome of all animals, including humans, attempts of nature to propagate a variety of different globin genes. The crystallographic studies of Perutz and coworkers have defined the oxygenated and deoxygenated structures of hemoglobin at ängstrom unit resolution and have provided an exquisitely detailed picture of how the globin chains and individual amino acid residues respond to the loading and unloading of oxygen. Thus, we know more about the function of hemoglobin than about virtually any other protein, and our knowledge of this mechanism provides a beautiful and intellectually satisfying culmination to decades of study by many investigators.

The oxygen dissociation curve of hemoglobin, shown in Figure 22-4 (Figure Not Available) , describes the percent saturation of hemoglobin with oxygen at different oxygen tensions. The sigmoidal shape of this curve is a result of interaction among the subunits of hemoglobin. Communication within the tetramer is called hemeheme interaction or cooperativity. This implies that the four heme groups do not undergo simultaneous oxygenation or deoxygenation, but rather that the state of each individual heme unit with regard to the presence or absence of bound oxygen influences the binding of oxygen to other heme groups. Myoglobin, a heme-containing protein with virtually the same tertiary structure as globin, exists in muscle as a monomer. The oxygen equilibrium curve of myoglobin is a rectangular hyperbola; in physiologic terms, it rapidly becomes fully saturated at low oxygen tensions and remains saturated as the oxygen tension plateaus. The difference in the oxygen equilibrium curves of myoglobin and hemoglobin lies in the tetrameric nature of the hemoglobin molecule and the cooperativity permitted by the association of similar but unlike subunits. Myoglobin, as compared with hemoglobin, has a very low P_{50} (the oxygen partial pressure at which the molecule is half saturated). It therefore has an extremely high oxygen affinity and would not be useful for delivering oxygen to tissues. The oxygen in myoglobin is passed on to the mitochondria, where oxidative metabolism occurs. The sigmoidal shape of the oxygen dissociation curve of hemoglobin indicates that the totally deoxygenated hemoglobin tetramer is slow to become oxygenated, but as oxygenation proceeds, the reaction of heme with oxygen accelerates. Perutz has drawn an analogy in which the appetite of heme for oxygen grows with the eating, and conversely, loss of oxygen by heme lowers the oxygen affinity of the remaining heme groups. The Hill coefficient *n*, which can be calculated from plots of oxygen equilibrium curves, is a description of hemeheme interaction or cooperativity that explains in part the oxygen-binding properties of hemoglobin and myoglobin. The Hill coefficient for myoglobin is 1, indicating no cooperativity; *n* is about 3 for the normal hemoglobin molecule.

The oxygen affinity of hemoglobin within the erythrocyte does not depend solely on the intrinsic properties of the tetramer. The position of the hemoglobin oxygen dissociation curve, and therefore the P_{50} , can be influenced by a number of heterotrophic modifiers, including temperature, pH, and small organic phosphate molecules in the cell. The effects of these modifiers on P_{50} are shown in Figure 22-4 (Figure Not Available) .

Hemoglobin is the prototype of an allosteric protein; its structure and function are influenced by other molecules. The major intracellular modulator of hemoglobinoxygen affinity in human erythrocytes is 2,3-BPG, an intermediate product of glycolysis

Figure 22-4 (Figure Not Available) Oxygen dissociation curve of hemoglobin. The percent saturation of hemoglobin with oxygen at different oxygen tensions is depicted by the red sigmoidal curve. The P_{50} (i.e., the oxygen tension at which the hemoglobin molecule is half saturated) is about 27 mmHg in normal erythrocytes (pink dotted lines). Heterotopic modifiers of hemoglobin function can shift the curve leftward by increasing or rightward by decreasing its oxygen affinity. *(From Benz EJ Jr: Synthesis, structure, and function of hemoglobin. In Kelly WN, DeVita VT (eds): Textbook of Internal Medicine. Vol. 1. JB Lippincott, Philadelphia, 1989, p. 236, with permission.)*

that is present within the erythrocyte at concentrations equimolar to hemoglobin. The synthesis of 2,3-BPG is enzymatically regulated, and its levels may change depending on the conditions extant. 2,3-BPG is able to bind stereospecifically within the central cavity of the hemoglobin tetramer. Hemoglobin prepared in the absence of 2,3-BPG has a very high oxygen affinity, but as 2,3-BPG is added to a hemoglobin solution, the oxygen affinity progressively decreases. BPG is a polyanion that binds strongly to the deoxygenated form of hemoglobin but poorly to its oxygenated or other liganded forms. Specific amino acids are involved in the binding of 2,3-BPG; these chain residues include the N-terminal valines, the H21 histidine (position 143), and the EF6 lysine (position 82). In oxyhemoglobin, the H helices of the chains are insufficiently spread to permit firm binding of 2,3-BPG; this, along with other conformational changes, favors the binding of this anion to the deoxygenated rather than the oxygenated form of hemoglobin. The binding of 2,3-BPG stabilizes the T (tense) structure of the deoxygenated form at the expense of the R (relaxed) structure of the oxyhemoglobin tetramer.

Transition from the deoxy (T) to the oxy (R) form of hemoglobin is accompanied by rotation of the dimers along the $_{1\ 2}$ contact region (Fig. 22-5 (Figure Not Available)). The T structure is stabilized by salt bridges, which are broken as the molecule switches into the R structure. Some abnormal hemoglobins with an intrinsically high oxygen affinity, or low P_{50} , occur as a result of an amino acid substitution that leads to loss of bonds that stabilize the tetramer in the T conformation. Hydrogen ions, chloride ions, and carbon dioxide all decrease the affinity of hemoglobin for oxygen by strengthening the salt bridges that lock the molecule into its T conformation. The corollary of the lowering of hemoglobin oxygen affinity by protons is the combination of hemoglobin with protons upon deoxygenation. This is known as the Bohr effect and is responsible for carbon dioxide transport in blood, another critical function of the hemoglobin molecule. Deoxyhemoglobin binds the hydrogen ion liberated by the reaction of carbon dioxide with water, thus increasing the concentration of bicarbonate. Within the lungs, hydrogen ion is lost as hemoglobin binds oxygen; therefore, carbon dioxide leaves solution and is excreted from the body via the lungs. Deoxyhemoglobin can also directly bind carbon dioxide; however, this process involves the minority of carbon dioxide exchanged by the red blood cells.

Recently, it has been found that the hemoglobin molecule is S-nitrosolated on the 93 cysteine residues when oxyhemoglobin forms in the pulmonary circulation. This is in addition to the binding of NO to heme. As deoxyhemoglobin is generated in the tissues and the R state is converted to the T state, this linkage is disrupted and NO is liberated to exert its effects on vascular tone. A new and unique physiologic and homeostatic function for hemoglobin may therefore be to provide NO, a vasodilator molecule, when oxygen consumption increases.

Red cells containing high levels of hemoglobin F have high oxygen affinity because it binds 2,3-BPG poorly. Physiologically this predicts that the hemoglobin of the fetus should be oxygenated at the expense of the maternal hemoglobin A. The high oxygen affinity of hemoglobin F is accounted for by a single change in its primary structure, the presence of a serine residue at helical position H21 in place of the histidine found in the -globin chain. This weakens the binding of 2,3-BPG and leads to stabilization of the molecule in its R state.

In summary, the primary amino acid structure of and non- globin chains dictates the inevitable quaternary structure in which resides the ability of hemoglobin to serve as a respiratory

Figure 22-5 (Figure Not Available) Subunit motion in the hemoglobin tetramer. The relative motion of hemoglobin subunits on oxygenation and deoxygenation is shown. The $_{1\ 1}$ dimer (shown in black) is moving relative to the $_{2\ 2}$ dimer (shaded). The oxyhemoglobin tetramer (R state) is more compact than the deoxyhemoglobin configuration (T state). *(From Dickerson RE, Geis I: Hemoglobin: Structure, Function, and Evolution Pathology. Figure 22-6 Maps of the -like and -like globin gene clusters located on **(A)** chromosome 11 and **(B)** chromosome 16. Within each gene cluster are pseudogenes, which are remnants of previously expressed globin genes that have become inactivated as a result of mutation. Active genes are shown in red boxes filled with clear introns; inactive or pseudogenes genes are shown in solid boxes, and the theta-globin gene is shown as a pink box. While this gene is transcribed, it is not clear whether it is represented in a cellular protein. The distance between the functional - and pseudo--globin gene is variable, owing to the presence of repeated elements. HS, LCR, locus control regions and DNA ase hypersensitive sites; E, enhancer;

, silencer.

protein. Cooperativity ensures rapid binding of oxygen in the lungs and unloading in tissues. Similarly, carbon dioxide is transported from tissues to lungs. The function of hemoglobin may be influenced by mutation as well as by heterotropic effectors such as protons and 2,3-BPG. The molecule itself changes shape as it provides oxygen for metabolism; it is a lung in miniature, breathing as it allows the body to respire.

Globin Gene Clusters

The amounts and types of human hemoglobin produced at any given age are determined primarily by the selective expression of the individual genes encoding each globin chain. The globin genes of humans are located in two clusters (Fig. 22-6): -like genes in about 30 kb of DNA on the short arm of chromosome 16 between band P13.2 and the telomere, and -like genes in about 70 kb of DNA on the terminal portion of the short arm of chromosome 11 (P15) (Fig. 22-6). Each gene shares certain basic organizational features. Each contains three exons separated by two introns. The introns of the -gene are both small (100300 bp); non--genes have one small and one large (1,0001,200 bp) intron. The second exon of each globin gene encodes the major components of the heme-binding pocket, and the third the non-contact points.

Flanking each gene at both the 5 and 3 ends are groups of conserved nucleotides. In conjunction with protein factors, these influence the promotion of gene transcription, ensure the fidelity of the transcript and its translatability, specify sites for the initiation and termination of translation, and improve the stability of the newly synthesized mRNA (Fig. 22-7). Also encoded within the genes are signals that permit the enzymatic machinery within the nucleus to excise precisely the introns from the mRNA precursor and splice together the exons to form a contiguous mature mRNA. The spliced mRNA is transported to the cytoplasm and translated into protein. These conserved signals lie at the junction of the exon and intron as well as within the introns themselves. They are recognized by small nuclear ribonuclear protein particles, which participate in the formation of a spliceosome, or splicing complex. Their preservation is critical for the splicing process to occur. When mutations occur within splice signal sites, globin synthesis is often impaired. The 5 end of the mRNA contains a cap structure, and the 3 end contains a poly(A) tail, as described in Chapter 1 .

Figure 22-7 Pathway of globin biosynthesis. Transcription of the globin gene results in a large pre-mRNA molecule containing intervening sequences. During intranuclear processing of this molecule, the intervening sequences are excised and the coding sequences ligated to form a contiguous stretch of RNA, which codes for the globin protein. The message is further processed by the addition of a CAP and a poly(A) tail. The mature message is transported from the nucleus to cytoplasm, where it is translated on polyribosomes by the addition of activated amino acids to a growing polypeptide chain. Globin acquires heme, /non- dimers are formed, and the hemoglobin tetramer is assembled. *(From Steinberg, MH: Hemoglobinopathies and thalassemias. In Stein JH (ed): Internal Medicine. 4th ed. Mosby-Year Book, St. Louis, MO, 1994, p. 852, with permission.)*

Figure 22-8 Hemoglobin switching during embryonic, fetal, and adult development. The and epsilon genes are transcribed during embryonic development and are soon replaced by the fetal - and adult -globin gene. At birth, fetal hemoglobin forms about 75% and hemoglobin A 25% of the total. Transcription of the gene begins to fall before birth, and by 6 months of age this gene is expressed only at very low levels. Expression of the -globin gene begins near birth. In adults, hemoglobin A makes up about 97%, hemoglobin A_2 about 2.5%, and fetal hemoglobin <1% of the total. *(From Steinberg MH: Hemoglobinopathies and thalassemias. In Stein JH (ed): Internal Medicine. 4th ed. Mosby-Year Book, St. Louis, MO, 1994, p. 852, with permission.)*

Conserved nucleotide clusters 5 to the coding portion of each globin gene are known, in the aggregate, to act as promoters (Fig. 22-7). Globin promoters are modular. Some modules are located relatively close to the initiation site of mRNA translation, and some are more distally placed. Promoters ultimately form the binding sites for the RNA polymerase complexes that catalyze gene transcription. Mutations within the promoter can affect the level of gene transcription and the amount of globin made. Surrounding and within each gene are other sequence elements that play important roles in its transcriptional regulation (Fig. 22-6). These clusters, termed enhancers, and silencers (see Chap. 1) may lie within introns or 5 and 3 to the coding sequences; in some instances, they are quite remote from the gene. The higher-order structure of DNA in chromatin may permit close approximation of these remote enhancers to the gene during transcription. Enhancers play important roles in the tissue-specific regulation of globin gene expression. Representative regulatory sequences near the globin genes are shown in Figure 22-7 (the regions make HS1, . HS5). DNA elements controlling globin genes are described in more detail later.

The -like and -like globin genes are ordered in the 5 to 3 direction in the same sequence expressed during embryonic, fetal, and adult development (Fig. 22-8). The functional significance of this arrangement is unclear. However, recent evidence suggests that the ordering of the epsilon-, -, and -genes could be an important factor influencing the ability of each locus to interact with distant control elements at different developmental stages.

The -like and -like gene clusters are likely the result of an ancient duplication of a primordial globin gene that existed early in the history of vertebrates, approximately 500 million years ago. Each gene cluster probably developed from duplication of ancestral genes and subsequent divergence through eons of evolution. Within the -like gene cluster, the -globin gene is expressed only very early in embryogenesis and participates in the formation of embryonic hemoglobins. The -globin genes are duplicated, a characteristic of most globin genes, and their encoded amino acid sequences are identical; therefore, only a single -globin polypeptide results. Minor differences within the second intervening sequence and the 3 flanking regions of the -globin gene permit identification of transcripts from each gene. The 5, or $_2$ -gene is expressed more efficiently than the 3, or $_1$ -gene, so that abnormalities of this gene are more apt to be clinically apparent. Both clusters contain genes that are actively transcribed, as well as pseudogenes whose defective structures prohibit expression at any time.

The gene 3 to the $_1$ -gene is the theta-gene, a somewhat mysterious element of the -gene cluster. While theta-gene transcripts are found in fetal tissue and adult erythroid marrow, it is unclear whether this genes translation product is able to participate in the formation of a functional tetramer. To date no theta-globin protein has been found, and deletion of the theta-globin gene does not appear to have any implications for the developing fetus.

The -like-globin gene cluster consists of the embryonic epsilon-gene, transcribed only during the first 611 weeks of life; the duplicated -globin genes that code for the dominant non--globin of fetal life; and the - and -globin genes that code for the hemoglobins of the adult. The coding sequences of the two -globin genes are identical, except at codon 136, where the 5 or (G)-gene codes for glutamic acid; the 3 (or A)-gene encodes an alanine residue. These genes are unequally expressed during fetal development. A switch in their relative rates of expression leads to a similar disparity between the amounts of G and A chains in adults. While the G/A switch is interesting from the standpoint of the control of gene expression, it is of little clinical importance. Hemoglobin F in both the fetus and the adult contains a mixture of G and A chains; the functional qualities of these hemoglobins are identical.

The - and -globin genes are probably the result of a duplication event that occurred >40 million years ago. The -globin gene has become the predominant gene, coding for most non- chains of the adult. The -globin gene has undergone mutation in several critical areas, so its expression is greatly curtailed. Its product, minor adult hemoglobin (Hb A_2), has become functionally insignificant by virtue of its very low level in the erythrocyte. It is likely that the -globin gene is a pseudogene in evolution. In time its expression may be totally abolished as it acquires an inactivating mutation. The pseudogenes dispersed

within both globin gene clusters provide interesting glimpses into the evolutionary history of globin genes. Pseudogenes are inactive remnants of previously expressed genes. As a result of relaxed selection, their mutation rate is higher than that of surrounding active genes. Hb A_2 is clinically useful, however, for characterizing hemoglobinopathies such as -thalassemia.

The expression of the human globin genes is highly regulated. Globin is synthesized in only one tissue, erythroid cells, and only during a narrowly defined stage of erythroid progenitor cell differentiationthe 57 days that commence with the proerythroblast stage and end when the enucleate reticulocyte loses the last traces of its RNA. Within the confines of these strict tissue-specific and differentiation stage-specific boundaries, the globin genes are extraordinarily active. By the late normoblast and reticulocyte stages, 9095% of all protein synthesis in these cells is globin synthesis.

Individual globin genes are expressed at different levels in developing erythroblasts of the human embryo, fetus, and adult (i.e., 3738 weeks gestation and beyond). Different subsets of - and non--genes are expressed and silenced at each developmental stage. Moreover, the overall balance of non--globin, -globin, and heme production is maintained throughout each of these complex switching events. The complex mechanisms ensuring the proper tissue-, differentiation stage-, and ontologic stage-specific expression are incompletely defined. Much recent information about relevant DNA control elements and transcription factors is emerging.

These are discussed later. First, however, the ontogeny of hemoglobin should be reviewed as necessary background.

Ontogeny of Hemoglobin

The hemoglobin composition of the erythrocyte varies depending on when in gestation or postnatal development it is measured. This is a result of sequential activation and inactivation (switching) among genes within the and non--globin gene clusters (Fig. 22-8). What controls these switches in globin gene transcription is not currently understood. The two early embryonic hemoglobins consist of and epsilon chains (Hb Gower-1) and and epsilon chains (Hb Gower-2). The -globin gene is akin to the -globin genes but is expressed only during early embryogenesis. The epsilon embryonic globin chain is -like. The combination of - and -globin chains forms hemoglobin Portland. These early hemoglobins are made primarily in yolk sac erythroblasts and are detectable only during the very earliest stages of embryogenesis except in certain pathologic states, in which they may persist until gestation is complete. The major hemoglobin of intrauterine life is fetal hemoglobin, or Hb F, which consists of two - and two -globin chains. -globin gene expression begins early in embryogenesis, peaks during midgestation, and begins a rapid decline just before birth. By 6 months of age in normal infants, only a remnant of prior -globin gene expression remains, and the level of fetal hemoglobin in the blood is <1% of the total. -globin gene expression starts early in the first trimester, peaks quickly, and is sustained for life. -globin gene expression also commences early in gestation and reaches its zenith within a few months after birth. The combination of - with -globin chains forms hemoglobin A, the predominant hemoglobin of postnatal life. Also present in adult cells is hemoglobin A_2 . The -globin gene, which directs synthesis of the non- chain of hemoglobin A_2 is very inefficiently expressed. Thus, only low levels of hemoglobin A_2 are present; defects in the -globin gene are of no clinical consequence. In adult blood, fetal hemoglobin is not evenly distributed among erythrocytes but is present in only a very small number of red cells, termed F cells. Hemoglobin A_2 is present in all red cells, albeit at levels <3.5% of the total hemoglobin in normal adults.

Hemoglobin Biosynthesis and its Regulation

Throughout development, genes coding for - and non--globin and heme exhibit coordinated expression. Nearly equal amounts of each of the moieties that ultimately constitute the hemoglobin tetramer are made. Excess unpaired globin chains and mutant globins are also removed from the cell by ATP-dependent proteases, ensuring a balance between and non- chain accumulation. Balanced chain synthesis and coordination of globin chain production with synthesis of heme are important because hemoglobin tetramers are highly soluble, while the components of hemoglobin (i.e., unpaired chains, protoporphyrin, and iron) are not. Precipitation of any of these is deleterious to cell survival. Erythroblast proteases are not efficient enough to eliminate the substantial excesses of unpaired chains that accumulate when an - or non--gene is selectively impaired by severe thalassemia mutations. The mechanisms regulating heme production, and some of the interactions between heme and globin synthesis, are discussed in Chapters 26 , 27 , and 29 .

The proper production of the individual globin chains within erythroid tissues at the appropriate states of differentiation and development is regulated predominantly at the level of transcription. The onset of phenotypic maturation at the proerythroblast stage is marked by the onset of globin mRNA biosynthesis in dramatically increasing quantities. - and non--globin gene expression began at essentially the same time, although some studies suggest a slightly earlier onset of -globin gene expression. Transcription persists at a high level throughout most of the remainder of erythropoiesis, declines as the nucleus condenses, and is eventually lost in late erythroblasts. Even as the absolute rates of globin gene transcription begin to fall, however, the relative percentage of total transcriptional activity devoted to globin gene expression continues to rise; this reflects the silencing of transcription of nearly every other gene in the erythroblast.

The transcriptional activation of the globin genes is the major event that must be understood to define and manipulate the regulation of hemoglobin biosynthesis and hemoglobin switching. However, post-transcriptional mechanisms contribute to the final distribution of globin and nonglobin mRNAs, and to the balance of - and non--globins within the erythroblasts. When compared with many other mRNAs, such as cytokine mRNAs, globin mRNAs are extraordinarily stable. Their half-lives have been estimated at 3050 hours. Most other mRNAs have turnover rates, or half-lives, measured within the range of a few minutes to 56 hours. Thus, the rise in the percentage of total mRNA that is globin mRNA is greatly accentuated because the newly transcribed globin mRNAs accumulate and remain quite stable in the cell, while nonglobin mRNAs, which are no longer being produced, are also disappearing at a faster rate. Consequently, the mRNA content of the reticulocytes consists of 9095% globin mRNA.

The transcription rates of the - and non--globin genes are not precisely equal. (This phenomenon has been studied in detail only in adult reticulocytes expressing the - and -globin genes.) A slight, but reproducibly detectable, excess of -globin mRNA is present in erythroblasts. However, -globin mRNA is translated somewhat more efficiently than -globin mRNA. These counterbalancing forces result in nearly equal synthesis of - and -globin polypeptide chains. In fact, there is a very slight excess of -globin production, resulting in a small pool of free -chains. Newly synthesized -chains are thus rapidly and completely incorporated into functional hemoglobin tetramers. Hemoglobin tetramers are remarkably stable throughout the life span of the circulating red cell. Only small amounts suffer oxidative or proteolytic damage. Hemoglobin molecules are thus exposed for prolonged periods to chemically active compounds in the milieu of the bloodstream. They often become nonenzymatically modified by such processes as glycosylation,

acetylation, and sulfation. One of these modifications, glycosylation, occurs more extensively during periods of hyperglycemia and leads to elevated levels of the glycosylated form of Hb A, Hb A_{1c} . This phenomenon is the basis of a useful test for control of the blood sugar in diabetics. Other post-translational modifications are of little clinical importance.

Transcriptional Regulation of Globin Gene Expression

The major molecular elements mediating regulation are trans-acting proteinaceous transcription factors and cis-acting short, specialized regions of DNA sequence that are recognized by some of these factors. The interaction causes these DNA elements to act as promoters, enhancers, or silencers of gene activity. Nuclear proteins that interact with the globin gene clusters include DNA-binding proteins and proteins that interact with the DNA-binding proteins by means of specific proteinprotein interactions, such as leucine zipper domains. (See Chap. 6 for background information about the basic features and properties of transcription factors.) Control of the - and non--globin genes is further complicated by the fact that each gene cluster functions as a larger unit, or DNA domain. The open or closed state of the -like globin cluster domain, with respect to access to transcriptional activating machinery, appears to be under the influence of an enhancer sequence, the locus control region (LCR). The -globin gene cluster is influenced by the HS-40 region that, while not a typical enhancer, has some similarities in function. Each of these regions is located several tens of kbs upstream of the epsilon-gene on chromosome 11 and the -gene on chromosome 16.

Locus control regions are modular DNA sequence elements. For example, several DNase 1-hypersensitive sites (see Chap. 1 and Fig. 22-6) can be detected within the - and -globin clusters LCR loci in chromatin from erythroid, but not nonerythroid, cells (Fig. 22-8). Minichromosome constructs, in which globin genes are attached directly to the LCR in the absence of most intervening DNA sequences, are expressed at rates approaching those of endogenous globin genes in cultured erythroid cells and transgenic mice. Some nonglobin genes are also expressed at very high levels in erythroid cells when attached to these LCR sequences. Thus, to a first approximation, the LCR regions can be regarded as master switches that promote access of other regulatory factors to individual globin promoters and enhancers within the clusters. The LCRs contain binding sites for the major erythroid transcription factors, GATA-1 and NFE-2, as well as sites for generic factors found more widely distributed in many cell types.

The LCR is unquestionably essential for the quantitatively high rates of -globin gene expression during erythroid differentiation. The role of the LCR in dictating tissue specificitythat is, shutdown of globin gene expression in other tissuesor the sequential activation of silencing of genes during hemoglobin switching, is less clear. Studies suggest that tissue specificity and qualitatively proper switching of - and -globin gene expression in transgenic mice could be obtained with DNA constructs lacking the LCR. However, these genes were invariably expressed only 0.55% as actively as the endogenous globin genes of the host cell. The degree and fidelity of tissue-specific expression also appeared to be dependent on several factors, such as the site of transgene integration.

The interrelationships among the LCR and individual promoters, enhancers, and silencers during erythroid differentiation and hemoglobin switching remain incompletely understood despite extraordinary experimental scrutiny. Most investigators agree that both tissue and developmental specificity and highly active and efficient expression of individual globin genes require interaction among the LCR, the individual promoter/enhancer elements flanking the globin gene selected for expression, and complexes of interacting transcription factors. A variety of looping and tracking models have been put forward as hypotheses to explain how a distant DNA sequence element and its bound transcription factors can interact with sequences located close to the transcription start site of a globin gene. No model has

explained all the experimental findings or biologic phenomena.

Despite uncertainty as to the precise molecular mechanisms involved, most investigators agree that opening of the globin gene cluster by the LCR is a prerequisite for expression of any globin genes; this change in chromatic configuration is presumably mediated by the interaction of the LCR with specific transcription factors. The essential role of promoters and enhancers located near the globin genes is suggested by the discovery of mutations in these regions that affect hemoglobin switching or that cause thalassemia-like syndromes. Moreover, competition for the stimulating activity of the LCR can be appreciated by manipulation of the number of copies of globin genes attached to the LCR, the order in which they appear, or the orientation in which they are transcribed. These manipulations alter both the relative amounts of globin mRNA produced from each locus and the stages of development at which individual genes are expressed. Evidence for the existence of LCRglobin gene interactions is thus clear, even though the nature of the interaction remains obscure.

The shutdown of the embryonic genes late in the first trimester and, possibly, the decline of -gene expression during the perinatal period may also require the participation of active silencing mechanisms. The predominance of -globin gene expression over -gene expression in adult life is thus not merely the result of preferential stimulation of -gene expression. Active repression of the -genes may also be relevant; these mechanisms, if they exist, may have to be reversed if one hopes to manipulate hemoglobin switching therapeutically.

The nuclei of erythroid cells contain numerous proteins that have been identified as transcription factors. Many of these are found in a wide variety of tissues. At least two factors, GATA-1 and NFE-2, are much more restricted in their range of expression and have been implicated as particularly important for globin gene expression.

GATA-1 is named on the basis of the DNA sequence motif (T/A) GATA (A/G), the GATA motif that it recognizes and binds. It is a zinc finger class DNA-binding protein (see Chap. 6). GATA-1 has been shown to activate promoters containing the cognate DNA sequence motif, even when placed in nonerythroid cells. NFE-2 recognizes the DNA sequence motif (T/C) GCT GA (C/G) TCA (T/C). It is a member of the B-zip class of transcriptional activators. Both GATA-1 and NFE-2 were originally identified and cloned on the basis of their interaction with their cognate sequences in the globin genes. Initially, each was thought to be present only in erythroid cells. However, further work has demonstrated that each protein has a wider range of tissue expression. For example, GATA-1 is also present in other hematopoietic cell lineages, whereas NFE-2 consists of two subunits, one that is widely expressed and one that is expressed in several hematopoietic lineages and the intestine. Erythroid Kruppel-like factor (EKLF) may be the most specific of the erythroid transcription factors yet discovered. EKLF interacts specifically with the -globin gene promoter, and may influence the - switch. Mice homozygous for disruption of the EKLF gene have lethal thalassemia.

Clearly, neither GATA-1 nor NFE-2 alone can be the sole determination of tissue specificity of the globin genes; otherwise globin gene expression should occur at some level in other tissues in which these proteins are present. However, there is no doubt that each of these proteins is indispensable for both globin gene expression and erythropoiesis. Gene knockout studies have shown that absence of either protein results in greatly impaired erythropoiesis.

GATA-1 and NFE-2 probably interact with each other, either

directly or by means of binding to intermediary proteins, to activate the expression of globin genes and other genes necessary for erythroid maturation. Several other proteins have been identified as binding to various control elements in the globin gene cluster. Some of these appear to be stage-specific selector elements that bind predominantly to the - or -globin gene enhancers and promoters. Others are generic transcription factors. Regulation at these sites is probably hierarchic, depending on the appropriate combination of DNA-binding proteins, the types of proteins that interact with them, and the activation state of the bound proteins through such processes as ribylation and phosphorylation. It is also possible that the same sequence element may interact with different combinational sets of proteins, with a different resulting effect on transcriptional activity, depending on the stage of differentiation and/or embryonic/fetal/adult development.

The precise molecular machinery necessary for regulation of transcription of individual globin genes is beginning to be defined. It is important to realize, however, that these molecular mechanics are susceptible to cellular, microenvironmental, and humoral influences affecting the proliferation and differentiation state of primitive erythroid stem cells in yolk sac, fetal liver, or bone marrow. Overwhelming evidence supports the hypothesis that the potential for expression of - and/or -genes is determined in primitive erythroid stem cells (i.e., BFU-E) long before actual expression of the globin genes is initiated at a later stage of differentiation. The relative percentage of maturing erythroblasts that will ultimately express Hb F or Hb A, or both, can be altered by factors such as cytotoxic drugs or bone marrow stress that alter the relative percentages of Hb F-potent or Hb A-potent stem cells undergoing cell cycle events, differentiation, and so forth. Drugs currently in use in an effort to manipulate Hb F switching seem to work primarily through these cellular mechanisms (see Chap. 15).

Post-transcriptional, Translational, and Post-translational Mechanisms

Processed globin mRNA is exported from the nucleus to the cytoplasm by a mechanism that is not yet clearly defined. mRNA translation occurs in the cytoplasm (Fig. 22-7). The triplet codons or mRNA are recognized by the anticodons of specific tRNAs that bring activated amino acid residues to the nascent polypeptide chains. The process of translation, in which an mRNA template directs the synthesis of protein, is typically divided into three phases: initiation, elongation, and termination (see Chaps. 1 and 2). Each phase is regulated by a variety of protein factors.

The globin mRNA molecule becomes associated with four to six ribosomes, forming the polyribosome. At least 11 eukaryotic translation initiation factors interact with the polyribosome. These mediate stabilization of a preinitiation complex, binding of the initiator methionine tRNA to ribosomal subunits, binding of mRNA to the preinitiation complex, stabilization of mRNA binding, recognition of the cap site at the 5 end of mRNA, and release of initiation factors from the preinitiation complex. Several elongation and termination factors have also been defined. Initiation, or an early step in the elongation process, is rate-limiting.

The first post-translational step in tetramer formation is the combination of and non- chains to form dimers, an event that appears to depend on the relative charge of each globin subunit. The dimers then spontaneously form tetrameric hemoglobin. Because of charge differences among non--globin chains, there is a hierarchy or affinity of these chains for chains. The combination of and chains is most favored, followed by a combination of - and - and -globin chains. Certain mutant hemoglobins that have either gained or lost a charge may alter this hierarchic arrangement. This may influence the proportion of variant hemoglobin present, especially when the patient also inherits an -thalassemia syndrome, in which the synthesis of -globin chains is reduced. The supply of available chains is then limited and non- chains compete with one another to form tetramers with the limiting chain pool.

Globin chain biosynthesis and heme synthesis are mutually important. Heme plays a role in the regulation of the initiation complex. A deficiency of heme (e.g., in iron deficiency) is associated with the accumulation of a repressor of translation initiation factors. -mRNA appears to be initiated more efficiently than -globin, conferring on the associated anemia some of the features of mild -thalassemia. This phenomenon occurs because heme deficiency depresses the availability of initiating factors for which the less efficient -mRNA must compete with the more efficient -mRNA.

HEMOGLOBINOPATHIESNOSOLOGY

Inherited abnormalities of the hemoglobin molecules that cause morbidity are called hemoglobinopathies and thalassemias. Many of these conditions produce disease (e.g., sickle cell anemia, thalassemia, methemoglobinemia) that are especially important to hematologists. A few acquired conditions lead to modification of hemoglobin (e.g., carbon monoxide exposure, producing carboxyhemoglobinemia) that produce clinical abnormalities.

TABLE 22-1 -- Classification of Hemoglobinopathies and Thalassemias

Structural hemoglobinopathiesmutations altering the amino acid sequence of a globin chain and altering physical or chemical properties of the hemoglobin tetramer in such a way that function is deranged.
Abnormal hemoglobin polymerizationsickle hemoglobin (Hb S); hemolysis, vaso-occlusion
Abnormal hemoglobin crystallization (e.g., Hb C)
High oxygen affinitypolycythemia (Hb Zurich)
Low oxygen affinitycyanosis (Hb Kansas)
Hemoglobins that oxidize or precipitate too readilyunstable hemoglobins (Hb Köln)
M hemoglobinsmethemoglobinemia, cyanosis (e.g., Hb Milwaukee)
Thalassemiadefective production of globin chains with hypochromia, anemia, hemolysis, altered erythropoiesis
-Thalassemia
-Thalassemia
-Thalassemias, -thalassemias, -thalassemias
Thalassemic hemoglobinopathiesmutations altering both synthesis and structure or function of the hemoglobin gene products (e.g., Hb E, Hb Terre Haute, Hb Lepore, Hb Constant Spring)
Hereditary persistance of fetal hemoglobinpersistence of high levels of Hb F into adult life
Pancellularhigh HbF levels in all red cells
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellularinherited increases in the percentage of F cells
Acquired hemoglobinopathies
Methemoglobinemia due to toxic exposures
Sulfhemoglobinemia due to toxic exposures
Carboxyhemoglobinemia due to toxic exposures
Hb H in erythroleukemias
Acquired elevations in F cells and Hb F
Erythroid stress [e.g., recovery from bone marrow suppression]
Bone marrow dysplasias
Exposure to agents altering stem cells or gene expression (e.g., hydroxyurea, butyric acid)

These situations are summarized by the term acquired hemoglobinopathies.

Most of the enormous number (nearly 1,000) of mutations of the globin gene that have been described produce no, or only trivial, clinical effects. The remainder can be classified according to the hematologic and clinical phenotypes that cause reduced solubility with hemolytic anemia (unstable hemoglobins and polymerizing hemoglobins, such as sickle hemoglobin), hemoglobins with altered oxygen affinity, methemoglobins, and the thalassemias involving abnormal synthesis of one or more globin chains with anemia, hemolysis, and alterations of erythropoiesis. Some mutations, such as that responsible for Hb E, can alter both the structure and synthesis of the molecule. The classification of hemoglobinopathies and thalassemias is summarized in Table 22-1 . Individual conditions are discussed in the chapters already cross-referenced in earlier sections of this chapter.

Chapter 23 - Approach to the Adult and Child with Anemia

Sandra F. Schnall
Nancy Berliner
Thomas P. Duffy
Edward J. Benz Jr.

ANEMIA IN THE ADULT

Cycle of Erythropoiesis

Anemia represents a reduction in the body's red cell mass. Under normal conditions, this quantity is maintained within prescribed limits through the regulatory feedback stimulus of the humoral factor erythropoietin. [1] [2] A sensing device responsive to tissue oxygen content within the kidney determines the degree of erythropoietin release from renal peritubular cells. [3] [4] Red blood cells (RBCs) circulate in the peripheral blood for approximately 90120 days, necessitating replacement of the approximately 1% of the body's red cells lost each day to senescence. The spleen is the major site for removal of aged RBCs; splenic macrophages may recognize an acquired RBC senescence antigen,

which facilitates trapping of these cells within the microvasculature of the spleen. [5] [6] The erythropoietic feedback loop ensures that the hemoglobin mass for oxygen delivery matches the body's needs and that production equals destruction of red cells under stable conditions.

Mechanisms of Anemia

Anemia, a deficiency in the RBC mass and the hemoglobin content of blood, occurs whenever any malfunction upsets normal coupling of RBC production with destruction. This pathologic condition can have many origins; in some circumstances, especially in patients with complex illnesses, several factors converge to produce anemia (multifactorial anemia). Anemias can be caused by a primary hematologic disorder within the marrow or by an accelerated loss or destruction of RBCs in the periphery. As well, a myriad of systemic derangements may perturb erythropoiesis or RBC survival. The hematopoietic microenvironment is exquisitely sensitive to the macroenvironment of the body. Anemia, like the sedimentation rate, is thus often a sickness index of the body. The diagnostic challenge in the workup of the anemic individual is to recognize it as a sign of an underlying pathology whose recognition requires an approach to the whole patient for delineation of the mechanism and cause(s) of the red cell deficit.

Normal Hematologic Values

Normal hematologic values are established by sampling large populations of men and women (Table 23-1). Adult males tend to have slightly higher hematocrits because androgen enhances both renal erythropoietin secretion and the enlistment of precursor cells into an erythropoietin-responsive state. Geographic differences also exist for these standards because ambient oxygen tensions affect hemoglobin oxygen saturation; the lower oxygen tensions at high altitudes are associated with increased RBC hemoglobin levels.

Three measurements that were previously performed manually, determination of the hemoglobin level (in grams per deciliter), RBC number × 10 [12] L, and hematocrit (in percent), are now determined by electronic counters. Both the RBC number and the mean corpuscular volume (MCV) are directly measured from a gated window pool, and the hemoglobin concentration is determined by chromatographic quantitation of the hemoglobin present in a defined volume of RBCs. These values are used to calculate the hematocrit, the mean corpuscular hemoglobin (MCH), and the mean corpuscular hemoglobin concentration (MCHC). The Coulter counter can also generate a red cell sizing index (the RDW). The RDW is a measure of the heterogeneity of sizes in patients' circulating red cell populations. High values indicate greater variability in size. In addition to this quantitative characterization of RBCs, the Coulter counter measures the white blood cell (WBC) and platelet counts, permitting a rapid and important assessment of the involvement of cell lines other than red cells. When present, multilineage involvement implies that the anemia is part of a stem cell disorder common to all three cell lines or involves exaggerated peripheral destruction of all lineages, as occurs in hypersplenic states.

TABLE 23-1 -- Criteria of Anemia in Adult Men and Women

	Women	Men
RBC × 10^{12} /L	<4.0	<4.5
Hemoglobin (g/dl)	<12	<14
Hematocrit (%)	<37	<40

Hyporegenerative versus Hyperregenerative Anemias

Each day approximately 0.8% of the RBC pool needs to be replaced by young erythrocytes released from the marrow. Reticulocytes are larger than mature RBCs, and because they still contain portions of polyribosomal RNA material, they can be stained selectively by supravital dyes and counted. Their number in the blood reflects the marrow's response to peripheral anemia. When the cause of anemia is blood loss or hemolytic destruction in the periphery, erythropoietin overdrive of the marrow leads to reticulocytosis (>0.52.0%) to compensate for the peripheral RBC deficit, provided that the marrow's capacity to produce more RBCs is intact. An absence of an appropriate reticulocytosis in the setting of anemia indicates that a lesion that interferes with RBC production is responsible. The reticulocyte count provides an easy means of suspecting either the marrow or the periphery as the *primary* source of anemia. This differentiation dictates further investigative workup by narrowing the focus to the marrow in reticulocytopenic states but to peripheral blood loss or hemolytic abnormalities, or both, when reticulocytosis is present.

The reticulocyte count is expressed as a percentage of the total RBCs examined in an individual patient. This number must be corrected for the presence of anemia

because it is spuriously elevated when it is related to the reduced number of RBCs present in an anemic patient (i.e., if RBCs, the denominator, are reduced, the percent reticulocytes will rise even if no additional reticulocytes are being produced). This correction is generated according to the formula in Table 23-2 . An additional correction in this index is necessary because reticulocytes released under intense erythropoietin stimulation remain in the peripheral blood for twice the usual 1-day survival time of nonstress reticulocytes. An alternative to this somewhat cumbersome corrected reticulocyte index is expression of the reticulocyte count in absolute numbers. The original reticulocyte percentage is multiplied by the RBC number to yield an absolute reticulocyte count; any value >100 × 10^{9}/L is considered evidence of an erythroid marrow compartment that is responding appropriately to a hematologic lesion outside the marrow.

Red Blood Cell Size as a Classification of Anemia

The Coulter counter generates a value for the average volume (MCV) of the red cells, which provides an important means of categorizing the types and causes of anemia. The normal MCV is 8095 fl; values above and below this range define macrocytic and microcytic anemias, respectively. The MCV is useful as a first step in approaching an etiologic diagnosis of an anemia because there are relatively few causes of microcytic and macrocytic anemias. The microcytic anemias have their origin in lesions that cause deficient hemoglobin synthesis. These states include iron deficiency anemia and the anemia of chronic disease, respectively the most common anemia overall and the most common anemia encountered in hospitalized patients. (Either of these forms can also be normocytic, however.) Inherited defects in globin synthesis, the thalassemias, as well as abnormalities in heme synthesis, as in the sideroblastic anemias, may also result in a hemoglobin-deficient hypochromic microcytic anemia.

Severely macrocytic anemias (MCV > 115 fl) almost always

TABLE 23-2 -- Reticulocyte Count

Corrected reticulocyte count = % reticulocytes ×
Absolute reticulocyte count = % reticulocytes × RBC count/mm^3
Absolute reticulocyte count > 100,000/mm^3 = hemolytic anemia

have their cause in folate or vitamin B_{12} deficiency, since both vitamins play an essential role in DNA metabolism. Less striking macrocytosis is usually caused by liver disease, some drugs (e.g., antifolates), or alcoholism; hypothyroidism also may be associated with macrocytic indices. Inherited abnormalities in purine/pyrimidine metabolism are rare causes of macrocytic anemias. The development of a refractory macrocytic anemia, especially in the elderly, should raise consideration of a myelodysplastic or leukemic syndrome.

Two causes of pseudomacrocytosis should not be overlooked: (1) since reticulocytes are polychromatophilic macrocytes, macrocytosis increases with increasing reticulocytosis; and (2) agglutination of RBCs in the presence of cold agglutinins or cryoglobulins may lead to false elevations in the MCV because the aggregates may be counted as large RBCs. Reversal of a high MCV by heating the specimen is proof that the latter phenomenon is involved.

The normocytic anemias include: hemolytic anemias of various causes (in the absence of striking reticulocytosis, which can elevate the MCV); aplastic anemias (although some are macrocytic); and the early stages of almost all anemias, including iron deficiency (in these cases the residual normal population of RBCs present when the anemia first develops counterbalances the emerging population of abnormal cells).

It is important to realize that the MCV is an average value representing the arithmetic mean volume of red cells. Combined abnormalities or deficiencies can result in a normal MCV when iron deficiency (decreased MCV) is accompanied by folate deficiency (increased MCV) or pernicious anemia supervenes in thalassemia. Failure to appreciate that the MCV represents an average RBC size creates the potential for overlooking the real cause(s) of the anemia. The RDW now permits recognition of this phenomenon because it demonstrates graphically the heterogeneity of RBC populations.

The MCH and MCHC values do not provide very much additional information for the categorization of anemias. Both values are low in iron-deficient hematopoiesis, but the reduction in MCV is the most commonly used marker of this state and occurs earlier than the reduction in hemoglobin concentration. However, one disease, hereditary spherocytosis, is characterized by an elevation in the MCHC because it is associated with a varying population of dense microspherocytes. The data generated from the Coulter counter can also be used as an internal control on the hemoglobin and hematocrit parameters. The hematocrit is usually about three times the measured hemoglobin value; a departure from this ratio occurs when intravascular hemolysis releases large amounts of hemoglobin beyond that contained in intact RBCs. Clostridial sepsis may advertise itself in this fashion. Agglutination of RBCs due to cold-reactive antibodies may falsely decrease the RBC value without altering the hemoglobin content of the specimen.

Examination of the Peripheral Blood Smear

Examination of the peripheral blood smear is a diagnostic maneuver of overriding importanceit is at least equal in importance and complementary to the machine-generated hematologic data. It confirms the RBC size categorization determined with the Coulter counter and permits recognition of the many variations in RBC size and shape that are frequently signposts of the causes of hemolytic anemias. Since nucleated RBCs are counted as WBCs by the Coulter counter, the smear must be examined to recognize and correct for this contribution to pseudoleukocytosis. Such erythroblastic findings are helpful clues to the diagnosis of severe thalassemia, myelophthisis, or marrow infiltrative disorders.[7] Examination of the WBCs may reveal hypersegmentation of polymorphonuclear cells as the earliest manifestation of a megaloblastic process[8] (Fig. 23-1). This may be the critical marker in pregnancy or in alcoholics, in whom a

Figure 23-1 Hypersegmentation of polymorphonuclear cell and macrocytosis as peripheral blood evidence of an underlying megaloblastic process.

normal MCV may occur because of a mixed iron-folate deficiency. Target cells, Howell-Jolly bodies, and nucleated RBCs may be clues to functional or anatomic asplenia (Fig. 23-2).

The red cell shape is frequently the most helpful aid in the differential diagnosis of hemolytic disorders. Diagnostic findings include RBC fragmentation as a result of traumatic hemolysis on artificial cardiac valves (Fig. 23-3); spherocytes as a marker of hereditary spherocytosis, immune hemolytic anemias, or hypersensitivity (Fig. 23-4); the oak leaf and sickle cells of sickle cell disease (Fig. 23-5); the target cell of thalassemia and hemoglobin C and liver disease (Fig. 23-6); the spur cell of liver failure (Fig. 23-7); the teardrop form of myelophthisic processes (Fig. 23-8); and the blister forms of glucose-6-phosphate dehydrogenase (G6PD) deficiency (Fig. 23-9). In addition, detection of intraerythrocytic parasites may demonstrate that a fever is caused by malaria (Fig. 23-10). The marked elevation in serum proteins in myelomatous states may result in a stacking of RBCs in rouleaux formation (Fig. 23-11A); aggregation of RBCs into crowded masses (as opposed to their stacking into rouleaux) should suggest cold agglutinin disease (Fig. 23-11B).

Figure 23-2 Howell-Jolly bodies in RBCs of asplenic patient.

Figure 23-3 Helmet cells, microspherocytes, and RBC fragments in microangiopathic hemolytic anemia.

Figure 23-4 Spherocytes and polychromatophilia in hereditary spherocytosis.

Figure 23-5 Target, oak leaf, and sickle cells in sickle cell disease.

Figure 23-6 Target cells, acanthocytes, and macrocytes in liver disease.

Figure 23-7 Marked acanthocytosis in advanced liver disease.

Figure 23-8 Teardrop and nucleated RBCs in myelophthisic anemia.

Figure 23-9 Blister RBCs in drug-related hemolytic anemia.

None of the quantitative values generated by the Coutler machine substitute for the plethora of information derived from a careful, informed examination of the peripheral smear. Omission of this simple and inexpensive undertaking deprives the clinician of what is often the critical clue to the cause of the anemia, and even the cause of nonhematologic disease.

Examination of the Bone Marrow

If anemia is caused by a hyporegenerative process, a bone marrow examination permits evaluation of the production fault responsible

Figure 23-10 Intraerythrocytic parasites in malaria.

Figure 23-11 (A) Stacking of RBCs with rouleaux formation in myeloma. **(B)** Aggregation of RBCs in cold agglutinin disease

for reticulocytopenic anemia. A marrow aspiration is usually coupled with a marrow biopsy; the former permits observation of cellular detail, whereas the latter provides a histologic section in which the marrow contents can be viewed in relation to the bony architecture housing the hematopoietic elements.

The marrow is the final arbiter in the diagnosis of iron deficiency anemia; iron-deficient erythropoiesis does not result in anemia until all iron has been mobilized from the marrow so that iron stores are absent in these patients. In microcytic anemias due to all other causes, detectable iron stores are present in the marrow. Marrow examination is essential for the diagnosis of sideroblastic anemias. Ringed sideroblasts can only be recognized on a marrow study. A marrow aspirate will reveal the megaloblastic origin of some macrocytic anemias and concomitantly provide an assessment of iron stores. A biopsy of the marrow permits recognition of general aplasia or hypoplasia, pure RBC aplasia, or hematologic malignancy (leukemia, lymphoma, or myeloma) as a cause of anemia. Infiltrative diseases of the marrow, sometimes heralded by a leukoerythroblastic picture (teardrop RBCs, nucleated RBCs, early WBC precursors, or abnormalities in platelet shape) in the peripheral blood, may be the initial manifestation of malignancy. Small cell carcinoma of the lung, and breast and prostate cancers frequently involve the marrow, creating so-called myelophthisic anemia. Myelofibrosis, a heavy deposition of collagen fibers within the marrow, can be demonstrated with special silver stains of the biopsy specimen; this abnormality is a component of myeloid metaplasia (myelofibrosis and extramedullary hematopoiesis) but may accompany such disparate states as hairy cell leukemia or mastocytosis.

The marrow may contain granulomas in tuberculosis or histoplasmosis: [9] culture of *Mycobacterium avium intracellulare* from the marrow of patients with AIDS is a frequent means of diagnosing this complication. The accumulation of pinkish glassy appearing acid mucopolysaccharide (ceroid) occurs in the marrow of patients with anorexia nervosa who develop anemia and other cytopenias secondary to their caloric deficiency state. [10] The presence of Gaucher cells in the marrow may explain an otherwise perplexing splenomegaly. [11]

The marrow examination is an initial tool in evaluation of the patient with reticulocytopenic anemia. Because it is an uncomfortable and frightening procedure, every effort should be made to minimize the number of times it must be performed in an individual patient. Anticipation of the specific information

desired should dictate handling of the specimen. Culture materials should be on hand if infection such as tuberculosis is a consideration; flow cytometry or chromosomal studies requiring special media should be arranged in advance. If marrow aspiration is not possible, a touch preparation of the biopsy specimen may provide enough cells to allow a diagnosis. Inaspirable marrows are frequent in myelofibrotic states; the very hypercellular marrows of leukemia or megaloblastic anemias may also resist aspiration.

Integration of Laboratory Data with History and Physical Examination Findings

Specific measurements of hematologic parameters are essential for differential diagnosis, but findings from the history and physical examination are equally crucial. The chronology of the process can be a useful clue: a previous record of an abnormal blood examination or a positive family history suggests an inherited, congenital form of anemia. Direct examination of a parent's hematologic values may confirm an autosomal dominant pattern of an inherited blood disorder. A family history of immune disease, including thyroid, adrenal, and skin (vitiligo) disorders, may suggest pernicious anemia because of the congregation of these immune-mediated diseases in family constellations. [12] The patient's occupation (lead and possible toxin exposures), social habits (alcohol and intravenous drug abuse), travel history (malaria), and diet (folate, iron) are all central to discovering the cause(s) of anemia. The presence of nonhematologic disease states such as renal failure, HIV/AIDS, carcinomatosis, autoimmune disease, or hepatic failure must be recognized, because these and other states can cause anemias or alter their behavior. Drug ingestion history is an essential component of any investigation of anemia; some perplexing anemias have been explained only after the contents of the medicine cabinet were individually reviewed.

The rate at which the anemia develops usually determines the symptoms experienced by the patient. Age and cardiovascular condition are also important in this connection. The classic signs of acute blood loss (tachycardia, postural hypotension) may not be present in chronic anemias, even if severe; the total blood volume may actually be increased in the latter situation secondary to an overexpanded plasma volume. Indeed, rapid administration of a blood transfusion to a patient with

severe chronic anemia may precipitate cardiopulmonary decompensation by aggravating an already expanded blood volume. The intersection of the decreased hemoglobin oxygen-carrying capacity with myocardial ischemia can result in elderly anemic patients presenting initially to a cardiologist. Cardiac symptoms may extend from dyspnea and weakness to angina and frank myocardial infarction.

The remainder of the physical examination may suggest or confirm the type and source of anemia. Both folate and vitamin B_{12} deficiency create the same morphologic type of megaloblastic, macrocytic anemias, but vitamin B_{12} deficiency is also responsible for the neurologic lesion of subacute combined degeneration, with loss of vibratory and position sensation in the lower extremities. Telangiectasis on the buccal mucosa may be the external evidence of the internal bleeding telangiectatic lesions in Osler-Weber-Rendu disease; this hereditary hemorrhagic disease usually presents as a chronic iron deficiency anemia. Jaundice may be the clue to hemolysis or liver disease. A caput medusae vascular pattern over the abdominal wall indicates portal hypertension with splenomegaly, resulting in a hypersplenic, pancytopenic state. Leg ulcers may accompany hemolytic anemias, especially sickle cell disease. Thus, the entire body must be examined in an effort to uncover the cause of anemia.

Because the hematologic system acts as a sickness index of the body's condition, hematologic abnormalities are frequently the clue to the presence of systemic disorders. The anemia of chronic disorders is an involvement of erythropoiesis in the host response to a broad range of bodily insults. [13] Infection, inflammation, and malignancy are all accompanied by this form of anemia.[14]

The problem in diagnosing these disorders may be complicated because fever, a common accompaniment of infection, inflammation, or malignancy, may also be caused by the primary hematologic process. Both hemolytic and megaloblastic anemias may have significant fever as a component of their presentation. Additional confusion arises because the classic manifestations of infection, such as Roth spots in endocarditis, may be due to severe anemia without any contribution of endocarditis.

Malignancies are also frequently accompanied by anemia even in the absence of direct marrow involvement by the tumor. Anemia may advertise the silent presence of a hypernephroma or pancreatic neoplasm.[15] Both acute and chronic renal diseases have a direct effect on erythropoiesis, which is not surprising, in light of the kidney's function as the source of erythropoietin. [16] The appearance of anemia in a diabetic individual may be the key indication that renal deterioration secondary to diabetic nephropathy has occurred. Anemia becomes an almost universal cause of morbidity as renal failure advances.

Endocrine disease also involves anemia as a frequent complication because most of the body's hormones have direct effects on erythrocyte production. Hypothyroidism is associated with an anemia that represents a down-tuning of the erythroid mass to parallel the lowered metabolic demands of the body. Parathyroid, adrenal, and pituitary disorders may all contribute to an anemic state. [17] [18]

Mild anemias that accompany primary nonhematologic disorders may be the minor detail that leads to the major diagnosis. Examination of the blood may provide a computer readout of the body, but this information must be integrated with the history and physical examination findings. It is this integration of data within a broad framework of diagnostic possibilities that constitutes the challenge in the approach to the patient with anemia.

Approach to Anemia with Decreased Red Cell Production

Patients with anemia and a low reticulocyte count have inadequate RBC production. Evaluation of the cause of such anemias may be guided by the MCV of the circulating red cells. [19] [20] None of the distinctions made below in characterizing microcytic, normocytic, and macrocytic anemias is absolute; nevertheless, the MCV can provide a useful guide to the analysis and laboratory investigation of the anemic patient.

Evaluation of Microcytic Anemia

Microcytic anemias generally result from inadequate hemoglobin synthesis. The failure of hemoglobin production may be caused by hereditary defects in globin synthesis, as in thalassemia; by defects in heme synthesis, as in sideroblastic anemias; or by inadequate iron incorporation into the heme moiety because of either iron deficiency or failure of iron mobilization, as seen in the anemia of chronic disease.

The laboratory evaluation of microcytic anemia should include determination of iron indices, namely serum iron, iron-binding capacity, and ferritin; examination of the peripheral blood smear for evidence of thalassemia trait or coarse basophilic stippling suggestive of sideroblastic anemia; and hemoglobin electrophoresis to assist in defining a potential thalassemia trait. The definitive diagnosis may require bone marrow aspiration to assess both iron stores and the effectiveness of iron incorporation into developing red cell precursors.

APPROACH TO ANEMIA WITH LOW MCV AND LOW RETICULOCYTES

Differential diagnosis

- Iron deficiency
- Sideroblastic anemia
- Thalassemia trait
- Anemia of chronic disease

Laboratory evaluation

- Iron, iron-binding capacity, and ferritin
- Examination of peripheral blood smear for evidence of target cells, stippling, etc.
- Hemoglobin electrophoresis for evidence of thalassemia
- Bone marrow aspirate for definition of iron stores, presence of ring sideroblasts.

Iron deficiency is by far the most common cause of anemia in general and of microcytic anemia in particular. In iron deficiency, the total serum iron should be low, and saturation of the serum iron-binding capacity should be less than 10%. [21] In patients who are iron deficient but who have recently ingested iron supplements, these measurements are unreliable. By contrast, serum ferritin, which is a reflection of total body iron stores, is essentially always low in iron deficiency regardless of iron therapy.[22] It must also be remembered that early iron deficiency is generally a normocytic anemia. (A useful guide is that the hematocrit usually falls to <30 before the MCV declines to <80.) Moreover, the RDW value is invariably elevated by the time iron deficiency anemia becomes microcytic. Consequently, evaluation of iron indices is indicated in virtually all anemic patients. Because iron deficiency is essentially always a sign of chronic blood loss, confirmation of the diagnosis in adult

men and postmenopausal women commits the physician to a full evaluation of the gastrointestinal tract to rule out a malignant bleeding source.

In sideroblastic anemia and in thalassemia trait, iron levels are usually normal to high, iron-binding capacity is normal, and ferritin levels are normal to high. [23] Although associated with profound microcytosis, thalassemia intermedia and thalassemia major do not present a diagnostic problem in this setting, as they are both associated with a slightly elevated (27%) reticulocyte count and characteristic physical stigmata of massive bone marrow expansion (see Chap. 29). Sideroblastic anemia is confirmed by the presence of ringed sideroblasts in a bone marrow aspirate (see Chap. 27). Confirmation of -thalassemia trait is by hemoglobin electrophoresis. -Thalassemia trait, in which two of the -globin alleles are deleted, causes microcytosis but minimal anemia, if any. If the diagnosis is suspected, it should be evaluated on a peripheral blood smear because the hemoglobin electrophoresis in -thalassemia is normal. Definitive confirmation can only be obtained with DNA analysis of the -globin gene loci. [24]

The most troublesome diagnostic difficulty related to microcytic anemia is in identifying the anemia of chronic disease. Although usually presenting as a normocytic anemia, this disorder must always be considered in the differential diagnosis of microcytic anemia. [25] [26] No definitive test will confirm a diagnosis of anemia of chronic disease; patients with this anemia classically have low serum iron levels, low iron-binding capacity, and elevated serum ferritin levels. In general, the saturation of the iron-binding capacity is >10%. The diagnosis is primarily one of exclusion, and diagnostic studies may involve a bone marrow aspirate confirming adequate iron stores with poor iron incorporation into siderocytes.

Evaluation of Macrocytic Anemia

The macrocytic anemias can be divided into two major groups, the megaloblastic anemias (see Chap. 28) and the nonmegaloblastic macrocytic anemias. The two can be distinguished on examination of the peripheral blood smear. Megaloblastic anemias affect all hematopoietic cell lines, and the peripheral smear shows evidence of hypersegmented neutrophils and large platelets. [27] [28] These cell lines are often depressed in megaloblastic anemia as well, and patients may in fact present with pancytopenia. By contrast, the nonmegaloblastic macrocytic anemias, other than those due to reticulocytosis, usually reflect membrane cholesterol defects related to constitutional abnormalities such as liver disease or hypothyroidism; consequently, the WBCs and platelets should be morphologically normal.

Additional laboratory evaluations include determination of RBC serum folate and serum vitamin B_{12} levels in patients with megaloblastic anemia, and thyroid and liver function tests in patients with isolated macrocytosis.

The main diagnostic challenge in evaluating patients with macrocytic anemia is identifying myelodysplastic syndromes. Although these syndromes are classically associated with megaloblastic changes, evidence of megaloblastic abnormalities in the peripheral blood of patients with myelodysplasia is frequently subtle or absent. [29] [30] In patients in whom megaloblastic anemia occurs despite normal serum folate and vitamin B_{12} levels, bone marrow aspiration and biopsy should be done to determine whether a myelodysplastic syndrome is present. Patients with an unexplained macrocytic anemia should also undergo bone marrow examination. The marrow evaluation should include cytogenetic studies.

In patients with megaloblastic anemia related to vitamin B_{12} deficiency, a Schilling test should be done to evaluate the presence of pernicious anemia. (The measurement of anti-intrinsic factor or antiparietal cell auto-antibodies is supplanting the Schilling test.) If that diagnosis is confirmed, evidence of other endocrine abnormalities, notably thyroid or adrenal insufficiency, or of gastrointestinal disease, should be sought.

Evaluation of Normocytic Anemia

The evaluation of normocytic anemias is complicated by the fact that many of the anemias classically associated with microcytosis or macrocytosis may in fact occur with a normal MCV, especially in the early stages. Iron deficiency, acquired sideroblastic

APPROACH TO ANEMIA WITH ELEVATED MCV AND LOW RETICULOCYTES

- Differential diagnosis
  - Megaloblastic anemia
    - Vitamin B_{12} deficiency
    - Folate deficiency
    - Myelodysplastic syndrome
    - Drug-induced anemia
  - Nonmegaloblastic anemia
    - Liver disease
    - Hypothyroidism
    - Reticulocytosis
  - Laboratory evaluation
    - Serum vitamin B_{12} , RBC folate
    - Examination of peripheral smear for hypersegmented neutrophils, giant platelets
    - Thyroid function tests, liver function tests
    - Bone marrow aspirate for evaluation for myelodysplastic features

APPROACH TO ANEMIA WITH NORMAL MCV AND LOW RETICULOCYTES

Differential diagnosis

- Early or mild iron deficiency
- Primary bone marrow failure
  - Aplastic anemia
  - Constitutional red cell aplasia (Diamond-Blackfan)
  - Acquired red cell aplasia
  - Myelophthisis
- Secondary bone marrow failure
  - Uremia
  - Endocrinology
  - Human immunodeficiency virus infection
  - Anemia of chronic disease

Laboratory evaluation

- Iron, iron-binding capacity, and ferritin
- Examination of peripheral blood smear for evidence of myelophthisis: teardrops, helmet cells, etc.
- Serum creatinine, thyroid function tests, liver function tests, cortisol levels if appropriate
- Erythropoietin level
- Bone marrow aspirate and biopsy to assess iron stores, red cell production, marrow cellularity

anemia, myelodysplasia, and the anemia of chronic disease all frequently manifest as normocytic anemias. In addition, mixed anemias (e.g., anemia in a patient who is both folate and iron deficient) may result in a normal MCV. Examination of the peripheral blood smear in patients with mixed anemias will reveal a mixed population of RBCs, which may help resolve the dilemma. The guide to the differential diagnosis of normocytic anemia, outlined in the box, consequently is not exhaustive. Early stages or mixtures of microcytic and macrocytic anemias must be considered as well.

The initial evaluation of a patient with a normocytic anemia should include iron studies because of the frequency with which iron deficiency presents as a normocytic anemia. Thereafter the evaluation focuses on establishing the presence or absence of a primary bone marrow failure syndrome. The diagnosis of aplastic anemia, red cell aplasia, or myelophthisis ultimately rests on examination of the bone marrow aspirate and biopsy specimen (to assess marrow cellularity, red cell production, and the presence of abnormal cells within the marrow); however, an inappropriately low reticulocyte count is usually a major initial clue. Examination of the peripheral smear may suggest the presence of myelophthisis, which is associated with teardrop cells and other morphologic red cell abnormalities (Fig. 23-8).

Secondary causes of bone marrow failure are sometimes readily recognizable. Most common among these is the anemia associated with uremia. A frequent dilemma in diagnosing uremia as the cause of anemia is the poor correlation between the serum creatinine level and the degree of anemia seen in the patient. This probably reflects the lack of a direct correlation between the loss of erythropoietin production and loss of glomerular function in the failing kidney. [31] [32] With the availability of erythropoietin assays it is now possible to assess the impact of renal dysfunction on RBC production. Individuals with anemia secondary to renal failure have low erythropoietin levels; virtually all other anemic persons have normal or elevated levels.

Many endocrine disorders, including hypothyroidism, hypoadrenalism, and hypopituitarism, are associated with mild anemia. [33] Although hypothyroidism may cause a macrocytic anemia, it is more commonly associated with a normocytic anemia.[34] Hyperthyroidism is also associated with anemia. Serum tests of endocrine function should be performed in keeping with the clinical picture of the patient.

The anemia in patients with human immunodeficiency virus (HIV) infection is multifactorial and is discussed in detail in Chapter 154 . The bone marrow commonly shows features compatible with the anemia of chronic disease. Other findings include plasmacytosis, lymphoid aggregates, and evidence of granulomatous disease in the marrow.[35]

Approach to Anemia with Increased Red Cell Turnover

Patients with anemia and an elevated reticulocyte count usually have adequate marrow function. The red cell turnover rate is increased, owing to acute blood loss, RBC sequestration, or hemolysis. If the reticulocyte response is adequate, bone marrow examination usually is not necessary in these patients because the disease process is extrinsic to the marrow. The initial evaluation should also establish whether there is evidence of acute bleeding or an enlarged spleen. The remainder of the evaluation is directed toward determining the cause of the hemolytic diathesis.

Patients who have spherocytes in the peripheral blood should be studied for the presence of warm antibody-mediated immune hemolysis by a direct and an indirect Coombs test.[36] Patients with a negative Coombs test should be tested for the presence of cold agglutinins and for other, rarer immune hemolytic disorders such as paroxysmal cold hemoglobinuria (see Chap. 34). [37] [38]

The evaluation of nonimmune hemolytic disorders is guided by the peripheral blood smear findings and the clinical history

APPROACH TO ANEMIA WITH ELEVATED RETICULOCYTE COUNT

Differential diagnosis

- Acute blood loss
- Splenic sequestration
- Hemolysis
  - Immune hemolytic anemia
  - Mechanical hemolysis
    - Valve hemolysis
    - Microangiopathic hemolytic anemia (DIC, TTP)
  - Hereditary hemolytic anemia
    - Hemoglobinopathies
    - Enzyme defects: G6PD deficiency, pyruvate kinase deficiency, etc.
    - Membrane defects: spherocytosis
    - Unstable hemoglobins
  - Acquired membrane defects: PNH, spur cell anemia
  - Infection-related hemolysis: *Clostridia* infection, malaria, babesiosis

Laboratory evaluation

- Examination of the peripheral blood smear for evidence of spherocytes, microangiopathic changes, features of hemoglobinopathies, bite cells
- Urinary hemosiderin
- Direct and indirect Coombs test
- Cold agglutinin titer
- Appropriate further tests as indicated by preliminary evaluation: hemoglobin electrophoresis, G6PD screen, Heinz body preparation, isopropanol stability test, P_{50} , sucrose lysis test, bacterial cultures, examination of smear for malaria, babesiosis, bartonellosis

EVALUATION OF HEMOLYTIC ANEMIA

The evaluation of hemolytic anemia can be guided by the findings in the peripheral blood smear. The smear may allow the crucial distinction to be made between immune and nonimmune hemolysis; this determination will then guide further evaluation. Spherocytes and microspherocytes are classic markers of immune hemolytic anemia; fragmented RBCs are markers of intravascular, nonimmune hemolytic anemia. Since extravascular hemolysis within the spleen does not result in hemoglobinemia, hemoglobinuria, or hemosiderinuria, detection of any of these implies an intravascular hemolytic process. Acute severe intravascular hemolysis may cause detectable hemoglobinemia, which can be seen on visual inspection of the patient's plasma. Hemoglobinuria may be detected with recent intravascular hemolysis. Chronic intravascular hemolysis can be detected by assays for urinary hemosiderin.

(see Chap. 35). Microangiopathic changes in the peripheral blood smear should be viewed in the clinical context in which they occur. Low-grade anemia in a patient with a prosthetic heart valve is probably due to a mechanical hemolysis, which may be chronic and insignificant, but an acute increase in hemolysis from a prosthetic valve should lead to evaluation for perivalvular leak or other valvular dysfunction. [39] Other causes of microangiopathic changes, specifically disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura (TTP), usually present as acute medical emergencies. [40] [41] In both settings the platelet count is usually decreased. The distinction can be made by clinical evaluation for evidence of a basis for DIC and by the presence of other markers of TTP, such as fever, neurologic dysfunction, or renal insufficiency. The diagnosis of DIC can be supported by elevations in the prothrombin time (PT) and partial thromboplastin time (PTT), which are most often normal in TTP. Low-grade chronic DIC, as may occur with malignancy, may require more extensive evaluation of fibrinogen and fibrin degradation products. [42]

The peripheral smear will also provide ample evidence for most hereditary hemolytic anemias. Sickle cell anemia (see Chap. 30) and severe thalassemia are usually readily diagnosed from a peripheral blood smear, and appropriate follow-up with hemoglobin electrophoresis will confirm the diagnosis. Hereditary membrane defects that give rise to spherocytosis or elliptocytosis are also diagnosed by examination of the peripheral smear (see Chap. 33).

Enzyme defects (see Chap. 32) of the RBC, most commonly G6PD deficiency, may manifest quite late in life, usually in the setting of an acute oxidant stress. [43] Evidence of a disorder in the peripheral blood smear is detectable as bite cells, which reflect splenic conditioning of red cells containing precipitated hemoglobin. [44] If this diagnosis is suspected, a Heinz body smear should be done to look for precipitated hemoglobin in circulating red cells, and G6PD levels should be determined. However, in the setting of an acute hemolytic episode, the circulating young red cells will have higher levels of G6PD, and most or all of the older cells with a very low G6PD level will have been cleared. Consequently, both the Heinz body smear and the G6PD assay may be negative. In this case the G6PD level should be

reassayed when the patient has recovered from the acute hemolytic episode.

Heinz body anemia is also seen in patients with unstable hemoglobins (see Chap. 31).[45] [46] The diagnosis can sometimes be made by hemoglobin electrophoresis, although many unstable hemoglobins are electrophoretically normal. Some show decreased stability in isopropyl alcohol, and others show an altered oxygen dissociation curve.

Other rare causes of nonimmune hemolysis include paroxysmal nocturnal hemoglobinuria (PNH) (see Chap. 20), which results in an acquired membrane defect in the red cell, thereby predisposing the cell to complement-mediated lysis. [47] Patients with PNH may be diagnosed by analysis of acid hemolysis, sucrose lysis, or cell surface marker. The leukocyte alkaline phosphatase score in patients with PNH is also low. Another acquired membrane defect that can be readily diagnosed from the peripheral blood smear is spur cell anemia, which is seen in patients with advanced cirrhosis. The smear reveals striking acanthocytosis; hemolysis results from splenic destruction of the abnormal red cells. [48]

Toxic hemolysis can result from parasitic and bacterial infections. Malaria, babesiosis, and bartonellosis cause hemolysis by direct parasitization of RBCs (see Chap. 35).[49] [50] [51] The appropriate diagnosis can be made from smears of the peripheral blood; in malaria and babesiosis, thick smears are frequently necessary to visualize the parasites. Dramatic, overwhelming hemolysis may be seen in patients with clostridial sepsis. The course of these patients is usually one of fulminant hemolytic anemia, shock, and death even before the bacterial diagnosis can be made. [52]

ANEMIA IN THE CHILD

The classification of anemia (Greek, without blood) can be based on physiologic, morphologic, or etiologic factors. The prospective approach to any individual patient, however, requires integrating the history and physical examination findings with results of laboratory tests (blood count, red cell indices, reticulocyte count, RBC morphology, specific tests [e.g., Coombs], hemoglobin electrophoresis, etc.), all directed toward determining the underlying disease or process. This section discusses only the special aspects of evaluating anemia in children.

The most straightforward approach to the diagnosis of anemia in both children and adults considers several broad categories: (1) decreased production of RBCs or blood loss; (2) size of RBCsnormal (normocytic), too large (macrocytic), or too small (microcytic); (3) knowledge of the relative frequency of the causes of anemia at various ages; and (4) an appreciation that the diagnosis of anemia depends on normal values related to the patient's age, sex (Table 23-3 (Table Not Available)), [53] cardiopulmonary status, and residence. Children from 6 months to 12 years of age appear anemic compared with adults, but children have higher concentration of 2,3-diphosphoglycerate and ATP in their RBCs, with a corresponding shift to the right of the oxygen dissociation curve. Increased tissue oxygenation compensates for the lower hemoglobin concentrations. The apparent anemia is thus a physiologically appropriate adaptation of the red cell mass to the increased efficiency of oxygen delivery.

The approach to a child with anemia differs from that for an adult in several ways, because of factors related to (1) age differences in normal values for hemoglobin/hematocrit (Hb/Hct) (Table 23-3 (Table Not Available)); [53] (2) the much lower incidence of neoplastic disease in childhood as either a direct or an indirect cause of anemia (<7,000 of the 1,000,000* new cases of cancer each year in the United States occur in individuals <15 years of age); (3) iron deficiency, which is almost always secondary to nutritional factors in children and requires less intensive follow-up evaluation; (4) the relative rarity of alcoholism and its related liver disease as an underlying problem in children; (5) anemia associated with thyroid disease, which is much less common in childhood; (6) the rarity of cardiovascular disease other than congenital heart disease, so that valve replacement, malignant

AN APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ANEMIA IN THE NEWBORN

TABLE 23-3 -- Red Blood Cell Values at Various Ages: Mean and Lower Limit of Normal (2 SD)

(Not Available)

Adapted from Dallman and Siimes,[53] with permission, as appeared in Oski FA: Pallor. In Kaye R, Oski FA, Barness LA (eds): Core Textbook of Pediatrics. 3rd ed. JB Lippincott, Philadelphia, 1989, p. 62, with permission.

hypertension, and the use of certain drugs are usually not factors; and (7) the frequent difficulty of obtaining adequate specimens for evaluation from newborns and neonates, especially for hemolytic processes such as pyknocytosis. Clinically significant anemia in childhood is more often associated with a primary hematologic abnormality (e.g., hypoplastic or hemolytic anemia), whereas in adults, anemia is more often a secondary manifestation of underlying illness. It is often emphasized that anemia is a symptom, not a disease; this is equally true in children, but the primary cause is in the hematopoietic system more frequently in children than in adults.

Anemia of clinical importance is relatively uncommon in children. When it does occur, the patient's age is often a helpful guide in identifying the underlying process. In the newborn, anemia is most often associated with blood loss or hemolysis. During the neonatal period and early infancy, pure red cell aplasia must be considered, and blood loss becomes a less important cause. Physiologic anemia also develops during this time and is accentuated in preterm infants (Fig. 23-12).[54] [55] [56] [57] From 6 months through 2 years, nutritional anemias and those associated with acute inflammation predominate, after which bone marrow infiltration (e.g., acute lymphocytic leukemia) becomes an important factor. Nutritional deficiency, in particular iron deficiency, becomes a major consideration again during adolescence.

Figure 23-12 Hemoglobin concentration and reticulocyte counts in premature and term infants. Mean values (red line) and 95% confidence intervals are indicated for each of three birth weight categories. (Hemoglobin values are from Lundström et al. [55] and Saarinen and Siimes,[56] reticulocyte values are unpublished data on the same infants from whom hemoglobin values were derived.) *(From Dallman,[57] with permission.)*

FEATURES OF THE PERIPHERAL BLOOD SMEAR OF DIAGNOSTIC IMPORTANCE FOR ANEMIA INTERPRETATION

Red Blood Cell Morphology	Interpretation
Normochromic normocytic	Acute inflammation
Hypochromic microcytic	Iron deficiency, thalassemias, lead poisoning, vitamin B_6 deficiency, sideroblastic processes, chronic inflammation
Macrocytic	Normal newborn, shift cells (reticulocytes), folate or vitamin B_{12} deficiency (macro-ovalocytes)
Target cells	Thalassemias, hemoglobins C, E, and S, liver disease, abetalipoproteinemia, postsplenectomy
Basophilic stippling	Hemolytic anemias, iron deficiency, thalassemias, lead poisoning
Heinz bodies	Normal newborn, hexose-monophosphate shunt abnormalities (e.g., G6PD deficiency, unstable hemoglobins, postsplenectomy)
Howell-Jolly bodies	Splenic hypofunction or absence, megaloblastic anemia
Teardrop cells	Bone marrow infiltration (leukoerythroblastosis)
Spherocytes	ABO incompatibility, G6PD deficiency or other hemolytic anemias, hereditary spherocytosis, hypophosphatemia
Schistocytes	Thalassemia, microangiopathic process (DIC)
Nucleated RBCs	Normal for first several days; hemolytic anemia, acute blood loss, or metaplasia
Polychromasia	Shift cells

Children who are anemic infrequently present in extremis; thus, there is ample opportunity to review the history (Table 23-4) and physical examination findings before ordering laboratory tests. In addition, patients who are anemic (in this section, a hematocrit or hemoglobin value 2 SD below normal for age is taken as the definition of anemia) may be functionally normal with respect to oxygen delivery in the microcirculation because of a compensatory shift to the right of the oxygen disassociation curve.

The history can often help focus on a diagnosis, but the physical examination findings are more often nonspecific. In children, signs of anemia include pallor (often misleading), sallow hue, color of the mucous membranes, jaundice, tachycardia, palpitations, wide pulse pressure, fatigue, dyspnea, poor feeding, weight gain, or other evidence of cardiac decompensation or decreased oxygen transport. Bruising, petechial and overt bleeding, splenomegaly, other abdominal organomegaly, and lymphadenopathy may point to an underlying process responsible for the anemia. In children, it is important to be alert to the specific dysmorphic features of Diamond-Blackfan and Fanconi anemias, vascular and skin changes of sickle cell anemia and sickle C disease, and the facies of -thalassemia major, since these congenital defects usually become symptomatic early in life.

The history is particularly important when deciding which patients should undergo further evaluation, especially when deviations of Hb/Hct from the normal range are small. Mild infections are common and recurrent during childhood, especially during the first several years. These mild infections can result in a transient decrease in Hb/Hct of sufficient magnitude

TABLE 23-4 -- Historical Factors That May Be of Importance in the Diagnosis of Anemia in Children

Factors	Newborn1 mo	1 mo1 yr	Older Infants Children, and Adolescents
Prematurity	Blood loss due to procedures, vitamin E deficiency, anemia of prematurity may respond to erythropoietin	Predisposes to iron deficiency	
Maternal			
Drug ingestion			
Dilantin Warfarin	Bleeding due to hypothrombinemia, treated with vitamin K		
Diuretics	Bleeding due to thrombocytopenia		
Sulfa, etc.	Hemolysis due to G6PD deficiency		
Infections			
Toxoplasmosis Syphilis Herpes	Bleeding due to thrombocytopenia or anemia secondary to red cell aplasia, hemolysis, or inflammation		
Rubella Hepatitis Cytomegalovirus Group B streptococcus			
Mechanical			
Placenta previa			
Abruptio placentae	Blood loss	Predisposes to iron deficiency	
Precipitous delivery			
Amniocentesis			
Cesarean section	Fetomaternal hemorrhage		

Hydralazine			Coombs test positive but rarely produces anemia
Socioeconomic		Pica: lead	
Prevalence of intoxication of iron deficiency is inversely related to status			
Systemic illnesses			
Cardiac disease: prosthetic valves or intracardiac patches		Waring blender syndrome and hemolysis	
Endocarditis			Anemia of chronic disease
Gastrointestinal			
Celiac disease, regional enteritis, ileal resection, chronic atrophic gastritis			Iron and vitamin B_{12} deficiency
Ulcerative colitis and Osler-Weber-Rendu disease			Iron deficiency
Cystic fibrosis		Vitamin K and E deficiency and anemia responsive to protein enrichment	
Liver disease			
Active processes		Shortened red blood cell survival and increased Heinz-body formation	
Renal disease			
Uremia		Shortened red blood cell survival Decreased red blood cell production	
Bloody diarrhea		Microangiopathic process (e.g., hemolytic uremic syndrome or thrombotic thrombocytopenic purpura)	
Dialysis			Folate deficiency
Hypothyroidism		Normochromic normocytic anemia with occasional irregularly contracted cells	
Collagen vascular diseases		Anemia of chronic disease with or without iron deficiency	
Infectious diseases			
Mild infections (e.g., otitis media, pharyngitis, gastroenteritis)		Transient mild decrease in hemoglobin/hematocrit (beware of evaluating mild anemias in children with intercurrent infections/inflammation)	
Sepsis (bacterial, viral, *Mycoplasma*)		Hemolytic anemias	

to suggest the presence of iron deficiency anemia, long considered the most likely cause of mild anemia in childhood, [58] [59] [60] even though iron deficiency anemia has recently become much less common in both low-income families and middle-class families. [61] [62] In the latter, a 3% prevalence of iron deficiency anemia was found in healthy children in Minneapolis. [62] The very low prevalence is almost identical to the 2.4% of normal individuals whose Hb/Hct falls to <2 SD in a normal distribution. This makes screening, further evaluation, and subsequent treatment uncertain on the basis of Hb/Hct alone. The decision concerning further evaluation in the setting of mild anemia should include the historical factors listed in Table 23-4 , socioeconomic status, and temporal relationship to mild infections. This will facilitate the differentiation of iron deficiency, thalassemia trait, and acute inflammation, the most common causes of anemia in childhood.

The basic laboratory evaluation for anemia, including accurate interpretation of the blood smear, often confirms the underlying process or suggests what further tests need to be done.

Collection and processing of specimens are considered routine but may introduce confounding variables, especially in very young children and in those who are quite ill. Finger sticks or heel sticks often produce Hb/Hct values greater than values in simultaneously obtained venous samples as a result of stasis of blood in the finger or heel. The extremity must therefore be warmed before the blood sample is drawn. An erroneously low Hb/Hct value can also be obtained if excessive pressure is used or the extremity is milked, thereby diluting the sample. Perfusion problems related to hydration status, cardiac disease, or infection must also be considered.

If the hematocrit is determined after capillary tube centrifugation, plasma trapping may lead to slightly higher values than those obtained by automated electronic methods. This difference can be accentuated by extreme anisocytosis, as in sickle cell disease, severe iron deficiency, and thalassemia.

In practice, the physician usually finds a hemoglobin or hematocrit value that is below the accepted range of normal. If these values are obtained in a laboratory with electronic cell counting, then red cell indices, RBC count, WBC count, and often the platelet count are included. The smear may or may not be noted. The physician must then decide whether to order further investigations (e.g., the free erythrocyte protoporphyrin is a simple, rapid alternative approach to detecting iron deficiency) or, if the history is consistent and there has been no infection within the previous month, undertaking a therapeutic trial of iron (3 mg/kg/day of ferrous sulfate or its equivalent for 1 month) and rechecking the hemoglobin at that time. An increase in hemoglobin of at least 1 g/dl after treatment indicates that iron deficiency was the correct diagnosis. If the patient is unresponsive or the response is incomplete, compliance must be reviewed (color of stools and amount of ferrous sulfate remaining in the bottle), RBC indices obtained, and the smear reviewed. This latter approach is justified because iron deficiency is still a frequent cause of anemia in children.

Microcytosis out of proportion to the reduction in hemoglobin concentration suggests thalassemia trait, which can be confirmed by hemoglobin electrophoresis. The hemoglobin electrophoresis should be deferred until iron stores are deemed adequate, since hemoglobin A_2 production may be affected. In a patient with microcytic red cells, a normal hemoglobin A_2 value, and adequate iron homeostasis, -thalassemia trait is inferred. This inference is strengthened by a brilliant cresyl blue preparation that is positive for Heinz bodies. Depending on location and time of year, lead poisoning is an important consideration, not so much for the correction of anemia but for the prevention of neurologic sequelae. A history of pica and the presence of basophilic stippling and elevated free erythrocyte protoporphyrin levels would suggest lead intoxication.

Careful examination of the peripheral smear often indicates abnormalities that point to a specific diagnosis or underlying

TABLE 23-5 -- Differentiation of Diamond-Blackfan Anemia from Transient Erythroblastopenia of Childhood

Parameter	Diamond-Blackfan	Transient Erythroblastopenia
Frequency	Rare	Common (? increasing)
Age of diagnosis	<1 yr (90% <6 mo)	0.54 yr
Etiology	Probably genetic	Acquired
Antecedent history	None	Viral illness
Physical abnormalities	Present (25%)	Absent
Course	Prolonged transfusion or steroid dependence	Spontaneous recovery in weeks to months
Laboratory		
MCV	Macrocytic	Normocytic
Hemoglobin F	Increased	Normal[a]
i Antigen	Present	Absent[a]
Fetal pattern of RBC glycolytic and HMP shunt enzymes	Present	Absent[a]
Elevated RBC ADA activity	Usually present	Usually absent

Data from Glader[63] and Lanzkowsky.[64]

[a]During recovery phase of transient erythroblastopenia, fetal RBC features may be detected.

abnormalities. Perhaps the most difficult group of patients are those with hemolytic anemias and red cell aplasia. In these patients and in those with hemoglobinopathies, critical information can often be obtained by examining the hemograms and peripheral blood smears from the parents. For these patients, the reticulocyte count, corrected as the reticulocyte index, is an important guide to further evaluation.

The three major causes of pure red cell aplasia in children are Diamond-Blackfan anemia, transient erythroblastopenia of childhood (TEC), and acquired hypoplastic anemia associated with chronic hemolysis.[63] Diamond-Blackfan anemia and transient erythroblastopenia are differentiated by the features listed in Table 23-5 .[63] [64] Aplastic crises associated with chronic hemolytic anemias are characterized by the underlying process, the precipitous decrease in reticulocytes and hemoglobin concentration, and the frequent association of human parvovirus B19 (see Chap. 19).

The hemolytic anemias are a complex group of disorders associated with an elevated reticulocyte index (Table 23-6).[65] The

TABLE 23-6 -- Features of Common Congenital Hemolytic Anemias

Diagnosis	Hemoglobin Electrophoresis Pattern		Pattern of Inheritance	Predominant Ethnic Group	Morphology
	Cord Blood	Adult			
Sickle cell diseases					
Sickle cell anemia	FS	SS	Autosomal recessive	Africans, black Americans, Arabs, East Indians, Hispanics, Mediterraneans	Sickle cells, target cells, elliptocytes, nucleated red blood cells, reticulocytosis
S--thalassemia	FSA	SA (A_2 >3.5%)	Autosomal recessive	Africans, black Americans, Arabs, East Indians, Hispanics, Mediterraneans	Microcytes, occasional nucleated RBCs, reticulocytosis, variable sickle cells
SC	FSC	SC	Autosomal recessive	Africans, black Americans, Arabs, East Indians, Hispanics, Mediterraneans	Target cells, rare sickle cells, mild reticulocytosis
CC disease	FC	CC	Autosomal recessive	West Africans, black Americans	Target cells
Unstable hemoglobin	FA	AA	Autosomal recessive	Varies with type	Occasional schistocytes, spherocytes, basophilic stippling, and polychromatophilia (Heinz bodies after brilliant cresyl blue stain, accentuated post splenectomy)
-Thalassemia major and intermedia	FF	FF (A_2 >3.5%)	Autosomal recessive	Mediterraneans, Chinese, East Asians, East Indians	Hypochromic macrocytes, microcytes, basophilic stippling, target cells, ovalocytes, nucleated RBCs, and marked poikilocytosis, anisocytosis, and reticulocytosis
Hb H disease	FA and Bart's >15%	AH	Autosomal recessive	Asians, Filipinos, Indonesians, occasionally Mediterraneans, rarely Africans	Microcytes, target cells (Heinz bodies after brilliant cresyl blue stain)
Hydrops fetalis	Barts	Nonviable			
Spherocytosis	FA	AA	Autosomal dominant	Northern European whites	Variable number of spherocytes (usually >10%), polychromatophilia
Elliptocytosis	FA	AA	Autosomal dominant	Various	Increased number of elliptocytes (may present in infancy as pyknocytosis)
Pyropoikilocytosis	FA	AA	Autosomal recessive	Black and occasionally white Americans	Bizarre poikilocytes
Stomatocytosis	FA	AA	Autosomal recessive and dominant forms	Unknown	1050% stomatocytes, reticulocytosis

Glucose-6-phosphate	FA	AA	X-linked	Africans, black Americans, Mediterraneans, Asians	Spherocytes, nucleated RBCs, polychromatophilia
Pyruvate kinase deficiency	FA	AA	Autosomal recessive	Northern Europeans	Macrocytosis, polychromatophilia

correct diagnosis in an individual patient may be apparent after the history, physical examination, and routine blood studies. Frequently, however, additional tests, including hemoglobin electrophoresis, haptoglobin determination, red cell osmotic fragility, specific assays of RBC enzymes, acid hemolysis test (Ham) or sugar water test, and tests for unstable hemoglobin, must be performed as outlined in other chapters.

Examination of the bone marrow is important in the diagnosis of relatively few kinds (and causes) of anemia in childhood. These conditions include megaloblastic, sideroblastic, aplastic, and dyserythropoietic anemias; acute leukemia; neuroblastoma; and lipid storage diseases.

Anemia is always an important finding that should prompt the physician to consider what underlying process may be responsible. In children, the most common causes of mild anemia, iron deficiency, acute inflammation, and thalassemia trait can be recognized and appropriately treated after a thorough medical history has been taken and a physical examination and routine laboratory tests have been performed. Acquired acute anemias often produce diagnostic and treatment difficulties that demand the critical application of specialized laboratory tests and clinical expertise for appropriate management.

Chapter 24 - Anemia of Chronic Diseases

Lawrence B. Gardner
Edward J. Benz Jr.

The long-term realization that diverse systemic illnesses may cause anemias with similar features has led to the concept of an anemia of chronic disease (ACD). This anemia, first described in chronic infections, was originally thought to reflect a block in iron utilization by red cells. [1] It is now appreciated that ACD may be found in a variety of inflammatory conditions,[2] including infection, rheumatologic disorders, and cancer, and that its etiology is multifactorial, involving not only abnormalities in iron utilization but a decreased life span of erythrocytes, a direct inhibition of hematopoiesis, and a relative deficiency of erythropoietin. Since the late 1980s, the biology and the role of cytokines in ACD has been better characterized, and treatment options have been explored. It is thus now realistic to regard ACD as a distinct pathophysiologic entity.

DESCRIPTION AND EPIDEMIOLOGY

Anemia of chronic diseases is an anemia of underproduction that is usually normocytic, normochromic, and relatively mild, with a hematocrit above 30%. [1] However, the anemia can be severe and the mean corpuscular volume (MCV) may be reduced in approximately 30% of patients[3] ; an MCV as low as 61 fl has been described.[4] ACD is one of the most common causes of anemia; over a 2-month period of observation, 52% of hospitalized patients with anemia who were not iron deficient, hemolyzing, or suffering from a hematologic malignancy met laboratory criteria for ACD [5] ; it has been diagnosed in up to 27% of outpatients with rheumatoid arthritis.[6] This anemia was first described in association with infection, [7] and can be induced experimentally by infection or sterile inflammation. [1] [8] Most hospitalized patients with ACD do have active infection, inflammatory conditions, or malignancy. However, others may have alcoholic liver disease, congestive heart failure, thrombosis, chronic pulmonary disease, diabetes, or a variety of medical problems. [5]

ETIOLOGY AND PATHOGENESIS

Anemia of chronic diseases is marked by low serum iron, but, in contrast to iron deficiency anemia, total iron stores are normal or elevated; these findings appear to parallel disease activity.[9] Early studies emphasized the role of iron in the pathogenesis of ACD.[8] Rats injected intraperitoneally with *Escherichia coli* lipopolysaccharide absorbed significantly less ^{59}Fe in 96 hours compared with control animals.[10] Endotoxin has also been shown to shorten ^{59}Fe serum half-life in rats.[11] Other studies using trace quantities of labeled iron have shown no direct impairment of iron incorporation into red blood cells, suggesting that inflammation might impair the release of iron from storage sites, thus decreasing plasma iron concentrations and also decreasing iron available for hemoglobin synthesis; indeed, sterile inflammation in a dog model impairs only the reutilization of iron from senescent red cells, suggesting that inflammation leads to a defect in the release of iron from tissues to the plasma transferrin pool.[12] Some early studies suggested that increased ineffective erythropoiesis and increased iron turnover occurred in patients with rheumatoid arthritis,[13] but other studies of patients with rheumatoid arthritis and a diagnosis of ACD show that iron turnover is decreased compared with either normal or iron-deficient control subjects.[14] There are several hypotheses of how such a defect in iron turnover could occur in ACD. Decreased transferrin receptors both in the serum[15] and on erythroblasts[16] have been noted in patients with ACD. Others have suggested that increases in the release of lactoferrin from neutrophils[17] or, more convincingly, in the synthesis of apoferritin,[18] lead to a pool of iron trapped in storage form, unavailable for hemoglobin synthesis (Table 24-1).[8]

In theory, any block in iron reutilization would be made more severe with shortened erythrocyte survival. Rats given endotoxin have a reduced erythrocyte half-life,[11] and a mildly shortened erythrocyte half-life has also been noted in patients with rheumatoid arthritis and ACD. However, most studies have found the decrease in survival to be mild. This mild decrease, even in combination with a reduction of hemoglobin precursors, cannot account for the extent of anemia found in most patients. It is probable that other compensatory hematopoietic factors are not functioning in ACD. Indeed, it is now thought that many of the abnormalities in iron are secondary to changes in hematopoiesis.

Two documented changes in hematopoiesis include (1) a direct inhibition of hematopoiesis, and (2) a relative deficiency of erythropoietin. The inhibition of hematopoiesis found in ACD is thought to be due to soluble factors present in the perturbed bone marrow microenvironment, as discussed in greater detail in the section on the biology of the disease. Studies have shown that removal of bone marrow-adherent cells (mostly macrophages and monocytes) from patients with ACD leads to increased erythroid colony formation; this can be reversed by coculture of ACD adherent cells but not by adherent cells from control marrow.[19] In a study of patients with rheumatoid arthritis with ACD, the numbers of erythroid progenitors in control and anemic patients were similar (not accounting for the difference in anemia between the two groups). Serum from patients with rheumatoid arthritis with anemia produced decreased erythroid burst-forming unit (BFU-E) proliferation, whereas serum from non-anemic arthritic patients did not.[20] Peripheral blood mononuclear cells from patients with rheumatoid arthritis also suppress in vitro BFU-E growth.[21]

Most of the supporting data for a direct inhibition in hematopoiesis are derived from in vitro studies. Data from more clinically relevant studies have clearly documented that in many chronic diseases associated with anemia, there is a *relative* deficiency of erythropoietin. Although serum erythropoietin levels may be increased, they are not as elevated as they should be for the degree of anemia present. In a study of 81 patients with solid tumors who exhibited laboratory data compatible with ACD without marrow involvement by tumor, the erythropoietin levels were higher than in control subjects without anemia, but were only half of what are typical of subjects with similar

TABLE 24-1 -- Etiologies of Anemia of Chronic Disease

1.	Block in reutilization of iron by erythrocyte
2.	Shortened erythrocyte survival
3.	Direct inhibition of erythropoiesis
4.	Relative deficiency of erythropoietin

hematocrits due to iron deficiency. In addition, the normal inverse relation between hemoglobin and erythropoietin level was not seen.[22] In 41 anemic patients with rheumatoid arthritis, 14 of whom had plentiful iron on bone marrow aspirate, serum erythropoietin levels for all rheumatoid patients were lower than for those with simple iron-deficiency anemia and comparable hemoglobin levels.[23] Serum erythropoietin has also been shown to be inappropriately low in human immunodeficiency virus (HIV)-positive patients with normochromic normocytic anemia,[24] and in lung transplant recipients.[25]

There are reports of diabetics with anemia, normal renal function, and lower-than-expected erythropoietin levels; this has been hypothesized to be secondary to diabetic neuropathy,[26] although there may also be a direct role of insulin on stem cells.[27] Up to 40% of patients with chronic liver disease are anemic, and although this anemia is clearly multifactorial, some studies have found a blunted erythropoietin response to anemia seen in cirrhosis.[28] However, at least one study of veterans with anemia and alcoholic liver disease found a serum erythropoietin level appropriate for the degree of anemia.[29] As is discussed later, the fact that exogenous erythropoietin can correct ACD supports the role of a relative erythropoietin deficiency as one of its main causes.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BIOLOGY AND MOLECULAR ASPECTS

An understanding of the role that inflammatory cytokines play in many of the diseases associated with ACD has suggested an underlying mechanism for much of its pathophysiology, including decreased erythrocyte survival, increased apoferritin synthesis, direct inhibition of hematopoietic progenitor growth, and an inadequate erythropoietin response to anemia.

Increased serum levels of cytokines, particularly interleukin-1 (IL-1), IL-6, tumor necrosis factor (TNF), and interferon- (INF-) and INF-, have been noted in many inflammatory diseases, including acquired immunodeficiency syndrome (AIDS) and other infections, rheumatoid arthritis, and cancer. [30] TNF, as the name implies, has been clearly shown to be elevated in patients with both solid and hematologic malignancies, as have several other cytokines. [31] Peripheral blood mononuclear cells from patients with rheumatoid arthritis secrete TNF-. [21] TNF- levels correlate with disease activity and the degree of anemia in patients with rheumatoid arthritis. [32]

Cytokines can induce many of the intestinal and extraintestinal symptoms of inflammatory bowel disease; the serum and intestinal mucosal concentrations of many cytokines, especially IL-1 and IL-6, have been found to be increased in inflammatory bowel disease, [33] with antigenic levels of IL-6 correlating with disease severity. [34] An increase in INF- mRNA in mucosal T cells has been described in Crohns disease. [35] In addition, patients with inflammatory bowel disease may have defective production of IL-1 receptor antagonists. [36]

In 37 pediatric patients infected with both HIV and *Mycobacterium avium-intracellulare*, TNF was markedly elevated and there was an association between TNF and anemia. [37] INF- has also been noted to be elevated in those with AIDS. [38] Erythrocytes infected with various strains of malaria, as well as peptides of *Plasmodium falciparum*, stimulate macrophages to secrete TNF, and elevated levels of several cytokines have been found in malarial infections. [39]

The fact that cytokines are thought to play such an important role in so many diseases associated with anemia suggests an association between inflammatory cytokines and anemia.

Cytokine-Induced Decreases in Red Cell Survival

Several studies suggest a role for decreased erythrocyte survival in the pathogenesis of the ACD. Early in vivo and in vitro experiments suggested that fever itself within a few days can induce rheologic changes in erythrocytes and lead to increased destruction, with as much as a 15% decline in red cell mass. [40] More recent evidence suggests that cytokines, the cause of fever in many of the diseases associated with ACD, may also alter red cell kinetics. For example, rats receiving chronic intraperitoneal injections of IL-1 and TNF showed a twofold decline in ^{59}Fe radioactivity, suggesting decreased erythrocyte survival; this effect has been postulated to involve cytokine-induced macrophage and reticuloendothelial system activation. [11]

Cytokine-Induced Abnormalities in Iron Metabolism

Many of the cytokines implicated in ACD appear to have in vivo effects on iron metabolism. Nude mice inoculated with Chinese hamster ovary cells that had been engineered to secrete TNF- show an almost 60% decline in serum iron after 3 weeks while maintaining normal bone marrow stores of iron. [41] Rats injected with IL-1 or TNF experienced a 40% drop in serum iron, and TNF also caused a significant decrease in iron incorporation into erythrocytes. [11] These findings are consistent with the observation that iron reutilization is defective in ACD. [12] TNF has also been shown to increase radiolabeled iron uptake by peritoneal macrophages without an increase in iron release, [42] suggesting that macrophage sequestration of iron may be cytokine induced.

Molecular evidence suggests a direct cytokine effect on iron metabolism. Even though IL-1 has no effect on ferritin transcription, it increases the synthesis of ferritin in human hepatoma cells by an increase in mRNA translation. [43] Increased translation depends on a 5 untranslated region, distinct from the well known iron-responsive element, but similar to a 38-nucleotide consensus sequence found in other IL-sensitive acute-phase reactants (see Chap. 26). [44] The increase in ferritin synthesis occurs without increased cellular transferrin receptor transcription or expression, and involves no new iron influx; [43] IL-1 could thus lead directly to the creation of an intracellular iron pool that is not available for hemoglobin synthesis.

Cytokines Leading to Direct Inhibition of Hematopoiesis

Recent data demonstrate that cytokines, including IL-1, INF, and TNF, can have a direct inhibitory effect on hematopoiesis. However, almost all of the evidence supporting such a role for cytokines is derived from in vitro experiments. Clinical relevance is unclear.

The role of IL-6 in the direct inhibition of hematopoiesis is controversial. Exogenous IL-6 given to monkeys causes a dose-dependent, mild, and short-lived anemia within four weeks. [45] Some studies have also shown that IL-6 has direct inhibitory effects on stem cells. [46] Other studies, however, have demonstrated that IL-6, elevated in rheumatoid arthritis, has no direct effect on bone marrow hematopoiesis. [47] Juvenile-onset chronic arthritis is *associated* with increased IL-6 and anemia, but this anemia is one of iron deficiency. [48] IL-6 has also been shown to cause bleeding in the rat intestinal wall. [49]

There is much better evidence for a role for INF in the direct inhibition of erythropoiesis. INF- can inhibit highly purified erythroid colony-forming units (CFU-E) from mice spleens in a dose-dependent manner. [50] [51] [52] Marrow stromal cells, retrovirally engineered to secrete INF-, inhibit hematopoiesis in long-term bone marrow cultures by blocking cell cycle progression and inducing apoptosis in CD34+ cells to a much greater degree than even exogenous INF. [53] INF inhibition can be reversed by exogenous dosing with murine INF- receptors. [51] Inhibition by INF- can be reversed in a dose-dependent manner by erythropoietin, a phenomenon also seen in ACD, [51] [54] and partial reversal can be achieved by stem cell factor. [55] The concentration of

INF- required to suppress BFU-E was less than that needed to suppress CFU-E, suggesting the suppression occurs at the earlier stages of erythroid development. [52]

Like INF-, INF- also appears to act directly on CFU-E: inhibition does not require accessory T cells or adherent bone marrow cells. [30] [56] Inhibition by INF- appears to work indirectly. Inhibition by either INF- or INF- is not reversed by erythropoietin. [56]

Tumor necrosis factor serum levels have been shown to correlate with the degree of anemia in the ACD. Erythroid growth is increased in the bone marrow of control and chronic anemia patients by monoclonal antibodies against TNF. [32] Transplantation of a Chinese hamster ovary cell line transfected with the human TNF gene led to anemia in nude mice within three weeks, with a significant decrease in both BFU-E and CFU-E. [41] Exogenous TNF decreases erythroid colony counts. [32] The

inhibition of BFU-E growth sustained by normal bone marrow cultured in the presence of peripheral blood mononuclear cells of patients with rheumatoid arthritis can be reversed with antibodies to TNF-.[21] However, there is evidence that the effect of TNF on hematopoiesis is an indirect one, mediated by the local release of other cytokines, including INF from accessory cells.[57] The inhibitory effect of TNF on CFU-E was completely abated by neutralizing antibodies against INF-, but not antibodies to INF- or IL-1.[30]

The effects of IL-1 also appear to be indirect. Growth of purified CFU-E is inhibited by recombinant IL-1 only in the presence of adherent T lymphocytes. The inhibition can be reversed by antibodies to INF-, suggesting that IL-1 may lead to lymphocyte secretion of INF.[58]

Cytokines Leading to Decreased Erythropoietin Secretion

Cytokines have also been implicated in the blunted, inappropriately low erythropoietin levels seen in ACD in several in vitro experiments. In an erythropoietin-producing human hepatoma cell line, HepG2, grown in diffusion-limited oxygen conditions, IL-1, IL-1, and TNF- significantly lowered erythropoietin production. IL-1 also inhibited erythropoietin production in perfused rat kidneys. These effects were not accompanied by alterations in -fetoprotein, showing that the effect was specific and not secondary to a generalized inhibitory growth effect.[59] Using another hepatoma cell line, Hep3B, hypoxia-driven erythropoietin production was also inhibited with IL-1, IL-1, and TNF- (with IL-1 being the most potent inhibitor) in a dose-dependent and additive manner. IL-6 stimulated erythropoietin production.[46]

As is discussed later, perhaps one of the strongest arguments for a role of erythropoietin in the etiology of ACD is that exogenous erythropoietin can at least partially reverse ACD (although supraphysiologic erythropoietin overcoming a direct inhibition of erythropoiesis is also possible). It has been shown that inhibition by INF- can be reversed by erythropoietin.[54] Moreover, the capacity of monocytes from patients with inflammatory bowel disease to secrete TNF predicts therapeutic response to exogenous erythropoietin.[60]

DIAGNOSIS

Because ACD is a multifactorial disease and is seen in many clinical settings, unequivocal diagnosis is often difficult. Thus, 2570% of patients with rheumatoid arthritis and iron studies consistent with the ACD are also iron deficient. [61] [62] Up to 70% of the anemia associated with rheumatoid arthritis may be multifactorial. [63] Many chronic illnesses are also associated with other factors leading to anemia, including iron and nutritional deficiency, bleeding, hemolysis, renal failure with absolute erythropoietin deficiency, and marrow fibrosis or infiltration

THE DIAGNOSIS OF ACD

The diagnosis of ACD is one primarily of exclusion, and is often difficult. Various laboratory tests have been suggested as helpful, but few of these are practical or have proven value in the general population. ACD occurs in too large a variety of acute and chronic illnesses. The best way to diagnose ACD, at least provisionally, is to document an anemia of underproduction (low reticulocyte index) with low serum iron and transferrin levels and an elevated serum ferritin in the setting of a systemic, usually inflammatory, illness. A thorough search may be necessary to document the precise underlying illness.

Other causes of anemia, such as hemolysis, nutritional deficiency, or sequestration, should be ruled out (see Chap. 23) and a component of iron deficiency should be strongly considered in a patient with a systemic inflammation and a low or normal serum ferritin. Often these other causes of anemia accompany ACD. A bone marrow examination is usually not helpful, but may occasionally be necessary to rule out malignancy (including a myelodysplastic syndrome), infection, or iron deficiency.

and replacement. The role of frequent phlebotomy in the hospitalized patient should also be fully appreciated. [64] As an example, the anemia of renal failure has traditionally not been thought of as an ACD, but rather as an anemia of absolute erythropoietin deficiency and mechanical marrow replacement by fibrosis; however, more recently it has been appreciated that efficient dialysis may lead to improved marrow responsiveness to erythropoietin. [65] This suggests that other factors, perhaps including cytokines, may play a role.

One of the major problems with prevalence studies is that ACD is primarily a diagnosis of exclusion. This may often necessitate an evaluation of the bone marrow to ensure adequate iron stores, to rule out infiltration by tumor, fibrosis, or infection, and to exclude a myelodysplastic syndrome; however, in a study of mostly older patients with an idiopathic mild anemia (10 ± 0.6 g/dl), a bone marrow aspirate and biopsy was found to add little to an extensive negative serological work-up and physical examination.[66]

The clinical setting in which the anemia is found helps with the diagnosis, yet 30% of the time no chronic illness can be found; acute illnesses can also lead to anemia.[5] Some argue that a normocytic/normochromic anemia may occur in otherwise healthy people; normal elderly people have also been noted to have mild anemia.[67]

Even though its etiology is no longer thought to be primarily due to a decrease in iron utilization, the diagnosis of ACD is usually made on the basis of elevated marrow iron stores (usually assessed by serum ferritin), and a low serum iron, transferrin, and total iron-binding capacity. A low serum ferritin associated with anemia is suggestive of iron deficiency. Some argue that a ferritin >50 ng/ml excludes any component of iron deficiency, even in inflammatory states. [68] But a normal or elevated ferritin level is more difficult to interpret because ferritin is an acute-phase reactant. Nomograms correcting ferritin for the degree of inflammation present have been published.[69] Others have shown that in acute inflammation, serum ferritins as high as 3,765 ng/ml can still exist with absent bone marrow iron stores by aspirate.[70] Most investigators maintain that serum iron studies cannot predictably rule out iron deficiency. [71]

Several algorithms have been generated to diagnose or rule out ACD. In 120 anemic patients with inflammatory, infectious, or malignant diseases with bone marrow aspirates to assess iron

stores, the serum ferritin was significantly lower in those who were iron deficient but still elevated (63.7 vs. 212 ng/ml); the combination of serum ferritin <70 ng/ml and a red cell ferritin 4 ag per erythrocyte had a specificity of 0.97 and a positive predictive value of 0.82, although these values were not validated in a prospective study.[62] A three-step algorithm for patients with rheumatoid arthritis and serologic evidence of ACD has been derived: male patients with hemoglobins <11.0 g/dl, and serum ferritin <40 g/l have iron deficiency, and those with MCV >85 fl, or those with an iron saturation >7%, have ACD. This formula led to a correct diagnosis in 89% of patients, but this finding was not independently validated. [61]

In ACD, zinc is incorporated into protoporphyrin IX instead of iron. Zinc protoporphyrin has been shown to be greatly elevated in ACD and to be corrected with treatment of the underlying inflammatory condition.[72] But zinc protoporphyrin levels fail to differentiate between ACD and iron deficiency. The number and affinity of transferrin receptors on erythroblasts have been found to be lower in rheumatoid arthritis patients with ACD, [16] thus differentiating it from iron-deficient anemia. Combining assessment of serum ferritin and plasma transferrin receptor concentration (although concentrations of the serum transferrin receptor appear to be unchanged[15]) with the erythrocyte sedimentation rate has also been suggested as an algorithm in differentiating iron deficiency and ACD in elderly women. [73]

TREATMENT

The anemia associated with chronic illness is usually mild. Correction is often not necessary, especially if as many contributing factors as possible are reversed. In fact, there may be a teleologic reason that ACD exists: not only has the fever associated with infections been shown to inhibit bacterial growth, but decreased iron concentrations (as seen in ACD) act synergistically with pyrexia to inhibit bacterial growth. [74] The attempt by hosts to withhold iron from invaders has been termed nutritional immunity, and has been postulated to be an adaptive factor of ACD. [75] However, ACD can be severe, and almost by definition those with ACD have comorbidities; optimizing any reversible process, including hemoglobin and oxygen content and delivery, may sometimes have a dramatic beneficial effect. A large, multicenter trial has shown that in anemic cancer patients not receiving cytotoxic therapy, performance and quality of life improve with increased hemoglobin concentrations. [76]

The optimal treatment of ACD is correction of the underlying disease process, if one can be clearly documented. It has been shown that ACD mirrors laboratory [47] [63] and clinical [9] correlates of disease activity and duration of disease in rheumatoid arthritis. Clearly, definitive treatment of chronic diseases is usually difficult. If the anemia is symptomatic or severe, treatment of the anemia itself may be indicated. Iron chelators such as deferoxamine have been shown in some animal studies to have mild effects on ACD, perhaps by decreasing free radicals and inflammation, but other studies have not duplicated this finding. [77] [78] Transfusion therapy may be the most common form of treatment for symptomatic ACD; unfortunately, red cell transfusions are costly, have the potential detriments of infection, alloimmunization, and graft-versus-host disease, and are a limited resource.

The realization that serum levels of erythropoietin, although often elevated in ACD, are not elevated appropriately for the degree of anemia, as well as the observation that inhibition of in vitro models of hematopoiesis by cytokines can be reversed by erythropoietin, [54] have led to several successful trials in the treatment of ACD with recombinant erythropoietin. This may be more cost effective as well as safer than transfusion. [79] A relatively small, multicenter, placebo-controlled trial monitored the effects of erythropoietin in patients with rheumatoid arthritis and laboratory data consistent with ACD. The results showed

TREATMENT OF ACD

Treating ACD is often not necessary if the patient is asymptomatic. However, the anemia may be severe and quality of life may be greatly improved with treatment, even in those patients who believed they felt well with their anemia.

The first priority should be to correct any reversible contributors to the anemia (e.g., iron deficiency, absolute erythropoietin deficiency). Because the extent of ACD mirrors the underlying diseases activity, all efforts should be made to treat the underlying disease.

Although transfusion is obviously the fastest way to reverse ACD, many studies have shown a 4080% response rate to standard-dose erythropoietin injections. This response may take 48 weeks. A low pretreatment serum erythropoietin level and a serum ferritin that decreases with erythropoietin treatment appear to be good predictors of response. Refinement of the approach to using erythropoietin in these disorders is likely to be attempted during the next several years.

a dose-dependent response to 50150 U/kg of erythropoietin three times a week; 11 of 17 patients had a response rate of almost six hematocrit points. [80] Responses can take up to four weeks. [80] [81]

Anemic patients with AIDS who were treated with recombinant erythropoietin had a significantly decreased transfusion requirement, especially if their endogenous erythropoietin level was <500 IU/l; however, all of these patients were also receiving zidovudine, a potential bone marrow suppressant. [82] The use of recombinant erythropoietin has also been shown to increase hemoglobin in a variety of nonhematologic neoplastic diseases, including squamous cell cancer, [83] breast cancer and colon cancer, [84] [85] and a variety of other malignancies. [76]

Response rates to erythropoietin in patients with cancer appear to range from 40% to 80% and take 48 weeks to occur. A response often significantly affects many aspects of quality of life, including mood, level of activity, pain and nausea, and anxiety. [76] [85] Prognostic indicators to predict response of ACD to erythropoietin include a low pretreatment erythropoietin level. [76] [84] Although baseline duration of malignant disease, previous and current cancer treatment, bone marrow involvement, and type of tumor (hematologic vs. solid tumor) were found to be negative predictors of response to erythropoietin treatment, only the absolute change in hemoglobin value, the absolute hemoglobin value, the serum erythropoietin level, and the ferritin level were found to be independent predictors in a multivariate analysis of 80 patients with chronic anemia of cancer. [86] Median survival in those responding was 12.6 months compared with 4.3 months in nonresponders. These investigators derived an algorithm: if after two weeks the serum erythropoietin level is >100 mU/ml and the hemoglobin concentration has not increased by at least 0.5 g/dl, or if after two weeks of treatment the serum ferritin level is >400 ng/ml, then response is very unlikely.

SUMMARY AND FUTURE DIRECTIONS

Anemia is common in many chronic inflammatory, infectious, and malignant conditions, and is often multifactorial. The anemia is exacerbated by inflammatory cytokines, which are thought to be one of the more important causative factors in ACD. ACD is difficult to diagnose, but can usually be strongly suspected on the basis of the clinical setting, the elimination of

other causes of anemia, a low serum iron and transferrin, and an elevated ferritin. Cytokines such as INF- and TNF have been shown to have wide-ranging effects, including an increase in ferritin that impairs iron availability for hemoglobin synthesis, and direct and indirect inhibition of hematopoiesis. There is also molecular evidence to suggest that cytokines lead to what may be the most important factor in ACD, a relative deficiency in erythropoietin for the degree of anemia found. ACD can often be reversed with recombinant erythropoietin. Further studies are required to delineate better the molecular and cellular pathways by which cytokines might lead to inhibition of hematopoiesis, and to explore the role of cytokine antagonists in treating ACD [87] as well as its underlying causes.

Chapter 25 - Erythrocytosis

Jerry L. Spivak

Under normal circumstances, the red cell mass is maintained within narrow limits and is relatively constant in a given person, although it can vary between people of the same age and sex by more than 10%. In the presence of adequate nutrients, the red cell mass is in a dynamic equilibrium in which the red cells lost from the circulation each day through senescence are replaced by newly formed ones. Red cell production is regulated by erythropoietin (EPO), a glycoprotein hormone produced primarily in the kidneys in adults. EPO is a highly conserved protein that bears significant homology (23%) only with the hematopoietic growth factor, thrombopoietin.[1] [2] The EPO gene is located on the long arm of chromosome 7 in humans,[3] and it encodes a protein of 166 amino acids, the terminal amino acid of which, Arg 166, is cleaved during the processing of the mature hormone.[4] In keeping with the constancy of the red cell mass in a given individual, the circulating level of EPO also remains constant unless hypoxia, anemia, or sudden blood loss intervenes. Indeed, EPO appears to be such an important regulatory or trophic factor that it is never absent from the plasma, even in the anephric state or with extreme erythrocytosis. This chapter examines the mechanisms leading to erythrocytosis and the role of EPO in this process.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF AN ELEVATED RED CELL MASS

Oxygen Transport

The principal function of the blood is to deliver oxygen from the lungs to the tissues. The primacy of oxygen transport in the bodys economy can be easily inferred from the fact that basal metabolic processes consume oxygen at a rate of 4 ml/kg/min, whereas oxygen stores amount to only 20 ml/kg. Overall, oxygen transport is a complex process involving a variety of components, including ventilatory rate and volume, pulmonary diffusing capacity, cardiac output, red cell mass, hemoglobinoxygen affinity, regional blood flow, and tissue capillary density, as well as ambient oxygen tension. The constancy of the red cell mass indicates that acute or transient changes in the tissue oxygen demands or in ambient oxygen tension are met

---

primarily by alterations in minute ventilation, cardiac output, distribution of blood flow, and hemoglobinoxygen affinity. [5] [6] [7] A sustained hypoxic stimulus, however, engenders changes in the red cell mass, the plasma volume, and, eventually, in vascularity at the capillary level. [7] [8] Erythrocytosis therefore suggests the presence of either sustained tissue hypoxia, autonomous EPO production, or (in the absence of an appropriate or inappropriate increase in EPO production) autonomous red cell proliferation.

Red Cell Production and Regulation

An understanding of EPO physiology is central to understanding the pathophysiology of erythrocytosis. Under normal circumstances, EPO is produced constitutively by peritubular interstitial fibroblasts in the inner cortex of the kidney, [9] [10] [11] which are the sites not only of EPO production but of the oxygen sensor that stimulates EPO production.[12] The oxygen sensor is a heme protein that up-regulates EPO mRNA transcription through the mediation of a set of nucleoproteins known as hypoxia-inducible factors (HIF) that interact with an enhancer element in the 3 region of the EPO gene. [13] [14] This mechanism is not unique to EPO but is a universal mechanism for oxygen-regulated gene expression.[15]

Erythropoietin production by individual renal peritubular interstitial fibroblasts appears to be an all-or-none phenomenon because anemia or hypoxia recruits additional cells to produce EPO, rather than increasing hormone production in the cells producing it constitutively. [11] As a corollary, the kidney has no preformed stores of EPO, and changes in circulating EPO are a direct consequence of changes in the production of the hormone. [16] With correction of anemia or hypoxia, EPO production ceases except in those cells that were producing it constitutively. Because no evidence has been found to suggest that hypoxia or anemia alters the plasma clearance of EPO, it appears that its concentration in the circulation is regulated at the level of gene expression. Indeed, studies in hypoxic rodents show a close correlation between renal EPO and plasma EPO concentrations, with the latter lagging behind the former. [17]

Erythropoietin is also constitutively produced in the liver in both hepatocytes and interstitial fibroblasts. In contrast to the situation in the kidneys, however, EPO production in hepatocytes is not an all-or-none phenomenon, but can be regulated in each cell. [18] The degree of hypoxia required to up-regulate liver EPO production is greater than that required to induce renal EPO production. Thus, with mild hypoxia, the liver contributes little to the plasma EPO concentration; with more severe hypoxia, the liver becomes a substantial source of EPO because of its bulk. [19]

Small but significant changes in serum immunoreactive EPO can be detected with hypoxia [20] or changes in the hematocrit if serial measurements are obtained [21] ; unequivocal elevations of serum EPO outside the normal range (426 mU/ml) do not occur until the hemoglobin level falls to <10.5 g/dl. [22] Thus, random EPO determinations are not a useful means for establishing the adequacy of EPO production in situations of slight anemia. Whether a similar threshold exists for hypoxia is unclear because no simple means is available for analyzing oxygen delivery at the tissue level. Careful studies of plasma EPO in patients with cyanotic congenital heart disease suggest that such a threshold does not exist. [20]

Changes in the level of circulatory EPO induced by hypoxia are instructive with regard to the bodys mechanisms. Hypobaric hypoxia results in a detectable increase in EPO within a few hours.[23] The elevation is not usually sustained, even though the hypobaric hypoxia persists. [17] [23] [24] [25] [26] The level usually falls back into the normal range unless the hypoxia is extreme.[26] However, because the normal range for plasma EPO is wide (426 mUml), an increase of 1020 mU/ml, although still within the normal range, can constitute a doubling of the plasma EPO concentration and would be expected to elevate basal red cell production.

This unusual behavior can be explained by the intervention of other hemodynamic compensatory responses. Hypoxia generates acute changes in minute ventilation, heart rate, tissue blood flow, and hemoglobinoxygen affinity. Hyperventilation improves alveolar oxygen delivery, increases arterial oxygen tension (PaO_2) and arterial oxygen saturation (SaO_2), and maintains the diffusion gradient between the blood and the tissues. An additional effect of hyperventilation is reduction in carbon dioxide tension, resulting in respiratory alkalosis. The change in arterial pH stimulates the synthesis in erythrocytes of the organic phosphate 2,3-diphosphoglycerate (2,3-DPG). This important compound, which is present in red cells in amounts equimolar with hemoglobin, [27] binds to hemoglobin and reduces its oxygen affinity. Although alkalosis increases hemoglobin oxygen affinitythat is, reduces the P_{50} of the hemoglobin (the partial pressure of oxygen at which hemoglobin is half-saturated with oxygen)the increase in red cell 2,3-DPG not only counteracts the increase in hemoglobinoxygen affinity but actually reduces it (increases P_{50}) and enhances oxygen unloading at the tissue level. The net effect is improved oxygen delivery to tissues.

These adaptive mechanisms can effectively correct hypoxia and improve tissue oxygen delivery, thereby removing the stimulus for EPO production. Plasma EPO then diminishes to the extent that the hypoxia is corrected. If, however, hypoxia is extreme, 2,3-DPG production alone cannot compensate for the respiratory alkalosis; hemoglobinoxygen affinity remains increased and elevated EPO production persists. Hypoxia does not have to be continuous, or even extreme, to stimulate EPO production. Thus, intermittent hypobaric hypoxia can produce erythrocytosis in rodents, [28] whereas supine hypoventilation or sleep apnea has the same effect in humans.[29] [30] [31]

It is worth emphasizing that hypoxia is also associated with a diminution in plasma volume. This abnormality appears to be independent of the cause of hypoxia because it occurs not only at high altitudes [8] but in cyanotic congenital heart disease [32] and in cigarette smokers.[33] Whether the reduction in plasma volume is part of a physiologic adaptation to tissue hypoxia is unclear. When it is extreme (as described later), it can have a deleterious effect.

An interesting counteracting effect of erythrocytosis is suppression of EPO production independent of tissue oxygenation. [34] This is probably a consequence of the hyperviscosity associated with elevation of the red cell mass. The observed reduction in plasma volume associated with hypoxic erythrocytosis probably serves as a means of facilitating this effect, thereby preventing an overexuberant response to hypoxia because elevation of plasma viscosity alone inhibits EPO production. [35] This

explains in part the observation that EPO levels are often within the normal range in patients with secondary erythrocytosis and compensated hypoxia.

CLINICAL MANIFESTATIONS

The signs and symptoms associated with erythrocytosis are nonspecific. Unless the cause of hypoxia is evident or unless erythrocytosis is extreme, there may be no unequivocal evidence of its presence. Indeed, William Osler, who provided one of the early and important descriptions of polycythemia rubra vera, also cautioned that even anemic patients could appear plethoric (anemia rubra). Thus, a high hematocrit, hemoglobin, or erythrocyte count, rather than a characteristic symptom or physical finding, may be the first clue to an elevation of the red cell mass. Because alterations in the plasma volume can influence these measurements, they cannot be relied on as indicators of the absolute red cell mass. Even when the plasma volume is

CAUSES OF A HIGH HEMATOCRIT

- Relative or spurious erythrocytosis
  - Hemoconcentration secondary to dehydration (diarrhea, diaphoresis, diuretics, deprivation of water, emesis, ethanol), hypertension, preeclampsia, pheochromocytoma, carbon monoxide intoxication
- Absolute erythrocytosis
  - Hypoxia
    - Carbon monoxide intoxication
    - Highoxygen-affinity hemoglobin
    - High altitude
    - Pulmonary disease
    - Supine hypoventilation syndrome
    - Sleep apnea syndrome
    - Right-to-left cardiac shunts
    - Neurologic defects (respiratory center dysfunction)
  - Renal disease
    - Cysts, hydronephrosis
    - Renal artery stenosis
    - Focal glomerulonephritis
    - Renal transplantation
  - Tumors
    - Hypernephroma

not diminished, the hematocrit and the red cell mass are not directly correlated. Therefore, consideration of the causes of a high hematocrit must include a number of possibilities that could artifactually raise the hematocrit, hemoglobin, or erythrocyte values.

When considering these diagnostic possibilities, it is important not to overlook clues provided by the peripheral blood smear and the red cell indices. For example, in true plethora, a properly prepared blood smear obtained from the fingertip shows red cell crowding out of proportion to what is expected from the apparent hematocrit value. Furthermore, an elevated red cell count in association with microcytosis should suggest the presence of autonomous or EPO-driven erythrocytosis because this situation otherwise occurs only with thalassemia minor, a disorder not associated with a high hematocrit or hemoglobin level. [36] The presence of leukocytosis, thrombocytosis, or splenomegaly should also suggest the presence of polycythemia vera, but these abnormalities are not always present early in the course of that illness.

LABORATORY EVALUATION

Red Cell Mass Determination

The first question confronting the physician when encountering a reproducibly high hematocrit or hemoglobin level is to determine whether the red cell mass shows an absolute increase. This can be done accurately only by direct measurement, using the technique of isotope dilution. With this technique, an aliquot of the patients red cells is labeled with a radioactive tracer and reinfused. The red cell mass can then be calculated from the degree of dilution of the isotopically labeled red cells. It is important to remember in this regard that, in erythrocytosis (particularly in patients with splenomegaly), equilibration of the injected labeled red cells with the total blood pool may be delayed relative to the situation when the blood volume is normal. Therefore, serial blood samples should be taken over a period of approximately 90 minutes to ensure that equilibration is complete and that the red cell mass will not be underestimated.

A direct measurement of the red cell mass effectively separates those patients with a reduced plasma volume from those with absolute erythrocytosis (see Chap. 61 for indications for and interpretations of red cell mass assays). Once the presence of erythrocytosis has been established, the cause must be sought. However, depending on the severity of the plethora, it may be necessary to initiate therapeutic phlebotomy even while the diagnostic evaluation is proceeding.

Serum Erythropoietin

Many factors can cause erythrocytosis. Defining the precise cause may not be possible either initially or even after prolonged evaluation; nonetheless, some guidelines can be suggested. Because erythropoiesis is regulated by EPO, a serum EPO level can provide an indication of whether the erythrocytosis is hormonally mediated or autonomous. Although prior assays for EPO in the serum were insensitive and not widely available, the introduction of recombinant EPO has led to development of a specific, sensitive, accurate, reproducible, and commercially available immunoassay. [37]

In patients with erythrocytosis due to uncompensated hypoxia, serum immunoreactive EPO is elevated; in those with compensated hypoxia, the serum immunoreactive EPO level is usually within the range of normal, [20] [38] [39] and in patients with polycythemia vera, serum immunoreactive EPO is usually low but can be normal (see Chap. 61). [22] [40] The number of patients with autonomous EPO production studied with a sensitive and specific EPO assay is too small to permit firm conclusions, but EPO levels in these patients can be either high or normal and may even fluctuate, suggesting that serial measurements may be necessary to detect an abnormality. [40] This would also be important in those patients with the supine hypoventilation syndrome or sleep apnea in whom serum EPO may be only intermittently elevated. [29] Thus, although an elevated serum EPO level suggests that erythrocytosis is a secondary phenomenon and a low EPO level supports the possibility of autonomous erythropoiesis, a normal serum EPO level excludes neither hypoxia nor autonomous EPO production as the cause of erythrocytosis.

Blood Gas Measurements

An elevated EPO level indicates that erythrocytosis is hormonally driven but does not establish the cause. A normal EPO level, however, does not exclude hypoxia as a cause of erythrocytosis. Therefore, a concomitant assessment of PaO_2 and SaO_2 is required in the evaluation of all patients with erythrocytosis because hypoxia is a correctable cause of this disorder. Patients with polycythemia vera invariably have a normal PaO_2 and an SaO_2 of 90% unless there is coexisting pulmonary disease. [41] However, it is important to be aware that the PaO_2 is a relatively insensitive indicator of hypoxia. This is because hemeheme interactions during oxygen binding render hemoglobin fully saturated over a wide PaO_2 range. It is only when the PaO_2 persistently falls to <67 mmHg that an appreciable increase in red cell mass is encountered. [42]

Arterial oxygen saturation is a more sensitive indicator of potential tissue hypoxia than PaO_2 because it is directly related

to red cell mass. [40] In this regard, it is important to remember that in the presence of an elevated red cell mass, the serum EPO level may be normal even if the SaO_2 is low, owing to the compensatory increase in tissue oxygenation due to the erythrocytosis or the development of hyperviscosity associated with erythrocytosis.

There are also two situations causing hypoxic erythrocytosis in which the SaO_2 can be misleading: highoxygen-affinity (low P_{50}) hemoglobins and carbon monoxide intoxication. In the former condition, the SaO_2 is normal, but tissue hypoxia exists because at ambient tissue oxygen tensions, highoxygen-affinity hemoglobins do not release their oxygen. Thus, for detection of a highoxygen-affinity hemoglobin, determination of its oxygen affinity (P_{50}) is mandatory.

The clinician must also be aware of the complexities of interpreting SaO_2 values in carbon monoxide poisoning. If an indirect method for determining SaO_2 is used (e.g., calculating it from the measured PaO_2 and a standard oxygen dissociation curve), a normal value will be obtained when the SaO_2 is in fact low owing to the binding by hemoglobin of carbon monoxide rather than oxygen. [43] Detection of carbon monoxide intoxication requires both a direct determination of SaO_2 by oximetry and quantitation of the percentage of carboxyhemoglobin. Unless carbon monoxide exposure is constant, however, it will be displaced from hemoglobin sufficiently rapidly to yield a normal SaO_2 .

Erythroid Cell Culture

The observation that polycythemia vera erythroid progenitor cells can proliferate in vitro in the absence of EPO led to the application of in vitro erythroid colony-forming assays for the diagnosis of polycythemia vera. Unfortunately, this type of behavior is not specific for polycythemia vera erythroid progenitor cells and cannot be recommended for the routine evaluation of unexplained erythrocytosis. However, studies of progenitor cells may be helpful if performed in laboratories with special expertise in stem cell assays (see Chap. 61 for details).

ETIOLOGIES

Hypoxic Erythrocytosis

Hypobaric Hypoxia

The prototypical model for hypoxic erythrocytosis is high-altitude hypoxia. Exposure to high altitudes leads acutely to the predictable changes in minute ventilation, heart rate, blood flow, and hemoglobinoxygen affinity described earlier. Serum EPO is elevated initially but eventually falls to within the normal range if the hypoxia is not extreme. This decline, however, does not prevent an increase in red cell mass, which will be sustained. This effect occurs because EPO can potentiate its own effects, because expansion of the erythroid progenitor cell pool is exponential, and because only picomolar quantities of the hormone are required to sustain the red cell mass under normal circumstances. Early erythroid progenitor cells, at least in vitro, require 10 ^{3} times as much EPO as do late erythroid progenitor cells.[44] Thus, the early unsustained increase in serum EPO probably serves to facilitate recruitment of additional erythroid progenitor cells to expand the progenitor cell pool, whereas smaller quantities of the hormone can maintain this pool once it is expanded.

Concomitant with the changes cited previously is a reduction in plasma volume. [8] Although initially this could be the consequence of fluid loss associated with hyperventilation and the low humidity of high altitude, similar changes are also seen at sea level in patients with hypoxic erythrocytosis due to cyanotic congenital heart disease,[32] in those with chronic carbon monoxide intoxication,[33] and in those with end-stage renal disease who are receiving recombinant human EPO. [45] Thus, a decrease in plasma volume appears to be a component of the compensatory EPO-induced erythrocytosis associated with hypoxia. Other noteworthy compensatory changes associated with high-altitude hypoxia are developmental and require sustained altitude exposure; they include an increase in lung volume and capillary density and a blunted ventilatory response to hypoxia. [7] [46] [47] Because the latter also occurs in patients with cyanotic congenital heart disease, [44] it is not peculiar to hypobaric hypoxia.

Chronic mountain sickness is an extreme response to hypobaric hypoxia in which the elevation of the red cell mass fails to compensate adequately for hypoxia. [48] In this situation, the erythrocytosis far exceeds that expected for the degree of hypobaric hypoxia, and there is symptomatic hyperviscosity. Chronic mountain sickness appears to be the consequence of an additional acquired ventilatory defect superimposed on the adaptive blunted ventilatory response that occurs during chronic exposure to high altitude.[47]

Chronic Pulmonary Disease

Hypoxia occurring with chronic lung disease represents a more complicated clinical situation than hypobaric hypoxia because the erythrocytosis expected for the measured degree of hypoxia is not always present. This, however, appears to be more a matter of patient selection than an indication of a new paradigm. [42] [49] For example, in some patients an increase in plasma volume due to fluid retention masks the increase in red cell mass. [50] In other patients, clinical measurements of tissue oxygenation may not accurately reflect the actual level of tissue oxygenation, whereas in still others, inflammation, infection, or renal disease may impair EPO production as well as the marrows responsiveness to EPO. Finally, as observed in certain patients with highoxygen-affinity hemoglobins, there may be tolerance to a particular level of tissue hypoxia.[51] In general, however, patients with impaired pulmonary function demonstrate the expected correlation between SaO_2 and red cell mass and may even have a steeper response than that of healthy people.[42] Their ability to produce EPO is also more vigorous and the threshold for this is reduced.[52]

The sleep apnea syndrome and supine hypoventilation due to premature airway closure are two special situations in which hypoxia can develop without overt evidence of pulmonary disease.[29] [30] [31] In each instance, hypoxia is intermittent. A random blood gas or EPO measurement may thus fail to reveal the underlying cause of the erythrocytosis.

Chronic Carbon Monoxide Intoxication

Chronic carbon monoxide intoxication, usually as the consequence of tobacco use, is probably the most common cause of erythrocytosis encountered clinically. It is responsible for the syndrome commonly referred to as stress erythrocytosis,[53] benign polycythemia, [54] or spurious erythrocytosis.[55] Carbon monoxide is the perfect respiratory poison. Odorless and colorless, carbon monoxide has an affinity for hemoglobin 210 times as great as that of oxygen. This is attributable not to a greater rate of association of carbon monoxide with hemoglobin compared with oxygen but rather to its slower rate of dissociation from hemoglobin. Not only does the binding of carbon monoxide with hemoglobin reduce the quantity of oxygen that can be bound, it also shifts the oxyhemoglobin dissociation curve to the left, thereby reducing the ability of hemoglobin to unload oxygen to the tissues. [56] Furthermore, carboxyhemoglobin has a reduced affinity for 2,3-DPG. At a high carbon monoxide concentration, red cell 2,3-DPG production is also suppressed. [57] Thus, carbon monoxide not only causes tissue hypoxia but subverts the mechanisms designed to compensate for the hypoxia.

An additional, but often unrecognized, effect of carbon monoxide

intoxication is diminution of plasma volume.[33] When combined with an elevation of the red cell mass, this creates a situation in which erythrocytosis occurs with a normal total blood volume, with the attendant problem of hyperviscosity. The variable extent to which elevation of the red cell mass and depression of the plasma volume can occur in patients with carbon monoxide intoxication has led to the description of syndromes of spurious erythrocytosis due to a high normal red cell mass or a low normal plasma volume,[55] but these syndromes probably represent only part of the continuum of carbon monoxide toxicity.

Although the term *benign polycythemia* has been used to describe erythrocytosis-associated carbon monoxide intoxication, the syndrome is anything but benign. Several series have demonstrated a substantial incidence of thromboembolic events, and in one study a mortality rate six times as great as expected for unaffected people of the same age was observed.[58]

Cyanotic Congenital Heart Disease

Congenital heart disease with anatomic right-to-left shunting is a predictable cause of erythrocytosis. [59] Such patients are similar to those with hypobaric hypoxia with respect to having a blunted ventilatory response and a low plasma volume, but they also may have a coagulopathy with a low fibrinogen and a low platelet count. [59] [60] [61] When the erythrocytosis compensates for arterial oxygen desaturation, the serum EPO level will be normal. [20] However, phlebotomy results in a marked increase

in serum EPO owing to the reversal of the compensatory erythrocytosis. In a manner similar to that encountered in hypobaric hypoxia, a syndrome resembling chronic mountain sickness can develop in patients with cyanotic congenital heart disease. This phenomenon results from hypoxia that cannot be compensated for by erythrocytosis.[62]

HighOxygen-Affinity Hemoglobins

Highoxygen-affinity hemoglobins that are unable to unload oxygen to the tissues at an acceptable tissue oxygen tension are an uncommon but interesting cause of hypoxic erythrocytosis. The first high-affinity hemoglobin, hemoglobin Chesapeake, was identified in 1966 in an 81-year-old man who was being evaluated for angina pectoris.[63] To date, over 40 such mutant hemoglobins have been described. These mutants may be stable or unstable; a few are not associated with erythrocytosis either because their increased affinity for oxygen is not marked or because they are too unstable. [64]

Hemoglobin normally exists in an equilibrium between its oxygenated (relaxed or R) state and its deoxygenated (tense or T) state (see Chaps. 22 and 31). The transition between these states involves changes in molecular conformation and intramolecular bonding. In the deoxy or T state, hemoglobin has a high affinity for 2,3-DPG and hydrogen ions, whereas in the oxygenated or R state, these affinities are reduced. In general, highoxygen-affinity hemoglobins arise from amino acid substitutions that prevent the obligatory conformational changes in the molecule during oxygenation and deoxygenation, particularly those that (1) involve the $_{1\,2}$ interface of the globin chains within the hemoglobin tetramer and stabilize it in the oxygenated state; (2) involve the C-terminal end of the -globin chain and prevent the formation of ionic bonds; or (3) impair 2,3-DPG binding. [64]

Clinically, erythrocytosis is the major abnormality associated with a highoxygen-affinity hemoglobin, and its extent is proportional to the P_{50} of the mutant hemoglobin.[65] Interestingly, occasional patients have a low plasma volume. Those affected are heterozygotes, with the mutant hemoglobin accounting for approximately 40% of their total hemoglobin. The inheritance pattern is therefore dominant. A family history can be revealing, if positive. A negative history does not rule out the diagnosis, however, because of the high frequency of spontaneous mutations. Because of the nature or position of the amino acid substitution, highoxygen-affinity hemoglobins cannot always be detected by routine electrophoretic techniques. Moreover, an electrophoretic abnormality alone would not establish that the hemoglobin had a high oxygen affinity. A P_{50} determination is the only reliable means of establishing this. Of course, carboxyhemoglobin or a low red cell 2,3-DPG can cause a low P_{50} . In evaluating the possibility of a highoxygen-affinity hemoglobin, a study of other family members is also important.

Inappropriate Erythropoietin Secretion

Erythrocytosis Due to Renal Disease

Because the kidneys are the major site of EPO production in adults, some forms of renal disease may cause erythrocytosis as well as anemia. Although it has been suggested that a high hematocrit associated with hypertension may be a clue to the presence of renal artery stenosis, [66] it must be remembered that hypertension per se is associated with a reduction in plasma volume.[67] Experimentally, renal artery stenosis does cause an

BEST ESTABLISHED ASSOCIATIONS BETWEEN TUMORS AND INAPPROPRIATE ERYTHROPOIETIN PRODUCTION

Hypernephroma[89] [90] [91] [92] [93]	More common in men. Erythrocyte sedimentation rate is often elevated. Associated with von Hippel-Lindau disease.
Wilms tumor[89]	
Renal adenoma[89]	
Undifferentiated renal carcinoma[89]	
Hepatoma[89] [95] [96]	More common in men. Increase in plasma volume may obscure the elevated red cell mass.
Liver hamartoma[89]	
Cerebellar hemangioblastoma[89] [97] [98]	More common in men. Metastases can be confused with those of a hypernephroma. Associated with von Hippel-Lindau disease.
Uterine fibromyoma[99] [100]	Tumor extracts (only from very large tumors) contain erythropoietic activity.
Pheochromocytoma[89]	Rare. Spurious elevation of the hematocrit can occur owing to decreased plasma volume. Associated with von Hippel-Lindau disease.
Adrenal adenoma or hemangioblastoma[91]	Associated with von Hippel-Lindau disease.
Paraganglioma[101]	
Meningioma[102]	

increase in serum EPO, but this is usually modest and not of the magnitude of the increase associated with anemia. [68] It has been suggested that this effect reflects a decline in renal oxygen consumption as renal blood flow falls. Whatever the mechanism, although examples of renal artery stenosis associated with erythrocytosis have been described, they are not common.[69] [70]

Renal cysts have been implicated as a cause of inappropriate EPO production, [71] but the most striking example of this has been in patients with autosomal dominant polycystic disease and renal failure, in whom anemia is unexpectedly mild while EPO levels are elevated. [72] Acquired cystic disease has also been described in patients undergoing chronic renal dialysis and presenting with a similar clinical picture. [73] More frequently, however, renal cysts develop in these patients without any amelioration of anemia or erythrocytosis.[74] In other patients, the erythrocytosis identified with renal cysts was actually due to polycythemia vera. [75]

Patients with focal glomerulonephritis, with or without the nephrotic syndrome, constitute another group in whom renal disease is associated with erythrocytosis. [76] [77] Indeed, this association has been described with sufficient frequency to suggest that renal function should be examined in patients with unexplained erythrocytosis. In general, the erythrocytosis is a temporary event during the course of the renal disease.

Erythrocytosis can also be a complication of renal transplantation. [78] [79] [80] [81] The mechanism for this is unclear, but it does not appear to involve rejection and has been seen with cadaver kidneys as well as with kidneys from living donors. [82] It has been postulated that the erythrocytosis in this situation does not arise from the transplanted kidney but rather from the patients own kidneys. [83] [84] In some instances, the erythrocytosis may actually be spurious and due to overzealous use of diuretics.[85] Studies suggest that angiotensin-converting enzyme inhibitors are effective in controlling post-transplantation erythrocytosis. [86] However, phlebotomy therapy should not be withheld pending the results of drug therapy in this situation. A rare cause of erythrocytosis associated with renal disease is Bartters

syndrome.[87] [88]

Tumor-Associated Erythrocytosis

Erythrocytosis associated with a tumor is a rare paraneoplastic syndrome that has excited the imagination of physicians far beyond its clinical frequency. [89] Unfortunately, few studies of this phenomenon have used a sensitive and specific assay for EPO. Renal tumors, both benign and malignant, have been associated with erythrocytosis, and the production of EPO mRNA by renal carcinoma cells has been demonstrated. [90] It is of interest that erythrocytosis associated with renal, hepatic, or cerebellar tumors is more common in men.[89] It is also of interest that three of the tumors associated with erythrocytosishypernephroma, cerebellar hemangioma, and pheochromocytomaare part of the constellation of von Hippel-Lindau disease, which suggests a common underlying genetic mechanism. [93] It is also noteworthy that, in patients with hepatomas, an expanded plasma volume can obscure the presence of erythrocytosis. [89] Although one might, on the basis of studies of EPO excretion,[94] expect EPO levels to be inappropriately high in patients with tumor-associated erythrocytosis, this is not usually the case.

Familial Erythrocytosis

Familial erythrocytosis is an uncommon entity for which the identified syndromes and causes are listed in the accompanying box (also see Chaps. 15 and 61 for detailed discussion of EPO and EPO receptor pathophysiology). Depending on the syndrome, inheritance may be dominant or recessive. [103] [104] [105] [106] [107] [108] [109] [110] [111] Few such families have been studied with a sensitive and specific

assay for EPO. When carefully studied, EPO levels were either normal or elevated and not always influenced by phlebotomy. Erythroid progenitor cell sensitivity to EPO was either normal or increased. In several families, abnormalities of EPO receptor gene expression or binding affinity were not observed. [111] In a number of families, erythrocytosis could be associated with mutations of the EPO receptor gene. Plasma EPO levels in this situation were either normal or low. [112]

Interestingly, DNA sequence analysis has revealed that in each case a nonsense or frameshift mutation caused truncation of the receptor because of the generation of stop codons, with loss of the terminal portion of its COOH domain. [113] [114] [115] Experimentally, removal of the terminal portion of the EPO receptor COOH domain increased its sensitivity to EPO,[116] [117] and human EPO receptors truncated in the same fashion as the familial genetic mutants also demonstrated hypersensitivity to EPO in vitro, at least at low concentrations of the hormone. [114] [115] Since hematopoietic cell phosphatase, which down-regulates EPO receptor signal transduction by tyrosine dephosphorylation, binds to its terminal COOH domain, [118] it has generally been held that the hypersensitivity of truncated EPO receptors is due to loss of hematopoietic cell phosphatase binding. However, data have been presented that suggest that the apparent increase in sensitivity to EPO is actually an increase in sensitivity to insulin-like growth factors, which are also present in the plasma and which are known to enhance erythropoiesis. [119] Support for a role of factors other than EPO in this situation is provided by the observation that not every patient with a truncated EPO receptor has erythrocytosis. [114]

The recently described endemic form of congenital polycythemia in the Chuvash population may reflect a defect in oxygen sensor function (see Chap. 61).

In one patient with erythrocytosis and a low erythrocyte 2,3-DPG level, a deficiency of diphosphoglycerate mutase was found. [110] Some patients with familial erythrocytosis, however, had an elevated red cell 2,3-DPG level, suggesting an unrecognized cause for hypoxia, whereas in others, the cause may have been unidentified renal disease or cigarette smoking. Whatever the mechanism, erythrocytosis has been observed to have adverse effects in a number of these patients, and phlebotomy therapy should be used to maintain the red cell mass at a safe level. [103] [104] It should also be remembered that polycythemia vera is occasionally familial.

Polycythemia Vera Rubra

Polycythemia vera is a form of myeloproliferative syndrome in which the granulocyte, monocyte, and platelet counts, as well as the red cell count, are usually elevated in the absence of a definable cause (see Chap. 61). This disorder appears to represent occupancy of the marrow by the progeny of a neoplastic clone of stem cells, which expands with inappropriate exuberance. Because polycythemia vera is discussed in detail in Chapter 61 , it is not considered further here, except to note that elevation of the counts in all three major cell lineages (red blood cells,

white blood cells, and platelets) and the presence of splenomegaly should lead the clinician to suspect this diagnosis strongly as a cause of an unexplained erythrocytosis.

EVALUATION AND MANAGEMENT

The two goals in dealing with a patient with erythrocytosis are identification of a correctable cause and reduction of the red cell mass. With respect to the medical history, prior blood counts are important in documenting the onset and duration of the erythrocytosis. The blood counts of family members may be useful in establishing an inherited basis for it. In general, with the exception of pruritus, the symptoms associated with polycythemia vera are not different from those associated with secondary erythrocytosis. The occupational, environmental, and social history of the patient may yield important clues, especially with regard to pulmonary disease and carbon monoxide intoxication. The drug history should not be overlooked because androgenic steroids, administered for therapeutic, cosmetic, or competitive purposes or mistakenly to improve libido, can cause erythrocytosis. [120] [121] [122] The physical examination may suggest a cardiac or pulmonary cause and, with respect to the latter, the sleep apnea syndrome must not be ignored. Splenomegaly should suggest the presence of a myeloproliferative disorder, but its absence does not exclude this possibility.

Laboratory evaluation should be dictated by common sense. Leukocytosis and thrombocytosis suggest polycythemia vera, but, once again, their absence does not exclude this disorder. A urinalysis is mandatory, and a serum EPO measurement should always be obtained, but only by an assay using recombinant-derived reagents.[37] If it is negative, a repeat assay may be worthwhile if an EPO-producing lesion is suspected. [40] If supine erythrocytosis is suspected, a blood sample for assay should be obtained under the appropriate circumstances. A direct measurement of SaO_2 should be obtained, as should a carboxyhemoglobin level. Because the half-life of carboxyhemoglobin is approximately 7 hours, the measurement may be normal if exposure has been interrupted before the patient seeks medical attention.

If the evaluation to this point has not been revealing, renal evaluation with respect to kidney size, presence of anatomic abnormalities, and blood flow is indicated. In the absence of neurologic signs or symptoms, an abdominal computed tomography scan should complete the evaluation for paraneoplastic erythrocytosis. Because highoxygen-affinity hemoglobins may not migrate abnormally on electrophoresis, and because even an electrophoretic abnormality does not by itself establish an oxygen-binding abnormality, a P_{50} determination should be obtained if the history is suggestive and no other cause of erythrocytosis is evident.

In the absence of a clinical assay for establishing clonality with respect to erythrocytosis, even after all the previously mentioned tests have been performed, the diagnosis may not be forthcoming. This problem should not influence the management protocol; treatment of unexplained erythrocytosis is no different from that of polycythemia vera. In each instance, the problem is an expanded red cell mass, which in the case of secondary erythrocytosis may be coupled with a reduction in plasma volume. The net result of these abnormalities is an increase in peripheral vascular resistance, a reduction in cardiac output, and a decline in systemic oxygen transport.[123] Cerebral blood flow is invariably reduced with any form of erythrocytosis, [124] [125] [126] and this may result in impaired glucose delivery to the brain. [127] Therefore, there is no such thing as benign erythrocytosis; thromboembolic complications have been recorded with every form of the disorder, and no symptoms may have been exhibited beforehand. It is therefore recommended that all patients with erythrocytosis without a correctable cause undergo a careful phlebotomy regimen.

In patients with pulmonary disease, cyanotic congenital heart disease, or a highoxygen-affinity hemoglobin, the extent of phlebotomy can be dictated by the patients symptomatic response or by the serum EPO level as a measure of tissue hypoxia. In these disorders, even limited phlebotomy has proved symptomatically beneficial.[128] [129] [130] [131] [132] In cyanotic congenital heart disease, proteinuria may be reduced [133] and the coagulopathy improved.[60] In patients with a low plasma volume, phlebotomy is not deleterious and actually stimulates an increase in the plasma volume. If possible, phlebotomy should be continued until the hematocrit is <45%, because anything less vigorous may be associated with a persistent reduction in cerebral blood flow. [125] Contrary to published commentary, it is always possible to control the red cell mass by phlebotomy if venous access is adequate, because sustained phlebotomy induces iron deficiency with certainty. Phlebotomy does not, despite commentary to the contrary, cause hyperviscosity by producing rigid microcytic red cells. In adults, induced iron deficiency can never cause clinically significant hyperviscosity due to the rigidity of iron-poor red cells [134] because with true iron deficiency it is impossible to increase the red cell mass sufficiently to cause hyperviscosity. Furthermore, it has been well demonstrated that chronic iron deficiency in adults in the absence of anemia does not impair functional aerobic performance.[135]

In summary, erythrocytosis presents a diagnostic challenge to the physician, and in some cases no conclusive answer concerning its mechanism is immediately evident. The clinical evaluation should follow a logical progression, and even in the absence of a firm diagnosis, therapeutic phlebotomy can and should be used. Chemotherapeutic agents are not indicated for the sole purpose of reduction of the red cell mass. [136] Because this is true in polycythemia vera as well as in secondary erythrocytosis, lack of a definite diagnosis does not adversely affect prognosis as long as the red cell mass is adequately controlled.

Chapter 26 - Disorders of Iron Metabolism: Iron Deficiency and Overload

Gary M. Brittenham

INTRODUCTION

Iron is an essential nutrient required by every human cell. A transition metal (atomic number 26, atomic weight 55.85), iron can serve as a carrier for oxygen and electrons and as a catalyst for oxygenation, hydroxylation, and other critical metabolic processes, in part because of its ability to reversibly and readily cycle between the ferrous (Fe^{2+}) and ferric (Fe^{3+}) oxidation states. As a result, iron is quantitatively the most important biocatalytic element in human enzymology, with vital roles in oxidative metabolism, in cellular growth and proliferation, and in oxygen transport and storage.

Iron is transported and stored as a component of a variety of iron compounds, not as a free cation. The very reactivity that is metabolically useful in iron porphyrin complexes and metalloenzymes makes inorganic iron compounds or ionized forms potentially hazardous. Ionic iron can participate in a number of reactions to produce free radical species, which in turn can damage cellular constituents. As a consequence, either a decrease or an increase in body iron may be clinically significant. If too little iron is available (iron deficiency), limitations on the synthesis of physiologically active iron-containing compounds may have deleterious consequences. If too much iron accumulates (iron overload) and exceeds the bodys capacity for safe transport and storage, iron toxicity may produce widespread organ damage and death.

IRON METABOLISM

Biological and Molecular Aspects

Proteins of Iron Transport, Uptake, Storage, and Regulation

A quartet of proteins provides for the iron requirements of the body. The internal supply and storage of iron is mediated by three principal proteins, transferrin, transferrin receptor, and ferritin, while their supply in turn is regulated by a fourth class of proteins, the iron regulatory proteins (IRPs). *Transferrin*, a transport protein, carries iron in the plasma and extracellular fluid to supply tissue needs. *Transferrin receptor*, a glycoprotein on cell membranes, binds the transferrin-iron complex and is internalized in a vesicle where the iron is released intracellularly; the transferrin-transferrin receptor assemblage then returns to the cell membrane, where apotransferrin is liberated into the plasma. *Ferritin*, an iron storage protein, sequesters iron in a presumably nontoxic form while holding it ready for prompt mobilization in time of need. The *iron regulatory proteins* (IRP-1 and IRP-2; previously known as the iron-responsive element-binding proteins [IRE-BPs], iron regulatory factors [IRFs], ferritin-repressor proteins [FRPs], and p90) are messenger ribonucleic acid (mRNA)-binding proteins that coordinate the intracellular expression of transferrin receptor, ferritin, and other proteins important for iron metabolism. Each of these principal proteins has been isolated, purified, and characterized. The chromosomal locations of the corresponding genes have been identified and their sequences determined. The available information is summarized in Table 26-1 , and the structures of the proteins are shown diagrammatically in Figure 26-1 .

Transferrin

Transferrin (Fig. 26-1A) is the sole physiologic carrier of iron between body tissues. [1] A single gene for apotransferrin has been identified and located at q21-qter on chromosome 3, near the gene for the transferrin receptor. Structural analysis suggests that the transferrin gene originated as the result of an unequal crossover between two primordial transferrin genes. [2] Apotransferrin is a single-chain glycoprotein (M_r 79,570; 6% glucosidic) with 678 amino acid residues and is composed of two homologous N-terminal and C-terminal lobes (Fig. 26-1A). [1] Each lobe can independently bind a single ferric ion, so the molecule can exist as apotransferrin or as monoferric or diferric transferrin. The lobes are in the shape of prolate ellipsoids, and

TABLE 26-1 -- Proteins of Iron Transport, Storage, and Regulation

	Transferrin	Transferrin Receptor	Ferritin	Iron Regulatory Proteins (IRP-1, IRP-2)
M_r	79,570	185,000	440,000	90,000
Chromosomal location of gene(s)	3q21-qter	3q26.2-qter	H subunit: 11 L subunit: 19	IRP-1: 9 IRP-2: 15
Structure	Single-chain glycoprotein with two iron-binding sites	Transmembrane glycoprotein dimer with two transferrin-binding sites	Spherical protein of 24 subunits, binds up to 4,500 iron atoms	Four-domain proteins; IRP-1 contains a [4Fe-4S] cluster
Function	Iron transport in plasma and extracellular fluid	Receptor-mediated endocytosis of ferric transferrin; is recycled	Iron storage	Coordinate translational regulation of critical proteins of iron metabolism

Figure 26-1 Structures of proteins of iron transport, uptake, storage, and regulation. **(A)** Apotransferrin. Schematic representation of the polypeptide chain shows that it is folded into two lobes, each in the shape of a prolate ellipsoid and containing a single iron-binding site, represented by a dot. Each lobe is in turn composed of two dissimilar domains, labeled I and II. The N-terminal and C-terminal lobes are indicated. *(From Bailey et al., [224] with permission.)* **(B)** Transferrin receptor. Schematic representation of the transferrin receptor on the cell surface shows it as a transmembrane glycoprotein dimer composed of two identical subunits linked by a disulfide bond. The transferrin receptor is amphipathic with a small hydrophilic cytoplasmic tail, a large hydrophilic extracellular domain, and a central hydrophobic region anchoring the receptor into the membrane. The receptor can bind two molecules of transferrin. *(From Huebers and Finch, [7] with permission.)* **(C)** Ferritin. Schematic representation of human isoferritins with different proportions of subunits. In the diagram, shaded subunits represent human H chains and plain subunits, L chains. Homopolymers of H chains and L chains are shown at the top and bottom of the figure, respectively, with heteropoly-mers of decreasing H-chain content placed between the homopolymers and the sources of the various ferritins labeled in the column on the right. *(Reprinted from Harrison and Arosio, [12] with permission from Elsevier Science.)* **(D)** Iron regulatory proteins (IRPs). This schematic representation of IRP-1 is based on the polypeptide fold of porcine mitochondrial aconitase provided by Lauble et al. [215] *(with permission from the American Chemical Society; copyright 1992.).* The molecule is folded into four domains; the first three (the lower portion of the molecule in the figure) are closely associated about the Fe-S cluster (shown in red), with the fourth (the upper portion of the molecule in the figure) attached by an extended hinge or linker peptide, creating an intermolecular cleft. The [3Fe-4S] cluster is coordinated by three cysteine residues while in the form of the protein; active as an aconitase, the fourth iron atom is inserted into the corner of the (4Fe-4S) cubane structure.

each is further divided into two dissimilar domains. Each iron-binding site is located within the interdomain cleft, where the iron is bound by two tyrosines, a histidine, and an aspartic acid residue. [3] An anion (bicarbonate or carbonate) is bound with each ferric ion, serving as a bridging ligand between the iron and protein. [3] Transferrin binds ferric iron with high affinity; under physiologic conditions the effective stability constant [1] [3] is about 10^{20} M^{1} . Binding of two atoms of ferric iron by transferrin results in major conformational changes: the interdomain clefts, which are open in apotransferrin, close when iron is bound, [4] making the molecule more compact, more soluble, and more resistant to oxidative or tryptic denaturation. The two iron-binding domains are similar, with more than 40% sequence identity, but differ in their detailed spectroscopic, thermodynamic, kinetic, and chemical properties. [5] The affinity of the C-terminal site for iron is about one order of magnitude greater than that of the N-terminal site, [6] and in vitro, apotransferrin in interaction with bicarbonate first binds iron at the C-terminal site and then undergoes conformational changes that lead to iron uptake at the N-terminal site. [3]

Most apotransferrin is produced by hepatocytes. [1] Although a variety of other sites of synthesis have been identified (including lactating mammary gland, testis, central nervous system [CNS], lymphocytes, and macrophages), none seems to be a quantitatively important source of plasma transferrin in vivo. The total amount of

apotransferrin in humans is about 240 mg/kg, equally divided between the plasma and extravascular fluids. [7] Apotransferrin is a true carrier that is not lost in delivering iron, so its turnover is unrelated to the plasma iron turnover; its half-life is about 8 days. [7] Each transferrin molecule undergoes 100200 cycles of iron binding and release during its lifetime in the circulation.

Transferrin Receptor

The number and stability of transferrin receptors on the cell surface are prime determinants of cellular iron uptake. The transferrin receptor not only provides transferrin-bound iron access into the cell, it also plays a critical role in the release of iron from transferrin within the cell. A single gene for the transferrin receptor has been identified; like the transferrin gene, it is located on the distal portion of the long arm of chromosome 3 in the region q26.2-qter. [8] The transferrin receptor (Fig. 26-1B) is a transmembrane glycoprotein dimer composed of two identical subunits (each with M_r 94,000) linked by a disulfide bond. The transferrin receptor is amphipathic, with a small hydrophilic cytoplasmic tail (62 amino acid units, M_r about 5,000), a large hydrophilic extracellular domain (648 amino acids, M_r about 140,000), and a central hydrophobic region anchoring the receptor to the membrane (28 amino acids). [9] The transferrin receptor can bind two molecules of transferrin; if each transferrin is diferric, the dimeric receptor can carry a total of four atoms of transferrin-bound iron. The affinity of the transferrin receptor for transferrin depends on both the iron content of transferrin and the pH. With amounts of iron-bearing transferrin sufficient to saturate receptors at a physiologic pH of 7.4, the receptor has very little affinity for apotransferrin, an intermediate affinity for monoferric transferrin, and the highest affinity for diferric transferrin, estimated at 2×10^{9} to 7×10^{9} M. Under such physiologic conditions, the affinity of the transferrin receptor for diferric transferrin is about four times that for monoferric transferrin. [7] At a pH of about 5, the affinity of the transferrin receptor for apotransferrin increases to that for diferric transferrin.

Transferrin receptors appear to be expressed on virtually all nucleated cells and are present in large numbers in erythroid precursors, placenta, and liver. The number of transferrin receptors on the cell surface is a prime determinant of cellular iron supply. In nondividing cells the receptor number is constant, but numbers increase markedly in proliferating cells. The number

of receptors seems to reflect cellular iron requirements; in the rat, the estimated number of transferrin receptors was found to be about 300,000 per cell in the early normoblast, about 800,000 per cell in the intermediate normoblast, and about 100,000 per cell in the reticulocyte. [10] The half-time for disappearance of transferrin receptors from the cell has been reported to range from <24 hours to 23 days. [11]

Ferritin

Ferritin, the major iron storage protein, is composed of 24 subunits of at least two types: L (or light: M_r 19,700; more acidic with pI 4.55.0) and H (or heavy: M_r 21,100; more basic with pI 5.05.7). [12] Genes for both the H and L chains belong to multigene families with members on several chromosomes, but most of these are pseudogenes. A functional H gene and a functional L gene have been mapped to chromosomes 11 and 19. [13]

Apoferritin (M_r 440,000) consists of a spherical protein shell about 1 nm thick and 12 nm in diameter that is composed of mixtures of oblong H and L subunits whose proportions depend on the tissue and iron status of the cell (Fig. 26-1C). Both subunits consist of four helix bundles with a fifth short helix at roughly 60 degrees to the bundle axis. Iron storage within ferritin requires oxidation of Fe^{2+}, movement of Fe^{3+} into the interior of the molecule, and the nucleation and growth of the core of ferric hydroxyphosphate. [12] H subunits are involved in Fe^{2+} oxidation, while L subunits participate in core formation. [14] Tissues functioning as major iron storage depots, such as liver and spleen, have isoferritins with a preponderance of the L subunit, while tissues that do not normally act as iron storage sites, such as heart, contain isoferritins with higher proportions of H subunits. Within a specific tissue, greater amounts of storage iron are associated with a greater predominance of L subunits. [15] These patterns suggest that ferritins enriched in L subunits have a long-term iron storage function while ferritins with a predominance of H subunits may be more active in iron metabolism. The ferritin H subunit contains a ferrioxidase site lacking from the L subunit. [16] Recombinant human homopolymers composed solely of H subunits have been found to take up iron at a rate several times that of homopolymers composed only of L subunits. [14] These variations in the proportions of H and L subunits and other factors such as the extent of glycosylation give rise to tissue isoferritins with different isoelectric points.

Ferritin is found in virtually all cells, providing both an accessible reserve of iron for synthesis of functional iron-containing compounds and a means of sequestering iron in a soluble, apparently nontoxic form. It is especially abundant in cells with specialized roles in the synthesis of iron-containing compounds (erythroid precursors) and in iron metabolism and storage (macrophages, hepatocytes). Within the apoferritin shell, the component subunits are arranged so that a total of eight hydrophilic channels are formed near the N-terminal ends of the subunits along the four threefold axes of symmetry, while an additional six hydrophobic channels lie along the three fourfold axes of symmetry, [12] apparently providing routes for movement of iron and small molecules in and out of the interior of the sphere. Each ferritin molecule can reversibly store as many as 4,500 iron atoms within the shell in an inorganic polynuclear core of ferric hydroxyphosphate; typically only about half that amount is present.

The half-life of hepatic ferritin is about 60 hours. Catabolism of cellular ferritin may result in digestion of the protein shell with reutilization of the iron core, or in conversion to hemosiderin, an amorphous water-insoluble storage compound with a higher iron content and slower turnover than ferritin. [12] [17] Ascorbic acid seems to retard ferritin degradation by reducing lysosomal autophagy of the protein. [18] Intracellular ferritin is synthesized by the smooth endoplasmic reticulum in amounts required to replace catabolized ferritin and hemosiderin and to store any additional iron entering the cell. Small amounts of ferritin are also secreted into the plasma. Plasma ferritin is apparently synthesized by the rough endoplasmic reticulum and glycosylated by the Golgi apparatus. Normally, the amount of plasma ferritin synthesized and secreted seems to be proportional to the amount of cellular ferritin produced in the internal iron storage pathway so that the plasma ferritin concentration is related to the magnitude of body iron stores. [12] [19] [20]

Iron Regulatory Proteins (IRP-1 and IRP-2)

The iron regulatory proteins IRP-1 and IRP-2 function as both sensors and controllers of intracellular iron supply. They are trans-acting cytoplasmic RNA-binding proteins (Fig. 26-1D) that modulate the expression of mRNAs containing a cis-acting regulatory structure termed the iron-responsive element (IRE). [21] [22] [23] The IRE is a conserved 28-nucleotide sequence in a hairpin-shaped, stemloop with bulge conformation that serves as the binding site for the iron regulatory proteins (Fig. 26-2B). [23] [24] [25] The two IRPs are structurally and functionally similar but differ in their binding specificities, their pattern of tissue expression, their modes of regulation, and their responses to specific stimuli. These similarities and differences provide redundancy, flexibility, and versatility in meeting the specialized iron requirements of each cell.

IRP-1 has been found to be the cytosolic aconitase (citrate [isocitrate] hydrolyase), an iron-sulfur protein that acts enzymatically within the Krebs cycle in the interconversion of citrate to isocitrate. [26] [27] [28] A cubane [4Fe-4S] cluster forms the catalytically active site of aconitase in which three of the iron atoms are linked to the protein backbone and the fourth is bound to an inorganic sulfur within the cubane cluster. [29] [30] Intracellularly, aconitase exists in both a mitochondrial and a cytoplasmic form. The mitochondrial form of aconitase, encoded by a gene on chromosome 22, is enzymatically functional but lacks IRP activity. The cytoplasmic form, the product of a gene on chromosome 9, can function both enzymatically as an aconitase and as the RNA-binding IRP-1. [29] [31] [32] The 18 active site residues of mitochondrial aconitase and of IRP-1 are identical. [26] IRP-1 can be reversibly converted from an enzymatically active aconitase (with low RNA-binding affinity) to a high-affinity RNA-binding form (with no aconitase activity) by alterations in the Fe-S cluster in response to changes in intracellular iron availability. As shown in Figure 26-2D , physiologic changes in iron availability reciprocally regulate the aconitase activity (increased with iron repletion) and RNA-binding affinity (increased with iron depletion) of the IRP-1, with the Fe-S cluster functioning as a sensor of iron availability. [29]

Human IRP-2 is highly similar to human IRP-1 [22] , but, lacking the amino acids present at the active site of aconitase, it has no enzymatic activity. IRP-2 binds to IREs with an affinity similar to that of IRP-1 and is just as effective as a translational repressor in vitro. Although the two IRPs bind with equally high affinity to IREs, IRP-1 and IRP-2 recognize distinct and different subsets of IREs. [33] The existence of IRP-specific groups of IREs suggests that IRP-1 and IRP-2 may each regulate different assortments of mRNAs. Changes in intracellular iron availability alter the mRNA-binding activity of both IRPs post-translationally but by different means (Fig. 26-2C). [34] The control of IRP-1 involves a switch from the (nonbinding) form with aconitase activity to the IRE-binding form (without aconitase activity), with little change in the amount of IRP-1 protein. By contrast, the binding activity of IRP-2 is regulated by the degradation of the protein in the proteasome when cells are iron replete. [35] With iron deprivation, new IRP-2 is synthesized. The relative proportions of IRP-1 and IRP-2 vary from one cell type to another, but in most cells, the amounts of IRP-1 are greater than those of IRP-2. Most tissues contain mRNA for both, but a mammalian cell line has been identified that fails to express IRP-1 protein or mRNA. [36]

Although all the IRE-binding activity

Figure 26-2 Cellular iron supply and storage. **(A)** Schematic representation of the process of cellular iron uptake and transferrin-receptor recycling. Iron delivery to the cell begins with the binding of up to two molecules of mono- or diferric transferrin to a transferrin receptor in an energy- and temperature-dependent process. Once bound, the iron-bearing transferrin-receptor complex rapidly clusters with other transferrin-receptor complexes in a clathrin-coated pit, which seals over and fuses to form an internal vesicle or endosome. Moving to the interior of the cell, the endosome then fuses with an acidic vesicle whose internal pH is below 5.5. In this acidic environment iron is released from transferrin and is then made available for cellular use or storage. Acidification within the endosome also increases the affinity of the now iron-free apotrans-ferrin for the transferrin receptor, with the result that the apotransferrin-receptor bond remains intact as the complex within the endosome is transported back to the cell surface. On exposure to the neutral pH of plasma, the apotransferrin loses its affinity for the transferrin receptor and is released from the membrane, which makes both the apotransferrin and the receptor available for neutralization. *(Adapted from Irie and Tavassoli,[216] with permission.)* **(B)** Structure of an IRE. The consensus structure for an IRE is shown, as derived from sequences and possible secondary structures of IREs from ferritin and transferrin receptor mRNAs. *(From Klausner et al.,[57] with permission.)* **(C)** Regulation of IRP-1 and IRP-2. The two IRPs are shown schematically as homologous four-domain proteins that bind to IREs. In iron-replete cells, IRP-1 assembles a cubane [4Fe-4S] cluster, becoming enzymatically active as a cytosolic aconitase but losing affinity for IRE binding. With iron deprivation, treatment with the iron chelator deferoxamine (DFO) or with nitric oxide (NO), IRP-1 disassembles the Fe-S cluster, losing aconitase activity, while slowly (over 15 hours) gaining high affinity for IRE binding. Exposure to hydrogen peroxide (H_2O_2) also abolishes aconitase activity with the development of high-affinity IRE binding but more rapidly (in <1 hour). The amounts of IRP-1 are little changed with these treatments. IRP-2 undergoes proteasome-mediated degradation in iron-replete cells, but this effect of iron is opposed by DFO and NO. With iron deprivation, new IRP-2 with high binding affinity for the IRE is synthesized. **(D)** Schematic representation of the coordinate regulation of transferrin receptor, ferritin, and erythroid-specific -aminolevulinic acid synthase (eALAS) synthesis by the iron regulatory proteins IRP-1 and IRP-2. Transferrin receptor synthesis is controlled by adjusting the amounts of cytoplasmic transferrin receptor mRNA. The 3 untranslated region (3 UTR) of transferrin receptor mRNA contains five IREs. Binding of IRPs to the IREs in the 3 UTR retards cytoplasmic degradation, increasing the concentration of cytoplasmic transferrin receptor mRNA and the rate of transferrin receptor synthesis. With an increased number of cellular transferrin receptors, iron uptake is enhanced. By contrast, ferritin and eALAS synthesis are controlled without changes in the amount of ferritin or eALAS mRNA present by repressing translation of ferritin or eALAS mRNA. The 5 untranslated regions (5 UTR) of both ferritin and eALAS mRNA contain a single IRE. Binding of an IRP to the IRE in the 5 UTR (1) arrests translation of ferritin mRNA, so that less ferritin is produced and iron sequestration is diminished and (2) stops translation of eALAS mRNA, decreasing production of eALAS and diminishing utilization of iron in the heme biosynthetic pathway.

in these cells is attributable to IRP-2, changes in ferritin and transferrin receptor synthesis in response to iron exposure or deprivation are appropriate.

IRP-1 and IRP-2 regulate intracellular iron metabolism not only by reacting to changes in iron availability but also by responding to other stimuli in a cell-specific manner. Oxidative stress and nitric oxide, an important mediator of the inflammatory response, influence the IRE-binding affinity of both IRPs but in different fashions for IRP-1 and IRP-2 (Fig. 26-2C).[37] [38] [39] [40] In erythroid cells, erythropoietin enhances the IRE-binding affinity of IRP-1, but this effect is not seen in cells of macrophage origin.[41] IRE-binding affinities of the IRPs are also influenced by the phosphorylation state of the IRPs. [42] In one macrophage cell line, stimulation with interferon (IFN)-/lipopolysaccharide (LPS) resulted in nitric oxide-dependent alterations of both IRPs but in opposite directions. [40] IRP-1 IRE-binding activity slightly increased, while IRP-2 binding activity was greatly decreased in conjunction with increased ferritin synthesis. Overall, these observations indicate that the contributions of both IRPs to overall regulation must be considered in understanding iron-regulated gene expression in individual cells. The existence of two forms of IRP that differ in their binding specificities, in their patterns of tissue and cellular expression, in their modes of regulation, and in their responses to specific signals potentially provides a subtle and adaptable means of meeting the unique iron requirements of each cell.

Cellular Iron Supply and Storage

Molecular Mechanisms of Cellular Iron Uptake

Cellular Iron Uptake via TransferrinTransferrin Receptor-Mediated Endocytosis

The coordinate roles of transferrin, transferrin receptor, and ferritin in cellular iron supply and storage are shown schematically in Figure 26-2A . Iron delivery to the cell begins with the binding of one or two molecules of mono- or diferric transferrin to a transferrin receptor in an energy- and temperature-dependent process [43] [44] that is complete within 23 minutes. At the neutral pH of plasma, the iron-transferrin complex is further stabilized by the binding of transferrin to the transferrin receptor, both for monoferric and for diferric transferrin. [44] [45] The efficiency of iron delivery to the cell depends on the amounts of mono- and diferric plasma transferrin available. With normal erythropoiesis and a normal transferrin saturation of about 33%, the higher affinity of the receptor for diferric transferrin results in most of the iron supply to cells being derived from this form, providing four atoms of iron with each cycle. At a transferrin saturation of about 19%, equal amounts of iron are provided by mono- and diferric transferrin, while at lower saturations, most of the iron is derived from the monoferric form. [7] [46] Whether mono- or diferric, the fate of transferrin bound to the transferrin receptor is the same. The iron-bearing transferrin-receptor complex rapidly clusters with other transferrin-receptor complexes in a clathrin-coated pit; a YXRF (Tyr-X-Arg-Phe) structural motif in the cytoplasmic domain of the transferrin receptor is required for internalization. [47] Phosphorylation of the receptor by protein kinase C enhances the initial rate but not the final extent of internalization. The phosphorylated and nonphosphorylated forms of the receptor seem otherwise to behave identically, [48] and the internalization sequence and phosphorylation site are distinct from the basolateral targeting signal. [49] Once assembled, the clathrin-coated pit is promptly internalized and detaches from the inner membrane. Within the cytoplasm the vesicle is rapidly stripped of clathrin [50] and the uncoated vesicles fuse to become multivesicular endosomes.[51] In the interior of the cell, a proton pump lowers endosome internal pH to about 5.6. [44] [52]

Role of Transferrin Receptor in the Release of Iron from Transferrin Within the Endosome

In the acidic environment of the endosome, the transferrin receptor plays a critical role in iron dissociation from both mono- and diferric forms of transferrin. [44] At the endosomal pH of 5.6, iron release from free transferrin has a half-time of >15 minutes, and release is predominantly from the N-terminal site. [53] For comparison, in endosomes of erythroid cells, iron release from both transferrin sites is virtually complete within 23 minutes. The interaction of transferrin receptor and transferrin in the complex seems to account for this difference in the rapidity and completeness of iron release, perhaps by producing conformational changes in transferrin. [44] [45] [53] At pH 5.6, iron release from unbound monoferric transferrins is three times faster for the N-terminal form (Fe_N Tf) than for the C-terminal species (Fe_C Tf). Binding to the transferrin receptor has little effect on release from the N-terminal monoferric transferrin (Fe_N Tf) but substantially increases release from the C-terminal site (Fe_C Tf). Binding to the transferrin receptor at pH 5.6 alters site-site cooperative interactions between the two sites of doubly occupied transferrin: iron at the N-terminal lobe is stabilized while iron at the C-terminal lobe is labilized. [44] Overall, transferrin receptor binding at endosomal pH seems to substantially enhance both the rate and completeness of iron release from transferrin within the erythroid cell while minimizing differences between the N- and C-terminal sites.

Transport of Iron Across the Endosomal Membrane via Nramp2

After release within the acidified endosome, the iron must be transported across the endosomal membrane. Nramp2 (natural resistanceassociated macrophage protein 2) has recently been identified as the putative transmembrane iron transport protein that provides both for the movement of iron out of the endosome and for normal intestinal iron absorption (Fig. 26-3A, B).[54] [55] [56]

Figure 26-3 Transport of iron across membranes via Nramp2, the putative transmembrane iron transport protein. **(A)** Twelve-transmembrane-domain model of the rat isoform of human Nramp2, DCT1 (divalent-cation transporter). The putative transmembrane domains 1 to 12 are indicated. The consensus transport motif is indicated in the fourth intracellular loop and putative N-linked glycosylation sites are identified in the fourth extracellular loop. *(Reprinted with permission from Gunshin et al.[55] Copyright 1997 Macmillan Magazines Limited.)* **(B)** Model for iron transport pathway in

mammals. In this model, Nramp2 transports iron from the intestinal lumen into enterocytes. The iron then passes by unknown means to the basolateral surface, is loaded onto transferrin, and is transported through the plasma. The iron-loaded transferrin is bound by a transferrin receptor on the surface of an erythroblast, internalized into an endosome, which is then acidified and the iron released. Nramp2 transports iron out of the endosome for cellular utilization. *(Modified from Vulpe and Gitschier,[217] with permission.)*

Nramp is a newly identified family of integral membrane proteins. Nramp1 was initially identified and named for its association with susceptibility to infection by intracellular pathogens and is expressed only in macrophages. The role of Nramp2 in iron transport was first recognized in efforts to identify the causative mutation in mice with microcytic anemia (*mk*), a mutant with severe defects both in iron absorption and in erythroid iron utilization. A missense mutation in Nramp2 was identified.[54] The rat isoform of human Nramp2 has been identified as a divalent-cation transporter (DCT1) with a broad substrate range that includes Fe^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Cd^{2+}, Cu^{2+}, Ni^{2+}, and Pb^{2+}.[55] DCT1 mediates active transport that is proton-coupled and depends on the cell membrane potential. DCT1 is ubiquitously expressed in tissues throughout the body, with notably high expression in enterocytes in the upper small intestine. In the 3 untranslated region of DCT1 cDNA, a putative IRE has been identified, suggesting, by analogy to transferrin receptor mRNA, that IRPs may regulate DCT1 mRNA levels by retarding RNA degradation. [55] Subsequent studies in the Belgrade rat, which has an autosomal recessive microcytic anemia with impaired intestinal iron absorption and defective erythroid utilization resembling that in the *mk* mouse, found a similar missense mutation in Nramp2.[56] In aggregate, these results provide strong evidence that Nramp2 is a mammalian iron transporter involved both in the movement of iron out of the endosome and in the absorption of iron from the gastrointestinal tract (Fig. 26-3B). The exact form and fate of the iron derived from the endosome are still unknown, but this newly released iron presumably is available to the mitochondria of the erythroid cell for heme synthesis or to ferritin for storage.

Return of the TransferrinTransferrin Receptor Complex to the Cell Surface

Acidification within the endosome increases the affinity of the now iron-free apotransferrin for the transferrin receptor, with the result that the apotransferrin-receptor bond remains intact as the complex is transported back to the cell surface within the endosome (Fig. 26-2A).[57] Some endosomes are briefly shunted to the Golgi apparatus for resialation and repair before returning to the membrane. [58] On exposure to the neutral pH of the plasma, apotransferrin loses its affinity for the transferrin receptor and is released from the membrane, making both apotransferrin and receptor available for reutilization. [44] [52]

Coordinate Regulation of Cellular Iron Uptake and Storage

Within the cell, IRP-1 and IRP-2 provide the means for the coordinate regulation of the physiologic uptake and storage of iron by translational control of the synthesis of transferrin receptor and ferritin (Fig. 26-2D).[23] [59] [60] [61] Transferrin receptor synthesis is controlled by adjusting the amounts of cytoplasmic transferrin receptor mRNA. The 3 untranslated region (3 UTR) of transferrin receptor mRNA contains five IREs. Binding of IRPs to the IREs in the 3 UTR retards cytoplasmic degradation, increasing the concentration of cytoplasmic transferrin receptor mRNA and the rate of transferrin receptor synthesis. With an increased number of cellular transferrin receptors, iron uptake is enhanced. Ferritin synthesis is controlled without changes in the amount of ferritin mRNA present by repressing translation of ferritin mRNA. The 5 untranslated region (5 UTR) of ferritin mRNA contains a single IRE. Binding of an IRP to the IRE in the 5 UTR arrests translation of the ferritin mRNA, so that less ferritin is produced and iron sequestration is diminished. Altogether, the coordinate regulation of intracellular iron availability by the IRPs has opposite effects on the synthesis of transferrin receptor and ferritin. A *decrease* in intracellular available iron results in an increase in the proportion of high-affinity IRPs. Increased IRP binding to IREs increases transferrin receptor protein production but decreases ferritin protein production. An *increase* in intracellular iron results, for IRP-1, in assembly of [4Fe-4S] clusters with loss of IRP-1 binding activity, and for IRP-2, in specific proteolysis. Fewer IRPs are bound to IREs, decreasing transferrin receptor protein production while increasing ferritin protein production. These balanced and opposing alterations in iron uptake and storage governed by the IRPs serve to maintain consistent intracellular physiologic iron homeostasis and to respond to both oxidative stress and inflammation. IRPs also bind to functional IREs in the 5 UTR of mRNAs of the erythroid-specific -aminolevulinic acid synthase (eALAS) and of mitochondrial aconitase and repress their synthesis under conditions of iron deprivation, linking iron utilization and cellular energy utilization to the regulation of iron homeostasis. [59] [62] [63] [64] [65]

Body Iron Supply and Storage

Body Iron Distribution

The concentration of iron in the human body is normally about 4050 mg Fe/kg body weight; women typically have lower amounts than men (Table 26-2).[66] [67] [68] [69] Most of this iron is contained in essential iron compounds. This functional iron compartment includes about 30 mg Fe/kg as hemoglobin iron contained

TABLE 26-2 -- Distribution of Iron in the Adult

Type of Iron	Concentration (mg/kg)	
	Men	Women
Functional iron		
Hemoglobin	31	28
Myoglobin	5	4
Heme enzymes	1	1
Nonheme enzymes	1	1
Transport iron		
Transferrin	<1 (0.2)	<1 (0.2)
Storage iron		
Ferritin	8	4
Hemosiderin	4	2
Total	50	40

within circulating red cells and an additional 67 mg Fe/kg that is present in tissues throughout the body in myoglobin and in a variety of heme enzymes (cytochromes, catalases, peroxidases) and nonheme enzymes (ribonucleotide reductase, metalloflavoproteins, iron-sulfur proteins). Transport iron consists of the small fraction (<0.5%) of the total body iron that is in transit to supply tissue iron needs. Iron in the transport compartment is bound to transferrin in plasma and extracellular fluid. The remainder of the iron (56 mg Fe/kg in women, 1012 mg Fe/kg in men) is storage iron in the form of ferritin and hemosiderin, principally in hepatocytes and in macrophages in the liver, bone marrow, spleen, and muscle, serving as a reserve in the event of blood loss.

Iron Balance: Iron Absorption and Loss

The major pathways of iron absorption and loss, and of internal iron exchange and storage are shown schematically in Figure 26-4 . *Iron balance* is determined by the difference between the amounts of iron entering and leaving the body. Humans are unique in their lack of any effective means to excrete excess iron. [70] Iron balance is physiologically regulated by controlling iron absorption: iron stores and absorption are reciprocally related, so that as stores decline, absorption increases. [71] Normally, iron exchange with the environment is extremely limited. Less than 0.05% of the total body iron is acquired or lost each day. Humans are unequaled in the effectiveness with which iron is conserved.

Both heme and nonheme iron are absorbed through the brush border of the upper small intestine. [72] [73] [74] The iron content

IRON REQUIREMENTS

Overall, the *iron requirement* for an individual includes not only that iron needed to replenish physiologic losses and to meet the demands of growth and pregnancy but also any additional amounts needed to replace pathologic losses. Physiologic iron losses are generally restricted to the small amounts of iron contained in the urine, bile, and sweat; the shedding of iron-containing cells from the intestine, urinary tract, and skin; occult gastrointestinal blood loss; and, in women, uterine losses during menstruation and pregnancy.[119] In normal men the daily basal iron loss is slightly less than 1.0 mg/day, and in normal menstruating women it is about 1.5 mg/day. The median total iron loss with pregnancy is about 500 mg, or almost 2 mg/day over the 280 days of gestation.[121]

Figure 26-4 Body iron supply and storage. A schematic representation of the routes of iron movement. The major pathway of internal iron exchange is a unidirectional flow from plasma transferrin to the erythron to the macrophage and back to plasma transferrin. Storage iron in the macrophages of the liver, bone marrow, and spleen is derived almost entirely from phagocytosis of senescent erythrocytes or defective developing red cells. The macrophage is virtually unable to take up iron from plasma transferrin, whereas the hepatocyte may either donate iron to or receive iron from plasma transferrin. Normally, the overall magnitude of iron exchange by hepatocytes is only about one-fifth that of macrophages. Other pathways of iron movement involve approximately equal exchanges for iron absorption and losses, for transfer between the plasma and extravascular transferrin compartments, and for movement between extravascular transferrin and parenchymal tissues. In a pregnant woman, iron is taken up via placental transferrin receptors and unidirectionally passed to fetal transferrin for utilization by fetal tissues. *(Data from Finch and Huebers.[68])*

of the diet is a function of caloric intake; typical diets in the United States contain about 7 mg/1,000 kcal. The availability of dietary iron for absorption is determined by the amount and form of the iron, the composition of the diet, and GI factors. Heme iron is usually only a small portion of the dietary iron but is highly available for absorption (2030% absorbable) and little affected by other components in the diet. [74] Most dietary iron (often <90%) is nonheme iron, which enters a common intraluminal pool, whose availability is determined by the balance between inhibitors (phytates, tannates, phosphates, etc.) and enhancers (amino acids, ascorbic acid) of absorption.[72] [73] Frequently, <5% of the nonheme iron is available for absorption. Iron availability is also influenced by GI factors such as gastric secretion, intestinal motility, and the consequences of surgery or bowel disease.

The absorption of available iron is regulated by the mucosal cells of the proximal small intestine. Mucosal regulation of iron absorption might occur by controlling one or more of the following steps: (1) mucosal uptake of iron across the brush border membrane, (2) retention of iron in storage form within the mucosal cell, and (3) transfer of the iron from the mucosal cell to the plasma. The molecular route of iron uptake is now believed to involve Nramp2, [54] [55] [56] but the details of the movement of iron from the gut have not been established with certainty. Evidence has also been developed for a pathway involving mobilferrin and paraferritin, [72] [73] but the relationship between this pathway and Nramp2 is unclear. Physiologically, the major determinants of mucosal iron absorption are the amount of body iron stores and the level of erythropoiesis: absorption increases with diminished storage iron and increased erythropoietic activity. [75] Hypoxia may also increase iron absorption independently of changes in erythroid activity. [76] A maximum of about 3.5 mg Fe/day may be absorbed from the diet, with adequate amounts of bioavailable iron and the enhanced level of absorption found in the iron-deficient state. [71]

Internal Iron Exchange

Once absorbed, iron is bound to plasma transferrin. The daily disposition of this transferrin-bound iron is summarized in Figure 26-4 , which provides an inventory of the distribution of iron in the body and a schematic representation of the patterns of iron utilization. [66] [67] [68] [69] In an iron-replete 70-kg man, the amount of transferrin iron in the plasma at any given time is only about 3 mg, but >30 mg of iron moves through this transport compartment each day. The *erythron* consists of the aggregate of all erythroid elements, including cells at all stages of development, in the marrow, circulation, and extravascular space. Although iron is an essential nutrient required by every human cell, most of the iron in the body is found within the erythron and most of its daily movement cycles through the erythron. Most iron in transit (24 mg Fe/day) is taken up by erythroid precursors in the marrow; the majority of this (17 mg Fe/day) becomes hemoglobin iron in circulating red cells, which are subsequently catabolized by specialized macrophages in the marrow, spleen, and liver. Iron is then released from the hemoglobin and returned to the plasma transferrin. Some of the erythroid marrow iron (7 mg Fe/day) arrives at the macrophage more directly because of phagocytosis of defective erythroid precursors or removal of erythrocyte ferritin, so that the macrophage returns to the plasma transferrin an amount of iron (22 mg Fe/day) almost equivalent to that donated to the erythron. The remainder of daily erythron iron turnover is derived from some of the newly absorbed iron from the GI tract and from the minor fraction (2 mg Fe/day) of hemoglobin iron that is lost into the plasma with enucleation of normoblasts or from intravascular hemolysis. This is bound to haptoglobin or hemopexin and delivered to the hepatocyte for eventual return to plasma transferrin.

Movement of iron to and from the erythron accounts for 80% of the iron flowing through the transferrin compartment each day. The remaining 20% of iron carried by transferrin includes (1) iron exchange with hepatocytes (5 mg Fe/day), (2) movement between the plasma and extravascular transferrin compartments (3 mg Fe/day), (3) exchange between extravascular transferrin and parenchymal tissues (2 mg Fe/day), and (4) limited external exchange of iron through obligatory losses and absorption of iron from the GI tract (1 and 1.5 mg Fe/day for men and women, respectively). The successive movement of iron through the major pathway of internal iron exchangefrom plasma transferrin to the erythron to the macrophage and back to plasma transferrinis summarized below, with particular attention to those factors that regulate the flow of iron through the cycle. [69]

Movement of Iron from Transferrin to the Erythron

The movement of iron from transferrin to the erythron is determined by (1) the aggregate number of transferrin receptors on erythroid precursors in the erythron and on cells in nonerythroid tissues and (2) the amounts of apo-, mono-, and diferric plasma transferrin. The number of transferrin receptors is a prime determinant of cellular iron supply. Because the number of transferrin receptors in nonerythroid tissues is stable under normal circumstances, the rate of erythropoiesis is the major determinant of the number of transferrin receptors in the erythron. As the rate of erythropoiesis increases, greater numbers of erythroid precursors with transferrin receptors are produced, increasing the rate of iron uptake.

Iron Uptake by Erythroid Cells.

The control of the acquisition, utilization, and storage of iron by erythroid cells seems to differ during different phases of erythropoiesis. Although the available evidence is fragmentary and incomplete, studies of human bone marrow and of erythroid cell lines in culture have suggested that erythropoietin acts as an inducer for the transcription of mRNA for the erythroid-specific enzymes -aminolevulinic acid (ALA) synthase and porphobilinogen (PBG) deaminase in the heme biosynthetic pathway and of - and -globin mRNA.[77] Repression of heme oxygenase, the enzyme responsible for heme degradation, has been proposed as an initiating event in the differentiation of erythroid progenitors. [78] In erythroblasts, heme enhances the transcription of globin mRNA and acts to increase the stability of globin mRNA. Other studies, using erythroid cells obtained from chick embryos at early stages of maturation, have found that the transferrin receptor gene is hyperexpressed and regulated at the transcriptional level by mechanisms that are not responsive to the availability of intracellular iron. [79] The rate of iron uptake from transferrin during erythroid cell development correlates closely with the number of transferrin receptors, suggesting that the level of transferrin receptors is the major factor determining the rate of iron uptake during erythroid cell development. The increase in transferrin receptor expression thus follows the increase in the expression of erythropoietin receptors but precedes the onset of heme synthesis. After hemoglobin synthesis is fully established in late erythroblasts and reticulocytes, translational control of the expression of transferrin receptor, ferritin, and heme seems to become the more important regulatory mechanism.

Use of Iron for Heme Synthesis in Erythroid Cells.

Almost all of the iron taken up by the erythron is used for the synthesis of heme, the prosthetic group of hemoglobin, with small amounts reserved for use in iron-containing enzymes in erythroid cells or sequestered within ferritin. In the adult, the erythron produces >85% of the total heme synthesized in the body, with most

of the remainder produced by the liver. Heme (ferrous protoporphyrin IX) is a planar molecule consisting of an atom of ferrous iron in the center of a tetrapyrrole ring. Heme is synthesized in eight biochemical steps, with the first and final three steps catalyzed by mitochondrial enzymes and the four intermediate steps taking place in the cytoplasm. The final step in heme synthesis is the formation of heme from protoporphyrin IX and ferrous iron, catalyzed by the mitochondrial enzyme ferrochelatase. In human erythroid cells, heme synthesis seems to be controlled at the first step in the production of protoporphyrin IX. Feedback inhibition by heme limits one or more steps that lead to the formation of -ALA, the first committed precursor in the porphyrin pathway. [77] In erythroid cells, this first enzymatic reaction in heme biosynthesis is catalyzed by the erythroid-specific form (see below) of 5-aminolevulinate synthase (ALA synthase) and consists of the condensation of glycine and succinyl CoA to form -ALA, a reaction requiring pyridoxal phosphate. Heme does not affect the level of mRNA for erythroid-specific ALA synthase and has no evident direct effect on the enzyme. Instead, heme seems to reduce the activity of the erythroid-specific ALA synthase by an indirect cellular process that has not yet been characterized.

The enzymes of the heme biosynthetic pathway must be expressed during the life of each cell in the body to provide for cytochrome and other vital heme enzymes. In addition to these constitutive or housekeeping enzymes produced during the life of all cells, erythroid-specific isozymes have been identified for ALA synthase, which catalyzes the first step in the heme biosynthetic pathway, and for PBG deaminase, which catalyzes the third. In humans, the two isozymes for ALA synthase are encoded by different genes, with the gene for the constitutive or housekeeping isozyme on chromosome 3p21 and that for the erythroid-specific form on the X chromosome (Xp21-q21).[80] Only a single gene for PBG deaminase is present in the human genome, but this gene has two overlapping transcription units. [77] An upstream promoter is active in all cells, while the downstream promoter is erythroid specific. Alternative splicing produces two mRNAs that encode the PBG deaminase isozymes. Studies of the promoter regions for the erythroid-specific forms of ALA synthase and PBG deaminase have established that both have cis-acting control motifs similar to those in the -globin

gene promoters, including both GATA-1 and NF-E2 binding sites. [77] These observations suggest that globin genes and the erythroid-specific forms of both ALA synthase and PBG deaminase are all subject to developmental control by common trans-acting factors during erythropoiesis. These trans-acting factors may mediate the effects of erythropoietin on the transcription of mRNAs for globin, ALA synthase, and PBG deaminase described above.

Iron-Dependent Translational Regulation of Erythroid ALA Synthase mRNA.

The erythroid ALA synthase gene on the X chromosome has also been found to contain an IRE motif in the 5 UTR that is not present in the housekeeping gene on chromosome 3. The available studies provide strong experimental evidence that the corresponding IRE is functional in vivo and that, if intracellular iron availability is low, binding of an IRP will prevent translation of the erythroid-specific ALA synthase mRNA (Fig. 26-2D). The IRE in the 5 UTR of the erythroid-specific ALA synthase mRNA may help coordinate iron uptake and heme synthesis in erythroid cells. [77] The observation that erythroid ALA synthase activity is decreased in erythroblasts from bone marrow obtained from patients with iron deficiency [81] is consistent with translational regulation of erythroid ALA synthase mRNA by IRPs. Altogether, the available evidence suggests that regulation of the activity of erythroid-specific ALA synthase, and thereby of the rate of heme synthesis in erythroid cells, involves (1) developmental transcriptional control by erythroid-specific trans-acting factors, (2) feedback inhibition by heme through a still undefined mechanism that does not influence the availability of the mRNA for the enzyme, and (3) intracellular iron availability through IRP control of the translation of the erythroid-specific ALA synthase mRNA.

Ferritin in Erythroid Cells.

Iron that is in excess of erythroid requirements for heme synthesis is sequestered within ferritin. The more immature erythroid precursors, the proerythroblasts and basophilic erythroblasts, contain higher concentrations of intracellular ferritin than mature forms and also have greater proportions of the H-type subunit. [12] The major determinants of the ferritin content of the erythroid cell appear to be the plasma transferrin saturation, reflecting the iron supply to the erythroblast, and the rate of hemoglobin synthesis, as an indicator of the erythroid iron requirement. Erythroid cell ferritin is decreased in patients with iron deficiency or with severe inflammatory disorders and increased in patients with other conditions in which hemoglobin synthesis is reduced, such as thalassemic disorders or sideroblastic anemias, or with iron overload. [12]

Other Regulatory Functions of Intracellular Iron Availability.

Iron availability in erythroid cells may not only specifically alter the rates of production of heme, transferrin receptor, and ferritin through the IRPs but may also have more general effects on the metabolism of the developing erythroid cell. The identification of a conserved and functional IRE in the 5 UTR of mammalian mitochondrial aconitase raises the possibility of a further role for iron availability in the regulation of cellular metabolism by coupling iron availability and the activity of the citric acid cycle. [62]

Movement of Iron from the Erythron to the Macrophage

The major pathway of iron movement from the erythron is to a specialized population of macrophages in the bone marrow, liver, and spleen as red cells reach the end of their life span (Fig. 26-4). Whereas the developing erythroid cell is dedicated to the acquisition of iron from transferrin for use in hemoglobin synthesis, these specialized macrophages are devoted to the extraction of iron from hemoglobin for prompt return to transferrin or, if necessary, for storage for future use. Less is known about the molecular mechanisms underlying the disposition of iron by the macrophage than about any other aspect of iron metabolism.

Removal and Catabolism of Senescent or Damaged Erythrocytes.

Senescent or damaged erythrocytes are selectively sequestered by a specialized population of macrophages in the bone marrow, liver, and especially the spleen. Macrophages in the bone marrow also cull defective immature erythroid cells to prevent their release into the circulation and remove some deposits of erythrocyte ferritin from developing red cells. During their time in the bloodstream, red cells undergo oxidant damage, alterations of membrane proteins and lipids, loss of surface sialic acid and electrostatic charge, decreases in ion gradients, and metabolic depletion of glycolytic and other enzymes, including protein kinases. Hemichrome formation with oxidative damage to membrane transport proteins may produce increased membrane permeability, and defective volume regulation and crosslinking by hemoglobin or hemichromes of membrane band-3 molecules and the formation of senescent antigens have been reported. Aged erythrocytes become dehydrated and lose surface area, with a decrease in cell volume and an increase in intracellular hemoglobin concentration, making the cells less deformable. Despite all these known changes in aged red cells, the characteristic or combination of characteristics that is the proximate cause of the removal of senescent erythrocytes from the circulation has yet to be determined.[82] Billions of red cells are normally eliminated from the circulation each day without any evidence of overt erythrophagocytosis, suggesting that some form of erythrocyte fragmentation occurs before ingestion by macrophages. [82]

The metabolism of catabolized hemoglobin in humans has been examined using heat-damaged erythrocytes labeled with radioactive iron. [83] After injection of the labeled red cells, a delay of 40 minutes precedes the appearance of radioiron in the plasma, presumably representing the time needed for phagocytosis of the damaged erythrocytes and catabolism of heme. Radioiron is then released in a biphasic manner. Two-thirds reemerges in an early, rapid phase of release, with a $t_{1/2}$ of slightly more than one-half hour; the remaining third is incorporated into macrophage stores and reappears in a late, slow phase ($t_{1/2}$ 6 days).[83] In iron deficiency, iron release is derived entirely from the recently catabolized erythrocyte. With increasing iron stores, the proportion of the radioiron derived from ingested red cells declines, especially during the early, rapid phase of iron output. The rate of late release is also influenced by the magnitude of iron stores: the greater the amount of storage iron, the longer is the delay in release. Inflammation and ascorbic acid deficiency also increase the proportion of catabolized erythrocyte iron retained within macrophages.[68] [84]

Studies of the catabolism of red cells by macrophages have suggested that each macrophage is able to fully process at least one ingested erythrocyte per hour. [85] Ingested antibody-coated erythrocytes are surrounded by projections of the plasma membrane and moved to the perinuclear area. Macrophage lysosomes fuse with the vacuole containing the phagocytized red cell, forming a network of interconnecting channels that fragment the erythrocyte as its components are digested. The erythrocyte membrane is lysed and the hemoglobin within is oxidatively precipitated. Almost all the hemoglobin is rapidly catabolized, with the globin proteolytically processed to amino acids, releasing heme. The heme is somehow transported to the endoplasmic reticulum of the macrophage to be degraded by heme oxygenase. Erythrophagocytosis induces synthesis of heme oxygenase.[86]

Catabolism of Hemoglobin Iron.

Heme oxygenase (M_r 32,000) is a microsomal enzyme that catalyzes the rate-limiting step in the oxidative catabolism of heme to yield equimolar quantities of biliverdin IX, carbon monoxide, and iron. Three isozymes of heme oxygenase have been identified, designated HO-1, HO-2, and HO-3. Heme oxygenase-1 (HO-1) is the inducible form of the rate-limiting enzyme of heme degradation that regulates the cellular content of heme. [87] HO-2 is the constitutive

form.[88] The function of HO-3 is unknown, but a regulatory role has been postulated. [89] The process of heme degradation by heme oxygenase has been characterized as a series of autocatalytic oxidations with the reaction intermediates as cofactors. [78] A total of three oxygen molecules and six reducing equivalents are required to oxidatively degrade one heme molecule to biliverdin IX, with one iron and one carbon monoxide molecule released. The precise reaction sequence has not been established, but a single heme oxygenase binds a single heme and cleaves the -methane bridge, leaving a biliverdin-iron complex. The -methane carbon is converted to carbon monoxide, the sole physiologic source of carbon monoxide in the body. Iron is then released from the biliverdin-iron complex, generating the linear tetrapyrrole biliverdin IXa, which is then reduced by biliverdin reductase to bilirubin IXa. HO-1 is required for efficient reutilization of iron for erythropoiesis; mice lacking functional HO-1 developed an anemia associated with abnormally low serum iron levels while accumulating hepatic and renal iron that contributed to macromolecular oxidative damage, tissue injury, and chronic inflammation. [90]

The disposition of iron after release from heme by heme oxygenase is incompletely understood. Presumably the iron freed from heme enters an intracellular reservoir where the IRPs monitor iron availability. The expression and regulation of IRP-1, IRP-2, transferrin receptor, and ferritin have been examined in cultures of human peripheral blood monocytes maturing to macrophages. Although peripheral blood monocytes have few transferrin receptors, cultured monocytes and macrophages of a variety of types seem to express surface transferrin receptors and seem to be able to take up iron by this route. By contrast, ferrokinetic investigations in humans have found no evidence for movement of iron from transferrin to the macrophage in vivo, [67] although these studies may be less sensitive than studies of individual cells. Maturation of monocytes to macrophages was associated with marked increases in high-affinity IRP binding and in both mRNA and protein for transferrin receptor and ferritin, probably as a result of increased gene transcription. [9] Most important, exposure of cultured macrophages to iron salts stimulated IRPs activity and seemed to be associated with a translationally mediated increase in both transferrin receptor and ferritin synthesis; treatment with the iron chelator desferrioxamine decreased transferrin receptor synthesis. [9] These results should be contrasted with the findings in erythroid cells, where an increase in iron exposure would diminish IRP activity, with a resultant decrease in transferrin receptor synthesis and an increase in ferritin synthesis; treatment with an iron chelator would result in an increase in transferrin receptor synthesis. Moreover, stimulation of a macrophage cell line with IFN-/LPS resulted in a slight increase in IRP-1 IRE-binding activity but a great decrease in IRP-2 binding activity in association with increased ferritin synthesis. [40] The consequences of these contrasting patterns of response to iron loading in macrophages and erythroid cells would apparently be to maintain a constant and consistent supply of iron for utilization in heme synthesis in the erythroid cell and to increase iron acquisition and storage in the macrophage. Overall, this pattern would serve to move iron to the erythron from the macrophage in times of lack and to store iron within the macrophage system during periods of excess.

Storage of Iron Within the Macrophage.

Under normal circumstances, the macrophages in the liver, spleen, and bone marrow that are dedicated to reprocessing hemoglobin iron from senescent erythrocytes maintain an equilibrium between iron storage and release. Whatever the molecular mechanisms involved, synthesis of ferritin is induced in response to erythrophagocytosis, and, in the absence of iron deficiency, a portion of the iron derived from the ingested erythrocyte is retained within the macrophage as ferritin iron. Based on studies of heat-damaged erythrocytes labeled with radioactive iron, the fraction of radioiron sequestered within the macrophage can vary from virtually none in association with iron deficiency to a maximum of almost 80% in the presence of marrow aplasia and a fully saturated plasma transferrin. [83] No matter what the circumstances, the macrophage does not seem able to retain more than 80% of the iron derived from the catabolized erythrocyte. Within the macrophage, this iron is stored predominantly in ferritin rich in L subunits. [12] Catabolism of cellular ferritin may result from digestion of the protein shell with reutilization of the iron core or conversion to hemosiderin, an amorphous, water-insoluble storage compound with a higher iron content and slower turnover than ferritin that is suitable for long-term storage of iron. [91] The ferritin and hemosiderin iron stored within the macrophage remains available for mobilization in time of need. With increasing amounts of storage iron within the macrophage, the proportion of iron stored within hemosiderin progressively increases. Ascorbic acid seems to retard ferritin degradation by reducing lysosomal autophagy of the protein, thereby increasing the amount of iron stored in cytoplasmic ferritin. [18]

Movement of Iron from the Erythron to the Hepatocyte

The remaining pathway of iron movement from the erythron provides a means for hemoglobin iron that is released into the plasma to be delivered to the hepatocyte for eventual return to the plasma transferrin (Fig. 26-4). With normal erythropoiesis, this portion of the total iron flux is minor, but it can increase substantially in disorders with increased ineffective erythropoiesis or intravascular hemolysis. Delivery of hemoglobin iron from the plasma to hepatocytes depends primarily on two glycoproteins: (1) haptoglobin for the binding and transport of dimers of hemoglobin, and (2) hemopexin for the binding and transport of heme, assisted, if needed, by albumin.

Haptoglobin Binding and Transport of Hemoglobin.

Hemoglobin may escape into the plasma with the enucleation of erythroblasts on their transformation into reticulocytes, with the destruction of defective developing red cells within the marrow or with hemolysis in the circulation. At the low plasma concentration of hemoglobin produced by these processes, most of the hemoglobin A dissociates into dimers. Pairs of dimers are then quickly bound in a symmetric fashion to a single molecule of haptoglobin. The half-life of apohaptoglobin is 5 days, but that of the hemoglobin-haptoglobin complex is only 1030 minutes, as the complexes are cleared by specific hepatocyte receptors. [92] The hemoglobin-haptoglobin complex (M_r 150,000) is too large to be filtered by the kidneys, a feature that helps restrict the renal loss of iron with hemoglobinemia. After binding to the haptoglobin receptor of the hepatocyte, the hemoglobin-haptoglobin receptor complex is then internalized and dissociated symmetrically by limited proteolysis into two subunits of M_r 82,000 having intact hemes. Unlike the transferrin-transferrin receptor complex, the haptoglobin-haptoglobin receptor is degraded and cannot be recycled. The hemes are then released to an unidentified carrier and catabolized by heme oxygenase, releasing iron within the hepatocyte. [92] [93] Consumption of haptoglobin does not induce increased hepatic production, with the result that sustained hemoglobinemia produces hypo- or ahaptoglobinemia. Haptoglobin is a positive acute phase reactant, so that inflammatory or infectious episodes may increase plasma concentrations.

Hemopexin Binding and Transport of Heme.

Hemoglobin leaked into the plasma that is not bound to haptoglobin is soon oxidized to ferrihemoglobin (methemoglobin), which in turn can dissociate into globin and ferriheme (metheme). Ferriheme (but not hemoglobin) can then be bound by hemopexin; a single hemopexin binds a single ferriheme. Hemopexin (M_r 70,000) is a glycoprotein synthesized by hepatocytes. The

half-life of apohemopexin is 7 days but that of the heme-hemopexin complex is 78 hours, as the complexes are cleared by specific hepatocyte receptors. [94] After binding to the hepatocyte hemopexin receptor, the heme-hemopexin-receptor complex is then internalized within clathrin-coated pits. Receptor-mediated endocytosis of the heme-hemopexin results in catabolism of heme but not of hemopexin or the hemopexin receptor, which are recycled to the cell surface for reutilization in a manner analogous to the transferrin-transferrin receptor complex. [92] Delivery of heme to the hepatocyte results in induction of heme oxygenase, which releases the iron from the heme in the cell. Despite recycling, hemopexin may become depleted in patients with hemolysis. Each molecule of human albumin contains two binding sites for ferriheme, but these have a much lower affinity than the binding site of hemopexin. Binding of ferriheme produces methemalbumin, which, after a delay of several days, also delivers the heme to the hepatocyte, where the iron is liberated for reuse.

Movement of Iron from the Macrophage to Transferrin

The final step in the movement of iron through the cycle shown in Figure 26-4 requires the return of iron derived from the catabolism of senescent erythrocytes to plasma transferrin for delivery to the erythroid marrow. The outpouring of iron to plasma apotransferrin from macrophages in the bone marrow, liver, and spleen normally constitutes the largest single flux of iron from cells in the body. Despite the importance and magnitude of this flow of iron, the mechanisms permitting the exit of iron from the macrophage remain an almost complete mystery.[95] Little information is available about (1) the form of iron within the cell before its departure, (2) the manner in which the iron is able to pass through the plasma membrane, (3) the form of the iron on its emergence from the cell, (4) the site and manner of delivery of the iron to plasma apotransferrin, or (5) the physiologic relevance and quantitative importance of iron release from the macrophage that is not mediated by transferrin but involves ferritin or other carriers.

Release of Iron from Macrophages to Plasma.

Variations in iron release from the macrophage have been considered to be responsible for diurnal variations in the plasma iron concentration. The amount of iron released is a function, in part, of the amount delivered to the macrophage. Modest increases in the red cell load to the macrophage without changes in the activity of the erythroid marrow may be matched by similar increases in iron release to the plasma, but with even larger amounts an increased proportion of the iron will be stored within the macrophage.[83]

In some manner, iron release from the macrophage also seems to be influenced by erythroid marrow requirements. With iron deficiency, all the iron derived from hemoglobin catabolism is promptly returned to the plasma and none is diverted to macrophage stores. [83] With the increase in erythropoiesis associated with acute blood loss, macrophage iron stores are mobilized, but the maximal rate of release from this source in the adult is limited to 4060 mg of iron per day. [96] If erythroid marrow activity is increased in association with a sustained hemolytic state in which nonviable cells are returned to the macrophage, as much as 80160 mg of iron per day may be released from the macrophage to transferrin.[96] Decreases in erythropoiesis can be matched by reductions in macrophage iron release to some extent, but a minimum of 20% of the iron load presented to the macrophage must be returned to the plasma daily. [67] [96] Iron release from macrophages may be inadequate to meet erythroid marrow needs in ascorbate deficiency[84] and copper deficiency. In copper deficiency, hypoferremia is corrected by the administration of ceruloplasmin but not by copper itself.[97]

Although the overall patterns of iron release from the macrophage in various circumstances have been described, the underlying mechanisms are almost entirely obscure. The release of iron is temperature dependent, [85] implying that they are energy-dependent processes. After the completion of erythrophagocytosis, iron export is not affected by iodoacetate, chloroquine, colchicine, cytochalasin B, or cyclohexamide, suggesting the lack of any role in the release process for glycolysis, acidification of an intracellular compartment, microtubule function, microfilament function, or protein synthesis. [85] Inflammatory states are associated with delayed processing and release of iron from the macrophage, an effect reproduced when isolated Kupffer cells are incubated with serum from rats with sterile, turpentine-induced abscesses. The exact mediators of this response with the macrophage are uncertain; no influence on the course of iron release from the Kupffer cell was found with interleukin (IL)-1, IFN-, or tumor necrosis factor. [85]

Apotransferrin Is Not Required for the Release of Iron from Macrophages.

Although transferrin acts as the sole physiologic means for the transport of iron to the erythroid marrow, a requirement for the presence of unsaturated transferrin for release of iron from the macrophage has not been established. Apotransferrin does not enter the macrophage and accepts iron only after the release of iron from the cell.[85] Studies in vivo found that release of iron derived from heat-damaged red cells was unaffected by transferrin saturation and that the injection of apotransferrin did not increase iron release. [68] [84] In vitro, the presence of apotransferrin has had little or no effect on the magnitude of iron release in most investigations. [85]

Release of Iron from Macrophages as Ferritin Iron.

Several studies have now found that much of the iron released from macrophages is in the form of ferritin both in experiments in vitro [85] [98] and in vivo, after the administration of heat-damaged red cells to rats, but the physiologic fate of this released ferritin and its iron remains uncertain. [98] Iron-loaded ferritin released by Kupffer cells after erythrophagocytosis in vitro has been shown to be readily taken up by hepatocytes, [85] [99] possibly by specific hepatocyte ferritin receptors. [98] These results have suggested the possibility that ferritin released by Kupffer cells may serve as an intrahepatic carrier of iron to the hepatocyte. Such a mechanism would protect the hepatocyte against iron deficiency but would also create the risk of iron loading with chronic hemolysis.

Other Pathways of Iron Movement.

Storage iron in the macrophages of the liver, bone marrow, and spleen is derived almost entirely from phagocytosis of senescent erythrocytes or defective developing red cells. Ferrokinetic studies have suggested that the macrophage takes up little if any iron from plasma transferrin. By contrast, the hepatocyte may either donate iron to or receive iron from plasma transferrin. At high transferrin saturations, iron moves from the plasma to the liver, while at low saturations, iron is mobilized from hepatocyte stores and supplied to plasma transferrin. Normally, the overall magnitude of iron exchange by hepatocytes is only about one-fifth that by macrophages. Other pathways of iron movement involve approximately equal exchanges: 1 mg Fe/day is absorbed and lost, 3 mg Fe/day is transferred between the plasma and extravascular transferrin compartments, and 2 mg Fe/day moves between extravascular transferrin and parenchymal tissues. In a pregnant woman the placenta is amply provided with transferrin receptors; these can successfully compete with the erythroid marrow for transferrin iron, which is taken up and unidirectionally passed to fetal transferrin for utilization by fetal tissues. Lactoferrin (M_r 76,000) is a glycoprotein that is structurally similar to transferrin, with a single polypeptide chain and two reversible binding sites for iron.[100] Lactoferrin has no established role in iron transport and is found principally in neutrophils and in bodily secretions. Lactoferrin seems to function as an antimicrobial scavenger of iron in acidic conditions, where transferrin binds iron poorly, and may also have

roles as a modulator of myelopoiesis and of mononuclear cell production and function. [101]

Laboratory Evaluation of Iron Status

The continuum of changes in iron stores and distribution in the presence of increased or decreased body iron content is shown in Figure 26-5 , along with characteristic values for clinically available indicators of iron status. The general usefulness of these measures will be considered here and their specific application in the diagnosis of iron deficiency and iron overload described below. Body iron supply and stores may be evaluated by both direct and indirect means, but no single indicator or combination of indicators is ideal for the evaluation of iron status in all clinical circumstances. As body iron content decreases from the iron-replete normal to the amounts found in iron deficiency anemia, or increases to the magnitudes found in iron overload, each available measure reflects in a different manner the continuum of changes shown in Figure 26-5 . In addition, each indicator may be affected by other conditions, such as infection, inflammation, liver disease, malignancy, or malnutrition, and must be interpreted with an awareness of the potential influence of such coexisting disorders.

Direct Measures

The direct measures of body iron status yield quantitative, specific, and sensitive determinations of body or tissue iron stores. Quantitative phlebotomy provides a direct measure of total mobilizable storage iron. [66] [67] [102] Repeated venesection to remove about 500 ml of blood weekly is performed until the hemoglobin concentration falls to <10 g/dl for 2 weeks without further phlebotomy. Mobilizable storage iron may then be calculated as the amount of hemoglobin iron removed, with corrections for the hemoglobin deficit and estimated GI iron absorption during the course of phlebotomy. Quantitative phlebotomy is inapplicable to most anemic disorders but is occasionally useful in the diagnostic evaluation of some forms of iron overload, for example, in patients with hereditary hemochromatosis who do not undergo liver biopsy.

Bone marrow aspiration and biopsy can provide information about (1) macrophage storage iron, by semiquantitative grading of marrow hemosiderin stained with Prussian blue, or if needed, by chemical measurement of nonheme iron; (2) the iron supply to erythroid precursors, by determining the proportion and morphology of marrow sideroblasts (i.e., normoblasts with visible aggregates of iron in the cytoplasm); and (3) the general morphologic features of hematopoiesis. [67] [103] Bone marrow aspiration and biopsy are useful in studies of iron deficiency but of limited applicability in the evaluation of iron overload because no information about the extent of parenchymal iron deposition is provided. In the evaluation of iron overload, liver biopsy is the best direct test for assessing iron deposition, permitting

quantitative measurement of the nonheme iron concentration and histochemical examination of the pattern of iron accumulation in hepatocytes and Kupffer cells. [67] [103] [104] [105] [106]

These direct methods for assessing iron status have the disadvantages of being invasive procedures, with their attendant discomfort, lack of acceptability to patients, and, in the case of liver biopsy, risk. Several noninvasive means of measuring tissue iron stores are under development, including determination of hepatic magnetic susceptibility,[107] [108] [109] computed tomography (CT),[110] and magnetic resonance imaging (MRI),[104] but as yet none is available for clinical use.

Indirect Measures

The indirect measures of body iron status have the advantages of ease and convenience, but all are subject to extraneous influences and lack specificity, sensitivity, or both. The measurement of plasma ferritin provides the most useful indirect estimate of body iron stores. [20] As noted earlier, ferritin is secreted into the plasma in small amounts. Although intracellular ferritin is produced by the smooth endoplasmic reticulum, plasma ferritin is synthesized by the rough endoplasmic reticulum and glycosylated

Figure 26-5 Continuum of changes in iron stores and distribution in the presence of increased or decreased body iron content. Abnormalities indicating the onset of specific stages of negative iron balance are enclosed in boxes. *(Adapted from Herbert,[216] with permission.)*

PLASMA FERRITIN CONCENTRATIONS

Decreased plasma ferritin concentrations are of great value in the detection of iron deficiency. Plasma ferritin concentrations decline with storage iron depletion; a plasma ferritin concentration below 12 g/L is virtually diagnostic of absent iron stores. The only known conditions that may lower the plasma ferritin concentration independently of a decrease in iron stores are hypothyroidism and ascorbate deficiency,[20] but these conditions would only rarely cause problems in clinical interpretation. Increased plasma ferritin concentrations may indicate increased iron stores, but a number of disorders may raise the plasma ferritin level independently of the body iron store. Plasma ferritin is an acute phase reactant, increased ferritin synthesis being a nonspecific response that is part of the general pattern of the systemic effects of inflammation. Thus, fever, acute infections, rheumatoid arthritis, and other chronic inflammatory disorders elevate the plasma ferritin concentration. Both acute and chronic damage to the liver, as well as to other ferritin-rich tissues, may increase plasma ferritin as an inflammatory process or by releasing tissue ferritins from damaged parenchymal cells; these tissue ferritins are not glycosylated.

by the Golgi apparatus. Under normal circumstances, the amount of plasma ferritin synthesized and secreted seems to be proportional to the amount of cellular ferritin produced in the internal iron storage pathway, so that the plasma ferritin concentration is related to the magnitude of body iron stores. [20] The small amounts of ferritin secreted into the circulation can be measured by immunoassay and have a logarithmic relationship to body iron stores in normal individuals. In the absence of complicating factors, plasma ferritin concentrations decrease with depletion of storage iron and increase with storage iron accumulation. A maximum glycosylated plasma ferritin concentration of 4,000 g/L has been postulated, [111] perhaps representing an upper physiologic limit of the rate of synthesis; higher concentrations are believed to be due to the release of intracellular ferritin from damaged cells.

Measurement of the plasma transferrin receptor concentration provides a useful new means of detecting iron deficiency. [112] The soluble transferrin receptor is a truncated form (M_r 85,000) of the tissue transferrin receptor that consists of the N-terminal cytoplasmic domain that has probably been proteolytically released from the cell membrane.[113] Immunoassays that can detect the soluble truncated form of the transferrin receptor in human plasma are becoming clinically available. Although much remains to be learned about the origin and fate of the plasma transferrin receptors, most are derived from the erythroid marrow, and the concentration of circulating soluble transferrin receptor is primarily determined by erythroid marrow activity. [112] Decreased levels of circulating soluble transferrin receptor are found in patients with erythroid hypoplasia (aplastic anemia, chronic renal failure), and increased levels are present in patients with erythroid hyperplasia (thalassemia major, sickle cell anemia, chronic hemolytic anemia). Iron deficiency also increases soluble transferrin receptor concentrations, although it is not clear to what extent this is the result of increased transferrin receptor expression in individual erythroblasts or simply appropriate to the degree of anemia and associated erythropoietin stimulation. Initial clinical experience indicates that the plasma transferrin receptor concentration reflects the total body mass of tissue receptor and that, in the absence of other conditions causing erythroid hyperplasia, an increase in concentration provides a sensitive, quantitative measure of tissue iron deficiency. [112] In particular, measurement of the plasma transferrin receptor concentration may help in differentiating between the anemia of iron deficiency and the anemia associated with chronic inflammatory disorders. Although the plasma ferritin concentration may be disproportionately elevated in relation to iron stores in patients with inflammation or liver disease, the plasma transferrin receptor concentration seems to be unaffected by these disorders and appears to provide a more reliable laboratory indicator of iron deficiency. Measurement of plasma transferrin receptor concentration is of no use in the detection of iron overload.

The measurement of urinary iron excretion with chelating agents, usually either desferrioxamine or diethylenetriamine pentaacetate (DPTA), offers another means of assessing body iron stores.[67] This test is not helpful in the detection of iron deficiency because of the overlap between values in individuals with normal and decreased iron stores; it is applied primarily to the evaluation of iron overload. The usefulness of the measurement of chelated iron in the urine is limited by a lack of correlation between chelatable iron excretion and the results of quantitative phlebotomy with parenchymal iron overload, and by the susceptibility of the test to extraneous influence by infection, inflammation, level and effectiveness of erythropoiesis, extramedullary hematopoiesis, liver disease, and ascorbic acid deficiency.

The erythrocyte zinc protoporphyrin provides an indicator of iron supply to erythroid precursors over a longer term. [114] In heme biosynthesis the final reaction is the chelation of a ferrous ion by protoporphyrin IX. If no iron is available, zinc is chelated instead to form zinc protoporphyrin. Because zinc protoporphyrin formed during development persists throughout the life span of the red cell, the blood concentration changes only as new cells are formed and old cells destroyed, providing a retrospective view of iron supply over the preceding several weeks. An elevated erythrocyte zinc protoporphyrin (sometimes measured as the zinc protoporphyrin/heme ratio) lacks specificity because concentrations increase not only with iron deficiency but also with other conditions that restrict iron availability, such as infection, inflammation, malignancy, and ascorbate deficiency; levels are also increased in many sideroblastic anemias and especially with chronic lead poisoning.[114] The test is useful for detection of lead poisoning but of no value in detecting iron overload.

Examination of the peripheral blood by measurements of hemoglobin concentration, hematocrit, red cell indices, red cell volume distribution, and reticulocyte count and by inspection of erythrocyte morphology reveals abnormalities only after depletion of iron stores restricts the availability of iron for erythropoiesis. The changes are not specific for iron deficiency and may be found in other conditions with defective hemoglobin synthesis, such as thalassemia, infection, inflammation, liver

TRANSFERRIN CONCENTRATION

An indicator of body iron stores that is much less sensitive than plasma ferritin is the transferrin concentration, usually measured in the clinical laboratory as the total iron-binding capacity (TIBC). Transferrin may increase with storage iron depletion and decrease with iron overload but is not a consistently reliable index because of the degree to which levels are altered by other factors. Inflammation, infection, malignancy, liver disease, nephrotic syndrome, and malnutrition all depress transferrin levels, whereas pregnancy and oral contraceptive use produce elevations.

PLASMA IRON AND TRANSFERRIN SATURATION

The plasma 2iron and the transferrin saturation, which equals the ratio of plasma iron to total iron-binding capacity, provide a measure of current iron supply to tissues.[72] After storage iron is depleted, the serum iron falls; a transferrin saturation of <16% is often used as the criterion for iron-deficient erythropoiesis. By contrast, the plasma iron and transferrin saturation are not reliably elevated with increased iron stores within macrophages, as occurs initially with transfusional iron overload, although the transferrin saturation may increase with parenchymal iron loading. Interpretation of the transferrin saturation is complicated by the substantial circadian fluctuations in plasma iron, as well as by day-to-day variations of 30%. Further, the plasma iron is decreased by infection, inflammation, malignancy, and ascorbate deficiency but increased by iron ingestion, aplastic and sideroblastic anemia, ineffective erythropoiesis, and liver disease.

disease, and malignancy. Iron overload does not produce any diagnostic abnormalities in the peripheral blood.

Future Directions

Continued rapid progress in understanding the molecular basis of cellular iron metabolism is anticipated. The identification of Nramp2 as a principal iron transporter both from the GI tract into the enterocyte and intracellularly from the endosome to the cytoplasm constitutes a major advance in our understanding of iron movement that will almost certainly lead to further advances in our knowledge of iron absorption and internal iron exchange. In conjunction with the identification of *HFE* as a candidate gene for hereditary hemochromatosis, we may finally begin to understand the molecular mechanisms involved in the control of iron absorption. Definitive identification of ligands for intracellular low molecular weight iron is still needed, along with an understanding of their interrelationship with the IRPs. Our understanding of the physiologic significance of differences in IRP-1 and IRP-2 in their binding specificities, patterns of tissue and cellular expression, modes of regulation, and responses to specific signals will be refined. The influence of oxidative stress and inflammation on iron homeostasis will be understood more thoroughly. More work is needed to better understand the details and distinctive features of iron metabolism in specialized cells and tissues, e.g., differences in iron metabolism within the hepatocyte and Kupffer cell.

IRON DEFICIENCY

Iron deficiency denotes a deficit in total body iron resulting from iron requirements that exceed iron supply. The continuum of decreased body iron is shown in Figure 26-5 and the changes in body iron movement and storage in Figure 26-6AC (Figure Not Available) . Three successive stages of iron lack may be distinguished. A decrement in storage iron without a decline in the level of functional iron compounds has been termed iron depletion (Fig. 26-6A (Figure Not Available)). After iron stores are exhausted, lack of iron limits the production of hemoglobin and other metabolically active compounds that require iron as a constituent or cofactor, and iron-deficient erythropoiesis (Fig. 26-6B (Figure Not Available)) develops, although the effect on hemoglobin production may be insufficient to be detected by the standards used to differentiate normal from anemic states. Further diminution in the body iron produces frank iron deficiency anemia (Fig. 26-6C (Figure Not Available)).

Epidemiology

Iron deficiency remains the most common cause of anemia, both in the United States[115] and worldwide.[116] In the United States the amounts of bioavailable iron in the diet, together with food fortification and the widespread use of iron supplements, have reduced the overall prevalence and severity of iron deficiency, but iron nutrition remains a problem in some subgroups, namely, toddlers, adolescent girls, and women of childbearing age. [115] Without iron supplementation, most women will become iron deficient during pregnancy.[117] Some minority groups also have an increased risk of iron deficiency. Globally, 30% of the estimated world population of almost 4.5 billion are anemic, and at least half of these, or 500 million people, are believed to have iron deficiency anemia. [116] Populations who have diets low in bioavailable iron, who suffer from chronic GI blood loss due to helminthic infection, or both have the highest prevalences of iron deficiency.

Etiology and Pathogenesis

The foremost task in the evaluation of a patient with iron deficiency is to identify and treat the underlying cause of the imbalance between iron requirements and supply that is responsible for the lack of iron (Table 26-3). The most common cause of increased iron requirements leading to iron deficiency is blood loss; in men and postmenopausal women, iron deficiency almost inevitably signifies GI blood loss. Within the GI tract, any hemorrhagic lesion may be responsible for blood loss, including hiatal hernia, esophageal varices, gastritis, duodenitis, peptic ulcer, cholelithiasis, intrahepatic bleeding, inflammatory bowel disease, diverticulosis, hemorrhoids, and adenomatous polyps. Iron deficiency is often the first sign of an occult GI malignancy. Chronic ingestion of drugs such as alcohol, salicylates, steroids, and nonsteroidal anti-inflammatory agents may cause or contribute to blood loss. Worldwide, the most frequent cause of GI blood loss is hookworm infection; about 1 billion people are believed to be infected. Other helminthic infections, such as *Schistosoma mansoni, Schistosoma japonicum,* and severe *Trichuris trichura* infection, may also cause GI blood loss. *Helicobacter pylori* gastritis has been documented as a cause of iron deficiency in an Alaskan community.[118] Less common causes of GI bleeding must also be considered in individual patients, including vascular purpura with scurvy, aberrant pancreas, Meckels diverticulum, hereditary hemorrhagic telangiectasia, other vascular ectasia of the bowel, and colonic polyposis.

In women of childbearing age, genitourinary blood loss with menses is often responsible for increased iron requirements. [119] Menstrual losses tend to be decreased with the use of oral contraceptives but are increased with the use of intrauterine devices. Other causes of genitourinary bleeding include uterine malignancies or fibroids; stones, infarction, infection with *Schistosoma haematobium* inflammatory disease, or malignancy of the urinary tract; and, rarely, chronic hemoglobinuria or hemosiderinuria resulting from paroxysmal nocturnal hemoglobinuria or chronic intravascular hemolysis.

Uncommonly, respiratory tract blood loss resulting from chronic recurrent hemoptysis of any cause may produce iron deficiency. In two rare conditions, idiopathic pulmonary siderosis and Goodpastures syndrome, hemoptysis and intrapulmonary bleeding may be inapparent but lead to the sequestration of iron in pulmonary macrophages. Although still within the body, this sequestered iron is lost for systemic utilization, and severe iron deficiency anemia may develop. Recurrent blood donation may lead to iron deficiency, particularly in menstruating women. [120]

In infants, children, and adolescents, the need for iron for growth may exceed the supply available from diet and stores. At birth the iron endowment of the infant is primarily determined

Figure 26-6 (Figure Not Available) Changes in body iron supply and storage with iron deficiency and with the anemia of chronic inflammation. **(A)** Iron depletion. Macrophage iron stores in the bone marrow, liver, and spleen are decreased without a decline in the level of functional iron compounds. **(B)** Iron deficient erythropoiesis. Iron stores are exhausted and the lack of iron limits the production of hemoglobin and other metabolically active compounds that require iron. **(C)** Iron deficiency anemia. Macrophage iron stores in the bone marrow, liver, and spleen are absent. **(D)** Anemia of chronic inflammation. Macrophage iron stores in the bone marrow, liver, and spleen are increased. *(Reprinted with permission from Brittenham GM: Red blood cell function and disorders of iron metabolism. by the birth weight and hemoglobin concentration. Mild maternal iron deficiency usually does not restrict iron delivery to the fetus, but moderate to severe iron deficiency anemia in the mother can result in both a decreased hemoglobin concentration and lower birth weight in the neonate. [121] Premature infants,

with a lower birth weight and a more rapid postnatal rate of growth, have a high risk of iron deficiency unless given iron supplements. With rapid growth during the first year of life, the body weight normally triples, and iron requirements (expressed as micrograms Fe per kilogram body weight) are at a high level. Iron requirements decline as growth slows during the second year of life and into childhood but rise again during the adolescent growth spurt.

Without supplemental iron, pregnancy entails the net loss of the equivalent of 1,2001,500 ml blood. On average, 270 mg of iron is donated to the fetus, an additional 90 mg is contained in the cord and placenta, and 150 mg is present in the lochia and blood lost at delivery, a total of slightly more than 500 mg of iron. [67] During pregnancy the red cell mass increases by more than a third, requiring almost another 500 mg of iron, which is returned to stores after delivery and not included in the net cost of a pregnancy. After delivery, the resumption of menstruation is usually delayed for some months, but if the infant is breast-fed, lactation requires about 0.51.0 mg Fe/day.

In some instances, an insufficient supply of iron may contribute to the development of iron deficiency. In infants [122] or women who have experienced heavy menstrual losses or multiple pregnancies,

the risk of iron deficiency is further increased by the habitual consumption of diets with insufficient amounts of bioavailable iron, such as those with little or no heme iron and with small amounts of enhancers or large amounts of inhibitors of nonheme iron absorption. For older children, men, and postmenopausal women, the restricted availability of dietary iron is almost never the sole explanation for iron deficiency, and other causes, especially blood loss, must be considered.

An impaired absorption of iron infrequently produces iron deficiency. In some patients, intestinal malabsorption of iron may occur as a manifestation of more generalized syndromes such as steatorrhea of various causes, sprue, celiac disease, or diffuse enteritis. Atrophic gastritis and the attendant achlorhydria may impair iron absorption. In persons of all ages and sexes but particularly in pregnant women and children, pica, the compulsive chewing or ingestion of food or nonfood substances, may contribute to iron deficiency if the material consumed inhibits iron absorption. Iron deficiency frequently complicates gastric surgery such as partial or total gastric resection or gastroenterostomy for bypass of the duodenum. Both the loss of gastric acid production and the decreased time available for iron absorption resulting from the increased rate of intestinal transit contribute to poor iron absorption; recurrent bleeding at the surgical site may also produce iron loss. Despite impaired absorption of dietary iron, therapeutic preparations of iron salts are usually well absorbed.

Increased iron requirements and an inadequate supply of iron often work in concert to produce iron deficiency. Infants fed cows milk receive a diet that not only contains small amounts of iron of low bioavailability but that also increases iron losses by causing GI bleeding. Menstruating women, with some of the highest iron requirements, may consume diets that both have a low content of iron and contain inhibitors of iron absorption, such as calcium. Patients with ulcer disease and increased GI blood loss may be treated with antacids, which diminish dietary iron absorption.

Clinical Presentation

Patients with iron deficiency may present (1) with no signs or symptoms, coming to medical attention only because of abnormalities on laboratory tests, (2) with the features of the underlying disorder responsible for the development of iron deficiency, or (3) with the manifestations common to all anemias. Patients may or may not exhibit one or more of the few signs and symptoms considered highly specific for iron deficiency, namely, pagophagia, koilonychia, and blue sclerae. No signs or symptoms have been ascribed to uncomplicated depletion of storage iron, although patients without iron reserves will not respond as rapidly to an increased need for iron resulting from blood loss, growth, or pregnancy.

Greater deficits in body iron, which restrict the synthesis of functional iron compounds and cause anemia, either may be asymptomatic or may produce a variety of clinical manifestations. Iron deficiency anemia produces the signs and symptoms common to all anemias: pallor, palpitations, tinnitus, headache, irritability, weakness, dizziness, easy fatigability, and other vague and nonspecific complaints. The prominence of these signs depends on both the degree and the rate of development of the anemia.[66] Because iron deficiency is often of insidious onset and prolonged duration, adaptive circulatory and respiratory responses may minimize these manifestations, permitting a surprising tolerance of low hemoglobin concentrations. With greater severity, anemia becomes increasingly debilitating as work capacity and tolerance of physical exertion are restricted, and it can eventually produce cardiorespiratory failure and even death.

Iron deficiency may also produce clinical manifestations independent of anemia. These seem to result from the depletion of functional iron compounds in nonerythroid tissues, resulting in impaired proliferation, growth, and function. Epithelial tissues have high iron requirements due to rapid rates of growth and turnover and thus are affected in many patients with chronic iron deficiency. Glossitis, angular stomatitis, postcricoid esophageal web or stricture (which may become malignant), and gastric atrophy may develop. The combination of glossitis, a sore or burning mouth, dysphagia, and iron deficiency is called the Plummer-Vinson or Patterson-Kelly syndrome. The prevalence of these abnormalities seems to vary geographically, which suggests that environmental or genetic factors may also be involved. [67]

Determining whether gastric atrophy is the cause or consequence of iron deficiency may be difficult, particularly in older patients; in some, pernicious anemia and iron deficiency coexist. Changes in the lingual or buccal mucosa have been suggested as factors causing or contributing to the pica that develops in many patients with iron deficiency. Pagophagia, a variant of pica in which ice is the substance obsessively consumed, is a behavioral abnormality that is considered to be a highly specific symptom of iron deficiency, resolving within a few days to 2 weeks after the beginning of iron therapy. [67] Other types of pica, with a variety of nonfoods such as clay, starch, paper, or dirt or with an assortment of foods, may occur in iron deficiency but are not as clearly linked to a lack of iron or as frequently responsive to iron therapy. Koilonychia, fingernails that are thin, friable, and brittle, with the distal half in a concave or spoon shape resulting from impaired nailbed epithelial growth, is considered virtually pathognomonic of iron deficiency but occurs in a small minority of patients. Blue sclerae, or sclerae with a definite or striking bluish hue, were recognized in 1908 by Osler as associated with iron deficiency [123] and have been reported to be both highly specific and sensitive as an indicator of iron deficiency. The bluish tinge is thought to result from thinning of the sclera, which makes the choroid visible; the thin sclera has been postulated to be the result of impairment of collagen synthesis by iron deficiency. Iron deficiency has also been postulated to have other nonhematologic consequences, still under investigation, involving impaired immunity and resistance to infection, diminished exercise tolerance and work performance, and behavioral and neuropsychological abnormalities.

Laboratory Evaluation

A characteristic sequence of changes in the clinically useful indications of iron status occurs as body iron decreases from the iron-replete normal to the levels found in iron deficiency anemia (Fig. 26-5). The patterns shown are those developing in the absence of complicating factors, such as infection, inflammation, liver disease, malignancy, or other disorders. Initially, owing to any of the causes listed in Table 26-3 , iron requirements exceed the available supply of iron. Iron is mobilized from body stores and iron absorption is increased. If the amounts of iron available from body reserves and absorption are inadequate, depletion of storage iron follows. At this stage bone marrow examination shows absent, or nearly absent, hemosiderin iron. The serum ferritin falls, while the total iron-binding capacity rises. Exhaustion of iron reserves then results in an inadequate supply of iron to the developing erythroid cell, and iron-deficient erythropoiesis commences. Plasma transferrin receptor concentrations increase as the total body mass of tissue receptor expands. The plasma ferritin decreases to <12 g/L, reflecting the absence of storage iron, and the total iron-binding capacity continues to rise. The plasma iron declines, and in combination with the increase in total iron-binding capacity, the transferrin saturation falls to <16%. As a result, most iron is derived from mono- rather than diferric transferrin, and most ferric transferrin-transferrin receptor complexes carry only one

or two atoms of iron rather than as many as four with each intracellular delivery cycle. Marrow examination shows, in addition to the absence of hemosiderin iron, a decrease in the proportion of sideroblasts because too little iron is available to support siderotic granule formation. The erythrocyte zinc protoporphyrin progressively increases with reduction of the amount of iron available for heme formation.

As hemoglobin production becomes restricted, frank iron deficiency anemia (Fig. 26-6C (Figure Not Available)) develops. The normocytic, normochromic red cells previously formed under iron-replete circumstances are gradually replaced by a microcytic hypochromic population. Both the time needed to replace the normal population and the extent of the disparity between erythroid needs and available iron supply determine the rate and degree of change in erythrocyte morphology and red cell indices, such as the mean corpuscular volume, mean corpuscular hemoglobin, and measures of the distribution of red cell volumes such as red cell volume distribution width. Chronic, long-standing iron deficiency anemia may produce severe microcytosis and hypochromia, with very pale, distorted red cells and dramatic reductions in the mean corpuscular volume and mean corpuscular hemoglobin. By contrast, some patients with mild iron deficiency anemia may have erythrocyte morphology and indices indistinguishable from those found in normal, iron-replete individuals. Nonetheless, laboratory evaluation of uncomplicated iron deficiency in otherwise healthy individuals is usually not difficult, and the characteristic patterns of indicators of body iron status shown in Figure 26-5 will typically be diagnostic.

Differential Diagnosis

Iron deficiency is the only microcytic hypochromic disorder in which mobilizable iron stores are absent; in all others, storage iron is normal or increased (Table 26-4). Thus the diagnosis of iron deficiency can almost always be verified by direct assessment of body iron stores using bone marrow examination: if no iron stores are present, the diagnosis of iron deficiency is established; if hemosiderin is found, iron deficiency is excluded. In addition, with iron deficiency sideroblasts will be absent or greatly decreased to <10% of normoblasts.[67] Rarely, previous parenteral iron therapy may cause difficulties in interpretation because of the presence of aggregates of iron that is effectively unavailable. Technical errors due to sampling or artifacts can usually be avoided by the examination of biopsy cores and of both stained and unstained aspirates containing ample amounts of stroma.

Difficulties in the evaluation of microcytic hypochromic disorders usually arise when direct assessment of marrow iron is unavailable and the diagnosis depends on indirect indicators of iron status. In otherwise healthy individuals, these indirect measures may be helpful, but in the presence of other disorders, which may include infection, inflammation, malignancy, malnutrition, alcoholism, or liver disease, their interpretation is often

THERAPEUTIC TRIAL OF IRON

The diagnosis of iron deficiency is often confirmed by the outcome of a therapeutic trial of iron. A specific, orderly response to, and only to, treatment with iron constitutes the final, definitive proof that a lack of iron is the cause of an anemia. The unequivocal diagnostic response consists of (1) a reticulocytosis, which begins about 35 days after adequate iron therapy is instituted, reaching a maximum on the eight to tenth day and then declining; and (2) a significant increase in the hemoglobin concentration, which should begin shortly after the reticulocyte peak, is invariably present by 3 weeks after iron therapy is begun, and persists until the hemoglobin concentration is restored to normal.[66] The result of a therapeutic trial of iron must be evaluated with due regard for possible confounding factors, such as poor compliance with iron therapy, malabsorption of therapeutic iron, continuing blood loss, and the effects of coexisting conditions, especially infectious, inflammatory, or malignant disorders. The therapeutic trial merely aids in the establishment of iron deficiency. The search for underlying causes must persist despite a positive response.

problematic. Of the indirect indicators, the plasma ferritin is most useful if the concentration is <12 g/L, for in the absence of hypothyroidism or ascorbate deficiency, such a low ferritin level is highly specific for iron deficiency. By contrast, a plasma ferritin concentration within the normal range does not necessarily indicate the presence of storage iron, for ferritin concentrations may be increased independently of iron status by infectious, inflammatory, and malignant disorders, liver disease, and other conditions. Measurement of the plasma transferrin receptor concentration may be useful in differentiating the anemia of iron deficiency from the anemia associated with chronic inflammatory disorders. While serum ferritin may be disproportionately elevated in relation to iron stores in patients with inflammation or liver disease, the plasma transferrin receptor concentration seems to be unaffected by these disorders and to provide a more reliable laboratory indicator of iron deficiency anemia. Disorders that restrict the iron supply may further complicate interpretation by lowering the plasma iron and transferrin saturation, increasing the erythrocyte zinc protoporphyrin, and in the peripheral blood by producing reticulocytopenia, microcytosis, hypochromia, and anemia. Because of the lack of sensitivity and specificity of the indirect indicators of iron status, the most reliable means of diagnosing iron deficiency in some patients is a bone marrow examination or a therapeutic trial of iron.

Specific entities to be considered in the differential diagnosis of hypochromic microcytic disorders are listed in Table 26-4; in all of these, body iron stores are normal or increased. In some, the hematologic abnormalities are associated with impaired iron metabolism. The anemia of chronic disease (Fig. 26-6D (Figure Not Available)) is the most common cause of anemia in hospitalized patients, typically developing over several weeks in those with chronic infectious, inflammatory, or malignant disorders.[124] The anemia is usually mild to moderate, the severity being approximately proportional to that of the chronic illness. Erythrocytes are normocytic or slightly microcytic and variably hypochromic. With the onset of the underlying disorder, an impairment of iron release from macrophages results in an accumulation of iron within these cells. The plasma iron level falls, and iron supply to tissue diminishes. Within the bone marrow is found the diagnostic combination of increased iron sequestered in

IRON DEFICIENCY AND COEXISTING DISORDERS

The detection of iron deficiency in the presence of chronic infectious, inflammatory, or malignant disorders is more problematic. Even if iron lack contributes to the anemia of chronic disease, the transferrin concentration will be decreased and the plasma ferritin concentration increased. In this circumstance bone marrow examination is definitive: if iron deficiency is present, iron stores are absent; if the anemia of chronic disease is alone responsible, iron stores are present and typically increased. A therapeutic trial of iron may also be helpful in determining if a lack of iron contributes to the anemia of chronic disease.

macrophage stores with decreased sideroblasts, reflecting the inadequate supply of iron to developing erythroid cells.

Although in uncomplicated iron deficiency the transferrin concentration (total iron-binding capacity) increases, in the anemia of chronic disease the transferrin concentration decreases, a characteristic feature useful in distinguishing between the two causes of anemia. The plasma ferritin may also be diagnostically helpful: concentrations fall to <12 g/L in uncomplicated iron deficiency but rise in the anemia of chronic disease. The plasma transferrin receptor concentration will remain within the normal range with the anemia of chronic disorders but will increase with iron deficiency. The ratio of the serum transferrin receptor concentration to serum ferritin has been advocated as an improved means of recognizing iron deficiency. [125] These indirect indicators of iron status usually allow differentiation of the anemia of chronic disease from uncomplicated iron deficiency.

Microcytosis and hypochromia resulting from defective absorption, transportation, or utilization of iron rarely occur. Congenital atransferrinemia is an autosomal recessive disorder in which plasma transferrin is nearly absent. A severe microcytic hypochromic anemia, present from birth, is refractory to iron therapy but responds to transferrin infusion. Iron absorption is normal or increased, and iron deposits are found in the liver and other parenchymal tissues but are scant or absent in the bone marrow. Patients die without transferrin infusion or blood transfusions and are at risk for the complications of iron overload.

Other rare congenital defects with microcytic hypochromic anemias of unknown cause have also been reported, sometimes in combination with parenchymal iron overload. A single patient was found to have an acquired microcytic hypochromic anemia resulting from an IgM autoantibody to the transferrin receptor, which diminished iron incorporation by erythroid precursors. In this patient serum iron was increased, but marrow iron stores were absent. [126] Defective uptake of iron by erythroid precursors was suggested by the findings in two siblings with a severe hypochromic anemia in conjunction with increased plasma iron, marked hepatic iron deposition, and fibrosis, but no definite cause was established. [127] Three siblings with microcytic hypochromic anemia apparently due to isolated malabsorption and defective utilization of iron have been described, but the exact cause of their disorder was not determined. [128] More recently, two siblings were identified with severe hypoproliferative microcytic anemia and unexplained iron malabsorption. [129] Abnormalities in Nramp2[54] [55] [56] may now be sought as potential explanations for some of the microcytic hypochromic anemias of unknown cause.

Microcytic hypochromic anemias resulting from disorders of globin synthesis (thalassemias, microcytic hemoglobinopathies) and from disorders of heme synthesis (sideroblastic anemias, congenital and acquired) are discussed in Chapters 27 and 29 . In general, the plasma iron, transferrin saturation, plasma ferritin concentration, and bone marrow iron stores are normal or increased in these disorders, and differentiation of such disorders from iron deficiency is not difficult.

Therapy

The goal of therapy for iron deficiency anemia is to supply sufficient iron to repair the hemoglobin deficit and replenish storage iron. Oral iron is the treatment of choice for almost all patients because of its effectiveness, safety, and economy. The risk of local and systemic adverse reactions restricts the use of parenteral iron to those few patients unable to absorb or tolerate adequate amounts of oral iron. Rarely, red cell transfusions are needed to prevent cardiac or cerebral ischemia in severe anemia or to support patients whose chronic rate of iron loss exceeds the rate of replacement possible with parenteral therapy.

Most patients are able to tolerate oral iron therapy without difficulty, but 1020% may have symptoms attributable to iron. [130] The most common side effects are gastrointestinal. The development of either diarrhea or constipation can usually be treated symptomatically because alterations in bowel habits do not appear to be related to the dose of iron and seldom necessitate a change in the oral regimen. Upper GI tract symptoms do seem to be dose related, reflecting the concentration of ferrous iron in the stomach and duodenum. These side effects occur within 1 hour of iron ingestion and may be mild, with nausea and epigastric discomfort, or severe, with abdominal pain and vomiting. Often upper GI side effects can be managed by administering the iron with or immediately after meals. If symptoms persist, reductions in the amount of iron in each dose may be helpful, either by changing to tablets that contain smaller amounts of iron or by using a liquid preparation of ferrous sulfate. Decreasing the amount of iron in each dose is usually effective in controlling side effects, but if symptoms persist, a reduction in frequency to a single dose per day may be helpful. After a time at lower doses, patients may subsequently be able to tolerate more iron. With patience and persistence, an acceptable oral iron regimen can be devised for virtually all patients. Costly iron preparations with other additives, with enteric coating,

ORAL IRON THERAPY

Oral iron therapy should begin with a ferrous iron salt, taken apart from meals in three or four divided doses and supplying a daily total of 150200 mg of elemental iron in adults or 3 mg of iron per kilogram of body weight in children. Simple ferrous preparations are the best absorbed and least expensive; ferrous sulfate is the most widely used, either as tablets containing 6070 mg iron for adults or as a liquid preparation for children. Administration between meals maximizes absorption. In patients with a hemoglobin concentration <10 g/dl, this regimen will initially provide about 4060 mg of iron per day for erythropoiesis, permitting red cell production to increase to two to four times normal and the hemoglobin concentration to rise by about 0.2 g/dl/day. [96] An increase in the hemoglobin concentration of at least 2 g/dl after 3 weeks of therapy is generally used as the criterion for an adequate therapeutic response. [67] For milder anemia, a single daily dose of about 60 mg iron per day may be adequate. After the anemia has been fully corrected, oral iron should be continued to replace storage iron, either empirically for an additional 46 months or until the plasma ferritin concentration exceeds 50 g/L. [130]

PARENTERAL IRON THERAPY

The most widely used parenteral iron preparation is an iron dextran containing about 50 mg of elemental iron per milliliter in a dark brown, colloidal suspension of ferric oxyhydroxide and low molecular weight dextran. The iron dextran may be given either intramuscularly or intravenously in a dose that is calculated from the deficit in body iron, with allowance both for iron to correct the hemoglobin deficit and for iron to rebuild stores.[130] Immediate life-threatening anaphylactic reactions, the most serious risk associated with the use of either intramuscular or intravenous iron dextran, occur in 0.51% of patients[220] and may have a fatal outcome, even with treatment.[221] Delayed but severe serum sickness-like reactions may develop in a substantial proportion of patients, with fever, urticaria, adenopathy, myalgias, and arthralgias.[220] Iron dextran may exacerbate arthritis in patients with ankylosing spondylitis[222] and rheumatoid arthritis.[223] With intramuscular administration, local reactions include skin staining (which may be minimized by using a Z-technique for injection), muscle necrosis, phlebitis, and persistent pain at the injection site. In animals given massive doses of iron dextran, sarcomas have developed at the injection site, but no conclusive evidence of a carcinogenic risk in humans has been presented. Before every intramuscular or intravenous injection of iron dextran, the manufacturer recommends that a 0.5-ml test dose be given at least 1 hour before the therapeutic injection. The value of this precaution is limited because anaphylaxis is not dose dependent and can occur with the test dose, so iron dextran should be administered parenterally only if the facilities and medical expertise for managing anaphylactic reactions are available.[220] In the past, repeated intravenous or intramuscular injections of iron dextran were considered less convenient and more hazardous than administration of the total dose of iron dextran in a single intravenous infusion.[220] At present, however, the manufacturer stipulates that the maximum intravenous or intramuscular daily dose should not exceed 2 ml of undiluted iron dextran, the equivalent of 100 mg of iron, and warns of an increased incidence of adverse effects with larger doses. This 2 ml/day limit may be compared with the total dose of 40 ml of iron dextran, the equivalent of 2,000 mg of iron, suggested by the manufacturer for an iron-deficient 70-kg individual with a hemoglobin level of 7 g/dl. Despite these risks and restrictions, parenteral iron therapy is still preferred for those patients who cannot be managed with oral iron, for the hazards and expense of chronic red cell transfusion are even greater.

or in sustained-release form do not appear to offer any advantages that cannot be achieved by simply reducing the dose of plain ferrous salts. Administering iron with food and decreasing the dose will diminish the amount of iron absorbed daily and thereby prolong the period of treatment, but haste in the correction of iron deficiency is rarely needed.

Parenteral iron therapy, with the risk of adverse reactions, should be reserved for the exceptional patient who (1) remains intolerant of oral iron despite repeated modifications in dosage regimen, (2) has iron needs that cannot be met by oral therapy because of chronic uncontrollable bleeding, or (3) malabsorbs iron.[131] A screening test for iron malabsorption is the administration to the fasting patient of 100 mg elemental iron as ferrous sulfate in a liquid preparation, followed by measurements of the plasma iron 1 and 2 hours later. In an iron-deficient patient with an initial plasma iron of <50 g/dl, an increase of 200300 g Fe/dl is expected; an increase in plasma iron of <100 g/dl suggests malabsorption and is an indication for a small bowel biopsy.[132]

Prognosis

The prognosis for iron deficiency itself is excellent, and the response to either oral or parenteral iron is similar. Frequently, both clinical and subjective impressions of constitutional improvement are present within the first few days of treatment, with an enhanced sense of well-being and increased vigor and appetite. Pica may resolve and soreness and burning of the mouth abate. Hematologically, mild reticulocytosis begins within 35 days, is maximal by days 810, and then declines. The hemoglobin concentration begins to increase after the first week and has usually returned to normal within 6 weeks. Complete recovery from microcytosis may take up to 4 months. With oral iron dosage totaling 200 mg/day or less, the plasma ferritin remains <12 g/dl until the anemia is corrected and then gradually rises as storage iron is replaced over the next several months.[133] Although epithelial abnormalities begin to improve promptly with treatment, resolution of glossitis and koilonychia may take several months. The overall prognosis depends on the underlying disorder responsible for the iron deficiency.

Failure to obtain a complete and characteristic response to iron therapy necessitates a review and reevaluation of the patient. A common problem is an incorrect diagnosis, with the anemia of chronic disease mistaken for the anemia of iron deficiency. Coexisting conditions, such as other nutritional deficiencies, hepatic or renal disease, or infectious, inflammatory, or malignant disorders, may impede recovery. Occult blood loss may be responsible for an incomplete response. With oral iron therapy, the adequacy of the form and dose of iron used should be reconsidered, compliance with the treatment regimen reviewed, and finally, the possibility of malabsorption considered.

Future Directions

The effects of iron deficiency apart from anemia need further investigation, both at the cellular level and more generally in terms of the effects of lack of iron on immunity and resistance to infection, exercise and work performance, and behavior and development, particularly in the infant and child. Important clues to the underlying mechanisms of these effects of iron deficiency apart from anemia have been provided by an improved understanding of the interconnections of iron metabolism with (1) nitric oxide and cytokine-mediated effects of infection and inflammation and (2) cellular energy utilization. In particular, iron deficiency would seem to preferentially affect the activities of IRP-1 and IRP-2 and their targets.[65] Diagnostically, an immunoassay for plasma transferrin receptor should soon be clinically available and should prove useful in distinguishing the anemia of iron deficiency from the anemia associated with chronic inflammation. Therapeutically, carbonyl iron continues to offer an effective means of preventing and treating iron deficiency that avoids the risk of accidental iron poisoning in children. Alternatively, further development of a gastric delivery system (GDS) for iron could potentially provide effective therapy with the virtual elimination of side effects.[134] The iron GDS preparation may be especially useful in patients who have difficulty in tolerating other iron preparations. Although iron nutrition has improved in the United States and other developed countries, iron deficiency remains a widespread problem in the rest of the world, and effective methods of iron fortification still represent an important need.

IRON OVERLOAD

Iron overload denotes an excess in total body iron resulting from an iron supply that exceeds iron requirements. Because requirements are limited and humans lack a physiologic means of excreting excess iron, any sustained increase in intake may eventually result in accumulation of iron. The continuum of increased body iron is shown in Figure 26-5 . In adults and children, iron overload may be caused by increased absorption of dietary iron, by parenteral administration of iron, or by a combination of the two. In the neonate and infant, iron overload is a rare disorder that apparently results from an abnormality in iron balance between mother and fetus. Focal iron overload may result from sequestration of iron, as in pulmonary hemosiderosis. Whatever the source of excess iron, when the accumulation overwhelms the bodys capacity for safe storage, potentially lethal tissue damage is the result. The toxic manifestations of iron overload depend in part on the amount of excess iron, the rate of iron accumulation, and the partition of the iron burden between relatively benign sites in the macrophage and more hazardous deposits in parenchymal cells. The recent identification of a strong candidate gene for hereditary hemochromatosis, [135] a frequent cause of iron excess, has increased interest in disorders associated with iron overload.

Epidemiology

The most common form of iron overload in the United States is a genetically determined disorder, the homozygous state for hereditary hemochromatosis, occurring in as much as 0.5% of the population or as many as 1 million individuals. [105] [106] [136] [137] Similar frequencies of an iron-loading gene have been found elsewhere. In the United States other forms of iron overload are less frequent but affect several thousand patients with iron-loading or transfusion-dependent anemias such as thalassemia major and acquired refractory anemias. Globally, thalassemia major and other iron-loading anemias are an important public health problem in countries bordering the Mediterranean and in an area extending from Southwest Asia and the Indian subcontinent to Southeast Asia. [138] Dietary iron overload resulting from intake of iron in brewed beverages is a common problem affecting many populations in sub-Saharan Africa and may also have a genetic component. [139] [140] [141] The various forms of neonatal iron overload [142] and the syndromes associated with focal sequestration of iron are all rare disorders.

Genetic Aspects

The forms of iron overload known to be genetically determined include hereditary hemochromatosis and certain of the iron-loading anemias. Hereditary hemochromatosis has an autosomal recessive mode of inheritance, and a strong candidate gene for this disorder has been identified on the short arm of chromosome 6. Only homozygotes are at risk for symptomatic iron overload. The hemochromatosis gene has been found to have a frequency of 57% in various countries, which suggests that 10% or more of their populations are heterozygous and 0.250.5% are homozygous for the gene. [105] [106] [136] [137] The iron-loading anemias with established genetic components include the inherited sideroblastic anemias (Chap. 29) as well as some of the hereditary disorders of globin synthesis (Chap. 27), such as homozygous states for various forms of -thalassemia and compound heterozygous states such as hemoglobin E--thalassemia.

Etiology and Pathogenesis

Iron overload is caused by conditions that alter or bypass the normal control of body iron content by regulation of intestinal iron absorption (Table 26-5). In hereditary (HLA-linked) hemochromatosis, a genetic abnormality results in an inappropriately elevated iron absorption, with a chronic progressive increase in body iron stores. [67] [105] [106] [137] Iron absorption is also increased in the iron-loading anemias, apparently as the result of erythroid hyperplasia with ineffective erythropoiesis. In dietary iron overload of the type found in sub-Saharan Africa, control of iron absorption is overwhelmed by the large amounts of bioavailable iron in the upper small intestine; a genetic component, not linked to the HLA-A locus, may be involved. [139] [140] [141] The iron contained in transfused red cells given to patients with refractory anemias such as thalassemia major circumvents intestinal regulation of body iron content and also produces progressive iron loading.

With each of these causes of systemic iron overload, the timing of the onset of toxic manifestations, the pattern of the organs affected, and the severity of tissue damage are known to be influenced by a variety of factors. These include (1) the magnitude of the body iron burden, (2) the rate of loading, (3) the distribution of the iron load between apparently innocuous storage deposits in tissue macrophages and potentially injurious accumulations in parenchymal cells, (4) ascorbate status, which helps determine the allocation of iron between macrophage and parenchymal cells, and (5) the extent of internal redistribution of iron between macrophage and parenchymal sites. In general, the amount and rate of iron accumulation within parenchymal cells of the liver, heart, pancreas, and other organs seem to be the principal determinants of tissue injury. The exact mechanisms whereby iron produces cellular injury have not been established, but lipid peroxidation of membrane lipids of subcellular organelles, iron-induced lysosomal disruption, or both may be involved. Tissue damage may also be produced by plasma iron not complexed with transferrin (i.e., non-transferrin-bound iron), which appears in the circulation of patients with iron overload. [143] [144] [145]

Iron overload as a result of increased iron absorption may result either from an abnormality in the control of iron absorption with a diet containing normal amounts of bioavailable iron or from consumption of such excessive amounts of bioavailable iron that a normal regulatory mechanism is overridden. In individuals homozygous for hereditary (HLA-linked) hemochromatosis, an inappropriately elevated iron absorption occurs at any level of body iron and produces progressive parenchymal iron accumulation, initially in the liver but later in the pancreas,

TABLE 26-5 -- Causes of Iron Overload

Increased iron absorption
From diets with normal amounts of bioavailable iron
Hereditary (HLA-linked) hemochromatosis
Iron-loading anemias (refractory anemias with hypercellular erythroid marrow)
Chronic liver disease (cirrhosis, portacaval shunt)
Porphyria cutanea tarda
Congenital defects (atransferrinemia and other disorders)
From diets with increased amounts of bioavailable iron
African dietary iron overload (may have genetic component)
Medicinal iron ingestion (?)
Parenteral iron overload
Transfusional iron overload

Inadvertent iron overload from therapeutic injections
Perinatal iron overload
Hereditary tyrosinemia
Cerebrohepatorenal syndrome
Perinatal hemochromatosis
Focal sequestration of iron
Idiopathic pulmonary hemosiderosis
Renal hemosiderosis
Hallervorden-Spatz syndrome

Figure 26-7 (Figure Not Available) Changes in body iron supply and storage with hereditary hemochromatosis and transfusional iron overload. **(A)** Hereditary hemochromatosis. Despite massive iron deposition in hepatocytes, macrophage iron stores in the bone marrow, liver, and spleen may be normal or only modestly increased. **(B)** Transfusional iron overload. Marked macrophage iron deposition is present along with iron overload in hepatocytes. *(Reprinted with permission from Brittenham GM: Red blood cell function and disorders of iron metabolism. heart, and other organs (Figure 26-7A (Figure Not Available)). Despite marked parenchymal iron deposition, macrophage iron in the bone marrow may be scant or even absent.[146] [147] Initially, the excess iron is deposited predominantly within the parenchymal cells of the liver, but subsequently the iron accumulates in the pancreas, heart, and other organs. The classic tetrad of clinical signs in homozygotes for hereditary hemochromatosis who present symptomatically in middle age or later consists of liver disease, diabetes mellitus, skin pigmentation, and gonadal failure. [106] [137] [148] [149] Cardiac failure eventually develops in some 1015% of untreated homozygotes for hemochromatosis. By the time symptoms of parenchymal damage develop, usually in middle or late life, body iron stores have typically increased from the normal range of 1 g or less to 1520 g or more.[148] Further increments in the body iron stores may be fatal, although some patients are able to tolerate a total iron accumulation of as much as 4050 g. Hereditary hemochromatosis is incompletely expressed in heterozygotes, [150] with about one-fourth developing evidence of minor, apparently harmless increases in body iron stores to totals of not more than 45 g.

Identification of the *HFE* Gene

The most important recent advance in understanding the etiology and pathogenesis of hereditary hemochromatosis has been the identification of a strong candidate gene for this disorder.[135] This gene was originally designated as *HLA-H* but, because of prior use of this identifier, is better termed *HFE*. For more than two decades the hemochromatosis locus has been known to be closely linked to the HLA-A locus on the short arm of chromosome 6. Located more than three megabases telomeric to the MHC, *HFE* is a gene with structural similarities to the MHC class 1 family. The HFE protein is a single polypeptide with a short cytoplasmic tail, a membrane-spanning region, and three extracellular domains analogous to the 1, 2, and 3 domains of other MHC class 1 proteins (Fig. 26-8). In the original study, missense mutations were found in *HFE* in 87% of chromosomes from patients homozygous for hereditary hemochromatosis. [135] The most prevalent (homozygous in 83% of patients) was a Cys282Tyr mutation. A second mutation in *HFE*, His63Asp, was enriched in patients who were compound heterozygotes for the Cys282Tyr substitution. Importantly, 13% of the patients examined had neither mutation but were indistinguishable clinically from the others. Further investigations in populations of European descent have found that the proportion of patients with hereditary hemochromatosis who are homozygous for the Cys282Tyr mutation varies from nearly 100% in Scandinavia to 69% in Italy;[151] the mutation seems to be rare in Asians.[152]

Cellular, biochemical, and molecular studies have begun to characterize the HFE protein and to examine the consequences of the Cys282Tyr mutation. Immunohistochemical studies of the pattern of expression in the GI tract of control subjects have found that the HFE protein has a unique perinuclear localization in cells in the deep crypts of the small intestine in proximity to the presumed sites of iron absorption. [153] Wild-type and His63Asp HFE proteins are expressed on the cell surface, while the Cys282Tyr mutant *HFE* is exclusively intracellular. [154] Further studies have found that, as predicted from the structure (Fig. 26-8), wild-type HFE binds $_2$ -microglobulin and that the Cys282Tyr mutation, but not the His63Asp mutation, completely

Figure 26-8 Hypothetical model of the HFE protein based upon its homology with MHC class I molecules. *(Redrawn with permission from Feder et al.[135] Copyright 1996 Macmillan Magazines Limited.)*

abolishes this interaction.[155] In 1994 de Sousa and her colleagues reported that mice deficient in $_2$ -microglobulin developed iron loading, predominantly in hepatocytes,[156] suggesting that a $_2$ -microglobulin gene product is involved in iron homeostasis. Reconstitution of mice deficient in $_2$ -microglobulin with normal hematopoietic cells failed to correct the increased iron absorption from the GI tract, but after transplantation the excess iron accumulated in Kupffer cells rather than in hepatocytes.[157] Targeted disruption of the murine homolog of the *HFE* gene found that the phenotype of *HFE*-deficient mice recapitulates that of human hereditary hemochromatosis, with an elevated transferrin saturation and an increased hepatic iron concentration with iron deposition predominantly in hepatocytes in a periportal distribution.[158] These findings provide strong support for the hypothesis that mutations in the *HFE* gene are responsible for hereditary hemochromatosis.

An important clue to the pathogenesis of hereditary hemochromatosis has now been provided by the findings that wild-type HFE protein forms a stable complex with the transferrin receptor and that wild-type HFE/$_2$ -microglobulin heterodimers decrease the apparent affinity of the transferrin receptor for transferrin. His63Asp HFE protein also formed a stable complex with the transferrin receptor but did not decrease the affinity of the transferrin receptor for transferrin. Moreover, the Cys282Tyr mutation almost completely prevents the association of mutant HFE protein with transferrin receptor. [159] These observations establish a molecular association between HFE and the transferrin receptor and suggest that the pathogenesis of hereditary hemochromatosis may be related to a disturbance of the transferrin-transferrin receptor mechanism, although the exact manner in which this alteration leads to excessive dietary iron absorption remains to be determined.

Specific Conditions

Juvenile hemochromatosis is a rare genetic disorder that causes an iron overload like that in hereditary hemochromatosis but with much earlier onset, often in late adolescence.[160] The clinical course is more severe, and patients often present with cardiac symptoms and endocrine dysfunction. Recent studies of a series of patients with juvenile hemochromatosis found none with the *HFE* Cys282Tyr or His63Asp mutations;[160] segregation analysis of 6p markers closely associated with *HFE* in families with consanguineous parents clearly showed that juvenile hemochromatosis is unlinked to 6p and thus genetically distinct from the *HFE* mutation.

Iron-loading anemias may be associated with excessive absorption of dietary iron that can produce severe iron overload. [67] [75] [149] [161] These refractory disorders, characterized by erythroid hyperplasia with marked ineffective erythropoiesis, include thalassemia major and intermedia, hemoglobin E--thalassemia, congenital dyserythropoietic anemia, pyruvate kinase deficiency, a variety of sideroblastic anemias, and other anemias associated with blocks in the incorporation of iron into hemoglobin. The rate of iron loading is not related to the severity of the anemia, and patients with nearly normal hemoglobin concentrations may develop massive iron overload. Any red cell transfusions will add to the iron burden. The amount and distribution of iron deposits resemble those found in hereditary hemochromatosis, with excess iron located predominantly in parenchymal cells, initially in the hepatocyte but later also in the pancreas, heart, and other organs.

Chronic liver disease with increased absorption of dietary iron may produce mild iron overload in some patients, [162] [163] [164] [165] [166] including those with alcoholic cirrhosis or with portacaval shunts. Patients with alcoholic liver disease are more commonly iron deficient as a result of repeated episodes of GI blood loss, but storage iron is increased in a minority. The gene for hereditary hemochromatosis is not responsible. The cause of the increased absorption is unknown, but alcohol-induced folate and sideroblastic abnormalities with ineffective erythropoiesis and hyperferremia may contribute. Storage iron is usually increased modestly, to

only 24 g. In contrast to the pattern of iron distribution found in hereditary hemochromatosis, iron deposition is predominantly in Kupffer cells rather than in parenchymal cells.

Mild iron overload from increased iron absorption is also found in patients with porphyria cutanea tarda, [149] [167] [168] a hepatic porphyria, described more fully in Chapter 27 , in which the liver produces excessive amounts of photosensitizing porphyrins, which circulate to the skin. In symptomatic patients hepatic iron stores characteristically are increased modestly, to 24 g. Alcoholic cirrhosis coexists in some patients, but more often no cause for the increased iron absorption is found. Clinically, the importance of iron for the clinical manifestations of porphyria cutanea tarda is shown by the dramatic effect of iron removal by phlebotomy, producing clinical and biochemical remission of the disease. Conversely, reaccumulation of iron results in recrudescence of symptoms. A high prevalence of the His63Asp *HFE* mutation has been reported in Italian patients with porphyria cutanea tarda.

Rare congenital defects associated with iron overload have been reported. In atransferrinemia, described earlier as one of the causes of microcytic hypochromic anemia, dietary iron is readily absorbed, but little is used for red cell production because of the lack of a physiologic means of transport to erythroid precursors. Instead, iron is deposited predominantly in the liver, pancreas, heart, thyroid, and kidneys. Little iron is found in the spleen and virtually none in the marrow. Another rare congenital defect, ascribed to defective uptake of iron by red cell precursors, is also associated with marked hepatic iron deposition and fibrosis. [127]

Hereditary aceruloplasminemia is a newly recognized, rare autosomal recessive disorder of iron metabolism resulting from deficiency of ceruloplasmin ferroxidase activity as a consequence of mutations in the ceruloplasmin gene. [169] [170] [171] [172] [173] Ceruloplasmin is an $_2$ -serum glycoprotein and multicopper oxidase that transports 95% of the copper found in the plasma; each molecule can bind up to six atoms of copper. Patients present with progressive neurodegeneration of the retina and basal ganglia and diabetes mellitus in middle age. Marked iron accumulation is evident in the liver, pancreas, and brain with smaller amounts of excess iron found in the spleen, heart, kidney, thyroid, and retina. [171] No abnormal copper deposits are present in the liver or other tissues. The serum copper is low and no detectable ceruloplasmin is present. The serum iron is low, the serum total iron-binding capacity normal, and the serum ferritin moderately elevated. Different mutations have been found in each of the families identified, but all have been in the ceruloplasmin gene on chromosome 3q. [169] [170] [171] [172] [173] For comparison, both Menkes syndrome (copper deficiency) and Wilsons disease (copper overload) are the result of mutations in genes of the cation-transport P-type ATPase family on chromosome 13q.[174] [175] The unique involvement of the CNS distinguishes the pattern of iron overload in aceruloplasminemia from that found in hereditary hemochromatosis, African dietary iron overload, or as a consequence of transfusion or iron-loading anemias. With early diagnosis of hereditary aceruloplasminemia, deferoxamine therapy might be a means of averting neurologic deterioration. [176] Hereditary aceruloplasminemia unequivocally establishes the importance of the copper protein in iron metabolism, but the exact relationships between the two metals are incompletely understood. Interestingly, a homologous copper oxidase has an essential role in iron metabolism in yeast. [177]

African dietary iron overload occurs in sub-Saharan Africa in association with greatly increased dietary iron intake from a fermented maize beverage that is made from locally grown crops and home-brewed in steel drums. Beverage consumption may supply as much as 50100 mg of iron daily, many times

---

The role of protracted medicinal iron ingestion as a cause of iron overload remains indeterminate. Equivocal evidence is found in case reports of apparently normal individuals who have taken medicinal iron chronically. The issue is complicated by the possible influence of an unrecognized allele for hemochromatosis in these case reports, although the consequences of increased iron intake in heterozygotes for hereditary hemochromatosis are not known. By contrast, medicinal iron ingestion can undoubtedly be harmful to patients with iron-loading disorders by further increasing their body iron burden.

the 1020 mg of iron in typical American diets. Iron burdens of a magnitude comparable to those found in hereditary hemochromatosis may accumulate, and liver disease (with cirrhosis and hepatoma), pancreatic disease (with diabetes mellitus), endocrine disorders, and cardiac dysfunction may develop. Although increased dietary iron intake was long considered the sole cause of the increased iron absorption in this disorder, pedigree analysis of African families suggested that a non-HLA-linked gene may be involved and might be common in populations of African derivation. [139] Subsequent studies have provided further support for the hypothesis that an iron-loading gene distinct from that for hereditary hemochromatosis may be involved in the pathogenesis of African dietary iron overload. [140] [141] [178] Recently, the presence of severe iron overload has been documented in U.S. patients of African ancestry, [179] [180] but the relationship to the possible genetic abnormality associated with African iron overload is uncertain. Nonetheless, an important clinical consequence of these observations is that individuals of African ancestry should be included in screening programs for iron overload.

Hyperferritinemia with autosomal dominant congenital cataract is a newly recognized disorder of iron metabolism in which affected family members present with early-onset bilateral nuclear cataracts and moderately elevated serum ferritin concentrations (1,0002,500 g/L), [181] [182] with both conditions co-inherited as an autosomal dominant trait. As described earlier, in normal individuals the serum ferritin is composed of a mixture of L and H subunits. By contrast, in patients with hyperferritinemia and autosomal dominant congenital cataracts, the serum ferritin is mostly of the L-type; H-type ferritin concentrations are too low to be detected. [183] Serum iron and transferrin saturation are normal or low, and body iron, as evaluated by phlebotomy, is not increased. On examination, no hematologic or biochemical abnormalities are evident in affected individuals. Molecular studies have identified mutations in the IRE of the L-ferritin mRNA affecting the highly conserved CAGUGU motif that constitutes the IRE loop and mediates the high-affinity interaction with the IRP. [182] [183] [184] In cultured lymphoblastoid cells from affected patients, the mutation was found to abolish the binding of IRP and result in a high constitutive, poorly regulated L-ferritin synthesis. [183] This mutation, the first reported example of a defect in iron-mediated translational regulation in a human disorder, has a surprisingly mild phenotype. The only sign of the mutation seems to be an accumulation of L-type ferritin in the lens, resulting in a cataract, although a direct relationship between the mutation and the lens deposit of ferritin has not been formally demonstrated.

Parenteral iron overload is usually the result of repeated red cell transfusions in patients with chronic anemia, but occasionally it is unintentionally produced by repeated injections of iron dextran or other parenteral iron preparations in patients with anemias unresponsive to iron therapy.

Transfusional iron overload progressively develops in patients with chronic refractory anemia who require red cell support. [109] [185] [186] [187] In patients with severe congenital anemias such as thalassemia major (Cooleys anemia) or the Blackfan-Diamond syndrome, transfusional iron loading begins in infancy. Severe iron loading may also develop in transfusion-dependent anemias that appear later in life, namely, aplastic anemia, pure red cell aplasia, hypoplastic or myelodysplastic disorders, and the anemia of chronic renal failure. If ineffective erythropoiesis and erythroid hyperplasia complicate the underlying anemia, increased absorption may contribute to the iron burden, but an adequate transfusion regimen will help suppress erythropoiesis and may reduce iron absorption to near normal levels. Patients with sickle cell anemia or sickle cell/-thalassemia are also at risk for iron overload if chronically given transfusions for the prevention of recurrent complications such as stroke, severe infections, and incapacitating painful crises, as well as other problems.

Perinatal iron overload develops in some rare metabolic disorders of the newborn, presumably as the result of disturbances in the regulation of fetal or maternal-fetal iron balance. In hereditary tyrosinemia (hypermethioninemia), moderate iron deposition is restricted to the liver, which is typically cirrhotic; renal abnormalities and hyperplasia of the pancreatic islet cells are also present. [188] The cerebrohepatorenal syndrome, or Zellwegers syndrome, is a fatal disorder with an autosomal recessive mode of inheritance, characterized by abnormal facies, hypotonia, and polycystic kidneys. Parenchymal iron deposits are found in the liver, spleen, kidney, and lungs.[189] Perinatal hemochromatosis,[149] [190] [191] [192] also known as neonatal hemochromatosis or neonatal iron storage disease, is a usually fatal disorder of the newborn of unknown cause. It is characterized by hepatic cirrhosis and iron deposition in parenchymal cells of the liver, heart, and endocrine organs but not in bone marrow or spleen.

Focal sequestration of iron[149] in other rare disorders produces various patterns of localized iron deposition. In idiopathic pulmonary hemosiderosis, repeated episodes of alveolar hemorrhage are followed by the uptake and sequestration of iron in pulmonary macrophages. This excess iron is not available for use elsewhere, and iron stores in the liver and bone marrow may be decreased or absent. In conditions with chronic hemoglobinuria, renal hemosiderosis may develop, but the renal iron deposits are harmless and have no apparent effect on kidney structure or function. The Hallervorden-Spatz syndrome [193] is a rare degenerative neurologic

disease with an autosomal recessive mode of inheritance. It is characterized by the juvenile onset of progressive motor abnormalities, dementia, dysarthria, and dysphagia, with optic nerve atrophy. Although the role of iron in the disorder has not been determined, marked iron deposition is found in the globus pallidus and reticular zone of the substantia nigra.

Clinical Presentation

Clinical manifestations of iron toxicity generally develop only in patients with forms of iron overload in which the magnitude of iron accumulation is sufficient to produce tissue damage. At risk are homozygotes for hereditary hemochromatosis and patients with iron-loading anemias, congenital defects in iron metabolism, African dietary iron overload, chronic medicinal iron ingestion, and parenteral iron loading. Heterozygotes for hereditary hemochromatosis and patients with chronic liver disease or porphyria cutanea tarda are usually spared because of the limited extent of the iron excess. Whatever the cause of the systemic iron overload, similar clinical features eventually develop with sufficient iron accumulation. Symptomatic patients may present with any of the characteristic manifestations of iron overload: increased skin pigmentation, hepatic disease, diabetes mellitus, gonadal insufficiency and other endocrine disorders, abdominal pain, cardiac dysfunction, arthropathy, and occasionally neurologic and psychological abnormalities. [106] [137] [148] In

homozygotes for hereditary hemochromatosis first seen in late middle age, the classic clinical tetrad consists of skin pigmentation, liver disease, diabetes mellitus, and gonadal failure, although not all these features occur in each patient. In younger patients with juvenile hemochromatosis, cardiac abnormalities and gonadal failure may be the presenting features.

Adequately transfused patients with thalassemia major or other congenital refractory anemias grow and develop normally during the first decade of life. Thereafter, without treatment for iron excess, growth fails, sexual maturation is delayed or absent, and liver disease, diabetes mellitus, and other endocrine abnormalities develop; patients usually die of heart disease in adolescence. [109] Transfusion-dependent forms of refractory anemia that are acquired later in life, such as aplastic, myelodysplastic, or sideroblastic anemias, ultimately follow a similar course.

Characteristic manifestations of iron toxicity are found in specific organ systems. Increased skin pigmentation, with a bronze hue in some patients and a slate gray coloration in others, often accompanies iron overload, although the change in pigment may be too slight to be readily evident clinically. Increased melanin is responsible for the bronzing, while the slate gray appearance is attributed to iron deposition in sweat glands and in the basal layers of the epidermis. Massive iron overload sometimes produces reverse freckling, with small pigment-free areas scattered over a conspicuous slate gray discoloration of the skin. [194]

Liver disease is the most common complication of systemic iron overload. With hereditary hemochromatosis, the excess iron absorbed from the diet is deposited predominantly within the parenchymal cells of the liver, but subsequently the iron accumulates in the heart, pancreas, and other organs. By the time that symptoms of parenchymal damage develop, usually in middle or late life, body iron stores have typically increased from the normal range of 1 g or less to 1520 g or more. [148] [195] Further increments in the body iron may be fatal, although some patients are able to tolerate a total iron accumulation of as much as 4050 g or more. The iron within transfused red cells progressively accumulates in patients with chronic refractory anemia who are transfusion dependent. Each unit of transfused red cells contains 200250 mg of iron. Most patients with severe refractory anemia require 200300 ml/kg/year of blood, or the equivalent of 610 g of iron per year in a 70-kg adult. [109] Without chelation therapy to remove iron, cardiac iron deposition develops in patients who have received 100 units of blood (20 g of iron) or more [196] and is often accompanied by other evidence of iron-induced damage to the liver, pancreas, and endocrine organs. In all varieties of iron overload, the development and severity of liver damage are closely correlated with the magnitude of hepatic iron deposition. Whether derived from transfused red cells or from increased absorption of dietary iron, progressive iron accumulation eventually produces hepatomegaly, functional abnormalities, fibrosis, and, finally, cirrhosis. Hepatocellular carcinoma seems to be an ultimate complication of cirrhosis in iron overload; the development of cirrhosis increases the risk of hepatoma by more than 200-fold. [148]

Diabetes mellitus is another common complication of all forms of systemic iron overload; [109] [195] the risk may be greater in patients with a family history of diabetes. Virtually all of the secondary manifestations of diabetes may develop, including retinopathy, nephropathy, neuropathy, and vascular disease. Gonadal insufficiency and other endocrine abnormalities also occur. Hypogonadism may result from primary testicular failure or may be hypogonadotrophic in origin. In hereditary hemochromatosis, impotence may be the presenting symptom. Abnormalities in pituitary and end-organ function may develop; hypothyroidism, hypoparathyroidism, and adrenal insufficiency are infrequent complications. During the second decade of life, both growth and sexual maturation are usually retarded in untreated patients with transfusional iron overload. Abdominal pain of unknown origin may be part of the initial complex of symptoms in as many as 25% of patients with hereditary hemochromatosis.[67]

Iron-induced cardiac disease, occurring as a cardiomyopathy with heart failure, as arrhythmias, or as both, may be a fatal complication of all varieties of systemic iron overload. Heart disease is the most frequent cause of death in patients with transfusional iron overload. [197] [198] About 1015% of patients with untreated hereditary hemochromatosis develop congestive heart failure.[67] Particularly severe cardiac disease may be the presenting symptom in young patients with juvenile hemochromatosis.[160]

Chondrocalcinosis and other forms of arthropathy are common complications of hereditary hemochromatosis and may be the presenting feature. [67] [105] [106] [137] The pathogenesis of the joint changes is unknown. In transfusional iron overload, arthropathy occurs but is uncommon. [109] Osteoporosis is found in some patients with hereditary hemochromatosis. Ascorbate acid deficiency occurs in transfusional siderosis and may play a protective role in some patients because a lack of ascorbate prevents the redistribution of iron from macrophage to parenchymal cells. The combination of ascorbic acid deficiency and osteoporosis is particularly common in African dietary iron overload.[67]

The effect of iron excess on the risk of infection remains uncertain; infection is not a characteristic complication of any of the iron overload syndromes. Nonetheless, clinical reports suggest that an increased availability of iron might be pathogenetically related to infections with certain organisms, including *Vibrio vulnificus, Listeria monocytogenes, Yersinia enterocolitica, Escherichia coli*, and *Candida* spp.[67] [106] [199]

Laboratory Evaluation

The characteristic sequence of changes in clinically useful indicators of iron status as body iron increases from the iron-replete normal to the amounts found in iron overload is shown in Figure 26-5 . The most useful of the indirect measures of body iron status are plasma ferritin and plasma iron and iron-binding capacity. In the absence of complicating factors, plasma ferritin rises to a maximum concentration of about 4,000 g/L as the body iron burden increases. In some circumstances the relationship between plasma ferritin and body iron stores is distorted: the plasma ferritin may greatly underestimate the extent of iron accumulation or may even be normal despite a considerable increase in body iron in a small number of patients with hereditary hemochromatosis, but the explanation for this disproportion is unknown.[20] [200] [201] The plasma ferritin may also underestimate the body iron burden in a small number of patients with transfusional iron overload; ascorbate deficiency may be responsible in some of these cases. [202] Conversely, coexisting liver disease, inflammation, infection, or malignancy may increase plasma ferritin concentrations and complicate the assessment of patients with iron-related hepatotoxicity, hepatitis, hepatoma, or other disorders.

The plasma iron, total iron-binding capacity, and transferrin saturation provide indications of the current iron supply to the tissues. An increased plasma iron and transferrin saturation and a decreased total iron-binding capacity suggest parenchymal iron loading but provide no measure of its magnitude. The transferrin saturation may be normal despite increased iron stores within macrophages, as is found in early transfusional iron loading; it is also affected by coexisting disorders such as liver disease, inflammation, or malignancy.

A liver biopsy is the direct and definitive means of determining the extent of parenchymal iron accumulation. Differentiation of the iron overload associated with chronic liver disease, especially of alcoholic origin, from hereditary hemochromatosis may require special study. The presence of liver disease complicates

TESTING FOR IRON OVERLOAD

A direct measure of body iron avoids the uncertainties inherent in the interpretation of indirect indicators of iron status. Liver biopsy is the definitive direct test for assessing iron deposition and tissue damage in iron overload, permitting measurement of the nonheme iron concentration, histochemical determination of the cellular distribution of iron between hepatocytes and Kupffer cells, and pathologic examination of the extent of tissue injury. In patients with hereditary hemochromatosis undergoing therapeutic venesection, quantitative phlebotomy provides an accurate retrospective determination of the amount of storage iron that can be mobilized for hemoglobin formation. When liver biopsy is contraindicated in a patient, quantitative phlebotomy is occasionally useful in establishing the diagnosis of hereditary hemochromatosis. Bone marrow aspiration and biopsy provide no information about the extent of parenchymal iron loading and are of limited value in the evaluation of iron overload. Iron overload produces no specific abnormalities in the peripheral blood.

the interpretation of plasma ferritin and transferrin saturation values. In this circumstance the results of liver biopsy are again definitive. In chronic liver disease iron is deposited principally in Kupffer cells, whereas in hereditary hemochromatosis the iron is found predominantly within hepatocytes. The hepatic iron index (hepatic iron concentration, corrected for the age of the patient) can also be used to distinguish between patients with alcoholic liver disease with iron loading and those with the heterozygous and homozygous forms of hereditary hemochromatosis.[203] [204] [205]

Differential Diagnosis

The detection and diagnosis of iron overload are most problematic in those conditions resulting from an increased absorption of iron (Table 26-5). Hereditary hemochromatosis is potentially detectable either genetically or phenotypically. After the identification of a candidate gene for hereditary hemochromatosis that is found in most (69100%) of patients with hemochromatosis, a diagnostic genotypic test for the *HFE* Cys282Tyr mutation has been developed. At present, the best use of the test is still under evaluation because initial studies have shown that some iron-loaded patients lack the mutation while some patients who are homozygous for the mutation do not have iron overload.[206] Thus, patients who are found to be homozygous for the *HFE* Cys282Tyr mutation are clearly at risk for iron overload and need phenotypic evaluation by liver biopsy or by quantitative phlebotomy to determine the extent of iron loading.

Patients who are not homozygous for the *HFE* Cys282Tyr mutation may still have iron overload and also require phenotypic evaluation. For these patients, the best indirect means of identifying individuals with iron overload is a combination of measurements of the plasma ferritin and of the plasma iron and transferrin saturation. If any of these measurements is abnormal, a definitive diagnosis can be made directly by liver biopsy, with biochemical measurement of the nonheme iron concentration, histochemical evaluation of the pattern of iron deposition, and pathologic determination of the extent of tissue injury. If the diagnosis of hemochromatosis is established, screening of family members at risk for the disease is mandatory, including siblings andbecause of the possibility of homozygous-heterozygous matingsparents and children. HLA typing may be useful in these family studies. Plasma ferritin and transferrin saturations should be determined; in younger individuals, these measurements should be repeated periodically because some affected individuals do not accumulate appreciable iron burdens until well into adult life. Practice guidelines for the detection, diagnosis, and management of hereditary hemochromatosis have recently been published by the College of American Pathologists.[207]

In patients with iron-loading anemias who are not transfusion dependent, the severity of anemia provides no indication of the risk of iron loading from increased dietary iron absorption. Patients with only minor anemia may accumulate major iron loads. In the diagnosis of these patients, examination of the peripheral blood may show changes of the underlying hematologic disorders. Either morphologic or ferrokinetic techniques may be used to estimate the extent of ineffective erythropoiesis and of erythroid marrow hyperplasia and may be useful in assessing the risk of iron loading. Plasma ferritin and transferrin saturations provide the best direct means of screening for iron overload.

The differential diagnosis of the remaining causes of iron overload listed in Table 26-5 pose few problems. Porphyria cutanea tarda is discussed more fully in Chapter 27 and is readily diagnosed by measurement of urinary porphyrins. The source of the iron overload in patients with parenteral iron loading is evident, whether from transfusion or from repeated injections of therapeutic iron. The various causes of perinatal iron overload are clearly distinguished by clinical and pathologic findings. The diagnosis of idiopathic pulmonary hemosiderosis should be considered whenever iron deficiency anemia develops with coexisting pulmonary abnormalities. Previously, demonstration of iron deposits in the basal ganglia of patients with the Hallervorden-Spatz syndrome was possible only at autopsy, but MRI now provides a means of detecting the localized brain iron during life. [193]

Therapy

The goal of therapy for iron overload is the reduction and maintenance of the body iron at normal or near normal amounts. If possible, phlebotomy is the treatment of choice for hereditary hemochromatosis,[106] [195] for iron-loading anemia if the hemoglobin concentration is high enough to permit venesection, [149] for porphyria cutanea tarda,[149] and for African dietary iron overload. [67] Once the diagnosis of iron overload is established, phlebotomy therapy should begin promptly, for any delay extends exposure to potentially toxic iron accumulations. For most patients phlebotomy should remove 500 ml of blood, containing 200250 mg of iron, once weekly, until storage iron is depleted. The regimen should be individualized; for patients with iron-loading anemia, smaller amounts of blood will need to be withdrawn weekly, while for heavily loaded patients with hereditary hemochromatosis, an even more vigorous program of phlebotomy twice weekly has been advocated. [208] The hematocrit or hemoglobin concentration should be measured before each phlebotomy. After an initial fall in the hemoglobin as erythropoiesis accelerates to keep pace with venesection, the hemoglobin will remain at about 90% of its initial value. The progress of iron removal can be followed by periodic measurements of plasma ferritin, iron, and transferrin saturation. The plasma ferritin concentration declines progressively as iron is removed, but the plasma iron and transferrin saturation remain elevated until iron stores near depletion. In a patient with porphyria cutanea tarda, a few weeks of phlebotomy will suffice, while in hereditary hemochromatosis and an initial body iron burden of 25 g, removal of the iron burden may require 2 years or more.

Occasionally, plasma iron falls and hemoglobin regeneration is temporarily delayed despite incomplete removal of excess iron, as indicated by continued elevation of the plasma ferritin

TIMING OF CHELATION THERAPY

In patients who are transfusion dependent from early infancy (i.e., those who have thalassemia major and other congenital refractory anemias), chelation therapy is best started after about 1020 transfusions, usually around 3 years of age.[109] In older patients with acquired refractory anemias who become transfusion dependent, it seems advisable to begin chelation early, after transfusion of 1020 units of blood. In patients with iron-loading anemias and those with sickle cell disease who are chronically transfused for prevention of complications, early therapy also seems prudent, beginning when the hepatic iron concentration or the serum ferritin increases to about two or three times the upper limit of normal. In each of these disorders, delay in beginning chelation therapy only exposes the patient to a greater risk of iron toxicity.

concentration. A brief halt in the phlebotomy regimen, presumably to allow mobilization of the remaining iron, is usually all that is needed before resuming weekly venesection. Eventually, when iron stores are exhausted, the ferritin will decline to <12 g/L, the plasma iron and transferrin saturation will be decreased, and the hemoglobin concentration will fall to <10 g/dl for 2 weeks without further phlebotomy. After complete removal of the iron load, lifelong maintenance therapy is needed, usually requiring phlebotomy of 500 ml every 34 months. Maintenance phlebotomy should preserve a normal transferrin saturation and a plasma ferritin of <50 g/L. Although well-controlled studies are lacking, phlebotomy is not generally recommended for patients with the modest iron overload that sometimes develops with chronic liver disease; removal of the iron load in these cases seems to have no clinical benefit. [209]

For patients with transfusion-dependent refractory anemias, most patients with iron-loading anemias, and the rare patients with hereditary hemochromatosis in whom phlebotomy is impossible, treatment with the iron chelator desferrioxamine is the only means of preventing or removing toxic accumulations of iron. [109] In patients with hereditary hemochromatosis and cardiac failure, a combination of phlebotomy and chelation therapy has been recommended. Unfortunately, desferrioxamine given orally is poorly absorbed; to be effective the drug must be administered by subcutaneous or intravenous infusion with a small portable syringe pump, ideally for 912 hours each day. Compliance with this regimen may be difficult, but a number of studies have now shown that regular chelation therapy with desferrioxamine can remove tissue iron, prevent organ damage, and prolong survival.

In patients with modest iron loads and no evidence of iron toxicity, slow subcutaneous infusion of desferrioxamine for 912 hours daily usually provides adequate therapy. In severely iron-loaded patients and in patients with evidence of iron toxicity, particularly those with cardiac complications, chronic slow intravenous infusions through an indwelling central venous catheter may permit more rapid reduction of the body iron burden. Administration of ascorbic acid can enhance desferrioxamine-induced iron excretion but carries the risk of an internal redistribution of iron from relatively benign storage sites in macrophages to a potentially toxic pool in parenchymal cells. Although the evidence is circumstantial, large doses of ascorbic acid should be regarded as hazardous in patients with iron overload. [210]
Ascorbate supplementation is probably not needed by patients whose diets regularly include ascorbate-rich foods. Desferrioxamine is a generally safe and nontoxic drug in the iron-loaded patient, but systemic complications have been reported, including allergic anaphylactoid reactions, infectious complications, visual abnormalities and auditory dysfunction, and growth retardation. [211] [212] The risk of many of these complications may be minimized by adjusting the desferrioxamine dose to the magnitude of the body iron load. Adequate desferrioxamine therapy should produce a progressive decrease in the body storage iron of almost any patient with iron overload. If no decline is observed, blood and desferrioxamine use, compliance, ascorbate status, and other features of the therapeutic regimen should be thoroughly reassessed.

Prognosis

The prognosis in patients with iron overload is influenced by many factors, including the magnitude, rate, and route of iron loading; the distribution of iron deposition between macrophage and parenchymal sites; the amount and duration of exposure to circulating non-transferrin-bound iron; ascorbate status; and coexisting disorders, especially alcoholism. The magnitude of iron accumulation seems crucial. In hereditary hemochromatosis the minor iron load found in some heterozygotes seems innocuous. [150] [195] Equal numbers of male and female homozygotes are expected, but symptomatic expression is as much as 10 times as common in men, presumably because iron losses during menstruation and pregnancy leave women with lower iron burdens. [148]

The hepatic iron concentration [213] is a major determinant of the risk of cirrhosis of the liver and in turn of hepatocellular carcinoma, now the two major causes of death in hereditary hemochromatosis. The development of cirrhosis increases the risk of hepatocellular carcinoma more than 200-fold. [148] Hepatomas, the ultimate cause of death in 2030% of patients with hemochromatosis, occur almost exclusively in patients with hepatic cirrhosis. Conversely, if the disease is diagnosed before tissue injury has occurred, phlebotomy therapy to remove the excess iron can prevent all the complications of hemochromatosis, including cirrhosis, and return the patients life expectancy to normal. [148]

Even if organ damage is present, further progression is prevented by phlebotomy, [214] and amelioration of some features of the disease is possible. Skin pigmentation diminishes; hepatic function may improve, while fibrosis is arrested or may sometimes regress; and cardiac abnormalities or even failure may resolve. Diabetes and other endocrine abnormalities usually improve only slightly, if at all, although reversal of hypogonadism has occurred. Arthropathy is usually not improved and may even continue to progress despite phlebotomy. In patients with iron overload who cannot be treated by phlebotomy, chelation therapy is effective in reducing the body iron burden and improving the prognosis. Chronic infusion of parenteral desferrioxamine decreases the hepatic iron concentration, improves hepatic function, promotes growth and sexual maturation, and helps protect against cardiac disease and early death. In all forms of iron overload the most effective means of avoiding complications is to prevent iron accumulation, either by early identification and phlebotomy treatment of homozygotes for hereditary hemochromatosis or by early institution of chelation therapy in patients with iron-loading or transfusion-dependent anemias.

Future Directions

Major advances in the understanding and diagnosis of hereditary hemochromatosis can be expected. The identification of *HFE* as a strong candidate for the gene responsible for most hereditary hemochromatosis, together with the identification of Nramp2 as the iron transport protein for GI absorption, has created an opportunity for rapid progress in our knowledge of the molecular basis for iron absorption and its control. The observation

of an association between *HFE* and the transferrin receptor now links the *HFE* Cys282Tyr mutation to the transferrin-transferrin receptor cycle, and the effects of the mutation on the regulation of iron homeostasis may soon be clarified. The availability of a genetic test for most individuals with hereditary hemochromatosis should stimulate the development of population screening programs that will make possible the early detection of affected individuals and the institution of preventive phlebotomy to avoid organ damage. Progress in noninvasive assessment of the body iron burden can also be anticipated. Several methods for the noninvasive diagnosis and measurement of iron overload are under development that would be most useful in the detection and management of patients with iron overload. Therapeutically, efforts to find iron-chelating agents that will avoid the difficulties with compliance associated with prolonged parenteral administration of deferoxamine will continue. The development of a safe, effective, inexpensive, and easily administered iron-chelating agent would be a major advance in the treatment of iron overload that could substantially improve both the quality and length of life of affected patients in the United States and provide important public health benefits worldwide.

Chapter 27 - Heme Biosynthesis and Its Disorders: Porphyrias and Sideroblastic Anemias

James S. Wiley
Michael R. Moore

INTRODUCTION

The porphyrias and the sideroblastic anemias are metabolic disorders that both involve defects in heme biosynthesis. Most forms of porphyria are inherited as Mendelian autosomal dominants, but some types are recessive and others are acquired through exposure to porphyrinogenic drugs and chemicals. A linked group of diseases, the porphyrinurias, are not porphyrias but have in common alterations of heme biosynthesis. Porphyrins are tetrapyrroles, ubiquitous in nature, that exhibit characteristic red fluorescence on exposure to ultraviolet light. The iron-porphyrin complex, heme, is central to all biological oxidation reactions. In plants, the porphyrin molecule is combined with magnesium to form chlorophyll. Porphyrin biosynthesis is thus one of the most essential biochemical processes in the great majority of life-forms. In man, mutations affecting the first enzyme of the heme biosynthetic pathway produce sideroblastic anemia. Inborn errors that occur at subsequent sites in this path way usually result in metabolic disorders known as the porphyrias (Fig. 27-1). Historical analysis of the potential presence of acute porphyria in the British Royal family has been completed, [1] as well as a study of the family of Vincent van Gogh. [2]

HEME BIOSYNTHESIS

Heme biosynthesis is an essential pathway and occurs in all metabolically active cells that contain mitochondria. It is most active in erythropoietic tissue where it is required for hemoglobin synthesis and in hepatic tissue where the heme forms the basis of various heme-containing enzymes such as the cytochromes P450, catalase, cytochrome oxidase, and tryptophan pyrrolase. The synthetic pathway starts with the condensation of glycine and succinyl CoA to form 5-aminolevulinate (ALA) under the control of the mitochondrial enzyme ALA synthase. This enzyme requires pyridoxal phosphate as a cofactor. A series of enzymes then controls the conversion of ALA first to the monopyrrole porphobilinogen (PBG) and then to the various porphyrins. Finally, iron is inserted into protoporphyrin by the enzyme ferrochelatase to form heme (Fig. 27-1). During the past ten years, cDNA clones have been obtained for all of the enzymes of heme biosynthesis and the structures of the corresponding genes have been determined. These advances are certain to improve both understanding of the pathogenesis of the porphyrias and methods for identification of carriers. The enzymes of the biosynthetic pathway have all been mapped to specific chromosomes (Table 27-1).

Figure 27-1 Pathway of heme biosynthesis in mammalian cells. The first step in the pathway is catalyzed by ALAS and occurs within the mitochondrion using pyridoxal 5-phosphate as a cofactor. ALA then leaves the mitochondrion and is converted by ALA dehydratase to give a monopyrrole, porphobilinogen. Four molecules of this are converted by porphobilinogen deaminase to a linear tetrapyrrole, hydroxymethylbilane. This molecule is then cyclized by uroporphyrinogen III synthase to uroporphyrinogen III, which is then decarboxylated to coproporphyrinogen III. This molecule enters the mitochondrion and is oxidized in succession by coproporphyrinogen III oxidase and protoporphyrinogen III oxidase. The product is protoporphyrin IX, a substrate for ferrochelatase, which catalyzes the insertion of Fe^{2+} to form heme. The defective steps associated with specific porphyrias and X-linked hereditary sideroblastic anemias are shown.

Heme synthesis and its disorders have been the subject of recent reviews. [3] [4] [5] [6] [7]

Control of Heme Biosynthesis

The overproduction of porphyrins and their precursors in the different porphyrias is mainly hepatic or erythropoietic in origin. In the acute porphyrias and in porphyria cutanea tarda, the liver is the main source of overproduction; in congenital porphyria the marrow is the main source; and in erythropoietic protoporphyria porphyrins are over-produced by both the liver and marrow.

Control of hepatic heme biosynthesis is regulated by the rate of the initial enzymatic step, ALA synthase (now designated ALAS1) which is under negative feedback control by heme. This occurs by more than one mechanism. Heme represses transcription of the ALAS-1 gene and also increases the rate of degradation of the mRNA (Fig. 27-2A). In addition, at the post-translational level, heme blocks the translocation of pre-ALAS1 into the mitochondrion. [8] In the mitochondrion the molecular weight of ALA synthase is smaller than that of the cytosolic pre-ALA synthase [9] due to the removal of the mitochondrial targeting sequence.

The erythroid bone marrow is the major heme-forming tissue in the body producing 85% of the daily heme requirement. Heme synthesis in erythroid cells differs from that in hepatocytes; it is linked to tissue differentiation and the half-life of the same end-product of the two is quite different. Heme complexed with globin is preserved in circulating red blood cells for approximately 120 days, whereas heme produced in liver

TABLE 27-1 -- Classification of Porphyrias

Classification	Disease	Biochemistry		Clinical Features

Nonacute porphyria	Porphyria cutanea tarda				
	Erythropoietic protoporphyria				
	Congenital porphyria				
Porphyrinurias	Lead Alcohol				
	Iron-deficiency anemia	Varying biochemical and clinical presentation			
	Liver disease				

Figure 27-2 (A) Control of heme synthesis in hepatic and other tissues. The rate of heme synthesis depends on the first and rate-limiting enzymatic step catalyzed by ALAS1. Heme represses transcription of the ALAS1 gene, increases the rate of degradation of its mRNA, and finally blocks the translocation of the ALAS1 isoenzyme into the mitochondrion. **(B)** Control of heme synthesis in erythroblasts. Cytosolic iron enhances the translation of mRNA of the pre-ALAS2 by inhibiting the interaction of a repressor protein with an iron-responsive element in the mRNA. The product of the last step, heme inhibits the uptake of iron from transferrin into the cytosol. Also heme may inhibit translocation of ALAS2 into the mitochondrion. The overall result is that the rate of heme synthesis is tightly linked to the availability of iron for the ferrochelatase reaction.

for cytochromes and enzymes, such as catalase, is subject to much more rapid turnover, measurable in hours. Regulation in the liver is exquisitely sensitive to fluctuations in intracellular heme levels [10] and responds rapidly to the requirements for synthesis as described in Fig. 27-2A . However, heme synthesis in the bone marrow shows a more leisurely response. This fundamental difference is explained by the finding of two different tissue-specific isoenzymes and two different cDNAs for human liver or housekeeping ALA synthase (ALAS1) and an erythroid ALA synthase (eALA.S or ALAS2) expressed exclusively in erythroid cells. [11] [12] [13] The gene for ALAS2 has been mapped to the X-chromosome and that for the hepatic enzyme to chromosome-3.[12] [13] The ALAS2 gene has 11 exons; exons 5 to 11 encode the catalytic domain of the enzyme and include a lysine residue that forms a Schiff base with the pyridoxal phosphate cofactor. Exon 1 contributes to the 5-untranslated region whose structure allows iron to regulate ALAS2 mRNA translation, whereas exons 1 and 2 contribute the sequence that targets the enzyme to the mitochondria

and is cleaved after import.

Enzyme levels of ubiquitous and erythroid isoenzymes of ALAS are controlled by different mechanisms. Ubiquitous ALAS1 levels in liver are regulated by negative feedback by heme that inhibits gene transcription and import of preALAS1 (Fig. 27-2A). In contrast, heme does not affect transcription of the ALAS2 gene, which is under the control of erythroid-specific promoters, e.g., GATA-1. Whether heme inhibits import of pre-ALAS2 into the mitochondrial matrix remains to be unequivocally established. Heme may possibly also prevent the accumulation of intracellular iron by controlling the acquisition of iron from transferrin (Fig. 27-2B).[7] Levels of intracellular iron in turn regulate the translation of ALAS2 mRNA. A specific repressor protein interacts with an iron-responsive element in the 5 untranslated region of the ALAS2 mRNA and prevents translation, and this repression is relieved by high iron levels. [9] Thus, iron uptake by erythroid cells has a positive effect on the enzymatic step catalyzed by ALAS2 (Fig. 27-2B). This effect ensures that protoporphyrin synthesis is coupled to iron availability.

A second rate-limiting step in the overall heme synthetic pathway lies at the level of porphobilinogen deaminase (PBGD), which has a low endogenous activity and is inhibited by proto- and coproporphyrinogen. There are also two forms of PBGD. The PBGD gene encodes two enzymes. This is because the 10kb long gene with 15 exons has two overlapping transcription units. The upstream promoter works in all cell types and produces a protein of size 4244kD whereas the downstream promoter is only active in erythroid cells and by differential splicing produces a smaller protein of size 4042kD. [14]

Erythroid porphobilinogen deaminase (ePBGD) is stimulated by erythropoiesis in vitro and may play a regulatory role in heme biosynthesis during differentiation. Studies of the erythroid promoter for ePBGD have found trans-acting factors that are common to the -globin gene promoter. [15]

The human porphobilinogen deaminase (PBGD) gene has attracted extensive investigation, because of the practical importance of detecting carriers of the gene for acute intermittent porphyria.[16] Studies of the genetic locus of PBG deaminase on chromosome 11 show great molecular heterogeneity[17] [18] [19] as also found in the parents of a homozygous case of AIP.[20] This heterogeneity results in several phenotypic subtypes of the enzyme at the protein level. Most are cross reacting immunological material (CRIM)-negative but some are CRIM-positive.[21] There is a high interspecies conservation of structure of the enzyme. Most human mutations have been described on exons 10 and 12[22] that is consistent with alteration of the binding sites for the dipyrromethane cofactor for the enzyme. [23] The three-domain structure of porphobilinogen deaminase has been defined by X-ray crystallography. The active site is located between domains 1 and 2. The dipyrromethane cofactor linked to cysteine protrudes from domain 3 into the mouth of the cleft. Flexible segments between domains 1 and 2 are thought to have a role in a hinge mechanism, facilitating conformational changes. Biochemical and X-ray crystallographic studies have shown that the enzyme from *E. coli, Euglena gracilis,* rat, and human has 12 conserved arginine residues in the cleft between the three protein domains. This would fit well with the need to bind six PBG molecules each with two carboxyl groupings.

PORPHYRIAS

Biologic and Molecular Aspects

The porphyrias are classified into acute and nonacute (cutaneous) according to clinical and biochemical features (Table 27-1).

Each of the different types of porphyria is linked to a reduced activity or deficiency of a specific enzyme in the heme biosynthetic pathway (Fig. 27-1). The enzyme deficiency impairs the production of the end product heme and there is overproduction and increased excretion of the heme precursors formed by the steps prior to the enzyme defect. In addition there is a compensatory increase in activity of the initial and rate-controlling enzyme ALA synthase. In the acute porphyrias there is overproduction of all the porphyrins and porphyrin precursors (ALA, PBG) formed proximal to the enzyme defect. The increased excretion of porphyrin precursors in the acute porphyrias is due to the decreased activity of porphobilinogen deaminase (PBGD) in these conditions. The decrease can be caused by genetic mutation of the enzyme (in acute intermittent porphyria) or by inhibition of PBGD by proto- and copro-porphyrinogen in variegate porphyria and hereditary coproporphyria, respectively.[24]

In the nonacute porphyrias there is overproduction of all porphyrins formed prior to the enzyme defect but no overproduction of porphyrin *precursors.* The cause of this lack of overproduction of porphyrin precursors in the nonacute porphyrias is unclear but it may result from a compensatory increase in the activity of the enzyme PBG deaminase in addition to increased activity of ALA synthase and to site-specific heme synthesis. [25] The pattern of overproduction and excretion of porphyrins and porphyrin precursors in the various porphyrias is shown in Table 27-2 . A consequence is that each of the different porphyrias is characterized by a different excretion pattern. Quantitative studies of the different porphyrins and precursors in the urine and feces will usually identify the particular type of porphyria. The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of the bile. Diverse techniques are used to measure porphyrins and precursors such as high pressure liquid chromatography, extraction, and various forms of fluorimetry. A recent addition has been fluorescence emission scanning to differentiate between variegate porphyria, erythropoietic protoporphyria, and other photocutaneous porphyrias. [26] The International Federation for Clinical Chemistry presents diagnostic information on the Internet (http://www.ifcc.org).

The clinical manifestations of an acute attack of porphyria can be explained by dysfunction of the central, peripheral, and autonomic nervous systems. The mechanism by which altered heme synthesis results in dysfunction is unknown. Several explanations for the pathogenesis of the neuropathy have been advanced:

1. Accumulation of porphyrins and their precursorsALA or, less likely, PBG, which are neurotoxic.
2. Deficiency of heme in neural tissues.
3. Depletion of essential substrates or cofactors resulting from the heme biosynthetic pathway defect, e.g., pyridoxal phosphate or zinc or glycine.
4. Abnormal products derived from other pathways, e.g., hemopyrrole, its lactam, peptides and porphobilin.

Perhaps the most likely hypothesis is that the clinical manifestations of acute porphyria arise as a result of heme deficiency within the nerve cells, although this does not exclude the possibility that ALA may also act as a pharmacological agent in these diseases, compounding the effects of heme deficiency. [27] Thus ALA has a pro-oxidant effect on rat brain tissues [28] and generates free radical species during its auto-oxidation. [27] [29] The concept of auto-oxidation or oxidative stress is supported by the hypothesis that manganese excess could contribute to induction of superoxide dismutase [30] and increased indicators of such stress in lead exposure.[31] There is evidence that ALA is incorporated into cells by a pathway common to it and GABA. [32]

Genetic Aspects

The enzymic links and genetic loci in each of the hereditary porphyrias are shown in Table 27-3 . Nearly all are inherited as

Figure 27-3 The Chester family pedigree. The propositus, Peter Dobson, was a salmon fisherman from a close-knit community living on the bank of the River Dee, which runs through the city of Chester, U.K. Most of the 330 descendents of his marriage in 1888 still live in the city. Many suffered disabling illnesses and psychiatric upsets, which often went unrecognized as porphyria. The family termed their illness Dobsons complaint. *(Courtesy Giles R. Youngs.)*

autosomal dominant traits. Few carriers of the abnormal gene show clinical signs of the disease, but most can be identified by intensive biochemical investigation. The rare congenital porphyria shows autosomal recessive inheritance. The mutations producing each of the acute porphyrias are heterogeneous at the molecular level and include complete or partial gene deletions, alterations of splicing or stability of mRNA, and missense mutations. An exception is variegate porphyria in South Africa in which the founder effect ensures a predominance of the Arg 59 Tryp mutation. [33] [34] Homozygotic or compound heterozygotic inheritance has been found in a number of the porphyrias as has concurrent inheritance of more than one defect. This may present as either two types of porphyria in one family [35] [36] [37] or as two types in one patient. [36] [37] [38] [39] [40] Examples of this concurrent porphyria are the Chester porphyria (acute intermittent porphyria and variegate porphyria) [36] and dual porphyria (variegate porphyria and porphyria cutanea tarda). [41]

The prevalence of the different forms varies widely. For example, in northern Europe and North America, approximately 1/10,000 individuals carries the gene for acute intermittent porphyria. It has been suggested that spontaneous mutation accounts for 3% of acute intermittent porphyria cases. [42] Variegate porphyria occurs in 1/400 white South Africans. There is a reduction in gene frequency in variegate porphyria from generation to generation that suggests that the allele associated with it is selectively deleterious. [43] The same is probably true of the other porphyrias. The pedigree of Chester porphyria is shown in Fig. 27-3 .

ACUTE INTERMITTENT PORPHYRIA

Clinical and Laboratory Manifestations

Acute intermittent porphyria is the most severe of the acute porphyrias. During an attack, patients display abdominal and neuropsychiatric or neurovisceral disturbances. Onset is in puberty; females exhibit a four-fold greater incidence of attacks. Attacks occur mainly in young adults, and become less frequent after menopause. It is very uncommon to see attacks in children.[44] Crises may vary in duration from several days to months. They are most commonly followed by complete remission, though deaths are still reported, especially with acute intermittent porphyria. [45]

Gastrointestinal symptoms occur in 95% of cases; most patients present with acute colicky central abdominal pain. Examination reveals tenderness, but little rigidity, and patients may also experience limb pain or generalised muscular aches. Severe

Figure 27-4 Bilateral wrist drop caused by peripheral neuropathy in a patient with acute intermittent porphyria.

PRECIPITATING FACTORS IN ACUTE PORPHYRIA: DRUGS

Most patients who have inherited acute porphyria will enjoy normal health and go through life without any knowledge of their disorder or ever experiencing an acute attack. All porphyrics, however, are at risk of developing an attack if exposed to various precipitating factors. Drugs are the most common precipitating agents. Other factors that may trigger attacks include alcohol ingestion, reduced caloric intake (due to fasting or dieting), and infection. Smoking can cause more frequent attacks.

Hormonal status is also important. Attacks are more common in females and rarely, occur before puberty or after menopause. Pregnancy and oral contraceptives may also precipitate attacks. Some women experience regular attacks, commencing in the week prior to the onset of menstruation. These may require Luteinizing Hormone Releasing Hormone (LHRH) antagonists for control.

Drugs	Other Stimuli
Alcohol	Fasting or dieting
Barbiturates	Hormonesstress
ACE inhibitors	Smoking
Anticonvulsants	
Antidepressants	
Calcium channel blockers	
Cephalosporins	
Ergot derivatives	
Erythromycin	
Steroids or anabolic steroids	
Contraceptives, hormone-replacement therapy	
Sulfonamides	
Sulfonylureas	

DRUG LISTS

Before prescribing any medication to a porphyric patient, advice must be sought from an appropriate specialist. Full drug lists are available on the Internet at http:/www.uq.edu.au/porphyria/ It should be borne in mind that such lists are far from encyclopedic, that new drugs are constantly being introduced to the pharmacopoeia, and that any form of combined preparation must be viewed with suspicion, since little is known about metabolic interactions in these diseases.

vomiting may occur, and constipation is usual. Hyponatremia occurs in severe attacks.

Motor neuropathy complicates two-thirds of porphyric attacks and may be the presenting feature. Motor involvement is most common but paresthesias may also occur. Paralysis usually starts peripherally and then spreads proximally; however, in some patients shoulder-girdle involvement may be the first manifestation. The neuropathy may progress rapidly, resulting in respiratory insufficiency. Weakness, usually symmetrical, involves proximal and distal limb muscles more often than

those of the trunk. Upper limbs and proximal muscles are often affected. Involvement of the wrists, ankles and small muscles of the hand may lead to a permanent deformity (Fig. 27-4), and trunk muscle weakness can lead to respiratory embarrassment. Death is usually due to respiratory paralysis. Progressive weakening of the voice may suggest this; treatment requires tracheotomy and intermittent positive pressure respiration. Paresthesias, numbness, and objective evidence of sensory impairment

may occur with loss of pinprick sensation, most marked around the shoulder and hip areas; generalized tonic-clonic seizures occasionally occur.

Severe anxiety, depression, and frank psychosis are the main psychiatric manifestations of porphyric attacks. These psychiatric manifestations may result in a patient being misdiagnosed as suffering from a primary psychiatric disorder. Agitation, mania, depression, hallucinations, and schizophrenic-like behaviour may occur. Psychiatric manifestations may persist between attacks. [46]

The cardiovascular system is involved in approximately 70% of attacks. Sinus tachycardia (up to 160 beats/minute) and hypertension can occur; these usually revert to normal after an attack. There is evidence that hypertension may occasionally be permanent, even in latent cases of acute intermittent porphyria.

Differential Diagnosis

Attacks of acute porphyria must be distinguished from other causes of acute abdominal pain or peripheral neuropathy sometimes associated with psychosis. Thus heavy metal poisoning (lead or arsenic), as well as Guillain Barre syndrome, must be considered as well as paroxysmal nocturnal hemoglobinuria with its characteristic early morning hemoglobinuria and abdominal pain.

During an attack, all patients excrete a massive excess of the porphyrin precursors, 5-aminolevulinic acid (ALA) and porphobilinogen (PBG) in their urine. Urine, when first voided, is clear and darkens on exposure to light as the hexa-hydro porphyrins, the porphyrinogens, are oxidized to porphyrins.

A rapid screening test during an acute attack is to mix equal volumes of urine and Ehrlichs aldehyde reagent and observe for the pink colour of porphobilinogen.

OTHER ACUTE PORPHYRIAS

Hereditary Coproporphyria

Hereditary coproporphyria (HC) combines the clinical features of acute porphyria with photosensitive skin manifestations. Coproporphyrinogen oxidase activity is decreased,[47] leading to overproduction of coproporphyrin.

The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of the bile.

Variegate Porphyria

Variegate porphyria (VP) is similar to HC except that there are more severe skin lesions, sometimes with scarring (Fig. 27-5). Protoporphyrinogen oxidase is the affected enzyme, thus protoporphyrin is the major circulating porphyrin. Conventionally, VP is most readily diagnosed by measurement of fecal porphyrin concentrations. However, it has been reported[48] that biliary porphyrin levels may provide a better discriminator from normal patients in the asymptomatic phase. As in erythropoietic protoporphyria, there is a tendency to cholelithiasis. The mechanism by which gall stones may form is not certain but some studies have suggested that porphyrins are cholestatic.[49] In both HC and VP the pathway intermediates produced in excess, coproporphyrinogen and protoporphyrinogen respectively, are inhibitors of the secondary rate-controlling enzyme PBG deaminase. [24] [50]

Plumboporphyria

In plumboporphyria, the ALA dehydratase activity is depressed, as occurs in lead poisoning. The clinical picture resembles acute intermittent porphyria but very few cases have been

Figure 27-5 Cutaneous lesions and scarring in a patient with variegate porphyria.

MANAGEMENT OF ACUTE PORPHYRIA

TREATMENT OF ACUTE ATTACK

An *oral carbohydrate* intake of 15002000 kcal/24 hours should be maintained throughout the attack to reduce porphyrin synthesis; give this orally or, for more severe attacks, via a fine bore Teflon nasogastric tube. If this cannot be tolerated, intravenous dextrose (e.g., 20% solution, 2 l/day) should be given. If early in the attack, 24 days from onset, give *intravenous hematin*, as heme arginate (NORMOSANG, Leiras), 24 mg/kg over 30 minutes once or twice a day, to further reduce the overproduction of porphyrin and precursors. [55] Hematin (PANHEMIN, Abbott) in similar doses may also be used, although it should be reconstituted in human albumin solution to avoid phlebitis and mild transient prolongation of coagulation times. No renal complications have occurred with the standard recommended dosages, and even patients with renal insufficiency tolerate hematin well, although the dosage should be reduced slightly. The action of heme therapy may be extended by heme oxygenase blockers, such as tin protoporphyrin.[56] [57]

PROPHYLAXIS

Many drugs are contraindicated and the patient must be warned to avoid precipitating factors. Alcohol should be restricted and smoking discouraged. Dieting (<800 kcal/day) must be avoided. Pregnancy should also be avoided if the disease is active. If a patient requires an anesthetic, nitrous oxide, ether and cyclopropane are safe, and suxamethonium appears to be a safe muscle relaxant. The opiates and belladonna derivates can be used for premedication and propofol for maintenance of anesthesia. Infection can precipitate an attack and should, therefore, be sought and treated. Blood relatives of patients should be screened to see if they carry the gene.

LHRH antagonists that suppress ovulation are a valuable form of prophylaxis in menstrually related attacks.[58] Estrogens and progestogens such as those in the contraceptive pill must be avoided in acute porphyria. The same applies to most steroids and receptor antagonists such as mifepristone.[59]

described and the disease only becomes manifest in homozygous cases when there is some precipitating factor. [51] [52]

Concurrent Porphyrias

The concurrent porphyrias are a rare group of conditions in which there is concurrent inheritance of two different defects within the heme biosynthetic pathway. There is good precedent for more than one defect within the pathway. Previous descriptions [35] [36] [37] [38] [39] [40] [41] have shown the presence of concurrent porphyria within a family, and toxicologically there is good evidence that exposure to poisons such as lead will induce multiple changes within the pathway. [53] Chester porphyria, for example, combines the clinical features of acute and cutaneous porphyria. PBG deaminase and protoporphyrinogen oxidase activity are reduced, leading to overproduction of PBG and protoporphyrinogen. This dual enzyme deficiency is linked to a locus on chromosome 11 separate from that for PBG deaminase. [54] However, even when the patients were symptom-free, the excretion pattern in the urine was typical of the pattern in acute porphyria with a rise in urinary porphyrins and precursors.

NONACUTE OR CUTANEOUS PORPHYRIAS

In all cutaneous porphyrias, porphyrins (which are photosensitizing) are deposited in the upper layers of the skin and these are responsible for the characteristic skin lesions.[60] In the development of these lesions, reactive oxygen species and other radicals are formed and probably induce oxidative membrane damage, in particular to mast cells, which would permit complement activation as one part of the inflammatory reaction. [61]

PORPHYRIA CUTANEA TARDA OR CUTANEOUS HEPATIC PORPHYRIA

Biologic and Molecular Aspects

Porphyria cutanea tarda (PCT) exists in inherited and acquired forms. An inherited homozygous form of this disease, hepatoerythropoietic porphyria (HEP), has been described.[62] In both inherited and acquired forms there is diminution in the activity of hepatic uroporphyrinogen decarboxylase, which converts uroporphyrinogen to coproporphyrinogen by the stepwise decarboxylation of the acetyl groups to methyl groups. The mode of control of the enzyme has been studied in a number of experimental models. These show that iron alone or chlorinated hydrocarbons can diminish activity of uroporphyrinogen decarboxylase and this effect is greatly potentiated when both are given together.[63] Patients may have clinical and biochemical evidence of liver disease. Hepatic siderosis invariably occurs and iron is one of the causative agents in acquired PCT. An association of PCT with hereditary hemochromatosis has been suggested, and studies have found a 44% incidence of a characteristic mutation (Cys 282 Tyr) found in a MHC class 1-like gene termed HLAH, which is highly associated with hereditary hemochromatosis. [64] [65] These results strongly implicate the HLAH gene as a genetic susceptibility factor in acquired PCT. An apparent association has emerged between HIV infection, hepatitis C infection, and PCT.[66] [67] The etiological role of viral infection in PCT is not yet clear. It is possible that therapy for HIV with zidovudine precipitates the disease but it is more likely that the association is either merely coincidental or that the viral infection unmasks the preexisting uroporphyrinogen decarboxylase defect. [68] [69]

Genetics

As in the other genetic lesions in the porphyrias, there is heterogeneity in the mutations causing PCT and HEP phenotypes. [70] [71] In the inherited form, enzyme activity is reduced in peripheral blood cells; this is not the case in the acquired forms. Little is known about structure-function relationships for the enzyme despite the breadth of other details of its form and function.[72] In different population groups it is difficult to find the relative numbers of acquired and familial disease. In one analysis in Hungary 77.5% of patients were found to suffer from the acquired form, and of the patients with the familial disease, the frequency in females was higher than in males, suggesting that inheritance may predispose patients to estrogen-precipitated disease. [73]

Clinical Features

The most striking clinical feature of both forms of PCT is a bullous dermatosis on light-exposed areas. This starts as erythema and progresses to vesicles that become confluent to form bullae (Fig. 27-6), which may hemorrhage and leave scars; pruritus is often troublesome. Milia are common and may precede or follow vesicle formation. Increased fragility of the skin is important and, in less severe cases, may be the only clinical sign. In severe cases photomutilation can result, usually because of infection of slowly healing lesions.

The thickening and scarring with calcification has been described as pseudoscleroderma. Hyper-pigmentation is common, and women often complain of hirsutism. Neurological change is not observed. Patients may have clinical and biochemical evidence of chronic liver disease, sometimes with cirrhosis. There is an association with hepatocellular carcinoma. Hepatomegaly is particularly common when alcohol intake is excessive.

Precipitating Factors

Alcohol is the most important precipitating agent. In more than 90% of patients, the intake is excessive. However, estrogenic steroids are also sometimes implicated, as are certain halogenated hydrocarbons. PCT may also develop in people treated with hemodialysis for kidney failure. An outbreak of cutaneous hepatic porphyria in southeast Turkey in 1956 was traced to seed wheat dressed with the fungicide hexachlorobenzene. A neoplastic subgroup has been identified secondary to benign or malignant liver tumors.

Differential Diagnosis

Other causes of bullous or vesicular skin lesions should be excluded, such as a drug reaction (see pseudoporphyria) or

Figure 27-6 A bullous skin lesion of porphyria cutanea tarda.

chronic renal failure. The distinction between PCT, VP, and HCP rests on biochemical testing of urine and feces, with the highest levels of urinary uroporphyrin found during attacks of PCT (Table 27-2).

ERYTHROPOIETIC PROTOPORPHYRIA

Biologic and Molecular Aspects

Although not described until 1961, this form of erythropoietic porphyria, also known as erythrohepatic protoporphyria, is much more common than congenital porphyria. Ferrochelatase activity is reduced in peripheral blood, liver, bone marrow, and skin, and protoporphyrin is synthesized in excess. [74] Thus the erythroid progenitor cells (burst-forming units-erythroid, or BFE) in erythropoietic protoporphyria (EPP) patients show intense fluorescence when viewed under 405 nm light. [75] The gene mutation in EPP shows heterogeneity as in other porphyrias. [76] [77] The last enzyme of the biosynthetic pathway, ferrochelatase, is important since its endogenous activity is relatively low and could act as a control point in the pathway. Ferrochelatase ligates iron in an iron-sulfur cluster bound to three cysteine residues.[78] It is still uncertain whether ferrochelatase exists in a multi-enzyme complex spanning the mitochondrial membrane with coproporphyrinogen oxidase and protoporphyrinogen oxidase.[79] Such a complex may allow for channeling of substrate from the cytoplasm to the mitochondrial matrix and also provide the reducing potential for the formation of intramitochondrial ferrous iron, essential for heme formation, from the extramitochondrial ferric iron. Immunological studies on human protoporphyria show that immunologically reactive ferrochelatase is present but that enzyme activity was only 17% of normal in 3 subjects. [80]

Genetics

EP is inherited as an autosomal dominant and symptoms may occur at any age including infancy and childhood. [81] Rarely, autosomal recessive inheritance has been described.[82] Several models of various complexity have been proposed to account for the expression of erythropoietic protoporphyria (EPP) [83] and a recent family study considered that the EPP phenotype resulted from co-inheritance of a low output but normal ferrochelatase allele and a mutant allele. [84] There is heterogeneity of the molecular defect, as in all other porphyrias. [74] [76] [85]

Clinical Features

The clinical features are mainly cutaneous on exposure to sunlight. They include pruritic urticarial swelling and redness of the skin on exposure to sunlight. The most distressing symptom is an unbearable burning sensation on the affected parts. Remarkably, such features are ameliorated during pregnancy, which has been linked to lowered protoporphyrin levels. [86] Hepatic involvement, which occurs in later life, involves deposition of hepatotoxic protoporphyrin in the liver and thus can lead to fatal liver failure from an active chronic hepatitis with cirrhosis. [87] Such protoporphyrin deposition may also cause cholelithiasis; the gall stones contain high concentrations of protoporphyrin. The liver disease of EPP seems to correlate with erythrocyte protoporphyrin concentrations. [88] Mild microcytic anemia has been reported[89] [90] as well as mitochondrial iron accumulation and ring sideroblasts in about 30% of patients. [91] Paradoxically, the serum iron and ferritin are low or normal.

Differential Diagnosis

Erythropoietic protoporphyria should be distinguished from other causes of a photosensitive skin rash. The distinction can be made by demonstrating fluorescence in a proportion of red cells (fluorocytes) in the peripheral blood and confirmed by measurement of greatly increased erythrocyte and fecal protoporphyrin. Patients with erythropoietic protoporphyria have a relatively high incidence of ring sideroblasts in the marrow. [91] This can lead to diagnostic difficulty since occasional patients with idiopathic sideroblastic anemia have been reported to have increased erythrocyte protoporphyrin. [92] [93] [94] [95] However, erythropoietic protoporphyria can be distinguished by the autosomal dominant inheritance, dermal photosensitivity, normal or low serum iron, and levels of protoporphyrin in red cells and feces.

CONGENITAL PORPHYRIA

Biologic and Molecular Aspects

Congenital porphyria or Gunthers disease, although extremely rare, was the first porphyria to be described in 1874. [96] Unlike the other porphyrias, it is inherited as a Mendelian autosomal recessive.

MANAGEMENT OF NONACUTE PORPHYRIA

Patients should avoid exposure to sunlight and use sun block and physical barriers such as cotton gloves.

PORPHYRIA CUTANEA TARDA

The clinical features are reversed by removing any precipitating agent such as alcohol, halogenated hydrocarbons, and drugs. The patient should be screened for hepatic neoplasm and hepatitic viral infection. The mainstay of treatment is to remove liver iron by venesection of 500 ml of blood weekly until clinical remission occurs or until the hemoglobin level falls below 12 g/dl. Chloroquine, at low doses of 125 mg twice a week for several months has also been helpful, as it enhances urinary clearance of porphyrin. Where venesection is difficult, desferrioxamine has been used to reduce liver iron stores. It is of value to screen the patient and first-degree relatives for hereditary hemochromatosis.

ERYTHROPOIETIC PROTOPORPHYRIA

Oral beta carotene offers effective protection in EPP against solar sensitivity. It does so by quenching the radical formation that is a feature of the skin damage. Yellowing of the skin (carotenemia) is one side effect. Interruption of the enterohepatic protoporphyrin circulation by bile salt sequestering agents, such as cholestyramine, reduces plasma protoporphyrin levels and may retard the development of the liver disease. Liver transplantation has been reported to be an effective measure in preventing the progression of this disease. [103]

CONGENITAL PORPHYRIA

Erythropoiesis should be reduced by means of erythrocyte hypertransfusion and by hematin or heme arginate infusion. [101] Bone marrow transplantation has given encouraging biochemical and clinical results but insufficient numbers of patients have been treated to be certain of future prospects of this therapy. [104] Splenectomy and chloroquine therapy (125 mg twice weekly) have an ameliorating effect, as does hypertransfusion, but life expectancy is usually severely shortened.

The onset of solar photosensitivity results from gross overproduction of porphyrins, caused in turn by deficiency of uroporphyrinogen III synthase. Like other porphyrias the defective enzyme results from point mutations at multiple sites within the gene. [97] Other enzymes are largely normal although there is an increase in ALA synthase activity. [98] Excess porphyrins, particularly uroporphyrin 1, accumulate in the normoblasts of the bone marrow and are excreted in the urine and feces. They are also deposited in bones and in the teeth, resulting in a pinkbrown discoloration, which fluoresces bright red in light of wavelengths around 400 nm. Dental restoration has been used to correct the esthetic appearance of the teeth. There are frequently profound changes in bone structure in congenital porphyria. This has been linked to vitamin D deficiency because of light avoidance. [99] However bone changes can be seen when vitamin D levels are adequate and one might speculate that the porphyrins deposited in bone are cytotoxic since similar bone changes are features of both homozygous variegate porphyria and hepatoerythropoietic porphyria. [100]

Clinical Features

Typically the onset of the disease is from birth, but occasionally late-onset cases have been reported. [101] The skin reaction is severe and can be devastating and the teeth become brownish-pink due to their high porphyrin content. Severe cutaneous photosensitivity is manifested by blistering of light-exposed areas and fragility of the epidermis. Skin thickening occurs and there is extensive scarring and hypertrichosis. The recurrent damage associated with scarring on the hand may produce a claw-shaped deformity and loss of digits. Dystrophic nails may curl up and drop off. Lenticular scarring may lead to blindness. Hemolytic anemia often occurs and is associated with increased erythrocyte fragility and splenomegaly. Dyserythropoiesis may contribute to the anemia. [102]

Differential Diagnosis

The most characteristic feature of congenital porphyria is the excess production of series 1 porphyrins rather than series 3 isomer produced in the other porphyrias.

Red cells fluoresce in ultraviolet light, as will the brown-stained teeth, because of high porphyrin content.

PSEUDOPORPHYRIA AND RENAL DIALYSIS

The term *pseudoporphyria* has been used to describe a bullous dermatosis associated with a number of dermatological conditions that bear some resemblance to porphyria.[105] This photosensitivity is often induced by drugs such as the tetracyclines, naproxen, furosemide, oxaprozin, and many others. In these conditions there is no alteration in porphyrin metabolism or excretion. It is, therefore, incorrect to name any of them a porphyria, and the term pseudoporphyria should not be applied to them, but only to conditions in which alterations of porphyrin metabolism can be found such as the bullous dermatosis of hemodialysis. [106] [107] Patients with renal failure can present with many biochemical features of porphyria prior to hemodialysis. These abnormalities normalize after dialysis, especially when electrolyte abnormalities like zinc deficiency are also corrected. [107] In a considerable proportion of patients with chronic renal failure, skin changes resembling porphyria cutanea tarda (PCT) develop some months to years after the onset of maintenance hemodialysis. In a minor proportion, genuine PCT can be diagnosed. [108] In such cases, there are elevated total porphyrin levels in plasma and in urine if the patient is not anuric. These patients present a therapeutic dilemma since they are normally anemic and thus unsuitable for phlebotomy therapy.

SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are a heterogeneous group of disorders characterized by anemia of varying severity and diagnosed by finding ring sideroblasts in the bone marrow aspirate. The peripheral blood shows hypochromic red cells, which are microcytic in the hereditary forms (Fig. 27-7A), but are often macrocytic in the acquired forms of the disease. The red cell parameters from automated cell counting may show bimodal volume distribution curves or widened range of cell sizes (Fig. 27-7B); however, this dimorphic size distribution is not always present. Tiny inclusions may be visible in the red cells; these can be confirmed as iron-containing Pappenheimer bodies by Prussian blue staining of the blood smear. The diagnostic test is bone marrow examination together with Prussian blue staining of the bone marrow smears. The presence of ring sideroblasts (Fig. 27-7C) is defined as erythroblasts containing iron-positive (siderotic) granules arranged in a perinuclear collar distribution around one-third or more of the nucleus. Electron microscopic examination has shown that these siderotic granules are mitochondria-containing amorphous deposits of ferric phosphate and ferric hydroxide.

Iron overload is a common clinical feature of refractory sideroblastic anemia and, in severe cases, may lead to complications that characterize secondary hemosiderosis (e.g., diabetes, cardiac failure). Marrow examination shows prominent erythroid hyperplasia, which is a sign of the ineffective erythropoiesis and is responsible for increased iron absorption. The sideroblastic anemias have diverse etiologies but have in common an impaired biosynthesis of heme in the erythroid cells of the marrow. Most sideroblastic anemias are acquired as a clonal disorder of erythropoiesis, with varying degrees of myelodysplastic features (Table 27-4). The inherited forms are uncommon and occur predominantly in males with an X-linked pattern of inheritance. A number of drugs have been associated with a reversible sideroblastic anemia, whereas ring sideroblasts may be found in patients with alcohol abuse (Table 27-4). The first descriptions of ring sideroblasts in association with chronic refractory anemias appeared in the late 1950s [109] [110] following an earlier description of familial X-linked hypochromic microcytic anemia. [111]

HEREDITARY SIDEROBLASTIC ANEMIA

Biologic and Molecular Aspects

Erythroid cells from patients with X-linked forms of hereditary sideroblastic anemia generally exhibit low activity of ALAS. [5] [112] [113] [114] [115] A defect in this enzyme is firmly established in patients whose anemia responds to pyridoxine therapy, since pyridoxal phosphate is an essential cofactor for ALAS. However, even affected females with moderate anemia unresponsive to pyridoxine have been documented to have low levels of ALAS in bone marrow lysates. [113] [115] In some male patients with X-linked pyridoxine-responsive sideroblastic anemia, the low ALAS activity in bone marrow increased to levels above the normal range when the patient took pyridoxine supplements and recovered from the anemia. [112] [113] [116] There are several possible explanations for this enhancement of ALAS activity by dietary pyridoxine supplements. First, pyridoxine (or its phosphate) may stabilize the ALAS during folding of the enzyme following its synthesis. [116] Second, pyridoxine may protect a mutant ALAS from degradation by mitochondrial protease. [112] Finally, the mutant enzyme may have a higher Michaelis constant (K_m) for pyridoxal phosphate so that increased amounts of its cofactor are required for normal activity. [113]

The gene for the ALAS2 isoenzyme has been localized to the X chromosome and this gene is now known to be the site of most but not all mutations giving rise to X-linked pyridoxine-responsive sideroblastic anemia. [12] [117] Over two dozen different mutations have now been identified in individuals or families with hereditary sideroblastic anemia and nearly all have resulted from single base alterations such as a C G substitution that results in an amino acid change from threonine to serine at residue 388 of ALAS2. [116] All known mutations lie between exons 5 and 11 of ALAS2, the region that codes for the catalytic domain, with most lying within exon 9 which contains the lysine at which binding of pyridoxal 5 phosphate occurs. [5] A mutation, Asp 190 Val, has been described in a pyridoxine-refractory patient and appears to affect the proteolytic processing of the ALAS2 during or after import into the mitochondrion. [118] The variety of different mutations in the erythroid ALAS2 gene responsible for X-linked sideroblastic anemia and their pyridoxine responsiveness have been reviewed. [4] [5]

Genetic Aspects

In the great majority of families with hereditary sideroblastic anemia, males are affected with an X-linked pattern of inheritance

Figure 27-8 Pedigree of a family with pyridoxine-responsive sideroblastic anemia showing X-linked recessive inheritance. , affected; carrier;

, unknown status. Diagonal lines indicate deceased members. This pedigree [116] has been abbreviated to show only the affected branches of the family. The arrow indicates the proband.

(Fig. 27-8). Thus, the assignment of the gene for erythroid ALAS2 to the X chromosome [12] [117] as well as the many mutations documented in erythroid ALAS2 provide the genetic basis for this X-linked disease. In several families, co-inheritance of other X-linked traits (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency or ataxia with sideroblastic anemia) has been described. [119] [120] [121] There are well-documented families in which the sideroblastic anemia was inherited as an autosomal dominant trait, [122] [123] as well as rare cases that are autosomal recessive. [124] Both sporadic as well as familial cases have been described that affect only females, [125] [126] [127] the latter possibly representing skewed X-chromosome inactivation involving the ALAS2 gene. [128] The absence of affected male members in these pedigrees suggests that the ALAS2 defects identified are lethal in hemizygous males.

Clinical and Laboratory Evaluation

Typically, the anemia presents in infancy or childhood but the milder forms of anemia may not be found until midlife. Even elderly patients have been diagnosed with this anemia. [129] Some cases may only be discovered during family surveys, which should always be undertaken when hereditary sideroblastic anemia is diagnosed. Still other patients may present with features of iron overload, such as diabetes or cardiac failure. Iron overload occurs commonly even with mild anemia and may occasionally be seen with female carriers. Enlargement of the liver and spleen may occur with mild abnormalities of liver function tests.

Anemia is extremely variable, but even when little or no anemia is present, the mean corpuscular volume (MCV) is low and the red cell volume distribution width may be increased. When anemia is severe the MCV may be as low as 50 fl (^{3}). The blood smear shows a population of cells with hypochromic, microcytic morphology (Fig. 27-7), which contrasts with the other normochromic, normocytic cells (dimorphism). Anisocytosis, poikilocytosis, elongated cells, and siderocytes may also be seen. The characteristic erythrocyte dimorphism is most prominent in patients with milder anemia, in female carriers, or in patients in whom pyridoxine has corrected the anemia but not restored the MCV to normal. Leukocyte values are normal, whereas the platelet count is normal or increased.

Serum iron concentration is increased and transferrin shows an increased percentage of saturation with iron. Serum ferritin levels are invariably increased. Ineffective erythropoiesis can be confirmed by ferrokinetic measurements showing that plasma iron clearance is rapid with subnormal retention of the iron

THERAPY FOR HEREDITARY SIDEROBLASTIC ANEMIA

A trial of pyridoxine 100200 mg/day taken orally is indicated for 3 months in all patients with hereditary sideroblastic anemia. Response is variable and ranges from complete correction of hemoglobin to no effect. Even when pyridoxine completely corrects the anemia (Fig. 27-9), the increase in MCV may not reach normal values and a population of hypochromic, microcytic cells remains. About 2550% of patients with hereditary sideroblastic anemia show a full or partial response to pyridoxine and this vitamin should be continued lifelong in the responders. A lower maintenance dose should be determined for each responding patient by progressive dose reduction since long-term therapy with pyridoxine at 100200 mg/day has been associated with peripheral neuropathy. [131] The adult nutritional requirement for pyridoxine is 12 mg/day; some patients have been maintained on as little as 4 mg/day as supplement. [116] Folic acid supplements should also be administered because the erythroid hyperplasia increases demand for this vitamin. There have been two reports of hereditary sideroblastic anemia responding to parenteral pyridoxal-5-phosphate after failing oral pyridoxine. [132] [133]

Transfusions are the mainstay of treatment for severe anemia that is unresponsive to pyridoxine. Regular administration of packed red cells using white cell filters should be given to relieve symptoms and permit normal childhood development. Iron overload and secondary hemosiderosis rapidly progress after transfusions begin; chelation therapy with desferrioxamine should be initiated from the onset.

Iron removal may be of great benefit for patients who have mild or moderate anemia and evidence of iron overload. [127] [130] These patients can often tolerate intermittent phlebotomy, which is preferable to chelation therapy for iron removal and should be continued to reduce ferritin levels to <300 ng/ml. All patients with iron overload should avoid ingestion of ascorbic acid supplements, which not only enhance iron absorption but also increase the tissue toxicity of elemental iron. Alcohol should also be avoided. Splenectomy is contraindicated in this disease.

Figure 27-9 Response of the hemoglobin and MCW to withdrawal and reinstitution of pyridoxine in a responsive hereditary sideroblastic anemia.

isotope in erythrocytes after 1014 days. Some other features of ineffective erythropoiesis may be variably present: mild increase in bilirubin, decrease in haptoglobin, mild increase in lactate dehydrogenase, and normal or slight increase in reticulocyte numbers. The magnitude of iron overload correlates poorly with the degree of anemia in patients who are not transfused. The degree of ineffective erythropoiesis is a better predictor of the degree of iron overload. Where ferrokinetics are unavailable, the extent of erythroid hyperplasia relative to normal acts as a rough measure of the magnitude of ineffective erythropoiesis. Several studies have shown that the relative increase in erythroid activity multiplied by the patients age shows a good correlation with the degree of iron overload, as measured by plasma ferritin. [127] [130]

Differential Diagnosis

Hereditary sideroblastic anemia should be distinguished from idiopathic hemochromatosis, as both have biochemical evidence of iron overload and a similar tissue pattern of iron deposition. Careful hematologic assessment of patient and family members should make the distinction, since hemoglobin and MCV will be normal in idiopathic hemochromatosis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACQUIRED IDIOPATHIC SIDEROBLASTIC ANEMIA

Acquired sideroblastic anemia may either be idiopathic or occur following chemotherapy or irradiation (Table 27-4). The clonal nature of hemopoiesis in this condition was first suggested by Dacie.[110] Nearly all cases show evidence of dyserythropoiesis in the marrow and there may also be dysplastic changes in either the myeloid precursors or megakaryocytes, or both. Acquired idiopathic sideroblastic anemia falls within the diagnostic category of refractory anemia with ring sideroblasts as defined by the French-American-British group.[134] Acquired sideroblastic anemia has also been described as a rare finding in myeloproliferative disorders such as idiopathic myelofibrosis. However, distinguishing between idiopathic myelofibrosis and myelodysplasia is sometimes difficult and some of the reported cases may represent disease that is intermediate or transitional between these two entities. [135] [136] [137]

Biologic and Molecular Aspects

Clonal hematopoiesis has been demonstrated in acquired idiopathic sideroblastic anemia as well as in the related myelodysplastic syndromes. Specific evidence was first provided by finding a single G6PD isoenzyme in erythrocytes, granulocytes, platelets, and B lymphocytes in a woman who was heterozygous for G6PD and thus carried two isoenzymes in her skin and T lymphocytes.[138] [139] This technique is applicable only to the few women who have G6PD heterozygosity, but restriction fragment length polymorphism analysis (see Chap. 1) can now be applied to most women using probes directed at other X-chromosome genes such as phosphoglycerate kinase or to an X-linked variable copy number tandem repeat sequence (see Chap. 1).[140] [141] The results show uniform monoclonality of hematopoiesis in acquired sideroblastic anemia either with or without associated myelodysplastic features. Initial reports of low levels of ALAS in bone marrow of acquired idiopathic sideroblastic anemia have not been confirmed and the cause of the defective heme synthesis in the abnormal clone is unclear. Some indirect evidence exists for a primary mitochondrial lesion, perhaps in the mitochondrial respiratory chain that impairs the reduction of Fe^{3+} since Fe^{2+} is essential for heme synthesis.[142] [143] [144]

Etiology

Clonal chromosomal changes are found in bone marrow cells in approximately 60% of patients with acquired sideroblastic anemia. Characteristic changes are monosomy 7, trisomy 8, deletions involving chromosomes 5, 7, 11, or 20 and a number of balanced translocations.[145] When sideroblastic anemia is acquired secondary to chemotherapy or irradiation, chromosomal changes are nearly always found and tend to be multiple.[145] Among these changes, the loss of an entire chromosome (5 and/or 7), deletion of a long arm [(del)5, (del) 7, or (del) 13] or an unbalanced translocation are typical.[146] [147] Indeed, when karyotype shows loss of material from chromosomes 5 and/or 7, a detailed occupational history may show exposure to potentially mutagenic chemical agents in a proportion of patients.[148] However, the development of visible chromosomal changes is probably a late event in acquired sideroblastic anemia and may be preceded by the expansion of a clone of genetically unstable stem cells.[149] This concept is in accord with the view that multiple genetic events underlie the pathogenesis of other myelodysplastic syndromes as well as acute myeloid leukemia.[139] [149] [150]

Clinical and Laboratory Evaluation

Typically this anemia develops insidiously in a middle-aged or elderly patient with normal or increased MCV and a blood smear showing a population of hypochromic red cells. Hepatosplenomegaly may be present. Leukocyte and platelet counts are usually normal, but some patients have thrombocytosis that occasionally exceeds $1{,}000 \times 10^9$ /l.[151] If leukopenia or thrombocytopenia is present, a careful search should be made for myelodysplastic features, which if present lead to the more descriptive term refractory cytopenia for the condition.[152] [153] An iron stain of the bone marrow aspirate shows ring sideroblasts, which should total more than 15% of all erythroblasts to make the diagnosis of acquired sideroblastic anemia.[134] [153] [154] [155] Iron cannot be assessed in the marrow trephine biopsy core since it may leach out during decalcification. The bone marrow also shows erythroid hyperplasia; although mild dyserythropoiesis (multinuclearity, nuclear budding) and megaloblastoid changes are present, both myelopoiesis and megakaryopoiesis are usually normal. When changes are confined to dyserythropoiesis, the condition has been termed pure sideroblastic anemia.[153] [156] However, dysplasia of myelo- and megakaryopoietic elements may be present (trilineage dysplasia) with the following features: Pelger-Huet-like anomaly, hypersegmentation or hypogranularity of neutrophils, micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with multiple small nuclei.[153] Dysmegakaryopoiesis is more easily detected in trephine biopsies than in marrow smears, while the trephine may also show unsuspected islands of myeloblasts characteristic of myelodysplasia.[157] The overall blast count in marrow smears is, by definition, <5% and peripheral blood monocytes $<1.0 \times 10^9$ l. Cytogenetic analysis of marrow aspirates provides important information, since a normal karyotype predicts long survival in any type of acquired sideroblastic anemia.[158]

Differential Diagnosis

Ring sideroblasts are not limited to acquired sideroblastic anemia; they also occur in other myelodysplastic conditions, such as refractory anemia with excess blasts, in which the blast count is >5%.[159] Careful examination of peripheral blood and bone marrow will distinguish acquired idiopathic sideroblastic anemia from these related myelodysplastic conditions. Family surveys are very useful in distinguishing acquired from hereditary forms of sideroblastic anemia, as the latter may present in late adult life.

Prognosis

Acquired idiopathic sideroblastic anemia and the related entity of refractory anemia have the most favorable outlook among

THERAPY FOR ACQUIRED SIDEROBLASTIC ANEMIA

Transfusions are indicated for relief of symptomatic anemia. A trial of pyridoxine at 100200 mg/day for 3 months is worthwhile in patients who have anemia but who do not display neutropenia or thrombocytopenia. However, few patients with acquired idiopathic sideroblastic anemia respond to this vitamin. If any response is achieved, maintenance therapy with pyridoxine at lower dosage is indicated. Recently, cyclosporin, 56 mg/kg/day has been reported to benefit the anemia of the closely related myelodysplastic condition of refractory anemia. [164]

the myelodysplastic syndromes, with a median survival of 4276 months and 312% incidence of leukemic progression in different series. [145] [160] [161] [162] The prognosis can be correlated with three factors. First is the severity of the anemia, since repeated transfusions markedly increase iron overload and invariably lead to the organ dysfunction characteristic of secondary hemosiderosis (e.g., heart and liver failure, diabetes). The second factor is whether neutropenia or thrombocytopenia, or both, are associated with the anemia. These cytopenias form the basis of a simple prognostic scoring system in which two or more of the following place the patient in a poor prognostic category: (1) hemoglobin <10 g/dl, (2) neutrophils $<2.5 \times 10^{9}$ /l, (3) platelets $<100 \times 10^{9}$ /l, and (4) blasts >5%.[160] [162] Finally, karyotypic analysis of marrow aspirates provides valuable information, since a normal karyotype carries a more favorable prognosis. Conversely, monosomy 7 or a partial loss of the long arm of chromosome 7 as a single defect imparts a high probability of transformation to acute myeloid leukemia. Multiple chromosomal abnormalities or del(20q) are also associated with an increased risk of progression to leukemia; by contrast, trisomy 8 has no adverse prognostic significance. [145] Evolution of acquired idiopathic sideroblastic anemia to other myelodysplastic conditions, such as refractory anemia with excess blasts, has been described. [163]

SIDEROBLASTIC ANEMIA AND PORPHYRINURIA SECONDARY TO DRUGS

Alcohol

Ring sideroblasts may be found in the bone marrow of malnourished anemic alcoholics, usually in the presence of associated folate deficiency. [165] [166] [167] In contrast, binge drinking or chronic alcohol ingestion in subjects with good nutrition is not associated with sideroblastic abnormality. Sideroblastic change is never the sole cause for the anemia of alcoholism. Alcohol has a direct toxic effect on hematopoiesis. [168] [169] An increased or high normal MCV and vacuolation of red cell precursors is often seen in addition to the ring sideroblast abnormality. Red cells show dimorphic morphology; evidence in the marrow of folate deficiency is present in one-half of the cases.[169] Transferrin saturation and marrow iron stores tend to be increased but may be low if gastrointestinal bleeding is present. The ring sideroblasts gradually disappear over 412 days when alcohol is withdrawn; [167] during this period, there may be a rebound erythroid hyperplasia, reticulocytosis, and thrombocytosis. Folic acid should be given for the associated megaloblastic changes after blood is taken for vitamin B_{12} and folate assays.

Alcohol consumption lowers the plasma concentration of pyridoxal phosphate, a cofactor for ALAS, the first step in heme synthesis. [170] [171] Conversion of ethanol to acetaldehyde is necessary for this effect and it has been shown that acetaldehyde acts by accelerating the degradation of intracellular pyridoxal phosphate in the liver, thus lowering plasma levels of this coenzyme. [172]

Chronic alcoholics have an altered heme metabolism with increased urinary excretion of coproporphyrin, mainly isomer 3 but normal urinary excretion of uroporphyrin, ALA, and porphobilinogen. Acute and chronic ethanol ingestion markedly depresses the activity of ALA dehydratase in peripheral blood. Ethanol administration to normal subjects results in increased activity of leucocyte ALA synthase and erythrocyte porphobilinogen deaminase, the two rate-controlling enzymes of the pathway. The activities of each of the other four enzymes are depressed. Ferrochelatase, the enzyme that inserts iron into protoporphyrin to form heme, shows the most marked depression, and in alcoholism there is prolonged depression of uroporphyrinogen decarboxylase which provides a rationale for the role of ethanol in the etiology of porphyria cutanea tarda. [173] [174] As noted earlier, ethanol is a major precipitating factor in acute porphyria. [175]

Isoniazid

Administration of the antituberculous drug isoniazid has been occasionally associated with development of a sideroblastic anemia after 110 months of therapy. The anemia is both hypochromic and microcytic with a dimorphic blood smear and ring sideroblasts in the marrow. This complication is thought to occur only in slow acetylators of isoniazid, allowing this drug to react nonenzymatically with pyridoxal and to form a hydrazone that is rapidly excreted in the urine. The anemia can be fully reversed by co-administration of pyridoxine, 2550 mg/day with isoniazid or by withdrawing the latter drug. [176] [177]

Chloramphenicol

Chloramphenicol is an antibiotic that produces a reversible suppression of erythropoiesis after several days of therapy (plasma levels 1015 g/ml). This effect is both predictable and separate from the rare idiosyncratic side effect of aplastic anemia in about 1 of 20,000 exposed persons. Nearly all patients given chloramphenicol >2 g/day develop vacuolation of the erythroid precursors, as well as ring sideroblasts. These effects are thought to arise from suppression of mitochondrial respiration. Chloramphenicol inhibits mitochondrial protein synthesis and reduces cytochrome a + a_3 and b levels.[178] [179] Serum iron concentrations are increased and reticulocyte numbers are subnormal, but these changes revert on stopping the antibiotic.

Other Drugs

A reversible acquired sideroblastic anemia has been described with penicillamine therapy and with triethylene tetramine hydrochloride, a copper-chelating agent used in the treatment of Wilsons disease. [180] [181] Acquired sideroblastic anemia has also been precipitated by progesterone given to a patient on two separate occasions 15 years apart, and this anemia promptly reversed on withdrawal of the drug. [182]

PRESENTATIONS ASSOCIATED WITH SIDEROBLASTIC ANEMIA AND/OR PORPHYRINURIA

Pearsons Syndrome

Pearsons syndrome is a rare entity that presents in early infancy with anemia and exocrine pancreatic dysfunction. The anemia is normocytic or macrocytic, reticulocytes are low, and variable neutropenia and thrombocytopenia is present. The bone marrow shows a striking vacuolation, as well as ring sideroblasts. [183]

Although usually fatal, milder forms of the anemia are consistent with survival into adult life. The syndrome, which is related to the Kearns-Sayre syndrome, is thought to result from deletions, mutations, or duplications of mitochondrial DNA variably affecting multiple tissues of the body. [184] [185] [186]

Copper Deficiency or Zinc Overload

The copper content of a Western diet averages 0.91.6 mg per day which is only a few times greater than the amount needed to maintain homeostasis of this essential element.[187] [188] Copper deficiency has been described only in malnourished premature infants [189] or in patients receiving long-term parenteral hyperalimentation. [190] [191] The syndrome of copper deficiency consists of sideroblastic anemia with hypochromic cells in the blood smear, accompanied by ring sideroblasts and vacuolated erythroid and myeloid precursors in the marrow, and of neutropenia with an absence of late myeloid forms in the marrow. Additional features may also be seen in infants, namely, osteoporosis and long bone changes, depigmentation of skin and hair, and central nervous system abnormalities. Platelet counts remain normal. Serum copper and ceruloplasmin levels are low, whereas serum iron and transferrin saturation are normal. Prompt reversal of the hematologic changes follows therapy with 25 mg/day copper sulfate taken orally or 100500 g/day copper supplement to the intravenous alimentation formula.

Large quantities of ingested zinc interfere with copper absorption and produce the neutropenia and sideroblastic anemia characteristic of copper deficiency. [192] [193] Zinc sulfate is freely available from health food stores, and as little as 450 mg/day for 2 years is sufficient for this effect. Serum zinc levels are high, while serum copper and ceruloplasmin levels are low. Zinc must be discontinued for 912 weeks for full reversal of the anemia and neutropenia.

Iron-Deficiency Anemia

In iron-deficiency anemia there is an accumulation of protoporphyrin in erythrocytes that rarely reaches the level found in erythropoietic protoporphyria. The zinc complex of protoporphyrin is produced, because ferrochelatase utilizes Zn^{2+} during iron-deficient erythropoiesis. [194] Erythrocyte protoporphyrin may be raised before changes appear in peripheral blood and may be helpful in diagnosing iron deficiency when serum iron and ferritin levels are rising as a result of patients having started iron therapy. In iron-deficient erythropoiesis, erythroid ALA synthase activity is reduced. [195]

Lead Poisoning

It has been known for some time that in patients suffering from lead poisoning, there is accumulation of protoporphyrin in erythrocytes and increased urinary excretion of ALA and coproporphyrin.[196] It should be noted that there are sex-related differences in the porphyrin synthetic response to lead with females showing a more profound coproporphyrinuria than men.[197] The elevated protoporphyrin chelated by zinc is retained in the erythrocyte which may explain the absence of photosensitivity. This accumulation of porphyrins and precursors is due to the inhibition by lead of the heme biosynthetic enzymes: ALA dehydratase, coproporphyrinogen oxidase, and ferrochelatase. An increase in the activity of the rate-controlling enzyme ALA synthase results.

Many of the clinical manifestations of lead poisoning may be the result of altered heme biosynthesis. [53] A mild to moderate anemia that can be hypochromic and microcytic occurs in a minority of patients, while basophilic stippling is prominent due to inhibition of pyrimidine 5 nucleotidase in the maturing reticulocyte. Ring sideroblasts have not been reported. The abdominal pain, constipation, and peripheral neuropathy that occur in lead poisoning are also seen in acute attacks of hepatic porphyria. Neuropathy, seen in lead poisoning, may also be the result of disorders of heme biosynthesis, as in the porphyrias. [196] Alterations in porphyrin metabolism have provided a useful means of detecting and assessing the severity of lead exposure and poisoning. The diminution in activity of erythrocyte ALA dehydratase and elevated erythrocyte protoporphyrin levels are the most sensitive measures.

Hypothermia

Thrombocytopenia, erythroid hypoplasia, and ring sideroblasts have been described in patients with hypothermia associated with neurologic disease. [198] These changes reverse slowly as body temperature returns to normal.

Other Conditions

In hereditary tyrosinemia excess urinary ALA is excreted because ALA dehydratase is inhibited by succinyl acetone. Like acute porphyria and lead poisoning, this disease is associated with neurobehavioural disturbance. In liver disease there may be increased urinary excretion of coproporphyrin predominantly the I isomer. [3] In the Dubin-Johnson syndrome the ratio of coproporphyrin isomer I to isomer 3 is markedly increased in the urine (>80%) possibly as a result of deficiency of hepatic uroporphyrinogen III cosynthase and increased activity of PBG deaminase. In Rotor syndrome, total urinary excretion of coproporphyrin is markedly increased and consists predominantly of coproporphyrin isomer I. In the unconjugated hyperbilirubinemia of Gilberts syndrome, depressed activity of protoporphyrinogen oxidase and increased activity of ALA synthase has been noted in peripheral leucocytes. [3] [199]

Chemical Sensitivity

It has been hypothesized that several otherwise unexplained chemical-associated illnesses, such as multiple chemical sensitivity (MCS) syndrome, may represent mild chronic cases of porphyria or other acquired abnormalities in heme synthesis. However, to date evidence for this is absent. [200] [201]

Chapter 28 - Megaloblastic Anemias

Aok C. Antony

GENERAL CONCEPTS

The term megaloblastic anemia is used to describe a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells. A common biochemical feature is a defect in DNA synthesis, with lesser alterations in RNA and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. The cell cycle of normal cells involves a coordinated series of events in DNA, RNA, and protein synthesis; a resting phase is followed by rapid doubling of cellular DNA in the S phase followed by mitosis and division into two cells. Therefore, at any given time the majority of cells have DNA values of 2N while a minority have DNA values of 4N (where N is the amount of DNA in the haploid genome). In contrast, the majority of megaloblastic cells are not resting but vainly engaged in attempting to double their DNA, with frequent arrest in the S phase and lesser arrest in other phases of the cell cycle. Thus, an increased percentage of these cells have DNA values between 2N and 4N because of delayed cell division. This increased DNA content in megaloblastic cells is morphologically expressed as larger than normal immature nuclei with finely particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater mature cytoplasm and cell volume. The net result of megaloblastosis is a cell whose nuclear maturation is arrested (immature) while its cytoplasmic maturation proceeds normally independently of the nuclear events. The microscopic appearance of this nuclear-cytoplasmic asynchrony (or dissociation) is morphologically described as megaloblastic. Each cell lineage has a limited but unique repertoire of expression of defective DNA synthesis. This is significantly influenced by the normal patterns of maturation of the affected cell line. Additional variables that affect RNA and protein synthesis can lead to the attenuation or modification of megaloblastic expression.

Megaloblastic hematopoiesis commonly presents as anemia, but this feature is only a manifestation of a more global defect in DNA synthesis that affects all proliferating cells. The peripheral blood picture is characteristic and reflective of megaloblastic hematopoiesis within the bone marrow. The diagnosis is therefore usually fairly simple. However, because any condition that specifically perturbs DNA synthesis may lead to megaloblastosis, determination of the precise etiology is necessary before institution of therapy. Inappropriate therapy can lead to disastrous consequences for the patient. Thus, the biochemical basis for megaloblastosis needs to be understood within the context of evaluation of potential and real variables affecting DNA, RNA, and protein synthesis in a given patient. The most common causes of megaloblastosis are true cellular deficiencies of vitamin B_{12} (cobalamin) or folate, vitamins that are essential for DNA synthesis. The pathophysiology of cellular deficiency is most readily discerned by the clinician who approaches megaloblastosis with a clear understanding of the physiology of these vitamins. A detailed discussion of cobalamin (Cbl) and folate therefore follows.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COBALAMIN (Cbl)

The term *cobalamin* (Cbl) refers to a family of compounds with the structure shown in Figure 28-1 ; Cbl itself lacks a ligand in the cobalt -position. Vitamin B_{12} is called cyano-Cbl because when it was originally isolated from liver, this position was occupied by a cyano group (an artifact generated in vitro). Details of the chemistry, nomenclature, and in vivo substitutions of Cbl are shown in Figures 28-1 , 28-2 , and 28-3 , and excellent reviews are available on the history, chemistry, and biology of Cbl.[1] [2] [3] [4] Cbl is synthesized and utilized by some microorganisms (e.g., bacteria, fungi). [5] Some strains produce Cbl in excess of their requirements, making them excellent commercial sources for Cbl used in therapy (cost, $60/year/patient requiring Cbl replacement in the United States). Cbl analogues with Cbl- or anti-Cbl-like effects (due to alterations in the corrin nucleus or the nucleotide portion) are produced by microbes or pure chemical interactions of Cbl in nature [5] [6] or as byproducts of Cbl metabolism in vivo.[3] [4] [5] [6] [7] [8]

Nutrition

Cbl is only produced in nature by Cbl-producing microorganisms. Humans receive Cbl solely from the diet. Herbivores obtain their dietary quota of Cbl from plants contaminated with Cbl-producing bacteria that grow in roots and nodules of legumes. Exogenous contamination of plants by feces (e.g., manure used in fertilization) may also be a source of Cbl. The ingested Cbl is utilized by animals for Cbl-dependent reactions in muscular and parenchymal tissues, and carnivores obtain their Cbl supply by ingesting these tissues. Although Cbl is produced by bacteria in the large bowel of humans, it is at a site that is too distal for physiologic Cbl absorption.

Although food Cbl is stable to high-temperature cooking processes, it can readily be converted to inactive analogues by ascorbic acid. Animal protein is the major dietary Cbl source.[9] Meats from parenchymal organs are richest in Cbl (>10 g Cbl per 100 g wet weight); fish and animal muscle, milk products, and egg yolk have 110 g per 100 g wet weight. An average Western diet contains 57 g per day of Cbl, which adequately sustains normal Cbl equilibrium. [10]

Cbl is exceptionally well stored in tissues in its coenzyme forms. Of the total body content of 25 mg in adults, 1 mg is in the liver. [11] There is an obligatory loss of 0.1% per day (1.3 g) regardless of total body Cbl content. It takes 34 years to

Figure 28-1 Cobalamin chemistry and nomenclature. Vitamin B_{12} , cyanocobalamin (CN-Cbl), is a complex molecule consisting of two major portions. A planar group consisting of four reduced pyrrole rings (the corrin nucleus) is attached at right angles to an unusual nucleotide. Three of the four reduced pyrrole rings (designated AD) are connected to one another by methylene carbon bridges; the -carbons of rings A and D are, however, directly linked. The pyrrole rings are linked to a central cobalt atom. One coordinate position of cobalt (above the plane of the corrin nucleus) occupied by CN in CN-Cbl can be occupied by various anionic group ligands (-R) in vitro and in vivo. Substitution at this position forms the basis for the specificity of the molecule as a coenzyme in vivo. The second coordination position of the central cobalt atom (below the plane of the corrin nucleus and nearly perpendicular to it) is a linkage with the glyoxalinium nitrogen atom of the imidazole ring of the nucleotide. The nucleotide consists of a base, 5,6-dimethylbenziminazole, attached to ribose phosphate by -glycoside linkages. The ribose is phosphorylated at C-3; the nucleotide is connected to the ring D of the corrin nucleus through an ester linkage. Compounds containing a corrin nucleus are given the generic name *corrinoid.* The addition of cobalt to the corrin nucleus containing standard side chains gives rise to cobyrinic acid. Additional substitutions in terminal carboxyl groups or modified carboxyl groups (designated *ag*) give rise to various compounds such as cobamic acid, cobinic acid, cobinamide, and cobamide. Cobamide is found in vitamin B_{12} , whose systematic name is therefore -(5,6-dimethylbenziminazolyl)cobamide cyanide. *(From Chanarin,[1] with permission.)*

deplete Cbl stores when dietary Cbl is abruptly malabsorbed, but it may take longer to develop nutritional Cbl deficiency, because of an efficient enterohepatic circulation, which accounts for turnover of 510 g/day of Cbl. [10]

Absorption

Cbl in food is usually in coenzyme form [5-deoxyadenosyl Cbl (Ado-Cbl) and methyl-cobalamin (Methyl-Cbl)], nonspecifically bound to proteins (Fig. 28-4). In the stomach, peptic digestion at low pH is a prerequisite for Cbl release from food protein. [10] This is of clinical significance in the 7080-year-old population among whom hypochlorhydria or achlorhydria is frequently present (in 2550%) leading to inadequate release of protein-bound Cbl via proteolysis with pepsin (pepsin requires a low pH for optimum activity). Although these individuals can absorb crystalline CN-[^{57} Co]Cbl, they may be unable to absorb CN-[^{57} Co]Cbl that is incorporated in vitro or in vivo into food protein.[12] [13] This forms the basis for a modified food-Cbl absorption test (to define the mechanism of Cbl malabsorption) in this cohort of individuals who are Cbl-deficient but have normal Stage I Schilling tests [14] (see discussion later in this chapter).

Once released by proteolysis, Cbl preferentially binds a high-affinity Cbl-binding protein called R protein because it migrates more *r*apidly on electrophoresis than the gastric Cbl-binding protein, intrinsic factor (IF). Gastric juice and salivary R proteins (150-kDa) have higher affinity for Cbl than IF at both acidic and neutral pH (50-fold higher at pH 2 and threefold higher at pH 8). Thus, R protein (also called haptocorrin) is the preferred binding protein once Cbl is released from food. [15] Further research using the porcine gastric haptocorrin cDNA should identify the basis for high Cbl-binding properties. [16]

The Cbl-R protein (holo-R protein) complex, along with excess unbound (apo)-R protein and IF pass through into the second part of the duodenum, where pancreatic proteases degrade both holo-R and apo-R proteins but not IF. The degradation of holo-R and apo-R proteins results in a 150-fold decrease in affinity for Cbl, with consequent transfer of Cbl to IF within 10 minutes. Failure to degrade holo-R proteins by pancreatic protease will preclude involvement of IF in Cbl absorption, because ileal IF-Cbl receptors are specific for IF-bound Cbl and not R-bound Cbl. Indeed, 30% of patients with pancreatic insufficiency malabsorb Cbl. [15] [17] Transfer of Cbl from R protein to IF is a physiologic event and once released from R protein, Cbl binds to IF (a 45-kDa glycoprotein) with high affinity ($K_a = 1.5 \times 10^{10} M^{1}$), 1:1 molar stoichiometry, stability, and resistance to proteolysis over a pH range of 3 to 9. [18] [19] Although R proteins bind both Cbl and most Cbl analogues with comparably high affinity, IF only binds Cbl.

IF is produced in the rough endoplasmic reticulum of parietal (oxyntic) cells in the fundus and cardia of the stomach, [18] [19] and release of IF involves membrane-associated vesicular transport as opposed to release from secretory granules. [20] IF has two binding sites: one for Cbl and another for the ileal IF-Cbl receptor. The IF-Cbl receptor binding site is located in the amino-terminal domain of IF [between amino acid 2562 of 399 amino acids], whereas the Cbl binding site is in the carboxyl-terminal end; glycosylation is apparently not necessary for the integrity of either of the two binding sites. [21] [22] IF is produced in far greater excess than is actually required for absorption [10] and the IF in 24 ml of normal gastric juice is all that is necessary to reverse Cbl deficiency in adults who lack IF. In the absence of IF, <2% of ingested Cbl is absorbed, whereas in its presence, 70% is absorbed.

IF is secreted in response to food in the stomach in a manner analogous to secretion of acid (i.e., by vagal and hormonal stimulation). There is, however, an

unexplained, subtle discordance between IF and acid secretion, since IF release is inhibited by long-term intake of H_2 blockers but not by the alternative $H^+ K^+$ -ATPase antagonist omeprazole. [23] [24] However, sustained

Figure 28-2 Cellular uptake and intracellular reactions involving Cbl. A large family of natural and synthetic cobalamins can be generated when the CN moiety (the upper axial ligand in CN-Cbl) is replaced.[402] On exposure to light, CN is gradually lost from CN-Cbl with the production of hydroxocobalamin (hydroxo-Cbl). Another intermediate reaction is the replacement of the hydroxo group by water, resulting in the formation of aquo-Cbl. In vivo substitutions include the replacement of hydroxo-Cbl or CN-Cbl by a 5-deoxyadenosyl group attached by a covalent bond, giving rise to Ado-Cbl. Methyl-Cbl is the main form in plasma. In vivo, 5-methyltetrahydrofolate readily donates its methyl group to Cob(I)alamin in a reaction involving methionine synthase to form Methyl-Cbl. The loci for defects in Cbl mutants *cbl-cblG* are indicated. Studies which indicate that Methyl-Cbl must be converted to Cob(II)alamin before binding and activation of human methionine synthase and other studies with the bacterial enzyme indicate that this diagram is an oversimplification. [55] [56]

achlorhydria from chronic omeprazole administration will reduce absorption of protein-bound Cbl [25] and eventually lead to food-Cbl malabsorption. [26] IF binds both biliary Cbl and newly ingested Cbl upon their transfer from R protein. [27] [28] Biliary Cbl analogues are not transferred from R protein to IF, resulting in an efficient method for fecal excretion of analogues while allowing for reabsorption of biliary Cbl. The stable IF-Cbl complex, in the form of oligomers and dimers, passes through the jejunum to the ileum, where specific membrane-associated IF-Cbl receptors for the IF-Cbl complex are located on microvilli of mucosal cells of the ileum. [18] [19]

The IF-Cbl receptors from several species have been isolated. The canine IF-Cbl receptor, 220-kDa, is composed of two pairs of subunits of 62-kDa and 48-kDa. [29] It requires Ca^{2+} for binding at pH above 5.4, does not bind free IF, Cbl, or R-Cbl, and is therefore highly specific for IF-Cbl (K_a 10^9 M^1). This receptor contains no carbohydrate, is immunologically distinct from IF, and orients itself in artificial bilayers [30] with its ligand binding site (for IF-Cbl) oriented to the luminal surface. The native hydrophobic species can be digested by papain to a hydrophilic form of 180 to 190-kDa, which retains its ligand binding site. The remaining fragment probably represents the membrane anchor of the receptor. This topology differs from that of porcine and human IF-Cbl receptors, which are believed to be composed of several pairs of two types of subunits;[32] a hydrophilic pair () faces the lumen and is enclosed by a pair of membrane-anchored hydrophobic () subunits, which are attached to -subunits by disulfide bonds. The IF-Cbl complex in dimer form apparently binds to the luminal portion of the receptor. The human ileum contains enough IF-Cbl receptors to bind up to 1 g of IF-bound Cbl; this is the rate-limiting factor in Cbl absorption.

The events following binding of IF-Cbl to IF-Cbl receptors on enterocytes have not been fully delineated. Although transport into the cells requires energy, [33] some studies suggest that the IF-Cbl complex is first internalized by endocytosis and then released from Cbl by lysosomal digestion, whereas others suggest that only Cbl, but not IF, is internalized. [34] Human colon adenocarcinoma (Caco-2) cells [35] exhibit many features common to human enterocytes; they express a 280-kDa IF-Cbl receptor on

Figure 28-3 Major pathways involving Cbl-folate interrelationships. Intra-mitochondrial dehydrogenases [403] which preferentially bind H_4 $PteGlu_5$ provide activated formaldehyde (via dimethylglycinesarcosineglycine). The activated formaldehyde nonenzymatically reacts with the enzyme-bound H_4 $PteGlu_5$ to form 5,10-CH_2 -H_4 $PteGlu_n$ for methionine synthase and thymidylate synthase. Another cytosolic dehydrogenase (glycine N-methyltransferase) that synthesizes sarcosine in the presence of S-adenosyl-methionine from glycine (with conversion of S-adenosyl-methionine to S-adenosyl-homocysteine) is activated on phosphorylation but is allosterically inhibited by (trapped and polyglutamated) 5-CH_3 - H_4 $PteGlu_5$ in Cbl deficiency. This effect 5-CH_3 -H_4 $PteGlu_5$ may lead to methionine-sparing, and the methionine could in turn inhibit the formation of more 5-CH_3 -H_4 $PteGlu_5$ from 5,10-CH_2 -H_4 $PteGlu_n$ and channel the latter for DNA synthesis. Alternatively, the phosphorylation of glycine N-methyltransferase itself may provide a mechanism for modulation of enzyme activity. [404] Nevertheless, this is an area where the methylfolate trap and formate starvation hypotheses are conceivably closely interrelated.

the apical brush border as well as transcobalamin II (TC II) intracellularly. Following uptake of IF-Cbl from the apical surface of these cells by IF-Cbl receptor-mediated endocytosis, there is a slow (over 20 hours) intracellular accumulation of Cbl. [36] The internalized IF is degraded with a half-time of 4 hours, and transcytosed free Cbl is detectable in the basolateral media 4 hours after the onset of endocytosis. TC II is secreted unidirectionally across the basolateral surface and Cbl apparently binds TC II within or at the basal surface of the ileal enterocyte. [37] [38] Thus, Cbl bound to IF is transcytosed from apical to basal direction, and during transcytosis, a transfer to TC II is accomplished. [39] After a delay of 3 to 5 hours, Cbl appears in the portal blood largely (over 90%) bound to TC II. Although some Cbl in the enterocyte is converted to Ado-Cbl, the majority is destined for the portal blood and reaches peak levels in 8 hours.

Cbl in large doses can also passively diffuse through buccal, gastric, and jejunal mucosa so that <1% of a large dose of oral Cbl (1 mg) appears in the circulation within minutes; this property is used to advantage in some individuals with Cbl malabsorption in lieu of parenteral replacement [40] (see discussion later in this chapter).

Transport

More than 90% of recently absorbed or injected Cbl is bound to transcobalamin II (TC II), which is a specific transport protein for delivery of Cbl to tissues. TC II, a 38-kDa polypeptide synthesized in many tissues, binds Cbl with a 1:1 molar stoichiometry and high affinity ($K_a = 1 \times 10^{11}$ M^1).[18] [19] [41] [42] [43] Unlike IF, it will also bind a variety of Cbl analogues (as R protein does). It does *not* however belong to the R protein family and is immunologically distinct from two other plasma Cbl-binding R proteins, TC I and TC III. Recent molecular studies suggest that TC II, TC I, and IF genes originated by gene duplications of an ancestral

Figure 28-4 Components and mechanism of cobalamin absorption. See text for details.

gene, but TC II, unlike the other two Cbl-binding proteins, is the product of a housekeeping gene. [44] [45] The TC II-Cbl complex is cleared so rapidly from the circulation (half-life 6 to 9 minutes) [10] that 98% of TC II in plasma is unsaturated. TC II-Cbl is rapidly bound to specific surface receptors for TC II which are present on several cells.[46] High-affinity TC II-Cbl binding to TC II receptors is specific only for holo- and apo-TC II ($K_a = 25 \times 10^{10}$ M^1). (Because some Cbl analogues can bind TC II with high affinity, these also have the same potential for cellular uptake as Cbl [10] .) Once bound to TC II receptors, TC II-Cbl is internalized by receptor-mediated endocytosis.[47] At the low pH extant in lysosomes, TC II dissociates from Cbl; it is then degraded, while the Cbl is reduced and converted to coenzyme forms (Fig. 28-2). The importance of the transport function of TC II is underscored by the fact that TC II deficiency leads to life-threatening cellular Cbl deficiency. [10] [48]

Cbl is not found free in plasma. Binding to TC II accounts for 1030% of the total serum Cbl, and most of the remaining Cbl is bound to the R protein, TC I. TC I has an N-terminal amino acid sequence similar to that of TC III, but differs from TC III by a higher content of sialic acid residues resulting in significant differences in clearance rates.[10] TC I is not a transport protein and Cbl-bound TC I has a slow clearance rate (half life of 912 days). Despite the fact that TC I binds 75% of the circulating Cbl (present predominantly as Methyl-Cbl) in fasting plasma, about half of the total TC I is in apo-form.

Neither the origin nor the physiologic importance of TC I in blood has been defined. Indeed, hereditary deficiency of TC I is apparently of no clinical consequence. [49] TC I may be a plasma storage form of Cbl, since it accounts for >0.5% of total cellular Cbl uptake. TC I is found in secondary granules of mature polymorphonuclear leukocytes with expression restricted to later stages of myeloid development. [50] TC III appears to have a transport function, since it is cleared from plasma within 3 minutes exclusively by hepatic asialoglycoprotein receptors, a mechanism common to a variety of asialoglycoproteins whose terminal -galactosyl end groups are intact. Conversely, desialation of TC I results in hepatic clearance identical to that of TC III. [10] TC III is derived from specific granules of granulocytes and is released during clotting. Because of its rapid clearance, it is predominantly unsaturated. Functionally, TC III binds a wide spectrum of Cbl analogues, which are rapidly cleared by the liver into bile for fecal excretion. [27] [28] In contrast, between 0.5 and 9 g of Cbl taken up by hepatic TC II receptors is secreted into bile, of which 75% is

reabsorbed, analogous to food Cbl.

Cellular Processing

Following TC II receptor-mediated endocytosis (Fig. 28-2) into lysosomes, the release of Cbl by lysosomal degradation of TC II is an obligatory process for further intracellular metabolism.[10] [47] [51] Following specific transport across the lysosome into the cytoplasm via a newly identified specific transport system, [52] >95% of intracellular Cbl is bound to two intracellular enzymes, methylmalonyl-CoA mutase and methionine synthase. [10] Many lines of evidence[53] [54] suggest that Cob(III)alamin, the most oxidized form of Cbl, must be converted to Cob(II)alamin and Cob(I)alamin by two sequential reductase steps (Fig. 28-2).

In mitochondria Cob(I)alamin is subsequently converted to its coenzyme form Ado-Cbl, which acts as a coenzyme in the *intra*molecular exchange of a hydrogen atom attached to one carbon atom with a group attached to an adjacent carbon atom. Methylmalonyl-CoA mutase in the presence of Ado-Cbl thus converts methylmalonyl-CoA to succinyl-CoA, thereby converting the products of propionate metabolism (i.e., methylmalonyl-CoA) into easily metabolized products.

In the cytoplasm Cbl, as Methyl-Cbl, functions as a coenzyme for the reaction involving methionine synthase, which catalyzes the transfer of methyl groups from Methyl-Cbl to homocysteine (Hcys) to form methionine.[55] [56] [57] In this process Methyl-Cbl is converted to Cob(I)alamin. The methyl group of 5-methyltetrahydrofolate (5-methyl-H_4 PteGlu) is donated to Cob(I)alamin, thus regenerating Methyl-Cbl; 5-methyl-H_4 PteGlu is thus converted to tetrahydrofolate (H_4 PteGlu). Folates and Cbl are thus required together for normal one-carbon metabolism. Spontaneous oxidation of Cob(I)alamin to the catalytically inactive Cob(II)alamin form requires reduction back to Cob(I)alamin before it can accept a methyl group since the cobalt atom in Methyl-Cbl has a 1+ valence. Methionine synthase also catalyzes the conversion of S-adenosyl-methionine to S-adenosyl-homocysteine, during which process the methyl group of S-adenosyl-methionine may also be utilized for re-methylation of Cob(I)alamin. Human methionine synthase binds Cob(II)alamin with a 1:1 molar ratio and contains 2 moles of iron per mole of enzyme. Because Cob(II)alamin must somehow be reduced to Cob(I)alamin before a methyl group can be added to form Methyl-Cbl, methionine synthase and S-adenosyl-methionine/ S-adenosyl-homocysteine together with a reducing system, may be involved in this process. [58] The physiologic importance of the key cofactor roles of the two forms of Cbl (Ado-Cbl and Methyl-Cbl) in methylmalonyl CoA mutase and methionine synthase, respectively, is that the products and byproducts of these enzymatic reactions are critical, as discussed later, for DNA, RNA, and protein biosynthesis.

The human methionine synthase gene that encodes for a 140-kDa protein is present on chromosomal location 1q43. [59] [60] Molecular studies have revealed that methionine synthase is a modular protein with four distinct and separate regions for binding Hcys, 5-methyl-tetrahydrofolate (5-methyl-H_4 PteGlu,) the Cbl prosthetic group, and S-adenosyl-methionine. [57] [61] This can explain how this enzyme plays a central role to catalyze the transfer of a methyl group from bound Methyl-Cbl to Hcys, yielding enzyme-bound Cob(I)alamin and methionine following which the free cofactor, Cob(I)alamin, is then re-methylated by [the methyl group from] 5-methyl-H_4 PteGlu, thereby completing the cycle (Fig. 28-2).

Renal conservation of Cbl is poorly understood. A 550-kDa membrane protein called megalin is found in renal proximal epithelial cells, and functions as a multi-ligand receptor for a variety of macromolecules such as plasminogen, protease inhibitor complex, lactoferrin, and polybasic drugs; interestingly, megalin also specifically binds to and mediates endocytosis of transcobalamin-Cbl complexes[62] in microperfused rat kidney proximal tubules. Because it is expressed in placenta and yolk sac and other tissues, its role in Cbl homeostasis warrants further study.

FOLATES

Nutrition

Folates (see Fig. 28-5 for chemistry and nomenclature), [1C] which are widely distributed in nature in reduced and polyglutamated forms, are synthesized by microorganisms and plants. Leafy vegetables (spinach, lettuce, broccoli, beans), fruits (bananas, melons, lemons), yeast, mushrooms, and animal protein (liver, kidney) are rich sources of folate. [1C] Folates are extremely thermolabile; prolonged cooking (for >15 minutes) in large quantities of water in the absence of reducing agents destroys folates. Oxidation of food folate by nitrites reduces its bioavailability. [63] Because some organisms require exogenous folate for growth, bacteriologic methods (using *Lactobacillus casei*) have been a mainstay for measuring the folate content of food and tissues. The minimum daily requirement of folate is 50 g; the recommended daily intake for folate is 3 g/kg/day (adults 100 g, children 50 g, pregnant women 500 g, and lactating women 300 g). A balanced Western diet contains adequate amounts of folate, but the net dietary intake of folate in many developing countries is often insufficient to sustain folate balance. [65]

Absorption

Dietary folates, which are in the form of pteroyl*poly*glutamates ($PteGlu_{(n)}$), are absorbed less efficiently than pteroyl *mono*glutamate (PteGlu). Although folates in some foods (cabbage, lettuce, orange) are not well absorbed, [1C] most other dietary folates are nutritionally available (i.e., bioavailable). Pteroyl-polyglutamates must be hydrolyzed to pteroylmonoglutamate derivatives prior to absorption by pteroylpolyglutamate hydrolase, an enzyme present in the brush border membranes of small intestinal cells. [6C] This enzyme, composed of two polypeptides of 145- and 115-kDa, has maximal exopeptidase activity at pH 5.5 in the presence of zinc, with equal affinity for $PteGlu_n$ of different glutamate chain lengths.

Luminal pteroylglutamate interacts with brush border membrane-associated folate-binding moieties [67] which exhibit rapid equilibrium binding (<5 minutes), pH dependency (pH 5 optimal), high affinity (K_d 0.08 M), and saturability. There is broad specificity for binding pteroyl *tri*glutamate, 5-methyl-H_4 PteGlu, and other reduced folates, with binding enhanced by physiologic (luminal) concentrations of zinc; transport of reduced-folates occurs within seconds in human brush border membrane vesicles. [68] [6C] [70] [71] Jejunal transport sharply increases with decreasing extravesicular pH from 7 to 5 while intravesicular pH is still 7, again supporting its physiologic relevance. The pH effect, which is probably multifactorial, involving the transporting carrier and PteGlu :OH exchange or PteGlu :H^+ transport, is not observed in the ileum. Some of these characteristics are shared by reduced-folate carriers (RFC) (discussed later in this chapter) which probably mediate the majority of intestinal folate absorption. In fact, the functional role of a 2.5-kb RFC cDNA encoding a 58-kDa brush border membrane protein in intestinal cells has been demonstrated, and RFC protein is also found in the brain, heart, liver, and human intestine. [72] Interestingly, RFC-1 gene expression is developmentally regulated, showing higher maximum capacity for 5-methyl-H_4 PteGlu influx in mature (absorptive) rather than proliferative crypt cells. [73]

Considerable gaps still exist in our knowledge of the structure and functional interrelationships of the human intestinal folate transport carrier, the precise mechanism of passage of

Figure 28-5 Folate chemistry and nomenclature. Folic acid (pteroylmonoglutamate, PteGlu) is the commercially available parent compound for over 100 compounds collectively referred to as folates. [1] PteGlu consists of three basic components: (1) a pteridine derivative, (2) a *p*-aminobenzoic residue, and (3) an L-glutamic acid residue. Before PteGlu can play a role as a coenzyme, it must first be reduced at positions 7 and 8 to dihydrofolic acid (H_2 PteGlu) and then to 5,6,7,8-tetrahydrofolic acid (H_4 PteGlu) and one to six additional glutamic acid residues must then be added via -peptide bonds to the L-glutamate moiety (where lower-case n in $PteGlu_n$ denotes polyglutamation). Folate coenzymes either donate or accept 1-carbon units in numerous reactions in amino acid and nucleotide metabolism. The various substitutions in H_4 $PteGlu_n$ occur either at positions 5 or 10 or both; thus position 5 can be substituted by methyl (CH_3), formyl (CHO) or formimino (CHNH), while position 10 can be substituted by formyl or hydroxymethyl (CH_2OH). Positions 5 and 10 can be bridged by methylene ($-CH_2-$) or methenyl (-CH=).

folate within the enterocyte, and interaction with lysosomal pteroyl-polyglutamate hydrolases. This 75-kDa enzyme is maximally active at pH 4.5 and cleaves both terminal and internal -glutamate linkages, in contrast with the brush-border enzyme that catalyzes hydrolysis of only terminal -glutamate linkages. The intracellular enzyme exhibits greatest affinity for $PteGlu_n$ with longer glutamate chains. [74] The basolateral membrane also possesses a carrier-mediated system, which apparently transports folate more efficiently than across brush borders, suggesting adaptation for eventual transport into portal blood. [75]

Ingested human milk, which contains specific folate-binding proteins (FBP) [76] probably regulates the nutritional bioavailability of ingested folate in neonates by binding with and thereby decreasing folate transport in the jejunum. [77] In the ileum, however, there is no alteration in transport between FBP-bound folate relative to free folate. The net result is a more gradual rise in plasma folate level, leading to slower urinary excretion. This is borne out by a clinical study which indicated that breastfed infants had higher tissue folate levels at 6 months than those weaned before 2 months. [78] Another effect of milk FBPs may be to withhold folate uptake by folate-requiring intestinal bacteria. [1C]

Passive diffusion of folate (M_r 441) across the intestinal mucosa is probably the primary mechanism of folate absorption at high pharmacologic concentrations. [79] In this context the small intestine has a large capacity to absorb folate. Peak folate levels in plasma are achieved 12 hours after oral administration. Whereas therapeutically administered PteGlu enters the portal blood unchanged, food $PteGlu_{(n)}$ is hydrolyzed before transport into the enterocyte, where it is completely reduced to H_4 PteGlu and methylated to 5-methyl-H_4 PteGlu before release into plasma.

Plasma Transport and Enterohepatic Circulation

The normal serum folate level is maintained by dietary folate and a substantial enterohepatic circulation that amounts to 90 g per day of folate. [80] Folates are rapidly cleared from plasma (up to 95% in 3 minutes) by tissues, including the liver. Transport of 5-methyl-H_4 PteGlu into isolated hepatocytes and basolateral membrane vesicles is via a concentrative process involving co-transport with H^+ ions and is electroneutral and is inhibited by other natural folates. [81] Biliary drainage results in a dramatic fall in serum folate (to 30% of basal levels in 6 hours) while abrupt interruption of dietary folate leads to a fall in serum folate levels in 3 weeks. In the plasma, one-third of the folate is free while two-thirds is nonspecifically and loosely bound to serum proteins. A small amount of folate is specifically bound to high-affinity, intrinsically soluble hydrophilic 40-kDa folate-binding proteins (FBP); the physiologic significance of this interaction is not clear. [82] [83] [84] In contrast to Cbl uptake, there is no specific *serum* transport protein that enhances cellular folate uptake.

Cellular Folate Uptake

Folate transport involves translocation of the ligand into cells from the extracellular compartment (i.e., cellular uptake mechanisms) and/or across cellular barriers from one compartment to another (i.e., transcellular mechanisms).[83] Two distinct components

are involved in cellular folate transport. The reduced-folate carrier (RFC) is a low-affinity, high capacity system that mediates the uptake of reduced-folates into cancer cells and probably intestinal cells predominantly at pharmacologic (micromolar, M) extracellular folate concentrations. Folate transport into cells is also mediated by 38- to 44-kDa membrane-associated folate-binding proteins (FBP) or folate receptors (FR) (these terms are synonymous) which bind physiologic folates (i.e., serum 5-methyl-H_4 PteGlu) with high affinity in the nanomolar (nM) range.

As highlighted earlier,[83] the pathway(s) for entry of folates and antifolates are likely to be distinct in different cells depending on the relative efficiency of FR- and RFC-mediated mechanisms, as well as the intra- and extracellular concentration of folates and antifolates (Fig. 28-6). There are probably other determinants in some malignant human cells; for example, despite high FR expression, the RFC was the preferential carrier of antifolates in some cells. [85]

Transcellular folate transport systems are operative in the placenta [86] and renal tubular cells.[87] Although choroid plexi contain a significant amount of FR, the role of these proteins in folate transport across the blood brain barrier/blood cerebrospinal fluid barrier is still unclear. [83] [84] A third pathway for cellular folate transport via passive diffusion[83] is also integrally involved (in concert with FR) in transplacental folate transport [86] (see discussion later in this chapter).

Folate Receptors (FR)

The biologic chemistry and function of FR has been comprehensively reviewed. [83] [84] Three human FR cDNA isoforms, FR-,[88] [89] [90] [91] [92] FR-,[93] [94] and FR-,[95] have been cloned. Although the open reading frames and the 3-untranslated regions of the reported FR- cDNA are identical, their 5-untranslated regions are heterogeneous in length and sequence because FR- contains 2 independent, tissue/cell-specific functional promoters (before exon 1 and exon 4). [96] The genomic organization of human FR has been identified in chromosome 11q13.2q13.5, [91] [97] where four FR-related genes were found within a 140 kb region. The FR- and FR- genes were in sequence (<23 kb apart), with two additional FR-related genes or pseudogenes located upstream of the FR- gene. Genomic clones containing FR- [94] [98] and FR- have been isolated.[96] Although FR can be regulated at the transcriptional level in response to low extracellular folate concentrations, the precise role of *cis*- and *trans*-factors in transcriptional control of FR expression has not yet been demonstrated.

Serum 5-methyl-H_4 PteGlu specifically binds with cell surface

Figure 28-6 Pathways for the entry and intracellular disposition of physiologic and pharmacologic folates and antifolates. The participation of each of the components involved in folate uptake are distinct in different cells depending on (1) the relative efficiency of folate receptor (FR)-mediated and reduced-folate carrier (RFC)-mediated mechanisms, (2) the basal intracellular content of FR and folates, as well as (3) the extracellular concentration of folates and anti-folates. *(From Antony,[83] with permission.)*

Figure 28-7 Folate receptor (FR)-coupled folate uptake and intracellular one-carbon metabolism involving folates. See text for details. *(Adapted from Shane and Stokstad,[143] and Rothberg KG, Ying Y, Kolhouse JF et al: The glycophospholipid-linked FR internalizes folate without entering the clathrin-coated pit endocytic pathway. J Cell Biol 110:637, 1990, with permission.)*

FR with 1:1 molar stoichiometry, high affinity (dissociation constants in the nM range), and in the range needed for binding serum folates. [83] [99] [100] [101] FR are glycosyl-phosphatidylinositol (GPI)-anchored. [102] [103] [104] [105] Recent molecular studies on FR- and FR- suggest Ser-234 and Asn-230, respectively, as the preferred sites of GPI-anchor attachment.[106]

FR transfers folate intracellularly by endocytosis via clathrin-coated pits [107] [108] or by caveolae.[109] In the latter model (which is controversial[84] [108] [110]), folate is dissociated from FR at acid pH generated within caveolae by a proton pump, and is transported through a putative folate transporter into the cytoplasm while apo-FR recycle back to the surface to bind more folate (Figs. 28-6 and 28-7).

FR- are predominantly expressed in most normal and malignant epithelial tissues. [111] This is significant since FR- and FR- exhibit differences in relative affinities (compared to folic acid) for the (6*S*) (physiologic) and (6*R*) (nonphysiologic) diastereoisomers of various folates. [112] Thus, the net efficiency of transport of various folates into cells would depend on the relative expression of one FR isoform over the other. Such data may eventually be important in optimizing efficient delivery of antifolates to effect maximal cytotoxicity of target cells while protecting normal cells. In this context, substitution of alanine in position 49 of FR- converted it to FR-. [113]

It is still controversial whether there is anatomic or functional coupling between the FR and RFC. Nevertheless, the RFC- and FR-mediated folate-transport systems do not communicate with one another (i.e., there is no cross-talk), and both RFC and FR are efficient in the transport of methotrexate and function essentially independently of one another.[114] And when enough FR are expressed, they can mediate the uptake of methotrexate and 5-methyl-H_4 PteGlu with comparable rates to cells expressing only the RFC. This has led to the conclusion that FR have both physiologic and pharmacologic importance, thereby directly confirming several earlier studies.[83]

Transfection of FR cDNA into various cells that do not constitutively express FR [115] [116] [117] [118] led to *greater* proliferation and survival when compared to controls cultured in *low* extracellular folate concentrations (i.e., an overall growth-promoting function). However, in cells that constitutively overexpress FR, further overexpression of FR cDNA leads to a reduction in cell proliferation in vitro and in vivo, because of an inverse relationship between cell proliferation and FR. [105] The underlying mechanisms of this relationship are still unclear.

FR are upregulated in response to extra- and intracellular folate concentrations in some cells, [119] [120] through either transcriptional regulation or by post-translational mechanisms (increase in FR mRNA stability),[121] or via a dominant modulation of FR synthesis at the translational level [122] in some malignant cells. Interestingly, translational control involves the interaction of an 18-base *cis*-element in the 5-untranslated region of FR- mRNA with a 46-kDa *trans*-factor that is critical for translation of FR.[123] Conversely, with excess extracellular folate concentrations of folates and antifolates, FR were downregulated with a reduction in FR mRNA [124] or by reduction of the synthesis of FR at the translational level. [122] Recent investigations have determined that perturbation of plasma membrane cholesterol [125] [126] and sphingolipids[127] also modulates the expression of FR through a poorly understood mechanism. In general, the precise mechanism(s) underlying regulation in most tissues are still unclear. The functional role of FR in mediating folate uptake has been extensively shown in vitro, [83] [84] and although they probably play an important role in vivo, this remains to be shown directly.

The functional role of FR, which are expressed in several normal tissues, [84] has been demonstrated in placenta, proximal renal tubular cells, and hematopoietic progenitor cells. And recently, because FR are overexpressed in some malignancies, they have become potential targets for exploitation as Trojan horses for the delivery of folate-tethered liposomes bearing various cargos (chemotherapy, imaging reagents, genes, or other agents). [128] [129]

FR are precursors to the small amounts of soluble (40-kDa) hydrophilic FBP released extracellularly. [76] [103] [130] [131] [132] [133] Conversion of hydrophobic GPI-anchored

FR to (soluble) hydrophilic FR that retain their folate-binding characteristics can be mediated by an FR-directed metalloprotease [133] [134] [135] or by GPI-specific phospholipases C/D. [102] [103] Neither the significance of soluble FR in folate metabolism, nor the influence of these enzymes on modulation of FRs expression in vivo, are known.

Reduced-Folate Carriers (RFC)

A second mechanism for folate uptake, primarily demonstrated in malignant cells, appears to be due to a carrier-mediated, pH- and energy-dependent process, which transports reduced-folates equally efficiently at higher than physiologic concentrations (Fig. 28-6). A RFC cDNA[136] located in chromosome 21q22.2q22.3, [137] which restores sensitivity to a methotrexate transport-resistant cell line functionally deficient in RFC, encodes a 58-kDa polypeptide and resembles the mammalian glucose transporter (GLUT1), which is a member of the 12-transmembrane domain-spanning membrane transporter family. Additional studies have confirmed the functional significance of RFC genes. [137] [138] [139] The acquisition of methotrexate transport-deficiency in some cells results from inactivating mutations of RFC-1 gene alleles. [140] It is of major clinical relevance that acquired transport resistance in relapsed acute lymphocytic leukemia is also associated with RFC expression. [141]

Cellular Retention and Excretion

Polyglutamation of folate is the major factor for intracellular retention, [142] [143] and the interaction of these forms with intracellular membrane-associated FR may also play a role (Fig. 28-6).[83] [130] As a corollary, human malignant cells with reduced folylpolyglutamate synthase are resistant to antifolates, which cannot be (polyglutamated and) retained intracellularly. [144] Recent studies in leukemia cells suggest that it is the intracellular concentration of (anti)-folates achieved that drives polyglutamation irrespective of the route of entry via FR or the RFC. [145] In human erythrocytes (RBC), folate is accumulated at earlier stages within the marrow by FR;[100] [101] upon maturation, >90% of $PteGlu_{(n)}$ molecules interact with hemoglobin, which, due to its high capacity, assists in intracellular folate retention. [146] RBC folate levels (by the original microbiologic assay) correlate with hepatic folate stores. [1] [3] [4] [10] [147] Intracellular FR may influence intracellular folate metabolism by binding 5-methyl-H_4 PteGlu and competing with dihydrofolate reductase for binding polyglutamates (Fig. 28-6).[130] The attenuating effect on methotrexate cytotoxicity in vitro by high pre-existing extracellular folate concentrations [119] appears to be due to the fact that folates can also passively diffuse into cells. [148] This is potentially significant for protocols involving high-dose (suprapharmacologic) antifolate therapy. [149]

Following glomerular filtration, luminal folate binds FR in the brush border membranes of proximal renal tubular cells [150] [151] and is internalized rapidly via FR-mediated endocytosis; in the low pH of endocytotic vesicles, there is dissociation of folates and slow transport across basolateral membranes into the blood, with recycling of apo-FR back to the luminal brush border membrane. [152] [153]

INTRACELLULAR METABOLISM AND COBALAMIN-FOLATE INTERRELATIONSHIPS

Pteroylpolyglutamates are the natural substrates for the various enzymes involved in one-carbon metabolism (Figs. 28-6 and 28-7). Thus, pteroyl*mono*glutamates must be *poly*glutamated by

folylpolyglutamate synthase before they participate in one-carbon metabolism. [142] This is best appreciated in mutant Chinese hamster ovary cells, which lack folylpolyglutamate synthase. [10] As a consequence of failure in polyglutamation, these cells have <10% of the intracellular folate content of wild-type cells, and an inability to generate reactions of one-carbon metabolism. The mutant cells therefore require that the *products* of one-carbon metabolism (methionine, glycine, purines, and thymidine) be exogenously supplied. In contrast, wild-type cells can grow as long as adequate folate, Cbl, and homocysteine (Hcys) are available (since they can synthesize their own folate polyglutamates, which then participate in one-carbon metabolism and generate these substances intracellularly).

Tetrahydropteroylglutamate (H_4 PteGlu) is the preferred physiologic substrate for folylpolyglutamate synthase and the polyglutamal form (H_4 $PteGlu_n$) plays a central role in one-carbon metabolism. [143] So factors that either limit the supply of H_4 PteGlu or regulate folylpolyglutamate synthase influence polyglutamation and cellular retention of folates. H_4 $PteGlu_n$ can be converted to (1) formate as 10-formyl-H_4 $PteGlu_n$ (used in *de novo* biosynthesis of purines) and (2) formaldehyde as 5,10-methylene-H_4 $PteGlu_n$ (for synthesis of thymidylate). Furthermore, 5,10-methylene-H_4 $PteGlu_n$ and 10-formyl-H_4 $PteGlu_n$ can be interconverted via intermediates (Fig. 28-7).

To understand the functions of folate coenzymes (Figs. 28-3 and 28-7), it is important to recognize at the outset that 5,10-methylene-H_4 $PteGlu_n$ can be utilized in either (1) the *thymidylate cycle* via thymidylate synthase for thymidine and DNA synthesis, or (2) the *methylation cycle* to form 5-methyl-H_4 $PteGlu_n$, which, via methionine synthase, leads to formation of methionine and H_4 $PteGlu_n$. Both methionine and H_4 $PteGlu_n$ are essential for polyglutamate formation (and thus for retention of folates and perpetuation of normal one-carbon metabolism) and for the interconversion to 5,10-methylene-H_4 $PteGlu_n$ (essential for DNA synthesis). Perturbation of either pathway, directly or indirectly, thus affects DNA synthesis. So thymidylate synthase- and methionine synthase-catalyzed reactions, coupled with the factors that control them via product inhibition, are central issues in protection from megaloblastosis. Additional reactions catalyzed by folate coenzymes involve amino acid interconversions and purine synthesis. [143]

Pteroylmonoglutamate (PteGlu, folic acid) is not a biologically active form of folate; when given therapeutically, it requires reduction to H_4 PteGlu by dihydrofolate reductase (20-kDa) in a two-step reaction {pteroylglutamate (PteGlu) *dihydro*pteroylglutamate (H_2 PteGlu)*tetrahydro*pteroylglutamate (H_4 PteGlu)}. The major form of folate transported into the cell by FR is 5-methyl-H_4 PteGlu (Fig. 28-7). The details of intracellular 5-methyl-H_4 $PteGlu_n$ movement in the cytoplasm and the precise order of channeling of folate along reactions by enzymes involved in one-carbon metabolism are not entirely clear. However, evidence suggests that folate-mediated one-carbon metabolism is indeed compartmentalized among intracellular organelles leading to substrate channeling along folate coenzymes. [154] As an example, some of the enzymes distal to H_4 $PteGlu_n$ are multifunctional, allowing sequential channeling of folate coenzyme forms (e.g., H_4 $PteGlu_n$ 5-CHNH-H_4 $PteGlu_n$ 5,10-H_4 $PteGlu_n$). Thymidylate synthase catalyzes the transfer of the formaldehyde from 5,10-methylene-H_4 $PteGlu_n$ to the 5 position of deoxyuridylate; in this process 5,10-methylene-H_4 $PteGlu_n$ is also reduced to dihydrofolate, which inhibits 5,10-methylene-H_4 $PteGlu_n$ reductase. Because methionine, the product of the methionine synthase reaction, also inhibits this enzyme, this illustrates that modulation of 5,10-methylene-H_4 $PteGlu_n$ reductase by levels of dihydrofolate and methionine can determine the degree of channeling of 5,10-methylene-H_4 $PteGlu_n$ into the methylation and thymidylate cycle (Figs. 28-3 and 28-7).

The mechanism whereby Cbl deficiency produces its megaloblastic effects is not precisely known. It is generally agreed that Cbl deficiency causes a functional intracellular deficiency of 5,10-methylene-H_4 $PteGlu_n$ (Figs. 28-3 and 28-7). The methylfolate trap hypothesis centers around the excess buildup (trapping) of 5-methyl-H_4 PteGlu due to inhibition of the Cbl-dependent methionine synthase; 5-methyl-H_4 PteGlu therefore leaks out of the cell, resulting in an intracellular folate deficiency. The formate starvation hypothesis centers around the relatively greater merit of formate (in the form of 10-formyl-H_4 $PteGlu_n$) and the precursor of formate, methionine, which is also decreased when methionine synthase is inhibited by Cbl deficiency. [155] When methionine is in excess intracellularly, its methyl group is oxidized to formate, which can be used to generate 5-formyl-and 10-formyl-H_4 $PteGlu_n$ (reactions 7 and 8, Fig. 28-7). There are articles that support either hypothesis. [156] [157] [158]

CONSEQUENCES OF PERTURBED ONE-CARBON METABOLISM

Thymidylate and DNA Synthesis

In either Cbl or folate deficiency a net decrease in 5,10-methylene-H_4 $PteGlu_n$ interrupts the reaction mediated by thymidylate synthase which converts deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP).[147] Although there is a salvage pathway via thymidine kinase, which normally accounts for 5 to 10% of thymidine synthesis,[159] this pathway cannot meet the remaining 90% demand for dTMP generation. (Salvage pathways for purine synthesis can be activated to compensate for diminished generation of purines through folate coenzyme-mediated reactions.) The resulting thymidine deficiency causes a marked increase in dUMP/dTMP ratio. Because of the decrease in dTMP [and eventually dTTP], dUMP and thereby deoxyuridine triphosphate (dUTP) increase. Because DNA polymerase cannot distinguish between dUTP and dTTP, this elevated dUTP promotes misincorporation of uridine residues into DNA. [160] [161] An editorial enzyme, DNA uracil glycosylase, recognizes this faulty misincorporation. It excises dUTP, but the inadequate supply of dTTP leads to failure to repair the break in this DNA strand. Repeated DNA strand breaks lead to significant fragmentation of DNA, with consequent leakage of DNA fragments out of the cell. [162] [163] [164]

The foregoing considerations form the basis for the dU suppression test that is occasionally employed clinically. [159] When cells containing normal dUMP/dTMP ratios are incubated with thymidine ^3H and excess unlabeled deoxyuridine (dU), <10% of thymidine ^3H is incorporated into DNA (by the salvage thymidine kinase pathway), since most of the unlabeled dU is utilized by thymidylate synthase to form dTMP. If the dUMP/dTMP ratio is increased (as in Cbl deficiency), unlabeled dU will not be utilized, and >10% of thymidine ^3H is incorporated into DNA. Addition of Cbl (but not 5-methyl-H_4 PteGlu) to another aliquot of these cells will lead to conversion of endogenous (and unlabeled) dUMP to dTMP; the net result is less thymidine ^3H incorporation into DNA via the salvage pathway. Addition of 5-methyl-H_4 PteGlu will facilitate conversion of dUMP to dTMP in folate-deficient cells but will have no effect in Cbl deficiency. Although this method of testing does not simply represent thymidylate synthase-catalyzed pathways but affects additional pathways involving nucleotide metabolism, [165] the reduction of prior increased thymidine ^3H incorporation in Cbl- or folate-deficient cells by the addition of exogenous Cbl or folate, respectively, has been practically useful to differentiate Cbl from folate deficiency; this is the principle of the diagnostic dU suppression test. [159] A modified diagnostic dU suppression test is useful when inborn errors of Cbl/folate metabolism are suspected[166] or when coincident iron deficiency or thalassemia masks the megaloblastic expression; [167] but in the latter instance, measurement of vitamin levels and/or metabolites to determine Cbl and/or folate deficiency is more practical in routine clinical use.

Chromosome and Cell Cycle Defects

Defective DNA synthesis is reflected by numerous chromosomal abnormalities. There is excessive chromosomal elongation with despiralization associated with random breaks and exaggerated centromere constriction, expression of folate-sensitive fragile sites in hematopoietic cells, and reduced biosynthesis, acetylation, and methylation of arginine-rich histone. [10] [147] [168] [169] All this leads to perturbation of the cell cycle with an increased proportion of cells in prophase of the mitotic cycle and G_2 . This arrest in various stages of DNA synthesis causes many cells to have DNA contents between 2N and 4N. [10] In a recent in vitro model of folate-deficient erythroblastosis, apoptosis of erythroblasts in the late stages of differentiation apparently led to decreased erythrocyte production and anemia. [170] In addition, there was persistent accumulation of p53 and p21; because thymidine prevents the apoptosis of folate-deficient erythroblasts in vitro, this implicated decreased thymidylate synthesis as the main cause of apoptosis in the folate-deficient erythroblasts. [160] Parenthetically, in folate-deficient rats, DNA strand breaks and selective hypomethylation of exons within the p53 tumor suppressor gene can somewhat explain how dietary folate deficiency may enhance carcinogenesis. [171]

Morphologic Expression of Megaloblastosis

There is widening disparity in nuclear-cytoplasmic asynchrony as a Cbl- or folate-deficient cell divides, until the more mature generations of daughter cells either die in the marrow or are arrested (as megaloblastic cells) at various stages in the cell cycle. [10] In fact, the plethora of bone marrow morphologic changes may lead the untrained observer to the diagnosis of acute leukemia. [172] All proliferating cells exhibit megaloblastosis, including epithelial cells lining the gastrointestinal tract (buccal mucosa, tongue, small intestine), cervix, vagina, and uterus. [10] However, megaloblastic changes are most striking in the blood and bone marrow. Ineffective hematopoiesis extends into the long bones, and the bone marrow aspirate (which is better than the biopsy

MORPHOLOGY IN MEGALOBLASTOSIS FROM COLBALAMIN AND FOLATE DEFICIENCY IS THE SAME

Peripheral Smear

Increased mean corpuscular volume (MCV) with macroovalocytes (up to 14 m)[a]
Nuclear hypersegmentation of polymorphonuclear neutrophils (PMNs) (1 PMN with 6 lobes or 5% with 5 lobes)
Thrombocytopenia (mild to moderate)
Leukoerythroblastic morphology (from extramedullary hematopoiesis)

Bone Marrow Aspirate

General increase in cellularity of all three major hematopoietic elements
Abnormal erythropoiesisorthochromatic megaloblasts
Abnormal leukopoiesis*giant* metamyelocytes and band forms (pathognomonic), hypersegmented polymorphonuclear neutrophils (PMNs)
Abnormal megakaryocytopoiesispseudohyperdiploidy

[a]Associated with varying anisocytosis and poikilocytosis.

for observing megaloblastosis) exhibits trilineal hypercellularity, especially in the erythroid series. In contrast to what appears as exuberant cell proliferation with numerous mitotic figures, the cells are actually very slowly proliferating. However, megaloblastosis induced in vitro by anti-FR antibodies causes a true increase in cell proliferative capacity initiated at the level of cell surface FR, suggesting a constitutive control of FR in hematopoietic cell proliferation. [83] [84] [101] [105] [173]

Erythroid hyperplasia reduces the myeloid/erythroid ratio from 3:1 to 1:1. Proerythroblasts are not as obviously abnormal as later forms; they may simply be larger (promegaloblasts). Megaloblastic changes are most strikingly displayed in intermediate and orthochromatic stages, which are larger than their normoblastic counterparts. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, sieve-like pattern. The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large sieve-like immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. The nucleus is often eccentrically placed in these large oval or oblong cells and lobulation or indentation of nuclei with bizarre karyorrhexis is often seen. In cells destined for the circulation as macroovalocytes, the nucleus may occasionally not be completely extruded. Of the potential progeny of proerythroblasts that develop into later megaloblastic forms, 8090% die in the bone marrow. Marrow macrophages effectively scavenge dead/partially disintegrated megaloblasts. This is the basis for ineffective erythropoiesis (intramedullary hemolysis).

Leukopoiesis is also abnormal. There is an absolute increase in these cells, which are large and have similar sieve-like chromatin. Spectacular giant (2030 m) metamyelocytes and band forms which are often seen are pathognomonic for megaloblastosis. There may be bizarre nucleoli with small cytoplasmic vacuoles. It is probable that giant metamyelocytes cannot easily traverse marrow sinuses and their maturation into circulating hypersegmented polymorphonuclear neutrophils (PMNs) is unlikely. Granulation of the cytoplasm remains unaffected.

Megakaryocytes may be normal or increased in numbers and may exhibit additional complexities in megaloblastic expression. The process of complex hypersegmentation (pseudohyperdiploidy) is associated with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is invariably decreased in severe megaloblastosis and abnormal but reversible platelet dysfunction has been documented. [174]

In early Cbl or folate deficiency, normoblasts may dominate the marrow with only a few megaloblasts seen. Complete transformation to megaloblastic hematopoiesis is observed in florid cases and is reflected by varying degrees of pancytopenia. *The earliest manifestation of megaloblastosis is an increase in mean corpuscular volume (MCV) with macroovalocytes (up to 14 m).* Because these cells have adequate hemoglobin, the central pallor, which normally occupies about one-third of the cell, is decreased. In severe anemia, poikilocytosis and anisocytosis are evident. Cells containing remnants of DNA (Howell-Jolly bodies), arginine-rich histone, and nonhemoglobin iron (Cabot rings) may be observed. Extramedullary megaloblastic hematopoiesis may also result in a leukoerythroblastic picture.

Ineffective utilization of iron results in an increased percentage of saturation of transferrin and increased iron stores. If there is associated iron deficiency, the MCV may be normal, and only iron therapy will unmask the megaloblastic manifestations in the peripheral blood. In thalassemia, the entire erythrocyte morphology normally expected in megaloblastosis is masked;[167] [175] however, megaloblastic leukopoiesis is still observed. Significant intramedullary hemolysis (ineffective erythropoiesis) involving >90% of megaloblastic precursors is reflected by a lowered

absolute reticulocyte count, increased bilirubin (up to 2 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (LDH), often above 1,000 units/ml. There is also a modest decrease in circulating RBC life span.

Nuclear hypersegmentation of DNA in PMNs strongly suggests megaloblastosis when associated with macro-ovalocytosis. Normally, <5% of PMNs have >5 lobes and no cells have >6 lobes in the peripheral blood. If megaloblastosis is suspected (>5% PMNs with >5 lobes or a single PMN with >6 lobes), a formal lobe count per PMN (lobe index) above 3.5 may be obtained.

Megaloblastosis in rapidly proliferating cells of the gastrointestinal tract leads to a variable degree of morphologic changes and atrophy of the epithelial cells of the luminal lining. This leads to functional defects, which include a failure in secretion of IF and malabsorption of Cbl and folate in certain subsets of patients. Thus, a vicious cycle whereby megaloblastosis begets more megaloblastosis is established that can only be interrupted by specific therapy with Cbl or folate. This fact must be recognized when interpreting diagnostic tests involving Cbl absorption (discussed later in this chapter). Interestingly, similar hematopoietic changes have recently been induced in a folate-deficient mouse model. [176]

Neurologic Dysfunction with Cobalamin (Cbl) Deficiency

Because megaloblastosis due to either folate or Cbl deficiency leads to a functional folate coenzyme deficiency, the morphologic manifestations of both deficiencies are understandably indistinguishable. However, only Cbl deficiency results in a patchy demyelination process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord. [177]

The precise role of Cbl in maintaining the integrity of the central nervous system has not been completely defined. Early studies of the Cbl-dependent enzyme, methylmalonyl-CoA mutase, revealed that the inability to adequately metabolize propionate results in accumulation of propionyl CoA, which can compete with acetyl CoA in pathways of fatty acid synthesis. Thus, fatty acids with odd numbers of carbon atoms can be incorporated into lipids; although this has been demonstrated in nerve biopsies from patients with Cbl deficiency, cause and effect have not been proved. Nitrous oxide (N_2O) was later recognized as an inducer of *functional* Cbl coenzyme deficiency in vivo, because individuals exposed to this gas developed both hematologic and neurologic manifestations similar to those with Cbl deficiency. Because methionine (required in numerous methylation reactions, including those in nerve tissue) also ameliorates the neurologic dysfunction in monkeys, this led to a focus on the methionine synthase-catalyzed reaction and on the potential importance of lack of methionine in Cbl deficiency. The potential etiologic role of some natural Cbl analogues[7] [178] [179] which have anti-Cbl effects, and have been shown to accumulate in the brains of N_2O-treated/Cbl-deficient fruit bats, [177] is still under investigation. Because elevated levels of serum methylmalonic acid (MMA) and total homocysteine (tHcys) are both positively correlated with Cbl-dependent neurologic dysfunction in humans, perturbation of the activity of both Cbl-dependent enzymes may be important. [180] [181] [182] [183] [184] [185] Conversely, hereditary defects in methionine synthase-catalyzed reactions are associated with neurologic dysfunction, [186] whereas methylmalonyl-CoA mutase deficiency is not. Moreover N_2O also inhibits methionine synthase much more than methylmalonyl-CoA mutase, thus elevating the importance of methionine synthase in maintaining the integrity of myelin in humans. Alternatively, there may yet be additional undiscovered pathways. Recent reviews have presented balanced views on various arguments. [187] [188]

SOME CLUES TO DISTINGUISHING COBALAMIN AND FOLATE DEFICIENCIES

Although the megaloblastic manifestations of Cbl and folate deficiencies are clinically indistinguishable, certain distinct patterns in mode of presentation provide clues to the type and etiology of deficiency. In general, the cause of folate deficiency will be found in the fairly recent past (within 6 months) primarily from the history and physical examination. By contrast, the cause of Cbl deficiency will be obscure until specific tests to define the etiology (e.g., Schilling test) are carried out. In bygone days, by the time anemia was symptomatic, >80% of patients had neurologic manifestations, and in 50% this led to some incapacity. Perhaps as a result of widespread use of multivitamins containing folic acid among patients (and even in the food given livestock in the West), the hematologic expression of Cbl deficiency is often substantially attenuated, leading to pure neurologic presentations. Studies highlight the apparent inverse correlation between hematologic and neurologic presentations such that in a third of patients with Cbl deficiency, the earliest signs are often purely neurologic, and symptoms related to paresthesias and diminished proprioception cause the patient to see the physician. Based on the multiple potential etiologies (see box, Megaloblastic Anemias), the truism that what the mind does not know, the eyes do not see is a caveat that cannot be taken lightly; failure to recognize Cbl deficiency as the etiology of neurologic disease and treatment of Cbl deficiency with folate or misdiagnosis of megaloblastosis as erythroleukemia represent significant extremes of deviation from the dictum *primum non nocere.* Areas of overlap in symptomatology in Cbl/folate deficiency are related to megaloblastosis (e.g., common cardiopulmonary and some gastrointestinal manifestations). Although pure folate deficiency in the alcoholic with thiamine deficiency (Wernickes encephalopathy) and peripheral neuropathy is almost indistinguishable from and may mimic Cbl deficiency, the remainder of the neurologic manifestations are uniquely due to Cbl deficiency. And as reviewed recently,[225] folate deficiency in adults has not been unequivocally shown to give rise to neurologic findings. Thus, coexistence of folate deficiency with neurologic disease should prompt investigations to rule out Cbl and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

Curiously, in fruit bats and monkeys, the neurologic dysfunction of N_2O-induced Cbl deficiency occurs when hematologic abnormalities are absent.[10] [189] This was verified clinically in humans, where there is an apparent *inverse correlation* between the extent of neurologic defects versus hematologic abnormalities.[190] [191] Recent studies also highlight the greater sensitivity of human glial cells in culture to short-term Cbl deprivation.[192] The demyelinating process involves patchy swelling of the myelin sheath followed by its breakdown (demyelination), leading to axonal degeneration. Microscopic foci coalesce with one another, giving the surface of the spinal cord (on cross-section) a spongy appearance; later there is secondary Wallerian degeneration of long tracts. Patchy demyelination usually begins in the dorsal columns in the thoracic segments of the spinal cord and then spreads *contiguously* to involve corticospinal tracts. These lesions spread throughout the length of the cord and ultimately involve spinothalamic and spinocerebellar tracts. There is also degeneration of the dorsal root ganglia,

celiac ganglia, and Meissners and Auerbachs plexus. Although demyelination may also extend to the white matter of the brain, it is unclear whether the peripheral neuropathy is due to a distinct lesion or is secondary to spinal cord disease; thus, the clinical manifestations may be extremely varied.[177] [193]

Other Effects of Cbl/Folate Deficiency

Cbl deficiency more often than folate deficiency can also result in sterility from the effects on the gonads. An unexplained finding is generalized melanin pigmentation that is reversible by specific nutrient replenishment. The mechanism of defective bactericidal activity and increased susceptibility to *Mycobacterium tuberculosis* in Cbl deficiency[194] remains unexplained. In folate deficiency, other effects include a reduction in lymphocyte subsets,[195] enhanced predisposition to chemical-induced gastrointestinal carcinogenesis[196] [which may have a clinical correlate in patients with ulcerative colitis with low folate status],[197] and delayed tumor growth.[198] Interestingly, severe folate deficiency impairs pancreatic exocrine function in rats;[199] if confirmed in humans, a resulting lack of R protein degradation could lead to Cbl malabsorption and Cbl deficiency (as noted with chronic folate deficiency).

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BIOCHEMICAL INDICATORS OF EVOLVING DEFICIENCY

Early manifestations of negative Cbl balance are an abnormal deoxyuridine suppression test [200] and increased serum methylmalonic acid (MMA) and tHcys levels.[181] [183] [184] [185] This occurs at a time when the total Cbl in serum is still normal. Continued negative Cbl balance leads to an absolute decrease in serum Cbl level. Likewise, metabolic evidence for folate deficiency (i.e., increased tHcys) is often found when serum folates are still in the low-normal range. Thus metabolite tests reflective of decreased intracellular nutrient availability are followed by biochemical evidence of abnormal thymidylate synthesis (impaired conversion of dUMP to dTMP), morphologic expression of perturbed DNA in PMNs (lobe index), macroovalocytosis, and anemia. The biochemical basis for selective nutrient deficiency in various tissues (e.g., cervical [201] or hematopoietic but not gastrointestinal cells [1] [147]) is still unclear.

Biochemical Evaluation of Cbl/Folate Deficiency

Total Serum Homocysteine (tHcys) and Methylmalonic Acid (MMA) Levels

Cellular nutrient *deficiency* of either Cbl or folate is reflected by decreased intracellular concentrations. *Defective utilization* of Cbl/folate due to intracellular Cbl/folate-dependent enzyme deficiency may allow normal intracellular coenzyme levels. Deficient coenzyme and enzyme levels are both reflected by perturbation of the major Cbl/folate-dependent enzyme-catalyzed reactions. Thus, there is reduced activity of methionine synthase, leading to substrate buildup and to elevated serum levels of tHcys, which can be measured by a sensitive assay.[182] In a classic series of studies, 77 of 78 patients with clinically confirmed Cbl deficiency had elevated values of tHcys, correlating with clinical parameters of Cbl deficiency. [183] In this patient group, 74 of the 78 also had increased serum MMA levels, indicating reduced activity of the second Cbl-dependent enzyme, methylmalonyl-CoA mutase, to convert methylmalonyl-CoA to succinyl-CoA. [181] Similarly, 18 of 19 patients with folate deficiency had elevated levels of tHcys due to reduced activity of the methionine synthase-catalyzed reaction. [183]

The combined use of serum tHcys and MMA can distinguish between Cbl and folate deficiency since most patients with folate deficiency have normal MMA levels, and the rest have only mild elevations. [181] [183] [184] [185] These two tests, which are now clinically available, are useful diagnostically and also in following the patients response to replacement since the abnormally high metabolites will only return to normal when replaced with the appropriate (deficient) vitamin. Thus, a positive response to Cbl, documented by falling levels of tHcys and MMA, is evidence of Cbl deficiency. Conversely, therapy with folate results in a decrease in the isolated tHcys level if folate deficiency is present. [181] [183] [184] [185]

Total homocysteine can be measured in either plasma[202] or serum. [203] In general, plasma levels are slightly lower. The normal value for serum tHcys is 5.113.9 M and serum MMA is 73271 nM, and in general, the higher the values, the more severe the clinical abnormalities. [202] However, there is a fairly wide range of normalcy in tHcys values because of age-, creatinine-, gender-, diet-dependent, [202] and race-dependent[204] variables; nevertheless, most investigators believe that the upper limit of normal should not be greater than 14 M. Children usually have very low values (36 M). Basal levels of MMA are usually <500 nM and in renal failure it rarely increases >1,000 nM.[203] [205] [206] (*Note:* if unseparated blood stands at room temperature, tHcys levels will *increase* over 4 to 24 hours. But frozen serum [from measurements of serum folate/Cbl] can be used for serum MMA and tHcys determinations.)

Among 1,160 elderly participants in the original Framingham Heart Study cohort, nearly one-third had high plasma tHcys that inversely correlated most with plasma folate levels, and to a lesser extent with Cbl and vitamin B_6 (pyridoxine; pyridoxal-5-phosphate is the active form). [207] Thus, a substantial majority of the cases of high tHcys in the elderly can be attributed to low vitamin status. The use of methionine-loading to stress the capacity of the trans-sulfuration pathway (whereby homocysteine is irreversibly degraded by a vitamin B_6 -dependent pathway),[208] has further defined the basis for homocysteinemia.

Because of some variables related to age and mild renal dysfunction that can falsely elevate these metabolites, proof of metabolic deficiency requires demonstration of a reduction in metabolite levels with vitamin supplementation. This was demonstrated in another study, where an intramuscular vitamin supplement (containing Cbl, folate, and pyridoxine) reduced initially elevated metabolite concentrations toward normal in a high proportion of elderly subjects. [209] *Thus it appears that metabolic evidence of vitamin deficiency is common in the elderly, even in the presence of normal serum vitamin levels.*

Serum Cobalamin (Cbl) Levels

Serum Cbl levels previously measured by microbiologic assay using the Cbl-dependent organism *Lactobacillus leichmannii* have been replaced by a simpler assay method that relies on the competitive inhibition by serum Cbl of the binding of CN-[^{57}Co]Cbl to IF (rather than R protein, which falsely measured Cbl analogues also). [8] [210] [211] For the most part, serum Cbl is an established biochemical indicator of Cbl deficiency. [212] [213] However, a report of neuropsychiatric disorders attributed to Cbl deficiency in some patients, despite both the absence of anemia and normal or minimally depressed Cbl levels, underscores the caution with which clinicians should proceed with when interpreting this test. [190] [191] [212] [213] [214] [215] A low serum Cbl is not synonymous with Cbl deficiency and several associated diseases and conditions can falsely raise or lower Cbl levels (Table 28-1). Studies have also identified patients with true Cbl deficiency who have Cbl levels in the low normal range (see discussion later in this chapter).

If the serum Cbl test is broadly used as a screening test, by virtue of the way normalcy is defined, 2.5% of nondeficient individuals will have low levels. Because many millions of individuals probably have serum Cbl tests done every year, several thousand will have low Cbl levels, which simply reflects our definition of the lower limit of normal for this test.[193]

TABLE 28-1 -- Serum Cbl Levels[a] False-Positive Tests and False-Negative Tests[b]

Falsely low serum Cbl in the absence of true Cbl deficiency
Folate deficiency (1/3 of patients)
Multiple myeloma
TC I deficiency
Megadose vitamin C therapy
Patients serum contains other radioisotopes (^{99m} Tc or ^{67} Ga and other radiopharmaceuticals used in organ scanning)

Falsely raised Cbl levels in the presence of a true deficiency
Cbl binders (TC I and II) increased (myeloproliferative states, hepatomas, and fibrolamellar hepatic tumors)
TC II-producing macrophages are activated (autoimmune diseases, monoblastic leukemias, and lymphomas)
Release of Cbl from hepatocytes (active liver disease)

[a]Although a low serum Cbl is not synonymous with Cbl deficiency, 5% of patients with true Cbl deficiency will have low normal Cbl levels.
[b] A potentially serious problem since the patients underlying Cbl deficiency will progress if uncorrected.

The serum Cbl is <300 pg/ml in 99% of patients with clinical hematologic or neurologic manifestations of Cbl deficiency. [185] [216] Conversely, a Cbl level of >300 pg/ml predicts for folate deficiency, or another hematologic disease (Table 28-2). However, if the serum folate levels are borderline/normal and the patient has megaloblastic anemia with Cbl levels >300 pg/ml, metabolite tests or a therapeutic trial may be necessary to rule out underlying folate deficiency.

How often do patients with Cbl deficiency have normal Cbl levels? Among 173 unambiguously Cbl-deficient patients, [185] 5% had normal Cbl levels and up to 10% of adults with true Cbl deficiency will have Cbl values in the low normal (200300 pg/ml) range. Although traditionally such patients would have been regarded as not having Cbl deficiency, they should now be tested with the more sensitive metabolite tests, MMA and tHcys, as discussed earlier in this chapter. Recent studies have again highlighted the need to be vigilant for clinical and biochemical evidence of Cbl deficiency in the elderly at normal Cbl concentrations. [217] And a study on 548 surviving members of the original Framingham Study revealed a prevalence of Cbl deficiency of 12%. [218] Nevertheless, 90% of older patients with serum Cbl levels <150 pmol/L show evidence of true tissue Cbl deficiency. [217]

Serum and RBC Folate Levels

Microbiologic assays of folate using *Lactobacillus casei* suffer from the same limitations as assays for Cbl, [10] and these too have been supplanted, primarily for convenience, by various radioisotope dilution assays. However, the clinical validity of these modifications has in many cases not been adequately documented. [10] There is also significant discrepancy in folate levels when a variety of kits are used on the same sample, raising questions as to the reliability of these assays for clinical use, and especially when compared to microbiologic assays. [219] [220] [221]

When combined with a clinical picture of megaloblastic anemia and additional results of Cbl levels, the serum folate is the cheapest and most useful initial biochemical test to diagnose folate deficiency (Table 28-2).[222] Serum folate level is highly sensitive to folate intake and a single hospital meal may normalize it in a patient with true folate deficiency. Rapidly developing nutritional folate deficiency first leads to a decline in the serum folate level below normal (<2 ng/ml) in 3 weeks; thus, it is a sensitive indicator of negative folate balance. [3] [4] However, isolated reduction of serum folate in the absence of megaloblastosis (i.e., a false-positive result) occurs in one-third of hospitalized patients with anorexia, following acute alcohol consumption, normal pregnancy, and those on anticonvulsants; [212] [213] [223] (unfortunately, these are the very groups who are

TABLE 28-2 -- Stepwise Approach to Diagnosis of Cobalamin (Cbl) and Folate Deficiency

Megaloblastic anemia or Neurologic manifestations consistent with Cbl deficiency plus Test results on serum Cbl and serum folate[a]			
Cobalamin (pg/ml)[b]	**Folate (ng/ml)[c]**	**Provisional Diagnosis**	**Proceed with Metabolites?**
>300	>4	Cbl/folate deficiency is unlikely	No
<200	>4	Consistent with Cbl deficiency	No
200300	>4	Rule out Cbl deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with (1) combined Cbl plus folate deficiency, or (2) isolated folate deficiency	Yes
>300	24	Consistent with (1) folate deficiency or (2) an anemia unrelated to vitamin deficiency	Yes

Test results on metabolites: Serum methylmalonic acid (MMA) and total homocysteine (tHcys)[d]		
MMA (normal = 70270 nM)	**tHcys (normal = 514 M)**	**Diagnosis**
Increased	Increased	Cbl deficiency is confirmed; folate deficiency still possible
Normal	Increased	Folate deficiency is likely; <5% may have Cbl deficiency
Normal	Normal	Cbl deficiency is excluded

[a] Both serum Cbl and folate tests are performed on the same specimen in one tube (cost for each of these tests in Indiana in 1997: $50). RBC folates (which are not recommended; see text) generate an independent charge of $120. If only serum folate levels are reported, call laboratory for the information they have on Cbl levels done at the same time the folate tests were generated.
[b] Serum Cbl levels: abnormally low <200 pg/ml; clinically relevant low-normal range 200300 pg/ml.
[c] Serum folate levels: abnormally low <2 ng/ml; clinically relevant low-normal range 24 ng/ml.
[d]The costs for testing serum MMA is $105 and for testing tHcys is $104. (Although the actual charges for both tests are $125 in one reference laboratory in Denver, the extra cost reflects a local mark-up for shipping and handling.) Any frozen-over sample from serum folate/Cbl determination can be subjected to metabolite tests.

at high risk for folate deficiency and who will also exhibit low serum folate levels when they become folate-deficient). [1] [224] Conversely, in 2550% of cases (predominantly alcoholics) with folate-deficient megaloblastosis, the serum folate levels may be low normal or borderline (i.e., 24 ng/ml by radioisotope dilution assay).[225] [226] [227] Thus, the serum folate level alone should never dictate therapy, and it is important to consider the clinical picture, peripheral smear and bone marrow morphology and to rule out underlying Cbl deficiency.

When negative folate balance is continued, hepatic folate stores are depleted in 4 months. [3] [4] This leads to tissue folate deficiency which was clinically correlated with a decrease in RBC folate (<150 ng/ml) by a microbiologic assay in the 1960s. [10] Thus, a reduction in serum and RBC folate in the setting of megaloblastic anemia was consistent with the diagnosis of folate deficiency. [1] [3] [4] However, RBC folate tests have major limitations in sensitivity and specificity [1] [227] [228] and are notoriously unreliable in alcoholics and in pregnancy; thus, it was normal or border- line (in the low normal range) in 30% of alcoholics [227] and 60% of pregnant patients[10] with clinically significant folate-deficient megaloblastic anemia. Furthermore, a reduction of RBC folate also occurs in 60% of patients with Cbl deficiency, since the trapped folate which cannot participate in the methionine synthase reaction due to Cbl deficiency (see Fig. 28-2) leaks out of the RBC, further limiting its diagnostic utility. [1] Consequently, the serum folate level is falsely low less often (<10%) with Cbl deficiency.

Other compelling evidence argues against the use of RBC folate in the diagnosis of folate deficiency. The original microbiologic assays for RBC folates have been replaced by radioassays currently used for measurement of *serum* folate levels. Apart from a lack of clinical validation of the use of *radio*assays for measuring RBC folates, these radioassays have had a long history of being unreliable (in several geographic areas) with respect to lack of precision and accuracy, generally leading to a lack of confidence in the results. [219] [225] [228] [229] [230] [231] Unlike the serum folate (which is entirely 5-methyl-tetrahydrofolate), RBC folates are a heterogeneous mixture of different coenzyme forms with varying polyglutamate chain lengths which (among other confounding variables) most likely contributes to these problems. In addition, a quality assurance study from Australia involving 134 laboratories identified nine operator controllable factors that could also lead to poor RBC folate results.[220] [221] In addition, a recent analysis of its clinical value led to the conclusion that the RBC folate test added little useful information to that provided by serum folate levels.[232] Together, these clinically relevant issues have considerably dampened enthusiasm for use of RBC folate tests, and have led several experts in the

United States to entirely avoid their use pending a resolution of problems related to reagent batch quality control, quality assurance, and equally important, provision of data on clinical validation by the various manufacturers of these kits. So for the present, based on information from several recent studies, a cost-conscious approach that primarily relies on measurement of the serum Cbl and serum folate levels as initial tests to define Cbl and/or folate deficiency has been developed (discussed later in this chapter; see also Table 28-2). [222]

Summary of the Clinical Usefulness of Tests for Cbl and Folate Deficiency

The sensitivity of the measurement of MMA and tHcys is best illustrated in patients with pernicious anemia who are on replacement therapy with Cbl. When these patients do not receive Cbl for some time, the levels of MMA and tHcys progressively increase much earlier than the drop in Cbl levels. [185]

An important study has conclusively demonstrated that overlooking true Cbl deficiency is highly unlikely when the two metabolites are measured, since one or both metabolites were increased in 99.8% of >400 patients with proven Cbl deficiency. [226] These data collectively indicate that these serum tests (MMA and tHcys) are the now the gold standard for the diagnosis of Cbl deficiency.

Based on the lower costs of serum Cbl and folate compared to serum MMA and tHcys, it is recommended (Table 28-2) to first use the cheaper tests that will assist in diagnosis of the majority of obvious cases of Cbl and folate deficiency. [222] [233] Clinicians should also restrict use of serum MMA and tHcys to patients (1) with borderline Cbl and folate levels; (2) with existing conditions known to perturb folate/Cbl tests leading to difficulties in the interpretation of test results (discussed earlier in this chapter); (3) when both Cbl and folate levels are low, where a high MMA is useful in confirming Cbl deficiency (rather than attributing the condition to folate deficiency alone); and finally, to patients (4) with clearly low serum levels but in whom there is an alternative explanation for the syndrome that led to obtaining a serum Cbl level (e.g., a diabetic or alcoholic with peripheral neuropathy, or an alcoholic with a high MCV and a low serum Cbl without anemia). Here, serum metabolites can assist in the diagnosis of vitamin deficiency.

Other Tests

(1) Alternative tests for Cbl deficiency that measure the percent saturation of TC II have been described. [234] However, there have been strong objections pointing out the imprecision of this test due to flaws in methodology [235] and another study has not been able to clinically validate this test. [236]

(2) Using a more convenient urinary MMA test, screening a total of 809 elderly individuals yielded a prevalence of up to 5.1% with elevated MMA levels (urinary MMA cost = $50). This study also verified earlier results that serum MMA levels are more sensitive than serum Cbl to diagnose Cbl deficiency. [237] However, inadequate clinical data is available (a) as to whether there is a greater sensitivity of measuring urinary MMA (greater convenience and low cost) versus serum MMA in patients with Cbl deficiency with wide ranges of serum MMA; (b) as to what extent renal dysfunction and dehydrationfactors that limit interpretation of serum MMA results [193] influence urinary MMA levels; (c) on the kinetics of reduction of urinary MMA to Cbl replacement (a reduction in serum MMA to Cbl treatment has been demonstrated). So what is urgently needed are prospective, blinded studies on patients with mild to severe Cbl deficiency (with or without folate deficiency) in whom both urine MMA and serum MMA levels are examined to determine the extent of concordance; (if they are the same, the current price and convenience would favor urinary MMA). However, cost-effectiveness studies comparing the relative merits of urine MMA over serum MMA tests must take into account the additional costs for determination of urine creatinine levels (to normalize urine MMA values), and this should be compared to the clinically significant advantages of being able to distinguish folate from Cbl deficiency (or combined folate and Cbl deficiency) using both serum tHcys and serum MMA tests (Table 28-2). Thus, it is somewhat premature at this time to endorse the urinary MMA test over serum MMA (and tHcys) tests.

(3) Although the deoxyuridine suppression test can diagnose folate or Cbl deficiency even earlier than metabolite tests, [200] it is unfortunately not widely available, and information is still insufficient to warrant its routine use in Cbl/folate deficiency.

PATHOGENESIS OF COBALAMIN (Cbl) DEFICIENCY

Nutritional Cbl Deficiency: Insufficient Cbl Intake

Among 138 vegetarian Indians residing in the United Kingdom (1380 years of age) with megaloblastic hematopoiesis, 95 had

nutritional Cbl deficiency, some with early neuropsychiatric manifestations. [194] The sole Cbl source for these individuals who abstain from consuming meats, eggs, and cheese was boiled milk and yogurt. One-third had evidence of intestinal malabsorption with osteomalacia, associated iron deficiency (attributable to the low bioavailability of iron in these diets) and an inordinately high incidence of tuberculosis. In northwest India, three-fourths of 136 consecutive cases of nutritional megaloblastic anemia[238] had Cbl deficiency with 60% presenting in the second and third decade with pancytopenia, mild hepatomegaly (46%), mild splenomegaly (34%), fever (42%), thrombocytopenic bleeding (80%), and neutropenia (43%). The hemorrhagic diathesis encountered with thrombocytopenia has been reversed within 1224 hours of replacement with Cbl.[174] [238]

Food faddists may also develop nutritional Cbl deficiency [239] when they practice strict vegetarianism for health reasons. However, owing to an efficient enterohepatic circulation, Cbl deficiency normally develops very slowly (over >10 years). Because the staying power of fads is often of shorter duration, this complication is rarely seen. Long-term maintenance therapy requires oral 5 g aqueous hydroxo-Cbl or 50 g Cbl tablets; this approach allows for continued vegetarianism. The breast-fed offspring of strict vegans (or mothers with tropical sprue and subclinical Cbl deficiency) are also recognized as being at high risk for developing nutritional Cbl deficiency.[240]

Intragastric Events Leading to Cbl Malabsorption

Inadequate Dissociation of Cbl from Food Protein

Dietary Cbl is bioavailable only following proteolytic digestion of food by gastric acid and pepsin. Thus, failure to release Cbl from food protein can present as Cbl deficiency even though gastric analysis reveals the presence of IF. [12] [13] [241] Some older patients (>50 years of age) with atrophic gastritis or partial gastrectomy with hypochlorhydria have low serum Cbl levels and normal absorption of crystalline Cbl, but poor absorption of CN- ^{57} CoCbl that is incorporated into food as a food-Cbl absorption test.[14] [241] Some of these patients may progress to overt clinical manifestations of Cbl deficiency. They may also represent a cohort who are in an early stage in the natural history of pernicious anemia. Geriatric patients with low-normal Cbl levels, abnormal food-Cbl absorption tests, and increased metabolite levels consistent with Cbl deficiency have been encountered in 14.5% of patients in some populations. [242]

Congenital Intrinsic Factor Deficiency

Congenital IF deficiency, transmitted as an autosomal recessive trait and expressed in homozygotes by the age of 2 years, is characterized by a pure IF deficiency without other gastric abnormalities. Only 40+ cases have been described; affected children present with irritability, vomiting, diarrhea, and loss of weight with megaloblastic anemia. Except for the absence of IF in gastric juice, gastric histology/function are normal. [243]

Loss or Atrophy of Gastric Oxyntic Mucosa

IF deficiency arising from atrophy of gastric parietal (oxyntic) mucosal cells must be associated with parallel insufficient HCl secretion and can be caused by (1) total or partial gastrectomy; (2) autoimmune destruction as observed in adult Addisonian pernicious anemia (PA) or, rarely, in a similar disease in children (juvenile PA); and (3) destruction of gastric mucosa by caustic (lye) ingestion.

Total gastrectomy that results in removal of IF-producing cells invariably leads to Cbl deficiency in 5 years (range 210 years), often associated with iron deficiency (dimorphic anemia).[10] In fact, one-third of post-gastrectomy individuals have metabolic evidence for Cbl deficiency [244] warranting close follow-up with metabolite measurements and replacement. But another approach is to assume that all total-gastrectomy patients are at risk and therefore begin prophylaxis shortly after surgery.

Cbl deficiency is observed in only 1020% of patients 8 years after partial gastrectomy, although 30% have Cbl malabsorption; [10] up to 6% of these Cbl-deficient patients will develop frank clinical manifestations of Cbl deficiency with megaloblastic anemia. The etiology is multifactorialcontributing factors include decreased IF secretion, hypochlorhydria (from atrophy of residual oxyntic mucosal cells), intestinal bacterial overgrowth of Cbl-consuming organisms, associated nutritional folate deficiency in 20%, and iron deficiency in 50%. The degree of Cbl deficiency depends on the size of the remaining gastric remnant. It is more common in Bilroth II than in Bilroth I surgery, in subtotal than in partial gastrectomy, and in gastric rather than duodenal peptic ulcer disease. [245] Morbidly obese patients treated surgically with gastric bypass also have more food Cbl malabsorption than patients treated with vertical banded gastroplasty. [246]

Absent IF SecretionPernicious Anemia

The most common cause of Cbl malabsorption is pernicious anemia (PA), a disease of unknown origin in which the fundamental defect is atrophy of the gastric (parietal cell) oxyntic mucosa eventually leading to the absence of IF and HCl secretion. Because Cbl is only absorbed by binding to IF and uptake by ileal IF-Cbl receptors, the net consequence is severe Cbl malabsorption leading to Cbl deficiency.

The incidence of PA is 25 new cases/year/100,000 persons older than 40 years. Although the average age of onset is 60 years, [1] it is increasingly encountered in persons 5 to 10 years younger.[247] PA is not a respecter of age, race, or ethnic origin.[248] The predisposition to developing PA may have a genetic basis but neither the mode of inheritance nor the initiating events or primary mechanism is precisely understood. There is a positive family history in 30% of patients, among whom the risk of familial PA is 20 times as high as in the general population; 20% of siblings of patients are projected to develop PA by the age of 90 years. PA developing concordantly in identical twins has been documented. [249]

There is a significant association of PA with other autoimmune diseases [1] [10] (i.e., the polyglandular autoimmune syndrome characterized by multiple endocrine hypofunction with antibodies to endogenous endocrine glands). Thus, PA is associated with Graves disease (30%), Hashimotos thyroiditis (11%), vitiligo (8%), Addisons disease, idiopathic hypoparathyroidism, and adult hypogammaglobulinemia. The histologic appearance of the gastric mucosa (infiltration with plasma cells

and lymphocytes) is also strongly reminiscent of autoimmune-type lesions. There is also a high incidence of anti-parietal cell IgG antibodies in the serum of 90% of patients with PA.[250] These anti-parietal cell IgG antibodies are cytotoxic to canine gastric parietal cells in vitro. [251] When chronically injected into rats, they decrease gastric HCl, IF, and pepsin secretion and lead to gastric atrophy. [10] The major antigen to which antibodies from patients with autoimmune gastritis and PA are directed is the acid-producing enzyme H^+ , K^+ -ATPase (a 92-kDa protein), found on the membrane of parietal cells. [252] The precise interplay of the various mechanisms for anti-parietal cell IgG-mediated dysfunction of parietal cells remains to be shown in vivo. It is not clear whether the target antigen of anti-parietal cell IgG found in up to 8% of the normal 3060-year-old population, 20% of women over 60 years old, and 5060% of patients with simple atrophic gastritis, is also H^+ , K^+ -ATPase, or another antigen. Anti-IF antibodies are found in the serum of 60% of patients with PA and in the gastric juice of 75%; 90% of patients with

PA have anti-IF antibodies in either serum or gastric juice. [10] Similar IF antibodies are quite rare in the general population; anti-IF antibodies are thus highly specific and confirmatory for PA.

There are two types of IF-antibodies: Type I are directed to the Cbl-binding site on IF and are usually of IgG subclass in the serum. In gastric secretions they may be both IgG and secretory IgA subclass. Type II IF antibodies bind to the IF-Cbl complex and prevent binding to ileal IF-Cbl receptors. Type II antibodies, usually not seen in the absence of type I antibodies, are found in 35% of patients with PA, although studies using a technique that detects both antibodies indicates a higher prevalence than previously documented.[253] Because of their functional properties, these intraluminal anti-IF antibodies may hasten the development of PA and interfere with tests for Cbl absorption.[10] Patients with anti-IF antibodies also have a higher T_4/T_8 cell ratio than those without anti-IF antibodies or controls. The significance of this is not clear, nor is the reason why patients with PA have an increased frequency of antibodies in serum directed against antigens from thyroid acinar cells, lymphocytes, renal collecting duct cells, and altered cellular immunity. [10]

The corticosteroid-responsiveness in some patients with PA (i.e., regeneration of atrophic gastric mucosa and increased IF secretion antedating a decrease in anti-IF antibodies) also implicates an autoimmune pathogenesis of PA.[10] The clustering of parietal cell dysfunction among first-degree relatives of patients with PA (in inbred populations), the fact that some individuals (96% of black women with PA) have high titers of blocking anti-IF antibodies but lack anti-parietal cell antibodies, [248] [254] and the fact that neither antibody may be detected in patients with PA and acquired agammaglobulinemia all suggest that the pathogenesis of PA is heterogeneous. Juvenile PA presents in the second decade with severe Cbl deficiency in conjunction with many of the associated endocrinopathies and autoantibodies observed in adults;[10] why these patients present so much earlier with an apparently identical disease is not known. Taken together, these facts suggest that although there is a genetic predisposition to PA, the full expression of the disease, which appears to have an autoimmune basis, may be modified by acquired environmental influences.

A very significant study from southern California determined that undiagnosed PA is common among the free-living elderly (over 60 years of age). [255] Among 729 individuals, 17 subjects were found to have PA, usually with only minimal clinical manifestations of Cbl deficiencyi.e., 1.9% of the survey population had unrecognized and untreated PA. The prevalence was 2.7% in women and 1.4% in men; but 4.3% of the black women and 4.0% of the white women had PA. Thus, undiagnosed PA is common among the elderly, especially among black and white women. It is significant that this study *did not* include elderly patients with Cbl deficiency caused by other disorders, or the still unknown number of younger people with unrecognized PA and other causes of Cbl deficiency. [255] If these findings can be extrapolated, 800,000 elderly people in the United States have undiagnosed and untreated PA! These individuals are at possible risk for masked Cbl deficiency if exposed to foods fortified with excess folate (discussed later in this chapter); this is the basis for calls for substantial caution, and more research, before further increasing the existing levels of folate fortification.

Abnormal IF Molecules

In three siblings, a defective IF molecule was identified by age 2 years that was identical to IF in all but one respectit was markedly susceptible to acid and proteolytic enzyme (pepsin or trypsin) digestion resulting in defective Cbl absorption by ileal IF-Cbl receptors and megaloblastic anemia. [256] In another case, an abnormal IF molecule having a 60-fold lower binding affinity for ileal IF-Cbl receptors resulted in lower (but not absent) Cbl absorption, probably accounting for the delayed clinical presentation with Cbl deficiency at the age of 13 years. [10]

Abnormal Events in the Small Bowel Lumen: Impaired Transfer of Cbl from R Protein to Intrinsic Factor

Insufficient Pancreatic Protease

Because 30% of patients with severe pancreatic insufficiency fail to degrade R proteins, there is no transfer of food Cbl to IF and consequent Cbl malabsorption (R-Cbl does not bind ileal IF-Cbl receptors). R proteins are highly susceptible to proteolysis by even small quantities of pancreatic protease released in response to food. Thus, in partial insufficiency there is abnormal absorption of CN- ^{57} CoCbl on an empty stomach but normal absorption when the CN-^{57} CoCbl is given with food. Administration of pancreatic extract normalizes Cbl malabsorption in those with complete pancreatic insufficiency. [10]

Inactivation of Pancreatic Protease

Pancreatic protease can be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger-Ellison syndrome. [10] The continued low pH of the luminal contents reaching the ileum may also perturb interaction of the IF-Cbl complex with IF-Cbl receptors (which requires a pH above 5.4).

Usurpation of Luminal Cbl

The near sterile condition of the small bowel is maintained by a combination of the mechanical cleansing action of peristalsis and the chemical action of gastric acid. Disorders conducive to relative stasis, impaired motility, and hypogammaglobulinemia are predisposing factors favoring colonization by bacteria. Many of these bacteria take up free Cbl, whereas the uptake of IF-bound Cbl is markedly diminished. However, if colonization extends proximally to the locus at which IF and Cbl interact, significant Cbl may be usurped before it can bind to IF. [10] Possible absorption of inert Cbl analogues produced by these bacteria may allow competition with normal Cbl to produce an additional anti-Cbl effect. [257] This Cbl malabsorption can be corrected to some extent by a 710 day course of antibiotic therapy; definitive surgical correction is indicated if the patient has significant symptoms (weight loss and diarrhea) that are only partially relieved by antibiotics. The malabsorption of food Cbl in patients with atrophic gastritis has also been normalized with antibiotics, thereby incriminating bacterial usurpation of food Cbl at a very proximal level. [258]

Approximately 3% of individuals infested with the fish tapeworm *Diphyllobothrium latum* develop frank Cbl deficiency. In the life cycle of this parasite, tapeworm eggs passed in human feces embryonate in cool freshwater; the ciliated embryos are swallowed by cyclops (the first intermediate host). After burrowing into the body cavity of the cyclops, they mature into the procercoid larval stage. The hapless cyclops (infected with procercoids) are then swallowed by freshwater fish (e.g., pike, perch, trout, salmon found in lakes in Russia, Japan, Switzerland, Germany, and North America) and procercoids then migrate into the fishs flesh (second plerocercoid larval stage). Humans become infected when they eat partially cooked or raw fish or fish roe containing plerocercoids which develop into adult worms in 6 weeks, growing to an amazing length of 10 meters (!) with up to 4,000 proglottids; [10] when these worms lay eggs, the life cycle is repeated. In a given patient the degree of Cbl deficiency is probably related to the number and extent to which worms lodge proximal to ileal IF-Cbl receptors. They are commonly found in the jejunum; poised in this strategic location, they avidly usurp Cbl for growth. [10] In fact, worm extracts

are so rich in Cbl that they have been used successfully to replenish Cbl in Cbl-deficient states. [10] Once ova have been identified in the stools, expulsion of the worms by praziquantel (510 g/kg, single dose, orally) and Cbl replenishment is invariably curative. So the price tag for eating raw fish or fish roe may involve more than the immediate expense for an exotic gastronomic delight.

Disorders of Ileal Intrinsic Factor (IF)-Cbl Receptors or Mucosa

Absence of IF-Cbl Receptors

The distal ileum has the greatest density of IF-Cbl receptors, and removal of only 12 feet of terminal ileum via resection or bypass can reduce ileal IF-Cbl receptor numbers or interaction with IF-Cbl, respectively, to result in Cbl malabsorption. [10] [259] [260] Thus, ileal bypass or diseased ileal architecture may lead to reduction in transenterocytic transport of Cbl (and folate) which is treatable with parenteral Cbl replacement.

Defective IF-Cbl Receptors or Post-IF-Cbl Receptor Defects

A heterogeneous group of congenital disorders in children involving selective Cbl malabsorption leading to megaloblastic anemias associated with mild, persistent, benign, nonspecific proteinuria (in 90% of cases) is collectively known as Imerslund-Gräsbeck syndrome. [10] These patients are heterogeneous with respect to precise biochemical abnormalities involving Cbl malabsorption. In one case an abnormality in ileal IF-Cbl receptors was demonstrated, [10] and recently among four cases from France, reduced IF-Cbl receptor activity was reported. [261] Most other cases appear to involve a post-receptor defect so parenteral therapy with Cbl bypasses the defect and reverses Cbl deficiency. [262]

Drug-Induced Defects

H_2 antagonists, but not omeprazole, inhibit IF secretion. [23] [263] However, the first of potentially several cases of malabsorption of Cbl from long term omeprazole has been reported.[264] Biguanides (i.e., metformin) appear to decrease IF and acid secretion in healthy volunteers; they also probably inhibit transenterocytic transport of Cbl in 7%;[265] given the magnitude of diabetics on metformin, this could lead to a significant problem. Other drugs (e.g., Slow-K, cholestyramine, colchicine, neomycin) probably also impair trans-epithelial transport of Cbl, [18] [19] manifested by a decrease in serum Cbl levels with mild to insignificant Cbl deficiency; these drugs also commonly interfere with the Schilling test.

Disorders of Plasma Cbl Transport

Absence of Transcobalamin I and Transcobalamin III

Congenital R-protein deficiency is not associated with cellular Cbl deficiency. However, because 80% of serum Cbl is bound to TC I, the serum Cbl levels will invariably be low. Two of six patients in one study have developed a biochemically uncharacterized neurologic syndrome, which has led to speculation that TC III deficiency may result in inability to clear Cbl analogues that may have a pathogenic role in the neurologic dysfunction. [10]

Deficiency of Transcobalamin II

Megaloblastic anemia in infancy associated with normal Cbl levels is the characteristic clinical presentation when TC II is absent or markedly deficient. [266] (Cbl levels are normal due to the TC I-bound Cbl, but this Cbl is unavailable for physiologic cellular uptake.) The impairment in intestinal absorption of Cbl in such patients is also due to the absence of TC II, which plays an important role in binding Cbl within the enterocyte prior to its entry into the circulation. In all, 30 patients have been described.[262] [267] They can be successfully treated by exploiting the property of passive intracellular diffusion of Cbl by daily or biweekly injections of 1 mg Cbl, which ensures Cbl delivery into cells. Based on animal studies, circulatory antibodies to TC II-receptor can cause its functional inactivation, suppress Cbl uptake by multiple tissues, and thereby cause severe Cbl deficiency and a failure to thrive. [268]

Defective Transcobalamin II

Defective TC II, also presenting with Cbl deficiency, can be diagnosed when the amount of TC II measured by radioimmunoassay (RIA) is normal but there is a qualitative abnormality based on its inability to bind Cbl. [48] Conversely, in another patient with normal amounts of TC II by RIA, the TC II was functionally active in binding Cbl but unable to facilitate the uptake of Cbl into cells. [269] Now, the molecular basis for these abnormalities can be determined since the human TC II gene has been cloned.[270]

Disorders of Intracellular Cbl Utilization

Congenital Metabolic Defects (Inborn Errors) of Cbl Metabolism, Cbl Mutants AF

The combination of megaloblastic anemia with increased tHcys and/or MMA in serum and urine despite normal Cbl and folate levels should suggest an inborn error of Cbl metabolism.[54] [262] [267] [271] The inherited defects of Cbl utilization (Fig. 28-2) are heterogeneous and are empirically defined as Cbl mutations *A* through *G* (*cblAcblG*) through the use of complementation studies involving in vitro fusion of cultured mutant fibroblasts obtained from skin biopsies. Mutants involving the synthesis of Ado-Cbl within the mitochondria involve defects in the reduction of Cob(II)alamin to Cob(I)alamin (*cblA*) and of Cob(I)alamin to Ado-Cbl by Ado-Cbl transferase (*cblB*). These defects result in an accumulation of excess MMA. The clinical picture in infancy is dominated by acidosis and ketosis associated with lethargy, failure to thrive, vomiting, dehydration, respiratory distress, hepatomegaly, and coma. Biochemical evidence of methylmalonic acidemia, ketonemia, and ketonuria *without* megaloblastosis is found. Because some of these defects are incomplete, treatment with large doses of Cbl may alleviate the defect. [54] [262] [267] [271]

Cloning of methylmalonyl-CoA mutase cDNA from fibroblasts of a patient with *mut*- phenotype where residual enzyme activity is evident in cultured cells exposed to high concentrations of OH-Cbl has identified a single base substitution (Gly ^{717} Val) as the basis for this mutant at the molecular level; moreover, this confirms that Ado-Cbl binds to determinants in the C-terminal portion of the enzyme. [272] Defects involving conversion of Cob(III)alamin to Cob(II)alamin (*cblC, cblD*) present with combined evidence of reduced activity of methylmalonyl-CoA mutase and methionine synthase (i.e., with increased tHcys and MMA in blood and urine). [54] [262] [267] [271] These patients have prominent neuropsychiatric problems with mental retardation, microcephaly, psychosis, delirium, and retinopathy with megaloblastosis. *cblC* mutants have hemolytic uremic syndrome as an integral manifestation of the spectrum of this disorder. [273] Although the disorder usually presents in infancy, some patients manifest problems in later childhood. Hydroxo-Cbl [Cob(III)alamin] appears to be more effective than CN-Cbl in these patients. *cblE* (distinguished by the lack of increase in MMA) is thought to be a defect arising from the inability to maintain Cbl bound to methionine synthase in its reduced state. [274] [275] *cblF* is due to the inability of Cbl to be transported from the lysosome

into the cytoplasm;[276] this has been visualized by quantitative electron microscopic radiography. [277] Recent molecular studies on a *cblG* patient have demonstrated defects in methionine synthase that can result in reduced activity. [59] [278] Among patients with mutant *cblG* defects, one patient presenting at the age of 21 years with a multiple sclerosis-like syndrome was initially undiagnosed simply because the serum Cbl level and studies of Cbl absorption were normal. [186] *This suggests that adults presenting with cerebral, myelopathic, or neuropathic disturbances (occasionally masquerading as multiple sclerosis) should be screened for such defects using the dU suppression test or serum tHcys and MMA levels that may reflect the biochemical disorder.*

Acquired Disorder of Cbl Utilization: Nitrous Oxide (N_2O) Exposure

N_2O inactivates coenzyme forms of Cbl by oxidizing the fully reduced Cob(I)alamin to Cob(III)alamin; this results in a state of *functional* intracellular Cbl deficiency. This syndrome was first identified in patients with tetanus given N_2O for up to 6 days;[279] subsequently, patients exposed to N_2O for open heart surgery, and through chronic (surreptitious, accidental, or occupational) exposure, such individuals have been recognized as being at high risk for developing megaloblastosis and Cbl-deficient neuromyelopathy. [280] [281] [282] Although megaloblastosis develops within 24 hours and lasts <1 week after a single exposure, the neurologic syndrome is usually seen with chronic intermittent exposure. However, severe neurologic deficits have been reported after prolonged intra-operative exposure to N_2O in patients with unsuspected Cbl deficiency.[283] The integrity of the methionine synthase-catalyzed reaction can be tested by measuring serum tHcys even after 75 minutes of exposure during surgery.[284] Reduced enzyme activity explains the metabolic block, which can be bypassed by 5-formyl-H_4 PteGlu (leucovorin).

CLINICAL EVALUATION OF CbI ABSORPTION

The Schilling Test

Nutritional deficiency and hereditary enzymatic defects of intracellular Cbl utilization account for a minority of cases of Cbl deficiency. Most patients with clinical Cbl deficiency have impaired Cbl absorption. If Cbl absorption is intact, CN- ^{57} CoCbl administered orally will first bind R-protein in the stomach. In the duodenum, the R-protein of the R-CN-^{57} CoCbl complex will be degraded by pancreatic protease resulting in rapid transfer of released CN- ^{57} CoCbl to the patients own IF. The CN-^{57} CoCbl-IF complex will travel down to the ileum where it interacts with specific IF-Cbl receptors. Once taken up by the enterocyte, CN- ^{57} CoCbl will be transported into the portal blood while bound to TC II. If the blood contains an excess of Cbl (from a flushing injection of exogenously administered Cbl), >8% of CN- ^{57} CoCbl will be excreted in the urine within 24 hours (*Stage I test*). If there is a decrease in endogenous IF, as in pernicious anemia (PA), <8% will ultimately be excreted; however, if IF is given exogenously with the CN-^{57} CoCbl, this abnormality will be corrected [1] (*Stage II test*). In situations in which there is usurping of CN- ^{57} CoCbl by bacterial overgrowth, resulting in decreased absorption of CN- ^{57} CoCbl plus IF, prior therapy with antibiotics for 710 days will correct Cbl malabsorption [1] [257] [258] (*Stage III test*); however, antibiotics will not correct Cbl malabsorption caused by fish tapeworm infestation or defects involving net deficiency of IF-Cbl receptors, e.g., ileal resection, fistulas, or diseases of the ileal mucosa (including TC II deficiency). (See Fig. 28-4 and Table 28-3.)

In pancreatic protease deficiency, CN-^{57} CoCbl remains bound to R protein and will not be transferred to IF, resulting in its diminished absorption and overall urinary excretion,[15] [17] an effect that is correctable by simultaneous administration of Pancrease (or Creon), or by carrying out the test while the patients pancreas is optimally stimulated with a meal or secretin. In the rare syndrome in which IF is unusually susceptible to degradation by acid and pepsin, the abnormal Schilling test can be partially corrected by administration of sodium bicarbonate. [256] Patients with hypochlorhydria and inability to proteolytically release food Cbl (with consequent low serum Cbl with or without clinical manifestations of Cbl deficiency) have a normal Stage I Schilling test since they have no problem with absorbing *crystalline* CN-^{57} CoCbl. The appropriate test to order under these circumstances is the food-CN- ^{57} CoCbl absorption test, which determines the patients capacity to release CN- ^{57} CoCbl bound to food (e.g., egg or chicken serum protein) and thereby identify malabsorption of food-bound CN- ^{57} CoCbl.[12] [13] [14] [241]

With rare exceptions, adults with Cbl deficiency have either Cbl malabsorption (from PA, food-Cbl malabsorption, infestation with *D. latum*, bacterial overgrowth, or ileal malabsorption), or in vegetarians, dietary Cbl insufficiency (see box on Etiopathophysiologic Classification of Cbl Deficiency). All of these conditions can be treated similarly with either monthly parenteral Cbl or daily oral Cbl (discussed later in this chapter). Because information on the cause and locus of Cbl deficiency does not appear to alter or direct therapy with Cbl, does the identification of the locus of Cbl malabsorption make any difference to the outcome in adults (i.e., should a Schilling test be done at all)? Two compelling arguments in favor of the Schilling test are: (1) The test results can suggest additional diagnostic tests (intestinal biopsy, examination of stool for malabsorption or

TABLE 28-3 -- Results of Schilling Tests

Condition	Material Administered				
	CN-[^{57} Co]Cbl Plus H_2O	CN-[^{57} Co]Cbl Plus IF	CN-[^{57} Co]Cbl After 710 Days of Antibiotics	CN-[^{57} Co]Cbl Plus Pancreatic Extract	CN-[^{57} Co]Cbl-Food Cbl Absorption Test

Inadequate dissociation of food Cbl	N				Low

[a]N, results indicate normal absorption; low, results indicate less than normal absorption.

ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF COBALAMIN DEFICIENCY

I. Nutritional Cbl Deficiency (insufficient Cbl intake) Vegetarians, vegans, breast-fed infants of mothers with pernicious anemia
II. Abnormal Epigastric Events (inadequate proteolysis of food Cbl)
Atrophic gastritis, partial gastritis with hypochlorhydria, omeprazole, H_2 -blockers
III. Loss/Atrophy of Gastric Oxyntic Mucosa (deficient IF molecules)
Total or partial gastrectomy, pernicious anemia, caustic destruction (lye)
IV. Abnormal Events in Small Bowel Lumen
  A. Inadequate pancreatic protease (R-Cbl not degraded, Cbl not transferred to IF)
    1. Insufficient pancreatic proteasepancreatic insufficiency
    2. Inactivation of pancreatic proteaseZollinger-Ellison syndrome
  B. Usurping of luminal Cbl (inadequate Cbl binding to IF)
    1. By bacteriastasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (scleroderma, pseudo-obstruction), hypogammaglobulinemia
    2. By *Diphyllobothrium latum* (fish tapeworm)
V. Disorders of Ileal Mucosa/IF-Cbl Receptors (IF-Cbl not bound to IF-Cbl receptors)
  A. Diminished or absent IF-Cbl receptorsileal bypass/resection/fistula
  B. Abnormal mucosal architecture/functiontropical/nontropical sprue, Crohns disease, TB ileitis, infiltration by lymphomas, amyloidosis
  C. IF-/post IF-Cbl receptor defectsImerslund-Gräsbeck syndrome, TC II deficiency
  D. Drug-induced effects (Slow-K, biguanides [metformin], cholestyramine, colchicine, neomycin)
VI. Disorders of Plasma Cbl Transport (TC II-Cbl not delivered to TC II receptors)
Congenital TC II deficiency, defective binding of TC II-Cbl to TC II receptors (rare)
VII. Metabolic Disorders (Cbl not utilized by cell)
  A. Inborn enzyme errors (rare)
  B. Acquired disorders: (Cbl functionally inactivated by irreversible oxidation)N_2 O inhalation

D. latum infestation) and specific therapy (gluten-free diet, folate, antibiotics, or antihelminthics), and (2) this in turn identifies the potential for reversibility and thereby dictates the duration of Cbl replacement.

The most common cause of an abnormal Schilling test[10] [212] is incomplete collection of urine. Patients with renal impairment will also excrete less than normal amounts of radioactive Cbl. Although this potential pitfall can be avoided by sampling plasma after administration of CN- ^{57} CoCbl, there is significant overlap of results between patients with true PA and normal individuals; and ideally this requires the use of equipment for whole body counting which is not widely available.

The flushing dose of unlabeled Cbl administered during the Schilling test will invalidate further testing of serum Cbl and initiate a hematologic response in Cbl-deficient patients. Technical difficulties (resulting in diagnosis of Cbl malabsorption in the face of normal Cbl status) include (1) renal failure; (2) incomplete urine collection; (3) failure to give either the test or flushing dose; (4) use of decomposed CN- ^{57} CoCbl or inert IF; and (5) simultaneous ingestion of drugs that impair Cbl absorption. False normal values in the presence of true Cbl deficiency can arise from contamination of urine with stool containing unabsorbed CN- ^{57} CoCbl and the presence of another isotope used in diagnostic tests (^{99m} Tc or ^{67} Ga). It is thus crucial to be alert to the timing of the Schilling test relative to other nuclear imaging studies. So with prior administration of ^{99m} technetium-based radiopharmaceuticals and ^{123} NaI wait 1 week; with ^{67} gallium-citrate and various ^{111} indium compounds,^{131} I-MIBG, and ^{201} thallous chloride wait 6 weeks, but with^{131} NaI, depending on residual thyroid uptake, wait 4 months. [285]

Furthermore, it should be re-emphasized that because Cbl/folate deficiency causes megaloblastosis of intestinal cells, the Stage I Schilling test (with CN- ^{57} CoCbl alone) may be abnormal in folate deficiency; or, a patient with IF deficiency (e.g., PA) may be diagnosed as having an abnormal Stage II test from an intestinal cause.[10] This phenomenon occurs often enough (2575% of cases) to warrant a repeat Stage II Schilling test in patients diagnosed as having Cbl malabsorption (from an intestinal cause) after 2 months of Cbl replacement; only patients with PA will correct in the Stage II test (Table 28-3).

Gastric Analysis

A significant titer of IF antibodies of the blocking type in gastric juice will lead to an abnormal Stage II Schilling test. This is overcome by using an augmented Stage II test with a higher dose of IF. Moreover, a clue as to whether these patients have gastric IF antibodies will be found in the serum, which may contain IF antibodies. Gastric analysis for achlorhydria in adults is valuable only in the single situation in which the presence of gastric acidity in response to maximal stimulation (e.g., Histalog) helps exclude the diagnosis of PA. In children, however, gastric analysis for IF and acid can differentiate between congenital IF deficiency (acid present), juvenile PA (acid and IF absent), and Imerslund-Gräsbeck syndrome (acid and IF present).

The assay for anti-IF blocking antibodies depends on the displacement of CN- ^{57} CoCbl binding to IF in vitro. This can be significantly affected by prior injection of Cbl (as given with a Schilling test) or by radioactive isotopes from other diagnostic tests (see discussion earlier in this chapter).

PATHOGENESIS OF FOLATE DEFICIENCY

Folate deficiency is usually recognized in the course of certain clinical presentations that predispose to negative folate balance and subsequent deficiency. It is instructive, therefore, to conceptualize cellular folate deficiency as arising from etiologic categories of *decreased supply* (reduced intake/absorption/transport/utilization), or *increased requirement* (metabolic consumption/destruction/excretion). However, in the same patient more than one mechanism may result in net folate deficiency. The precise contribution of one mechanism over the other is often not obvious. Specific tests to define each mechanism are not routinely available for clinical use.

Manifestations of folate deficiency may be hematologic (pancytopenia with megaloblastic marrow), cardiopulmonary, gastrointestinal (megaloblastosis with or without malabsorption), dermatologic (skin pigmentation), genital (megaloblastosis of cervical epithelium), infertility (sterility), and psychiatric (Table 28-4). These manifestations are discussed within the context of the history and physical examination. Cases of neuropathy attributed to folate deficiency are rarely encountered; when they are, the possibility of alcoholism with thiamine deficiency must be considered. In any case, every patient with neuropathy, myelopathy, or psychiatric manifestations associated with megaloblastosis

TABLE 28-4 -- Megaloblastic Sequelae of Folate and Cbl Deficiency and Several Clinical Manifestations Are the Same[a] (***However, the neurologic spectrum of dysfunction with Cbl deficiency is distinct***)**

Hematologic	Pancytopenia with megaloblastic marrow
Cardiopulmonary	Congestive heart failure
Gastrointestinal	Beefy-red tongue and added stigmata of broad spectrum malabsorption in folate deficiency[b]
Dermatologic	Melanin pigmentation and premature graying
Genital	Cervical/uterine dysplasia
Reproductive	Infertility/sterility
Psychiatric	Depressed affect/cognitive dysfunction
Neuropsychiatric[c]	Unique to Cbl deficiency with cerebral, myelopathic, or peripheral neuropathic disturbances including optic and autonomic nerve dysfunction

[a]Inadequate hemoglobinization (from inadequate iron stores and/or globin synthesis) will mask the expected erythroid megaloblastic morphology in the bone marrow and peripheral smear, and only specific therapy (e.g., iron) will unmask classic megaloblastic manifestations (*masked megaloblastosis*). Megaloblastic leukopoiesis will be unchanged.
[b]If folate deficiency is uncorrected for >23 years, Cbl deficiency will supervene.
[c]Dorsal tract involvement is earliest manifestation in >70% patients with Cbl deficiency. Neuropsychiatric manifestations are unassociated with megaloblastosis in up to 30% of patients.

must be investigated in detail to rule out Cbl deficiency. It must be remembered that gastrointestinal megaloblastosis begets further folate malabsorption, which propagates a vicious cycle of folate deficiency in the short term and Cbl deficiency in the long term. With the exception of drug-induced defects or inborn errors of folate metabolism that result in decreased utilization of intracellular folates, all etiologies, irrespective of mechanism, result in reduced net delivery of folates to normal proliferating cells. So in pursuing the causes of folate deficiency in a given patient, efforts should be directed toward obtaining positive evidence for all possible conditions predisposing to negative folate balance and deficiency.

Nutritional Causes of Folate Deficiency

Decreased Intake and/or Increased Requirements

The body stores of folate are adequate for only 4 months. [1] [3] [4] [286] The requirement for folate is 100 g/day in adults and 50 g/day in children, which is 5 times the adult requirement on a weight-for-weight basis. Folate stores are probably depleted much earlier in individuals who are chronically in negative folate balance or who have additional conditions that can tip them into true folate deficiency. The incidence of folate deficiency in the setting of general malnutrition in developing countries is very high and is invariably a problem of multiple vitamin deficiencies when associated with protein-calorie malnutrition (38,000 children die *every day* of hunger and starvation-related illness). [287] Decreased availability of folate-rich foods (in winter, after natural disasters, or the wet season in central Africa), poverty, various cultural/ethnic diets (consisting of maize, rice or well-cooked beans and vegetables), and cooking techniques that destroy food folate, coupled with the anorexia that accompanies chronic illnesses, are just a few of the reasons for rapid development of folate deficiency. [1] [3] [4] [65] [288] [289]

The rapidly proliferating tissues in children have an absolute requirement for exogenously supplied folate. Although human or cows milk is barely adequate to maintain folate balance in breast-fed infants, superimposition of associated illnesses that lead to anorexia or folate malabsorption readily shifts them into negative folate balance. Infants fed powdered milk formulas, goats milk (only 6 g/L folate), or milk that has been boiled (over 50% of folate may be destroyed) are at high risk in this regard, as are those on restricted formulas for phenylketonuria and maple syrup urine disease. In Western countries food faddism, alcoholism, and slimming diets usually lead to decreased folate intake in young to middle-aged individuals. [1] [10] Although beer has a higher folate content than other alcoholic beverages, alcoholism may lead to neglect of healthy dietary practices in favor of the high calories and high of alcohol. The edentulous, infirm, or neglected elderly who are too ill to prepare their meals, as well as psychiatric patients, are particularly at risk for nutritional folate deficiency. [147]

Pregnancy, Infancy, and Human Development

Except for malnutrition in children, pregnancy with poor folate intake is the most common cause of megaloblastic anemia in the world. Pregnancy and lactation are associated with significantly higher folate requirements (300400 g/day) for growth of the fetus, placenta, breast, and other maternal tissues; recent studies have identified increased catabolism of folate during pregnancy as yet another cause predisposing to deficiency. [290] This demand for folate must be met by adequate dietary intake. The placenta has a large number of folate receptors (FR), [103] [291] which facilitate binding and transport of folates to the developing fetus (see discussion later in this chapter). In fact, preferential delivery of folate to the fetus can cause or aggravate folate deficiency in the mother. [10] [147] This is observed clinically when a mother with severe folate deficiency gives birth to a baby who has normal folate stores. Although this invariably recalls the metaphor of the fetus as a parasite, [10] it is

also a vivid physiologically relevant experiment of nature that indicates the existence of a clearly defined mechanism to protect the fetus from the consequences of folate deficiency during critical stages in its growth and development. Folate deficiency in the pregnant mother can nevertheless lead to decreased placental weight and premature, low birth weight infants.[10] In this context, it is significant that (folate-responsive)-hyperhomocysteinemia is now recognized as a risk factor for women with unexplained recurrent early pregnancy loss,[292] [293] as well as in placental abruption or infarction;[294] thus the very significant protective role of folates for the fetus.

How do folates traverse the placenta from mother to fetus? Prior studies have determined that although transplacental folate transport involves a system that is concentrative and resistant to decreased maternal folate, it is sensitive to maternal folate loads such that, when presented with higher than normal folate levels, transport to the fetus is enhanced. Recently, an ex vivo human placental cotyledon perfusion model demonstrated that under physiologic conditions, placental FR had a major functional role in transplacental folate transport.[86] These studies (Fig. 28-8) indicate that net maternal-to-fetal folate transfer is a process consisting of two steps: First, is the concentrative component in which circulating 5-methyl-tetrahydrofolate (5-methyl-H_4 PteGlu) is bound to (i.e., captured by) placental FR on the maternally facing chorionic surface. Although kinetics favor binding, a dynamic state exists wherein a gradual release of 5-methyl-H_4 PteGlu from this pool adds to incoming circulating folates to generate an intervillous blood level 3 times that in the maternal blood. In the second step, folates are transferred to the fetal circulation along a downhill concentration gradient. Thus, it turns out that the prodigious, reversible, high-affinity binding of maternal folates by placental FR [103] [291] is *the* key modulator of transplacental folate transport. In fact, once captured, placental FR-bound folates are predestined for transplacental folate transport, since incoming (dietary) folates displace placental FR-bound folates which then passively diffuse down a concentration gradient to the fetus. And so this elegant cycle goes on, ensuring continued unidirectional transplacental folate transport (Fig. 28-8).

The incidence of megaloblastic marrows in the United States, Canada, and the United Kingdom during late pregnancy is

Figure 28-8 Diagrammatic representation of maternal-to-fetal transplacental folate transport involving placental folate receptors (PFR). *(Adapted from Henderson et al.,[86] with permission. Copyright 1990 by Annual Reviews.)*

25% but in southern India it is 55%.[10] Folate deficiency is eight times as high in twin pregnancies. Multiparity (multiple frequent pregnancies with a prolonged state of negative folate balance) and hyperemesis gravidarum commonly lead to folate deficiency. Because the anemia of pregnancy is most frequently caused by iron deficiency, combined iron and folate deficiency (dimorphic anemia) is the more frequent clinical presentation. Increased utilization of folates in newborns leads to a drop in folate levels by 6 weeks. This drop is exaggerated in premature infants, who because of feeding difficulties, infection, or hemolytic disease often develop pure folate deficiency.[1] [65] [147]

Unambiguous evidence now shows that *periconceptional* folate supplementation (800 g/day) for *normal women* reduces the incidence of neural tube defects (spina bifida, meningocoele, anencephaly).[295] The recognition that folate consumption is not optimal in adolescent girls [296] is a matter for concern given the importance of optimizing folate status in women of childbearing age to prevent neural tube defects. The Food and Drug Administration (FDA) has recommended food fortification with folic acid to certain foods to ensure adequate folate intake in order to prevent folate-responsive neural tube defects (discussed later in this chapter). In addition, periconceptional folic acid in higher doses (4 mg per day) also protects 75% of fetuses of women at risk (defined as women who have previously given birth to a child with neural tube defects) who have a 10-fold increased risk for delivering a subsequent child with the same disorder. [297] [298] In addition, unconfirmed data also suggest that folic acid administered periconceptionally in high doses (10 mg/day) may reduce the incidence of cleft lip. [299] [300]

The issue of folate supplementation has been extended to the animal sciences where the dramatic increase in conception rate, live births, and overall reproductive performance achieved[301] [302] verifies many of the clinical observations discussed earlier in this chapter.

From studies on periconceptional folate supplementation, folate is clearly necessary for the developing fetal nervous system. In addition, in newborns with congenital folate malabsorption syndrome (where a concomitant reduction of folate transport into the nervous system is accompanied by mental retardation, cerebral calcifications, seizures, and peripheral neuropathy), several of these complications can be avoided with early recognition and therapy with parenteral folate alone. [10] [225] [303] Interestingly, folate-deficient weanling mice tend to discard and spill more food than controls! [304]

The mechanism whereby periconceptional folate intake reduces both the *occurrence and recurrence* risk of neural tube defects is incompletely understood. A genetic basis for elevation of plasma tHcys levels has been identified in some families with spina bifida offspring involving a common 677CT mutation in the 5,10-methylene-tetrahydrofolate reductase gene, which causes thermolability of the enzyme (thermolabile MTHFR). There was a significantly higher prevalance of a ++ genotype among spina bifida patients and their mothers with the strongest risk if both mother and child were homozygous for the mutation. [304] [306] However, this genetic basis accounts for only 15% of all cases of spina bifida. Of related significance, most subjects with intermediate hyperhomocysteinemia (i.e., >40 M; nearly 3 times more than normal limits) in the general population have the C677T mutation combined with low folate status, and a daily supplement of low-dose folic acid will reduce and often normalize their tHcys level. [307] [308]

Intrinsic Hematologic Disease

Because folate is necessary for hematopoiesis, folate requirements are increased when there is (1) significant compensatory erythropoiesis in response to peripheral red blood cell destruction, (2) abnormal hematopoiesis, or (3) infiltration by abnormal cells in marrow. The recognition that folate deficiency developing in hemolytic disorders can lead to an acute aplastic crisis has led to routine prophylactic administration of folate. An unexpected increase in transfusional requirement or a fall in platelets should also suggest folate deficiency.[1] [65] [147]

Folate Malabsorption with Normal Intestinal Mucosa

Inhibition of brush border pteroylpolyglutamate hydrolase has been suggested but not documented as a mechanism whereby some drugs cause folate deficiency. Further functional studies following purification of the enzyme,[66] which is apparently functionally active,[309] should clarify the issue.

Congenital Folate Malabsorption

Patients with this disorder (usually the progeny of consanguineous marriages) present in the first 3 months with failure to thrive, diarrhea, sore mouth, megaloblastic anemia with low serum-, RBC-, and cerebrospinal fluid folates, normal Cbl levels, progressive mental retardation, seizures, cerebral calcification, athetosis, and ataxia. They do not respond to oral folate or 5-formyl-H_4 PteGlu (5 mg) because of specific intestinal folate malabsorption as well as defective folate transport into the central nervous system.[310] [311] Parenteral therapy in high concentrations

is necessary to ensure passive folate transport. These experiments of nature are the best evidence for (1) a specific, carrier-mediated transport system for folates in the gut and central nervous system, and (2) the occurrence in vivo of passive folate transport at high extracellular folate concentrations. Although the details of the former are incompletely understood, the latter has been experimentally demonstrated in vitro,[148] and in vivo during high-dose antifolate protocols.[149] Furthermore, the mental retardation and peripheral neuropathy in some of these individuals suggest a role of folates in maintenance of normal functioning of the nervous system. To establish the diagnosis, it is necessary to document that the patient has normal gastrointestinal absorption of other nutrients, intact pancreatic function, and normal mucosa on small intestinal biopsy. The differential diagnosis includes congenital IF deficiency, Imerslund-Gräsbeck syndrome, TC II deficiency, and inborn errors of Cbl metabolism.

Folate Malabsorption with Intestinal Mucosal Abnormalities

Tropical Sprue

Residents of, and visitors to, endemic areas in the tropics can acquire a disorder of unknown etiology characterized by small intestinal malabsorption. [10] [147] [312] [313] Generalized, nonspecific small bowel malabsorption leads to a wide spectrum of clinical manifestations arising from defective absorption of fat, carbohydrate, albumin, calcium, folate, and in later stages, Cbl.[10] The endemic nature of this disorder in the tropics, (and in certain households), [10] and the beneficial response to antibiotics [1] all suggest an infectious etiology. However, the dramatic response to folate, which is curative in the first year in 60% of cases (this cure is cited to be almost diagnostic of the disease) has not been explained. [1] [10] [147] It is unlikely that pure folate deficiency is the primary cause, since nutritional folate deficiency does not result in tropical sprue; the clinical response to antibiotics suggests a close interplay between a pathogenic infectious agent, endogenous flora, and the folate status of the enterocyte.

There is a varying degree of villous atrophy and loss of intestinal functional surface. Although less severe than in nontropical sprue, it is more extensive, involving the entire small intestine. There is abrupt onset of explosive, intermittent, or continuous diarrhea, abdominal distension, and pain associated with anorexia, vomiting, and extreme fatigue. Stools are fluid or semisolid and frequently contain mucus and blood. This stage is followed weeks to months later by nutrient deficiency. Later, as steatorrhea continues, megaloblastosis dominates the clinical picture. In the short term malabsorption leads to folate deficiency, but later in the chronic (longer than 3-year) phase of the disease, Cbl malabsorption contributes additional clinical manifestations of Cbl neuropathy. [1] [10] [147]

Coexisting iron deficiency (common in these areas) leads to a dimorphic blood picture; pellagra and beri-beri may also coexist in these patients. Treatment of the chronic phase with folate will cure the hematologic manifestations but exacerbate Cbl-deficient neurologic disease. In Southern India, among 64 patients with megaloblastic anemia from tropical sprue, 21% were due to Cbl deficiency, 33% to folate deficiency alone and 44% to combined Cbl and folate deficiency. [1] [10] [147] After investigations for associated iron, Cbl, and folate deficiency, therapy with folate and a broad-spectrum antibiotic is indicated together with symptomatic treatment of diarrhea, vomiting, fluid, mineral and electrolyte imbalance, and associated additional nutritional deficiencies. [10]

Nontropical Sprue (Celiac Disease, Gluten-Induced Enteropathy)

Nontropical sprue is the most common cause of intestinal malabsorption in temperate zones. It results from a possibly inherited sensitivity to gluten (a glutamine-rich protein found in wheat and other grains) and a related substance, gliadin. [10] The precise mechanism for induction of sensitivity is not known. The intestinal lesion (villous atrophy with hypertrophied crypts and lymphocytic and plasma cell infiltrate of the lamina propria), is more florid than that seen in tropical sprue but occurs to a greater extent in the proximal small intestine with relative ileal sparing; as a result, Cbl malabsorption is less common. The consequences of malabsorption are otherwise the same. Patients present between the ages of 3050 years with intermittent or persistent diarrhea (abrupt in 20%), weight loss, abdominal distension with discomfort, glossitis, and megaloblastic anemia. Diagnosis is established by demonstration of anti-gliadin and anti-endomysial antibodies (*gt;90% specificity), malabsorption, the characteristic radiographic moulage sign, and jejunal biopsy. The symptoms are exacerbated following a challenge with gluten and institution of a gluten-free diet not only is curative but also decreases the risk of subsequent malignancy (small intestinal lymphoma or gastrointestinal carcinoma, especially esophageal). Evidence of iron deficiency may be prominent in children. The megaloblastosis responds well to folate therapy. [1] [10] [147]

Regional Enteritis and Other Small Intestinal Disorders

The distal small intestine is involved in 80% of individuals with Crohns disease, but folate is efficiently absorbed in other more proximal areas. Thus, only with extensive involvement or

ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF FOLATE DEFICIENCY

I. Nutritional Causes
   A. Decreased dietary intake Poverty and famine, institutionalized individuals (psychiatric/nursing homes)/chronic debilitating disease/goats milk (low in folate), cultural/ethnic cooking techniques (food folate destroyed), or special slimming diets or food fads (folate-rich foods not consumed)
   B. Decreased diet and increased requirements
      1. Physiologic: Pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy
      2. Pathologic: *Intrinsic hematologic diseases* involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration with malignant disease *Dermatologic disease*psoriasis
II. Folate Malabsorbtion
   A. With normal intestinal mucosa
      1. Some drugs (controversial)
      2. Congenital folate malabsorption (rare)
   B. With mucosal abnormalities: tropical and nontropical sprue, regional enteritis
III. Defective Cellular Folate Uptake Familial aplastic anemia (rare)
IV. Inadequate Cellular Utilization Folate antagonists (methotrexate) Hereditary enzyme deficiencies involving folate
V. Drugs (multiple effects on folate metabolism) Alcohol, sulfasalazine, triamterine, pyrimethamine, trimethoprim-sulfamethoxazole, diphenylhydantoin, barbiturates
VI. Acute Folate Deficiency (intensive care unit setting, uncertain etiology)

fistulas do these patients develop folate deficiency. Even in this case, the blood picture is more that of an iron deficiency or anemia of chronic disease. Frank, pure megaloblastic anemia occurs rarely enough in this setting to suggest another etiology for folate or Cbl malabsorption. [1] [147] HIV infection results in an enteropathy, in the absence of opportunistic infection, which leads to the malabsorption of folates. [314]

Defective Cellular Folate Uptake (Familial Aplastic Anemia)

A very rare syndrome of familial aplastic anemia thought to result from defective cellular folate uptake is presumed to reflect a defect in the physiologic membrane transporter for folates.[315] Although the precise biochemical defect is uncertain, patients with this syndrome only respond to suprapharmacologic doses of folates (which presumably enter cells by passive diffusion or via the RFC). The disorder presents in young adulthood with pancytopenia, megaloblastosis, and an aplastic (or myelodysplastic) marrow.[316] The diagnosis should be considered when serum Cbl and folate are normal and the red blood cell folate (by microbiologic assay) is low and Cbl metabolic defects have been excluded.

Inborn Errors of Folate Metabolism

Knowledge of the intracellular metabolic pathways involving folates can help predict the net effect of deficiency of a single enzyme (Fig. 28-7). Substrate buildup or product deficiency leads to the clinical manifestations. The precise biochemical defects can be proved by specific enzyme assays of the patients fibroblasts.

Deficiency of 5,10-methylene-tetrahydrofolate reductase (MTHFR) is the most frequent of these rare disorders and presents with excess tHcys in the serum and urine and with hypomethioninemia. The disease is recognized in infancy because of developmental delay/mental retardation, with motor abnormalities and disturbance in gait. It has, however, occasionally remained undiagnosed until the teenage years. Serum folates are normal or low, but Cbl is normal. There is no megaloblastosis, TC II levels are normal, and there is often a poor response to PteGlu. Despite a variety of treatments administered, no consistent pattern of response has emerged (which may reflect significant genetic heterogeneity within this disorder). [329] Excellent reviews of these and other inborn errors of folate metabolism are available. [262] [267]

Acute Folate Deficiency

The cause of acute folate deficiency in some patients in intensive care units is not known. Clinically the presentation is acute megaloblastic arrest of hematopoiesis with thrombocytopenia. These patients are often acutely ill and in subclinical negative folate balance. The combination of additional insults (decreased intake, total parenteral nutrition containing ethanol, dialysis, surgery, sepsis, drugs) appears to provoke frank folate deficiency. The serum folate, remarkably enough, is often normal in the face of megaloblastosis in the bone marrow without obvious peripheral blood abnormalities. The dU suppression test has documented intracellular folate deficiency, but there is no data on MMA and tHcys levels in this condition. Empiric therapy with 5-formyl-H_4 PteGlu (leucovorin) is recommended. Exposure to N_2O [279] should also be considered in the differential diagnosis. [147] [225]

MEGALOBLASTIC ANEMIA NOT DUE TO FOLATE OR COBALAMIN DEFICIENCY

In Western countries, chemotherapeutic agent-induced megaloblastic anemias may be more common than those caused by folate or Cbl deficiency. Several chemotherapeutic agents (antimetabolites, alkylating agents, etc.) kill malignant cells primarily by interfering with DNA synthesis; megaloblastosis is therefore an expected side effect. Hereditary orotic aciduria usually presents in the first year of life, due to deficiency or absence of enzymes that convert orotic acid to uridine monophosphate via orotidine monophosphate. The net cellular deficiency of uridine monophosphate leads to perturbed synthesis of DNA as well as RNA. [10] Thiamine deficiency in the DIDMOAD syndrome (*d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, *m*egaloblastosis, *o*ptic *a*trophy, and sensorineural *d*eafness) due to an inability to transport physiologic thiamine is another rare cause for megaloblastosis in childhood. [330]

CLINICAL PRESENTATIONS AND EVALUATION FOR FOLATE AND Cbl DEFICIENCY

Clinical presentations and evaluations for folate and Cbl deficiency are shown in Table 28-4 .

Interview

The patients general demeanor and answers to questions may reveal a blunted affect with evidence of depression, irritability, forgetfulness, and sleep deprivation (common in pure folate deficiency). Alternatively, Cbl deficiency may present with paranoid ideation (mimicking paranoid schizophrenia), dementia, cognitive dysfunction, delusions, or lack of energy manifested by slowed responses. Hallucinations or even obtundation may preclude obtaining an adequate history. The family may indicate the progressive evolution of a marked personality change and may be able to help trace the evolution of symptoms and deviations from the time when the patient was last well. Intermittent therapy with multivitamins, liver pills, and/or injections (often given by a well-meaning family member or unregistered practitioner) is a common quick fix remedy in many cultures. The family is a good source for details on the patients dietary habits (food faddism, vegetarianism, alcohol intake), and family history of medical problems (blood diseases, gluten sensitivity, autoimmune diseases).

A past medical history of epilepsy or alcoholism with seizure disorder (anticonvulsant therapy) is important. Rarely, patients with autoimmune hemolytic anemias may be lost to follow-up and return with acute aplastic crises when they run out of folate. A past surgical history of total or partial gastrectomy and/or anastomosis, fistula, or bowel resection will reveal the potential for perturbation of physiologic absorption (loss of IF, bypassing or loss of absorptive surface, blind loop syndromes). Surreptitious

MISCELLANEOUS MEGALOBLASTIC ANEMIAS NOT DUE TO COBALAMIN OR FOLATE DEFICIENCY

I. Congenital disorders of DNA synthesis
   A. Orotic aciduria
   B. Lesch-Nyhan syndrome
   C. Congenital dyserythropoietic anemia
II. Acquired disorders of DNA synthesis
   A. Deficiencythiamine responsive (DIDMOAD)
   B. Malignancyerythroleukemia
      1. Refractory sideroblastic anemias
      2. All antineoplastic drugs that inhibit DNA synthesis (including antinucleosides used against HIV and other viruses)
   C. Toxicalcohol

or accidental inhalation of N_2O in an occupational setting (dental or anesthesiology professionals) and deliberate inhalation of N_2O (cartridges attached to whipped cream dispensers or visits to houses of laughter, where N_2O can be inhaled for a small fee) will be revealed only on direct questioning. Visits to tropical countries and the development of intermittent episodic diarrhea may give a clue to tropical sprue; prolonged (>3 years) chronic gastrointestinal symptoms followed by insidious development of neurologic problems predicts a combined (folate followed by Cbl) deficiency.

Systemic review of symptoms may range from none (incidental increased mean corpuscular volume and/or PMN hypersegmentation) to severe (unstable angina from severe anemia). With slow development of anemia, the patient will often not develop cardiopulmonary symptoms until there is a 50% reduction in hemoglobin concentration, which leads to dyspnea on exertion, palpitation, and generalized fatigue or lethargy. Only when hemoglobin is below 5 g/dL will the patient develop dyspnea at rest and angina on modest exertion or even at rest. Congestive heart failure is heralded by pedal edema, nocturia, orthopnea, and tender hepatomegaly.

Upper gastrointestinal symptoms with anorexia associated with intrinsic gastrointestinal disease or anemia with heart failure must be distinguished from symptoms due to glossitis. The latter may lead to inability to wear dentures, tolerate hot drinks or spicy foods because of burning, and even odynophagia, which may compromise further food intake (seen in both Cbl and folate deficiency). The patient may volunteer that glossitis is relieved by multivitamin ingestion, at which time the interviewer should remember to ask questions related to the subsequent evolution of neurologic symptoms. Weight loss in Cbl deficiency is not as severe as in folate deficiency arising from intrinsic gastrointestinal disease. Episodic or chronic diarrhea with steatorrhea is commonly due to tropical sprue, although it may be brought on by gluten-containing foods. Although these symptoms may be accompanied by abdominal pain, pain in the absence of diarrhea could be due to tabetic crisis (vomiting, abdominal rigidity, absence of leukocytosis, or fever) accompanying spinothalamic involvement in Cbl-deficient myelopathy.

The patient with PA may have two or three semisolid bowel movements per day; although this may be construed as a normal pattern, it may in fact represent a change since the last time the patient was well. Constipation may be related to obstipation arising from involvement of Meissners and Auerbachs plexus within the gastrointestinal tract. Similarly, incipient loss of

DRUGS THAT PERTURB FOLATE METABOLISM

Ethanol in amounts >80 g/day is toxic to hematopoietic precursors and can directly lead to megaloblastosis with abnormal vacuolization of normoblasts as well as to sideroblastic anemias; these toxic changes seen in severe alcoholics are usually associated with significantly higher alcohol consumption and revert to normal with alcohol withdrawal. Patients who have one nutritious meal each day tend to stave off the eventual development of folate deficiency. [317] Alcohol consumption leads to a relatively rapid (24-day) fall in serum folates. This is a result of the combined effects [147] of increased urinary folate excretion (by decreasing the percentage reabsorption and increasing the fractional excretion of 5-methyl-H_4 $PteGlu_n$) leading to net impaired renal conservation; [318] interruption of the enterohepatic circulation (resulting from an effect on hepatic pteroylpolyglutamate synthesis and reduced release of tissue folates into plasma and/or bile); formation of acetaldehyde/H_4 PteGlu adducts (5,10-(CH_3-CH)-H_4 Pte-Glu_n); increased catabolism of 5-methyl-H_4 $PteGlu_n$ folic acid by ethanol acetaldehyde/xanthine oxidase generated superoxide; [319] malabsorption of folate by inhibition of jejunal folate pteroylpolyglutamate hydrolase; [320] perturbation of methionine synthase activity (which results in altered dUTP to dTTP balance, increased apoptosis, and regenerative proliferation of hepatic cells in a model of ethanol-fed micropigs); [321] and increased urinary excretion of formate, which is normally metabolized via folate-requiring enzymes. [10] [312] [322] The relative degree to which each of these mechanisms contributes to folate deficiency remains to be comprehensively determined. Excess alcohol consumption is probably the most common cause of folate deficiency in the United States. [323]

Trimethoprim and *pyrimethamine* bind to bacterial and parasitic dihydrofolate reductase with much greater affinity than to human dihydrofolate reductase but patients with underlying folate deficiency appear to be more susceptible to the drugs. [324] The ensuing megaloblastosis can be reversed by 5-formyl-H_4 PteGlu. *Methotrexate* binds to human dihydrofolate reductase (K_i 7×10^{10} M) and leads to trapping of folate as a metabolically inert form (H_2 PteGlu). This leads to a true depletion of H_4 $PteGlu_n$ within hours and consequently to functional deficiency of 5,10-methylene-H_4 $PteGlu_n$ and reduced thymidylate synthesis. Although megaloblastosis can develop rapidly, the toxic effects of methotrexate can be avoided by administration of 5-formyl-H_4 PteGlu within 12 hours. However, the effects of repletion on tumor 5,10-methylene-H_4 $PteGlu_n$ presents a problem. FR take up methotrexate at lower doses, but RFC-mediated and/or passive diffusion appears to be the main route of cellular uptake at high doses (Fig. 28-6). Once in the cell, methotrexate is polyglutamated and this determines its cytotoxicity. The maintenance of a gradient between the extracellular and intracellular compartment appears to determine polyglutamation and thus efficiency of cytotoxicity. *Sulfasalazine* produces megaloblastosis in up to 67% of patients taking full doses (>2 g/day) by decreasing absorption of folates (decreasing conversion of H_4 $PteGlu_n$ to H_4 PteGlu), and induction of Heinz body hemolytic anemia (increased requirements). It is still not clear whether cases in which megaloblastic anemia develops while patients are receiving *oral contraceptives* represent a cause-and-effect relationship. Oral contraceptives may increase folate catabolism (metabolic consumption) or may weakly interfere with DNA synthesis. It is significant that the megaloblastosis of cervical epithelium often reverses with folate therapy alone. [147] The mechanism for reduction of serum folate by *anticonvulsants* during prolonged therapy is probably due to the combined action on reduced absorption [147] as well as through induction of microsomal liver enzymes. [325] It is unclear how folates provoke a return of seizures in some patients receiving anticonvulsants, but this effect may be mediated by glutamate (or related) receptors. [326] Despite this potential risk, consensus guidelines have stressed the importance of ensuring that pregnant women with epilepsy be prescribed folates together with anticonvulsants. [327] [328] Although *antineoplastics* and *antiretroviral antinucleosides* such as azidothymidine lead to megaloblastosis, the temporal sequence and investigations to rule out Cbl/folate deficiency should easily lead to correct causal assignment.

bladder or bowel control due to Cbl myelopathy may present with urgency or nocturia.

In contrast to musculoskeletal symptoms (arthralgia or frank arthritis) of autoimmune diseases, nocturnal cramps or pain in upper and lower extremities may indicate spinothalamic tract involvement. Hypoparathyroidism or systemic lupus erythematosus, alone or associated with PA, leads to significant overlap of cerebral, musculoskeletal, and neurologic presentations.

Review of skin symptoms may elicit a history of increased diffuse or blotchy generalized brownish skin pigmentation, especially of nail beds and skin creases. This is common in Cbl and folate deficiency; associated vitiligo suggests autoimmune disease.

Although symptoms related to neurologic dysfunction may be volunteered, a complete detailed questionnaire should be formulated during the interview. Questions should be directed to perversions in taste or smell, decreased visual acuity, changes in color vision, and eye pain (neuritis), tinnitus, or headache. Dizziness with orthostatic hypotension and blacking out may be related to severe anemia. Vertigo or difficulty in walking in the dark (loss of proprioception and position sense), difficulty in ambulation (which may feel like walking on cotton wool), stiffness of extremities (corticospinal tracts), or ataxia (spinocerebellar tracts) may be indicative of a serious Cbl myelopathy. Early symptoms are symmetrical tingling (pins and needles), extending from the tips of the toes to a glove and stocking distribution in later stages. Burning feet syndrome, or more commonly, complaints of difficulty in performing simple tasks such as buttoning clothes, may also be a presenting symptom. When loss of bladder and bowel control brings the patient to the physician, advanced neurologic dysfunction is invariably present.

Other genitourinary symptoms such as recurrent cystitis from bladder dysfunction, impotence (Cbl neuropathy) or a recent Pap smear indicative of cervical dysplasia may, rarely, be presenting symptoms. Multiple pregnancies with short intervals between delivery and conception predispose to a high risk for overt folate deficiency. (Cbl deficiency is more often associated with infertility.)

Physical Examination

Physical examination may reveal different features in well nourished patients (Cbl-deficient vegetarians or PA patients) and poorly nourished (folate-deficient) individuals. The latter will show evidence of significant weight loss or other stigmata of multiple deficiency due to broad-spectrum malabsorption. Thus, associated deficiency of vitamins A, D, and K and/or protein-calorie malnutrition may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Varying degrees of pallor with lemon-tint icterus (a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis.

When anemia is severe, the patient may have a low-grade fever. The skin may reveal either a diffuse brownish pigmentation or abnormal blotchy tanning. Special emphasis should be given to pigmentation of skin creases and nail beds. (Mucous membrane pigmentation will not be noted, in contrast to Addisons disease.) Premature graying is observed in both light- and dark-haired individuals.

A blunted mask-like facies is extremely common in folate deficiency. Alternatively, there may be evidence of classic hyper- or hypothyroid facies (associated with PA). Special attention should be given to the eyes and eyebrows for signs of thyroid dysfunction.

Examination of the mouth may reveal glossitis with a smooth (depapillated), beefy red tongue with occasional ulceration of the lateral surface. The neck may reveal thyromegaly (diffuse or with nodules) if there is associated disease. Increased jugular venous distension should alert the examiner to cardiovascular failure, with its attendant gallop, cardiomegaly (with or without pericardial effusions), pulmonary basal crepitations, and pleural effusion, tender hepatomegaly, and pedal edema. Nontender hepatomegaly, but more often mild splenomegaly, may rarely be due to extramedullary hematopoiesis in severe anemia, but a mid-epigastrium mass raises the ominous possibility of gastric carcinoma (three times as likely in PA).

An inverse correlation has been identified between the extent of anemia and neurologic dysfunction. Patients with normal complete blood count values will often have neurologic signs and symptoms. In prolonged Cbl deficiency, neurologic examination will reveal clear-cut evidence of involvement of posterior and pyramidal, spinocerebellar, and spinothalamic tracts. Among the earliest signs of posterior column dysfunction are loss of position sense in the index toes (before great toe involvement), which is elicited by passive movement, and loss of the ability to discern vibration of a high-pitched (256 cycles/sec) tuning fork (a very early elicitable, objective sign) which invariably *precedes* by many months the loss of ability to sense the vibration of a lower-pitched (128 cps) tuning fork. Usually the patient loses vibration sense to 256 cps from toe to hip before loss of 128 cps vibration sense even begins. Because of the slow coalescence of contiguous spinal cord lesions, a constellation of elicitable signs may be obtained. Upper motor neuron disease is indicated by weakness and progressive spasticity with increased muscle tone, exaggerated deep tendon reflexes with clonus, extensor plantar response, and incoordinate or scissor gait, which may progress to spastic paraplegia. The involvement of peripheral nerves may markedly modify these signs to include flaccidity and the absence of deep tendon reflexes. A positive Romberg sign is not uncommon and a positive Lhermitte sign may be elicited. Loss of sphincter and bowel control, altered cranial nerve dysfunction with altered taste, smell, and visual

acuity or color perception, and optic neuritis (unexplained predominance in males) may be other physical signs indicating Cbl deficiency. Inability to carry out serial subtraction of 7 from 100 is a valuable test to document reduced cerebral function (the electroencephalogram often reveals slow wave frequency) in PA.

Recent Insights into the Changing Spectrum of Cbl Deficiency

The biochemical and clinical spectrum of presentations of Cbl deficiency has changed dramatically compared with earlier descriptions. For instance, earlier in developing countries, the majority of cases with nutritional Cbl deficiency presented in the second and third decade with pancytopenia, mild hepatosplenomegaly, fever, and thrombocytopenic bleeding, all of which are in keeping with the concept of ineffective hematopoiesis of megaloblastosis. [238] [231] Implicit in the earlier literature was the dictum that the neurologic and psychiatric syndrome uniquely associated with Cbl deficiency usually developed in 80% by the time anemia was symptomatic, and in 50% of patients, this led to some incapacity. [1] [332] However, from southern Africa among 144 consecutive adults (who were not vegetarian, pregnant, or lactating) with megaloblastic anemia [333] and similar presentations of megaloblastosis as reported from India, there was a high incidence of neurologic disease among patients with mild to moderate anemia due to Cbl deficiency (in 86%), mostly from pernicious anemia (PA). This reverses previous presumptions that the primary cause of megaloblastic anemia in this population in developing countries is invariably folate deficiency.

That such classic hematologic presentations are infrequently observed in the West was initially recognized when anemia and macrocytosis were not invariably associated with Cbl deficiency. [12] [190] [215]

When the clinical spectrum and diagnosis of Cbl deficiency was reevaluated among a cohort of unselected consecutive patients in New York and Colorado who fulfilled criteria for unambiguous Cbl deficiency, normal values in hematocrit, mean cell volume, and LDH were found in over one-third of patients, and 80% had normal WBC and platelets and serum bilirubin levels. [216] Strikingly, 33% of the patients blood smears were not identified as diagnostic when evaluated by laboratory personnel, when compared to 94% when evaluated by the investigators themselves. This fact is important because the majority of physicians in general practice rely heavily on laboratory personnel to flag an abnormal blood smear. Equally striking was the important finding that neuropsychiatric abnormalities were noted in nearly one-third of patients often in the absence of anemia, macrocytosis, or both. [190] These data formed the basis for reevaluating the diagnostic sensitivity and specificity of serum tHcys and MMA in clear-cut Cbl deficiency (406 patients) or folate deficiency (119 patients). [226] In patients with Cbl deficiency, serum MMA levels were elevated in 98.4% and serum tHcys in 95.9%; both metabolites were normal in only one patient (0.2%). For patients with folate deficiency, the serum tHcys was increased in 91% and MMA was elevated in 12.2%, but in all but one, this was attributed to renal insufficiency or dehydration, conditions which are known to falsely raise concentrations of this metabolite. These data allowed for the conclusion that *normal levels of both MMA and tHcys rule out clinically significant Cbl deficiency with virtually 100% certainty.*[226]

The changing pattern of neurologic presentations also deserves special mention. From a classic review of 153 episodes of Cbl deficiency involving the nervous system, the following facts emerged:[191] First and foremost, in over a quarter of these patients, there was no reduction in the hematocrit despite neurologic disease, and only a minority of patients had combined hematologic and neurologic disease. The inclusion of anemic and nonanemic patients who were Cbl-deficient led to the dramatic conclusion that the higher the hematocrit, the more severe is the neurologic disorder! (This has its experimental correlates in monkeys and fruit bats, which have severe neurologic disease in the absence of anemia. [10] [189]) Profoundly anemic patients frequently had no neurologic deficits, and the level of Cbl had no correlation with either the existence or severity of neurologic disease. Although simultaneous consumption of folate may have negated the development of potential hematologic abnormalities in Cbl deficiency, this could not be documented. Among patients studied, 65% had mild, 25% had moderate and 10% had severe neurologic deficits. Paresthesias or ataxia were most commonly the first symptoms and diminished vibratory sensation and proprioception in the lower extremities were the most common objective early signs. Although multiple neurologic syndromes were often seen in the same patient, the spectrum of objective signs could include loss of fine/coarse touch, decreased or increased deep tendon reflexes with spasticity or muscle weakness, urinary or fecal incontinence, orthostatic hypotension, amaurosis, dementia, psychosis, or mood disturbances.[191] Overall, although the neurologic deficits were mild in the majority of cases, the severity was judged related to the duration of symptoms prior to diagnosis; not unexpectedly, those with the shorter duration responded most to appropriate replacement. The demonstration of cognitive improvement in 11 of 18 geriatric subjects with low Cbl and quantitative cognitive dysfunction treated with Cbl, and the observation that there is a limited window of opportunity for effective intervention also highlights the importance of early diagnosis for this population. [334]

Although the basis for these changes in clinical presentation is speculative, it may be due to heightened awareness of Cbl deficiency, better diagnostic tools, or supplementary folates taken by humans and given to livestock (which correct megaloblastosis but aggravate neuropsychiatric disease).

Diagnostic Issues Related to Information from the Peripheral Smear and Bone Marrow

Although not specific for megaloblastic anemia, macroovalocytes are the hallmark of megaloblastosis (Table 28-5). This distinction is important because only 55% of 109 patients with MCV >105 fl had vitamin deficiency[335] (this percentage may be lower or higher depending on the population under study). Thus, in nearly one-half of all cases, macrocytosis per se is not associated with megaloblastosis (see Table 28-5) and additional tests are necessary for complete diagnosis.

The frequency of hypersegmented PMNs (5% with 5 lobes or 1% with 6-lobed PMNs) in patients with megaloblastic hematopoiesis is 98%. [336] The sensitivity decreases to only 78% in alcoholics although the specificity of this finding is 95%. [227] With a combination of hypersegmented PMNs and macroovalocytosis, the specificity is 9698%[225] [227] and the positive predictive value of either folate or Cbl deficiency is 94%. [225] (*Note*: Hypersegmentation of PMNs is insufficiently sensitive, when compared to metabolite levels, to be used as a clinical tool in the diagnosis of *mild* Cbl deficiency.[337])

Is a bone marrow aspirate always necessary to diagnose Cbl/folate-deficient megaloblastosis? With the addition of highly sensitive serum tests for the specific diagnosis of Cbl and folate deficiency, the need for a bone marrow test is often dictated by the urgency to diagnose megaloblastosis (with results available in an hour). For example, in the case of florid hematologic disease with or without neurologic disease suggestive of Cbl or folate deficiency, a bone marrow aspiration carried out as soon as possible is invaluable in assisting in rapid diagnosis of megaloblastosis. However, in the outpatient setting, or when the patient has a characteristic peripheral smear, or with a primary neuropsychiatric presentation, a case can be made to initiate the sequence of diagnostic tests without a bone marrow aspiration by proceeding with measurement of serum levels of vitamins or metabolites (see Table 28-2). In a pregnant patient with pancytopenia with macroovalocytes, hypersegmented PMNs, and reticulocytopenia with a history of noncompliance with prenatal supplements (and no neurologic findings suggestive of Cbl deficiency), a bone marrow aspiration may not be necessary to initiate therapy for a strong presumptive diagnosis of folate deficiency. Of course, if there is no evidence of response within 10 days, a bone marrow aspiration is indicated.

TABLE 28-5 -- Clinical Conditions Not to Be Confused with Megaloblastosis

Macrocytosis[a] without megaloblastosis[b]
Reticulocytosis
Liver disease
Aplastic anemia
Myelodysplastic syndromes (especially 5q)
Multiple myeloma
Hypoxemia
Smokers
Spurious increases in MCV without macroovalocytosis[c]
Cold agglutinin disease
Marked hyperglycemia
Leukocytosis
Older individuals

[a]The central pallor which normally occupies about one-third of the normal red blood cell is *decreased* in macroovalocytes. This contrasts with the finding of *thin macrocytes* where the central pallor is *increased.*
[b]While megaloblastosis implies that a bone marrow test has been performed, with the recent addition of highly sensitive tests for the specific diagnosis of Cbl and folate deficiency, the need for a bone marrow test is often dictated by the urgency to make the diagnosis (see text).
[c]When the Coulter counter readings of a high MCV are not confirmed by looking at the patient or the peripheral smear.

Masked Megaloblastosis

The term masked megaloblastosis is reserved for conditions in which true Cbl/folate deficiency with anemia is not accompanied by classic findings of megaloblastosis in the peripheral blood and bone marrow. This occurs when there is a coexisting condition that neutralizes the tendency to generate megaloblastic cells (usually involving reduction in RBC hemoglobinization, as in iron deficiency or thalassemia). Among the 123 episodes of folate deficiency in 119 patients, the MCV was normal in 25%.[225] [233] A wide RBC distribution width (RDW) on the Coulter counter readout in the presence of a normal mean corpuscular hemoglobin (MCH) or MCV may reflect either megaloblastic anemia[338] or dimorphic (macroovalocytes plus microcytic hypochromic RBC) anemia. Because megaloblastic WBCs and precursors are unaffected by deficient hemoglobinization, these pathognomonic findings (giant myelocytes and metamyelocytes, and hypersegmented PMNs) remain; the latter may persist for up to 2 weeks after replacement with Cbl/folate.[339] Thus, the recognition of masked megaloblastosis should initiate investigations to rule out iron deficiency, anemia of chronic disease, or hemoglobinopathies. Indeed, appropriate replacement with Cbl or folate will elicit a maximal therapeutic benefit only when iron deficiency is corrected. Conversely, if combined iron and Cbl deficiency (total gastrectomy) or iron and folate deficiency (pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

APPROACH TO DIAGNOSIS AND THERAPY OF MEGALOBLASTOSIS

In general, there are three stages in approaching a patient. (1) *recognizing* that megaloblastic anemia is present; (2) *distinguishing* whether folate, Cbl, or combined folate and Cbl deficiencies have led to the anemia; and (3) diagnosing the *underlying disease* and *mechanism* causing the deficiency. Establishing that the patient does have megaloblastosis is, in theory, straightforward. This is easily done by evaluating the complete blood count, mean corpuscular volume, and peripheral smear, followed by a bone marrow aspiration. Clues to whether Cbl or folate deficiency is responsible for megaloblastosis can be obtained by serum Cbl and serum folate levels; additional testing of serum MMA and serum tHcys will define the true nature of the deficiency. [223] However, this ideal and orderly workup is not always feasible in clinical practice, where the patient may (1) present for the first time with or without associated neurologic disease; (2) be referred after a variable workup has already been initiated for possible megaloblastosis; (3) present with symptoms primarily attributed to a disease predisposing to Cbl or folate deficiency, in which case anemia or neurologic dysfunction may only be a minor symptom; (4) present with isolated neurologic disease in the absence of anemia; or (5) be referred after empiric therapy has been given for presumed Cbl and/or folate deficiency. The immediate question therefore pertains to the overall status of the patient.

*If the patient is decompensated or decompensation is imminent***,** obtain serum folate and Cbl levels and a bone marrow aspiration to confirm megaloblastosis and proceed with transfusion of 1 unit of packed RBCs *slowly*, with vigorous diuretic therapy and/or simultaneous phlebotomy (from the other arm) to obviate further congestive heart failure from fluid overload. Both Cbl and folate should be administered simultaneously in full doses. Tests for Cbl absorption can be deferred until the patient is more stable. Transfusion does not apparently alter serum folate/Cbl levels but will alter red cell folate levels. [340]

If the patient is moderately symptomatic (but not in heart failure), the strong likelihood of a dramatic response (in the sense of well-being and relief of sore tongue) within 2 to 3 days before hematologic improvement argues against immediate blood transfusion. [341] Therefore, proceed with appropriate diagnostic workup as for the well compensated patient.

If the patient is well compensated, and in the outpatient setting, the physician has time to develop an orderly sequence of diagnostic tests. First, check the peripheral smear and rule out other macrocytic anemias (thin macrocytes with a normoblastic marrow in contrast to macroovalocytes). Draw blood for Cbl and folate levels (*before* the patients first hospital meal) to sort out whether the problem is due to deficiency of folate and/or Cbl, or some other deficiency (see Table 28-2). Assuming that there is no urgency to make the diagnosis, the physician can elect to wait for the results of these tests before proceeding with the next test in the diagnostic workup. If making the diagnosis is urgent, a cost-effective test is the bone marrow aspirate; results (indicating megaloblastosis or not) will be available within an hour. If a bone marrow aspiration is performed, send samples for special stains (periodic acid-Schiff positivity for erythroleukemia), flow cytometry, and chromosomal analysis (myelodysplastic syndromes can exhibit some megaloblastic changes in the erythroid series but megaloblastic granulopoiesis is not seen). If the marrow is not obviously megaloblastic but the iron stain reveals absent stores, review the morphology again with special emphasis on granulocytic precursors and promegaloblasts, and look for more subtle megaloblastic changes.

If the patient refuses a bone marrow aspirate and serum Cbl and folate levels are equivocal (i.e., in the low normal range), a strong case can be made to test for serum tHcys and MMA. Serum MMA and tHcys are ordered together (the same sample remaining from the serum sent for Cbl and folate may be used if they were frozen away). Integrating the results of serum MMA and tHcys (which will be available after a week or more) with those of the serum Cbl and folate levels will help distinguish Cbl and/or folate deficiency (see Table 28-2). A normal MMA and tHcys level eliminates Cbl deficiency with 100% confidence, and normal tHcys levels suggest that megaloblastic anemia is *not* due to folate deficiency. These tests are particularly useful (1) if the patient has pure neurologic disease (no hematologic manifestations from Cbl deficiency), or (2) if there are associated conditions like iron deficiency or thalassemia that will mask megaloblastosis. Note that administration of folate or Cbl immediately invalidates the diagnostic value of the serum folate and Cbl levels; also, because the elevated serum tHcys and MMA levels begin to drop and normalize only after about 1 week, there is a period of slightly <1 week after administration of folate/Cbl to clinch the diagnosis. [184] In the rare situation when a defect in utilization of Cbl or folate is suspected, consultation with experts who have published in this area is advised.

A reticulocyte count, indicative of a hypoproliferative state, is useful to follow the patients response to appropriate replacement therapy. Additional supporting studies documenting increased serum lactate dehydrogenase, haptoglobin, and bilirubin (evidence for intramedullary hemolysis) may be performed. Later, studies to define the mechanism for Cbl malabsorption with a Schilling test can then be carried out.

When the megaloblastic state is established, try to determine the underlying mechanism of Cbl/folate deficiency. The etiology of folate deficiency is usually sorted out by this time from the history, physical examination, and the clinical setting. If pure folate deficiency has been prolonged, expect associated Cbl deficiency to ensue (special emphasis should be given to identifying subtle manifestations of neurologic disease). If Cbl deficiency is suspected, test for serum anti-IF antibodies (highly specific for PA), and after this, proceed with the Schilling test (Table 28-3) to differentiate PA from other causes of Cbl deficiency. (*Note*: the Schilling test will initiate a reticulocytosis by the second or third day in pure Cbl deficiency and may also give a partial response in pure folate deficiency.) Additional tests for associated autoimmune diseases should be made (if indicated) by this time. If serum IF antibodies are negative, gastric analysis for Histalog-fast

MODIFIED THERAPEUTIC TRIALS

The traditional therapeutic trial using physiologic doses of vitamins (100 g of folate or 1 g of Cbl given daily while monitoring the reticulocyte response) has given way to a modified therapeutic trial: Here, the intention is often not so much to make the diagnosis of a deficiency, but to confirm the clinical suspicion that the patient does not have deficiency.[225] This would be demonstrated by lack of response to full replacement doses of both vitamins (1 mg of folic acid orally for 10 days and 1 mg of Cbl intramuscularly for 10 days). Clinical scenarios in which such trials may be applicable (after drawing blood for serum Cbl and folate) are as follows:

1. When there is a clinical suspicion that the underlying disease is *not* due to a vitamin deficiency, but this is not supported by clinical, morphologic, and biochemical evaluation. Such conditions include anemia with a megaloblastic bone marrow which may be secondary to chemotherapy, myelodysplastic syndromes, or acute myeloid leukemia, when time is of the essence in making the diagnosis, or the levels of Cbl are likely to be falsely abnormal because of these diseases, or there is underlying dehydration or renal dysfunction which predictably gives falsely high levels of metabolites.
2. In other situations (i.e., pregnancy, AIDS, or alcoholism) with a multifactorial basis for anemia, the response (or lack thereof) to full doses can eliminate Cbl/folate deficiency and thereby narrow the (often extensive) differential diagnosis.
3. In instances when severe anemia with megaloblastosis is clinically obvious, but is also so serious that one cannot wait for the results of specific tests for deficiency. Here again, *full doses* of both vitamins are administered, and if there is a response manifested by brisk reticulocytosis by day 57, retrospective assignment of the deficiency is based on the results of blood samples drawn before beginning the trial.

It is important to emphasize that in all therapeutic trials, if there is no evidence of response within 10 days, a bone marrow is indicated to identify another primary hematologic disease.

achlorhydria need not be performed, except in children for whom it is necessary to distinguish congenital IF deficiency from juvenile PA and Imerslund-Gräsbeck syndrome. In adults, a strong presumptive diagnosis of PA can usually be made with the Schilling test (Table 28-3).

Therapy

Routinely, treatment with full doses of parenteral Cbl (1 mg/day) and oral folate (folic acid) (15 mg) before knowledge of the type of vitamin deficiency is established should only be reserved for the severely ill patient. An appropriate regimen for conditions in which Cbl replenishment will correct cellular Cbl deficiency (but will not correct the underlying problem that led to the deficiency [e.g., PA] is 1 mg of intramuscular CN-Cbl per day (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg/month for life (15% or 150 g will be retained 48 hours after each 1 mg Cbl injection).

Because the doses of Cbl are much greater than that required physiologically, any theoretical advantage of OH-Cbl over CN-Cbl (greater binding to Cbl-binding proteins, greater serum levels, and less renal excretion) is of little significance in general clinical practice. For patients who refuse monthly parenteral therapy or prefer daily oral therapy, or in those with disorders of hemostasis, 1 mg/day tablets are recommended for patients with Cbl malabsorption (where Cbl is passively absorbed at high doses).[10] [342] This is applicable for patients with PA and patients with inability to absorb food Cbl. It is important to emphasize that the physician must ensure that (1) the patients depleted Cbl stores are rapidly repleted by parenteral Cbl *before* switching to oral Cbl in the long-term, and (2) the patient is compliant and demonstrates adequate Cbl levels and resolution of hematologic and neurologic abnormalities on follow-up. For nutritional Cbl deficiency (e.g., vegetarians) when the entire circuitry in Cbl absorption is intact, oral tablets or a syrup of Cbl (50 g/day for life) will suffice.

Oral folate (folic acid) at doses of 15 mg per day results in adequate absorption (even where intestinal malabsorption of physiologic food folate is present). Therapy should be continued until complete hematologic recovery is documented. If the underlying cause leading to folate deficiency is not corrected, folate may be continued. Folinic acid (aka 5-formyl-H_4 PteGlu, leucovorin) should be reserved *only* for rescue protocols involving antifolates (methotrexate or trimethoprim-sulfamethoxazole) or for 5-fluorouracil modulation protocols, and in the rare acute folate deficiency syndrome. It is too expensive for conventional repletion in folate-deficient states.

Response to Replenishment

The response of the patient to appropriate replacement is reversion of megaloblastic hematopoiesis to normal hematopoiesis (probably initiated at the stem cell level) within the first 12 hours; by 48 hours normal hematopoiesis is re-established, and the only evidence for a prior megaloblastic state may be the persistence of a few giant metamyelocytes. Because megaloblastosis caused by Cbl/folate deficiency can be reversed in 24 hours by administration of folate (i.e., a nutritious hospital meal), delay of a diagnostic bone marrow aspirate is to be avoided for this reason. Clinically, the first 36 to 48 hours are often highlighted by the awakening of an occasional semi-stuporous individual whose chief complaint is amazement at the remarkably improved sense of well-being experienced, with increased alertness and appetite and reduced soreness of the tongue. The ongoing normoblastic hematopoiesis is evidenced by decreases in plasma iron and potassium (12 mEq/dL drop in 48 hours), MMA, tHcys, and phosphate excretion. The patient must be given supplemental potassium if borderline or low potassium levels are found *before* therapy is initiated to obviate potentially fatal arrhythmias. The elevated serum MMA and tHcys levels will return to normal by the end of the first week.

Accelerated turnover of normal DNA in erythroid precursors is associated with an increase in serum urate, which usually peaks by the fourth day, and with increased cellular phosphate uptake for nucleotide synthesis. This may precipitate an attack of gout if the patient has a gouty predisposition. The reticulocyte count increases by the second to third day and peaks by the fifth to eighth day (the peak reticulocyte count is directly proportional to the degree of pre-existing anemia). This is followed by a rise in RBC count, hemoglobin, and hematocrit by the end of the first week, which eventually normalizes by 2 months regardless of the initial degree of anemia. By the end of the third week, the RBC count should be above 3×10^6 mm^3 ; if it is not, additional causes of underlying iron deficiency, hemoglobinopathy, chronic disease, or hypothyroidism should be considered (Table 28-6).

Hypersegmented PMNs continue to remain in the blood for 1014 days; however, the number of normal PMNs and platelets rises and normalizes within the first week. During this process, there may be a transient left shift to include myeloid

TABLE 28-6 -- Causes for Nonresponsiveness of Megaloblastosis to Therapy with Cbl or Folate

Wrong diagnosis
Combined folate/Cbl deficiency being treated with only one vitamin

Associated hypothyroidism

precursors. The reduced intramedullary hemolysis (as a result of normalized hematopoiesis) leads to a gradual reduction in the serum bilirubin by the end of the first week, and LDH levels will drop concomitantly.

In response to Cbl, progression of neurologic damage and dysfunction is inhibited. In general, the degree of functional recovery (reversal of neurologic damage) is inversely related to the extent of disease and duration of signs and symptoms. As a rough estimate, signs and symptoms that have been present for less than 3 months are usually completely reversible; with longer duration, there is invariable residual neurologic dysfunction. The reversibility of neurologic damage is slow (a maximal response may take 6 months). Substantial increments (in recovery) are unlikely to be gained after the first 12 months of appropriate therapy, which indicates irreversibility at this point. However, the majority of neurologic abnormalities have improved in up to 90% of patients with documented subacute combined degeneration.

Follow-up

Patients with neurologic dysfunction from Cbl deficiency have traditionally been given more frequent doses of Cbl (biweekly rather than monthly therapy for the first 6 months), despite the lack of evidence that this form of therapy is more beneficial. This approach, nevertheless, serves a purpose in that improvement in neurologic status can be carefully documented. Once maximal responses have been established and patients are deemed capable of administering Cbl independently, they can be given vials of Cbl with appropriate instructions for lifelong monthly injections. Follow-up outpatient visits every 6 months should be instituted in order to ensure adequate maintenance of hematopoiesis, as well as early diagnosis of other diseases commonly associated with the Cbl/folate-deficient state. Follow-up of 95 patients with PA indicates that individuals >60 years are prone to developing iron deficiency which arises from poor iron absorption from achlorhydria. [343] Thus, all patients with PA, especially the elderly, should be screened for iron deficiency both at the beginning and during follow-up.

Although patients with PA have a twofold increase in proximal femur and vertebral fractures and a threefold increase in distal forearm fractures, it is unclear whether this is reduced by therapy with Cbl. Because Cbl stimulates proliferation of bone marrow stromal osteoprogenitors and osteoblastic cells, the suppressed activity of osteoblasts may contribute to osteoporosis and fractures in patients with PA. [344]

Studies of a cohort of 5,072 patients with PA registered in Denmark (from 19771989) revealed that in addition to the well-established increased risk for stomach cancer, there was also a twofold increase in the relative risk for cancer of the buccal cavity and pharynx; however, previously reported elevated risks for other digestive tract cancers were not confirmed. Because of the excess risk of gastric cancer and carcinoid tumors in patients with PA, [345] the value of endoscopic surveillance was studied prospectively; in 56 patients, two patients each with early gastric cancer and gastric carcinoids were identified. Gastric carcinoids associated with PA are clinically indolent tumors, particularly when they are smaller than 2 cm. [346] This information can be used to formulate general guidelines for more frequent surveillance of patients with PA who have larger gastric carcinoids.

Routine Supplementation of Cbl and Folate

Routine *periconceptional* supplementation of folate for (1) normal women[295] and (2) in higher doses for women at risk for delivery of babies with neural tube defects[297] provides effective prophylaxis against the development of neural tube defects. Supplementation with folate throughout pregnancy also helps to prevent premature delivery of low birth weight infants,[10] and routine supplementation for premature infants and lactating mothers is also recommended.

In addition to hematologic diseases leading to increased folate requirements (autoimmune hemolytic anemia, -thalassemia, etc.), folic acid supplements appear to reduce the toxicity of methotrexate in rheumatoid arthritis and psoriasis. [347] [348] [349] Table 28-7 summarizes conditions that warrant routine folate or Cbl supplementation. Although a small randomized study demonstrated a beneficial role of Cbl plus pyridoxine and thiamine in somatic and autonomic symptoms of diabetic neuropathy,[350] the independent role of Cbl [351] as well as its role in persistent sleep wake schedule disorders [352] [353] is unclear. Also, the roles of folate/Cbl in reversing vitiligo,[354] aphthous stomatitis,[355] and of high-dose folate for psychiatric disease [356] [357] [358] require further study. Finally, the fact that increased serum tHcys is a risk factor for occlusive arterial disease (see discussion later in this chapter) indicates that future intervention trials related to early reversal of Cbl/folate deficiency-related increase in serum tHcys will be forthcoming.

Because low serum Cbl levels are associated with faster human immunodeficiency virus (HIV-1) disease progression, [359] there have been calls for intervention studies to determine whether correction of low serum Cbl levels in early HIV-1 infection influences the natural history of disease progression.

Public Health Issues in the Debate on Fortification of Foods with Folates

The problem: Despite recommendation for periconceptional supplementation of normal women with folates to prevent neural

TABLE 28-7 -- Indications for Prophylaxis with Cbl/Folate

Prophylaxis with Cbl Infants of mothers with PA[a]
Infants on specialized diets[a]
Vegetarians/vegans[a]
Total gastrectomy[b]
Prophylaxis with folic acid[c]
All women contemplating pregnancy (at least 400 g/day)
Pregnancy and lactation, premature infants
Mothers at risk for delivery of infants with neural tube defects[d] [e]
Hemolytic anemias/hyperproliferative hematologic states
Patients with rheumatoid arthritis or psoriasis on therapy with methotrexate[f]

[a]In food Cbl malabsorption secondary to inability to cleave food Cbl by acid and pepsin, replacement therapy should be 50 g tablets/day orally. In all other conditions involving any abnormality of Cbl absorption, Cbl tablets of 1,000 g/day should be administered orally to ensure that Cbl transport via passive diffusion across the intestine is sufficient to meet daily needs.
[b]Consider late development of Cbl deficiency and iron malabsorption (prophylaxis with oral Cbl and iron).
[c]Ensure that the patient does not have symptoms of Cbl deficiency (most common, paresthesias/numbness) before initiating folate prophylaxis.
[d] Previous delivery of a child with neural tube defects (spina bifida, encephalocele, meningocele) gives a 10-fold greater risk for subsequent delivery of infant with neural tube defects.
[e] Folic acid (4 mg/day) administered *periconceptionally and throughout first trimester*.
[f]To reduce toxicity of the antifolate.

tube defects,[360] this may not have the desired effect for several years until there is widespread education of women and health care providers. In the meantime, because up to 50% of pregnancies are unplanned, such women will continue to be at risk of giving birth to children with neural tube defects. Fortification of foods such as bread/flour and cereals with folates can theoretically overcome this problem, provided there are no untoward effects from such action. However, demonstration of the widespread prevalence of biochemical evidence for Cbl deficiency in the elderly (discussed further later in this chapter), is a matter of significant concern. The fact that these individuals manifest a response to Cbl suggests that they have clinical (albeit subtle) evidence of Cbl deficiency. When such individuals receive additional

folate in their diet, this might quench the expression of Cbl-deficient hematopoiesis while leading to progression of Cbl-deficient neurologic dysfunction. [233] This could go unrecognized unless there were established surveillance programs to identify these cases. Although one solution could be to fortify foods with folate *and* Cbl, this could lead to new problems stemming from alteration of the color of supplemented foods with a potentially unacceptable or unpalatable reddish to pink tinge of Cbl (which is normally a brilliant blood-red color). Finally, there are unresolved questions which relate to the precise dose of folate to be added to foods, the potential for conversion of supplemented folate and Cbl to inactive analogues due to chemical interactions with foods and other nutrients [8] [9] as well as the influence of packing/canning and shelf-life on the bioavailability of supplemented folates.

A progress report: In addition to the continued problem of compliance with consumption of folate-rich foods (which necessitates knowing which foods are rich in folates)[361] and the intrinsically lower bioavailability of food folate, [362] daily supplements of folic acid or fortification of food with folate appeared to be the only reasonable option to ensure adequate folate consumption by women of childbearing age. Accordingly, in March 1996, the Food and Drug Administration issued regulations that folic acid be added to enriched cereal-grain products (flours, corn meals, pasta, breakfast cereals, and rice) by January 1998. This amount of folate fortification (140 g of folate per 100 g) is projected to accomplish some prevention, but it is still a conservative amount and there is a move to consider further increases in the level of fortification (discussed later in this chapter).

There are still several obstacles to nationwide consumption of the recommended 400 g of folate for women of childbearing age. For example, a Gallup Organization-March of Dimes survey in January 1997 [361] determined that 30% of nonpregnant women reported taking daily multivitamin supplements containing folic acid; this number is nevertheless up from the 23% of women who were polled two years before. But of major significance, only 19% of nonpregnant women <25 years (who contribute to 39% of the births in the United States) were compliant with the recommendations, as opposed to 33% of those >25 years. This highlights a pathetically low awareness of folic acid and of the Public Health Service recommendation, and illustrates the need for further aggressive educational strategies directed at women of childbearing age on the beneficial effects of folic acid.

Estimates of potential benefits and risks for the elderly population suggest that, at the current level of folate fortification, the benefits of projected decreases in homocysteine level and heart disease risk (see discussion later in this chapter), greatly outweigh the expected risks. [363] Projections that higher fortification levels would prevent up to 50,000 premature deaths each year from coronary disease need to be tempered by considering whether this could be harmful to other populations. This is not simply a theoretical issue because projections suggest that there may be 800,000 elderly individuals in the United States who have undiagnosed and untreated pernicious anemia (PA).[255] Furthermore, the number of younger individuals (<60 years of age) with PA, as well as undiagnosed individuals with Cbl deficiency who are unable to release dietary Cbl from food, is unclearbut is also expected to be large. This raises the ominous possibility that several of these individuals will develop Cbl-responsive neuropsychiatric and neurologic disease that could go unrecognized if their diets are supplemented with folate through food fortification policies. This issue, and the development of methods to avoid misdiagnosis of Cbl deficiency within the context of intervention studies with higher doses of folate, are under active consideration by the FDA. Nevertheless, once data on the quantification of the actual risks associated with Cbl deficiency are available such analyses could determine whether even higher levels of folic acid fortification would further reduce risks from folate-responsive hyperhomocysteinemia.[363]

Hyperhomocysteinemia

Normally in cells, homocysteine is metabolized by a methylation and a transsulfuration pathway. In the methylation pathway, homocysteine is methylated to methionine in a reaction involving the Cbl-dependent enzyme (methionine synthase) and 5-methyl-tetrahydrofolate (5-methyl-H_4 PteGlu) which donates its methyl group to homocysteine (Figs. 28-2 , 28-3 , and 28-7). Cellular 5-methyl-H_4 PteGlu is provided by the enzyme 5,10-methylene-tetrahydrofolate reductase (MTHFR). The critical nature of the function of this MTHFR (to provide 5-methyl-H_4 PteGlu to drive the methylation cycle) is highlighted by evidence that in some adults with homocysteinemia, a polymorphism within its folate-binding pocket (involving a CT substitution at nucleotide 677 which converts an alanine to valine) results in a dysfunctional thermolabile MTHFR.[364] [365] [366] This leads to a pathologic buildup of homocysteine, which exits from cells into the circulation where it predisposes the patient to premature occlusive vascular disease. In addition, the transsulfuration pathway, which is vitamin B_6-dependent, can also be activated to reduce cellular homocysteine. So in general, the level of plasma tHcys depends on genetically regulated levels of essential enzymes and the intake of folic acid, vitamin B_6 (pyridoxine), and Cbl, as well as other conditions (renal dysfunction, increased age, nitrous oxide, and antifolates).

Chronic hyperhomocysteinemia is now established as a major risk factor in occlusive vascular diseases. [208] [367] [368] [369] These include myocardial infarctions from coronary atherosclerosis,[370] [371] extracranial carotid artery stenosis,[372] and stroke,[373] vascular disease in end-stage renal failure, [374] [375] thromboangitis obliterans, aortic atherosclerosis,[376] venous thromboembolism,[208] [371] [377] and placental abruption or infarction. [294] (*Note*: An increment of 5 mol/L of tHcys elevates coronary artery disease risk by as much as cholesterol increases of 20 mg/dL. [378])

Although there is no question of the adverse role of homocysteinemia in vascular disease, it is still controversial whether the thermolabile MTHFR is, or is not, a risk factor for vascular disease among different populations. For example, there are several reports in favor of the conclusion that there is a correlation of thermolabile MTHFR (i.e., the C677T mutation) with plasma tHcys in patients with premature coronary artery disease. [379] [380] [381] [382] However, other reports indicate that thermolabile MTHFR is not a major risk of premature coronary artery disease or myocardial infarction, or for restenosis after coronary angioplasty, [366] [383] [384] or for typical late-onset vascular disease. [385] [386]

The basis for this controversy is unclear, but it may relate to distinctly different populations (with additional covariables). For example, the extent to which folic acid supplements can lower elevated tHcys is dependent on the initial tHcy and folate, Cbl and vitamin B_6 (pyridoxine) levels, multivitamin use,[387] and whether the individual has the heterozygous or homozygous form of thermolabile MTHFR. In one study, folate was the most important determinant of plasma tHcys, even in subjects with apparently adequate nutritional status of this vitamin. [293]

So how much folate supplementation is necessary to reduce tHcys levels? A trial of daily intake of 1 or 2 mg of folic acid supplements on tHcy levels revealed that both dosages lowered tHcy levels similarly.[388] Interestingly, homozygotes of thermolabile MTHFR had increased susceptibility to high levels of tHcy at marginally low plasma folate levels, and enhanced responses to folic acid. Therefore, one-third of heterogeneity in responsiveness can be attributable to baseline tHcy and folate levels and to multivitamin use. An unknown variable is that there could exist additional polymorphisms (in genes responsible for maintaining homeostasis of homocysteine) that have not been identified but which may account for increased vascular disease. [389]

A notable study among 365 individuals in the NHLBI Family Heart Study[390] raises issues of a gene-environment interaction: Among subjects with lower plasma folate concentrations (<15.4 nmol/L), those with the homozygous thermolabile MTHFR genotype had fasting tHcys levels that were 24% greater than those with the normal genotype. Because a difference between genotypes was not seen among individuals with folate levels >15.4 nmol/L, this suggests that a gene-environment interaction might increase the risk by elevating tHcys, especially when folate intake is low. So homozygotes probably have a higher folate requirement to maintain optimum homocysteine homeostasis, and folate supplementation may be necessary to prevent fasting hyperhomocysteinemia in such persons.

High plasma tHcys levels are a risk factor for deep-vein thrombosis in the general population. [391] Although the available data supports the concept that selected individuals with thromboembolism should have tests for hyperhomocysteinemia, it is doubtful that many will have evidence for thermolabile MTHFR. [392] It is significant that apparently healthy men with coexistent hyperhomocysteinemia and Factor V Leiden mutation are at substantially increased risk of developing future venous thromboembolism.[393] In addition, the risk of venous thromboembolism among doubly affected individuals with Factor V Leiden appears far greater than the sum of the individual risks associated with either abnormality alone. [393]

In a case-control study involving 19 centers in 9 European countries, a total of 750 cases of atherosclerotic vascular disease (cardiac, cerebral, and peripheral) and 800 controls of both sexes younger than 60 years were assessed for fasting plasma tHcys and after a standardized methionine-loading test to stress the transsulfuration pathway (which irreversibly degrades tHcys; this test picks up another 25% individuals at risk). The results of this study led to the conclusion that an increased plasma tHcys level confers an independent risk of vascular disease similar to that of smoking or hyperlipidemia and powerfully increases the risk associated with smoking and hypertension.[208]

To summarize the clinical data, homocysteinemia in adults with occlusive vascular disease can arise from deficiencies in folate, Cbl, and/or vitamin B_6 (pyridoxine), as well as in individuals with thermolabile MTHFR. The majority of subjects with hyperhomocysteinemia >40 mol/L in the general population have thermolabile MTHFR

combined with low folate status. Daily supplement of low-dose folic acid will reduce and often normalize their tHcy levels. [307] This and other studies have uniformly led to a call-to-arms to undertake randomized controlled trials of the effect of vitamins (pharmacologic doses of folic acid, pyridoxine, Cbl, or betaine) that reduce plasma tHcys levels on vascular disease risk.

How does hyperhomocysteinemia contribute to atherogenesis? There are several plausible mechanisms among which platelet activation, hypercoagulability, increased smooth muscle cell proliferation, induction of endothelial cytotoxicity and/or dysfunction, and stimulation of low-density lipoprotein oxidation have been suggested.[369] Total homocysteine can alter the expressivity of multiple genes, including a stress protein and several novel genes that may contribute to atherogenesis.[394] Hcys stimulates vascular smooth muscle cell proliferation, which is a hallmark of arteriosclerosis, by stimulating cyclin A protein levels and cyclin A-associated kinase activity in vitro. [395] Total homocysteine specifically stimulates aortic cyclin-dependent kinase at the transcriptional level, with the possible consequence of proliferation of aortic cells. [396] Furthermore, S-adenosyl-homocysteine appears to be a physiologic modulator of Apo-1-mediated apoptosis APO-1/Fas (CD95) receptor, which mediates apoptosis in various cell types. [397] Whether this pathway is identical to that found in ethanol-fed micropigs which exhibit similar increases in S-adenosyl-homocysteine [321] requires further study.

Neurocristopathies are a group of diseases arising from defects in the proliferation and migration of neural crest cells during critical periods of embryogenesisexperimentally, this can give rise to diverse defects such as cleft lip/palate and defects in heart septation (ventricular septal defects). The biologic basis whereby folate supplementation protects against some neurocristopathies and neural tube defects is still unclear. An avian embryogenesis model has demonstrated that homocysteine causes dysmorphogenesis of the heart and neural tube, but folate supplementation lowered tHcys and prevented the teratogenic effect.[398] Direct rodent embryotoxicity of tHcys is suggested to be through inhibition of transmethylation reactions by increased embryonic S-adenosyl-homocysteine levels.[399]

Renal Failure and Cbl Replenishment

When coupled with a predisposition to chronic disease anemia, the demonstration of a borderline or low Cbl level arising from increased Cbl clearance during high flux hemodialysis is a matter of some concern[400] especially because (1) MMA and tHcys levels are elevated in patients with renal dysfunction, and (2) elevated tHcys represents an independent risk factor for vascular events in patients on peritoneal dialysis and hemodialysis. [374] [375] So should such individuals be treated during hemodialysis with Cbl, pyridoxine, and folate? Although routine low-dose (1 mg folic acid, 10 mg B_6, and 12 g Cbl) supplementation fails to control hyperhomocysteinemia in 75% of dialysis patients, a placebo-controlled eight-week trial [401] showed that adding supraphysiologic dose folic acid (15 mg/day), B_6 (100 mg/day), and Cbl (1 mg/day) led to a significant reduction in homocysteine without toxicity; and one-third had virtually complete correction to within the normative range. Therefore until additional data is forthcoming, it would be prudent to employ this regimen in such patients.

CONCLUSIONS

In this age of spiraling costs for health care delivery, and the ongoing debate on ways to reduce these costs, few instances in internal medicine yield more satisfying dividends than diagnosing and treating Cbl and folate deficiency. These conditions are devastating when undiagnosed, misdiagnosed, or when Cbl deficiency is treated with folate alone. Recognition of changes in the clinical presentation of Cbl deficiency and availability of sensitive and specific tests should reduce uncertainty in diagnosis. The studies on folate supplementation during pregnancy which identified new folate-responsive diseases are a paradigm for identification of hitherto unrecognized roles for other nutrients in human development. Furthermore, the significant impact of supplemental folates in relieving human suffering consonant with reducing costs for intensive- and long-term care of infants with prematurity and/or neural tube defects, are major achievements and outstanding examples of cost-effective preventive medicine. As a result of parallel research in the veterinary sciences, folate supplements have also profited the meat

industry! Finally, decisions on the optimum amount of folates needed for fortification of food to prevent this devastating complication in newborns must also respect the dictum of *primum non nocere* for the millions of elderly with Cbl deficiency who could be adversely affected from folate supplementation alone. But consideration of any adverse effects on these Cbl-deficient individuals also needs to be tempered by the projected beneficial effects in correction of hyperhomocysteinemia and occlusive vascular disease in many more subjects. Resolution of this very complex debate will establish yet another paradigm for fortification of foods with nutrients that can be beneficial for some but harmful for other population groups.

Chapter 29 - Thalassemia Syndromes

Bernard G. Forget

INTRODUCTION

The thalassemia syndromes are a heterogeneous group of inherited anemias characterized by defects in the synthesis of one or more of the globin chain subunits of the hemoglobin tetramer. The clinical syndromes associated with thalassemia arise from the combined consequences of inadequate hemoglobin accumulation and unbalanced accumulation of globin subunits. The former causes hypochromia and microcytosis; the latter leads to ineffective erythropoiesis and hemolytic anemia. Clinical manifestations are diverse, ranging from asymptomatic hypochromia and microcytosis to profound anemia, which can be fatal in utero or in early childhood if untreated. This heterogeneity arises from the variable severity of the primary biosynthetic defects and co-inherited modulating factors, such as increased synthesis of fetal globin subunits. Palliative treatment of the severe forms by blood transfusion is eventually defeated by the concomitant problems of iron overload, alloimmunization, and blood-borne infections.

As a group, the thalassemias represent the most common single gene disorder known. In many parts of the world, they constitute major public health problems. Laboratory analysis of these disorders has been one of the most productive and enlightening endeavors of biomedical research. Study of the molecular defects underlying the thalassemia syndromes has led to fundamental advances in our understanding of eukaryotic gene structure and function. For each of these reasons, a thorough understanding of thalassemia and its related disorders is essential to the hematologist. This chapter surveys the major features of these syndromes. Readers wishing more detailed information than can be included here are referred to the comprehensive monographs and chapters written by Weatherall and Clegg, [1] Bunn and Forget, [2] Weatherall, [3] Orkin and Nathan, [4] and Forget and Pearson. [5]

The classification, genetic basis, and pathophysiology of the thalassemia syndromes are based on a thorough understanding of the human hemoglobins, their biosynthesis, their encoding

globin gene families, and their function as soluble oxygen-carrying pigments. Therefore, the readers of this chapter should first familiarize themselves with the material presented in Chapters 15 and 22 . The material presented in this chapter is also substantially clarified by prior reading of Chapter 26 , since the principles underlying the pathophysiology of and therapy for thalassemia draw heavily on knowledge of iron metabolism.

DEFINITIONS AND NOMENCLATURE

The term thalassemia is derived from a Greek term that, roughly, means the sea (Mediterranean) in the blood. [1] It was first applied to the anemias frequently encountered in people of the Italian and Greek coasts and nearby islands. [6] [7] [8] The term is now used to refer to inherited defects in globin chain biosynthesis. Individual syndromes are named according to the globin chain whose synthesis is adversely affected. Thus, -globin synthesis is absent or reduced in -thalassemia, -globin synthesis in -thalassemia, -globin and -globin synthesis in -thalassemia, and so forth. In some contexts it is also useful to subclassify the syndromes according to whether synthesis of the affected globin chain is totally absent (i.e., ^{0} -thalassemia) or only partially reduced (i.e., $^{+}$ -thalassemia).

The most common forms of thalassemia arise from total absence of structurally normal globin chains or a partial reduction in their synthesis. In contrast to the structural hemoglobinopathies (e.g., sickle cell anemia), which are characterized by the production of normal amounts of mutant globin chains having deranged physical or chemical properties, thalassemias are quantitative disorders: the primary lesion lies in the amount of globin produced. However, some rare forms of thalassemia are characterized by the production of structurally abnormal globin chains in reduced amounts. These thalassemic hemoglobinopathies share features of both thalassemia and structural hemoglobinopathies. [9]

Some mutations alter the patterns of fetal to adult hemoglobin switching. These conditions, called hereditary persistence of fetal hemoglobin (HPFH), are not generally associated with clinical symptoms; nonetheless, they merit consideration in this chapter. Their importance lies in their role as modulating factors when co-inherited with other hemoglobinopathies, and in their usefulness both as models for investigating the molecular basis for globin gene regulation during human development and as paradigms for rational therapy for the major -chain hemoglobinopathies, namely, sickle cell anemia and -thalassemia.

ETIOLOGY, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

The thalassemias are inherited as pathologic alleles of one or more of the globin genes located on chromosomes 11 and 16 (see Chap. 22). These lesions range from total deletion or rearrangement of the loci to point mutations that impair transcription, processing, or translation of globin mRNA. The precise nature of the defects is summarized in a later section.

Thalassemias have been encountered in virtually every ethnic group and geographic location. They are most common in the Mediterranean basin and equatorial or near-equatorial regions of Asia and Africa. The thalassemia belt extends along the shores of the Mediterranean and throughout the Arabian peninsula, Turkey, Iran, India, and southeastern Asia, especially Thailand, Cambodia, and southern China. [10] [11] [12] [13] The prevalence of thalassemia in these regions is in the range of 2.515%. Like sickle cell anemia, thalassemia is most common in those areas historically afflicted with endemic malaria. Malaria seems to have conferred selective survival advantage to thalassemia heterozygotes, in whom infection with the malaria parasite is thought to result in milder disease and less impact on reproductive fitness.[1] [2] [14] Therefore, the gene frequency for thalassemia has become fixed and high in populations exposed to malaria over many centuries.

PATHOPHYSIOLOGYGENERAL PRINCIPLES

The pathophysiology and molecular genetics of individual forms of thalassemia are closely intertwined. Therefore, detailed consideration of these syndromes is best deferred to their individual subsections. This section considers only mechanisms common to the pathogenesis of all of these syndromes. [1] [2] [3] [4] [5] [15]

The primary lesion in all forms of thalassemia is reduced or absent production of one or more globin chains. For all practical purposes, the major impact on clinical well-being occurs only when these lesions affect the - or -globin chains necessary for the synthesis of hemoglobin (Hb A; $_{2}$ $_{2}$). (Severe impairment of -, epsilon-, or -globin production is presumably lethal in utero.) One consequence of reduced globin chain production is immediately apparent: reduced production of functioning hemoglobin tetramers. As a result, hypochromia and microcytosis are characteristic of virtually all patients with thalassemia. In the milder forms of the disease, this phenomenon may be barely detectable.

The second consequence of impaired globin biosynthesis is unbalanced synthesis of the individual - and -subunits. Hemoglobin tetramers are highly soluble and have reversible oxygen-carrying properties exquisitely adapted for both oxygen transport and delivery under physiologic conditions. Free or unpaired -, -, and -globin chains are either highly insoluble or form homotetramers (Hb H and Hb Barts) that are incapable of releasing oxygen normally and are relatively unstable and precipitate as the cell ages. For poorly understood reasons, no compensatory regulatory mechanism exists whereby impaired synthesis of one globin subunit leads to a compensatory downward adjustment in the production of the other (partner) globin chain of the hemoglobin tetramer. Thus, useless excess -globin chains continue to accumulate and precipitate in -thalassemia, whereas excess -globin chains form Hb H in -thalassemia. During uterine development, excess -globin chains form Hb Barts in -thalassemic individuals.

The abnormal solubility or oxygen-carrying properties of these chains lead to a variety of physiologic derangements. Indeed, in the severe forms of thalassemia, it is the behavior of the unpaired globin chains accumulating in relative excess that dominates the pathophysiology of the syndrome, rather than the mere underproduction of functioning hemoglobin tetramers. The precise complications of this pathophysiologic phenomenon are diverse and depend on both the amount and the identity of the globin chain accumulating in excess. For the moment, the fundamental principle that must be appreciated is that thalassemias cause symptoms both by underproduction of hemoglobin and by accumulation of unpaired globin subunits. The unpaired subunits are usually the major source of morbidity and mortality.

The predominant circulating hemoglobin at the moment of birth is fetal hemoglobin (Hb F [$_{2}$ $_{2}$]) (see Chap. 22). Although the switch from - to -globin biosynthesis begins before birth, the composition of hemoglobin in the peripheral blood changes much later because of the long life span of normal circulating red cells. Hb F is thus slowly replaced by adult hemoglobin (Hb A), so that infants do not depend heavily on normal amounts and function of Hb A until they are 46 months old. The pathophysiologic consequences of these considerations are that -chain hemoglobinopathies tend to be symptomatic in utero and at birth, whereas individuals with -chain abnormalities are asymptomatic until 46 months of age. These differences in the onset of phenotypic expression arise because -chains are needed to form both Hb F and Hb A, whereas -chains are required only for Hb A.

-THALASSEMIA SYNDROMES

Nomenclature

Many different mutations cause -thalassemia and its related disorders such as -thalassemia and the silent carrier state. They are inherited in a multitude of genetic combinations responsible for a heterogeneous group of clinical syndromes. -Thalassemia major, also known as Cooleys anemia or homozygous -thalassemia, is a clinically severe disorder that results from the inheritance of two -thalassemia alleles, one on each copy of chromosome 11. As a consequence of diminished Hb A synthesis, the circulating red cells are very hypochromic and abnormally shaped; they contain markedly reduced amounts of hemoglobin. Accumulation of free -globin chains leads to the deposition of precipitated aggregates of these chains to the detriment of the erythrocyte and its precursor cells in the bone marrow. The anemia of thalassemia major is so severe that chronic blood transfusions are usually required.

The term -thalassemia intermedia is applied to a less severe clinical phenotype in which significant anemia occurs but chronic transfusion therapy is not absolutely required. It usually results from the inheritance of two -thalassemia mutations, one mild and one severe; the inheritance of two mild mutations; or occasionally, the inheritance of complex combinations, such as a single -thalassemia defect and an excess of normal -globin genes, or two -thalassemia mutations co-inherited with heterozygous -thalassemia (in this last form, known as -thalassemia, the -thalassemia allele reduces the burden of unpaired -chains). [16] [17] [18] Simple heterozygosity for certain forms of -thalassemic hemoglobinopathies can also be associated with a thalassemia intermedia phenotype, sometimes called dominant -thalassemia. [19] [20]

Thalassemia minor, also known as -thalassemia trait or heterozygous -thalassemia, is due to the presence of a single -thalassemia mutation and a normal -globin gene on the other chromosome. It is characterized by profound microcytosis with hypochromia but mild or minimal anemia.

-Thalassemia is also called by several other names, including Cooleys anemia, Mediterranean anemia, von Jakschs anemia, [1]

target cell anemia, erythroblastic anemia, and familial macrocytosis.

Molecular Pathology

Forms of -thalassemia arise from mutations that affect every step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation of mature mRNA, and post-translational integrity of the -polypeptide chain (Fig. 29-1 and Table 29-1). Large deletions removing two or more non--genes are found in rare cases, as are smaller partial or total deletions of the -gene alone (Fig. 29-1). Most types of -thalassemia are due to point mutations affecting one or a few bases. (The original literature for this section is massive; it

Figure 29-1 Model of human -globin gene showing sites and types of various mutations causing -thalassemia. *(From Kazazian,[23] with permission.)*

is summarized in several reviews.[2] [3] [4] [5] [21] [22] [23] [24] [25] [26]) Of the more than 125 point mutations causing -thalassemia, about 15 account for the vast majority of affected patients, with the remainder responsible for the disorder in only relatively few patients. It has been determined that five or six mutations usually account for more than 90% of the cases of -thalassemia in a given ethnic group or geographic area (Table 29-1).[22] [23]

Transcription

Several mutations alter promoter regions upstream of the -globin mRNA sequence, impairing mRNA synthesis, whereas mutations that derange the sequence used as the signal for addition of the poly-(A) tail (polyadenylation signal; see Chap. 22) have been shown to result in abnormal cleavage and polyadenylation of the nascent mRNA precursor, with resulting reduced accumulation of mature mRNA.[21] [22] [23] [24]

Processing

Many forms of -thalassemia are due to mutations that impair splicing of the mRNA precursor into mature mRNA in the nucleus or that prevent translation of the mRNA in the cytoplasm. The molecular pathology of splicing mutations is complex (Fig. 29-1). Some base substitutions ablate the donor (GT) or acceptor (AG) dinucleotides (see Chap. 22), which are absolutely required at the intron-exon boundaries for normal splicing, and thereby completely block production of mature functional mRNA. Thus, no -globin can be synthesized (^{0} -thalassemia). Other mutations alter the consensus sequences that surround the GT- and AG-invariant dinucleotides and decrease the efficiency of normal splicing signals by 7095%, resulting in $^{+}$ -thalassemia; some consensus mutations even abolish splicing completely, causing ^{0} -thalassemia. A third type of splicing aberration results from mutations that are not in the immediate vicinity of a normal splice site. These alter regions within the gene, called cryptic splice sites, which resemble consensus splicing sites but do not normally sustain splicing (Fig. 29-2). The mutations activate the site by supplying a critical GT or AG nucleotide or by creating a sufficiently strong consensus signal to stimulate splicing at that site 60100% of the time. The activated cryptic sites generate an abnormally spliced, untranslatable mRNA species. Only 1040% of the mRNA precursors are thus spliced at the normal sites, which causes $^{+}$ -thalassemia of varying severity. The mutation responsible for the most common form of -thalassemia among Greeks and Cypriots (Fig. 29-2) activates a cryptic splice site near the 3 end of the first intron (position 110). [27] [28] The determinants that dictate the degree to which each mutation alters splice site utilization remain largely unknown.

Translation

Mutations that abolish translation occur at several locations along the mature mRNA and are very common causes of ^{0} -thalassmia (Fig. 29-1 and Table 29-1). The most common form of ^{0} -thalassemia in Sardinians results from a base substitution in the gene that changes the codon encoding the 39th amino acid of the -globin chain from CAG, which encodes glutamine,

Figure 29-2 $^{+}$ -Thalassemia arising from alternative mRNA splicing due to a mutation activating a cryptic splicing site. **(A)** The g a mutation is shown enclosed in squares, located near the 3 end of intron 1 (IVS-1); it creates a sequence motif closely mimicking a pre-mRNA acceptor splice site. The product of the alternative splicing event is also shown. Note that use of the activated cryptic site generates a mature mRNA that contains an in-frame termination codon and therefore does not encode a functional -globin chain. *(From Benz,[21] with permission).* **(B)** Diagram of the means by which use of the cryptic splice site 90% of the time (the observed value) causes only 10% of the mRNA precursor molecules to be spliced normally into translatable mature mRNA, thus causing $^{+}$ -thalassemia. *(From Bunn and Forget,[2] with permission.)*

Figure 29-3 ^{0} -Thalassemia arising from a mutation changing an amino acid codon to a termination codon (nonsense mutation). *(From Takeshita et al.,[309] with permission.)*

to TAG, whose equivalent (UAG) in mRNA specifies termination of translation (Fig. 29-3).[29] [30] A premature termination codon totally abrogates the ability of the mRNA to be translated into normal -globin. Premature translation termination also results indirectly from frameshift mutations (i.e., small insertions or deletions of a few bases, other than multiples of 3, that alter the phase or frame in which the nucleotide sequence is read during translation). [30] An in-phase premature termination codon is invariably encountered within the next 50 bases downstream from a frameshift.

Other Sites

Rare mutations that affect gene function by intriguing mechanisms have been described. An extremely large deletion of the -globin gene cluster has been described that removes the epsilon-, -, and -genes. [31] The patient has a severe -thalassemia phenotype, but the -globin gene and 500 bases of adjacent 5 and 3 DNA have an entirely normal nucleotide sequence. The -gene functions normally in surrogate cells. The important aspect of this deletion is that it removes the critical locus control region (LCR)[3] [5] [32] (see Chap. 22) located thousands of bases upstream from the beginning of the globin gene cluster at the 5 end of the epsilon-globin gene; loss of this region severely impairs -gene expression. A number of additional deletions involving the LCR and various portions of the -gene cluster, but sparing the -gene itself, have the same phenotype.[3] [4] [5] [32] In other cases of -thalassemia, the -gene and adjacent DNA are structurally normal, and the basis of abnormal gene expression is unknown.[23]

The relationship between an individual mutation and the clinical severity of the -thalassemia phenotype associated with that particular mutation is complex. [22] [23] For example, the A G mutation at position 29 of the -gene promoter commonly encountered in blacks is associated with a different clinical severity than that found in Chinese patients inheriting the same mutation.[33] Clearly, the genetic context of the mutation is different in the two populations. The mutant -globin gene in the two different racial groups probably arose in different chromosomal backgrounds that have different potentials for -gene expression, as discussed in the following paragraph.

Multiple forms or haplotypes of normal non--globin gene clusters exist in various human populations. These are defined by the patterns of restriction fragment length polymorphisms[34] detected when DNA is digested with restriction endonucleases and analyzed by Southern gene blotting for the fragments bearing the non--globin genes. Haplotypes differ according to whether each restriction site is present along the gene cluster. More than 12 haplotypes have been defined by examination of several restriction sites located along the cluster that are present or absent in a polymorphic manner in normal individuals. [34] The clinical variability encountered in two different groups bearing identical primary mutations correlates best with the haplotype or chromosomal background on which the mutation is inherited. The differences in physiologically important functions among haplotypes that modulate severity remain unknown, but a possible explanation lies in the varying ability of the -globin genes on different chromosomes to respond to severe erythroid stress (see Chap. 15) by increased expression during postnatal life. The -globin genes carried on some haplotypes differ in the degree to which they can respond in this manner. [35] Because Hb F synthesis reduces the severity of -chain hemoglobinopathies,[1] the level of -gene expression from a given chromosome can play an important modulating role.

Pathophysiology

The biochemical hallmark of -thalassemia is reduced biosynthesis of the -globin subunit of Hb A ($_{2}$ $_{2}$). In -thalassemia heterozygotes, -globin synthesis is about half-normal (/ synthetic ratio 0.50.7). In homozygotes for ^{0} -thalassemia, who account for about one-third of patients, -globin synthesis is absent. -Globin synthesis is reduced to 530% of normal levels in $^{+}$ -thalassemia homozygotes or $^{+}$ /^{0} -thalassemia compound heterozygotes, who together account for about two-thirds of cases. [1]

Because synthesis of Hb A ($_{2}$ $_{2}$) is markedly reduced or absent, the red cells are hypochromic and microcytic. -Chain synthesis is partially reactivated, so that the hemoglobin of the patient contains a relatively large proportion of Hb F. [1] However, these -chains are quantitatively insufficient to replace -chain production.

In heterozygotes (with -thalassemia trait), relatively little -globin accumulation occurs. Output from the single normal -globin gene supports substantial Hb A formation, thus preventing harmful accumulation of excess -globin chains. Thus, one encounters hypochromia with microcytosis but relatively little evidence of anemia, hemolysis, or ineffective erythropoiesis.

Individuals inheriting two -thalassemic alleles experience a more profound deficit of -chain production. Little or no Hb A is produced; more important, the imbalance of - and -globin production is far more severe (Fig. 29-4). The limited capacity of red cells to proteolyze the excess -globin chains, a capacity that probably exerts a protective effect in heterozygous -thalassemia, is overwhelmed in homozygotes. Free -globin accumulates, and unpaired -chains aggregate and precipitate to form

inclusion bodies, which cause oxidative membrane damage within the red cell, [36] and destruction of immature developing erythroblasts within the bone marrow (ineffective erythropoiesis). [37] Consequently, relatively few of the erythroid precursors undergoing erythroid maturation in the bone marrow survive long enough to be released into the blood as erythrocytes. The occasional erythrocytes that are formed during erythropoiesis bear a burden of inclusion bodies. These abnormal cells are removed

Figure 29-4 Pathophysiology of severe forms of -thalassemia. The diagram outlines the pathogenesis of clinical abnormalities resulting from the primary defect in -globin chain synthesis.

prematurely by the reticuloendothelial cells in the spleen, liver, and bone marrow, producing hemolytic anemia.

Defective -globin synthesis exerts at least three distinct yet interrelated effects on the generation of oxygen-carrying capacity for the peripheral blood (Fig. 29-4): (1) ineffective erythropoiesis, which impairs production of new red cells; (2) hemolytic anemia, which shortens the survival of the few red cells produced; and (3) hypochromia with microcytosis, which reduces the oxygen-carrying capacity of those few red cells that do survive. In the most severe forms of the disorder, these three factors conspire to produce a catastrophic anemia, complicated by the effects of exuberant hemolysis.

The profound deficit in the oxygen-carrying capacity of the blood stimulates production of high levels of erythropoietin in an attempt to promote compensatory erythroid hyperplasia. Unfortunately, the ability of the marrow to respond is markedly impaired by ineffective erythropoiesis. Massive bone marrow expansion does occur, but very few erythrocytes are actually supplied to the circulation. The marrow becomes packed with immature erythroid progenitors, which die from their -globin burden before they reach the reticulocyte stage. Profound anemia persists, driving erythroid hyperplasia to still higher levels. In some cases, erythropoiesis is so exuberant that masses of extramedullary erythropoietic tissue form in the chest, abdomen, or pelvis.

Massive bone marrow expansion exerts numerous adverse effects on the growth, development, and function of critical organ systems. Children with thalassemia develop a characteristic chipmunk facies due to maxillary marrow hyperplasia and frontal bossing (Fig. 29-5). Thinning and pathologic fractures of the long bones and vertebrae arise from cortical invasion by erythroid elements. Profound growth retardation and endocrine malfunction are common.

Hemolytic anemia results in massive splenomegaly and high-output congestive heart failure. Conscription of so many caloric resources for futile sustenance of erythroid hyperplasia leads to inanition, susceptibility to infection, and, in untreated cases, death during the first two decades of life. Treatment with red cell transfusions sufficient to maintain hemoglobin levels at >9.010.0 g/dl improves oxygen delivery, suppresses the excessive ineffective erythropoiesis, and prolongs life. Unfortunately, as discussed in more detail later, complications of chronic transfusion therapy, including iron overload, in the past usually proved to be fatal before age 30. Iron chelation therapy, initiated at an early age, can prolong survival beyond the third decade.

Clinical Manifestations

The advent of modern hypertransfusion therapy has had a major impact on the clinical and laboratory features of thalassemia major. These regimens have ameliorated many of the most striking

Figure 29-5 Thalassemic facies. See text for description. *(From Jurkiewicz et al.,[252] with permission.)*

manifestations of the disease. The disastrous symptom constellation so prevalent in the past is now, at least in North America and most industrialized countries, of largely historical importance. Nonetheless, the clinical manifestations and complications of untreated or undertreated -thalassemia major described in this section best illustrate the principles of the pathophysiology just outlined. These descriptions apply to the

CLINICAL HETEROGENEITY OF THALASSEMIA

The severity of -thalassemia is remarkable for its variability in different patients. Two siblings inheriting identical thalassemia mutations sometimes exhibit markedly different degrees of anemia and erythroid hyperplasia. Many factors contribute to this clinical heterogeneity. Individual alleles vary with respect to severity of the biosynthetic lesion. Other modulating factors ameliorate the burden of unpaired -globin inclusion bodies. Co-inheritance of the -thalassemia trait actually reduces clinical severity because it restricts production of excess -globin. High levels of Hb F expression persist to widely varying degrees in -thalassemia. Since -globin can substitute for -globin, simultaneously generating more functional hemoglobins and reducing the -globin inclusion burden, this is a powerful modulating factor. Patients may also vary in their ability to solubilize unpaired globin chains by proteolysis. Occasional heterozygous patients have had more severe anemia than expected, apparently because of defects in these proteolytic systems; or because of the type of thalassemic mutation. Inheritance of more than the usual complement of -globin genes has also been claimed to increase with severity of -thalassemia because of additional production of unpaired -globin chains. All these factors emphasize the essential role of -globin inclusions in the pathophysiology of -thalassemia.

disease as it was seen before 1965 and is still prevalent in many parts of the world. Current clinical management and associated clinical manifestations and complications have been reviewed in a number of publications. [38] [39] [40] [41] [42] [43]

Protected by prenatal Hb F production, the infant with Cooleys anemia is born free of significant anemia, although deficient -chain synthesis can be demonstrated at birth. Quantitative Hb A determinations of cord blood reveal that thalassemia homozygotes have <2% Hb A; heterozygotes have 6.89.9%, and normals have 20%. [44] Clinical manifestations usually emerge during the second 6 months of life. The diagnosis is almost always evident by 2 years of age. [45] Pallor, irritability, growth retardation, abdominal swelling due to enlargement of the liver and spleen, and jaundice are the usual presenting features. [46] Facial and skeletal changes develop later. Untreated victims die in late infancy or early childhood as a consequence of severe anemia. In a retrospective review from Italy, the average survival of children with untreated thalassemia major was less than 4 years; approximately 80% died in the first 5 years of life. [47]

Clinical and Laboratory Evaluation

Blood

The anemia of thalassemia major is characterized by severe hypochromia and microcytosis. The hemoglobin level decreases progressively during the first months of life. When the child becomes symptomatic, the hemoglobin level may be as low as 34 g/dl. Red cell morphology is strikingly abnormal, with many microcytes, bizarre poikilocytes, teardrop cells, and target cells (Fig. 29-6). A characteristic finding is the presence of extraordinarily hypochromic, often wrinkled and folded cells

(leptocytes) containing irregular inclusion bodies of precipitated -globin chains.

Nucleated red cells are frequently present. The reticulocyte count is 28%, lower than would be expected in view of the extreme erythroid hyperplasia and hemolysis. The low count reflects the severity of intramedullary erythroblast destruction. The white blood cell (WBC) count is elevated. A moderate polymorphonuclear

Figure 29-6 Morphology of the peripheral blood film in severe -thalassemia. Note the many bizarre cells, the hypochromia, nucleated RBCs, target cells, and leptocytes. *(From Pearson and Benz,[308] with permission.)*

leukocytosis and normal platelet count are typical unless hypersplenism has developed. The bone marrow exhibits marked hypercellularity consequent on normoblastic hyperplasia. These red cell precursors also show defective hemoglobinization and reduced amounts of cytoplasm. Prodigious elevations in circulating nucleated RBCs, an increased WBC count, and thrombocytosis all occur after splenectomy.

The osmotic fragility is strikingly abnormal. The red cells are so markedly resistant to hemolysis in hypotonic sodium chloride solution that some are not entirely hemolyzed, even in distilled water. The serum iron is increased, and iron-binding proteins are fully saturated. [48]

The hemoglobin profile reveals predominantly Hb F. In patients with homozygous ^{0} -thalassemia, no Hb A is found. In the newborn with $^{+}$ -thalassemia, about 90% is Hb F; with advancing age Hb F slowly decreases, but it is always considerably higher than normal (by 1090%). Transfusions will confound the estimation of the true Hb F level. The Hb A_2 /Hb A ratio, which in the normal person is about 1:40, is increased to >1:20 in thalassemia trait, but Hb A_2 levels in thalassemia major are variable, probably because of increased numbers of F cells that have a decreased Hb A_2 content.[1] Other biochemical abnormalities of the red cell in thalassemia major include a postnatal persistence of the i antigen and a decrease of red cell carbonic anhydrase; these findings are probably also due to the elevated levels of circulating F cells.

The intraerythrocytic inclusions in the peripheral blood cells, first described by Fessas, [49] are especially prominent after splenectomy. These inclusions, best seen by supravital staining with methyl violet or by phase microscopy, are aggregates of precipitated, denatured -chains. [50] They are also found in large numbers within erythroid precursors in the bone marrow.

The serum is icteric; unconjugated bilirubin levels are in the range of 2.04.0 mg/dl. Hepatitis, biliary obstruction from gallstones, or cholangitis should be considered if the value is higher. Red cell survival in thalassemia major is variable but usually markedly decreased. The ^{51}Cr half-life ranges between 6.5 and 19.5 days, in contrast to the normal half-life of 2535 days.[37] Increased plasma iron turnover and poor utilization of radiolabeled iron indicate ineffective erythropoiesis. [37] Serum SGOT and SGPT are frequently increased, reflecting hepatic damage secondary to hemosiderosis or viral hepatitis. Lactate dehydrogenase levels are markedly elevated as a consequence of ineffective erythropoiesis. Haptoglobin and hemopexin are reduced or absent. [51]

Low levels of serum zinc are present. A relationship between this finding and growth failure has been postulated but not established. [52] [53] Low levels of serum and leukocyte ascorbic acid are common in thalassemic patients because increased metabolism of the vitamin to oxalic acid occurs in the presence of iron overload. [54] Biochemical evidence of folic acid deficiency has been described and is presumably due to excessive consumption secondary to increased requirements. [55] [56] Daily supplementation with 1.0 mg of folic acid is therefore reasonable, especially if the diet is not optimal. The large amounts of iron present in patients with thalassemia major, coupled perhaps with malabsorption secondary to pancreatic and hepatic fibrosis, may lead to decreased levels of vitamin E. Serum levels of -tocopherol are often reduced to less than <0.5 mg/dl, and increased red cell membrane lipid peroxidation has been described. [57] [58] [59] Unfortunately, therapy with large doses of vitamin E neither improves survival of transfused red cells nor decreases transfusion requirements. [60] Nevertheless, supplemental vitamin E may decrease the toxic effects of iron overload on various tissues.

Coagulation abnormalities similar to those found in patients with liver disease of any cause (i.e., lowered levels of factors II, V, VII, IX, X, and XI) occur, particularly in older patients. Only rarely are the abnormalities sufficient to require specific therapy. A general correlation exists between the coagulation status and the other parameters of hepatic function. Both deteriorate in patients with massive iron overload. [61] Six of nine thalassemia patients studied for platelet function had slightly prolonged bleeding times and abnormal platelet aggregation. [62] Although these changes are probably not of great clinical significance, salicylates should be used with caution. On the other hand, thrombocytosis frequently develops following splenectomy and is thought to contribute to pulmonary vascular obstruction, pulmonary hypertension, and hypoxemia.[63] [64] [65] Salicylates or dipyridamole may be beneficial in such a setting. [65]

Skeletal Changes

Skeletal abnormalities (Fig. 29-7) result primarily from hyperplasia and expansion of the erythroid marrow. [66] These cause widening of the marrow space and thinning of the cortex, with consequent osteoporosis.[67] Striking changes in the skull and facial bones include expansion of the frontal bone with prominent frontal bossing. The membranous bones of the skull do not expand adjacent to the sutures, resulting in a hot cross bun configuration of the skull. Radiographs reveal the diploic spaces to be widened. At first the skull has a granular appearance, but later perpendicular bony trabeculae appear, giving the classic hair on end or crew cut appearance (Fig. 29-7).

The maxilla is regularly involved. Pneumatization of the sinusoids is markedly delayed; marked overgrowth of the maxilla results in severe malocclusion, jumbling of the upper incisors, and prominence of the malar eminences.[68] These bone changes produce the classic facies. The earliest skeletal changes are observed in the metacarpals, metatarsals, and phalanges, where expanded medullary cavities produce a rectangular and then a convex shape (Fig. 29-7). Marked osteoporosis and cortical thinning may predispose to pathologic fractures of the extremities; compression fractures of the vertebrae may also occur (Fig. 29-8). Premature fusion of the epiphyses of the long bones is common in patients who are more than 10 years old. Irregular fusion of the epiphyses of the proximal humerus results in characteristic shortening of the upper arms.[69] [70]

Several abnormalities in the ribs may occur, including notching and osteolytic lesions. [66] [71] The ribs become very wide, especially at the points of their attachment to the vertebral column. Marrow masses may extrude from these sites, creating the appearance of paravertebral masses (Fig. 29-9). An unusual complication is expansion of paravertebral hematopoietic tissue into the spinal canal with resultant cord compression. [72] Decompressive laminectomy or radiation therapy may be necessary to prevent permanent paralysis.[73] [74] Although rarely seen today in properly transfused patients with -thalassemia major, it is not infrequently observed in patients with thalassemia intermedia whose marrow is not suppressed by regular transfusions.

The character and degree of the bone lesions change significantly with age. In older children, the bone lesions regress in the more distal portions of the skeleton (hands, arms, and legs), a feature correlating with the normal developmental replacement of red marrow by fatty marrow. The characteristic changes of the hands and other peripheral areas are thus diminished and may disappear in later life. [75] [76] However, in the skull, spine, and pelvis (which are sites of active, persistent erythropoiesis), the radiographic changes become more conspicuous.[75]

Liver and Gallbladder

Hepatomegaly is prominent in severely affected patients. This is a consequence of extramedullary hematopoiesis initially, so that early hepatomegaly can be reduced by hypertransfusion.[77] Later in the course of the disease, hepatomegaly is associated with extensive cirrhosis. Iron deposition, first present in the Kupffer cells, ultimately engorges the parenchymal cells, resulting in an appearance that is indistinguishable from that of idiopathic hemochromatosis. [78] [79] The hepatocellular injury of

iron overload may be due to the liberation of hydrolases resulting from initiation by the ferrous form of iron of peroxidative damage of lysosomal membrane lipids. [80]

Viral hepatitis may augment liver damage. In Italy, a high incidence of hepatitis B surface markers (HBsAg) and antihepatitis B core antigen (anti-HBc) and anti-HBs antibodies was found in a group of 253 children. [81] In other reports, a high frequency of chronic active hepatitis was observed. Multiply transfused patients also have a high prevalence of seropositivity for anti-hepatitis C antibody, indicating a likely additional factor contributing to chronic liver disease. It has also been postulated that liver iron overload may facilitate persistence of virus-induced progressive liver diseases. [82] The most important abnormalities of liver function include hypergammaglobulinemia, hypoalbuminemia, moderate decreases in the coagulation factors that are synthesized in the liver, and increased levels of transaminases.[61]

Pigmentary gallstones due to high levels of bilirubin production are found in an increasing number of patients more than 4 years old. Two-thirds of patients have multiple calcified bilirubinate calculi after the age of 15. [83] Gallbladder surgery is not

Figure 29-9 Chest radiograph typical of severe -thalassemia. Note widening of the rib ends and cardiac dilation. *(From Pearson and Benz,[308] with permission.) A B*

usually indicated unless biliary colic or obstructive jaundice has occurred.

Heart

Cardiac abnormalities are important causes of morbidity and mortality in patients with thalassemia major. Cardiac dilation secondary to anemia is almost always present in untreated young children (Fig. 29-9). Unless intensive chelation therapy is started in the first decade

of life, myocardial hemosiderosis is inevitable during the second decade, when serious cardiac disorders become frequent. Early electrocardiographic abnormalities include a prolonged PR interval, first-degree heart block, and premature atrial contractions. [84] Later, ST-segment depression and ventricular ectopic beats constitute ominous indicators of myocardial damage. Periodic evaluation of cardiac function is essential. Echocardiographic estimation of left ventricular function may reveal abnormalities before there are any symptoms. The left ventricular end-systolic pressure-dimension relationship (ejection fraction), as determined by echocardiography, provides a noninvasive measure of ventricular contractility. [85] Sterile pericarditis occurs in many patients with massive iron overload. [86] Although pericarditis is most often attributed to hemosiderosis, an association with -hemolytic streptococcal infection has also been suggested. [87] Therapy is symptomatic: bed rest, treatment of infection, management of superimposed congestive heart failure, and salicylates or corticosteroids for pain. Occasionally pericardiectomy may be indicated.

Cardiomegaly and left ventricular dysfunction progress to chronic refractory congestive heart failure. In addition to standard therapy for failure, the hemoglobin level must be maintained at >1012 g/dl and intensive chelation therapy instituted or continued. The iron-overloaded myocardium has little capacity to improve its performance unless excess iron is removed. Arrhythmias may cause sudden death. Supraventricular tachycardia and atrial fibrillation may necessitate the use of antiarrhythmic agents, even though these agents can further depress ventricular function. These complications are the usual cause of death in patients with thalassemia major.

Lungs

Mild abnormalities of pulmonary function are common. Some patients exhibit primarily restrictive defects; [88] [89] others experience mild to moderate small airway obstruction and hyperinflation. [90] [91] Most patients have a decreased maximal oxygen uptake and anaerobic threshold; these do not normalize after transfusion. [92] As previously mentioned, postsplenectomy thrombocytosis may predispose to pulmonary vascular occlusion and pulmonary hypertension. [63] [64] [65] Treatment with high doses of the iron chelator deferoxamine may also be associated with deterioration of pulmonary function. [93]

Kidneys

The kidneys are frequently enlarged, owing in part to extramedullary hematopoiesis and in part to marked dilation of the renal tubules. [94] The urine is often dark brown, reflecting the excretion of products of heme catabolism. [95] The urine also contains large amounts of urates and uric acid.

Growth and Endocrine Status

Growth retardation, including skeletal and dental age, [96] was common even in young children until the use of hypertransfusion regimens restored relatively normal growth during the first decade. The adolescent growth spurt is delayed or absent without intensive chelation therapy; most patients, even those well maintained by transfusion, do not attain normal stature. [45] [97] Menarche is frequently delayed. Breast development may be poor, and many female patients are oligomenorrheic or amenorrheic. Induction of cyclic uterine bleeding with low-dose estrogen and progesterone may be of psychological benefit. Pregnancy may occur even in patients who have been transfusion dependent from infancy, provided that they have been intensively treated with chelation therapy. [98] [99]

Boys are frequently immature, with sparse facial and body hair. Although spermatogenesis may be normal, libido is often decreased. When lack of secondary sexual characteristics is emotionally disturbing, small doses of androgen may be used to produce phallic enlargement, deepening of the voice, and growth of facial and body hair.

A multicenter study of 250 adolescent patients in northern Italy showed that despite hypertransfusion and 710 years of iron chelation therapy, two-thirds of males and one-third of females more than 14 years old were 2 SD below the mean for height. [100] Many adolescents aged 1218 years lacked any secondary sexual changes of puberty. However, the mean serum ferritin level in the entire group was 3,500 ng/ml, indicating persistence of a high level of excess iron burden in most of this group. More intensive chelation therapy started in the first decade of life frequently will allow normal onset of puberty and development of secondary sexual changes.

Growth retardation and hypogonadism are also found in association with zinc deficiency. Because urinary excretion of zinc is increased by hemolysis, a clinical trial of zinc supplementation was conducted in Turkey; [101] it showed enhanced growth velocity in the treated group. Since these patients did not receive adequate transfusion or chelation therapy, the applicability of these findings to comprehensively treated patients is uncertain.

Abnormal carbohydrate metabolism is common in older patients with thalassemia major. Prepubertal children usually have normal insulin-stimulated glucose metabolism, but pubertal patients exhibit impaired responses despite normal steady-state blood glucose levels. Impaired oral glucose tolerance and higher than normal insulin levels in response to hyperglycemia are also encountered. [102] The defect in these patients appears to be related to insulin resistance, with insulin

deficiency developing later in the progression to diabetes. Multiple endocrine abnormalities such as hypoparathyroidism, [103] [104] hypothyroidism,[105] and hypothalamic pituitary insufficiency[106] are usually detectable only by provocative tests.

Spleen and Splenectomy

Massive splenomegaly is unusual in hypertransfused patients. Thrombocytopenia and neutropenia may result from hypersplenism in untreated patients, although infection and bleeding are unusual. The usual indication for splenectomy is a progressive shortening of the survival rate of transfused blood cells, as evidenced by an increased transfusion requirement. The transfusion requirements of splenectomized patients are considerably less than those of patients whose spleens are intact. [107] [108] A transfusion requirement of >180200 ml/kg/year of packed RBCs usually represents excessive red cell breakdown and a need for splenectomy. Occasionally, serologic evidence of isoimmunization may be documented, permitting selection of compatible donor cells that have normal survival. Red cell survival studies and determination of splenic sequestration by the ^{51}Cr method are not usually of value for prediction of response. Splenectomy should be deferred as long as possible, certainly until after 5 or 6 years of age.

After splenectomy, striking thrombocytosis may occur. Increased numbers of nucleated red cells appear in the blood, and the presence of many red cells containing inclusion bodies composed of precipitated -globin chains can be demonstrated. The urine may become considerably darker.

Patients with thalassemia major are at significant risk for the development of overwhelming, often fatal, infection after splenectomy (postsplenectomy syndrome). The problem is most common in young children. *Streptococcus pneumoniae* causes two-thirds of cases; *Hemophilus influenzae* type B and *Neisseria meningitidis* account for most of the remaining infections. Typically, there is a fulminant clinical course, proceeding from mild fever and headache to hyperpyrexia, prostration, shock, and death within 612 hours; in one study, 1030% of splenectomized children with thalassemia major developed this complication, [109] but antibacterial vaccines administered before splenectomy and prophylaxis with antibiotics following splenectomy have dramatically reduced the incidence.

Removal of the spleen impairs immunity in many ways. The monocyte/macrophage tissues of the spleen are uniquely suited for clearance of bacteria from the blood in the absence of specific antibody.[110] The spleen may actively participate in antibody formation, especially in the early hours of an infection, [111] and is probably crucial to the alternate complement pathway needed for opsonization when specific antibody is lacking. Levels of IgM are also low in splenectomized patients. [112] A role for high levels of serum iron and saturation of iron-binding protein, which may predispose to infection, has been suggested but remains controversial. [113] When bacteria gain entrance to the bloodstream of a splenectomized patient, they are not cleared but proliferate rapidly in the circulation. Enormous numbers accumulate in a relatively short time, causing hyperpyrexia, shock, disseminated intravascular coagulation, adrenal hemorrhage, and, potentially, death.

Splenectomy should clearly be deferred as long as possible. Patients are more likely to have developed humoral immunity to a broad range of bacteria if the spleen is present for the first few years of life. Before splenectomy, polyvalent antipneumococcal, antimeningococcal, and anti- *H. influenzae* vaccines should be administered.[114] [115] [116] Oral penicillin therapy, used as prophylaxis against postsplenectomy infection, is now generally given to splenectomized patients with thalassemia. However, pneumococcal sepsis is not totally preventable, because not all pneumococcal strains are represented in the vaccine. In addition, penicillin-resistant strains of *S. pneumoniae* have emerged with a prevalence in the United States of 510%, or even higher in some localities. Following splenectomy, the patients parents should be instructed to seek medical attention immediately if significant fever (>102°F) develops. In addition to postsplenectomy sepsis, *Yersinia enterocolitica* or pseudotuberculosis infections have been noted in patients with thalassemia major receiving the iron chelator deferoxamine. [117] [118] [119] [120]

Transfusion Therapy

Transfusion therapy for thalassemia was once regarded as a palliative measure. [121] If palliation is defined as the prevention of discomfort and the maintenance of as nearly normal a life as possible, the transfusion programs then in general use were unsatisfactory even for those limited purposes. Symptoms of anemia and the cosmetic and other consequences of overgrowth of erythropoietic tissue rendered life unpleasant and uncomfortable. Because many of the problems of children with thalassemia major could be related to anemia, several centers initiated chronic, more aggressive transfusion programs designed to ameliorate these symptoms. The programs were designed to maintain hemoglobin levels at >910 g/dl. These more vigorous regimens have been designated hypertransfusion.

The clinical benefits of hypertransfusion programs were dramatic. The growth of younger children returned to normal percentiles for height and weight. [122] Erythropoiesis was partially but substantially suppressed, as evidenced by decreased numbers of reticulocytes and normoblasts and marked reduction in the level of Hb F. Enlargement of the liver and spleen receded. Abnormal facies and osteoporosis of long bones either did not develop or regressed. Cardiac dilation improved, and normal age-appropriate activities were possible. [76] [123]

Hypertransfusion programs require an increase of 125% in the amount of administered blood. Fears that this would result in accelerated iron overload, more rapid development of complications, and death at an earlier age were not realized. The life expectancy of children maintained by hypertransfusion programs has not been shortened, probably because the amelioration of severe anemia is associated with a significant reduction in gastrointestinal iron absorption; this offsets to some degree the increased transfusional iron load. The clinical superiority of hypertransfusion has led most treatment centers in industrialized countries to adopt it as standard management. Complications of anemia and erythropoietic hypertrophy have thus become uncommon.

More vigorous transfusional programs (supertransfusion) aimed at keeping hemoglobin levels at >12.0 g/dl have been used to suppress erythropoiesis further. After a transient increase in blood consumption during the first several months, [124] the blood requirements are not increased in splenectomized ^{0}-thalassemia patients during these regimens, although they

THERAPY FOR -THALASSEMIA MAJOR

Current therapy for thalassemia major consists of regular red cell transfusions to maintain a baseline hemoglobin level >9 g/dl, coupled with intensive parenteral chelation therapy with deferoxamine. Splenectomy is appropriate when transfusion requirements increase considerably more than expected for growth; these patients should also receive immunization against pneumococcal and *Hemophilus influenzae* B infections, as well as penicillin prophylaxis. Folic acid supplements may be added to meet the needs of increased erythropoiesis. Specific endocrine deficiencies associated with iron overload may require appropriate interventions. Psychosocial problems are common, as is true for many children with chronic disease; early intervention is necessary. Better treatment, screening, and genetic counseling and accurate prenatal diagnosis have shifted the age distribution of patients; a higher proportion of cases are now occurring in adolescents and adults.

commonly do increase in $^{+}$-thalassemia and in unsplenectomized children. A significant reduction in blood volume can be documented. [125] [126] This probably reflects the blood volume needed to support the expanded marrow tissues at lower levels of transfusion. The long-term effect of this more aggressive transfusion strategy on well-being and prognosis has not been determined.

An experimental transfusion program has been designed to reduce transfusion requirements by using a young population of red blood cells (neocytes) prepared by differential centrifugation or cell separators. [126] [127] These neocyte preparations should circulate longer in the recipient because they have a mean cell age of 30 days, compared with the mean cell age of 60 days of unfractionated blood. However, in two prospective clinical trials, blood requirements were reduced only by means of 13% and 16%.[128] [129] Neocyte preparations are two to four times more expensive than ordinary packed or glycerol-frozen red blood cells. Their use also entails

greater risks of isoimmunization and viral infections owing to the increased number of donor units needed. [128] An even more complicated procedure involving the use of neocyte/gerocyte exchange transfusions has been suggested as a method for further reducing iron overload. [126] [130] The method attempts to remove nearly senescent red cells before they are catabolized, thereby adding their iron to the body stores. Unfortunately, these methods are extraordinarily expensive.

Before the first blood transfusion is given to an infant with thalassemia major, a complete genotype of the RBCs should be obtained. This precaution applies to all patients facing long-term transfusion therapy. This information is valuable for identifying minor blood group incompatibility if isoimmunization develops later. In an Italian cooperative study of 1,435 patients, 5.2% had significant red cell alloantibodies (136 antibodies in 74 patients). [131] Group- and type-specific red cells that are compatible as determined by the indirect antiglobulin reaction should be used. Blood should be as fresh as possible, preferably before 2,3-diphosphoglycerate levels decline (45 days). [132]

Febrile reactions are frequent in patients who have had multiple transfusions. Pretransfusion therapy with acetaminophen and diphenhydramine or prior treatment of cells by freezing in glycerol, thawing, and washing may reduce the severity of the reaction. Glycerol-frozen red cell preparations contain very few leukocytes and produce few febrile reactions; [133] filtered blood is equally effective in preventing reactions. [134] Isoimmunization and transfusion reactions may still occur even with scrupulous techniques. [135] A superimposed autoimmune hemolytic process with circulating autoantibodies has been described in thalassemia patients. [136] A syndrome of post-transfusional hypertension, convulsions, and cerebral hemorrhage of uncertain etiology has also been reported. [137]

In practice, it is usually most efficient to give 13 donor units of red cells every 35 weeks, depending on the size of the patient and the destruction rate of transfused cells. Except for very young patients, those with hypersplenism, and those with thalassemia intermedia, a regularly scheduled transfusion every 3 weeks is both possible and convenient without the need of extra visits for measurement of hemoglobin levels. In more severely anemic patients, several initial transfusions may be necessary to increase the hemoglobin level to 1214 g/dl, but no more than 15 ml/kg of packed red cells should be given within a 24-hour period. More detailed guidelines on transfusion therapy for thalassemia major have been published. [38] [138] [139]

Patients receiving chronic transfusion therapy are at particular risk of acquiring viral infections from blood products, including infections with hepatitis B and C viruses, cytomegalovirus, and human immunodeficiency virus (HIV). Immunization against hepatitis B should be given early to thalassemia major patients, particularly in areas where the virus is common. [140] The current use of serologic screening of donor blood for anti-hepatitis C and anti-HIV antibodies greatly reduces the risk of infections. In a 1987 study of patients in Europe who received transfusions for hemoglobinopathy, 1.6% were shown to be HIV positive, including two patients with clinical AIDS. [141] In New York, where there is a higher incidence of AIDS than in Europe, a 1987 study of 70 chronically transfused thalassemia patients indicated that 17.1% were positive for HIV antibody and one had clinical AIDS. [142] In Philadelphia, only two of 60 similar patients were HIV positive; none have developed AIDS. [143]

Hemosiderosis and Chelation Therapy

Iron accumulation in thalassemia major depends directly on both the number of blood transfusions received and the age of the patient. Transfusional hemosiderosis is the major cause of late morbidity and mortality in thalassemia major. Establishment of a more favorable iron balance should lead to improved survival; this belief has motivated detailed study of various approaches for iron chelation or removal.

The calculated daily acquisition of iron in the transfusion-dependent child average 816 mg of iron, given a dose of 250500 ml of RBCs every month. [144] Excessive gastrointestinal absorption of iron adds to this burden, although absorption is reduced when a hemoglobin level of >9 g/dl is maintained. [145] No physiologic way to induce significant excretion has been found. Phlebotomy, the most efficient method of removing iron in other situations, is obviously precluded in this disease, although it may be applicable in thalassemia intermedia. A pharmacologic approach using specific iron-chelating agents has thus been adopted.

Several drugs with chelating properties have been synthesized or recovered from microorganisms. Many lack iron specificity or are inefficient; others cause significant toxicity. Only one has achieved clinical utility. Deferoxamine mesylate (Desferal, DFO) a siderophore isolated from cultures of *Streptomyces pilosus*, was introduced in 1960; it is a nearly specific iron-chelating agent (i.e., no other ions are chelated) with relatively low toxicity. [146]

Increased iron excretion following administration of DFO is proportional to body iron stores. To offset the amount of iron received by way of transfusions and attain negative iron balance, the chelating agent must cause the daily urinary excretion of 115 mg of iron. In the case of DFO, this was initially achieved in a British controlled study by daily intramuscular injections of 0.5 g/day for several years, which led to a reduced

rate of hepatic iron accumulation and hepatic fibrosis in thalassemic patients. [147] An Australian study using an injection of 1.0 g/day showed decreases in cardiac and hepatic size and improved cardiac function in a small group of patients treated for 210 years. [148] These studies were valuable in that they demonstrated potential efficacy, but lifelong daily intramuscular injection is clearly impractical as a method for dispensing the drug. The observation that iron excretion induced by DFO is markedly enhanced by slow intravenous or subcutaneous injection of the drug was an important advance. [149] A prolonged infusion period permits a longer exposure of the drug to a relatively small chelatable iron pool present at any given time in equilibrium with a nearly nonchelatable pool. In iron-overloaded, ascorbic acid-replete patients, urinary iron excretion >300 mg/day can be accomplished with large continuous intravenous doses. [150]

Slow infusion of DFO will achieve negative iron balance in many transfusion-dependent patients over 45 years of age. [38] [151] [152] [153] [154] [155] This involves daily 10- to 12-hour subcutaneous injections of about 2.0 g of DFO using a small battery-driven pump. The pump impels a syringe that infuses an aqueous solution of DFO through a no. 25 butterfly needle placed under the skin of the abdomen or thigh. Most patients use the pump during sleeping hours. In patients who are poorly compliant with subcutaneous therapy or in those with severe iron overload, home administration of DFO in high doses can be accomplished intravenously via a central venous catheter. The injection site is either a totally implantable reservoir or in the external end of the catheter. Intravenous DFO may also be useful for rapidly lowering the total iron burden and even for reversal of short-term cardiac morbidity.

Measurement of serum ferritin levels is a convenient way to assess efficacy. [153] In compliant patients, a clear drop in ferritin should occur after 1 year of treatment, with continued decline to a level of <1,000 ng/ml in 35 years. [151] [153] [156] Although urinary measurements are usually used to evaluate excreted iron, an approximately equal amount of iron is lost in the stool during long-term therapy.

The optimal age for starting this program has not been established. Some reports describe success in children as young as 24 years, [157] but there may be an adverse effect on growth. Many centers wait until the patient is 56 years old, when significant iron excretion can be accomplished and patient cooperation is better. The hard, painful lumps that occur at the injection sites from time to time can usually be avoided by careful placement of the needle for subcutaneous rather than intradermal injection.

Infections, hypersensitivity, and tachyphylaxis are rare. After 10 years of use, results with DFO protocols are very encouraging, especially in younger patients. [38] [151] [152] [153] [158] Children begun on chelation before 810 years of age show significant decreases in serum ferritin levels and may attain normal levels after 35 years of use. With persistence of DFO administration, the onset of cardiac disease may be prevented, particularly in children started on treatment in the first decade of life. [159] [160] [161] [162] [163] Results in older patients have not been as promising. Many patients begun on chelation therapy after 10 years of age have developed evidence of the progressive cardiac dysfunction associated with hemosiderosis. Nonetheless, severe cardiac disease, either congestive heart failure or ventricular arrhythmias, has been reversed in some patients by intensive high-dose (15 mg/kg/hour for 10 hours per day) intravenous DFO treatment. [152] [164] The treatment may be self-administered nightly at home through a central venous catheter.

A relationship between iron overload and ascorbic acid depletion (first suggested by the epidemiology of scurvy among the Bantu) exists in thalassemia major. [165] [166] Enhancement by ascorbic acid treatment of DFO-induced urinary iron excretion in thalassemia major has been well documented. Administration of 100200 mg/kg/day of oral ascorbic acid results in an approximate doubling of DFO-induced urinary iron excretion. However, cardiac toxicity manifested as arrhythmias and decreased ventricular contractility has been attributed to vitamin C therapy. [167] Ascorbic acid should only be used while DFO is being administered and only in patients who are ascorbate depleted. As ferritin levels decrease toward normal, the efficacy of vitamin C for augmenting iron excretion disappears.

In general, DFO is well tolerated. Chronic administration of >100 mg/kg/day of DFO has caused cataracts in dogs, but this effect has not been observed in thalassemic patients. The most serious current concern regarding toxicity is decreasing visual and auditory acuity. Some clinics have found that many patients experience impaired sight and hearing, which is partially or completely reversible on discontinuing DFO; [168] others have encountered a lower incidence. [169] Any

patient receiving DFO treatment long term should undergo periodic tests of vision and hearing. DFO should be discontinued if abnormalities arise, with cautious re-initiation when abnormalities reverse. High doses of intravenous DFO may cause acute pulmonary disease, which is reversible with discontinuation of the drug. [93]

Existing chelation protocols are highly imperfect, expensive, and inconvenient. Chronic infusion requires a great deal of dedication and persistence on the part of the patient and family; noncompliance is frequent. These realities have stimulated a search for oral chelators. 2,3-Dihydrobenzoic acid, another iron-chelating agent, enhances iron excretion when given orally. However, it is not very effective; iron excretion is increased to only about 4.5 mg/day. [170] A more promising source for a long-awaited effective oral iron chelator consists of the 1-alkyl-3-hydroxy-2-methylpyrid-4-ones, which can be easily synthesized from the inexpensive natural plant product, maltol.[171] [172] [173] [174] [175] [176] One compound, 1,2-dimethyl-3-hydroxypyrid-4-one (L1, or deferiprone), has not been toxic in mice or rabbits at doses effective in humans for oral chelation.[173] Initial clinical trials in London in eight iron-loaded patients, four with -thalassemia major (1326 years old) and four with myelodysplasia (4765 years old), showed maximal 24-hour urinary iron excretions of 4699 mg in thalassemia patients with daily L1 doses of 23 g; these results are comparable to those of urinary iron excretion induced by DFO in the same patients. [174] However, L1 does not increase fecal iron excretion, [177] whereas DFO induces substantial fecal iron excretion in addition to the urinary excretion. These findings may limit the efficacy of L1.

The effectiveness of L1 in reducing body iron burden and serum ferritin is still under investigation. One short-term study showed unchanged serum ferritin levels after L1 therapy.[177] However, other studies showed significant decreases in hepatic iron as well as serum ferritin levels. [178] [179] In a series of patients treated with L1 for a mean duration of approximately 3 years, hepatic iron stores either decreased or remained stable below the threshold level associated with increased risk of cardiac disease from iron overload.[180] However, additional follow-up studies are said to indicate that hepatic iron concentrations and fibrosis actually increased in a substantial percentage of patients treated with L1. [163] [181] Another long-term trial indicated no significant overall change in iron stores, with 50% of patients having liver iron content above the level associated with a high risk of cardiac disease. [182] Both mild adverse reactions, including musculoskeletal pain and stiffness, and infrequent but more serious side effects, including agranulocytosis in approximately 2% of patients, have been reported with L1 therapy. [179] [180] [183] [184] [185] Additional clinical trials with L1 will be necessary to determine both efficacy and safety.

A number of other classes of orally effective iron-chelating drugs are being developed and tested. [175] In the United States, however, DFO is the only effective iron-chelating agent approved

by the Food and Drug Administration for use in patients with transfusional hemosiderosis.

Bone Marrow Transplantation

Since 1982, when bone marrow transplantation (BMT) in thalassemia major was first successfully accomplished, [186] much additional experience has been gained, particularly in Italy. [187] [188] [189] [190] [191] [192] [193] [194] [195] [196] [197] [198] [199] [200] Procedure-related deaths and nonengraftment have occurred; the currently reported mortality of 1020% and disease-free survival after 35 years of 7590% depend on age and iron status at the time of the procedure. Impressive recent results of early BMT suggest that it be considered seriously when feasible; however, the persistent 1020% mortality at most centers, coupled with the improving efficacy of conventional treatment, makes decisions regarding bone marrow transplantation very difficult on both clinical and ethical grounds. [201] [202] [203] [204]

The largest experience has been reported by Guido Lucarelli and associates in Pesaro, Italy. [189] [190] [192] [193] [194] [195] [196] [197] [198] [199] [200] This group has performed more than 800 BMTs for thalassemia major. They have reported that when BMT was performed early in life with marrow obtained from an HLA-matched donor relative, there was a 90% probability of cure in the best prognostic category (class 1), i.e., those who lacked hepatomegaly and portal fibrosis and who were receiving adequate iron chelation therapy. In patients with either hepatomegaly or portal fibrosis (class 2), the event-free survival rate was approximately 80%, whereas in more heavily iron overloaded patients with both hepatomegaly and portal fibrosis (class 3), the event-free survival rate was only approximately 50%. [192] [193] [194] A number of smaller series from other medical centers have been reported, with varying success rates. [195] [196] [197]

The remarkable results in class 1 patients reported by Lucarellis group have led some authorities to recommend that BMT be strongly considered in any young patient with thalassemia major who has a compatible donor.[201] [202] [205] This opinion is probably justified on the basis of the high cure rate, great expense of lifelong conventional transfusion-chelation therapy, and the high prevalence of noncompliance with chronic iron chelation therapy with DFO. Nevertheless, there are dissenting views and certain reservations. [201] [202] [203] [204] [205] [206]

At this time, a decision to recommend or not to recommend BMT in a young thalassemia major patient who has a suitable donor is controversial. Families should be apprised of the risks and potential benefits of the procedure and helped to make an informed decision. If a related HLA-compatible donor is not available, BMT is not generally considered an acceptable option. However, with improved results of BMT in other disorders using matched unrelated donors, partially mismatched family donors, or unrelated cord blood donors, such options may be considered for selected patients.

BMT in older children and adults, many of whom have significant hepatic hemosiderosis and fibrosis, has been less extensively attempted and usually has not been very successful. Nevertheless, Lucarelli et al. [198] recently described excellent results of BMT in older patients who were iron overloaded and had significant hepatic abnormalities. Eighty percent of the adult patients had long-term disease-free survival. These results will lead to a re-evaluation of the use of BMT in older class 2 patients with thalassemia major. Results of BMT in class 3 patients are less encouraging. [194]

After successful BMT, some post-thalassemic patients remain severely iron overloaded and therefore need to undergo a phlebotomy program to reduce iron stores.[206] Rare patients develop a state of stable chimerism in which there is a return of recipient thalassemic erythropoiesis along with a stable proportion of normal donor erythropoiesis that can be sufficient to render the patient no longer transfusion-dependent. [207]

Experimental Therapies

Gene Manipulation and Replacement

Much recent effort has focused on stimulation of -globin gene expression or replacement of defective -globin genes. Enhanced -globin gene expression would ameliorate the unbalanced globin chain synthesis. Normal -globin genes, if introduced into stem cells in such a way as to allow them to function normally, would directly correct the -globin chain deficit.

Active -globin genes are hypomethylated in utero but are methylated and inactive after birth. Hypomethylation of the -globin genes can be induced by the drug 5-azacytidine; indeed, short-term administration of this drug produced the predicted effect in vivo. [208] Despite much subsequent experimental work, it remains unclear whether the effect was due to direct stimulation of fetal genes by demethylation or to recruitment and accelerated differentiation of primitive burst-forming unit-erythroid (BFU-E) progenitor cells, which have greater potential to produce Hb F. [209] [210] [211] Hydroxyurea has an effect on BFU-E similar to that of 5-azacytidine and is a safer drug for long-term use. Short-term as well as longer trials with both agents have been reported in a number of patients with thalassemia or sickle cell disease;[209] [210] [211] [212] [213] [214] [215] [216] [217] [218] [219] [220] [221] [222] [223] total hemoglobin and Hb F levels do rise in some patients with thalassemia intermedia, but toxic effects are frequent and long-term efficacy remains unproved. The combination of hydroxyurea with recombinant hematopoietic growth factors such as erythropoietin has also been tested for possible additional potentiating effects on Hb F production. [211] [224] [225] Recombinant erythropoietin alone has also been administered to patients with -thalassemia intermedia and resulted in a sustained increase in total production of RBCs, but without a specific or selective effect on Hb F production. [226]

Butyrate and other short-chain fatty acids have been demonstrated to augment Hb F production in various animal model systems as well as in man. [209] [217] [227] These compounds are thought to act by altering chromatin configuration, perhaps due to increased histone acetylation. Short-term treatment with intravenous infusions of arginine butyrate in a limited number of patients resulted in increased levels of -globin chain production that were quite striking in some cases and resulted in a marked increase in /-globin chain synthetic ratios. [228] One patient who was homozygous for Hb Lepore and could not be transfused because of alloimmunization was treated on a compassionate basis for a longer period of time, with a resulting rise in the total hemoglobin level (virtually all Hb F) from less than 5.0 g/dl to approximately 10.0 g/dl over approximately 60 days and healing of a leg ulcer. [228] [229] In a subsequent longer-term trial, five patients with various other forms of severe -thalassemia did not have a sustained hematologic response. [230] In yet another trial, administration of arginine butyrate intravenously in pulsed fashion to patients with sickle cell anemia and thalassemia resulted in favorable hematologic responses, raising the possibility of hematologic toxicity and suboptimal responses with continuous infusions of the drug. [231] Orally absorbable compounds also have been reported to result in an increase in F cell and -globin chain production, but the

effect was not as sustained or as quantitatively important as that originally obtained with intravenous arginine butyrate. [232] [233] [234] [235] [236] [237] Although no severe toxic side effects were observed in these relatively short-term trials in humans, the infusion of high doses of butyrate into baboons did result in significant neurologic toxic effects.[238] Further studies will be required to assess the long-term safety and efficacy of therapy with butyrate.

Successful gene replacement in thalassemia remains a goal for the future despite intensive investigation in this area. Techniques for isolating specific human genes and inserting them into the DNA of other cells have been developed. [239] However, formidable problems must be solved before it becomes routinely possible to place genes in a human stem cell, ensure their

safe and active expression at effective levels, and preserve normal growth, differentiation, and proliferation of the genetically transformed stem cell. [240] [241] [242]

Thalassemia Intermedia

Approximately 10% of patients with homozygous -thalassemia exhibit a phenotype characterized by intermediate hematologic severity. [1] [2] [3] [4] The / ratios of globin chain synthesis are usually higher than those found in typical thalassemia major, indicating the presence in these patients a less severe defect in -globin chain synthesis. For example, homozygous -thalassemia in blacks, Portuguese, and others may be relatively mild, at least for the first two decades. [243] [244] Homozygotes or mixed heterozygotes for forms of -thalassemia associated with normal Hb A_2 and normal Hb F (silent carrier state) also tend to have mild to moderate disease. [245] [246] Certain patients have a milder clinical phenotype because they have co-inherited a form of -thalassemia, [16] [17] [18] or because they carry one (or two) -thalassemia chromosome(s) with a higher than usual potential for high levels of -globin gene expression.

Individuals with thalassemia intermedia do not need regular blood transfusions and usually experience only moderate splenomegaly. The ability to maintain a hemoglobin level compatible with comfortable survival in the absence of regular transfusion is the generally accepted criterion for the diagnosis of thalassemia intermedia. Some of these patients can survive well into adult life, frequently with normal maturation and sexual development. However, some patients with thalassemia intermedia develop cardiomegaly, osteoporosis, fractures, arthritis, and splenomegaly. Complications of extramedullary hematopoiesis in the thorax, skull, and pelvis may occur, including spinal cord compression and growths resembling tumors or abscesses. [247] Disfiguring facial changes may result in a grotesque appearance that causes considerable emotional and psychological distress. Complications can be prevented by a transfusion program designed to suppress erythropoiesis by maintaining normal hemoglobin levels, in which case the patients must be reclassified as having thalassemia major.

These patients pose a therapeutic dilemma. If transfusions are begun, progressive hemosiderosis will develop. However, failure to institute transfusions may be associated with unacceptable morbidity. Each patients treatment must be individualized with consideration of the patients clinical condition, not just the hemoglobin level. An index of the degree of abnormal bone expansion may be useful, [248] but risks of transfusion and iron overload must also be considered. The further availability of more effective oral chelation therapy may make the therapeutic decision easier.

Whether or not patients with -thalassemia intermedia receive regular transfusions, they ultimately experience progressive iron overload because of increased absorption of dietary iron induced by ineffective erythropoiesis. By the third or fourth decade, the total iron burden may attain the levels seen in transfusion-dependent patients.[249] Regular consumption of tea with meals to reduce iron absorption is advisable (the tannins in tea chelate iron in the gut). [250] Chelation therapy with DFO is indicated when patients become significantly iron loaded. [251] The orally effective iron chelator deferiprone (L1) is also effective in thalassemia intermedia. [178] Reconstruction of the maxilla may be needed to provide cosmetic improvement of facial asymmetry and malocclusion.[252] Gallstones regularly occur by the second decade of life. Leg ulcers often occur in late adolescence or afterward, potentially necessitating transfusions until they heal. Folic acid supplementation is particularly important because of the marked marrow hyperplasia. Aplastic crises associated with parvovirus or other infections may result in life-threatening anemia. Splenectomy usually is required in cases of secondary hypersplenism, a state that can worsen the degree of anemia in the absence of transfusions.

Some patients with heterozygous -thalassemia will have a moderately severe clinical disorder, with anemia, hemolysis, and splenomegaly. Some of these patients carry a greater than normal number of -globin genes, owing to triplication of one of the -globin gene loci: /. [253] [254] However, most heterozygous patients with triplicated -globin gene loci are clinically similar to those with simple -thalassemia trait. Most cases of severe heterozygous -thalassemia have so-called dominant -thalassemia which is due to the inheritance of a gene for a -thalassemia hemoglobinopathy associated with a structurally abnormal, unstable, -globin chain that may form inclusion bodies.[20] [21] For those heterozygotes with disease of unusual clinical severity, splenectomy may be beneficial.

-Thalassemia Minor (Thalassemia Trait)

Inheritance of a single -thalassemia allele results in a mild hypochromic microcytic anemia. The hemoglobin level averages 1 or 2 g/dl lower than that seen in normal persons of the same age and sex. Elevations in Hb A_2 and Hb F occur during the early years of life. [255] [256] [257] Hb F levels decline more slowly than normal; the diagnostic elevated Hb A_2 levels are established by about 6 months of age. Strong intrafamilial correlations of both Hb A_2 and mean corpuscular volume (MCV) are noted. [255] Osmotic fragility is decreased; indeed, a one-tube osmotic fragility test has been used for mass screening. [258] The red cell count is increased or normal. The red cells are characteristically hypochromic (mean corpuscular hemoglobin [MCH] <26 pg) and microcytic (MCV <75 fl). The smear shows varying numbers of target cells, poikilocytes, ovalocytes, and basophilic stippling (Fig. 29-10). The reticulocyte count is normal or slightly elevated. Red cell survival is normal, iron utilization is decreased, and slight ineffective erythropoiesis is present. [259] Most patients are asymptomatic.

During pregnancy the anemia of thalassemia trait often becomes more severe, and transfusions are sometimes necessary. Because iron deficiency may occur during pregnancy, iron supplementation has been advised to avoid compounding the causes of anemia. [260] [261] In many instances, iron deficiency anemia is erroneously diagnosed, and iron therapy is given without significant improvement.

Microcytic anemia refractory to iron therapy should always suggest the possibility of thalassemia trait. Although a variety of indices calculated from blood count parameters have been suggested to differentiate thalassemia from iron deficiency, each has some degree of inaccuracy; most are no better than the MCV alone. [262] Direct tests for iron deficiency are preferable. In general, the MCV is rarely >75 fl or the hematocrit <30 in -thalassemia trait. In iron deficiency, the hematocrit usually falls to <30 before the MCV falls to <80 fl. Free erythrocyte porphyrin levels are normal in thalassemia trait but are elevated in iron deficiency (see Chap. 26).[1]

There may be characteristic racial differences in the hematologic severity of -thalassemia trait. In blacks, the condition is invariably milder, red cell morphologic abnormalities less marked, and / synthetic ratios higher than in whites and Asians with the trait. [263]

The diagnosis of -thalassemia trait is established in most instances by the demonstration of altered proportions of Hb A_2. The level of Hb A_2 in -thalassemia trait averages 5.1% (range, 3.57.0%), approximately twice the normal level (1.53.5%); the Hb A_2 /HbA_1 ratio is 1:20 instead of the normal 1:40. This increase is probably due to a post-translational (assembly) phenomenon with increased opportunity for -globin chains to combine with -globin chains in the face of -globin chain deficiency.[2] If concomitant severe iron deficiency anemia occurs, Hb A_2 levels may fall, sometimes into the normal range.[264]

Figure 29-10 Morphology of the peripheral blood film in **(A)** heterozygous -thalassemia and **(B)** heterozygous -thalassemia. Note the profound hypochromia and microcytosis and the many target cells. *(From Pearson and Benz,[308] with permission.)*

Hb F levels are inconsistently elevated in -thalassemia. In about one-half of cases, Hb F is within the normal range (<2.0%); in the remainder it is moderately elevated

(2.15.0%). However, in almost every instance, a minor population of red cells (F cells) containing substantial amounts of Hb F can be demonstrated by the Kleihauer technique.[1] Rarely, an individual with heterozygous thalassemia, as evidenced by a reduced / synthetic ratio or by virtue of having a child with thalassemia intermedia or major, has normal Hb A_2 , Hb F, and hemoglobin electrophoresis, without (silent carrier) or with (quiet carrier) minor hematologic changes. [246] Rare individuals have been encountered who exhibit characteristically abnormal red cell morphology but normal levels of Hb A_2 and Hb F.[1] [2] [3] [4] Such individuals are probably carriers of -thalassemia.[1] [2] [3] [4] Iron deficiency must be excluded and globin chain synthesis or gene mapping studies done to establish a diagnosis with certainty.

Prenatal Diagnosis

Thalassemia mutations can now be routinely and reliably diagnosed by using fetal DNA obtained between the 8th and 18th weeks of gestation. The most reliable methods are based on identification of the abnormal gene by direct DNA analysis. [22] [23] Both amniocentesis and chorionic villus biopsy have been used with success. In experienced hands, the latter method is preferable because adequate amounts of DNA can be obtained safely at an earlier gestational age. A technique has also been developed for the isolation from maternal peripheral blood of fetal nucleated RBCs as a source of DNA for prenatal diagnosis. [265] The DNA is analyzed by a variety of polymerase chain reaction (PCR)-based or other methods for the presence of the thalassemia mutation. [191] [266]

The heterogeneity of thalassemia mutations complicates the approach to antenatal diagnosis. More than 125 independent mutations can cause -thalassemia. [25] [26] However, three major factors have improved the speed, efficacy, and reliability of DNA diagnosis. First, extensive surveys of most populations in which these alleles are frequent have revealed that about 15 -thalassemia mutations account for more than 90% of individuals afflicted worldwide. Within any given ethnic group, three to six mutations usually account for the vast majority of severe cases (Table 29-1).[22] [23] One can thus customize the search for mutations according to the ethnic origins of the family at risk. Second, PCR techniques and exquisitely precise hybridization assays (allele-specific oligonucleotide hybridization), which detect single base changes with great reliability, can now be combined to permit screening of minute DNA samples for several mutations very rapidly (Fig. 29-11). This procedure can also be done using nonradioactive oligonucleotide probes immobilized to filters, so-called reverse dot blot analysis. [267] [268] Third, amplification and direct sequencing of the -globin genes (in cases where the mutation is unknown) can now be carried out by use of PCR techniques in about the time formerly needed to culture amniocytes and perform Southern blot analysis.

Most cases of severe -thalassemia can be diagnosed using similar approaches. The vast majority of cases of clinically significant -thalassemia syndromes arise from gene deletions that are readily detected. Therefore, genetic counseling and antenatal diagnosis should be offered to all families at risk of either severe - or -thalassemia.

Screening for Thalassemia Trait

Mass screening and genetic counseling programs are active in Italy, Greece, and other areas in which the frequency of thalassemia is very high. Population screening, combined with prenatal diagnosis, has dramatically decreased the incidence of thalassemia

Figure 29-11 Example of the use of allele-specific probes for diagnosis of a common form of -thalassemia. The mutation shown is that discussed in Figure 29-2 and the text. Two oligonucleotide probes are synthesized, differing only at the position of the mutation. When hybridized under sufficiently stringent conditions, each probe will anneal only to the gene that is perfectly complementary by Watson-Crick base-pairing. Thus, a homozygous normal fetal DNA sample (N/N) will anneal only to the normal probe, homozygous -thalassemic DNA (T/T) only to the thalassemic probe, and DNA from a heterozygote (N/T) to both probes, but with a reduced intensity to each. *(From High and Benz,[310] with permission.)*

major births in these countries.[269] [270] These programs require a critical mass of expert professional and laboratory backup. Voluntary informed participation, confidentiality of results, and meaningful counseling must be ensured.

The most definitive methods for diagnosis of thalassemia trait include quantitative determinations of Hb A_2 , Hb F, and globin chain synthetic ratios, as well as DNA studies for specific mutations. These are accurate but too expensive for initial mass screening. Since thalassemia is almost invariably associated with significant hypochromia (MCH <26 pg) and microcytosis (MCV <75 fl), determination of red cell indices has been used as a preliminary indicator of possible thalassemia trait. [271] Microcytosis due to iron deficiency must be excluded.[272] A number of alternatives have been described for follow-up diagnostic tests. Measurement of free erythrocyte porphyrin levels is useful in the evaluation of individuals with microcytosis, as results may be obtained rapidly and inexpensively from a drop of blood. [1] Serum ferritin and iron and iron-binding capacity studies are also important in the diagnosis of iron deficiency.

Most screening programs use a simple but sensitive initial screening test such as red cell MCV or osmotic fragility. These tests exclude the great majority of individuals who do not have thalassemia trait, but they do not differentiate precisely between thalassemia trait and iron deficiency. Hb F determinations and hemoglobin electrophoresis are necessary to diagnose -thalassemia and Hb Lepore traits in microcytic persons. No simple screening procedures will detect the so-called silent carrier.

-Thalassemia, which occurs in the same populations as -thalassemia, makes screening more complicated. This diagnosis is suggested by a mild, familial hypochromic microcytosis, with low or normal levels of Hb A_2 and Hb F and no evidence of iron deficiency. Precise diagnosis of -thalassemia requires demonstration of -globin gene deletions or a high /-globin chain synthetic ratio.

Figure 29-12 Genetic origins of the classic -thalassemia syndromes due to gene deletions in -globin gene cluster. Hb Constant Spring (Hb CS) is an -globin chain variant synthesized in such small amounts (12% of normal) that it has the phenotypic impact of a severe nondeletion -thalassemia allele; however, the - ^{cs} allele is always linked to a functioning -globin gene, so that it has never been associated with hydrops fetalis.

-THALASSEMIA SYNDROMES

The -thalassemias are more difficult to diagnose because characteristic elevations in Hb A_2 or Hb F, seen in -thalassemia, do not occur. However, the gene deletions responsible for the most common varieties are readily detectable by molecular biology methods. [271] [272]

Molecular Pathology and Pathophysiology

The four classic -thalassemia syndromes are -thalassemia-2 trait, in which one of the four -globin gene loci fails to function; -thalassemia-1 trait, with two dysfunctional loci; Hb H disease, with three loci affected; and hydrops fetalis with Hb Barts, in which all four loci are defective. These syndromes are usually due to deletion of one, two, three, or all four of the -globin genes, respectively (Fig. 29-12). Nondeletion forms of -thalassemia, which account for 1520% of patients, arise from mutations similar to those described for -thalassemia. [273] [274] Figure 29-13 (Figure Not Available) illustrates the different -thalassemia mutations and phenotypes. Structurally abnormal hemoglobins have been associated with -thalassemia. The Quong Sze -globin chain (^{125LeuPr}) is an exceedingly labile -globin chain destroyed so rapidly after its synthesis that no hemoglobin tetramers can be formed. [275]

-Thalassemia-2 trait is an asymptomatic silent carrier state

Figure 29-13 (Figure Not Available) Pathophysiology of Hb H disease and hydrops fetalis with Hb Barts. *(From Benz,[21] with permission.)*

that is commonly associated with the deletion of a single -globin gene. Offspring of an individual with -thalassemia-2 whose spouse has -thalassemia-1 trait can inherit a form of -thalassemia more severe than either of these, namely Hb H disease.

-Thalassemia-1 trait results from deletion or nonfunction of two -globin alleles. In Asian and Mediterranean populations, a deletion that removes both loci from the same chromosome (cis deletion) is common;[273] [274] homozygosity for -thalassemia-2 (trans deletion) is also seen. In blacks, both -globin genes are only rarely deleted in cis, whereas homozygosity for -thalassemia-2 (trans deletion) is quite common. [276] Both genotypes produce asymptomatic hypochromia and microcytosis.

Hb H disease usually results from co-inheritance of the cis -thalassemia-1 deletion and -thalassemia-2 trait. -Globin chain production is only 2530% of normal; -globin chains accumulate during gestation and -globin chains during adult life (Fig. 29-13 (Figure Not Available)). The unpaired -globin chains are somewhat more soluble than the -globin chains that accumulate in -thalassemia, forming recognizable -tetramers designated Hb H. Hb H forms relatively few inclusions in erythroblasts; rather, it precipitates slowly within mature circulating red cells. Patients with Hb H disease thus have a moderately severe hemolytic anemia but relatively little ineffective erythropoiesis. Patients usually survive into adult life. These clinical observations illustrate the central role of unpaired globin chains and ineffective erythropoiesis as determinants of clinical severity. Hydrops fetalis with Hb Barts results from the homozygous state for the -thalassemia-1 cis deletion. The -globin genes are totally absent; no -globin is produced, so that no physiologically useful hemoglobin accumulates beyond the embryonic stage. Free -globin accumulates, forming $_4$ tetramers called Hb Barts (Fig. 29-13 (Figure Not Available)). Hb Barts has an extraordinarily high oxygen affinity, comparable to that of myoglobin. It binds oxygen delivered to the placenta but releases almost none of it to fetal tissues. Severe asphyxia occurs at the tissue level, causing profound edema (hydrops), congestive heart failure, and death in utero. These fatal complications do not occur in fetuses with Hb H disease because enough Hb F is made to sustain life.
-Thalassemia-2 trait is very common in blacks, having a gene frequency of 2030% in some populations. However, the cis -thalassemia-1 deletion is rare in blacks. Thus, even though -thalassemia-2 trait and the trans deletion form of -thalassemia-1 are very common, Hb H disease is rarely encountered, and hydrops fetalis has not yet been reported in blacks. [276] [277]

Clinical Manifestations

Silent Carrier (-Thalassemia-2 Trait)

-Thalassemia-2 trait has no consistent hematologic manifestations. The red cells are not microcytic, and Hb A_2 and Hb F are normal. During the newborn period, small amounts (3%) of Hb Barts ($_4$) may be seen by electrophoresis or column chromatography. This condition is most often recognized when an apparently normal individual becomes the parent of a child with Hb H disease after mating with a person with -thalassemia-1 trait. The mild excess of -globin chains is probably removed in erythroblasts by proteolysis. [278] -Thalassemia-2 is particularly common in Melanesia, as well as in Southeast Asia and in American blacks, reaching a prevalence of >80% in north coastal Papua New Guinea. At the molecular level, -thalassemia-2 has been found to be associated with two common gene deletions resulting from different nonhomologous crossing over events between the two linked -globin genes: a 3.7-kb rightward deletion (^{3} .7) resulting in a fused $_{2\ 1}$ -globin gene, and a 4.2-kb leftward deletion (^{4} .2) resulting in loss of the 5 ($_2$) gene.[273] [274] [279] The level of -globin gene expression differs in the two conditions, as discussed in the following section.

-Thalassemia Trait (-Thalassemia-1 Trait)

-Thalassemia-1 trait is characterized by levels of Hb A_2 in the low to low normal range (1.52.5%) and / synthetic ratios averaging 1.4:1. During the perinatal period, elevated amounts of Hb Barts are noted (38%). Microcytosis is present in cord blood erythrocytes.

Studies of newborns from the archipelago of Vanuatu in the southwest Pacific and from Papua New Guinea, indicate that homozygotes for the rightward ^{3} .7III deletion (where only a fused $_{2\ 1}$ -globin gene, mostly of the $_2$ type, remains) have lower Hb Barts levels (3.5 ± 0.8%) than those of infants homozygous for the leftward ^{4} .2 deletion (where only the $_1$ -globin gene remains) (6.0 ± 1.4%). These results suggest that the 5 $_2$ -globin gene has a higher output than the 3 $_1$ -globin gene, a conclusion supported by direct measurement of $_2$ /$_1$ mRNA ratios.[280] [281]

Hb H is not detected in hemolysates of peripheral red cells, probably because of rapid proteolysis of Hb H or free -globin chains. However, about 1% of erythroblasts and marrow reticulocytes have inclusions.[276] When an -thalassemia gene occurs in persons who are also heterozygous for -globin chain variant hemoglobins, such as Hb S, Hb C, or Hb E, the proportion of the abnormal hemoglobin is lower than seen in simple heterozygotes. [282] The lower level of the abnormal hemoglobin is due to post-translational control because of higher affinity of ^{A} chains for a limited pool of -globin chains, [283] coupled with proteolysis of the uncombined ^{varian} chains.

Hb H Disease

Hb H disease is associated with a moderately severe but variable anemia, resembling thalassemia intermedia with osseous changes and splenomegaly; [284] however, the clinical phenotype may be considerably milder. It occurs predominantly in Asians and occasionally in whites (Mediterraneans) but is rare in blacks.

Because Hb H is unstable and precipitates within the circulating red cell, hemolysis occurs. Hb H can be demonstrated by incubation of blood with supravital oxidizing stains such as 1% brilliant cresyl blue. Multiple small inclusions form in the red cells (Fig. 29-13 (Figure Not Available)). Electrophoresis of a freshly prepared hemolysate at alkaline or neutral pH demonstrates a fast-moving component amounting to 330% of the total hemoglobin. Concomitant iron deficiency may reduce the amount of Hb H in the patients red cells. [285] A syndrome of Hb H disease associated with mental retardation, other congenital anomalies, and large deletions on chromosome 16 has been noted in several white families. [272] [274]

Hydrops Fetalis with Hb Barts

Hydrops fetalis with Hb Barts occurs almost exclusively in southeastern Asians, especially Chinese, Cambodians, Thais, and Filipinos. Affected fetuses usually are born prematurely and either are stillborn or die shortly after birth. [1] [2] [3] [4] Marked anascara and enlargement of the liver and spleen are present. Severe anemia usually is present, with hemoglobin levels of 310 g/dl. The red cells are markedly microcytic and hypochromic and include target cells and large numbers of circulating nucleated RBCs. These morphologic abnormalities and a negative Coombs test exclude hemolytic diseases due to blood group incompatibility. Hemoglobin electrophoresis reveals predominantly Hb Barts, with a smaller amount of Hb H. A minor component identified as Hb Portland ($_{2}$ $_{2}$) migrating in the position of Hb A is seen also. Normal Hb A and Hb F are totally absent. [286]

Hydropic infants have massive hepatosplenomegaly. Extreme extramedullary erythropoiesis occurs in response to the

profound hypoxia and hemolytic anemia characteristic of this disease. The universal edema characteristic of the hydrops fetalis syndrome is a reflection of severe congestive heart failure and hypoalbuminemia in utero. This is partly a consequence of anemia, but the strikingly abnormal oxygen affinity of the tetrameric Hb Barts is probably the most important determinant of the severe tissue hypoxia. The oxygen dissociation curve of Hb Barts lacks the normal sigmoid form due to noncooperativity during oxygen loading and unloading and is markedly shifted to the left. The shift is so great that little oxygen is released under conditions of low oxygen concentration in the tissues.

Infants with this syndrome do not die in an earlier trimester of pregnancy because of the presence of Hb Portland ($_{2}$ $_{2}$). This hemoglobin does display cooperativity in a manner similar to that of Hb F and therefore has a much more favorable oxygen dissociation pattern than that of Hb Barts. A high incidence of toxemia of pregnancy has been described in women carrying severely affected infants, providing an increased rationale for prenatal diagnosis of this condition.

Prenatal Diagnosis

Using molecular hybridization technology, Dozy, Kan, and associates detected the complete absence of -globin genes in fetal fibroblasts obtained by amniocentesis in a pregnancy at risk of homozygous -thalassemia-1 and the hydrops fetalis syndrome. [287] The presence of hydrops can also be detected by ultrasonography. DNA studies or globin synthesis evaluation may be used to confirm the diagnosis in utero. PCR-based assays are available for the detection of the common -thalassemia-1 deletions. [288]

Therapy

Fetuses with homozygous -thalassemia-1 usually die in utero because of severe hydrops fetalis and are stillborn. However, some infants have had successful blood exchange immediately after birth and have been maintained by chronic transfusion therapy afterward. [289] [290] [291] [292] It is also possible to salvage affected fetuses by in utero blood transfusions. [293] [294]

Patients with Hb H disease usually require neither red cell transfusions nor splenectomy. Splenectomy can result in a clinically important rise in hemoglobin level and thus should be considered in patients with marked anemia. Oxidant drugs can accelerate precipitation of Hb H and exacerbate hemolysis; they should therefore be avoided.

Infants with heterozygous -thalassemia-1 trait lose their Hb Barts during the first few months of life and are left with the hematologic findings of -thalassemia trait, a mild hypochromic microcytosis that persists throughout life. [1] The degree of morphologic abnormality varies greatly among different individuals. That -thalassemia can be easily diagnosed by hemoglobin electrophoresis at birth gives some impetus to cord blood screening studies.

THALASSEMIC STRUCTURAL VARIANTS

Certain structural hemoglobin variants are characterized by the presence of a biosynthetic defect as well as abnormal structure. [9] Thalassemic hemoglobinopathies are unusual forms of thalassemia caused by such structural variants.

Hb Lepore

Hb Lepore ($_2$ [$_2$]) is the prototype of a group of hemoglobinopathies characterized by fused globin chains. [1] [2] [3] [4] The chains begin with a normal -chain sequence at their N terminus and end with the normal -chain sequence at their C terminus. These hemoglobinopathies arise by unequal or nonhomologous crossover or recombination events that fuse the proximal end of one gene with the distal end of a closely linked structurally homologous gene (Fig. 29-14 (Figure Not Available)). During meiosis, mispairing and crossover of the highly homologous - and -globin genes can occur, resulting in a Lepore chromosome, which contains (in addition to -globin genes) only the fused gene, and an anti-Lepore chromosome, which contains the reciprocal fusion product (), as well as intact - and -globin genes. [1] [2] [3] [4]

Lepore globin is synthesized in low amounts presumably because it is under the control of the -globin gene promoter, which normally sustains transcription at only 2.5% the level of the -globin gene. [295] Patients with Hb Lepore have the phenotype of -thalassemia, distinguished by the added presence of 515% Hb Lepore. By contrast, the anti-Lepore globin (Miyada) is not associated with a -thalassemia phenotype because of the presence of an intact and functionally normal -globin gene on the same chromosome.

Heterozygotes for Hb Lepore have the clinical phenotype of -thalassemia trait; homozygotes are usually similar to patients with homozygous -thalassemia. Compound heterozygotes for

Figure 29-14 (Figure Not Available) Genetic origins of Hb Lepore, anti-Lepore Hb, and Hb Kenya. *(From Benz,[21] with permission.)*

Hb Lepore and a classic -thalassemia allele usually have severe thalassemia. Hb Lepore thus interacts with thalassemia in the same way as a severe -thalassemia gene does, although occasional cases have a milder phenotype of the thalassemia intermedia variety, perhaps due to an associated higher than usual level of -globin gene expression. The presence of Hb Lepore should be suspected in hypochromic microcytic individuals who also have a small amount of an abnormal hemoglobin migrating in the position of Hb S on routine hemoglobin electrophoresis. Hb Lepore accounts for 510% of the -thalassemias seen in Greek and Italian populations. Several forms of Hb Lepore have been described that differ in the position at which the transition from to DNA and amino acid sequence occurs.

An analogous variant, Hb Kenya ([^{A}]$_2$), arises from nonhomologous crossing over between the ^{A} - and -globin genes[296] (Fig. 29-14 (Figure Not Available)) and is associated with the phenotype of ^{G} HPFH. It is now clear that a DNA sequence about 600 bases downstream from the -globin gene acts as a strong enhancer, promoting the erythroid-specific expression of the -globin genes in adult cells. [3] [4] [24] The fused ^{A} gene as well as the linked upstream ^{G} gene are thought to come under the influence of the enhancer, because of its abnormal proximity, and thus are expressed at high levels in adult life. Hb Kenya is rare.

Hb E

Hb E ($_{2\ 2}$ ^{26GluLys}) is a common variant (1530% of the population) in Cambodia, Thailand, parts of China, and Vietnam. Hb E trait resembles very mild -thalassemia trait. Homozygotes exhibit more microcytosis but are still asymptomatic.[297] Compound heterozygotes for Hb E and a -thalassemia gene (Hb E--thalassemia) resemble patients with -thalassemia intermedia or -thalassemia major. Hb E is very mildly unstable, but this instability does not alter red cell life span significantly. The high frequency of the Hb E gene is due to the thalassemia phenotype associated with its inheritance.

The only nucleotide sequence abnormality found in the ^{E} -gene is a base change in codon 26 that causes the amino acid substitution. This mutation, which occurs in a potential cryptic RNA splice region, alters the consensus sequence surrounding a potential GT donor splice site and thus activates the cryptic site. Alternative splicing at this position occurs approximately 4050% of the time, generating a structurally abnormal globin mRNA, which cannot be translated appropriately. [298] The other mRNA precursors are spliced at the normal site, generating functionally normal mRNA, which is translated into ^{E} -globin because the mature mRNA retains the base change that encodes lysine at codon 26.

Hb E is important because it is so common in Southeast Asian populations. With increased emigration of Southeast Asians to North America, Hb E syndromes are being seen there with increased frequency. Genetic counseling of these individuals should emphasize the potential consequences of the interaction of Hb E with -thalassemia. Hb E is also an instructive example of the pleiotropic effects that point mutations may have on the amounts and types of gene products derived from a single mutant gene.

Hb Constant Spring

Hb Constant Spring (Fig. 29-12) is an elongated -globin variant resulting from a mutation that alters the normal translation termination codon. [299] Polyribosomes read through the usual translation stop site and incorporate an additional 31 amino acids until another in-phase termination codon is reached within the 3 untranslated sequence. The amount of ^{cs} mRNA is markedly reduced, and ^{cs} -globin is synthesized in only minute amounts. [279] [300] Six possible mutations of the normal translation termination codon (UAA) in -globin mRNA could result in the generation of a sense codon. [301] Of these, five variants have been identified, each having a markedly underproduced abnormal variant, indicating that disruption of normal translation termination is in some way associated with abnormal mRNA accumulation, presumably due to instability of the mRNA.[279] The output of -globin from the ^{cs} allele is only about 1% of normal, and the gene is thus rendered -thalassemic. The ^{cs} allele has been identified only on chromosomes containing a cis-linked functionally normal -globin gene. [1] [2] [3] [4] Thus, -thalassemia-2 trait and Hb H disease (/^{cs}) associated with Hb Constant Spring are common, but hydrops fetalis cannot occur in association with this variant. Homozygosity for the variant is associated with a relatively severe form of Hb H disease.[1] [2] [3] [4]

Extraordinarily Unstable Hemoglobins

Rare cases of -thalassemia (e.g., Hb Quong Sze[273]) and -thalassemia (e.g., Hb Indianapolis, recently renamed Hb Terre Haute [302] [303]) arise from mutations that produce extremely labile globin chains. The chains fail to pair with the complementary chain, or they precipitate and are degraded so rapidly that they never form

tetramers. These post-translational lesions have the same pathophysiologic effects on hemoglobin biogenesis as reduction of globin mRNA production or function. Another group of -globin chain variants, usually due to mutations in exon 3 of the -globin gene, are associated with inclusion body formation and a phenotype of dominant -thalassemia intermedia.[19] [20]

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

HPFH consists of a group of rare conditions characterized by continued synthesis of high levels of Hb F in adult life. [1] [2] [3] [4] [304] No deleterious effects on patients are observed, even when 100% of the hemoglobin produced in HPFH homozygotes is Hb F. These patients thus demonstrate convincingly that prevention or reversal of the Hb F to Hb A switch would provide efficacious therapy for sickle cell anemia and -thalassemia.

Two major types of HPFH have been described. Pancellular HPFH is characterized by very high levels of fetal hemoglobin synthesis and uniform distribution of Hb F among all red cells. Heterocellular HPFH results from inherited increases in the number of F cells (see Chaps. 15 and 22).

HPFH shows ethnic differences. In blacks with heterozygous pancellular deletional HPFH, the Hb F is within a range of 1535% and contains ^{G} - and ^{A} -chains in a ratio of 2:3. In Greeks with pancellular nondeletional HPFH, Hb F levels are lower, 1020%, and the Hb F is 90% of the ^{A} type. Hb A_2 levels are lower than normal, but there are no other hematologic abnormalities in these persons, although /-globin chain synthesis ratios may be decreased in some black heterozygotes.

A few black patients have been described with homozygous HPFH. All hemoglobin within the red cells of these patients is Hb F. Mild microcytosis and hypochromia of the red cells are present without anemia. In fact, hemoglobin levels are mildly elevated, presumably due to increased erythropoiesis stimulated by the left-shifted oxygen dissociation curve of red cells rich in Hb F. Globin chain synthesis reveals a / synthetic ratio of approximately 0.5.

Pancellular HPFH can be divided into two classes. The deletional forms arise from large deletions within the -globin gene cluster that remove the - and -globin genes, part of the intergenic DNA, and DNA downstream (to the 3 side) from the -globin genes. [1] [2] [3] [4] [304] The deletions appear to bring enhancer sequences into the proximity of the remaining -globin genes, promoting their high expression. Homozygotes for this condition produce only Hb F. In nondeletional HPFH, the - and -globin genes are present. Single base changes have been shown

to occur in the promoter regions of either the ^{A} - or ^{G} -globin gene, resulting in overexpression of that form of Hb F. [1] [2] [3] [4] [304] In these individuals, Hb F levels rarely account for more than 20% of total hemoglobin.

HPFH/-thalassemia resembles -thalassemia trait except for a higher proportion and regular distribution of Hb F in the red cells. [1] [2] [3] [4]

In both -thalassemia and HPFH, persistence of Hb F after the period of perinatal Hb F to Hb A switching is more marked than in the classic (high Hb A_2) forms of thalassemia. Indeed, -thalassemia and HPFH represent varying degrees of the same genetic phenomenon. Both conditions frequently arise from deletions of DNA that remove or inactivate the -globin gene. [1] [2] [3] [4] [304]

Heterocellular HPFH appears to result in many cases from mutations outside the -globin gene cluster. One controlling locus resides on the X chromosome. [305] [306] Patients with these conditions probably represent the extreme end of a distribution of polymorphic capacities to produce F cells in adult life. Hb F levels are usually much lower than in the pancellular forms. In some situations, elevated levels of Hb F are seen in otherwise normal individuals. In others, the high levels of Hb F become apparent only when other factors producing erythroid stress are present.

ACKNOWLEDGEMENT

Portions of this chapter have been modified and updated from previous chapters we have written. [21] [24] [307] [308]

Chapter 30 - Sickle Cell Disease

Stephen H. Embury
Elliott P. Vichinsky

INTRODUCTION

Sickle cell disease is an inherited disorder that has as its cardinal features chronic hemolytic anemia and recurrent painful episodes. These and all other elements of the disease are the result of mutant sickle cell hemoglobin (Hb S) within the red blood cells. The resultant illness is influenced by the psychosocial adjustment of patients to the multisystem disease. Due to the complexity of the illness, a comprehensive, combined-modality approach offers the best method of management. [1] [2] [3] The further exigency of living with a painful, life-threatening chronic disease in an ethnically diverse society provides additional complexity to the psychosocial aspects of this illness.[4] Traditional concepts of sickle cell pathophysiology ascribe all features of disease to sequential effects of the AG nucleotide substitution in the sixth codon of the -globin gene, substitution of valine for glutamic acid on the outer surface of the Hb S molecule, reduced solubility and polymerization of Hb S when deoxygenated, sickling and poor deformability of polymer-containing erythrocytes, and occlusion by sickle red cells of the microvasculature (Fig. 30-1). [1] [2] [5] [6] [7] [8] [9] [10] While polymerization remains the *sine qua non* of sickle cell disease,[7] [8] a contemporary understanding of pathophysiology requires an integrated perspective derived from physical chemistry, molecular and cellular biology, biochemistry, coagulation, and genetics. [9] [10] [11] [12] [13]

The syndromes (and genotypes) that make up sickle cell disease are mainly sickle cell anemia (Hb SS), sickle cell-° thalassemia, Hb SC disease (Hb SC), and sickle cell-$^{+}$ thalassemia. Sickle cell trait (Hb AS) lacks anemia and recurrent pain, which distinguishes it from the disease. This chapter presents the history, epidemiology, genetics, pathophysiology, clinical manifestations, laboratory diagnosis, and treatment of the sickle cell syndromes. Normal hemoglobin synthesis, structure, and function are described in Chapter 13 ; the thalassemias are considered in Chapter 29 .

BACKGROUND

The chronicle of sickle cell anemia, sickle cells, and Hb S began in 1910 with a report by Dr. James Herrick of Chicago on the recurrent pain, anemia, and sickled appearance of the red blood

Figure 30-1 A schematic view of the pathophysiology of sickle cell disease. The GAGGTG mutation in the sixth codon of the -globin gene results in the substitution of valine for glutamic acid as the sixth amino acid of -globin. The inclusion of mutant ^{S} chains in the tetramer creates the variant Hb S. The insolubility of deoxygenated Hb S results in its polymerization and the loss of deformability and sickling of deoxygenated sickle erythrocytes. Vessels become occluded as a result of several processes, including the poor deformability of polymer-containing sickle cells.

cells of a dental student from Granada named Noel (Fig. 30-2).[14] [15] Disease manifestations had been recognized long before in Africa, where different tribes had bestowed on the malady various appellations that evoked the basic nature of recurrent pain. [16] Attention first was directed to the importance of deoxygenation of sickle red cells in 1927 when Hahn and Gillespie demonstrated that oxygen deprivation induced a sickle-like deformation, which was reversible on reoxygenation. [17] Later studies showed that the bulk viscosity of sickle cell suspensions rose dramatically and reversibly on deoxygenation. [18] Evidence that the unique pathologic properties of sickle red cells were due to an abnormal hemoglobin was provided in 1940 when a Johns Hopkins medical student named Sherman discovered that sickle but not normal erythrocytes exhibited optical birefringence when deoxygenated. [19] In the same year, Ham and Castle proposed the vicious cycle of erythrostasis hypothesisa synthesis of the combined knowledge regarding the interactions of deoxygenation, acidic pH, and viscosity of sickle cells. [20]

The abnormality of hemoglobin was confirmed in 1949 when Pauling et al. [21] reported that the electrophoretic mobility of Hb

Figure 30-2 Peripheral blood smears showing the peculiar elongated forms of the red corpuscles. *(Originally seen by Herrick,[14] with permission.)*

S differed from that of normal adult hemoglobin (Hb A). In 1950 the importance of Hb S to the pathobiology of sickle red cells was established by Harris description of reversible sol-gel transformation of deoxygenated Hb S solutions [22] and by Perutz and Mitchisons report of the insolubility of deoxygenated Hb S solutions. [23] Unification of the electrophoretic and solubility abnormalities of Hb S was provided by Ingram, who identified the substitution of valine for glutamic acid as the sixth amino acid of the -globin chain. [24] [25] [26] While the polymerization-sickling doctrine had come full circle, the earlier observation by Diggs and Bibb [27] of a population of irreversibly sickled cells (ISCs) that would not revert to discocytes on reoxygenation forewarned that there was more to sickle cell pathophysiology than polymerization alone.

GENETICS, EVOLUTION, MALARIA, AND G6PD DEFICIENCY

Genetics

The first evidence that sickle cell anemia was inherited was the finding by Huck [28] in 1923 that red blood cells from unaffected parents and relatives could be made to sickle, a phenomenon that led Sydenstricker et al. to suggest active and latent varieties of sickle cell disease. [29] The conclusion that sickle cell anemia results from homozygous inheritance of a genetic determinant from heterozygous parents was reached independently in 1949 by Beet [30] and Neel[31] and was confirmed in the original electrophoretic studies of Pauling and colleagues, which found patients with sickle cell anemia to have virtually all Hb S but their parents to have both Hb S and Hb A.[21] Before these reports, Silvestroni and Bianco[32] had described a variety of sickle cell disease with small sickle cells that was inherited from one parent carrying the sickling disorder and another with constitutional microcytosis. This was the first evidence that the sickle cell and -thalassemia genes were alleles.

Near the -globin gene on chromosome 11[33] are a number of restriction fragment length polymorphisms,[34] [35] distinct constellations of which define -globin haplotypes having specific ethnogeographic origins. [36] The association of the sickle cell gene with different haplotypes constitutes evidence that the sickle cell mutation has arisen at least five times throughout the course of evolution, four times within Africathe Senegal, Benin, Bantu, and Cameroon haplotypesand once withoutthe Arab-Indian haplotype (Fig. 30-3). [37] Despite rigorous scrutiny,[37] [38] no evidence has been obtained to suggest that haplotypes have provided selective evolutionary pressures on the sickle cell gene. [37]

Philadelphia, W.B. Saunders, 1949.)*

Malaria Hypothesis

The mystery of a gene with devastating clinical effects having persisted despite an intrinsic negative evolutionary pressure was explained partly by the concept of heterozygous advantagein any population the much greater number of individuals heterozygous for a particular gene compared with those homozygous creates a positive evolutionary pressure, provided the heterozygous condition offers some selective advantage. Allison [39] [40] concluded that the stable frequency of the sickle cell gene existing in areas of hyperendemic falciparum malaria was the result of a balance between gene exclusion due to the premature death of homozygotes and gene selection due to the resistance of heterozygotes against death from malaria, thereby defining the concept of genetic polymorphism. Indeed, children with sickle cell trait have lower rates of parasitemia and cerebral malaria. [41] In this regard, the selection of the sickle cell gene in Africa was related to the introduction 2,000 years ago of slash-and-burn agriculture, which, by destroying the root structure of tropical jungles that had drained standing water and by introducing sunlight into these previously shadowy areas, provided a breeding ground for the mosquito vector *Anopheles gambiae*.[42] [43] As a result of the selective advantage against death from malaria conveyed by the sickle cell gene, its worldwide distribution parallels that of falciparum malaria, with its highest frequencies occurring in the malaria belt (Fig. 30-3).[44]

The mechanism by which the sickle cell gene protects against malaria is not completely understood, [37] [42] but it has been suggested that rigid sickle cell trait red cells repel parasitic invasion.[45] Equal infection rates of sickle cell trait and nonsickle erythrocytes, [46] however, indicate that the inhospitable nature of the host erythrocyte is manifest at some later stage.[47] Consistent with this conclusion is the retarded parasite replication in sickle cell trait red cells at low oxygen tension. [48] Other disruptive influences on the symbiosis of malarial parasite and sickle trait red cell include the more rapid sickling and removal from the circulation of parasitized sickle cell trait erythrocytes related to intracellular oxygen consumption by parasites [49] and to reduced intraerythrocytic pH levels,[50] oxidation of parasite and red cells as a consequence of iron released from denatured sickle cell hemoglobin, [51] cellular potassium loss that inhibits parasite growth, [50] poor nutrition provided parasites by Hb S,[52] and physical disruption of parasite membranes by Hb S polymer.[53] These notions regarding the mechanisms of protection against malaria must be interpreted in the context of evidence that protection from severe malaria is related to the common West African human leukocyte class I antigen HLA-Bw53, [54] which provides the ability to present liver-stage specific malarial antigens to cytotoxic T cells as part of the immune response. [55]

G6PD Deficiency

The influence of G6PD deficiency, another common African polymorphism, on the epidemiology, expression, and frequency of the sickle cell gene has been a matter of debate. G6PD deficiency was reported to have greater frequency among patients with sickle cell disease. [56] [57] More recent reports have emphasized that the detection of G6PD deficiency is easily confounded by the young age of circulating sickle erythrocytes and have not confirmed a higher frequency of the mutant G6PD gene.[58] [59] Neither greater hemolysis nor more frequent pain was found among male subjects having both sickle cell disease and G6PD deficiency. [60]

Prevalence

The distribution and frequency of the sickle cell gene in different areas of the world has been influenced by evolutionary pressures [37] and transmission of the gene via trade routes and slave trade.[61] Among African Americans, the prevalence of sickle cell trait is 810% among newborns, [62] and in this population the frequencies of the sickle cell (0.045), Hb C (0.015), and -thalassemia (0.004) genes [62] indicate that there are 4,000 to 5,000 pregnancies a year at risk for sickle cell disease. [63] The burden of this disease in the United States is dwarfed by that in the rest of the world, as evidenced by a prevalence for the sickle cell gene as high as 2530% in western Africa[64] and an estimated annual birth of 120,000 babies with sickle cell disease in Africa. PATHOPHYSIOLOGY

The striking influence of deoxygenation on Hb S polymerization, cellular sickling, and blood viscosity enunciates the pathophysiology of sickle cell diseaseeach of the manifestations of sickle cell disease is attributable to Hb S polymerization. [7] [8] Despite the appeal of this interpretation, a more complete valuation of the several processes involved in sickle cell pathophysiology is needed for a more comprehensive understanding. [1] [2] [5] [6] [9] [10]

Hb S Polymer

Although oxygenated Hb S is as soluble as Hb A, the increased surface hydrophobicity of Hb S tetramers (due to valine rather than glutamic acid as the sixth amino acid) causes decreased solubility of the deoxygenated molecule. [65] Intermolecular bonding of deoxy-Hb S tetramers generates polymer filaments that associate into bundles (Fig. 30-4). [66] The basic polymer structure is a double-stranded filament, seven of which combine into a 21-nm diameter, 14-stranded fiber having one inner and six peripheral double filaments organized so that adjacent double strands have antiparallel orientation. [66] [67] Numerous studies indicate that one of the two ^{6val} forms a lateral contact with the essential [85] phenylalanine and [88] leucine residues within the F helix hydrophobic pocket of an adjacent Hb S tetramer (Fig. 30-5).[67] [68] [69] The second ^{6val} residue does not participate in intermolecular bonding, a fact relevant to considerations of the degree to which $_2{}^S$ mixed tetramers participate in

polymerization when both Hb S and Hb F are present.[70] Many other residues participate in intermolecular bonding to form axial and lateral contacts within the double filament and lateral contacts between double filaments. [67] [69] [71] Critical residues (and the mutant hemoglobins that ablate their bonding) include lateral contacts (6, 73 [Korle Bu], 66 [I-Toulouse], 83 [Pyrgos], 87 [D-Ibadan], axial contacts (121 [O-Arab], 16 [J-Baltimore], 17 [J-Amiens], 19 [D-Ouled Rabah], 22 [G-Coushatta], 16 [Hb I], 116 [O-Indonesia]), and interpair contacts (54 [J-Mexico], 47 [Sealy], 75 [Winnipeg], 78 [Stanleyville II], 6 [Sawara], 11 [Anantharaj], 68 [G-Philadelphia]).

Polymerization

The solubility of Hb S is approximately 17 g/dl, a level far below the intraerythrocytic concentration of hemoglobin of approximately 34 g/dl; deoxygenation results in supersaturation of deoxy-Hb S solutions, aggregation of deoxy-Hb S molecules,

Figure 30-6 Model for the polymerization and alignment of deoxy-hemoglobin S showing homogeneous and heterogeneous nucleation. *(Adapted from Hofrichter et al., [65] with permission.)*

and formation of deoxy-Hb S polymer.[65] Studies of the kinetics of polymerization have determined that the delay time to polymer formation is inversely proportional of the deoxy-Hb S concentration with 15th30th-order kinetics, a finding that demonstrates that the early stages of polymer formation involve aggregation of 15 to 30 tetramers into a single nucleus of polymerizationhomogeneous nucleation. [65] As polymer forms, the fiber provides a surface that provides more nuclei for polymer formationheterogeneous nucleation (Fig. 30-6).[72] Eaton and Hofrichter[7] explained the pathophysiology of sickle cell disease as a function of polymerization, sickling, and perturbations of blood flow that prolong the duration of cellular transit to exceed the delay time to polymerization. A different approach to understanding polymerization derives from measuring the maximal amount of polymer generated under equilibrium conditions, a system driven by thermodynamics rather than kinetics.[8] Both interpretations concur that polymerization is detrimental to sickle cells and strongly influenced by Hb S concentration, but there are important practical differences between the two. The kinetic interpretation is based on oxygenated morphologically normal cells having no persistent polymer providing nucleation sites,[73] and is consistent with vaso-occlusion occurring after a delay time for nucleation in *postcapillary* vessels. The thermodynamic version holds that polymer persists in some cells at arterial oxygen tensions, [74] that deoxygenated cells lose deformability before sickling, [75] and that the site of vaso-occlusion is the *prearteriolar sphincter*. [8] Kinetic considerations pertain to the greater majority of cells with lower mean corpuscular hemoglobin concentration (MCHC), a lesser polymerization tendency, and no persistent polymer when reoxygenated. Thermodynamic interpretations describe the minority of dehydrated sickle cells having very high MCHC, a strong tendency toward polymerization, and persistent polymer at arterial

INHERITANCE PATTERN OF SICKLE CELL DISEASES

The sickle cell diseases are inherited in an autosomal codominant manner. Sickle cell trait results from the simple heterozygous inheritance of a sickle cell gene from one parent and an Hb A gene from the other; the red cells contain Hb A ($_2{}^A{}_2$) and Hb S ($_2{}^S{}_2$) in a 60:40 distribution. Sickle cell anemia results from the homozygous inheritance of a sickle cell gene from each parent; the red cells contain virtually all Hb S. Hb SC disease results from the compound heterozygous inheritance of a sickle cell gene from one parent and an Hb C gene from the other; the red cells contain nearly equal amounts of Hb S and Hb C ($_2{}^C{}_2$). Sickle cell- thalassemia results from the compound inheritance of a sickle cell gene from one parent and a -thalassemic gene from the other; the red cells contain virtually all Hb S in sickle cell-° thalassemia; the red cells contain mostly Hb S with 530% Hb A in sickle cell-$^+$ thalassemia.

Sickle cell-hereditary persistence of fetal hemoglobin (sickle cell-HPFH) results from the compound heterozygous inheritance of a sickle cell gene from one parent and an HPFH gene (i.e., a deletion of the - and -globin genes that allows continued high-level expression of the fetal -globin genes in adult life) from the other. Sickle cell-HPFH is not associated with anemia or vaso-occlusive symptoms because the presence of large amounts (2535%) of Hb F ($_2{}_2$) in all red cells inhibits Hb S polymerization.

oxygen tensions. Studies of flow ex vivo showed the postcapillary sphincter to be the site of vasoocclusion, [76] as predicted by kinetic models.

Nitric oxide (NO ; NO) is one of the nitrogen monoxides, which are produced in vivo by the actin of NO synthases (NOS) on L-arginine.[77] [78] [79] NOs numerous biologic functions are the result of this free radical forming an ironnirosyl complex in a target protein. [77] Of particular interest to considerations of Hb S polymerization are its unique interaction with the hemoglobin molecule[80] and its complex interactions with heme oxygenase (HO) and carbon monoxide (CO).[81] Oxygen binding to the heme iron of hemoglobin promotes reversible binding of NO to ^{93Cys} to form S-nitrosohemoglobin,[80] which may be the mechanism by which exposure of sickle erythrocytes to NO increases their oxygen affinity.[82] [83] While this effect on oxygen affinity was predicted to *reduce* polymerization, sickling, and vasoconstriction,[82] the effect of NO on sickle cell pathophysiology is influenced by CO liganding to the heme prosthetic groups of NOS, which diminishes the enzymatic activity of NOS, [79] resulting in decreased NO production. Since increased amounts of CO are generated by the action of heme oxygenases [81] during hemolysis[84] [85] [86] [87] , the salubrious influence of NO on Hb S polymerization may be countered. Greater levels of complexity are provided to these interacting second messenger systems by the direct liganding of CO to heme iron, increasing oxygen affinity,[88] and the induction of heme oxygenase activity by hypoxia.[89] The net effects of these compounds on pathophysiology is not clear; however, recognition of their involvement points out the potential incompleteness of hypotheses based solely on the oxygenation/deoxygenation cycle.

Inherited Influences on Polymerization

When the switch from - to -globin synthesis occurs in the fetus, adult hemoglobin (in the case of sickle cell anemia, Hb S) replaces Hb F. [90] [91] Because of the inhibitory effect of Hb F on Hb S polymerization[70] and cellular sickling,[92] the high fraction of Hb F at birth masks the expression of sickle cell disease until Hb S levels increase to 75% at about 6 months of age (Fig. 30-7).[2] [6] Conditions that preserve elevated levels of Hb F into adulthood similarly modulate the course of sickle cell disease.[93] The compound heterozygous conditions sickle-hereditary persistence of fetal hemoglobin (Hb S-HPFH) and sickle cell- thalassemia both have higher Hb F levels and milder clinical courses than are characteristic of sickle cell anemia. [6] [94] Additional mitigating influences in sickle cell- thalassemia are elevated levels of Hb A_2 [7] and, in sickle cell-$^+$ thalassemia, levels of Hb A up to 30%. These affect both the solubility and polymerization of Hb S. Hb F is a more active inhibitor of polymerization than Hb A, as shown by Hb S solutions with 1530% Hb A (resembling sickle cell-$^+$ thalassemia) having delay times 10 to 100 times longer than pure Hb S solutions, and Hb S solutions with 2030% Hb F (resembling Hb S-HPFH) having delay times 1,000 to 1,000,000 times longer. [95] [96] The greater activity of Hb F than Hb A in increasing Hb S solubility is related to an important molecular difference: Hb A is excluded but $_2{}^A$ hybrid tetramers are included in Hb S polymer, while both Hb F and $_2{}^S$ hybrid tetramers are excluded.[70] [97] [98] A further influence mitigating the polymerization, sickling, and clinical aspects of sickle cell- thalassemia is the reduced MCHC, which retards Hb S polymerization. Hematologic values for sickle cell anemia, the sickle cell- thalassemias, and Hb S-HPFH are found in Table 30-1 .

Alpha thalassemia also modulates the clinical expression of sickle cell disease, in part by reducing the MCHC. [99] Prevalences of the silent carrier of thalassemia syndrome (genotype /) and -thalassemia trait (genotype /) among African Americans are approximately 30% and 2%, respectively. [100] The lower intraerythrocytic concentrations of Hb S associated with thalassemia modulate the hematologic, pathophysiologic, and clinical manifestations of disease, [99] [101] [102] [103] [104] [105] [106] particularly the severity of anemia, which is diminished after

Cellular Sickling

The original assumption that sickled-appearing red cells must be rigid was confirmed by the observation that a dramatic increase in bulk viscosity of sickle cell suspensions occurred when they were deoxygenated.[18] Within 0.5 seconds of deoxygenation, sickle cells accumulate Hb S aggregates and lose deformability despite having normal morphology; by 3 seconds, the biconcave discs contain short linear polymer; by 15 seconds, the discs acquire protuberances and longer linear polymer; and by 30 seconds, the cells gain a holly-leaf shape and considerable amounts of polymer. [75] [109] Reoxygenation results in loss of much polymer within 3 seconds, in very little polymer but persistent cell deformation at 5 seconds, and in no polymer or cell deformation at 10 seconds. During both deoxygenation and reoxygenation, viscosity parallels the presence of polymer. The poor deformability of reversibly sickled cells was confirmed using laser diffraction viscosimetry and filtration methods.[110] [111] [112]

Both the rate of deoxygenation and the presence of shear stress influence the alignment of intracellular polymer domains, which in turn may affect the rheologic properties of sickle cells and blood. The earliest reports of sickle cells described heterogeneous morphologic changesclassic sickle forms, holly-leaf shapes, and granular deformities.[14] Subsequent studies using electron microscopy[113] [114] and linear dichroism[115] found a correlation between sickle cell morphology and the pattern of intraerythrocytic polymer domains: archetypal crescents have a single domain of highly aligned polymer that seems to have arisen by homogeneous nucleation from a single nucleus; holly leaves have a few less well-aligned domains that appear to have arisen by heterogeneous nucleation from a limited number of nuclei; and granular cells have multiple poorly aligned domains that apparently have arisen by heterogeneous nucleation from many nuclei (Fig. 30-8). The rate of deoxygenation influences the formation of polymer domainsslower deoxygenation is associated with homogeneous nucleation, and rapid deoxygenation favors heterogeneous nucleation.[116] [117] Shear stress also influences polymer formation: shear applied during the delay period accelerates the onset of polymerization and increases viscosity, perhaps by creating more nucleation sites; shear applied after polymerization has occurred diminishes viscosity by shattering the solid polymer phase.[118] [119]

The impact of deoxygenation rate and shear remains speculative, because there is little knowledge of the effect of domain patterns on the rheologic properties of sickle cells or blood. One study found that slow deoxygenation of cell suspensions generates crescentic cells containing single, well-aligned polymer domains and a progressive increase in bulk viscosity. In contrast, rapid deoxygenation created granular cells with multiple domains and an abrupt increase in bulk viscosity; continued deoxygenation transformed these cells into elongated cells with one domain of aligned polymer and lowered the bulk viscosity. [120] The influence of polymer domain patterns on individual cell deformability remains to be clarified.

Irreversibly Sickled Cells

The original observation of cells that remain sickled on reoxygenation [27] demonstrated an aspect of pathophysiology that was not immediately oxygenation-dependent. The preponderance of ISCs among the most dense sickle cells [121] [122] suggested that the common pathway of sickle cell destruction is via dehydration. However, Bertles and Milner[123] found among the densest cells a group of younger cells having unexpectedly low hemoglobin F contentcells apparently predestined to early destruction by lacking the protective effect of Hb F against polymerization and sickling. [70] [92] The relative youth of the most dense cell fraction was confirmed using glycosylated hemoglobin as a measure of cell age. [124]

The rheologic disadvantage of ISCs is demonstrated by their poor deformability [125] and short circulatory survival,[126] but the mechanisms responsible for the generation of ISCs are not completely understood. Although shells of membrane skeletal proteins from ISCs have characteristically elongated shapes, [127] their poor cellular deformability is substantially improved by reducing their MCHC with osmotic manipulation, [128] [129] a fact incompatible with rigid membranes causing their rheologic impairment. An alternative understanding of ISCs derives from their elongated (rather than crescentic) shape, which is

Figure 30-8 Schematic showing that in a slowly deoxygenated cell the sickle morphology results from the formation of a single domain of well-aligned fibers. In a more rapidly deoxygenated cell the holly leaf morphology results in the formation of a number of smaller domains of shorter aligned fibers. In the most rapidly deoxygenated cells the granular morphology results from the formation of a large number of very small domains of randomly oriented short fibers. *(Adapted from Eaton and Hofrichter,[822] with permission.)*

probably due to the rapid polymerization of highly concentrated Hb S, [7] [129] generating multiple small polymer domains. This interpretation is consistent with the importance of recurrent sickling and unsickling to ISC formation both in vitro [130] and in vivo.[131] The similarities of ISCs to the calcium-loaded, potassium-depleted, dehydrated nonsickle erythrocytes that have undergone calcium-sensitive potassium loss by the Gardos phenomenon and the ability to generate ISCs by metabolic depletion in vitro suggests a role of ATP depletion. [132] However, metabolic depletion is unnecessary for ISC production, as there is a population of cells that becomes dehydrated by the Gardos phenomenon while energy-replete. [133] [134]

The clinical importance of ISCs relates to their presence as sickled forms on the peripheral blood smear (in contrast with reversibly sickled cells, which by definition become morphologically normal when exposed to ambient oxygen tensions). The ISC number is generally constant in individual patients and correlates mainly with the degree of anemia.[135] The number of ISCs on the peripheral smear does not change with episodic complications of disease and is not a reliable indicator of events such as the acute painful episode.[136] However, painful episodes have been reported following artificial perturbation of their numbers to exceed steady-state levels. [131] The main clinical use of detecting ISCs on the peripheral smear is in diagnosing sickle cell syndromes: ISCs are seen in all sickle cell disease genotypes but not in sickle cell trait.

Cation Homeostasis and Cell Dehydration

During their brief circulatory sojourn, sickle cells become profoundly dehydrated, [123] a process gravely important to ISC generation, the unique pathobiology of Hb SC red cells, and certain disease complications. The extreme dehydration of sickle cells (MCHC ranging up to 50 g/dl) [7] [128] promotes Hb S polymerization by a direct effect of higher MCHC[8] and by an indirect effect related to the peculiar inverse relationship between Hb S concentration and oxygen affinity. [137]

The mechanism by which sickle cells become dehydrated has recently come into clearer focus. Several energy-driven systems, gradient-driven systems, and pathways contribute to the depletion of the major intracellular monovalent cation, potassium, and water from sickle erythrocytes. [138] [139] While certain aspects of this process are the result of deoxygenation, polymerization, and sickling, others are induced by the mere presence of mutant hemoglobin within the cell. Deoxygenation-induced passive cation leak results in balanced potassium efflux and sodium influx that exceed by an order of magnitude that of normal erythrocytes and oxygenated sickle cells; the fixed stoichiometry of three sodium ions pumped out for every two potassium ions pumped into the cell during reparative attempts by

sodiumpotassium ATPase[140] [141] results in a net depletion of cellular monovalent cation and water. [142] [143] These facts notwithstanding, mathematic modeling of sickle cell volume regulation indicates that the major effectors of cell dehydration are calcium-dependent potassium loss (the Gardos pathway) and potassiumchloride cotransport, acting interdependently. [133] Although not consistent with all the data, [139] a reasonable approximation derives from the notion that a population of calcium-sensitive reticulocytes preferentially lose potassium by the Gardos effect, thereby acquiring intracellular acidosis, which potentiates further potassium loss via potassiumchloride cotransport.[134] The calcium content of sickle cells is also elevated, particularly in ISCs. [144] Although most calcium is sequestered in vesicles, [145] it appears that sufficient free calcium is available to participate in the Gardos phenomenon. [134] Factors that contribute to potassium loss include shape transformation [146] and oxidation of membrane transport proteins. [147]

Among the clinical consequences most directly attributable to cell dehydration are the renal complications of sickle cell trait. The loss of urine-concentrating ability and hematuria in these individuals demonstrate that even Hb AS cells can cause vaso-occlusion when severely dehydrated by the hypertonic environment of the renal medulla.[148] [149] [150]

Another demonstration of the clinical impact of cellular dehydration is the clinical morbidity in Hb SC disease. Although sickle cell trait and Hb SC red cells each contain heterozygous amounts of Hb S and another hemoglobin that does not participate in polymerization, [151] individuals with sickle cell trait are asymptomatic carriers, while those with Hb SC disease have anemia and painful vaso-occlusion. [6] This important difference is the result of higher Hb S concentrations within Hb SC cells due to greater fractional content of Hb S (50% vs. 40%) [151] and to the cellular dehydration [151] [152] mediated by Hb C-induced potassiumchloride cotransport activity.[152] [153]

A third clinical correlate of red cell dehydration, the interaction of thalassemia and sickle cell anemia, is perhaps more important for broadening the perspective of sickle cell pathophysiology than for reaffirming the importance of polymerization. Clearly the less severe anemia associated with coexistent thalassemia (Table 30-2)[99] [103] [104] is accompanied by findings that interdependently support the importance of polymerization: the lower MCHC [103] [104] retards polymerization; [7] [8] the fewer dense cells and ISCs[102] [104] [154] extend the known relationship between the severity of anemia and the number of ISCs; [135] and the diminished deoxygenation-induced cation leak[101] is consistent with the better hydration [155] and greater deformability of -thalassemic sickle cells. [102] [156] Despite the internal consistency of this synthesis, [157] exceptions to its strict interpretation demonstrate the need for a pathophysiologic understanding that extends beyond polymerization. The lack of -thalassemia effect on anemia prior to age 7 years (Table 30-2)[107] [108] suggests the existence of an age-dependent, polymerization-independent factor that enables the influence of MCHC on polymerization. In this regard, it has been suggested [99] that persistent splenic conditioning in early childhood may deprive -thalassemic sickle cells of their fundamental advantagethe greater degree of membrane redundancy, [158] which protects them against deformation-induced cation loss[146] during polymerization. The limitations of polymerization-based interpretations are further demonstrated by the detrimental clinical effects associated with thalassemiathere is an increased incidence of osteonecrosis, [99] [159] [160] and the higher hemoglobin levels are associated with a greater frequency of pain, which after age 20 years is associated with a higher mortality rate. [161] Coexistent beneficial and detrimental influences of thalassemia demonstrate the doubtful validity of using polymerization equations to predict disease severity [94] and the need for pathophysiologic interpretations that include the polymerization-independent mechanisms of cell pathobiology[11] and the detrimental rheologic effects of higher hematocrit and viscosity. [125] [156]

Therapeutic strategies aimed at decreasing the MCHC have used methods of improving cellular hydration and of reducing MCH. Induction of hyponatremia in patients was reported to swell red cells osmotically, lower MCHC, and ameliorate painful episodes. [162] Pharmacologic preservation of sickle cell hydration by cetiedil citrate, an agent that inhibits the Gardos phenomenon and induces passive sodium influx, has shown therapeutic potential. [163] [164] [165] Therapeutic options for maintaining cell hydration also are provided by the administration of imidazole inhibitors of the Gardos pathway [166] [167] or of magnesium supplements, which inhibit potassiumchloride cotransport.[168] It also is possible to reduce the MCHC by reducing the MCH with iron deficiency. It has been observed that spontaneous or induced iron deficiency sufficient to reduce the serum ferritin, mean corpuscular volume (MCV), and MCHC resulted in variably improved Hb S polymerization, red cell survival, level of anemia, and clinical status. [169]

Oxidative Damage

In addition to its abnormal electrophoretic mobility and solubility, Hb S is unstable. [170] [171] [172] [173] Consequences of Hb S instability are the increased degeneration of methemoglobin [174] and release of heme,[175] processes that contribute to the increased degeneration of oxidative radicals by sickle red cells. [175] [176] In addition, the normal physiologic processes of hemoglobin oxygenation and deoxygenation generate methemoglobin S and oxidative radicals continuously. [177] These processes perpetuate an oxidative stress within sickle cells that has major pathophysiologic importance to metabolism, membrane lipids, membrane proteins, and the integrity of the Hb S molecule itself.[11] [178]

The effects of oxidative stress on red cell metabolism are particularly important to sickle cell pathophysiology because the resultant impairment of reductive defense mechanisms potentiates other oxidative damage to the cell. The presence of free heme within sickle red cells inhibits the activity of several enzymes necessary for the generation of the NADH and NADPH required for protection against oxidation. [176] Indeed, sickle cells have been found to have decreased NADH redox potential, [179] hexose monophosphate shunt activity, [180] [181] and GSH content.[181] The metabolic disadvantages of sickle red cells provide underappreciated but important contributions to sickle cell pathobiology.

Both the lipids and proteins that make up erythrocyte membranes are targets of oxidative damage. The combination of increased generation of metHb S, [174] impaired metHb S reduction, and absence of metHb S from sickle erythrocytes[182] suggests the rapid disappearance of metHb S, a suggestion consistent with its degradation to hemichrome from which heme is liberated to cause oxidant damage of cytoplasmic and membrane components.[183] [184] Both heme and nonheme iron have been found in increased amounts on sickle cell membranes. [178] The accumulation of hemichrome aggregates on the cytoplasmic portion of band 3 initiates the coclustering of band 3 molecules in the membrane and the assembly of IgG and complement on the extracellular domains of band 3 molecules, [185] [186] which promotes sickle cell recognition by macrophages[187] and adherence to endothelial cells. [188] The uneven distribution of band 3 and of another transmembrane protein, glycophorin A, [189] demonstrates that the membrane skeletons of sickle cells are disrupted. Abnormalities of the proteins that make up this skeleton are demonstrated by the impaired association of the major membrane skeletal protein, spectrin, into sickle cell membranes. [190] There is also direct evidence for oxidative damage to the membrane skeletal proteins spectrin, ankyrin, band 3, and band 4.1. [191]

In addition, there is evidence for oxidative damage to sickle cell membrane lipids. [192] It is probable that similar abnormalities of membrane lipids are related to their reduced lateral mobility in sickle cell membranes[193] and to the loss of phosphatidylinositol-anchored membrane proteins such as DAF and MIRL, as discussed in the Mechanisms of Hemolysis section.[194]

The role of membrane-bound iron in the oxidative damage perpetrated on sickle erythrocytes is supported by the finding that the oral administration of L1, an effective iron-chelating agent, [195] diminishes the heme and nonheme iron bound to erythrocyte membranes, thereby protecting them from lipid peroxidation and hemichrome deposition.[196]

A unifying observation regarding the role of reactive oxygen species in sickle cell pathophysiology is the inverse relationship reported between clinical severity and intraerythrocytic levels of the enzyme that modulates the generation of peroxide and hydroxyl radicals, superoxide dismutase. [197]

Sickle Cell Adherence

The discovery that sickle red cells were more adherent to cultured vascular endothelial cells [189] [198] has contributed greatly to our understanding of sickle cell pathophysiology.[11] [199] [200] The importance of sickle cell adherence was appreciated by noting that the vaso-occlusive severity of individual patients was directly related to the adhesivity of their sickle cells [201] and that the initiation of vaso-occlusion ex vivo is by adherence of sickle cells to vascular endothelium (Fig. 30-9). [76] Subsequent studies have revealed that adherence differs according to subpopulation of sickle cells, source of endothelial cells, cytoadhesive ligands, and cell membrane receptors.[11] [202] In general, the least dense, reticulocyte-enriched fraction of sickle cells is the most adherent. [76] [203]

Adherence of sickle erythrocytes to unstimulated endothelium employs numerous receptors and ligands, the consideration of which reveals the great complexity of the adhesive process. High-molecular-weight von Willebrand factor (vWF) bridges glycoprotein (GP) Ib or integrins of sickle cells to GP Ib of endothelial cells; thrombospondin links CD36 or sulfated glycans of sickle reticulocytes to CD36 or $_{v\,3}$ integrin of endothelial cells; $_{4\,1}$ integrin of sickle reticulocytes ligands to fibronectin of the endothelial glycocalyx; sickle erythrocyte lipids bind to matrix thrombospondin and laminin; exposure of cryptic portions of sickle red cell band 3 provides

adhesivity; and CD44 of sickle cells binds to matrix laminin and fibronectin. [202] [204] [205] [206] [207] [208] [209]

Figure 30-9 Adhesion of sickle erythrocytes in venules. **(A)** Adherent discocytic sickle cells tethered to the endothelial wall of a venule and aligned in the direction of the flow (arrow). **(B)** Increased adherence of sickle cells at venule or bending and at junctions of smaller-diameter postcapillary venules. The postcapillary vessels (small arrows) are totally blocked. Large arrow indicates flow direction. *(From Kaul et al.,[76] with permission.)*

A general scheme of sickle erythrocyte and endothelial receptors and soluble ligands is depicted in Figure 30-10 .

Adherence of sickle erythrocytes to activated or injured endothelial cells [210] [211] involves additional adhesive mechanisms, [199] [212] which, along with the adhesive contributions of platelets [213] [214] neutrophils (PMN), [215] add to the complexity of sickleendothelial cell adherence. Even normal endothelial cells have potential for binding sickle cellslatent adhesiveness, a large array of adhesive membrane glycoproteins, and pronounced adhesogenic responses to stimulation. [199] [212] [216] [217] [218] Endothelial adhesivity may be enhanced by factors that have the capacity to activate or injure them. Elevated levels or activity of many of these in steady-state, and especially during vaso-occlusive crises or infections, underscores their relevance to the pathogenesis of sickle cell disease. Thrombin generation is increased in sickle cell disease, [219] [220] and this enzyme has been observed to enhance endothelial cell adhesivity for sickle erythrocyte by a mechanism involving interendothelial cell gap formation. [221] Interleukin-1 also occurs at high levels in sickle cell disease and promotes expression of receptors for vWF (GP Ib) and vitronectin, secretion of high-molecular-weight vWF, and potentiation of adhesivity for sickle cells. [222] [223] [224] [225] [226] Tumor necrosis factor- levels are increased, and this cytokine induces expression of GP Ib and vascular cell adhesion molecule-1 and enhances sickle cell adherence. [222] [223] [227] Gamma-interferon promotes expression of CD36 and vWF, both of which

Figure 30-10 Receptors and ligands known to mediate sickle erythrocyte adherence to the vascular endothelium. *(Adapted from Bunn,[373] with permission.)*

participate in sickle erythrocyte adherence. [228] [229] Endothelial cells infected with herpesvirus-1 express Fc-like receptors that bind sickle erythrocytes via the abnormal amounts of immunoglobulin on sickle cell membranes. [188] Other viruses and double-stranded RNA also induce vascular cell adhesion molecule-1 expression. [230] The finding of increased adhesivity of viral-infected endothelial cells [188] suggests an explanation for the frequent occurrence of painful episodes during viral illness. [231]

Oxygen deprivation of endothelial cells also has the potential for altering vaso-occlusion via its effects on endothelial cell coagulant properties, synthesis of interleukin-1, and induction of interendothelial cell gap formation, which, by analogy to thrombin, may account for the higher levels of sickle cell adherence reported. [232] [233] [234] [235] Many of the toxic effects of hypoxia on cells and tissues are worsened substantially by reperfusion. [236] Because of its many features resembling ischemia/reperfusion, [237] [238] [239] [240] [241] [242] sickle cell disease appears to be an apt paradigm for this type of potentially adhesogenic injury. It has been proposed that the immune deficiency of sickle cell disease allows the sequence of chronic inflammation, upregulated endothelial cell adhesion molecules, enhanced sickle cell adherence, and cell trapping, all of which potentiate vaso-occlusion. [243]

Therapeutic opportunities derived from these relationships include inhibiting adherence and aggregation with emulsifying agents such as Poloxomer 188 (RheothRx) [244] [245] or with polyethylene glycol (PEG) [246] or PEG-coated red cells [247] and the potential for future interventions using antibodies and oligopeptides that interfere with ligandreceptor interactions.

Role of Neutrophils

The possible role of PMNs in the pathophysiology of sickle cell disease was suggested by a study of the effects of oxygen inhalation in three subjects during steady state. [131] After cessation of oxygen inhalation, the leukocyte counts of all three rose to abnormal levels, and two experienced painful crises at the time of maximal white cell counts. A subsequent example was the association of a severe painful episode with pulmonary infiltrates and hypoxemia with a leukocyte count of 63,000/l following the administration of granulocyte colony-stimulating factor to a patient with sickle cell disease. [248] Additional circumstantial evidence suggesting a role for PMNs in the pathophysiology of sickle cell disease is derived from comparisons of Hb SS and Hb SC disease. In Hb SS, chronic leukocytosis is much more common, [249] pain is twice as frequent, [161] and life expectancy is two decades shorter. [250] Within the Hb SS group, there is a direct relationship of the leukocyte count and mortality rate, [250] hemorrhagic stroke, [251] and acute chest syndrome. [252] The observed correlation of clinical response to hydroxyurea with reduction in PMN count has been interpreted to indicate a pathophysiologic role of PMNs. [253] [254] [255] However, this association may simply reflect better compliance with drug administration rather than a causal effect.

The cellular mechanisms by which PMNs may influence vaso-occlusion include the poor deformability of PMNs compared with normal erythrocytes, [256] the increased adherence to endothelium and the frequent upregulation of CD64 on membranes of PMNs from patients having pain crisis, [257] the activation of PMNs by sickle erythrocytes, [215] and the important role of PMNs in ischemia/reperfusion injury, [236] [258] [259] a process that resembles the intermittent flow of sickle cell disease. [237] Complex blood cell interactions involving PMNs are suggested by observations of plateletsickle erythrocyte aggregates in the blood, [214] plateletleukocyteendothelial cell adherence on the vessel wall, [260] and participation of PMNs in generating the thrombin- or hypoxia-induced interendothelial cell gaps [258] [259] [261] [262] [263] that facilitate sickle cell adherence. [221]

Coagulation and Platelet Perturbations

The state of frequent, perhaps continuous, perturbation and activation of the hemostatic system in sickle cell disease provides evidence that there may be no real steady state. [12] [241] Increased platelet activation in vivo is suggested by several lines of evidenceincreased levels of -thromboglobulin [264] and platelet factor 4, [265] increased activation-associated antigens on platelet membranes, [214] reduced amounts of thrombospondin in circulating platelets, [266] and increased urinary levels of thromboxane. [267] Reduced platelet count and the shortened platelet survival during acute painful episodes suggest that platelet activation occurs during these events and may be responsible for the aforementioned findings. [268] Further support for this conclusion is provided by the finding of decreased platelet thrombospondin levels during pain crises. [269]

Evidence suggests that steady-state levels of procoagulants and of the natural anticoagulants protein C, protein S, and antithrombin III are abnormal in sickle cell disease. [12] There is direct evidence for increased thrombin generation and activity in sickle cell disease, including elevated levels of thrombinantithrombin III complexes, activation fragment 1.2, and fibrinopeptide A. [219] [220] Administration of low-dose acemocoumerol reduced the elevated levels of fragment 1+2, [270] and in a small study administration of minidose heparin reduced hospitalization time by 75%. [271] It is uncertain whether the prefibrinolytic system is abnormal, but increased levels of fibrin degradation product provide evidence for ongoing fibrinolysis. [12] Further evidence for a thrombophilic state is the correlation between hyperhomocysteinemia and the incidence of stroke in sickle cell disease. [272] Despite the evidence for chronic activation of coagulation and fibrinolysis, data have been presented supporting hepatic dysfunction as the cause of the measured abnormalities. [273]

A source of hemostatic activation specific for sickle cell disease is the red cell itself. Both ISCs and deoxygenated reversibly sickled cells express abnormal amounts of phosphatidylserine on the outer membrane leaflet, which results in activation of the coagulation cascade. [274] In addition, cellular sickling results in the exovesiculation of phosphatidylserine-rich membrane vesicles, [275] which have the ability to activate coagulation. [276] Another mechanism by which abnormal sickle cell membrane properties perturb hemostasis pertains to the increased fraction of phospholipids in the hexagonal II phase, which induces antiphospholipid antibodies. [277] Although the high prevalence of these antibodies in sickle cell patients [277] [278] is reported to have no clinical consequences, [278] the occurrence of right atrial thrombosis has been reported with one patient having both sickle cell disease and antiphospholipid antibodies. [279]

Perturbation of vascular endothelial cells is yet another source of hemostatic activation. [280] The increased levels of thrombin found in sickle cell disease [219] [220] [269] stimulate endothelial cells to release vWF, prostacyclin, plasminogen activators, and platelet activating factor, to express tissue factor and cytoadhesive molecules on

the cell membrane, to promote vasoconstriction, and to activate thrombomodulin. Other known endothelial cell agonists active in sickle cell disease may evoke a procoagulant effect of these cells. [280]

The possible occurrence of a microvascular process similar to thrombotic thrombocytopenic purpura is suggested by the case of a patient having life-threatening multiorgan failure resembling thrombotic thrombocytopenic purpura who responded to plasma exchange, [281] and possibly by another patient whose pain crisis responded to fresh-frozen plasma infusion. [282]

Vascular Regulation

Passage of sickle red blood cells and blood through blood vessels is affected by the lumen size of the blood vessels. In addition to established humoral and neurogenic mediators, vascular tone is subject also to regulation from local autocrine and paracrine influences. [283] Certain molecules involved in vascular homeostasis are relevant to the pathophysiology of sickle cell disease. Among the local paracrine processes, endothelial cells produce prostacyclin, which causes vasodilatation and inhibits platelet aggregation and PMN adherence. [284] Prostacyclin production by endothelial cells is increased by the presence of sickle red cells. [267] [285] Endothelin is a potent vasoconstrictive agent whose synthesis by endothelial cells is stimulated by their contact with sickle erythrocytes. [286] Platelet-derived growth factor also is a powerful vasoconstrictor, and its synthesis is increased by hypoxic conditions, which are common in sickle cell disease.

Nitrous oxide, previously referred to as endothelial cell relaxation factor, is produced in endothelial cells by the effect of NOS on arginine. [78] [283] The binding of oxygen to the heme iron of hemoglobin promotes the binding of NO to ^{93}Cys and the formation of S-nitrosohemoglobin. [80] When hemoglobin is deoxygenated in the tissues, the NO is dissociated to cause vasoconstriction [80] by its action on vascular smooth muscle cells. [78] This process allows variations in physiologic oxygen gradients to balance the local blood flow with oxygen requirements. The administration of an NOS inhibitor to decrease NO production in rats caused decreased cerebral flow of infused sickle cell blood and increased adherence of sickle red cells to the cerebrovascular endothelium. [287] Thrombomodulin is a transmembrane protein of endothelial cells that is activated by thrombin to catalyze the effect of protein C on inhibiting clotting. Soluble levels of this molecule have been proposed as indicators of endothelial cell injury or microvascular disease. [288] [289] [290]

Pathophysiology of Vaso-occlusion

Understanding sickle cell vaso-occlusion as the result of multiple interdependent pathophysiologic processes does not refute the fundamental importance of polymerization and sickling to the disorder. [13] A comprehensive concept of pathophysiology evolves from critical reassessment of what is known about polymerization, sickling, and vaso-occlusion. Paramount to this understanding is the realization that sickling is a chronic, ongoing process, rather than a sudden cataclysmic one. Sickle cells are deoxygenated, on average, at least once a minute; there is no reason to believe that patients experience systemic deoxygenation or that hypoxemia accounts for routine pain crises. Moreover, certain polymerization-independent processes associated with vaso-occlusion are chronically activated, which suggests that there may be no real steady-state circulation of sickle cell blood. [241]

While the clinical morbidity associated with high intraerythrocytic concentrations of Hb S in Hb SC disease, [151] the clinical benignity associated with the high amounts and pancellular distribution of Hb F in sickle cell-HPFH, [291] and the clinical complications caused by specific circumstances known to enhance polymerization [292] [293] [294] emphasize the importance of polymerization, there are sufficient exceptions to this association that polymerization and sickling should probably be regarded as necessary but not sufficient for understanding vaso-occlusion. The argument that polymerization tendency is the major determinant of clinical severity [94] is valid only as it pertains to the severity of anemia. This proviso is further exemplified by the interaction of thalassemia with sickle cell anemia, where the lower MCHC and polymerization tendency improves the level of anemia, [104] but the higher blood viscosity [156] is detrimental to vaso-occlusive severity. [161] The major influence of Hb F on polymerization [70] and sickling [92] has only small effects on the frequency of pain. [295] The profound effect of Hb S concentration on polymerization is most important to cells having high MCHC (ISCs), but the frequency of pain fails to correlate with

the fraction of ISCs in the circulation [136] and in fact appears to have an inverse relationship. [296] [297] Ex vivo studies of sickle cell blood flow indicate that vaso-occlusion is initiated by the adherence of younger cells with lower MCHC to the vascular endothelium (Fig. 30-9), and that the role of poorly deformable, polymerization-prone ISCs is to propagate but not initiate the process. [76]

Increasing evidence for the importance of sickle cellendothelial cell adherence, hemostatic activation, vascular reactivity, and leukocyte participation suggests that polymerization considerations provide only a first approximation of the severity of sickle cell disease, [94] moment-to-moment vaso-occlusive changes are better understood by considering a wider variety of processes. [13] It has been suggested that the apparent lack of predictability in the periodic vaso-occlusion of sickle cell disease may not be random but chaotic and, thereby, dictated by specific internal deterministic parameters [298] and that vaso-occlusion may be better understood as a chaotic process than as the result of any one external determinant. [13]

The observation of an inverse relationship between severity of pain and NO levels [299] may reflect the complexity of known actions of NO on sickle cell oxygen affinity, [82] blood flow regulation, [80] vasomotor regulation, [300] [301] inflammation and vascular permeability, [302] [303] and neurotransmission. [77] [304] [305]

Mechanisms of Hemolysis

Premature destruction of sickle erythrocytes occurs both extravascularly and intravascularly. [306] Extravascular hemolysis results from abnormalities of the sickle cell that allow its recognition and phagocytosis by macrophages [307] and from impaired deformability of sickle red cells, which allows their physical entrapment. [308] Changes in sickle cell membranes from oxidative damage by unstable Hb S and from recurrent sickling promote binding to the membrane of increased amounts of IgG, which mediates recognition by macrophages. [307] [309] Oxidatively denatured hemoglobin binds to the cytosolic portion of the transmembrane protein, band 3, which signals adherence of IgG and complement to the band 3 exterior. [185] [186] Impaired complement inactivation on sickle cell membranes [310] allows the presence of complement, which facilitates the recognition and phagocytosis of sickle cells by macrophages. [187] Mechanical trapping of poorly deformable ISCs also contributes to extravascular hemolysis, as evidenced by the poor deformability of ISCs, [125] their brief circulatory survival, [126] and correlation of their numbers with the severity of anemia. [135] The declining fraction of dense cells and slight worsening of anemia during painful episodes, [311] [312] and the selective trapping of dense cells in ex vivo flow systems [308] suggests further that mechanical trapping contributes to extravascular hemolysis.

Elevations of free plasma hemoglobin suggest that one third of the total hemolysis in sickle cell anemia is intravascular. [306] One mechanism of intravascular hemolysis is sickling-associated exovesiculation [275] [313] of vesicles rich in phosphatidylinositol-anchored membrane proteins, [314] depleting the cell of the complement regulatory proteins DAF and MIRL and leaving the cells susceptible to complement-mediated intravascular lysis. [194] Another component of intravascular hemolysis is increased mechanical fragmentation of sickle cells, [315] [316] which accounts for the accelerated hemolysis in sickle cell patients during exercise. [315]

Immune Deficit

The propensity of children with sickle cell disease to contract *Streptococcus pneumoniae* infection is related to impaired splenic function [317] and diminished serum opsonizing activity. [318] Even before the anatomic autoinfarction of the spleen in patients with sickle cell anemia, [319] defective splenic function is demonstrable by Howell-Jolly bodies on the peripheral blood smear, [317] visible pits on the surface of red blood cells, and abnormal results of radionuclide spleen scanning. [320] Splenic function is restorable by transfusion prior to the second decade. [321] Specific syndromes exhibiting greater rates of hemolysis cause loss of splenic function at earlier agessickle cell anemia > Hb SC disease > sickle cell- $^{+}$ thalassemia. [320] Using red blood cell pit counts and radionuclide liverspleen scanning, it has been found that the functional asplenia in Hb SC disease is usually delayed until after 4 years of age, which suggests that the routine administration of prophylactic penicillin to infants and young children with Hb SC disease may not be necessary. [322]

Opsonization defects and abnormalities of the alternate complement pathway coexist in patients with sickle cell disease, [323] but evidence of a causal relationship is lacking. [324] Rather, the opsonic defect is the result of an abnormality in natural antibody response that impairs the effector arm of opsonization assays. [324] The variable opsonic defects for different bacteria may depend on selective antibody requirements for opsonization of the different microbes.

The decreased titer of antibody against *S. pneumoniae* antigens following splenectomy in individuals without sickle cell disease [325] suggests that splenic hypofunction

may mediate the opsonic deficiency of sickle cell disease. This conclusion is consistent with the earlier loss of splenic function in genotypes characterized by more rapid hemolysis,[320] the correlation between free plasma hemoglobin levels and the rate of consumption of alternate complement pathway components, [326] and the suppression of B-lymphocyte activity by phosphatidylserine-rich vesicles, [327] such as those shed by sickle erythrocytes during sickling. [328] It has been suggested that an underlying immunologic defect may lead to chronic inflammation, enhanced endothelial cell adhesivity, and vaso-occlusive complications. [243]

CLINICAL MANIFESTATIONS

The clinical manifestations of sickle cell disease vary tremendously between and among the major genotypes. Even within the genotype regarded as being most severe, sickle cell anemia, some entirely asymptomatic patients are detected only incidentally, while others are disabled by recurrent pain and chronic complications. Typically, patients are anemic but lead a relatively normal life punctuated by painful episodes. Virtually every organ system in the body is subject to vaso-occlusion, which accounts for the characteristic acute and chronic multisystem failure of this disease. Important clinical features less directly related to vaso-occlusion are growth retardation, psychosocial problems, and susceptibility to infection. This section describes the systemic manifestations of disease and those of specific organ systems. Specific therapeutic recommendations are included. For detailed discussions the reader is referred to the monographs of Serjeant, [2] Mankad and Moore,[329] and Embury et al.[1] Practical monographs recommended include *Management and Therapy of Sickle Cell Disease*[330] and a review of pediatric therapy by Vichinsky and Lubin.[331]

Life Expectancy

Decreased life expectancy is one of the original correlates of sickle cell disease. In 1973 Diggs reported that the mean survival was 14.3 years; [332] in 1994 Platt et al. reported that the life expectancy was 42 years for men and 48 years for women with sickle cell anemia.[250] The remarkably prolonged survival over the past 20 years is more the result of improved general medical care than of successful antisickling therapy. The impact of prophylactic

penicillin therapy on preventing death from pneumococcal sepsis [333] may now be affecting survival.

Chronic Anemia

Chronic hemolytic anemia is one of the hallmarks of sickle cell disease. As discussed above, the major cause of anemia is hemolysis. Sickle erythrocytes are destroyed randomly, with a mean life span of 17 days.[334] The survival of ISCs is much shorter than of other sickle cells, [123] and the overall hemolytic rate reflects the number of ISCs.[135] The degree of anemia is most severe in sickle cell anemia and Hb S-° thalassemia, milder in Hb S- $^{+}$ thalassemia and Hb SC disease,[249] and, among patients with sickle cell anemia, less severe in those who have coexistent -thalassemia (Tables 30-1 and 30-2).[99] There are also inappropriately low erythropoietin levels;[335] this is more severe in adults than in children, [335] suggesting the presence of subclinical renal disease. The lower erythropoietin levels in sickle cell disease may reflect the retardant effect of increased blood viscosity on erythropoietin production. [336]

The level of chronic anemia is of considerable predictive value. Patients with more severe anemia are more likely to develop infarctive and hemorrhagic stroke, [251] to have glomerular dysfunction, [337] [338] and perhaps to give birth to low-birthweight babies. [339] [340] Conversely, they have fewer episodes of acute chest syndrome, [252] less frequent pain crises,[161] and (after age 20 years) a lower mortality rate. [161]

Exacerbations of Anemia

The rather constant level of hemolytic anemia may be exacerbated by any of several events, more commonly aplastic crises and acute splenic sequestration and less commonly sequestration in other organs, chronic renal disease, bone marrow necrosis, deficiency of folic acid or iron, and hyperhemolysis.

Aplastic crises are transient arrests of erythropoiesis characterized by abrupt falls in hemoglobin levels, reticulocyte number, and red cell precursors in the marrow. Although these episodes typically last only a few days, the level of anemia may be severe because the hemolysis continues unabated in the absence of red cell production. While the mechanisms that impair erythropoiesis in inflammation are operative in infections of all types (see Chap. 24),[341] human parvovirus B19 specifically invades proliferating erythroid progenitors, [342] which accounts for its importance in sickle cell disease (see Chaps. 19 and 24).[343] Parvovirus B19 accounts for 68% of aplastic crises in children with sickle cell disease, [344] but the high incidence of protective

SPLENIC SEQUESTRATION CRISIS

Splenic sequestration crisis may cause rapid, severe worsening of anemia accompanied by persistent reticulocytosis and a tender enlarging spleen. There is a risk of hypovolemic shock, particularly in children. Young children with sickle cell anemia (Hb SS) have a 30% incidence of this complication, and patients of all ages with Hb SC disease (Hb SC) and sickle cell- thalassemia (Hb S- thal) are at risk. There is a 15% mortality rate. Sequestration is recurrent in 50% of cases, so splenectomy is recommended after the acute event remits. In young children chronic transfusion can be used to prevent recurrence until splenectomy can be performed safely. These episodes often occur concomitant with a viral illness, so parents are trained to palpate enlarging spleens during viral illnesses to detect this complication in its early stages.

antibodies in adults[345] makes parvovirus a less frequent cause of aplasia in this age group. Other reported causes of transient aplasia are infections by *S. pneumoniae*, [346] [347] salmonella,[348] streptococci,[346] and Epstein-Barr virus.[347] Bone marrow necrosis, characterized by fever, bone pain, reticulocytopenia, and a leukoerythroblastic response, also causes aplastic crisis, [349] [350] which too may be the result of parvovirus infection.[351] [352] Inhaled oxygen therapy also causes transient red cell hypoproduction; supraphysiologic oxygen tensions curtail erythropoietin production promptly and suppress reticulocytosis within 2 days. [131]

The mainstay of treating aplastic crises is red cell transfusion. When transfusion is necessitated by the degree of anemia or cardiorespiratory symptoms, a single transfusion usually will suffice, since reticulocytosis resumes spontaneously within a few days. Transfusion may be avoided by keeping severely anemic patients at bed rest to prevent symptoms and by avoiding supraphysiologic oxygen tensions. [353] A useful guideline for transfusion is the reticulocyte count. A patient having an exacerbation of anemia with an elevated absolute reticulocyte count is less likely to require urgent transfusion than one with a normal or low absolute reticulocyte

count.

Acute splenic sequestration of blood is characterized by acute exacerbation of anemia, persistent reticulocytosis, a tender, enlarging spleen, and sometimes hypovolemia.[354] Patients susceptible to this complication are those whose spleens have not undergone fibrosisyoung patients with sickle cell anemia and adults with Hb SC disease or sickle cell-$^{+}$ thalassemia.[355] Sequestration may occur as early as a few weeks of age[356] [357] and may cause death before sickle cell disease is diagnosed.[358] In one study, 30% of children had splenic sequestration over a 10-year period, and 15% of the attacks were fatal. [354] [359] The basis of therapy is to restore blood volume and red cell mass. Because splenic sequestration recurs in 50% of cases, [354] splenectomy is recommended after the event has abated. Alternatively, chronic transfusion therapy is used in young children to delay splenectomy until it can be tolerated safely. [360] Because recurrence is possible during transfusion therapy,[360] parents should be trained to detect a rapidly enlarging spleen and to seek immediate medical attention in this event. Less common sites of acute sequestration include the liver[361] and possibly the lung.[362]

Hyperhemolytic crisis is the sudden exacerbation of anemia with increased reticulocytosis and bilirubin level. It has been argued that many diagnoses of hyperhemolytic crisis are actually occult splenic sequestration or aplastic crises detected during the resolving reticulocytosis. In one report, seven of the eight children with hyperhemolysis had G6PD deficiency.[363] If hyperhemolysis exists, it is probable that many cases are related to some complicating etiology, such as G6PD deficiency or immune hemolysis.

The onset of chronically more severe anemia may be due to developing renal insufficiency (see Chap. 148) or deficiency of folic acid or iron (see Chaps. 26 and 28). Inadequate erythropoietin production in chronic renal failure [364] results in deficient compensation for sickle cell hemolysis. It often is possible to forestall the inevitable transfusion dependence that results from progressive renal failure by taking measures to diminish the hemolytic rate or to stimulate erythropoiesis. We recommend the initial use of hydroxyurea therapy alone; this can be supplemented as necessary with recombinant human erythropoietin, or erythropoietin can be administered alone.[365] In using recombinant human erythropoietin, caution must be exercised not to elevate the hematocrit to levels that result in hyperviscosity. [365] Chronic hemolysis results in increased utilization of folic acid stores, [366] and megaloblastic crises from folic acid deficiency have been reported. [367] [368] Despite increased intestinal absorption of iron in sickle cell disease, [369] the combination of nutritional deficiency[370] and urinary iron losses[371] results in iron deficiency

in 20% of children with sickle cell disease. [370] The diagnosis of iron deficiency may be obscured by the elevated serum iron levels associated with chronic hemolysis, necessitating the detection of a low serum ferritin or an elevated serum transferrin level for the diagnosis.

An unanticipated worsening of anemia has been reported to occur due to bystander destruction of antigen-negative recipient erythrocytes during a delayed hemolytic transfusion reaction.[372]

Acute Painful Episode

An episode of acute pain was originally called a sickle cell crisis by Diggs, who used the expression crisis to refer to any new rapidly developing syndrome in the life of a patient with sickle cell disease.[231] In modern parlance, the term acute painful episode is favored over crisis, in part to diminish the catastrophic associations with this disease. While most authorities have ascribed the acute painful episodes to vaso-occlusion, [1] [7] [373] [374] one expert has argued that pain is more likely the result of shunting of blood flow.[375] [376]

Acute pain is the first symptom of disease in more than 25% of patients, the most frequent symptom after age 2 years,[377] and the complication for which patients with sickle cell disease most commonly seek medical attention.[378] [379] Although a general correlation of vaso-occlusive severity and genotype has been posited, [94] there is tremendous variability within genotypes and in the same patient over time. In one large study of patients with sickle cell anemia, one third rarely had pain, one third were hospitalized for pain approximately two to six times per year,

TREATMENT OF PAIN

The object of analgesic therapy in patients with acute painful episodes is to relieve pain rapidly and safely. The most successful approach to this end has been achieved by comprehensive centers that provide individualized therapy in a setting apart from the emergency ward. A helpful approach to dealing with the patient in pain is to provide psychosocial support by teams of physicians, social workers, and nurses who are known to the patient. Parents and the extended family of pediatric patients should be included. Some programs using oral medication are successful, but often parenteral narcotics are necessary. Recommended agents, doses, schedules, and drug combinations are shown in Table 30-6 . After initial control of pain using aggressive narcotic regimens, rescue therapy by patient-controlled analgesia is useful for maintenance inpatient management. The use of constant intravenous infusion of narcotics must be monitored closely because of the risk of respiratory depression, which is particularly dangerous for patients with sickle cell disease. The newer agents toradol and Tramadol offer the advantages of less respiratory depression and addictiveness. The switch from parenteral to oral analgesics may be problematic because of inadequate dosing of oral drugs and their variable absorption. Following discharge of children from the clinic, emergency ward, or hospital, it may be helpful to provide school re-entry liaison services. Patients should be discharged from the hospital with a limited supply of analgesics to avoid fostering drug-seeking behavior, which may become detrimental to future pain management. Narcotic addiction is no more frequent in sickle cell patients than in any others requiring analgesia and is more closely related to societal issues than to problems specific to sickle cell disease.

and one third had more than six pain-related hospitalizations per year. [380] The frequency of pain peaks between ages 1939 years; over age 19 years, more frequent pain is associated with a higher mortality rate.[161] Over a 5-year period in the National Cooperative Study of Sickle Cell Disease, 40% of patients had no painful episodes, 5% of patients accounted for one third of the emergency room visits, and pain frequency correlated with high total hemoglobin levels and low Hb F levels.[161] Medical personnel who see patients only in the emergency department gain a biased view of sickle cell disease skewed by a frequently afflicted minority whose severe disease is the result of specific hematologic determinants.[381]

Pain may be precipitated by events such as cold, dehydration, infection, stress, menses, and alcohol consumption, but the majority of painful episodes have no identifiable cause.[239] It can affect any area of the body, most commonly the back, chest, extremities, and abdomen, may vary from trivial to excruciating, and is usually endured at home without a visit to the emergency department. There are often premonitory symptoms.[382] The duration averages a few days.[383] Painful episodes are biopsychosocial events[239] caused by vaso-occlusion in an area of the body having nociceptors and nerves. [384] Pain is an affect and, as such, consists of sensory, perceptual, cognitive, and emotional components.[239] Frequent pain generates feelings of despair, depression, and apathy that interfere with everyday life and promote an existence that revolves around pain. This scenario may lead to a chronic debilitating pain syndrome; fortunately, this is rare. The management of pain is discussed in the Therapy section.

Approximately half the episodes present with objective clinical signs such as fever, swelling, tenderness, tachypnea, hypertension, nausea, and vomiting. [297] Numerous laboratory tests have been found to lack specificity as indicators of acute vaso-occlusionleukocytosis, [385] D-dimer fragments of fibrin,[386] and markers of

platelet activation.[387] The most promising laboratory indicators of acute vaso-occlusion are changes in the density distribution of sickle cell subpopulations and the rheologic properties of the blood. [240] [312] Just before the onset of pain there is an increase in the fraction of dense cells and a decrease in the maximum deformability of sickle cells; during the evolution of pain, the dense cell fraction declines and the overall red cell deformability increases. The evolution of pain is also associated with changes in the levels of acute phase reactants, [241] [388] serum lactic dehydrogenase,[389] interleukin-1, tumor necrosis factor,[233] and serum viscosity.[390] These tests are of clinical utility only if they are readily available and can be compared to baseline data.

Pain is more frequent with the Hb SS genotype, low levels of Hb F, -thalassemia, higher Hb levels, [161] and sleep apnea.[391] The frequency of pain is reduced during chronic transfusion therapy. [392]

Multiorgan Failure

This disastrous acute event involves multiple organ systems, including the lungs, brain, kidneys, liver, hematologic system, and heart, and usually leads to death. [393] It may be precipitated by infection, vaso-occlusion, or fat embolus and consists of a constellation of life-threatening processes including hypoxemia, acidosis, inflammation, vascular permeability, severe anemia, disseminated intravascular coagulation, renal failure, and hepatic failure. [394] [395] [396] In addition to therapy specific for these processes, red cell exchange, plasma infusion or exchange, and corticosteroids should be considered. [281] [282]

Psychosocial Issues

Modern insights into the psychosocial adjustment of patients with sickle cell disease have provided a level of understanding

that allows interventional therapy. [397] [398] [399] While most patients with sickle cell disease are generally well adjusted, [400] there are risks of depression, low self-esteem, social isolation, poor family relationships, and withdrawal from normal daily living. [400] [401] [402] Particular stressors are recurrent pain and the response to it, [403] curtailed activity due to pain,[404] misinterpretation of the meaning of pain,[405] and depression leading to learned helplessness. [406] While some patients with sickle cell disease become addicted to narcotics, this is uncommon[407] and usually is the result of social influences rather than pain therapy. [408] Well-adjusted patients have active coping strategies,[409] family support,[410] and support from the extended family unit common in African-American society.[411] Interventional approaches should emphasize recognizing and reinforcing individual strengths, confronting pathologic behavior, and establishing coping skills through reinterpreting pain, diverting attention from pain, and using support systems. Attention to psychosocial concerns is vital to the psychosocial well-being and integration into society of patients with sickle cell disease.[410] [412]

Growth and Development

By age 2 years, children with sickle cell disease have detectable growth retardation that affects weight more than height and has no clear gender difference. [413] By adulthood normal height is achieved, but weight remains lower than that of controls. More severe growth delay is noted in children with sickle cell anemia and sickle cell-° thalassemia; Hb SC disease is associated with a less severe growth delay. Skeletal maturation is also delayed. [414] Girls with sickle cell disease have retarded sexual maturation that is greater in those with sickle cell anemia and sickle cell-° thalassemia than those with Hb SC disease and sickle cell- $^{+}$ thalassemia; [413] it is associated with elevated gonadotropin levels for the stage of sexual development [415] and delayed menarche.[416] Boys also have delayed sexual maturation, which is more severe in those with sickle cell anemia than those with Hb SC disease. [413] Retarded sexual maturation in males can be due to primary hypogonadism,[417] hypopituitarism,[418] or hypothalamic insufficiency. [419] The association of retarded growth with abnormalities of the growth hormone and insulin-like growth factor-I suggests a therapeutic role for these factors in children with sickle cell disease who have delayed growth. [420] [421]

Delayed growth in sickle cell disease is associated with accelerated erythropoiesis, elevations of whole body protein turnover, and basal metabolic rate. [422] [423] When children have both sickle cell disease and hypersplenism, splenectomy may result in improved protein turnover, metabolic rate, and growth parameters. [422] [424] Similarly, weight gain has been reported with transfusion. [425] It also has been possible to restore normal growth by nutritional supplementation. [426] There have been reports of responses to folic acid[427] and zinc supplementation,[428] but these approaches are not recommended as standard care.

Infections

Infectious complications of sickle cell disease are a major cause of morbidity and mortality. [429] [430] The infections caused by particular organisms are shown in Table 30-3 (Table Not Available) and the specific organisms affecting different target organs are shown in Table 30-4 (Table Not Available) . [431]

Bacteremia in children with sickle cell disease is most commonly caused by *S. pneumoniae*.[430] [432] [433] Before the use of prophylactic penicillin, *S. pneumoniae* bacteremia accounted for 510 episodes per 100 patient-years in infants. [429] This event is accompanied by leukocytosis, a left shift, aplastic crisis, sometimes disseminated intravascular coagulation, and a 2050% mortality rate. [429] The risk of recurrent *S. pneumoniae* sepsis and death in patients who have had previous sepsis is much increased; all patients having a history of pneumococcal sepsis should remain on penicillin prophylaxis indefinitely and are not candidates for outpatient management of febrile episodes (see Therapy section). [434] While concerns about *S. pneumoniae* sepsis are largely for young children, this complication also occurs in adults, often with devastating results. [435] [436] The second most

common organism responsible for bacteremia in these children, *Hemophilus influenzae* type b, has accounted for 1025% of episodes. [437] [438] *H. influenzae* bacteremia affects older children and is less fulminant than *S. pneumoniae* bacteremia, but it may be fatal. [429] [439] Therapeutic advances in childhood bacteremia have resulted from vaccination against *S. pneumoniae* and *H. influenzae* type b, prophylactic penicillin, and the long-acting, broad-spectrum antibiotic ceftriaxone.

While unconjugated pneumococcal vaccination has been generally disappointing, [333] [440] [441] regular booster immunization has been found to improve antibody titers,[442] and new conjugated vaccines with pneumococcal polysaccharides linked to tetanus or diphtheria toxoid afford greater immunogenicity and boosterability. [443] Conjugated *H. influenzae* type b vaccines produce excellent antibody responses in children with sickle cell disease [444] and now are administered in early infancy.

Randomized, double-blind, placebo-controlled studies of prophylactic penicillin beginning in infancy, including the PROPS study, have found that this therapy reduced the incidence of *S. pneumoniae* bacteremia by 84% in children younger than 3 years.[333] [440] Its use is currently recommended (see the Therapy section).[432] Concerns regarding this approach have been the uncertainty regarding the safety of discontinuing prophylaxis as a result of suppression of anti- *S. pneumoniae* antibody production and the emergence of penicillin-resistant organisms. A randomized, double-blind, placebo-controlled study, the PROPS II study, found that it is safe to stop prophylactic penicillin therapy at age 5 years in children who have not had prior severe pneumococcal infection or splenectomy and are receiving regular follow-up care.[445] However, penicillin-resistant strains have emerged in one third of nasal *S. pneumoniae* carriers.[446]

The efficacy of ceftriaxone therapy for *S. pneumoniae* and *H. influenzae* infection[447] [448] has led to new treatment algorithms that recommend outpatient therapy for

most patients, as outlined in the Therapy section. However, in certain geographic areas, resistant *S. pneumoniae* have emerged, necessitating a thorough knowledge of local resistance patterns to guide the choice of alternate antibiotics (in particular, vancomycin, to which resistance has not been observed). [449] Bacteremia in older patients is more likely due to *Escherichia coli* and other gram-negative organisms, as are urinary tract infections. [429] [433] [450]

Meningitis in sickle cell anemia is primarily a problem of infants and young children, is caused most frequently by *S. pneumoniae*, and occurs in the setting of bacteremia.[430] Rapid administration of antibiotics has resulted in a lower incidence of meningitis among bacteremic patients than 20 years ago, when the incidence was 50%.[433] [451] *H. influenzae* type b is a less common cause of meningitis.[430] Antibiotic therapy is discussed in the Therapy section.

Bacterial pneumonia may be the cause of the acute chest syndrome. Patients with any combination of dyspnea, cough, chest pain, fever, tachypnea, or leukocytosis should be evaluated by chest x-ray, arterial blood gases, blood and sputum culture, cold agglutinins, and serologic study for *Mycoplasma pneumoniae, Chlamydia pneumoniae*, and *Legionella. S. pneumoniae* and *H. influenzae* type b are uncommon causes of acute chest syndrome, even in children.[452] *M. pneumoniae* and *C. pneumoniae* account for approximately 20%. [452] [453] Antibiotic therapy for the acute chest syndrome should cover these four agents, as discussed in the Therapy section. Respiratory viruses are common causes of pulmonary infection. General therapy for the acute chest syndrome is discussed in the section, Pulmonary Complications.

Osteomyelitis occurs more commonly in sickle cell disease than in normal individuals, [430] probably as a result of infection of infarcted bone. In this patient population osteomyelitis is commonly caused by *Salmonella* species. [454] *Staphylococcus aureus,* the most common etiology in patients without sickle cell disease, accounts for <25% of sickle cell disease cases.[455] [456] Infection usually affects long bones, often at multiple sites. [457] Diagnosis is confirmed by culture of blood or infected bone, before parenteral antibiotics covering *Salmonella* and *S. aureus* are begun,[454] as discussed in the Therapy section. Articular infection is less common and is often due to *S. pneumoniae*.[454]

The specificity of the parvovirus B19 for erythroid precursor cells, [342] [458] coupled with the accelerated erythropoiesis in hemolytic anemias, leaves sickle cell patients vulnerable to infection by this agent.[459] In sickle cell disease, parvovirus infection is a common cause of aplastic crisis, especially in children. [343] [347] [351] [460] [461] It has been reported to cause bone marrow necrosis,[351] [352] acute chest syndrome, pulmonary fat embolism,[351] [462] [463] [464] hepatic sequestration,[465] and glomerulonephritis.[466]

It has been reported that the rate of bacterial infection is reduced during chronic transfusion therapy. [392]

Neurologic Complications

Neurologic complications occur in 25% of patients with sickle cell disease [467] and include transient ischemic attacks (TIAs), cerebral infarction, cerebral hemorrhage, seizures, unexplained coma, spinal cord infarction or compression, central nervous system infections, vestibular dysfunction, and sensory hearing loss. [468] [469] [470] One study reported that the median age for strokes was age 6 years and that after age 14 years, strokes occurred infrequently. [471] Another described a pattern in which infarctive strokes were common in children and those over age 30 years, while hemorrhagic stroke was most common between ages 20 and 30 years. [251]

The most common signs of cerebrovascular accident (CVA) in patients with sickle cell disease are hemiparesis, seizures, coma, speech defects, and visual impairment. CVA may occur spontaneously or intercurrently with other complications, such as pneumonia, aplastic crises, painful episodes, or dehydration. [472] Risk factors for CVA include more severe anemia,[251] [473] higher reticulocyte counts,[473] lower Hb F levels, [474] higher white cell counts,[251] [471] the Hb SS genotype (rather than Hb SC disease or sickle cell- thalassemia), sleep apnea, [475] migraines,[476] elevated homocysteine levels,[272] and relative systolic hypertension (i.e., those at the high end of the lower-than-normal range characteristic of sickle cell disease). [477] We recommend that those risks that are reversible be treated. Genetic markers of increased risk are the Central African Republic haplotype [478] and the absence of -thalassemia.[478] [479]

Cerebral thrombosis, which accounts for 7080% of all CVAs in sickle cell disease, [467] [480] [481] results from large vessel occlusion (Fig. 30-11)[482] [483] [484] rather than the more typical microvascular occlusion of sickle cell disease. CVAs are heralded by focal seizures in 1033% of cases [467] [468] [473] and by TIAs in 10%.[467] [472] [481] CVAs are fatal in approximately 20% of initial cases, recur within 3 years in nearly 70%, and are the cause of motor and cognitive

ACUTE CNS EVENTS

Both children and adults with sickle cell disease have an increased risk of CVA. Infarctive strokes can be predicted using transcranial Doppler study and prevented using prophylactic chronic transfusion. Patients with hemiparesis, seizures, coma, speech defects, or visual impairment should be evaluated for CVA. Cerebral thrombosis accounts for 7080% of all cases of CVA in sickle cell disease, causes death in approximately 20%, recurs within 3 years in 70%, and causes motor and cognitive impairment in the majority. Thrombosis occurs in all age groups, but hemorrhage is far more common in older patients. Intracranial hemorrhage results in the same signs as thrombosis, but neck stiffness, photophobia, severe headache, vomiting, and coma are more common. The mortality rate may be as high as 50%, but the morbidity of survivors is low.

Patients with symptoms and signs of CVA should be evaluated immediately by CT scanning or MRI to distinguish cerebral thrombosis and hemorrhage. In those with thrombosis, prompt partial exchange transfusion is performed, and chronic transfusion is begun to maintain the Hb S level <30% and to prevent recurrent thrombosis. Those with hemorrhage should have angiography after partial exchange transfusion is performed to avoid complications associated with injected contrast material. Hemorrhages due to ruptured aneurysm are amenable to surgical intervention.

Figure 30-11 Right common carotid arteriogram taken in anteroposterior projection, demonstrating complete occlusion of the origin of the right anterior cerebral artery (arrowhead). *(From Stockman et al.,[484] with permission.)*

impairment in the majority.[467] Thrombosis occurs in all age groups; hemorrhage is confined to older patients. [467]

Intracranial hemorrhage results in the same signs as thrombosis, but neck stiffness, photophobia, severe headache, vomiting, and altered consciousness are more common. Coma suggests hemorrhage rather than thrombosis.[473] A typical presentation is coma and seizures without hemiparesis. Although the mortality rate may be as high as 50%,[485] [486] [487] [488] the morbidity of survivors is low.[489] Hemorrhage may be subarachnoid, intraparenchymal, or intraventricular, which can be differentiated by angiography. [486] [487] The favorable neurosurgical outcome in subarachnoid hemorrhage due to ruptured aneurysm justifies an aggressive approach to diagnosis, transfusion, vasodilatory therapy, and surgery. [486] [487] [490]

Patients with symptoms and signs of CVA should be evaluated immediately using computed tomography (CT) scanning or magnetic resonance imaging (MRI) to distinguish TIA, cerebral thrombosis, and hemorrhage. In those with hemorrhage, angiography is indicated, after partial exchange transfusion is performed to avoid

complications associated with the injected contrast material. In those with thrombosis, prompt partial exchange transfusion is performed, and chronic direct transfusion to maintain the Hb S level below 30% is instituted to prevent recurrent thrombosis [472] [483] and promote resolution of arterial stenoses. [472] [491] Although recurrent CVAs during chronic transfusion have been reported, [492] this therapeutic modality provides the best means of preventing recurrence (Fig. 30-12).[483] [493] This treatment also provides incidental protection against pain crises, bacterial infections, acute chest syndrome, and hospitalization. [392] After 5 years of red cell transfusion, clinical response and blood flow[491] [494] are reassessed to guide the decision regarding discontinuing therapy. Transfusion therapy may be required indefinitely in those with persistent flow abnormalities. For those with recurrences soon after discontinuing therapy, indefinite transfusion is reinstituted. [495]

Subclinical cerebral infarction or ischemia has been detected by MRI, positron emission tomography, transcranial Doppler (TCD) flow studies, and autopsy. [210] [496] [497] [498] [499] In a study of 194 children with sickle cell disease, of whom 4.6% had had a prior

Figure 30-12 Comparison of stroke recurrence over 62 months in a transfused group and in untransfused historical control groups.[467] [823] *(Adapted from Pegelow et al.,[493] with permission.)*

stroke, 17.9% were found to have MRI abnormalities; global and specific intellectual dysfunction and neuropsychiatric impairment correlated strongly with prior stroke but also with silent infarcts detected by MRI. [500] Neurodevelopmental abnormalities resulting in poor school performance may be the outcome of silent cerebral infarcts.[501] Noninvasive imaging is useful also in predicting CVA; 30% of children with evidence of arterial stenosis by TCD developed stroke, while none developed stroke in the group without detectable stenosis.[499] In the Stroke Prevention in Sickle Cell Disease trial, 120 children diagnosed by TCD with clinically silent cerebral artery stenosis on the basis of cerebral flow rates 200 cm/sec were randomized to receive chronic transfusion therapy or not; after 16 months follow-up, 11 of 60 untransfused subjects had developed strokes, but only 1 of 60 transfused subjects had had a minor neurologic event. [502]

In 30% of patients with sickle cell disease, major vessel stenosis results in the formation of friable collateral vessels that appear as puffs of smoke (moyamoya in Japanese) on angiography.[503] [504] Moyamoya disease predisposes to thrombotic and hemorrhagic strokes, seizures, and cognitive disability. [505] Surgical approaches to therapy, such as extracranialintracranial bypass, have been useful in improving the perfusion of affected regions of the brain. [506] [507]

Seizures occur more commonly among patients with sickle cell disease. In one study, 21 of 152 patients in a pediatric clinic had seizures, 4 of which were related to meperidine therapy. Most had nonfocal CT and MRI studies but focal electroencephalographic changes. [470]

Pulmonary Complications

Pulmonary disease is the leading cause of death in sickle cell disease. [250] [508] There are both acute and chronic pulmonary manifestations of sickle cell disease. The acute chest syndrome consists of dyspnea, chest pain, fever, tachypnea, pulmonary infiltrate on radiography, and leukocytosis. It affects approximately 30% of patients with sickle cell disease and may be life-threatening. [452] [509] The usual etiology is vaso-occlusion, infection, or both simultaneously, [510] and antibiotics are often indicated as therapy. Microbial pathogens are more commonly identified in children. [510] Many episodes in which common pathogens are not cultured are due to atypical agents (*Mycoplasma, Legionella*, and *Chlamydia*), [452] [453] suggesting that antibiotic therapy include agents directed at atypical agents.

Pulmonary fat embolus, evidenced by stainable fat in pulmonary macrophages obtained by bronchoalveolar lavage or sputum induction, is found in 4460% of cases of acute chest syndrome.[462] [511] Aspiration pneumonia and cardiopulmonary resuscitation may cause lipid-laden macrophages. [512] Acute chest syndrome due to pulmonary fat embolus is associated with more severe hematologic and clinical abnormalities [513] and elevated plasma levels of free fatty acids and phospholipase A_2 [395] [514]

Acute chest syndrome is often preceded by febrile episodes in children and by vaso-occlusive pain crisis in adults (Fig. 30-13). [513] [515]

ACUTE CHEST SYNDROME

Symptoms and signs of the acute chest syndrome include dyspnea, cough, chest pain, and less commonly abdominal pain, fever, tachypnea, leukocytosis, and a pulmonary infiltrate on the chest radiograph. This event has a mortality rate of approximately 10%. The process is usually due to infection or vaso-occlusion but may also be the result of noncardiogenic pulmonary edema or of pulmonary embolization from a distant thrombus or infarcted bone marrow. Responsible infectious agents include *S. pneumoniae, H. influenzae, Mycoplasma, Chlamydia, Legionella,* and viruses. Infection with pyogenic bacteria is more common in children than in adults, and the urgency to initiate antibiotic therapy is greater in the pediatric population. In adults the decision to initiate antibiotics is a matter of clinical judgment. Antibiotic coverage must include *S. pneumoniae, H. influenzae* type b, *M. pneumoniae*, and *C. pneumoniae*for example, cefuroxime and erythromycin.

Whatever the etiology, the major danger of the acute chest syndrome is hypoxemia and its attendant widespread sickling and vaso-occlusion, which create a risk of multiorgan failure. The tachypneic patient should be evaluated with arterial blood gas measurements to distinguish metabolic acidosis, hypoxemia, and anxiety. Thereafter, hypoxemia can be followed by pulse oximetry. If a p_{AO2} >70 mmHg cannot be maintained by oxygen inhalation, the patient is transferred to intensive care, where an emergency partial exchange transfusion is performed. Again, there is a greater sense of urgency regarding hypoxemia in children than in adults, and many pediatricians elect partial exchange transfusion at the first sign of the acute chest syndrome. After transfusion, there is often rapid improvement in oxygenation despite continued radiographic abnormalities. Severe episodes may not respond to this therapy and require support with artificial ventilation or even extracorporeal membrane oxygenation while awaiting recovery.

RIGHT UPPER QUADRANT SYNDROME

An acute complication manifest by some or all of the following featureshyperbilirubinemia, abdominal pain, fever, right upper quadrant abdominal tenderness, hepatomegaly, abnormal liver function tests, and hepatic failurehas been called the right upper quadrant syndrome. Possible etiologies include cholelithiasis, viral hepatitis, biliary cholestasis, and hepatic ischemia. Hemoglobin levels usually do not change greatly. An asymptomatic syndrome of benign cholestasis associated with severe hyperbilirubinemia that resolves in 710 days has been reported in children. A syndrome more common in adults is associated with fever, leukocytosis, abdominal pain, and deteriorating liver function tests. This hepatic crisis usually progresses to hepatic failure, coagulopathy, encephalopathy, and death. This syndrome appears to be caused by hepatic ischemia, but viral hepatitis may produce the same clinical picture. Autoimmune liver disease may present as hepatitis, fulminant hepatic failure, or cholangitis. Hepatitis C is common. Because of the nearly uniform mortality of this type of hepatic crisis, exchange transfusion and plasmapheresis and liver transplantation have been used as therapy. No controlled data are available to support this approach.

Pulmonary fat embolus is often preceded by an acute painful episode. [462] In adults the mortality rate is four times higher than in children. [513] Noncardiogenic pulmonary edema also has been observed.[516] Some patients have a rapidly progressive course associated with a precipitous decrease in arterial oxygen tension; they may require intensive care treatment.[510] When arterial oxygen tension cannot be maintained above 70 mmHg with inhaled oxygen, partial exchange transfusion is indicated.[408] In extreme circumstances, artificial ventilation and extracorporeal membrane oxygenation have been used. [517] It has been reported that the inhalation of NO was beneficial to two children with severe acute chest syndrome.[518] Acute chest syndrome is less common during chronic transfusion programs.[392]

Figure 30-13 Age-specific associated events within 2 weeks preceding acute chest syndrome. *(Adapted from Vichinsky et al.,[513] with permission.)*

Evaluation of chronic pulmonary status in patients with sickle cell anemia reveals restrictive and obstructive lung disease, hypoxemia, and pulmonary hypertension singly or in combination, not restricted to but more common in those with a past history of acute chest syndrome. [519] [520] [521] High-resolution, thin-section CT scanning of the lungs revealed chronic interstitial fibrosis. [522] Pulmonary hypertension usually occurs in adults and carries a poor prognosis. [523] The condition can be diagnosed by cardiac catheterization or echocardiogramDoppler study. There is no efficacious treatment, and these patients may be considered for hydroxyurea therapy, vasodilators, anticoagulation, or oxygen inhalation.

Airway hyperreactivity occurs in nearly two thirds of children with sickle cell disease not diagnosed as having asthma. [524] Thirty-six percent of 53 children with sickle cell disease were found to have sleep-related upper airway obstruction, 16% had hypoxemia, and all 15 who underwent adenotonsillectomy were symptomatically improved and had improved hypoxemia.[525] Sleep apnea may be associated with surgically reversible exacerbations of painful episodes [391] and strokes.[475] Etiologies unrelated to prior acute episodes may relate to chronic impairment of pulmonary blood flow [241] or to oxidative damage mediated by free plasma Hb S.[526] Blood gas and pulmonary function measurements should be obtained as baseline data for all patients.

Hepatobiliary Complications

The prevalence of pigmented gallstones in sickle cell disease is directly related to the rate of hemolysis. [527] In sickle cell anemia, gallstones occur in children as young as 3 to 4 years of age[528] and are eventually found in approximately 70% of patients. [529] Some have recommended the surgical removal of asymptomatic gallstones to avoid subsequent difficulty in distinguishing gallbladder pain from acute painful episodes. [530] This approach has become more feasible with the availability of laparoscopic cholecystectomy.[531]

Potential causes for the common hepatomegaly and liver dysfunction in sickle cell disease are intrahepatic trapping of sickle cells, transfusion-acquired infection, transfusional hemosiderosis, and autoimmune liver disease. [532] [533] Histologic examination of the liver shows centrilobular parenchymal atrophy, bile pigment, periportal fibrosis, hemosiderosis, and cirrhosis. In addition to infection with hepatitis viruses, there are acute hepatic episodes, some of which are unique to sickle cell disease. In all of these, the combination of hemolysis, hepatic dysfunction, and renal tubular defects results in strikingly high serum bilirubin levels, sometimes >100 mg/dl.[534] One of these syndromes, benign cholestasis of sickle cell disease, results in severe, asymptomatic hyperbilirubinemia without fever, pain, leukocytosis, hepatic failure, or death. [535] A far graver event is the hepatic crisis, [231] in which hepatic ischemia results in fever, pain, leukocytosis, severe hyperbilirubinemia, and abnormal liver function tests. [536] It may progress to liver failure, which has a dismal prognosis. [537] [538] Corticosteroid and azathioprine therapy may induce responses in autoimmune liver diseases, including hepatitis, sclerosing cholangitis, and acute hepatic failure. [533] [539]

Chronic hepatitis C infection in sickle cell disease occurs with a prevalence that is related to the number of transfusions received; it may be a leading cause of cirrhosis.[540] Liver transplantation has been used successfully as therapy for this complication. [541]

Obstetric and Gynecologic Issues

Although gynecologic complications (delayed menarche, dysmenorrhea, ovarian cysts, pelvic infection, and fibrocystic disease of the breast) are more common in women with sickle cell disease,[542] the major reproductive concern in these patients is

pregnancy. The fetal complications of pregnancy, most of which are related to compromised placental blood flow, are the increased incidence of spontaneous abortion, intrauterine growth retardation, pre-eclampsia, low birthweight, and death; maternal complications include increased rates of painful episodes, severe anemia, infections, and death.[543] [544] [545] [546] It is controversial whether the degree of anemia predicts the birth of babies with low birthweight. [339] [340] The course of pregnancy is more benign in Hb SC disease than in sickle cell anemia. [544] [545] Better fetal and maternal outcomes in recent years are largely due to generally improved antenatal and obstetric care.[546] An unresolved specific issue pertains to the role of transfusions in pregnancy. [547] Some experts recommend prophylactic transfusion,[548] but a large controlled study showed no improvement in fetal outcome from this management option.[549] The type of delivery does not appear to represent a problem, both spontaneous delivery and cesarean section being well tolerated.

Some experts advise that hypertonic saline injections are contraindicated for elective termination of pregnancy because of the risk of sickling-induced vaso-occlusion. However, most methods of abortion are well tolerated. Based on personal experience, there is a very high incidence of acute painful episodes after therapeutic abortion; inpatient intravenous hydration before and for the 24 hours after the procedure is recommended.

Oral contraceptives containing low-dose estrogen are a safe and recommended method of birth control. [550] The choice of barrier methods, oral contraception, and injections of medroxyprogesterone every 3 months for birth control must weigh the risk versus benefit of each.

Renal Complications

The kidney is particularly vulnerable to complications in sickle cell disease because of its hypoxic, acidotic, and hypertonic microenvironment. [293] [551] Clinical manifestations result from medullary and distal tubular, proximal tubular, and glomerular abnormalities. Occlusion of the vasa rectae compromise flow to the medulla (Fig. 30-14), resulting in inability to concentrate the urine, papillary infarction with hematuria, incomplete renal tubular acidosis, and abnormal potassium metabolism. Isosthenuria, reversible with red cell transfusion up to age 15 years, accounts for a propensity to dehydration when fluid intake is insufficient. [552] [553] A common complication is hematuria from papillary infarction, which is usually unilateral from the left kidney, may be massive, and appears to be more common in sickle cell trait than disease because of the much greater frequency of the heterozygous condition. [554] Patients with sickle cell disease or trait who have hematuria must be evaluated to exclude life-threatening etiologies. This can be accomplished using ultrasonography, which obviates the risks associated with contrast material in intravenous pyelography. Therapy with hydration, alkalinization of the urine, and diuresis is standard, [555] [556] but epsilon-aminocaproic acid, [557] triglycyl vasopressin, [558] intravenous distilled water, [555] and nephrectomy [559] have been required. Patients with sickle cell disease cannot excrete acid and potassium normally but usually do not develop systemic acidosis or hyperkalemia without an additional acid load such as renal insufficiency. [560] [561] Abnormal proximal tubular function, partly related to chronic use of analgesics, results in increased clearance of uric acid [562] and creatinine and reabsorption of phosphate. [563]

Glomerular abnormalities result from vaso-occlusion, hyperperfusion, immune complex nephropathy, and parvovirus infection. [466] [564] In sickle cell disease, glomerular filtration is not elevated commensurately with renal plasma flow, glomeruli have increased permeability, and progressive loss of filtration rate is associated with reduced glomerular porosity. [337] [565] Chronic renal insufficiency may be predicted by albuminuria, [565] and is usually preceded or accompanied by hypertension, hyperkalemia, or

Figure 30-14 Postmortem microangiographic studies of the vasa recta in a normal individual **(A)** and a patient with sickle cell anemia **(B)**. *(From Bertles and Döbler,[824] with permission.)*

worsening anemia. Risk factors for the development of chronic renal failure include relative hypertension, [477] use of nonsteroidal anti-inflammatory drugs, [566] [567] [568] and genetic predisposition associated with the CAR -globin haplotype; the latter has been suggested as an indication for bone marrow transplantation to prevent this outcome. [569] [570] Glomerular disease may be detected using renal ultrasound to detect a pattern of diffusely increased reflectivity. [571] The nephrotic syndrome occurs in 4% of patients, leads to chronic renal failure in two thirds, and results in death in 2 years in half the patients; chronic azotemia is associated with a much worse prognosis. [572] The average age of onset of chronic renal failure is 23 years in sickle cell anemia and 50 years in Hb SC disease. [569] Therapy with an inhibitor of angiotensin-converting enzyme was used to diminish hyperperfusion and was found to diminish proteinuria but did not improve the glomerular filtration rate. [573] Renal transplantation is recommended for patients with sickle cell and end-stage renal diseases. [570] [574] [575] [576] [577] [578]

Priapism

Priapism has been defined as an unwanted painful erection. It has been reported to affect 6.442% of males with sickle cell disease, [579] has peak frequencies between ages 5 and 13 years and 21 and 29 years, [580] and is most likely to develop in patients with lower Hb F levels and reticulocyte counts, increased platelet counts, and the Hb SS genotype. [581] [582] [583] Its onset can be acute, recurrent, chronic, acute on chronic, or stuttering. [584] The engorgement in priapism affects the corpora cavernosa but spares the glans penis and corpus spongiosum. [585] In a minority of patients, usually postpubertal, the engorgement also affects the corpus spongiosum and glans; [586] tricorporal priapism can be diagnosed using nuclear scanning of the penis. [587] As a result of recurrent priapism, sickle cell patients have abnormal nocturnal penile tumescence and scarred fibrotic corpora, [588] which may eventuate in impotence. [582] Impotence is more frequent in tricorporal priapism. [586]

PRIAPISM

Priapism affects nearly two thirds of males with sickle cell disease. It typically is bicorporal, affecting the corpora cavernosa and sparing the glans penis and corpus spongiosum. Tricorporal priapism is less common, affects also the corpus spongiosum and glans, and more frequently results in impotence. Preventing recurrences may be accomplished by self-administration of the -adrenergic agent etilefrine orally and by intracavernous injection of this agent for episodes lasting >1 hour. Recommended management includes monitoring response to therapy by intercavernous pressure measurements and to transfusion therapy by quantitative hemoglobin electrophoresis. Initial therapy consists of intravenous hydration and analgesia. If priapism persists 12 hours, partial exchange transfusion, intended to reduce the Hb S level to <30%, is performed. If there is no resolution within 12 hours of transfusion, corporal aspiration with saline and -adrenergic agents is recommended. If there is no response within 12 hours of irrigation, surgery is recommended. The Winter procedure of creating a fistula between the glans penis and the corpora cavernosa by inserting a large-bore needle through the glans under general anesthesia is the procedure of choice. If there is no resolution following the Winter procedure, the Grayhack saphenous vein bypass shunt is recommended.

A successful approach to preventing the recurrence of priapism entails self-administration of the -adrenergic agent etilefrine orally and, for episodes lasting over an hour, by intracavernous injection. [589] A more traditional approach [590] involves monitoring response to therapy by intracavernous pressure measurements and transfusion therapy by quantitative hemoglobin electrophoresis. First-line therapy is conservative, consisting of intravenous hydration and analgesia. If priapism persists 12 hours, partial exchange transfusion [591] is performed to reduce the Hb S level to <30%. If no resolution ensues within 12 hours of transfusion, corporal aspiration with saline and -adrenergic agents is recommended. [592] If there is still no response within 12 hours of irrigation, surgery is recommended. [593] The procedure of choice is the Winter procedure, creating a fistula between the glans penis and the corpora cavernosa by inserting a large-bore needle through the glans under general anesthesia. [594] If this is unsuccessful, the creation of a more formal shunt, such as the Grayhack saphenous vein bypass, may be attempted. [595] Whether conservative or aggressive therapy is used, 45% of patients who have priapism develop some degree of impotence. [582] [583] When impotence persists 12 months, a semirigid penile prosthesis may be implanted. [596]

Ocular Complications

Ophthalmologic complications can include anterior chamber ischemia, tortuousity of conjunctival vessels, retinal artery occlusion, angioid streaks, proliferative retinopathy, and retinal detachment and hemorrhage. [597] [598] The retina is particularly vulnerable to vaso-occlusion, and routine retinal examination is part of routine health-care maintenance for patients with sickle cell disease. Superficial retinal hemorrhages have a pink salmon patch appearance that resolves into an iridescent schisis cavity. Deeper retinal hemorrhages have a black sunburst appearance. Postmortem examination using the ADPase flat-embedded retina technique to define the morphometry of retinal vessels found that autoinfarction occurs at the preretinal capillary rather than the feeding arteriole level and that sea fans tend to develop at the site of arteriovenous crossings. [599] Clinically the retinopathy is best seen using fluorescein angiography (Fig. 30-15). The earlier onset and greater frequency of proliferative retinopathy in Hb SC disease and sickle cell- $^{+}$ thalassemia compared to sickle cell anemia and sickle cell-° thalassemia [600] suggest that retinal vessels are more susceptible to occlusion by more viscous blood than by more rigid individual cells. Peripheral sickle retinopathy may require vision-saving therapy with laser

photocoagulation.[601]

Orbital compression syndrome due to vaso-occlusion of the periorbital marrow space and subperiosteal hemorrhage has been observed to result in headache, fever, and palpebral edema.[602] In this situation, culture, CT scan, and MRI should be used to rule out infectious, neoplastic, and other hemorrhagic etiologies. Conservative therapy, including local measures, analgesia, fluids, transfusion, and careful ophthalmalogic surveillance, is recommended, unless compression of the optic nerve ensues, in which case surgical decompression should be considered.

Bone Complications

Chronic tower skull, bossing of the forehead, and fish mouth deformity of vertebrae are the result of extended hematopoietic marrow causing widening of the medullary space, thinning of the trabeculae and cortices, and osteoporosis. [603] Osteonecrosis may cause a steplike depression of vertebrae, selected shortening of the cuboidal bones of the hands and feet, and acute aseptic or avascular necrosis. [604] [605] The excruciating pain of bone infarction in the hand-foot syndrome that occurs around age 2

Figure 30-15 Fluorescein angiography demonstrating a sea fan appearance of sickle proliferative retinopathy. *(Kindly provided by WC Mentzer.)*

years is often the first symptom of sickle cell disease (Fig. 30-16).[606] This dactylitis resolves spontaneously and is treated with hydration and analgesia. Bone infarcts are demonstrable using nuclear medicine scintigraphy or MRI. [607] [608] [609] Serial scans specific for bone osteoclasts, bone marrow macrophages, and inflammatory cells may be useful adjuncts for distinguishing bone marrow infarction from osteomyelitis, [607] but it is essential to obtain cultures directly from the affected tissue before starting antibiotics. Treatment of osteomyelitis is addressed in the Infection and Therapy sections.

Infarction of bone trabeculae and marrow cells causing osteonecrosis occurs in all sickle cell disease genotypes, but

Figure 30-16 Radiogram showing the bone infarctions in the hands of a child with the hand-foot syndrome dactylitis. *(Kindly provided by WC Mentzer.)*

most frequently in sickle cell anemia with coexistent -thalassemia. [159] [610] The process is associated with increased intraosseous pressure, [611] and is most sensitively detected by MRI.[612] Necrosis occurs with equal frequency in the femoral and humeral heads, but the femoral heads more commonly undergo progressive joint destruction as a result of chronic weight bearing [159] [160] [613] [614] Core decompression surgery to relieve increased intraosseous pressure can be used in early-stage osteonecrosis (i.e., no radiographic evidence of bone collapse) to prevent disease progression. [611] In more advanced disease, a choice must be made whether to accept limited joint mobility or to attempt major reconstructive therapy. This decision must take into account the 30% likelihood that a second hip revision will be required within 45 years of prosthetic hip placement in patients with sickle cell disease. [159]

Arthritic pain, swelling, and effusion [615] may be related to periarticular infarction [616] or gouty arthritis. [617] Appropriate therapy is with nonsteroidal anti-inflammatory agents.

Bone marrow infarction causes reticulocytopenia, exacerbation of anemia, a leukoerythroblastic picture, and sometimes pancytopenia. [349] Pulmonary fat embolism is a rare complication of marrow infarction.[618] It is associated with fat globules in the sputum [618] and refractile bodies visible in the optic fundi. [619] It is a life-threatening event that may require prompt exchange transfusion and perhaps the use of heparin and corticosteroids. [618]

Dermatologic Complications

Leg ulcers are major causes of morbidity in sickle cell disease as a result of their frequency, chronicity, and resistance to therapy. Most occur near the medial or lateral malleolus (Fig. 30-17), and they are frequently bilateral. [620] [621] They may begin spontaneously or as a result of trauma and may become infected, most commonly by *S. aureus, Pseudomonas*, streptococci, or *Bacteroides*.[622] Systemic infection, osteomyelitis, and tetanus are rare complications. [620] Ulcers are resistant to healing[623] and tend to be recurrent in well over half the cases.[622] Their incidence has been reported to vary from 0%[624] to 75%.[620] Ulcers rarely occur in patients younger than age 10 years and are most common in sickle cell anemia, less common in sickle cell-° thalassemia, and nonexistent in Hb SC disease and sickle cell- $^{+}$ thalassemia. [621] The incidence in sickle cell anemia patients declines substantially in those who have coexistent thalassemia. [621] Males have a threefold greater risk for developing leg ulcers than females. [620] [621]

Figure 30-17 Chronic leg ulcer near the medial malleolus. *(Kindly provided by WC Mentzer.)*

Treatment of leg ulcers requires persistence and patience; healing usually requires weeks. Therapy begins with gentle debridement to remove nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and Duoderm hydrocolloid dressings facilitate devitalization. Once debridement is complete, zinc oxide-impregnated Unna boots are used to promote healing. Bed rest speeds healing, [625] and topical antibiotics may be required. [626] It may be necessary to use elastic wraps or leg elevation to control edema. Oral zinc, local hyperbaric oxygen, chronic transfusion, recombinant erythropoietin, hydroxyurea, propionyl-L-carnitine, skin grafts, and pentoxifylline are unproven modalities that may be tried.

Myofascial syndromes consist of soft-tissue swelling in subcutaneous edema that may have a peau dorange appearance. These may be large or discrete lesions a few centimeters in diameter.

SKIN ULCERS

Leg ulcers occur in patients with sickle cell disease beginning in the teenage years. They usually occur near the lateral or medial malleolus and may become chronic and debilitating. Their pathogenesis presumably is related to vaso-occlusion in the skin microvasculature leading to tissue necrosis. Ulcers occur most commonly in males, those with more severe anemia, and those with lower Hb F levels. Treatment of leg ulcers begins with cleansing, debridement, and topical antibiotics. Gentle debridement removes nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and Duoderm hydrocolloid dressings facilitate autodebridement of nonviable surrounding tissues. Once debridement is complete, zinc oxide-impregnated Unnas boots are used to promote healing. Leg edema retards healing of ulcers and can be treated using elastic wraps or leg elevation. Trauma to the area is to be minimized, and shoes must be selected accordingly. Transfusions may be required. Skin grafting has been successful in the most recalcitrant cases.

These lesions are probably the result of dermal or subdermal vaso-occlusion. Treatment is symptomatic.

Cardiac Complications

Although there is no convincing evidence for a specific cardiomyopathy in sickle cell disease, there are important cardiac considerations in the management of patients with sickle cell disease. The chronic anemia of sickle cell disease is compensated by high cardiac output, [627] which results in chronic chamber enlargement and cardiomegaly,[628] even in young children.[629] While the exercise capacity of sickle cell patients is diminished, [630] congestive heart failure is uncommon,[631] and restriction of activity is seldom necessary. An age-dependent loss of cardiac reserve [632] creates a greater risk of heart failure in adult patients during fluid overload, transfusion, reduced oxygen-carrying capacity, or hypertension. [628] Cardiac function can be improved by transfusion. [633] The electrocardiogram shows evidence of left ventricular hypertrophy, and less often first-degree block and nonspecific ST-T wave changes. [634] Acute myocardial infarction in the absence of coronary disease has been reported,[635] and in one autopsy series 9.7% of 72 consecutive patients with sickle cell disease had myocardial infarction. [636] It appears that myocardial infarction may occur with normal coronary arteries as a result of increased oxygen demand exceeding limited oxygen-carrying capacity, or as a result of microcirculatory impairment. In the latter regard, second-degree A-V block associated with septal hypoperfusion affecting the A-V node and His bundle has been observed during a pain episode.[637] It has been suggested that the increased rate of sudden death observed in sickle cell disease may be related to cardiac autonomic dysfunction, as detected by abnormal heart rate variability in response to selected postural maneuvers. [638]

VARIANT SICKLE CELL SYNDROMES

The sickle cell syndromes that result from inheritance of the sickle cell gene in simple heterozygosity or in compound heterozygosity with other mutant -globin genes are sickle cell trait, Hb SC disease, and sickle cell- thalassemia. These and sickle cell anemia with coexistent -thalassemia are reviewed in this section.

Sickle Cell Trait

The prevalence of sickle cell trait is approximately 810% in African-Americans [62] and as high as 2530% in certain areas of western Africa.[64] There are approximately 2.5 million people in the United States and 30 million in the world who are heterozygous for the sickle cell gene. Sickle cell trait is a benign carrier condition [148] with no hematologic manifestationsred cell morphology, red cell indices, and the reticulocyte count are normal, and sickle forms (ISCs) are not seen on the peripheral blood smear. The usual partition of Hb A and Hb S in sickle cell trait is 60:40 due to a greater post-translational affinity of chains for ^{A} than for ^{S} chains. [639] When thalassemia is coinherited with sickle cell trait, the preferential affinity results in a decreased percentage of hemoglobin S relative to the number of -globin genes deleted (i.e., / 40% Hb S; / 35% Hb S; / 29% Hb S; / 21% Hb S).[99]

Few clinical complications of sickle cell trait have been reported. [148] Splenic infarction occurs at high altitude, [640] curiously more often in Caucasians than in those of African ancestry.[641] In evaluating the etiology of hematuria, it must be remembered that sickle cell trait is a common cause among African Americans. [642] Impaired urine-concentrating ability is directly related to the intraerythrocytic concentration of Hb S and, therefore, to the number of -globin genes inherited. [149] [150] The degree of

hyposthenuria in children progresses with age, and up to a certain age is reversed by transfusion. [643] The frequency of urinary tract infection may be increased in sickle cell trait.[644] [645] There is no increased incidence of anesthetic complications associated with sickle cell trait. [646] The 30-fold increased incidence of unexplained sudden death during basic training of military recruits was apparently related to exercise-induced vaso-occlusion and rhabdomyolysis. [647]

Despite the known complications, past experiences with discrimination in the employment market and health insurance industry provide reminders that the rare clinical events in sickle cell trait provide no real justification for regarding it as anything but a benign carrier condition. [648] Newborn screening programs detect a large number of infants with sickle cell trait; for these parents, genetic counseling is essential. Parents should understand that their child has a benign hereditary condition, not a disease, but that there is a risk for a subsequent child to be born with sickle cell disease.

In individuals who appear to have sickle cell trait but are symptomatic, the laboratory diagnosis must be verified. Hemoglobins other than S that polymerize may account for reports of sickle cell trait associated with clinical problems. Examples are heterozygous Hb S ^{Antilles64§} and Hb Quebec-CHORI.[650] In the latter case, the hemoglobin variant was distinguished from Hb A using mass spectroscopy.

Hb SC Disease

The gene for Hb C ($_{2\ 2}$ ^{6GluLys}) is approximately one-fourth as frequent among African Americans as the sickle cell gene, [62] accounting for a corresponding prevalence of Hb SC disease and sickle cell anemia. Although oxygenated Hb C forms crystals, [651] Hb C does not participate in polymerization with deoxy-Hb S. [151] As discussed above in the section Cation Homeostasis and Cell Dehydration, the red cell desiccation that results from potassiumchloride cotransport sustained by the presence of Hb C[152] [153] raises the intraerythrocytic concentration of Hb S [151] [152] to levels that support polymerization, sickling, and clinical symptoms. Compound heterozygosity for Hb S and C results in a disease that is less severe than sickle cell anemia. [652] [653] Splenomegaly may be the only physical finding, and clinical complications may be less frequent than in sickle cell anemia. As a result of a longer circulatory survival of Hb SC red cells compared to Hb SS cells (i.e., 27 vs. 17 days), [334] the degree of anemia and reticulocytosis is frequently mild: 75% of the patients have a milder level of anemia (hematocrit level >28%) than is usually seen in sickle cell anemia.[249] The predominant red cell abnormality on the peripheral smear is an abundance of target cells; folded (pita bread) cells, ISCs, billiard ball cells, and crystal-containing cells also may be seen. [654]

The great clinical heterogeneity within this genotype notwithstanding, the clinical course is generally milder than that of sickle cell anemia. The frequency of acute painful episodes is approximately half that of sickle cell anemia, [161] and the life expectancy is two decades longer. [250] The incidence of fatal bacterial infection is less than in sickle cell anemia, [429] but there is still an increased risk of *S. pneumoniae* and *H. influenzae* infection.[655] Leg ulcers are uncommon.[621] There is a higher incidence of peripheral retinopathy in Hb SC disease than in sickle cell anemia, [600] but the higher incidence of osteonecrosis reported [656] has been disproven.[159]

Sickle Cell- Thalassemia

The gene frequency of thalassemia among African Americans is 0.004, one-tenth that of the sickle cell gene, [62] and hence there is one-tenth the prevalence of compound heterozygous sickle cell- thalassemia is this population. Sickle cell- thalassemia is divided into sickle cell- $^{+}$ thalassemia and sickle cell-° thalassemia, which have, respectively, reduced or no amounts of Hb A present. [657] [658] Most -thalassemia mutations among African Americans result in $^{+}$ thalassemia,[659] [660] and sickle cell-$^{+}$ thalassemia is subclassified according to the percentage of Hb A present: type I has 35%; type II has 814%; and type III has 1825%. [659] [661] Eighty percent of African-American -thalassemia mutations are due to the promoter region mutations [88 (CT) and 29 (AG)] that result in a type III phenotype. [659] [660] Compound heterozygous sickle cell-° thalassemia occurs infrequently.

The hematologic and clinical severity is a function of the amount of Hb A inherited. [661] [662] In sickle cell- thalassemia, the red cells are hypochromic and microcytic, and the ISCs present on the peripheral blood smear are more numerous in sickle cell-° thalassemia than in sickle cell- $^{+}$ thalassemia. The hematologic severity is a function of the amount of Hb A inherited, as demonstrated in Table 30-1 .

The more benign clinical nature of sickle cell- $^{+}$ thalassemia compared to sickle cell-° thalassemia is reflected by its threefold higher incidence of incidental diagnosis (26% vs. 9%), later mean age of presentation (3.2 years vs. 8.2 years), approximately threefold more frequent leg ulcers (23% vs. 8%), approximately twice as frequent acute chest syndrome (24% vs. 14%), priapism in 4 of 28 versus 0 of 27, and aplastic crises in 2 versus 0. [663] Splenomegaly occurred in approximately one third of both groups. There was a higher incidence of proliferative retinopathy in sickle cell- $^{+}$ thalassemia (18% vs. 10%), consistent with the notion that sickle cell syndromes having higher hematocrits are more likely to be associated with ocular complications. Growth and development was more retarded in sickle cell-°

thalassemia than in sickle cell- $^{+}$ thalassemia.[413]

Sickle Cell Anemia with Coexistent Thalassemia

The use of gene mapping to detect the -globin gene deletions responsible for thalassemia [664] [665] demonstrated a gene frequency of 0.16 for the -thalassemia-2 haplotype () among African Americansnearly 1 in 3 are silent carriers of thalassemia (genotype /), and 2% have -thalassemia trait due to homozygous -thalassemia-2 (genotype /).[100] This high frequency, combined with the powerful effect of Hb S concentration on kinetics [7] and extent[8] of Hb S polymerization, suggested that the lower MCHC of thalassemia would influence the pathophysiology in a large number of patients with sickle cell anemia. This prediction was substantiated by the finding of milder anemia in subjects with sickle cell anemia who had the deletion of either one (genotype /) or two (genotype /) -globin genes (Table 30-2).[103] [104] [106] This effect was related to a diminished hemolytic rate[105] and was not demonstrable until approximately 7 years of age (Table 30-2).[107] [108] The mechanisms by which thalassemia benefits the hematologic aspects of sickle cell anemia were discussed in the Cation Homeostasis and Cell Dehydration section.

Besides milder anemia, thalassemia is associated with fewer reticulocytes [103] [104] [106] and ISCs.[102] [104] The peripheral blood smear contains less polychromasia and fewer sickle forms and more hypochromia and microcytosis, commensurate with the numbers of -globin genes deleted. There are increased Hb A $_2$ levels associated with increasing -globin gene deletions; the Hb F levels are not consistently affected. [103] [104] [106] The prediction of increased affinity of for chains, resulting in higher levels of Hb F when chains are limiting, is not consistently realized, apparently as a result of the selective survival of -thalassemic sickle cells precluding the Hb F effect.[666]

The clear-cut clinical effects of this epistatic interaction are of inconsistent advantage. The reported decreased incidence of acute chest syndrome [104] was not substantiated in another study;[106] there is a decreased incidence of leg ulcers [104] [621] but an increased incidence of osteonecrosis, [155] [160] and the original suggestion

of a decreased incidence of peripheral retinopathy [597] was found to correlate with the higher hemoglobin, MCV, and MCHC levels. [667] The frequency of retinal vessel closure is higher, but not the incidence of retinopathy. [668] In a large multicenter study there was a higher incidence of acute painful episodes associated with higher hemoglobin levels, but the influence of thalassemia did not extend beyond its influence on level of anemia. [161] While one group reported longer life expectancy in subjects having sickle cell anemia and thalassemia, [154] [669] a large multi-institutional national study documented an increased mortality rate associated with higher hemoglobin levels after age 20 years.[161] The interaction of thalassemia with sickle cell anemia has shown clearly the imprudence of extrapolating broadly from polymerization formulas to assumptions of disease severity.[94]

Sickle Cell-° Thalassemia

The -thalassemia locus usually is one of several large deletions of the - and -globin genes that fail to retard the switch from fetal to adult hemoglobin production, thereby allowing an attempted switch from the expression of -globin to that of deleted genes (see Chaps. 22 and 29). This is an uncommon compound heterozygous condition associated with Hb S, F, and A $_2$, with the 1525% Hb F distributed in a heterocellular fashion. Anemia and reticulocytosis are mild and clinical complications infrequent.[670]

Sickle Cell-HPFH

Hereditary persistence of fetal hemoglobin results from one of several large deletions of the - and -globin genes that retard the switch from the production of Hb F to adult hemoglobin (see Chaps. 22 and 29). A more recently discovered variety of HPFH is not due to a deletion, but to one of many point mutations that upregulate the expression of the -globin gene. The clinical expression of deletional and nondeletional HPFH differs in that the 1535% Hb F in the former is distributed in a pancellular fashion, the 15% Hb F in the latter is distributed in a heterocellular fashion, and certain mild types of nondeletional HPFH express high Hb F levels not in simple heterozygosity but only in conditions of erythropoietic stress, such as compound heterozygosity with the sickle cell gene. It is likely that many cases of apparent sickle cell anemia with unexplained elevations of Hb F are the result of a nondeletion HPFH mutation.

The gene frequency of the deletional HPFH locus is 0.0005 among African Americans, [671] resulting in a calculated incidence for compound heterozygous sickle cell-deletional HPFH of 1/100 that of sickle cell anemia. Sickle cell-deletional HPFH provided the first evidence that Hb F was a potent inhibitor of Hb S polymerizationindividuals with pancellular distribution of 25% Hb F were generally neither anemic nor afflicted with vaso-occlusive manifestations (Table 30-1). [291] Hemoglobin electrophoresis revealed only Hb S, F, and A $_2$, which resembles sickle cell anemia, sickle cell-° thalassemia, and sickle cell-° thalassemia. Notable differences, however, are the pancellular distribution of 1535% Hb F, Hb A $_2$ levels <2.5%, and the absence of anemia.[672] The generally benign course of sickle cell-deletional HPFH is uncommonly associated with vaso-occlusive complication. [291]

Sickle Cell-Hb Lepore Disease

The Hb Lepore gene is a crossover fusion product of the - and -globin genes, the product of which, in the case of Hb Lepore Boston, has the same alkaline electrophoretic mobility as Hb S. Because of the thalassemic expression of the fusion gene, individuals with simple heterozygosity for Hb Lepore Boston resemble on hemoglobin electrophoresis sickle cell trait, with only 12% Hb S. Compound heterozygous Hb S-Hb Lepore Boston resembles sickle cell anemia or sickle cell-° thalassemia electrophoretically but has less severe anemia, resembling that of sickle cell- $^{+}$ thalassemia. The combination of predominantly Hb S with microcytosis suggests sickle cell- thalassemia, but the diagnosis is suggested by the low to low-normal Hb A $_2$ levels that result from the incapacitation of one -globin gene by the crossover. Hb F levels vary. The peripheral smear shows microcytosis, hypochromia, and ISCs. Vaso-occlusive complications occur, and splenomegaly is common.[673]

Sickle Cell-Hb D Disease

Because Hb D Punjab or Hb D Los Angeles ($_2$ $_2$ ^{121GluGln}) has a similar electrophoretic mobility to Hb S under alkali conditions, Hb SD disease was first reported as an unusual case of sickle cell anemia.[674] Hb D can be distinguished from Hb S by acid electrophoresis or isoelectric focusing. There is moderately severe hemolytic anemia, and the peripheral smear shows marked anisocytosis and poikilocytosis, target cells, and ISCs. The clinical manifestations of this syndrome are similar to those of sickle cell anemia.[675]

Sickle Cell-Hb O Arab Disease

Although Hb O Arab ($_2$ $_2$ ^{121GluLys}) was first described in an Israeli Arab family, [676] its distribution is widespread. Sickle cell-O Arab disease resembles Hb SC disease on alkaline electrophoresis, but Hb O Arab can be distinguished from Hb C by acid electrophoresis or isoelectric focusing. This syndrome is associated with moderately severe hemolytic anemia, and the peripheral smear shows anisocytosis, poikilocytosis, and ISCs. [677]

Sickle Cell-Hb E Disease

Hb E ($_2$ $_2$ $^{26Glu Lys}$) is a -thalassemic hemoglobinopathy found predominantly in southeast Asia (see Chap. 29). The structural mutant has an electrophoretic mobility similar to Hb E and C under alkaline conditions [678] [679] but can be resolved by acid electrophoresis or isoelectric focusing. The GAGAAG mutation in codon 26 activates a cryptic splice site within the first intron of the ^{E} gene, causing alternate splicing and decreased expression of the structural mutant. [680] As a result, Hb E makes up only 30% of the total hemoglobin in compound heterozygosity for the sickle cell and Hb E genes. Hb SE disease is reported to cause mild hemolysis, no vaso-occlusive complications, and no remarkable abnormality of red blood cell morphology. [681] [682] [683] However, one report documented hematuria and a probable splenic infarct during air travel, [684] and another described moderately severe hemolysis, jaundice, bone pain, splenic infarction, recurrent pneumonia, and ISOs on the peripheral blood smear of three siblings having Hb SE. [685] Patients with Hb SE disease having vaso-occlusive complications justify the inclusion of this syndrome among the sickle cell diseases.

DIAGNOSIS

Both the methods of diagnosing sickle cell syndromes and the goals of diagnostic programs vary depending on the developmental stage of the subject. Characterization of adult hemoglobins is challenging in the fetal and newborn periods because of the predominance of Hb F, which confounds reliable detection of Hb S by solubility testing. In infancy, the diagnosis of sickle cell disease is also influenced by the absence of anemia. As Hb S increases and Hb F declines in the first months of life (Fig. 30-7), the clinical manifestations of sickle cell disease emerge. [686] ISCs can be seen in the peripheral blood of children with sickle cell anemia at 3 months of age, and by 4 months of age moderately severe hemolytic anemia is evident. Useful diagnostic

Figure 30-18 Comparative analyses of several mutant hemoglobins using alkaline electrophoresis, acid electrophoresis, and thin-layer isoelectric focusing. On the right are shown the components of the standard (at the top) and the phenotypes of the other six samples. Their analyses are shown by alkaline hemoglobin electrophoresis in the left panel, acid electrophoresis in the center panel, and thin-layer isoelectric focusing in the right panel. Locations of the various hemoglobin bands are shown below the left and center panels. *(Kindly provided by MH Steinberg.)*

SICKLE CELL DISEASE DIAGNOSIS

Diagnosis of sickle cell syndromes (genotypes) involves examination of the peripheral smear, solubility testing, and hemoglobin electrophoresis (or thin-layer isoelectric focusing).

- The peripheral smear is normal in sickle cell trait (Hb AS), but sickle cells are seen in each of the major sickle cell disease syndromessickle cell anemia (Hb SS), Hb SC disease (Hb SC), and sickle cell- thalassemia (Hb S- thal).
- Solubility tests are abnormal in all syndromes having at least one sickle cell genesickle cell trait (Hb AS), sickle cell anemia (Hb SS), Hb SC disease (Hb SC), and sickle cell- thalassemia (Hb S- thal).
- Hemoglobin electrophoresis (or thin-layer isoelectric focusing) provides definitive diagnostic information.
  - Newborns with sickle cell anemia (Hb SS) and sickle cell-° thalassemia (Hb S-° thal) have Hb S and F (SF pattern); older patients have predominantly Hb S (SS pattern).
  - Newborns with Hb SC disease (Hb SC) have Hb S, C, and F (SCF pattern); older patients have Hb S and C (SC pattern).
- Both sickle cell trait (Hb AS) and sickle cell-$^{+}$ thalassemia (Hb S-$^{+}$ thal) have Hb S and A, but in different proportions. In the former Hb A > S; in the latter Hb S > A.
  - Newborns with sickle cell trait (Hb AS) have Hb A, S, and F (ASF pattern); older patients have Hb A and S (AS pattern).
  - Newborns with sickle cell-$^{+}$ thalassemia (Hb S-$^{+}$ thal) have Hb S, A, and F (SFA pattern); older patients have Hb S and A (SA pattern).

methods include those that separate species according to amino acid composition (i.e., hemoglobin electrophoresis or thin-layer isoelectric focusing) (Fig. 30-18), solubility testing, and examination of the peripheral blood smear (Fig. 30-2).[6] [687] [688]

Older Children and Adults

The purpose of correct diagnosis in this age group is to identify those who need therapy for sickle cell disease and counseling for the disease or the trait. Cellulose acetate electrophoresis at pH 8.4 is a standard method of separating Hb S from other variants. However, Hb S, G, and D have the same electrophoretic mobility with this method. Using citrate agar electrophoresis at pH 6.2, Hb S has a different mobility than Hb D and G, which comigrate with Hb A in this system. A solubility test such as the Sickledex also distinguishes Hb D and G from Hb Sonly Hb S precipitates. Thus, the combination of cellulose acetate electrophoresis with either citrate agar electrophoresis or a solubility test allows a definitive diagnosis of a sickle cell syndrome. Alternatively, thin-layer isoelectric focusing will separate Hb S, D, and G and can replace the two electrophoretic methods. Even with thin-layer isoelectric focusing, it is still necessary to use a confirmatory solubility test for Hb S. The sickle cell prep using metabisulfite or dithionite is not in routine clinical use at this time and is of historical interest only.

Results from electrophoresis or thin-layer isoelectric focusing are similar in sickle cell anemia and sickle cell-° thalassemianearly all the hemoglobin consists of Hb S. While differences in the Hb F and Hb A_2 levels may be useful in distinguishing these syndromes, the presence of microcytosis or one parent without sickle cell trait are more useful indicators of sickle cell-° thalassemia. The diagnosis of Hb SC disease is straightforward; nearly equal amounts of Hb S and Hb C are detected. Sickle cell-$^{+}$ thalassemia and sickle cell trait both have substantial amounts of Hb A and Hb S. This superficial electrophoretic similarity does not provide an obstacle to diagnosis: sickle cell trait is associated with neither anemia nor microcytosis and has an Hb A fraction >50%, [639] and sickle cell-$^{+}$ thalassemia is associated with anemia, microcytosis, and an Hb A fraction that ranges from 5% to 30%. [6] Solubility tests are positive

in both sickle cell disease and sickle cell trait, but sickled forms (ISCs) occur on the peripheral smear only in the sickle cell diseases and not in sickle cell trait. In sickle cell anemia, ISCs predominate and target cells may be few; in either variety of sickle cell- thalassemia, ISCs, target cells, and hypochromic microcytic

discocytes are prominent; in Hb SC disease, target cells predominate and ISCs are rare.

Newborn Screening

The use of prophylactic penicillin [333] and the provision of comprehensive medical care during the first 5 years of life have reduced mortality from approximately 25% to <3%, thereby providing impetus for early identification of infants with sickle cell disease. [437] Based on its economy and superiority of detection, universal screening of all newborns is preferred [689] over ethnically targeted approaches. [690] Blood samples for testing are obtained by heel stick and spotted onto filter paper for stable transport and subsequent electrophoresis or thin-layer isoelectric focusing. [691] [692] Results of solubility testing may be invalid due to the large amount of Hb F present.

A requirement for tests used in newborn screening is the capability to distinguish Hb F, S, A, and C. According to convention, the patterns of hemoglobins present are described in descending order according to the quantities detected. Newborns with sickle cell anemia have predominantly Hb F, with a small amount of Hb S and no Hb A (FS pattern). An FS pattern is obtained also in newborns who have sickle cell-° thalassemia, sickle cell-HPFH, and sickle cell-Hb D or sickle cell-Hb G (i.e., Hb D and E have the same electrophoretic mobility as Hb S). Family studies are confirmatory; in the newborn with sickle cell-° thalassemia, one parent has sickle cell trait and the other -thalassemia minor. When family members are not available, the diagnosis is established by DNA-based testing or repeat hemoglobin analysis at age 34 months.

The newborn with sickle cell trait will have Hb F, Hb A, and Hb S (FAS pattern). The quantity of Hb A is greater than that of Hb S. If the quantity of Hb S exceeds that of Hb A, the presumptive diagnosis is sickle cell- $^{+}$ thalassemia (FSA pattern). It may not be possible to distinguish FAS and FSA patterns in newborns, so DNA-based testing or repeat hemoglobin testing at age 36 months is recommended.

In the future, polymerase chain reaction-based diagnosis from blood spotted onto a filter paper may be used to detect sickle cell genes directly. [693]

Prenatal Diagnosis

The limited efficacy of available treatment options for sickle cell disease accounts for the importance of prenatal diagnosis to its overall management. This endeavor is best performed by a team of obstetricians, geneticists, counselors, and support staff that provides a comprehensive approach. [694] One large survey found that parents at risk for having a child with sickle cell disease were interested in prenatal diagnosis and would consider termination of pregnancy for an affected fetus. [695] Community acceptance of reproductive genetic services depends on the effectiveness of education and counseling. [696] Despite the considerable attention being paid to the social, ethical, and legal issues pertaining to prenatal diagnosis, these remain controversial. [697] [698] [699] [700] [701] One major ethical issue pertains to our diagnostic skills having outstripped our ability to predict the severity of diagnosable conditions. The lack of reliable markers for clinical severity in sickle cell disease was confirmed in a search for such markers in children from Jamaica. [702]

The first successful prenatal diagnoses relied on obtaining fetal blood samples for analysis of globin chain synthesis. [703] Discovery of a restriction fragment length polymorphism in linkage disequilibrium with the sickle cell gene established DNA-based

Figure 30-19 PCR-based restriction analysis for the sickle cell gene. The genotypes of the DNA samples tested are shown below. The size in base pairs for the undigested PCR product and the products resultant from Oxa NI are shown at the left in base pairs. The fragments from normal -globin DNA (AA) shows complete Oxa NI cleavage, from sickle cell trait DNA (AS) shows partial cleavage, and from sickle cell anemia (SS) shows no cleavage. *(Adapted from Chehab et al., [710] with permission.)*

testing as a method not influenced by the presence of Hb F [34] and spurred the development of second-trimester amniocentesis for obtaining fetal DNA for testing. [704] Direct detection of the GAGGTG mutation responsible for the sickle cell gene employed allele-specific hybridization with labeled synthetic DNA probes [705] or restriction endonuclease analysis to determine whether the cleavage site of the enzyme Mst II was ablated by the mutation. [706] The development of the polymerase chain reaction (PCR) for amplifying DNA sequences of interest in vitro [707] allowed testing of minute quantities of DNA [708] and motivated the development of several new methods for detecting the sickle cell generestriction analysis (Fig. 30-19), [709] [710] allele-specific hybridization, [711] reverse dot-blotting, [712] and allele-specific fluorescence PCR. [713] PCR-based diagnosis for Hb SC disease is possible using specific molecular methods for detecting the Hb C gene, [714] [715] and the diagnosis of sickle cell- thalassemia can be made using reverse dot-blot methodology to screen the many African-American -thalassemia mutations, [659] [660] [716] [717] as well as the Hb S and Hb C mutations, in a single hybridization reaction. [718] Fetal DNA samples are obtained by chorionic villus sampling at 810 weeks gestation. [704] Preimplantation diagnosis [719] and testing of fetal cells isolated from the maternal circulation [720] are under development.

Other Laboratory Testing

The chronic hemolytic anemia of sickle cell disease is usually associated with mildly to moderately low PCV, hemoglobin and red cell levels, reticulocytosis of approximately 315% (accounting for high or high-normal MCV), unconjugated hyperbilirubinemia, and elevated lactate dehydrogenase and low haptoglobin levels. There may be polychromasia indicative of reticulocytosis and Howell-Jolly bodies demonstrating hyposplenia on the peripheral blood smear. The red cells are normochromic unless there is coexistent thalassemia or iron deficiency. If the age-adjusted MCV is not elevated, the possibility of sickle cell- thalassemia, coincident thalassemia, or iron deficiency must be considered.

The Hb F level is usually slightly to moderately elevated; the degree varies among patients. The amount of Hb F present is a function of the number of reticulocytes that contain Hb F, the

extent of selective survival of Hb F-containing reticulocytes to become mature Hb F-containing erythrocytes (F cells), and the amount of Hb F/F cell. [721] The -globin cluster haplotypes mentioned in the Pathophysiology section [722] appear to be related to factors that regulate production of Hb F. The Arab-Indian and Senegal haplotypes are associated with higher levels of Hb F than the others, [722] probably as a result of linkage with important -globin regulatory sequences in the locus control region. [723]

A comprehensive analysis of the clinical laboratory data collected from 2,600 subjects with sickle cell disease provides a background for interpreting laboratory abnormalities in this patient group. [249] In particular, normal ranges were established according to genotype, age, and gender. White cell counts are higher than normal in sickle cell anemia, particularly in patients under age 10 years. Mean white cell counts are not elevated in Hb SC disease or sickle cell- $^{+}$ thalassemia. Mean platelet counts are elevated in sickle cell anemia, particularly in patients under age 18 years, but are normal in those with Hb SC disease and sickle cell- $^{+}$ thalassemia.

The serum bilirubin level is higher in sickle cell anemia than in Hb SC disease or sickle cell- $^{+}$ thalassemia as a result of a greater hemolytic rate. The level rises after the first decade, possibly as a result of chronic hepatobiliary dysfunction. AST and ALT levels are often elevated, particularly in adult patients with sickle cell anemia, but mean levels are normal. Alkaline phosphatase levels are elevated in all genotypes until puberty, which occurred later in males and in those with sickle cell anemia.

Serum creatinine levels are low in all genotypes until age 18 years, when males experience a rise, apparently related to increasing muscle mass. Creatinine levels increase with age in all genotypes, presumably due to declining renal function.

THERAPY

Treatment recommendations specific for sickle cell disease can be divided into general health-care maintenance and specific indications or modalities for therapy. [408]

Health-Care Maintenance

Patients with sickle cell disease should have routine office appointments to establish baseline physical findings, laboratory values, and relationships with health-care professionals. These steady-state values provide standards for comparison at times of clinical exacerbations. Red cell phenotyping is performed and individualized blood bank files are instituted during chronic-phase visits. Education regarding the nature of the disease, genetic counseling, and psychosocial assessments of patients and their families are best accomplished during these routine visits. Parents of small children are instructed regarding early detection of infection and palpating enlarging spleens. Children are immunized against *S. pneumoniae, H. influenzae*,[440] [441] [444] hepatitis B, and influenza. For children under age 5 years, prophylactic penicillin recommendations are 125 mg penicillin V orally twice daily until age 2 to 3 years, and 250 mg thereafter. [432] It has been recommended that penicillin prophylaxis be discontinued at age 5 years. [445] Folic acid, 1 mg orally per day, is administered.[366] The routine assessment of cerebral blood flow using TCD is a recommendation based on the evidence that CVA in children can be predicted by TCD and prevented by chronic transfusion therapy. [502] Retinal evaluation is begun at school age and continued routinely, more frequently in the event of retinopathy. Sexually active women should have routine pelvic exams and birth control instructions; oral contraception with low-dose estrogen can be administered safely. [550] An obvious conclusion that follows from these considerations is that continuity of care by an expert caregiver is essential for optimizing the clinical state of these patients.

Infections

The most critical aspect of infectious illness in sickle cell disease is the evaluation and treatment of the febrile child. Routine evaluation includes a physical examination, a complete blood count, blood and urine cultures, a lumbar puncture if meningitis is suspected, and a chest x-ray to evaluate for pneumonia. Results of the complete blood count are compared to baseline values. A left shift in the differential count suggests bacterial infection. Due to the high mortality rate of bacteremia, hospitalization, blood and CSF cultures, and parenteral antibiotics has been the standard of care for children with fevers >38.5°C. [724] [725] However, the recent demonstration of the efficacy of ceftriaxone[447] [448] has led to a different set of guidelines. Those with sickle cell anemia or sickle cell-° thalassemia who appear toxic, have temperatures >40°C, or are not receiving prophylactic penicillin are hospitalized for administration of intravenous ceftriaxone (75 mg/kg). For those with sickle cell anemia or sickle cell-° thalassemia who have temperatures <40°C and are compliant with prophylactic penicillin, and those with Hb SC disease or sickle cell-$^{+}$ thalassemia who have temperatures >38.5°C, the recommended approach is to obtain blood cultures, administer intramuscular ceftriaxone (75 mg/kg to a maximum dose of 2 g), observe for several hours in the emergency department before discharge, and follow the patient closely as an outpatient. For those with Hb SC disease or sickle cell-$^{+}$ thalassemia who have temperatures <38.5°C, therapy is as indicated symptomatically. [447] [448] Therapy for documented *S. pneumoniae* bacteremia is with parenteral penicillin or ceftriaxone for several days.

Meningitis therapy should cover *S. pneumoniae* and probably *H. influenzae* type b[451] and should be continued for at least 2 weeks.

THE CHILD WITH A HIGH FEVER

The most important infectious disease consideration of sickle cell disease is the child with a high fever. Evaluation includes a physical examination, complete blood count, blood and urine cultures, lumbar puncture if meningitis is suspected, and a chest x-ray. A left shift in the differential count suggests bacterial infection. In the past the standard of care has been hospitalization, blood and CSF cultures, and administration of parenteral antibiotics for children with fevers >38.5°C. This remains a reasonable approach in areas where antibiotic-resistant strains of *S. pneumoniae* have emerged; the antibiotic recommended in these areas is vancomycin. In areas lacking antibiotic-resistant *S. pneumoniae*, the following alternative approach may be employed. Only those with sickle cell anemia or sickle cell-° thalassemia who appear toxic, have temperatures >40°C, or are not receiving prophylactic penicillin are hospitalized for administration of intravenous ceftriaxone (75 mg/kg). Those with sickle cell anemia or sickle cell-° thalassemia who have temperatures <40°C and are compliant with prophylactic penicillin and those with Hb SC disease or sickle cell-$^{+}$ thalassemia who have temperatures >38.5°C are given intramuscular ceftriaxone (75 mg/kg to a maximum dose of 2 g) after blood cultures are obtained, observed for several hours prior to discharge, and followed closely as outpatients. For those with Hb SC disease or sickle cell-$^{+}$ thalassemia who have temperatures <38.5°C, therapy is as indicated symptomatically.

Therapy for documented *S. pneumoniae* bacteremia is parenteral penicillin or ceftriaxone for several days. Vancomycin is recommended in areas where *S. pneumoniae* may be antibiotic-resistant.

When antibiotics are used to treat the acute chest syndrome, they should cover *S. pneumoniae, H. influenzae* type b, *M. pneumoniae*, and *C. pneumoniae*. The combination of cefuroxime and erythromycin is recommended.

For osteomyelitis, the diagnosis is confirmed by culture of blood or infected bone. Parenteral antibiotics that cover *Salmonella* and *S. aureus* are given, and antibiotic therapy is based on culture results. Parenteral antibiotics are continued for 2 to 6 weeks. [454] Surgical drainage or sequestrectomy may be required. Most patients are

cured by this approach, but there may be recurrences. [454]

Transfusion Therapy

Patients with sickle cell disease have the same indications for transfusion as do those without hemoglobinopathies, oxygen-carrying capacity and blood volume replacement (aplastic crisis, splenic sequestration), as well as indications that are unique to the special needs of their disease, protection from imminent danger (e.g., acute chest syndrome, septicemia, metabolic acidosis) and improved rheologic properties of blood (e.g., prevention of recurrent cerebral thrombosis, priapism, probably preoperatively). [726] [727] [728] Transfusion complications include alloimmunization, iron overload, and transmission of viral illness. The 30% incidence of alloimmunization in transfused sickle cell patients is due in part to minor blood group incompatibilities in racially mismatched blood. [729] [730] Accordingly, antibodies against the Rh (E, C), Kell (K), Duffy (Fya, Fyb), and Kidd (Jk) antigens present the greatest problem in transfusing these patients. [729] [730] Approaches to minimizing this complication include transfusing extended-matched, phenotypically compatible blood, [729] [731] [732] PEG-coated red cells whose antigens are masked from antibodies, [247] or artificial blood substitutes, such as perfluorocarbon emulsions and hemoglobin-based substitutes. [733] In the latter regard, infusion of a polymerized bovine hemoglobin-based oxygen carrier into asymptomatic adult sickle cell disease subjects resulted in no complications and improved exercise performance compared to control subjects. [734]

Despite earlier impressions to the contrary, [735] as sickle cell patients live longer, iron overload has become a problem in those chronically transfused. [736] Chelation with deferoxamine is recommended when the total body iron level is elevated. [737] Chelation guidelines for patients with sickle cell disease are similar to those for other chronically transfused, iron-overloaded patients; serum ferritin levels should not be allowed to exceed 2,000 g/ml. [738] This therapy is inconvenient and expensive, and the development of oral chelating agents [739] [740] will provide a tremendous advantage to these patients.

Transfusion transmission of HIV, hepatitis B and C, and human T-cell leukemia/lymphoma virus-1 has diminished with improved screening of banked units [741] but remains a problem in patients with sickle cell disease. [726] [727] In addition to better screening programs, the use of leukocyte-depleted red cell transfusions may be of value in reducing this hazard. [742]

Simple transfusion is used for single transfusions to restore oxygen-carrying capacity or blood volume, but partial exchange transfusions are recommended for emergencies and chronic transfusion because of the improved viscosity effects and reduced iron burden of this approach. [726] [727] The volumes required for simple and exchange transfusions (Table 30-5 (Table Not Available)) are particularly important for transfusing children. For normal-size adults, the general rule is that each unit of red cells infused increases the hemoglobin level approximately 1 g/dl. Partial exchange transfusion in adults is accomplished by phlebotomizing 500 ml, infusing 300 ml normal saline, phlebotomizing another 500 ml, and infusing 45 units of packed red cells. [735]

We have chosen to include the indications for transfusion in the discussions of specific disease complications, except for the issue of prophylactic preoperative transfusion. The controversy

TRANSFUSION THERAPY

Transfusion of red cells has been used for almost every complication of sickle cell disease, but its value has been demonstrated for few. Indications for transfusion include the need for oxygen-carrying capacity (i.e., aplastic crisis), blood volume (i.e., splenic sequestration), improved blood rheology (i.e., prevent CVA recurrence, leg ulcers, priapism), and protection from imminent danger (i.e., acute chest syndrome with p_{AO2} <70 mmHg, acute CVA, septicemia, metabolic acidosis). Simple transfusion is sufficient to supply oxygen-carrying capacity and blood volume. Partial exchange transfusion is recommended for acute indications and for chronic programs, where avoiding hyperviscosity and iron overload are important. Hemoglobin levels much above 10 g/dl must be avoided during transfusion because they may result in hyperviscosity and vaso-occlusive complications. A formula useful for manual partial exchange transfusion in adults is to phlebotomize 500 ml whole blood, infuse 300 ml normal saline, phlebotomize another 500 ml whole blood, and infuse 45 units packed red blood cells. In typical patients with sickle cell anemia having hemoglobin levels of 8 g/dl, this generally results in hemoglobin levels of 10 g/dl with <50% Hb S.

Preoperative simple transfusion sufficient to raise the Hb level to 10 g/dl is recommended for patients with Hb SS. For those with Hb SC, partial exchange preoperative transfusion is effective.

Each patient should be characterized according to red blood cell antigen phenotype, and this record should be maintained in the blood bank. Alloimmunization is diminished by transfusing extended-matched red cells.

surrounding this practice [743] [744] has largely been resolved by the results of a multicenter cooperative study. [745] The findings of this study were that prophylactic preoperative transfusion resulted in lower rates of surgical mortality and acute chest syndrome than no transfusion, and that direct transfusion to achieve Hb of approximately 10 g/dl and Hb S <60% was as effective and caused less morbidity than aggressive partial exchange transfusion to achieve Hb S <30%. [745] The efficacy of preoperative partial exchange transfusion in patients with Hb SC disease undergoing abdominal surgery suggests that this type of transfusion be performed preoperatively in this group of patients. [746]

Pain Management

The acute painful episode is the most frequent reason for which patients with sickle cell disease seek medical attention. When a patient presents complaining of pain, the physician is charged with ruling out etiologies other than vaso-occlusion (e.g., an infectious cause); maintaining optimal hydration by oral or intravenous fluid resuscitation (particularly in children); and providing aggressive relief of pain using narcotics, other analgesics, or other modalities. [747] [748] Patients are often undertreated for pain because many physicians and other health-care providers are unfamiliar with the pharmacology of analgesia and overly concerned with the potential for addiction. Consequently, the duration of painful episodes may be prolonged, a drug-seeking(pain-relieving?) behavior pattern is encouraged, and a pain-oriented personality may evolve. Prompt administration of appropriate doses of analgesia will diminish this potential. The existence of individuals with sickle cell Munchausen syndrome [749] must not interfere with this recommended approach. The absence of ISCs on the peripheral smear provides an immediate means of determining whether a patient has sickle cell disease.

Patients in pain are treated optimally in a familiar ambulatory setting that avoids the hectic environment of the emergency ward. [750] Comprehensive management of the biopsychosocial pain experience includes the use of psychosocial support systems, local anesthetics, epidural anesthetics, combinations of nonsteroidal anti-inflammatory agents and narcotics, and antidepressant drugs. [748] [751]

Hospitalization and intravenous administration of fluid and narcotics are often required for the treatment of severe pain. Table 30-6 presents a description of analgesics and recommendations for their use in the treatment of the painful episodes of sickle cell disease. [747] [748] [752] We recommend an aggressive approach to obtaining prompt pain relief such as intravenous morphine, followed by rescue or maintenance analgesia such as patient-controlled analgesia. [753] The use of patient-controlled analgesia precludes the risk of respiratory depression associated with constant-infusion narcotics, which has been reported to result in death due to respiratory depression.[754] In assessing patient responses to conventional doses of analgesia, it must be remembered that those with sickle cell disease metabolize narcotics rapidly.[755] [756]

Newer approaches to the management of acute pain include

TABLE 30-6 -- Recommended Dose and Interval of Analgesics Necessary to Obtain Adequate Pain Control in Sickle Cell Disease

	Dose/Rate	Comments
Severe/Moderate Pain		
1. Morphine	Parenteral: 0.10.15 mg/kg q 34 h. Recommended maximum single dose 10 mg. P.O.: 0.30.6 mg/kg q 4 h	Drug of choice for pain; lower doses in the elderly and infants and in patients with liver failure or impaired ventilation
2. Meperidine	Parenteral: 0.751.5 mg/kg q 24 h. Recommended maximum dose 100 mg. P.O.: 1.5 mg/kg q 4 h	Increased incidence of seizures. Avoid in patients with renal or neurologic disease or those who receive monoamine oxidase inhibitors.
3. Hydromorphone	Parenteral: 0.010.02 mg/kg q 34 h	
4. Oxycodone	P.O.: 0.040.06 mg/kg q 4 h P.O.: 0.15 mg/kg/dose q 4 h	
5. Ketorolac	Intramuscular: Adults: 30 or 60 mg initial dose, followed by 1530 mg Children: 1 mg/kg load, followed by 0.5 mg/kg q 6 h	Equal efficacy to 6 mg MS; helps narcotic-sparing effect; not to exceed 5 days. Maximum 150 mg first day, 120 mg maximum subsequent days. May cause gastric irritation.
6. Butorphanol	Parenteral: Adults: 2 mg q 34 h	Agonist-antagonist. Can precipitate withdrawal if given to patients who are being treated with agonists.
Mild Pain		
1. Codeine	P.O.: 0.51 mg/kg q 4 h. Maximum dose 60 mg.	Mild to moderate pain not relieved by aspirin or acetaminophen; can cause nausea and vomiting
2. Aspirin	P.O.: Adults: 0.36 mg q 46 h. Children: 10 mg/kg q 4 h.	Often given with a narcotic to enhance analgesia. Can cause gastric irritation. Avoid in febrile children.
3. Acetaminophen	P.O.: Adults 0.30.6 g q 4 h. Children: 10 mg/kg.	Often given with a narcotic to enhance analgesia
4. Ibuprofen	P.O.: Adults: 300400 mg q 4 h. Children: 510 mg/kg q 68 h.	Can cause gastric irritation
5. Naproxen	P.O.: Adults: 500 mg/dose initially, then 250 q 812 h. Children: 10 mg/kg/day (5 mg/kg q 12 h).	Long duration of action. Can cause gastric irritation.
6. Indomethacin	P.O.: Adults: 25 mg q 8 h. Children: 13 mg/kg/day given 3 or 4 times.	Contraindicated in psychiatric, neurologic, renal diseases. High incidence of gastric irritation. Useful in gout.

the use of potent nonsteroidal anti-inflammatory drugs, opioid receptor-binding agents, surfactants that inhibit cell adherence and aggregation, inhaled NO, anticoagulants, glucocorticoids, and epidural anesthesia. Ketorolac (Toradol) is a potent nonsteroidal anti-inflammatory that can be given by injection or orally. As a single parenteral agent, it provides analgesia superior to parenteral meperidine, causes no respiratory depression, and is especially effective for relieving bone pain.[757] Because of its severe gastrointestinal side effects, its administration should be limited to a 5-day course, it should be administered with H_2 blockers, and it may be used best with other analgesics to provide a narcotic sparing effect. [3] Tramadol is a centrally acting analgesic that is administered orally, binds to the -opioid receptor, inhibits norepinephrine and serotonin reuptake, induces minimal respiratory depression, has a low potential for abuse or addiction, relieves postoperative pain efficaciously, and is useful in the management of chronic painful conditions. [758] [759] Poloxomer 188 is an artificial polyoxyethylene/polyoxypropylene surfactant that reduces cellcell adherence;[244] given as a 48-hour infusion, it reduced the narcotic requirement of patients having acute painful episodes. [245] It may gain a role in the initial management of painful episodes.

It is difficult to define which of the many biologic effects of NO may result in pain relief, but based on its ability to increase the oxygen affinity of sickle erythrocytes in vitro and in vivo, its predicted use for relieving vaso-occlusive pain, [82] and its apparent efficacy in treating severe acute chest syndrome, [518] the utility of inhaled NO in relieving acute sickle cell pain is under study. On the basis of evidence for a hypercoagulable state in sickle cell disease, acemocoumerol was administered in low doses that achieved mean International Normalized Ratios of 1.64 and reduced the elevated levels of prothrombin activation fragment (fragment 1+2) to 50% of pretreatment levels.[270] No attempt was made to assess the efficacy of this treatment on pain. Minidose heparin, 5,0007,500 units every 12 hours, administered to four patients for 26 years, reduced hospitalization and emergency room time by 75%, and pretreatment pain frequency recurred after heparin was discontinued. [271] Methylprednisolone given as an intravenous infusion of 15 mg/kg to a total dose of 1,000 mg on admission and again 1 day later was found to provide pain relief superior to that of placebo, but there was an unacceptable rate of rebound pain after discontinuation of this therapy. [760] Epidural analgesia is a useful adjunct for the treatment of severe painful episodes.[761]

The rare chronic sickle cell pain syndrome may require therapy similar to that used for the management of the pain of terminal cancer, [762] such as long-acting morphine and fentanyl patches.

Hydroxyurea

Hydroxyurea (HU) is an inhibitor of ribonucleotide reductase without known carcinogenicity. [763] It also induces therapeutically significant increases in Hb F synthesis, [425] [764] [765] [766] an effect that is potentiated by conjoint administration of recombinant human erythropoietin. [767]

A double-blind, placebo-controlled, intention-to-treat multicenter study of HU as treatment of pain crisis in sickle cell disease found that HU produced definite hematologic changes. There were significant declines in the mean level of leukocytes, PMN, reticulocytes, and dense sickle cells and significant increases in the levels of hemoglobin, PCV, MCV, Hb F, F cells, and F reticulocytes [255] (Table 30-7 (Table Not Available)). The significant clinical changes were decreased rate of acute painful episodes, longer interval to first and second acute painful episode, fewer episodes of acute chest syndrome, and diminished number of subjects and units transfused[253] (Table 30-8). No significant changes were observed in the incidence of stroke, hepatic sequestration,

TABLE 30-7 -- Hematologic Effects of Hydroxurea Therapy

(Not Available)

Adapted from Charache et al.,[255] with permission.

or death. No short-term toxicity due to HU was observed. One child born to a subject taking HU and two born to partners of subjects taking HU were normal at birth. The possible long-term effects are under investigation.

A persistent concern pertaining to the use of HU in sickle cell disease is its putative leukemogenic effect. This concern derives from reports on HU treatment of myeloproliferative diseases, conditions associated with an inherent propensity for leukemic conversion. While the use of HU combined with ^{32}P or alkylating agents is associated with increased leukemic conversion,[768] reports claiming a leukemogenic effect for HU alone either lacked controls[769] or were not designed to provide useful information on this issue.[770] In the only study in patients lacking the potential for leukemic conversion, children with erythrocytosis secondary to inoperable cyanotic congenital heart disease, no leukemic conversion was observed.[771]

Studies of HU as therapy for children with sickle cell disease have begun. In one such study, the degree of anemia was lessened, the frequency of pain may have decreased, and there were no short-term side effects.[772]

The mechanism of action of HU remains an enigma. The original interest in this agent was based on the premise that it induced Hb F production. However, before the trial began, there was evidence of therapeutic response preceding changes in Hb F levels.[765] Other changes in sickle erythrocytes that may be independent of Hb F include increased water content,[773] improved deformability,[774] and decreased adherence to the vascular endothelium,[775] the last of which may relate to the decreased $_{4\,1}$ and CD36 molecules on sickle reticulocytes induced by HU.[776] Much remains unknown about the mechanisms by which HU influences sickle cells and vaso-occlusion. However, at this time it appears that myelosuppression may be as important to the beneficial influence of HU as any putative switching effect.

TABLE 30-8 -- Clinical Effects of Hydroxyurea Therapy

Variable	Hydroxyurea	Placebo	p Value
Acute pain crisis rate	2.5/year	4.5/year	<0.001
Hospitalization rate for acute pain crisis	1.0/year	2.4/year	<0.001
Interval to 1st pain crisis	3.0 months	1.5 months	<0.001
Interval to 2nd pain crisis	8.8 months	4.6 months	<0.001
Acute chest syndrome	25	51	<0.001
Subjects transfused	48	73	= 0.001
Blood units transfused	336	586	= 0.004

NEW THERAPEUTIC MODALITIES

The cure of sickle cell disease has been an elusive goal. Many agents have been proposed and tested, but, short of bone marrow transplantation, no cure has been found. As new therapies are developed, it is important to offer cautious optimism but not false hope to patients with sickle cell disease. Newer therapeutic compounds, classified according to their mechanisms of action, are described below.

Membrane-Active Agents

As discussed previously, membrane-active agents that improve sickle cell hydration and deformability, such as cetiedil citrate, [163] [164] [165] have shown limited therapeutic success in a controlled clinical trial. [163] Oral administration of agents that inhibit the cellular dehydration caused by the Gardos and potassiumchloride cotransport pathways,[133] [134] such as the imidazole compound clotrimazole, which inhibits the Gardos pathway [166] [167] or magnesium supplements, which inhibit potassiumchloride cotransport,[168] have been shown to improve the pathobiology of sickle erythrocytes. Compounds that improve membrane deformability are not effective.[777]

A nonionic block copolymer (Pluronic F-68, RheothRx, or Poloxamer 188), the emulsifying agent in the perfluorochemical blood substitute Fluosol DA, improves the rheologic properties of sickle red cells and inhibits their adherence to endothelial cells as a result of a lubricating effect on cell surfaces. [244] [778] [779] Results of a pilot study indicated that compared to placebo, a 48-hour infusion diminished the narcotic requirement significantly and the duration of pain and hospitalization less so. [245] A more extensive multicenter study is underway to determine the efficacy of this approach in the initial treatment of acute painful episodes.

Vasoactive Compounds

Vasodilating agents that improve membrane deformability have not been found effective. [780] However, as discussed above, inhalation of NO at 80 ppm for up to an hour was found to increase the oxygen affinity of sickle cells in vivo [82] and to improve the clinical status of two patients having acute chest syndrome. [781] This treatment is undergoing trial as therapy for sickle cell vaso-occlusion.

Antioxidant Agents

A systematic study of antioxidant agents intended to counter the detrimental effects of oxidation on sickle cells has not been accomplished. Such a study would be complicated by the relative redox potentials of participants in the auto-oxidative processHb S, oxidative radicals, free heme, hemichromes, nonheme iron, membrane lipid, membrane protein, and intermediate metabolites. An agent capable of reducing one component may oxidize another, and a clinical study would have to be carefully controlled to dissect the complex interdependence of oxidation-reduction substrates.

Induction of Hb F Synthesis

The experience with HU was discussed above. The basis and active agents of pharmacologic modulation of Hb F production are reviewed in reference 782 . Butyric acid appears to block the switch from fetal to adult hemoglobin, [783] but enthusiasm for its apparent ability to induce increased numbers of Hb F-containing reticulocytes[784] is tempered by concerns regarding uncertain efficacy, [785] [786] neurologic toxicity, [785] and unacceptably severe nausea and vomiting. [787] New formulations of this agent, some of which are absorbable in oral form, and a host of other Hb F-inducing agents are being evaluated. [788] [789]

Bone Marrow Transplantation

The success of allogeneic bone marrow transplantation (BMT) in curing -thalassemia major [790] encouraged this approach in sickle cell disease. The application of BMT to sickle cell disease is challenged by the selection of appropriate recipients, procurement of compatible donor sources, minimization of procedural risks, and consideration of cost-effectiveness.[791] [792] [793] [794] [795] [796] The choice of BMT candidates presents a dilemma. Transplanting only those who have had serious complications may allow serious disability prior to BMT, [791] [797] while transplanting those predicted by genetic polymorphisms to have severe disease may subject those misidentified to unnecessary risks. [478] The extremely poor prognosis of sickle cell disease in Africa supports the widespread use of BMT, [798] [799] but decisions in better-developed countries hinge on less absolute considerations. In the United States, the increasing life expectancy [250] and large fraction of asymptomatic patients[161] [380] suggest that BMT should be reserved for those with severe disease. These considerations influence the relatively better results of European groups who transplant healthier African patients, compared to American groups who transplant only more severely afflicted patients. [800] [801] [802] [803] The use of standard supportive regimens resulted in serious neurologic complications, including stroke and seizures, in 7 of 21 sickle cell patients undergoing allogeneic BMT, [804] presumably as a result of prior cerebral vasculopathy. Adjusting the procedural approach to BMT in these patients, including altering the preparative regimen, maintaining the hemoglobin >11 g/dl and the platelet count >50,000/ml, and aggressively treating elevated blood pressure, has remedied this risk. [803] [804]

The usual expectation of one HLA-compatible acceptable donor per three siblings [805] is reduced further to approximately one HLA-matched, acceptable donor in five for sickle cell disease.[806] After patients are counseled on the 10% risk of mortality and the 25% risk of graft-versus-host disease (GVHD), approximately 10% of patients with sickle cell disease accept the option of BMT. [797] Solutions to this problem include broadening the ethnic composition of the donor registry pool, improving BMT results using partially matched donors, correcting the genetic defect in autologous marrow erythroid precursors by gene therapy (see following section), and using peripheral blood stem cells as a donor source.

An abundant source of peripheral blood stem cells is umbilical cord blood (UCB). [790] [807] Blood from a single cord and placenta contains enough stem cells to reconstitute the marrow of an adult recipient.[808] Transplantation of nonsickle cell recipients with UCB results in excellent rates of engraftment, recovery, GVHD, and survival.[808] [809] Most importantly, the use of UCB allows crossing the HLA barrier using HLA-disparate stem cells without an increased risk of GVHD. [809] [810] This outcome apparently is the result of the less alloreactive lymphocytes contained in UCB compared to marrow. [811] It permits less aggressive prophylaxis for GVHD.[808] UCB is being used to transplant subjects with sickle cell disease. [812]

The issue of the cost effectiveness of BMT gains perspective from the comparative costs of $150,000 to $200,000 for an uncomplicated BMT in the United States versus up to $112,000 annually for conventional medical care of a chronically transfused, iron-overloaded patient. [792]

Gene Therapy

Recent advances in gene therapy technology provide promise for the future of sickle cell disease. [813] [814] The singular importance of a single nucleotide substitution to

a disease so thoroughly understood renders the sickle cell gene an ideal candidate for

this technology. Efficient gene transfer has been accomplished using replicative defective retroviral vectors. [815] High-level expression is attained by including in the vector regulatory sequences from the locus control region [816] and by inserting the normal gene into its native environment by homologous recombination (an approach that offers the additional advantage of knocking out the mutant gene by inserting the normal). [817] Sustained expression of the corrected gene is gained by transfer into self-replicating stem cells. [818] Successful expression of the human sickle gene in transgenic mice demonstrates the potential feasibility of this approach. [819] Its safety remains to be determined. [820] (See Chap. 95.)

Chapter 31 - Hemoglobin Variants Associated with Hemolytic Anemia, Altered Oxygen Affinity, and Methemoglobinemias

Edward J. Benz Jr.

INTRODUCTION

Hemoglobinopathies are inherited diseases due primarily to mutations affecting the globin genes. Nearly 1,000 mutations that alter the structure, expression, or developmental regulation of individual globin genes, and the hemoglobins they encode, have been described; most do not produce clinical disease. Many are highly instructive for students of gene structure, function, and regulation, but further consideration of most is not warranted in a clinically oriented textbook. Sickle cell anemia and the thalassemia syndromes are by far the most important mutations that cause clinical morbidity, in terms of both the complexity of the clinical syndromes they cause and the number of patients affected. These conditions are considered in detail in other chapters (see Chaps. 29 and 30). This chapter reviews other abnormalities of the hemoglobin molecule that produce clinical syndromes. Each variant is uncommon. In the aggregate, however, hemoglobinopathies represent important problems for hematologists because they must be considered as possible etiologies for conditions about which hematologists are often consulted: hemolytic anemia, cyanosis, polycythemia, jaundice, rubor, splenomegaly, or reticulocytosis.

The major hemoglobinopathies producing clinical symptoms, other than sickle cell anemia and thalassemias, can be classified as those hemoglobins exhibiting altered solubility (unstable hemoglobins), hemoglobins with increased oxygen affinity, hemoglobins with decreased oxygen affinity, and methemoglobins (Table 31-1). A few acquired conditions, in which toxic modifications of the hemoglobin molecule are important (e.g., carbon monoxide poisoning), are also considered briefly.

The sections that follow emphasize hemoglobinopathies that produce the most severe or dramatic alterations in clinical phenotype and those in which a single clinical abnormality (e.g., hemoglobin precipitation) predominates. However, it is important to emphasize at the outset that of the >100 mutations altering globin chain structure that have been shown to affect solubility or affinity, or both, only a few are clinically important.

TABLE 31-1 -- Classification of Hemoglobinopathies

Structural hemoglobinopathieshemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties
Abnormal hemoglobin polymerizationHb S
Altered oxygen affinity
High affinitypolycythemia
Low affinitycyanosis, pseudoanemia
Hemoglobins that oxidize readily
Unstable hemoglobins, hemolytic anemia, jaundice
M hemoglobinsmethemoglobinemia, cyanosis
Thalassemiasdefective production of globin chains
-Thalassemias
-Thalassemias
-, -, -Thalassemias
Structural hemoglobinopathiesstructurally abnormal Hb associated with coinherited thalassemia phenotype
Hb E
Hb Constant Spring
Hb Lepore
Hereditary persistence of fetal hemoglobinpersistence of high levels of Hb F into adult life
Pancellularall red cells contain elevated Hb F levels
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellularonly specific subpopulation of red cells contain elevated levels of Hb F
Acquired (see below)
Acquired hemoglobinopathies
Methemoglobin due to toxic exposures
Sulfhemoglobin due to toxic exposures
Carbonoxyhemoglobin

Hb H in erythroleukemia
Elevated Hb F in states of erythroid stress and bone marrow dysplasia, usually heterocellular

The abnormal functional properties of most mutant hemoglobins can be detected readily in sophisticated research laboratories, but do not produce laboratory or clinical abnormalities relevant to clinical practice. Moreover, many mutations are pleiotropic, affecting several functional properties of the hemoglobin molecule. Thus, a single mutation can increase oxygen affinity and reduce solubility, or produce methemoglobinemia and reduce solubility.

Table 31-2 (Table Not Available) summarizes the major forms of structurally abnormal hemoglobin, with examples. This table serves as a point of reference for the remaining sections of the chapter.

UNSTABLE HEMOGLOBINS

The term unstable hemoglobins refers to hemoglobins exhibiting reduced solubility or higher susceptibility to oxidation of amino acid residues within the individual globin chains. More than 100 unique unstable hemoglobin mutants have been documented. Most exhibit only mild instability in in vitro laboratory tests and are associated with minimal clinical manifestations. Both - and -globin variants can cause this condition. Approximately 75% of the mutations described, however, are -globin variants. This probably reflects the potential for -globin variants to exert pathologic effects in utero. Clinical symptomatology of unstable hemoglobins also depends in part on the quantitative proportion of the abnormal hemoglobin. Because the -globin genes are duplicated, mutations in an individual locus generally produce only 2535% abnormal globin. By contrast, a simple heterozygote at the single -globin locus produces 50% of the abnormal variant.

The mutations that impair hemoglobin solubility usually disrupt hydrogen bonding or the hydrophobic interactions that retain either the heme moiety within the heme binding pockets or hold the tetramer together (Fig. 31-1 (Figure Not Available)). Some alter the helical segments (Hb Geneva [^{28LeuPrc}]), others weaken contact points between the - and -subunits (Hb Philadelphia [^{35TyrPhe}]), whereas still others derange interactions of the hydrophobic pockets of the globin subunits with heme (e.g., Hb Köln [^{98ValMe}]). The common pathway to reduced solubility ultimately leads to weakening of the binding of heme to globin. Actual loss of heme groups can occur, for example, in Hb Gun Hill, in which five amino acids, including the F8 histidine, are deleted. In other cases, mutations that introduce prolines into helical segments disrupt the helices and interfere with normal folding of the polypeptide around the heme group. Another feature of these mutations is disruption of the integrity of the tetrameric structure of globin chains. Only the intact hemoglobin tetramer can remain dissolved at the high concentrations that must be achieved within the circulating red cell (see Chap. 29).

Pathophysiology of Unstable Hemoglobin Disorders

The mechanisms by which unstable hemoglobin mutations produce hemoglobin precipitation remain incompletely understood. However, the major outlines of the process have been described (Fig. 31-2). The fundamental step in the pathogenesis appears to be derangement of the normal linkages between heme and globin. Loss of appropriate globin chain folding and interaction may ultimately destabilize the heme-globin linkage or lead to partial proteolysis of the chain, thereby releasing heme from that linkage. Once freed from its cleft, heme probably binds nonspecifically to other regions of the globin molecule, forming precipitated hemichromes, which lead to further denaturation and aggregation of the globin subunits to form a precipitate containing - and -globin chains, globin fragments, and heme, called the Heinz body.

Heinz bodies interact with delicate red cell membrane components (see Chap. 33), thereby reducing red cell deformability. These cells tend to be trapped in the splenic microcirculation and pitted, reflecting attempts by the splenic macrophages to remove the Heinz bodies. Red cell damage may be aggravated by the release of free heme into the red cell. Several biochemical perturbations correlate with the presence of free heme, such as generation of reactive oxidants (i.e., hydrogen peroxide, superoxide, and hydroxyl radicals). The end result of this process is premature destruction of the red cell, producing the hemolytic anemia.

Individual unstable hemoglobins vary in their propensity to generate Heinz bodies and hemolysis. For example, Hb Zurich exhibits relatively mild insolubility. Hemolysis is virtually absent in patients with this variant. Hemolysis may become clinically apparent only in the presence of additional oxidant stresses, such as infection, fever, or the ingestion of oxidant agents. Because of the propensity of these molecules to be hypersensitive to oxidation, some patients with unstable hemoglobins can exhibit episodic hemolysis in response to the same oxidative stressors as those exacerbating the clinical phenotype of glucose-6-phosphate dehydrogenase (G6PD)-deficient patients.

Patterns of Inheritance and Clinical Manifestations

Unstable hemoglobins are usually inherited as autosomal dominant disorders. However, the rate of spontaneous mutation appears to be high, so that the absence of affected parents or sibs does not rule out the presence of an unstable hemoglobin in an individual family. Nonetheless, the presence of a positive family history can be a useful adjunct to diagnosis, and should

Figure 31-1 (Figure Not Available) Hemoglobin tetramer showing the position of the more common, clinically significant hemoglobin mutants. Most of those that have been described occur on the -chain at invariant residue sites, near critical intermolecular contacts, or in proximity to the prosthetic heme-binding site. *(Modified from Dickerson RE, Geis I: Hemoglobin: Structure, Function, Evolution, and Pathology. Benjamin-Cummings, Menlo Park, CA, 1983, with permission. Copyright Irving Geis.)*

Figure 31-2 Presumed mechanisms by which denaturation of hemoglobin leads to erythrocyte destruction. The rate of travel through the various pathways probably differs for the different hemoglobin variants and for a variety of stresses to which the protein is subjected. *(From Wynngaarden JB, Smith LH Jr, Bennett JC (eds): Cecil Textbook of Medicine. WB Saunders, Philadelphia, 1992, with permission.)*

provoke consideration of an unstable hemoglobin as the cause of the familial hemolytic diathesis.

The clinical syndrome associated with unstable hemoglobin disorders is often called congenital Heinz body hemolytic anemia. This term derives its origins from the fact that only the most severe cases were detected before the widespread availability of sophisticated methods for detecting and characterizing abnormal hemoglobins. Clinical manifestations are highly variable, ranging from a virtually asymptomatic state in the absence of environmental stressors to severe hemolytic

anemia presenting at birth. Patients with chronic hemolysis present with variable degrees of typical symptoms, including anemia, reticulocytosis, hepatosplenomegaly, jaundice, leg ulcers, and propensity to premature biliary tract disease.

For hemoglobin variants with a given degree of reduced solubility, the degree of anemia may vary because some of these variants also exhibit altered oxygen affinity. Thus, Hb Köln has increased oxygen affinity, resulting in relatively higher levels of tissue hypoxia and erythropoietin stimulation at any given level of hematocrit (see next section); therefore, patients with Hb Köln tend to have higher hematocrits than expected on the basis of hemolytic severity because of increased erythropoietin stimulation. By contrast, Hb Hammersmith exhibits decreased oxygen affinity, improving oxygen delivery and allowing patients to function at a lower hematocrit. Hb Zurich possesses, for complex molecular reasons, a higher-than-normal affinity for carbon monoxide. A high hemoglobin carbon monoxide level develops in patients with Hb Zurich who also smoke. Binding of carbon monoxide protects Hb Zurich from denaturation, thus reducing hemolysis, so these people tend to exhibit lesser degrees of hemolytic anemia than do nonsmoking relatives.

Diagnosis

The presence of an unstable hemoglobin should be suspected in patients with one or more stigmata of accelerated red cell destruction: chronic or intermittent hemolytic anemia or jaundice, premature development of bilirubin gallstones or biliary tract disease (due to accelerated red cell turnover), unexplained reticulocytosis, or bouts of intermittent symptoms that can be related to exposure to oxidant drugs or infections. Other suggestive symptoms include dark urine, transient jaundice, or leg ulcers.

Laboratory diagnosis depends on identification of a mutant hemoglobin that precipitates more easily than normal hemoglobin. The peripheral blood smear may or may not show evidence of hemolysis, (i.e., poikilocytosis, polychromasia, or shift cells). The morphologic evidence for precipitated hemoglobin is the Heinz body, the intraerythrocytic inclusion body detected by staining the peripheral blood smear with a supravital dye, such as brilliant cresyl blue or new methylene blue.

The spleen removes Heinz bodies efficiently, especially if hemolysis is not particularly acute or brisk. Thus, Heinz bodies may not be demonstrable at all times. Two provocative laboratory maneuvers are used to aid detection, both of which unmask the tendency of unstable hemoglobins to precipitate: the heat instability test (heating of a hemoglobin solution to 50°C) or the isopropanol instability test (insolubility in 17% isopropanol).

Hemoglobin electrophoresis should be performed but *should not be relied on as the major diagnostic criterion for ruling in or ruling out a hemoglobinopathy.* Many amino acid substitutions that have a profound effect on solubility do not change the overall charge on the hemoglobin molecule. For example, Hb Köln, the most common of the unstable hemoglobin mutations, arises from a mutation changing the valine at position 98 to a methionine. This mutation is electrically neutral; it does not alter electrophoretic mobility. Therefore, these variants do not form an abnormal band on an electrophoresis gel. Demonstration of an abnormal band would clearly add strong evidence in support of the diagnosis. A normal electrophoretogram, however, should never be regarded as strong evidence against the presence of a mutant hemoglobin, especially if the clinical picture or family history otherwise supports the diagnosis.

Sophisticated analyses of hemoglobin can be obtained from reference laboratories if detailed characterization seems warranted. For example, abnormal hemoglobin or globin bands migrating to novel positions on an isoelectric focusing gel can result from hemoglobin or globin moieties lacking heme in groups. When heme is added to the sample and the proteins are reanalyzed, these bands disappear. This behavior is nearly diagnostic of an unstable variant.

Detection of unstable hemoglobins is occasionally compromised by the selective precipitation of the unstable variant into Heinz bodies. Because most patients are heterozygotes, this phenomenon greatly reduces the apparent percentage of the variant in soluble form. Thus, even a variant possessing altered electrophoretic mobility may be very difficult to detect. Indeed, some unstable hemoglobins, such as Hb Geneva or Hb Terre Haute, are so unstable that no mutant gene product can be detected in the steady state. These abnormal hemoglobins actually produce a thalassemic phenotype (see Chap. 29). They are detectable only by isotope labeling studies or direct analysis of the globin genes.

The differential diagnosis of unstable hemoglobin variants is usually straightforward if the general category of hemolytic disorders is suspected. The most common form of G6PD deficiency can also present with bouts of intermittent or chronic

hemolysis exacerbated by oxidant drugs or infection (see Chap. 32). This diagnosis should be considered, as should other causes of chronic or intermittent hemolytic anemia, such as red cell membrane disorders (e.g., hereditary spherocytosis) or immune hemolytic anemias. Spherocytes are relatively rare in unstable hemoglobin disorders; this is sometimes a useful discriminant.

Management

The severity of the clinical complications of unstable hemoglobins varies enormously. Many patients can be managed adequately by observation and education to avoid agents that provoke hemolysis. Some patients may require transfusions during bouts of severe acute hemolytic anemia. Patients who have significant morbidity because of chronic anemia or repeated episodes of severe hemolysis should be considered candidates for splenectomy, especially if hypersplenism has developed. Children with severe hemolysis may require transfusion support until they are old enough (age 3 or 4 years) to undergo splenectomy without unacceptable immunologic compromise. Splenectomy is usually effective for abolition or reduction of symptoms. Infection often exacerbates hemolysis. Fever should therefore prompt close monitoring of patients for evidence of hemolysis or anemia.

HEMOGLOBINS WITH INCREASED OXYGEN AFFINITY

Oxygen transport by hemoglobin depends on the sigmoid shape of the hemoglobin-oxygen affinity curve. During the transition from the fully deoxygenated to the fully oxygenated state, the initial oxygenation steps occur with difficulty. In fact, the act of binding the first oxygen molecule increases the affinity of the molecule for subsequent oxygen-binding events, thus creating the sigmoid shape of the curve. The necessary intramolecular reorganization occurs only when the proper arrangement of hydrogen bonds, hydrophobic interactions, and salt bridges are broken and formed in the proper sequence.

Mutant hemoglobins exhibiting altered oxygen affinity arise from amino acid substitutions at the interface between - and -chains or in regions affecting the hydrogen bonds, hydrophobic interactions, or salt bridges that influence the interaction of heme with oxygen. A second major class of mutations alters binding to 2,3-diphosphoglycerate (2,3-DPG; see Chap. 22), which in turn alters oxygen affinity when bound to hemoglobin.

Pathogenesis and Pathophysiology

High-affinity hemoglobins exhibit higher avidity for oxygen, causing the oxygen dissociation curve to shift to the left; an example is Hb Kempsey (^{99AspAsn}) (Fig. 31-3). These hemoglobins bind oxygen more readily than normal and retain more oxygen at lower PO_2 levels. They thus deliver less oxygen to tissues at normal capillary oxygen pressures. The PO_2 in the normal lung (PO_2 = 90100 mmHg) is well above that needed to saturate hemoglobin fully with oxygen (60 mmHg). These variant hemoglobins cannot acquire any additional oxygen in the lung despite their higher affinity. At capillary PO_2 (3545 mmHg), however, high-affinity hemoglobins deliver *less* oxygen. At normal hematocrits, a mild tissue hypoxia results; this stimulates erythropoietin release, causing elevated red cell production and polycythemia. In extreme cases, hematocrits of 6065% can be encountered.

Many types of mutations can increase oxygen affinity. Some alter interactions within the heme pocket, others disrupt the Bohr effect or the salt-bond site, and still others impair the binding of Hb A to 2,3-DPG. Loss of 2,3-DPG binding results in increases in oxygen affinity (see Chap. 22). These and numerous other examples that have been analyzed at the molecular level

Figure 31-3 Hemoglobinoxygen dissociation curves are illustrated for normal hemoglobin (Hb A) and for model abnormal hemoglobins with high and low oxygen affinities. On the abscissa, the partial pressure of oxygen is indicated in millimeters of mercury. On the left ordinate, the saturation of hemoglobin with oxygen is indicated as a percentage; on the right ordinate, the oxygen content of the hemoglobin is expressed as volumes percent. The three inverted arrows show the P_{50} for the three hemoglobins (the partial pressure of oxygen at which the hemoglobin is 50% saturated). This value is lowest for the high-affinity hemoglobin. As the partial pressure of oxygen drops from 100 (arterial) to 40 (tissues), hemoglobin desaturates, giving up a portion of its bound oxygen; the numbers on the brackets indicate the amount of oxygen unloaded by the three hemoglobin types expressed as volumes percent. Note that the high-affinity hemoglobin delivers less than one-half the oxygen that Hb A gives to the tissues, resulting in tissue anoxia, increased erythropoietin secretion, and erythrocytosis. Conversely, the low-affinity hemoglobin is even more efficient than Hb A in supplying tissues with oxygen, resulting in diminished erythropoietin production and anemia. *(From Wynngaarden JB, Smith LH Jr, Bennett JC (eds): Cecil Textbook of Medicine. WB Saunders, Philadelphia, 1992, with permission.)*

have greatly aided our understanding of the molecular basis for reversible oxygen binding.

Diagnosis

High-affinity hemoglobins are a cause of familial unexplained erythrocytosis (see Chap. 25). Functional testing of the hemoglobin is the key to diagnosis. Oxygen affinity is usually measured as P_{50} , the partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen (Fig. 31-3). The hemoglobin preparation is exposed to increasing oxygen pressures and the relative percentages of oxyhemoglobin and deoxyhemoglobin are determined. The values are plotted on a curve, and the 50% saturation point is determined. A shift to the left means that the hemoglobin reaches 50% saturation at a lower partial pressure of oxygen. High-affinity variants are thus associated with a lower-than-normal P_{50} value. Hemoglobin electrophoresis can, but may not, reveal an abnormal band.

The most common etiology of a low P_{50} value is carbon monoxide. Carbon monoxyhemoglobin has an extremely left-shifted oxygen affinity curve. Carbon monoxide (CO) stabilizes hemoglobin in the R oxy state without the need for oxygen binding. The clinical consequences of mild chronic CO poisoning are the

same as those seen with high-affinity hemoglobin variants. The most common cause of carbon monoxide toxicity is cigarette smoking, although chronic carbon monoxide exposure can elevate the hematocrit in people such as caisson workers or tunnel toll collectors. Severe acute CO poisoning can cause rapid death due to tissue hypoxia.

Management

Most patients with high-affinity hemoglobins have mild erythrocytosis; they do not require intervention. Very rarely, the hematocrit is very high (>5560). The blood viscosity is then sufficiently elevated to require therapeutic phlebotomy.

HEMOGLOBINS WITH DECREASED OXYGEN AFFINITY

Pathogenesis

Low-affinity hemoglobin variants, such as Hb Kansas (^{102AsnThr}), arise from mutations that impair hemoglobin oxygen binding or reduce cooperativity. In Hb Kansas, the threonine position, ^{102}, cannot form a hydrogen bond with aspartic acid at position ^{94}. Because this aspartate residue stabilizes the R (oxy) state, Hb Kansas binds oxygen less well and exhibits a right-shifted P_{50} value (Fig. 31-3).

Most low-affinity variants possess enough oxygen affinity to become fully saturated in the normal lung. At the low capillary PO_2 in other tissues, these hemoglobins deliver *higher*-than-normal amounts of oxygen. They become more desaturated than normal hemoglobins. Two abnormalities result from this high level of oxygen delivery. First, because tissue oxygen delivery is so efficient, normal oxygen requirements can be met by lower-than-normal hematocrits. This situation produces a state of pseudoanemia, in which the low hematocrit is deceiving because both oxygen deliveryand the patientsare completely normal. Second, the amount of desaturated hemoglobin circulating in capillaries and veins can be >5 g/dl. Cyanosis may thus be associated with these variants. This usually ominous finding is entirely misleading in these individuals, since it reflects no morbidity.

Diagnosis

Patients with unexplained anemia or cyanosis who appear to be entirely well in all other respects should be evaluated, especially if there is a positive family history. Testing for the abnormal variant follows the same reasoning as that just described for high-affinity variants. The O_2 dissociation curve will be shifted to the right, and the numeric value of the P_{50} will be higher than normal.

Management

Patients with low-affinity hemoglobins are usually asymptomatic. No treatment is required. It is important to document that a low-affinity hemoglobin is the cause of an apparent anemia or cyanosis to preempt inappropriate work-ups and provide reassurance to the patient. Cyanosis in some patients can pose a cosmetic problem, but correction with transfusions is rarely justified.

METHEMOGLOBINEMIAS

Methemoglobin results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Normal oxygenation of hemoglobin causes a partial transfer of an electron from the iron to the bound oxygen. Iron in this state thus resembles ferric iron and the oxygen resembles superoxide (O_2). Deoxygenation returns the electron to the iron, with release of oxygen. Methemoglobin forms if the electron is not returned. Methemoglobin constitutes 3% of the total hemoglobin in normal humans. These levels in humans are in fact maintained at 1% by the methemoglobin reductase enzyme system (nicotinamide adenine dinucleotide [NADH]-dehydratase, ADH-diaphorase, erythrocyte cytochrome b_3).

Pathogenesis and Clinical Manifestations

Methemoglobinemias of clinical interest arise by one of three distinct mechanisms: (1) globin chain mutations that result in increased formation of methemoglobin, (2) deficiencies of methemoglobin reductase, and (3) toxic methemoglobinemia, in which normal red cells are exposed to substances that oxidize hemoglobin iron such that normal reducing mechanisms are subverted or overwhelmed (see Chap. 32 ; Table 31-3).

Abnormal hemoglobins producing methemoglobinemia (M hemoglobins) arise from mutations that stabilize the heme iron in the ferric state. Classically, a histidine in the vicinity of the heme pocket is replaced by a tyrosine; the hydroxyl group of the tyrosine forms a complex that stabilizes the iron in the ferric state (Fig. 31-4 (Figure Not Available)). The oxidized heme iron is relatively resistant to reduction by the methemoglobin reductase system.

Methemoglobin has a brownish to blue color that does not revert to red on exposure to oxygen. These patients thus appear to be cyanotic. In contrast to truly cyanotic people, however, PaO_2 values are usually normal. Patients with these hemoglobins are otherwise asymptomatic because methemoglobin is rarely >3050%, the levels at which symptomatology becomes apparent.

Hereditary methemoglobinemia resulting from methemoglobin reductase deficiency (cytochrome b_5 reductase deficiency) is very rare. Some patients also exhibit neurologic defects. The mutation might thus affect isoforms of the enzyme common to both erythrocytes and other tissues, including brain. Other patients exhibit only the methemoglobin abnormality.

Like patients with M hemoglobins, patients with methemoglobin reductase deficiency exhibit slate-gray pseudocyanosis. Even homozygotes, however, rarely accumulate >25% methemoglobin, a level compatible with absence of symptoms. Heterozygotes can have normal methemoglobin levels but are especially sensitive to agents causing methemoglobinemia.

A third toxic form of methemoglobinemia is caused by exposure to certain chemical agents and drugs that accelerate the oxidation of methemoglobin (Table 31-4). Nitrite compounds are especially notorious and common. Some of these compounds also have a propensity to exacerbate G6PD deficiency and the precipitation of unstable hemoglobins.

Nitrates are a frequent environmental cause of toxic methemoglobinemia. Nitrates do not directly interact with either hemoglobin or the reductase pathway, but are converted to nitrites in the gut. Well water is a frequently encountered source of excessive nitrates. In general, substantial intake of these agents is required before significant amounts of methemoglobin

TABLE 31-3 -- Types of Methemoglobinemia

Figure 31-4 (Figure Not Available) Modifications of the heme and its environment that account for two common M hemoglobins. **(A)** Hemoglobin A has a His residue at the 58(E7) position. **(B)** In hemoglobin M-Boston, the histidine is replaced by a tyrosine, the phenolic side chain of which is capable of covalently binding to the heme iron, resulting in stabilization in the oxidized form. **(C)** Hb A has a Val residue at position 67(E11). **(D)** Hb M-Milwaukee has a glutamic acid substitution for the 67 valine. The carboxylic side chain of the Glu forms a bond with iron, shifting the equilibrium toward the ferric state. *(Modified from Dickerson RE, Geis I: Hemoglobin: Structure, Function, Evolution, and Pathology. Benjamin-Cummings, Menlo Park, CA, 1983, with permission. Copyright Irving Geis.)*

are generated. Very young infants are more susceptible to these agents than are adults, but all age groups are at risk given sufficient exposure.

Acquired methemoglobinemia is virtually the only situation in which life-threatening amounts of methemoglobin accumulate.

TABLE 31-4 -- Drugs and Chemicals Having Toxic Effects on Hemoglobin Molecule

Agent	Hemoglobin-Derivative Observed	
	Methemoglobin	Sulfhemoglobin
Acetanilid, phenacetin	+	+

Nitrites (farryl, amyl, sodium, potassium, nitroglycerin)	+	+
Trinitrotoluene, nitrobenzene	+	+
Aniline, hydroxylamine dimethylamine	+	+
Sulfanilamide	+	+
p-Aminosalicylic acid	+	
Dapsone	+	
Primaquine, chloroquine	+	
Prilocaine, benzocaine, lidocaine	+	
Menadione, naphthoquinone	+	
Naphthalene	+	
Resorcinol	+	
Phenylhydrazine	+	+

In general, the only symptom produced when methemoglobin comprises <30% of total hemoglobin is the cosmetic effect of cyanosis. As levels of methemoglobin rise to >30%, however, patients begin to exhibit symptoms of oxygen deprivation, such as malaise, giddiness, and other alterations of mental status. The symptoms reflect a true lack of oxygen availability at the tissue level. Methemoglobin is a markedly left-shifted hemoglobin that delivers little oxygen to the tissues. When methemoglobin is >50% of total hemoglobin, loss of consciousness, coma, and death can rapidly ensue. At this level, the blood is chocolate brown.

Diagnosis

Methemoglobinemia should be suspected in patients with unexplained cyanosis. It is obviously a medical emergency when any patient has cyanosis and altered mental status; a normal PaO_2 should trigger a consideration of methemoglobinemia. The ingestion of nitrites as a suicide gesture, especially in people knowledgeable with respect to chemistry, medicine, or pharmacology, should be considered. Methemoglobinemia can be suspected from the brownish color of blood when it is drawn. Laboratory detection is simple; methemoglobin exhibits characteristic peaks of absorption at 630 and 502 nm, rendering it easily distinguishable from normal hemoglobin. The inherited M hemoglobin mutants are frequently detectable by altered electrophoretic mobility, especially if ferricyanide treatment in vitro

is used to convert all the hemoglobin solution to methemoglobin.

In the case of toxic methemoglobinemia, recognition of exposure to an appropriate agent provides the most important historical clue. Acute poisoning can represent a life-threatening emergency; therefore, laboratory evaluation for methemoglobin should be requested for any person displaying atypical cyanosis or cyanosis occurring along with normal blood gas values. Methemoglobin due to deficiencies of the reductase system can be further evaluated in reference laboratories by direct analysis of these enzymes.

Management

Patients with M hemoglobins are usually asymptomatic and require no management. The secondary cyanosis can present a cosmetic problem. The cyanosis is not reversible because ascorbic acid and methylene blue are usually ineffective.

Patients with deficiency of the reductase system usually do not require treatment. Cyanosis in these cases can be improved by treatment with oral methylene blue, 100300 mg/day, or 500 mg/day of oral ascorbic acid. Riboflavin (20 mg/day) has also been reported to be effective and may be the preferred agent, because methylene blue produces discolored (blue) urine, and ascorbic acid can cause sodium oxalate stones.

Emergency treatment of high levels of toxic methemoglobinemia begins with 12 mg/kg of intravenous methylene blue as a 1% solution in saline. It is usually infused rapidly (1015 minutes); the dose may be repeated if necessary. This treatment is usually effective. Methylene blue acts through the NADPH reductase system, which in turn requires G6PD activity. The method is therefore ineffective in patients who also have G6PD deficiency. These patients, or patients who are severely affected, may require exchange transfusion. Oral ascorbic acid is not useful for emergency situations because it acts too slowly. Follow-up maintenance management, however, can be accomplished with either ascorbic acid or oral methylene blue.

Mild cases of methemoglobin intoxication do not require treatment. The patient can be monitored for 13 days, during which time methemoglobin levels gradually return to normal if the offending agent is eliminated. The most important follow-up therapy for patients with toxic methemoglobinemia involves a thorough search for the offending agent and its removal from the environment.

Chapter 32 - Red Cell Enzymopathies

Josef T. Prchal
Xylina T. Gregg

Red cell enzymes have received the intense attention of hematologists, biochemists, and physiologists principally because they are easily accessible. Simple laboratory methods for the rapid purification of erythrocytes facilitated studies of congenital and acquired erythrocyte disorders.

Clinically significant abnormalities of red cell enzymes cause diverse phenotypes including hemolytic anemia, polycythemia, and methemoglobinemia. In other instances, although there is no detectable red cell phenotypic abnormality, red cell enzymes can be used to diagnose systemic disorders such as galactosemia, adenosine deaminase deficiency, and some vitamin deficiencies. In addition, the study of red cell enzymes helped uncover important biological principles such as X-chromosome inactivation and provided the groundwork for important principles of population genetics, biochemistry, and molecular biology.

Mature erythrocytes are the product of a highly specialized cellular process involving loss of the nucleus prior to release from the bone marrow and loss of mitochondria and ribosomes after 12 days in circulation. Unable to carry out oxidative phosphorylation and protein synthesis, the erythrocyte still has to sustain an active metabolism to maintain its viability and to preserve hemoglobin in its functional form to ensure adequate oxygen delivery to tissues.

Red cell enzymes support two important metabolic pathways: glycolysis and the pentose shunt (Fig. 32-1). These two pathways generate three important metabolic intermediates: NADH, NADPH, and adenosine triphosphate (ATP). Under physiological conditions, approximately 90% of glucose is consumed in the glycolytic pathway while about 10% is utilized in the pentose shunt. However, in conditions of increased oxidant stress the contribution of the pentose shunt may be significantly increased.

In order to provide proper oxygen delivery, the erythrocyte must (1) maintain the flexibility and integrity of the red cell membrane using ATP from glycolysis, (2) maintain a high ratio of NADH to NAD for continuous reduction of methemoglobin to reduced hemoglobin, (3) maintain a high concentration of 2,3-BPG

Figure 32-1 Glycolysis (Embden-Meyerhof pathway). GSH, reduced glutathione; GSSG, oxidized glutathione; G6PD, glucose- 6-phosphate dehydrogenase; 6PG, 6-phosphogluconate; 2,3-BPG, 2,3-Bisphosphoglycerate; DHAP, dihydroxyacetone-P; GAPD, glyceraldehydephosphate dehydrogenase.

generated in the Rapoport-Luebering shunt of glycolysis to ensure optimal oxygen delivery to the tissue, and (4) maintain a high ratio of NADPH to NADP (generated in the pentose shunt from the glycolytic intermediate glucose-6-phosphate) for reduction of glutathione and protection against oxidant damage.

Other erythrocyte enzymes participate in nucleotide degradation and salvage and are essential for the removal of nucleotide precursors that may be toxic to erythrocytes, e.g., pyrimidine 5 nucleotidase. In addition, erythrocytes contain enzymes, such as glutamine-oxaloacetic transaminase (GOT), with no obvious physiological function; these may be remnants of its nucleated past.

This chapter is divided into four sections. The first three sections are based on the phenotype of the enzymopathy: methemoglobinemia, hemolytic anemia, and polycythemia. The final section of the chapter addresses heterogeneous issues not associated with a specific red cell phenotype, such as acquired enzyme abnormalities associated with nutritional deficiencies, use of red cell enzymes for the diagnosis of systemic diseases, and uses of red cell enzymes for population genetics and other studies.

METHEMOGLOBINEMIA

Methemoglobin

Methemoglobin Formation

Methemoglobin is a derivative of hemoglobin in which the ferrous (Fe^{++}) irons are oxidized to the ferric (Fe^{+++}) state. The ability of hemoglobin to transport oxygen is dependent on the

Figure 32-2 Auto-oxidation of hemoglobin. Iron is in the ferrous state (Fe^{++}) in deoxyhemoglobin. When oxygen is bound, an electron is partially transferred from the iron moiety to the bound oxygen, forming a ferric-superoxide anion complex (Fe^{+++}-O_2). During deoxygenation, some of the oxygen leaves as a superoxide (O_2) radical. The partially transferred electron is not returned to the iron moiety, leaving the iron in the ferric state (Fe^{+++}) and forming methemoglobin (metHb).

oxidation state of its iron moiety. Oxygen binds easily to the ferrous form of iron present in deoxyhemoglobin. In the formation of oxyhemoglobin, one electron is partially transferred from iron to the bound oxygen, forming a ferric-superoxide (Fe^{+++}-O_2) anion complex. [1] During deoxygenation, some of the oxygen leaves as a superoxide (O_2) radical. The partially transferred electron is not returned to the iron moiety, thus leaving the iron in the ferric state and forming methemoglobin (Fig. 32-2). This autooxidation of hemoglobin occurs spontaneously at a slow rate, creating 0.53% methemoglobin per day. [2] [3]

Methemoglobin is also formed from the oxidation of hemoglobin in other reactions with endogenous compounds and free radicals, including hydrogen peroxide (H_2O_2), nitric oxide (NO), O_2, and hydroxyl radical (HO). [4] [5] Exogenous compounds may oxidize hemoglobin to methemoglobin directly, by a metabolic derivative, or by

generating O_2 and H_2O_2 during their metabolism.

The ferric hemes of methemoglobin are unable to bind oxygen. In addition, the oxygen affinity of the accompanying ferrous hemes in the hemoglobin tetramer is increased.[6] As a result, the oxygen dissociation curve is left-shifted and oxygen delivery is impaired.

Methemoglobin Reduction

Although several potential mechanisms exist to reduce methemoglobin back to hemoglobin, only the NADH-dependent reaction catalyzed by cytochrome b_5 reductase (b5R) is physiologically important. Cytochrome b5R, previously known as diaphorase [7] and methemoglobin reductase, [8] contains a noncovalently-bound prosthetic flavine adeninedinucleotide (FAD) group that acts as an electron acceptor. [9] [10] [11] NADH generated from glycolysis reduces FAD to $FADH_2$, which then reduces the heme protein cytochrome b_5. Electrons from the reduced cytochrome b_5 are in turn transferred to methemoglobin, reducing iron back to the ferrous state (Fig. 32-3).

Figure 32-3 NADH-dependent methemoglobin reduction. NADH is generated during glycolysis in the reaction mediated by glucose-3-phosphate dehydrogenase (G3PD). A pair of electrons from NADH is transferred to the FAD prosthetic group of cytochrome b_5 reductase, reducing it to $FADH_2$. Two molecules of ferric (Fe^{+++}) cytochrome b_5 are then sequentially bound and reduced, forming ferrous (Fe^{++}) cytochrome b_5. An ionic complex between ferrous (Fe^{++}) cytochrome b_5 and a ferric (Fe^{+++}) subunit of a hemoglobin (methemoglobin) tetramer is formed and an electron transferred between the two hemes, creating ferrous (Fe^{++}) hemoglobin. G3P, glyceraldehyde-3-phosphate; 1,3-BPG, 1,3-bisphosphonate glyceraldehyde.

Figure 32-4 NADPH-dependent methemoglobin reduction. NADPH methemoglobin reduction can be activated by exogenously administered methylene blue. G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate; G6PD, glucose-6-phosphate dehydrogenase.

An alternative pathway mediated by NADPH-flavin reductase uses NADPH generated by glucose-6-phosphate dehydrogenase (G6PD) in the hexose monophosphate shunt as a source of electrons to reduce redox dyes, such as methylene blue, and flavin (Fig. 32-4).[12] [13] [14] Reduced methylene blue, or leukomethylene blue, nonenzymatically reduces methemoglobin. Since these electron acceptors are not physiologic, this electron transfer is not significant under normal conditions and NADPH-flavin reductase deficiency does not cause methemoglobinemia.[15] However, methylene blue administered in the treatment of methemoglobinemia serves as an exogenous electron acceptor, bypassing blocks in the cytochrome b_5 reductase pathway. Since the reduction of methemoglobin by methylene blue is dependent on NADPH generated by G6PD, methylene blue may be ineffective in the treatment of methemoglobinemia in individuals with G6PD deficiency. [16] In addition, the use of methylene blue in these patients is potentially dangerous because it may produce hemolysis. [16]

Methemoglobin can also be reduced directly by ascorbic acid, reduced glutathione, reduced flavin, tetrahydropterin, cysteine, cysteamine, 3-hydroxyanthranilic acid, and 3-hydroxykynurenine;[4] however, these reactions occur slowly and play a minor role in methemoglobin reduction.

Methemoglobinemia

Normally, the formation and reduction of methemoglobin by the mechanisms described above act to maintain a steady-state level of methemoglobin of 1% of total hemoglobin. Methemoglobinemia occurs when an imbalance due to either increased methemoglobin production or decreased methemoglobin reduction is present.

Acquired or Acute Toxic Methemoglobinemia

Most cases of methemoglobinemia are acquired, resulting from increased methemoglobin formation by various exogenous agents. Many drugs and toxins have been implicated (see box, Substances Associated with Methemoglobinemia).[17] [18]

Methemoglobinemia may occur as a result of overdoses or poisoning but may also occur at standard doses, particularly in individuals with partial deficiencies of b5R.[19] [20] Infants are particularly susceptible because their erythrocyte b5R activity is normally 5060% of adult activity. [21] [22] [23] Activity in the premature infant is even lower. Although b5R levels rise to those of an adult within months of birth, young infants are unusually vulnerable to developing toxic methemoglobinemia upon ingestion of nitrates.[24] Nitrates do not oxidize hemoglobin directly but are converted to nitrites by intestinal bacteria. Methemoglobinemia caused by nitrates in well water continues to be a problem in infants in rural areas. [25]

Methemoglobinemia has also been associated with diarrheal illnesses in infants without known toxin exposure. [26] [27] The exact mechanism leading to methemoglobinemia is unknown but may involve increased endogenous nitrite production. [28] An association with weight in the lower percentiles has been reported. [29] [30]

Although individuals with congenital, chronically elevated methemoglobin concentrations are generally asymptomatic, acute acquired methemoglobinemia may be associated with symptoms at similar methemoglobin levels. The cyanosis or slate-blue color of the skin and mucous membranes results from the different absorbance spectrum of methemoglobin compared to oxyhemoglobin. Cyanosis is clinically discernible when the absolute level of methemoglobin exceeds 1.5 gm% (1015% methemoglobin at normal hemoglobin concentrations).[31] Symptoms of methemoglobinemia are related to impaired O_2 delivery to tissues. Early symptoms include headache, fatigue, dyspnea, and lethargy. At higher levels, respiratory depression, altered consciousness, shock, seizures, and death may occur. [18]

Hereditary Methemoglobinemia

Francois[32] probably reported the first case of congenital methemoglobinemia in 1845 when he described one of his patients with chronic congenital cyanosis without obvious cardiac or pulmonary disease. A familial incidence of autotoxic cyanosis and methemoglobinemia was later described by Hitzenberger in 1932. [33]

There are three types of hereditary methemoglobinemia. Most cases are due to a deficiency of the red cell enzyme b5R. This enzyme deficiency is inherited in an autosomal recessive pattern and was the first hereditary condition in which an enzyme deficiency was identified. [8]

Deficiency of cytochrome b_5 is a rare disorder that also causes congenital methemoglobinemia. Only one well-documented case of cytochrome b_5 deficiency has been described [34] compared to over 500 reported cases of b5R deficiency. This patient, a product of an Israeli consanguineous marriage, was also a male pseudohermaphrodite. Further analysis revealed that he was homozygous for a splicing mutation in the cytochrome b_5 gene,

SUBSTANCES ASSOCIATED WITH METHEMOGLOBINEMIA

Acetaminophen (nitrobenzene derivative)

Acetanilide

Aniline dyes

Local anesthetics

- Benzocaine
- Lidocaine
- Prilocaine

Dapsone

Flutamide

Metoclopramide

Nitric oxide

Nitrites

- Amyl nitrite
- Isobutyl nitrite
- Sodium nitrite
- Nitrates (bacterial conversion to nitrites)

Nitrobenzenes/nitrobenzoates

Nitroethane (nail polish remover)

Nitrofurans

Nitroglycerin

Paraquat/monolinuron

Phenacetin

Phenazopyridine (pyridium)

Primaquine

Sulfamethoxazole

resulting in a premature stop codon and truncated protein.[35] Another family with probable cytochrome b_5 deficiency, as other causes of methemoglobinemia were excluded, was described prior to the recognition of this entity.[36] However, the inheritance pattern in this family was autosomal dominant.

The third type of hereditary methemoglobinemia, hemoglobin M (Hb M) disease (see Chap. 31), is due to an abnormal globin and is autosomal dominant. It is associated with an abnormal pattern of spectrophotometric absorbance and sometimes with abnormal migration on hemoglobin electrophoresis.

Cytochrome b5 Reductase

Function of Cytochrome b_5 Reductase

B5R, a housekeeping enzyme and a member of the flavoenzyme family of dehydrogenases-electron transferases, is involved in the transfer of electrons from the NADH generated by glyceraldehyde 3-phosphate in the glycolytic pathway to cytochrome b_5.[37] [38] Cytochrome b_5 serves as an electron donor in a variety of reactions; in erythrocytes, it transfers electrons to methemoglobin to reduce it to hemoglobin. In other cells, a reaction catalyzed by stearyl-CoA desaturase transfers electrons from cytochrome b_5 to stearyl-CoA in the endoplasmic reticulum.[39] This reaction plays an important role in fatty acid desaturation and drug metabolism.

b5R Gene

The b5R gene locus (DIA1) has been mapped to chromosome 22.[40] [41] [42] Only the rat b5R gene has been comprehensively studied;[43] [44] [45] this gene has several potential transcripts generating multiple isoforms (Fig. 32-5). Differences at the 5 ends of rat liver and reticulocyte cDNAs suggest the use of alternative promoters for the production of all forms of b5R.[43]

Two putative promoters with different characteristics have been well-described. A constitutive promoter region has similarities with housekeeping genes as it does not contain a TATA box or CAAT box but instead contains five GC box sequences (GGGCGG and CCGCCC), representing potential binding sites for the transcription factor Sp1.[46] The erythroid-specific promoter region contains several possible regulatory elements found in erythroid promoter regions, including a TATA box, CAAT-like sequences, two binding sites for the erythroid-specific transcription factor GATA-1, and a GT box.[44] Two additional promoter regions have been identified but not yet fully characterized.[45]

Figure 32-5 Cytochrome b5 reductase gene. The transcription and translation of the b5R gene is complex and utilizes multiple promoters and multiple AUG translation initiation sites (arrowheads). In addition to a strong constitutive promoter (C) and a separate erythroid specific promoter (E), weaker promoters (X and Y) are also present. Four transcripts, utilizing alternate first exons and a common downstream exon, have been reported. The strong constitutive promoter initiates transcription at the first exon, which encodes a myristylation consensus sequence and a 14-amino-acid stretch of uncharged amino acids. This transcript generates a ubiquitously expressed isoform with a 300-amino-acid residue product containing a myristylation group (closed rectangle) covalently attached to the N terminus (open diamond). The erythroid-specific promoter initiates transcription downstream at an alternate exon. This transcript contains at least two translation initiation start sites (arrowheads);

the stronger start site generates a soluble isoform consisting of 275 amino acid residues that are identical to those found in the membrane-bound ubiquitously expressed form (open rectangle). The weaker start site generates a unique membrane-bound form with an N-terminus sequence (closed diamond) that differs from that found in the membrane-bound ubiquitously expressed isoform. Two other transcripts have also been detected, albeit in small amounts; these arise from the transcription of alternate exons and are ubiquitously expressed. While the peptide sequences have been inferred from the cDNA sequences, the identity of all of the isoforms has not been unambiguously confirmed.

b5R Isoforms

Multiple isoforms of b5R are believed to be generated from a single gene by a combination of alternative promoters and alternative initiation of translation. [44] [45] One isoform, found in nonerythroid cells and reticulocytes but not in erythrocytes, is a membrane-associated isoform located on the endoplasmic reticulum (ER) membrane and the outer mitochondrial membrane (OMM).[47] [48] The ER-bound isoform participates in cholesterol biosynthesis, [49] desaturation and elongation of fatty acids, [50] [51] and drug metabolism;[52] the function of b5R on the OMM is unknown. This membrane-bound enzyme is an amphophilic protein consisting of a 275 amino acid hydrophilic moiety that contains the active site and a hydrophobic domain at the NH_2 -terminal end that anchors the protein to the membrane.[53] [54] [55] This isoform is myristylated at its amino terminus.[56] The myristylate residue appears to function in targeting this b5R isoform to the OMM; the targeting mechanism for the ER membrane remains to be determined.[57]

Two isoforms are found solely in erythroid cells. The isoform involved in methemoglobin reduction is soluble and consists of the same 275 hydrophilic amino acids found in the ubiquitously expressed membrane-associated isoform.[58] [59] The other erythroid-specific isoform is membrane-associated with an N-terminal hydrophobic sequence that differs from the sequence found in the ubiquitously expressed isoform.[44] This isoform is not myristylated and may play a role in vitamin E recycling.[60] Although this isoform contributes only 2025% of erythocyte b5R activity in adult humans, it represents a greater proportion in infants due to a decreased cytosolic form.[61] A fourth soluble isoform has been detected in rat and rabbit liver and in human placenta.[62] [63] [64]

Cytochrome b5 Reductase Deficiency

Clinical Features

Deficiency of b5R is inherited in an autosomal recessive pattern and a history of consanguinity may be present. There are two clinical types.

Type I b5R Deficiency

The majority of cases of enzymopenic congenital methemoglobinemia are type I, in which the functional deficiency of b5R is limited to erythrocytes. Homozygotes or compound heterozygotes[65] [66] have methemoglobin concentrations of 1035% and appear cyanotic but are usually asymptomatic even with levels up to 40%.[31] Some patients have reported nonspecific symptoms of headache and easy fatigability. Life expectancy is not shortened and pregnancies occur normally. Significant polycythemia (erythrocytosis) is only rarely observed. The cyanosis is of cosmetic significance only, but can be treated with methylene blue or ascorbic acid, both of which facilitate the reduction of methemoglobin through alternate pathways.[67]

In contrast to the asymptomatic, chronically methemoglobinemic homozygotes (or compound heterozygotes), heterozygous individuals are at risk for developing acute, symptomatic methemoglobinemia after exposure to exogenous methemoglobin-inducing agents. The classic description by Cohen and colleagues [19] of acute toxic methemoglobinemia in US military personnel receiving malarial prophylaxis in Vietnam demonstrated for the first time that heterozygotes for an autosomal recessive disease can, under certain conditions, develop a disease state that is more clinically significant than that of their asymptomatic homozygous peers.

Type I b5R deficiency is distributed worldwide but is endemic in the Athabascan Alaskans,[68] [69] Navajo Indians,[70] and Yakutsk natives of Siberia.[71] [72] The Navajo Indians and the Athabascan Indians of Alaska are known to share a common ancestor; the high frequency of b5R deficency in these groups suggests a common origin for all three of these populations. However, it remains to be determined whether the molecular defect resulting in b5R deficiency is identical in these populations. In other ethnic and racial groups the defect occurs sporadically. Although cyanosis is difficult to detect due to skin pigmentation, type I deficiency has been reported in two unrelated African-American families.[73]

Type II b5R Deficiency

In type II b5R deficiency, which represents 1015% of cases of enzymopenic congenital methemoglobinemia, b5R is deficient in all cells. Type II b5R deficiency has a sporadic distribution. In addition to methemoglobinemia and cyanosis, patients exhibit mental retardation and developmental delay with failure to thrive.[74] Other neurological symptoms may be present, including microcephaly, opisthotonus, athetoid movements, strabismus, seizures, and spastic quadriparesis. Life expectancy is significantly shortened. The mechanism resulting in the neurological problems is currently unknown but may involve abnormal lipid elongation and desaturation in the central nervous system.[75]

Methylene blue or ascorbic acid improves the cyanosis, as in type I b5R deficiency; however, this therapy has no effect on the neurologic aberrations. Theoretically, a bone marrow or liver transplant would alleviate the neurological problems of type II individuals if they are caused by a problem with circulating fatty acids; however, these approaches have not yet been tested. Because the enzyme defect is found in fibroblasts, analysis of b5R activity in cultured amniotic cells for prenatal diagnosis is possible.[76] [77] [78]

Assays of Enzyme Activity

Types I and II b5R deficiency are distinguished by their clinical phenotype and by analysis of enzymatic activity in erythroid and nonerythroid cells. Reports of decreased b5R activity are difficult to compare since several different assays of b5R activity, varying in their substrate and in their normal values, have been used.[2] [65] [66] [68] [72] [73] [79] [80] [81] These assays also vary in their technical difficulty. The first widely accepted b5R activity assay used a difficult to produce methemoglobin-ferrocyanide complex and its reduction by an enzyme containing tissue homogenate.[82] The most rigorous b5R enzyme activity is based on partial purification of the enzyme by an ultracentrifugation and uses the physiological enzyme substrate (cytochrome b_5 prepared by a recombinant DNA technology);[54] this assay is not readily available and is too complex for nonspecialized research laboratories. A more recent assay uses readily available ferricyanide [83] and readily differentiates type I and type II b5R deficiency because patients with type I deficiency have normal enzyme activity in platelets, fibroblasts, EBV-transformed lymphocytes, and granulocytes, while in type II deficiency the activity in nonerythroid tissues is markedly to moderately decreased.[73] [83] [84] [85]

Two families with type III deficiency, in which b5R activity was decreased not only in erythrocytes but also in platelets and leukocytes, have been described.[86] [87] However, the existence of this entity is difficult to accept since these individuals did not exhibit the neurological abnormalities characteristic of type II deficiency. Re-evaluation of one of the patients using the complex recombinant cytochrome b_5 assay confirmed b5R activity in the platelets, leukocytes, and fibroblasts consistent with type I deficiency.[88]

b5R Gene Mutations

Four point mutations in patients with type I b5R deficiency have been reported; all are missense mutations, resulting in an amino acid substitution (Table 32-1). Three of these mutations are found in the 5 end of the b5R gene.[89] [90] A fourth mutation, a G

Jenkins and Prchal[91]	G A	Missense	E212K	8	African American	

to A transition in exon 8 (E212K) in an African-American family, occurs in the 3 end. [85]

An additional mutation, resulting in the replacement of threonine by serine at codon 116, was found in exon 5 (T116S) in an African-American family with type I b5R deficiency.[91] However, this mutation was not responsible for the enzyme deficiency because the amino acid substitution causes no readily appreciable disruption of the b5R secondary structure. This missense mutation has been determined to be a high-frequency polymorphism of b5R specific for African Americans.

Type II mutations have been reported in both the 5 and 3 ends of the b5R gene (Table 32-2).[80] [81] [84] [92] [93] [94] [95] Type II mutations are heterogeneous, including deletions, point mutations, splicing site mutations, and premature stop codons, whereas all the mutations found in the type I individuals have been missense mutations.

B5R enzyme activity is affected only in erythrocytes in type I deficiency. The mutant enzyme is heat-labile and presumably is unstable and easily degraded. [96] Thus, although b5R is abnormal in all cells, only mature red cells, which cannot synthesize proteins and replace the enzyme, are significantly affected in type I b5R deficiency. Since b5R is coded by a single gene, it is hypothesized that type I b5R deficiency results from mutations producing an unstable enzyme while mutations in type II deficiency either affect the catalytic function or cause underproduction of the enzyme, resulting in a generalized decrease in functional b5R activity.

Diagnosis of Methemoglobinemia

Methemoglobinemia may be clinically suspected when cyanosis occurs in the presence of a normal PaO_2, as obtained by arterial blood gases. Pulse oximetry is inaccurate in monitoring oxygen saturation in the presence of methemoglobinemia. The blood in methemoglobinemia is dark red or a characteristic chocolate color and the color does not change with the addition of oxygen. Methemoglobinemia causes clinically discernible cyanosis when the absolute level of methemoglobin exceeds 1.5 gm%; this correlates with approximately 1015% methemoglobin.[31] Sulfhemoglobin in concentrations greater than 0.5 gm% also causes cyanosis with a normal PaO_2 and may be erroneously measured as methemoglobin. The laboratory diagnosis of methemoglobinemia is based on analysis of its absorption spectra. A fresh specimen should always be obtained because methemoglobin levels tend to increase with storage. Methemoglobin has peak absorbance at 631 nm. The standard method of assaying methemoglobin utilizes a microprocessor-controlled, fixed wavelength co-oximeter. This instrument interprets all readings in the 630 nm range as methemoglobin; thus false positives may occur in the presence of other pigments including sulfhemoglobin and methylene blue. [97] [98] Methemoglobin detected by co-oximeter should be confirmed by the specific Evelyn-Malloy method.[99] In this assay, cyanide (CN) is added and binds to the positively charged methemoglobin, eliminating the peak at 630635 nm in direct

proportion to the methemoglobin concentration. The subsequent addition of ferricyanide converts the entire specimen to cyanomethemoglobin for measurement of the total hemoglobin concentration. Methemoglobin is expressed as a percentage of the total concentration of hemoglobin.

Distinguishing the hereditary forms of congenital methemoglobinemia requires interpretation of family pedigrees as well as biochemical analyses. Cyanosis in successive generations suggests the presence of the autosomal dominant Hb M disease, whereas normal parents but possibly affected siblings imply the very rare autosomal recessive b5R or cytochrome b_5 deficiencies. Incubation of blood with methylene blue distinguishes b5R deficiency from Hb M disease because this treatment results in the rapid reduction of methemoglobin through the NADPH-flavin reductase pathway in b5R deficiency but not in Hb M disease. [100] [101] [102] To distinguish b5R deficiency from cytochrome b_5 deficiency, measurement of the level of b5R activity or cytochrome b_5 is required; however, these assays are not commercially available.

Treatment

Offending agents in acquired methemoglobinemia should be discontinued. No other therapy may be required, but if the patient is symptomatic, which is often the case in deliberate or accidental overdoses or toxin ingestion, specific therapy is indicated. Methylene blue, 12 mg/kg over five minutes, provides an artificial electron acceptor for the reduction of methemoglobin via the NADPH-dependent pathway. Response is usually rapid; the dose may be repeated in one hour, but frequently is unnecessary. Caution should be exercised to avoid overdosage because large (>7 mg/kg) cumulative doses have been reported to cause dyspnea, chest pain, and hemolysis.[103] [104] Since co-oximetry detects methylene blue as methemoglobin, it cannot be used in determining methemoglobin levels. Methylene blue should not be administered to patients with G6PD deficiency; pretreatment screening of populations with a high incidence of G6PD deficiency (e.g., African Americans, Mediterraneans, and Southeast Asians) is reasonable. If methylene blue is contraindicated, ascorbic acid may be given.

Treatment of the cyanosis in individuals with types I and II b5R deficiency is indicated for cosmetic reasons only. Treatment options include methylene blue (100300 mg/day orally) or ascorbic acid (3001,000 mg/day orally in divided doses), although this therapy has been associated with renal calculi formation. The use of riboflavin (2030 mg/day) has also been reported.[105] Unfortunately, there is currently no therapy for the neurological disorder associated with type II deficiency.

RED CELL ENZYMOPATHIES ASSOCIATED WITH HEMOLYTIC ANEMIA

The red cell enzyme deficiencies causing hemolytic anemia may be divided arbitrarily into those directly or indirectly involved with the maintenance of a high ratio of reduced to oxidized glutathione, those participating the glycolytic (Embden-Meyerhof) pathway, and pyrimidine 5 nucleotidase deficiency (nucleotide degradation and salvage pathway).

Inheritance

G6PD and phosphoglycerate kinase (PGK) are encoded on the X chromosome and are subject to dosage compensation by X chromosome inactivation. The remaining enzymes are present on the autosomal chromosomes; deficiencies of these enzymes may cause a clinical phenotype if the subject is either homozygous or doubly heterozygous for separate defects affecting both alleles.

Clinical and Laboratory Manifestations

The hemolysis associated with a red cell enzyme deficiency may be chronic or acute intermittent. Acute intermittent hemolysis is typically seen in enzyme disorders affecting glutathione metabolism, e.g., G6PD. During the hemolytic episodes, either normal red cell morphology or nonspecific abnormalities (anisocytosis, polychromasia) may be observed. In defects of enzymes affecting glutathione metabolism, the morphological sequelae of the oxidative denaturation of hemoglobin, i.e. Heinz bodies, may be seen either directly on microscopic evaluation of the blood film or after the red cells are preincubated with oxidants such as phenylhydrazine.[106] The only enzyme deficiency associated with hemolysis that causes consistent morphological abnormalities is 5 nucleotidase deficiency wherein basophilic stippling is observed. Although laboratory screening tests such as the autohemolysis test [107] were previously advocated to detect enzyme disorders causing hemolysis, they are not based on sound physiological basis and should play no role in modern hematology practice. [108] [109]

Enzymopathies of Glutathione Metabolism

Glutathione Metabolism

Erythrocytes contain a remarkably high concentration of glutathione (2 mM),[110] more than any other cell in the body. Oxidant damage converts reduced glutathione (GSH) to the oxidized form (GSSG) and also forms mixed disulfides of proteins (such as hemoglobin) containing free SH groups.

A high GSH to GSSG ratio is the major mechanism protecting the red cell proteins from oxidant damage. Enzymes involved in this metabolic pathway (Fig. 32-6) include -glutamyl cysteine synthase and GSH synthase, which synthesize glutathione; glutathione reductase, which reduces GSSG to GSH; and G6PD, which generates the NADPH required for the reduction of GSSG. Although GSH is actively synthesized in the red cells, its half-life is only three to four days due to the efflux of oxidized glutathione by an active transport mechanism. This transport mechanism provides additional protection from severe oxidative stress. [111] [112]

Although G6PD deficiency is very common, deficiencies of

Figure 32-6 Glutathione pathway. GSH, reduced glutathione; GSSG, oxidized glutathione; G6PD, glucose-6-phosphate dehydrogenase; G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate.

other enzymes of the glutathione pathway are rare. Deficiencies of these enzymes are expected to resemble G6PD deficiency with precipitation of hemolysis and formation of Heinz bodies after exposure to certain drugs, infections, and other oxidant stresses, but these enzyme defects are sometimes also associated with additional clinical manifestations.

G6PD Deficiency

History

The discovery of G6PD deficiency represents a legendary example of clinical investigation that led to the delineation of important biochemical and genetic principles. Ernest Beutler, a young physician from the University of Chicago, and his colleagues were contracted by the US Armed Forces to investigate a newly developed promising malaria drug, primaquine.[113] [114] As was standard in those years, the drug was tested on inmate volunteers in an Illinois state prison. [109] [114] [115] While the drug was tolerated by the majority of male volunteers, it was noted that some inmates developed acute hemolytic episodes. These episodes were short lasting and typically did not recur after immediate reintroduction of the drug, but could recur when the drug was reintroduced after a period of several months. These drug-induced reactions were seen in subjects of particular ethnic groups including African Americans and individuals of Mediterranean extraction. Biochemical analysis of erythrocytes during an acute hemolytic episode revealed a decrease in reduced glutathione. [114] Shortly thereafter, Carson[116] found that the cause of these unique hemolytic episodes was a deficiency of the first step of pentose shuntG6PD. Subsequent studies of carrier females by these investigators and others led to the co-discovery of X chromosome inactivation.[117] [118] [119] Further investigations of this phenomenon have played a pivotal role in our understanding of the hierarchy of hematopoiesis,[120] [121] [122] clonality of malignant neoplasms,[123] and the mechanism of X chromosome inactivation.[117] [124]

Biology and Molecular Aspects

G6PD is a housekeeping enzyme that plays an essential role not only in the reduction of NADPH from NADP but also in the generation of five carbon sugars. In the reaction catalyzed by G6PD, electrons generated by the conversion of glucose 6 phosphate to 6-phosphogluconate are transferred to NADP. The G6PD gene has been cloned;[125] [126] [127] it spans approximately 20 kilobases with 13 exons. The first exon is noncoding [127] and the second intron is unusually long, about 10 kilobases.[125] The enzyme locus *Gd* has been assigned to chromosome Xq28 near the telomeric region of its long arm [128] and is in close proximity to another important disease causing gene, factor VIII, which is only about 100 kilobases upstream. [129] G6PD activity decreases significantly as erythrocytes age, with a half-life of about 60 days.[130] Reticulocytes have five times higher enzyme activity than the oldest erythrocyte subpopulation. [131]

G6PD Deficient Variants

More than 300 G6PD variants have been defined; most are sporadic but some occur at a high frequency. G6PD variants can be divided into three categories: (1) those associated with chronic hemolytic anemia, (2) those associated with acute intermittent hemolytic anemia, and (3) those associated with no obvious risk of hemolysis. A detailed list of these variants is continuously up-dated and can be found elsewhere. [132]

In the past, new variants were defined by their enzyme activity, thermal stability, K_M for the normal (G6P, NADP) and artificial (2-deoxy G6P, deamino-NADP) substrates, K_i for NADPH, and electrophoretic mobilities under various conditions. [133] However, when the nucleotide structure of the wild-type G6PD enzyme, designated G6PD B, was established,[127] some of these previously described different variants were found to represent identical mutations [134] although in some instances they arose independently on different haplotypes of the G6PD gene. [135]

The vast majority of the mutations are missense. Mutations associated with chronic hemolysis tend to cluster in the vicinity of the NADP-binding domain of the G6PD gene while those associated with acute intermittent hemolysis or no hemolysis are scattered throughout the gene. Unlike disease-causing mutations of other genes, deletions and insertions causing frame shift and stop codon mutations are not observed; these events would be expected to be fatal since G6PD is a housekeeping gene essential for basic cellular functions. [136] One intronic mutation of the G6PD gene (G6PD Varnsdorf) has been described; [137] this mutation is associated with chronic hemolysis but the molecular consequences of this mutation have not been fully elucidated. [138]

Of the G6PD deficient variants that occur at a high frequency, the best-known are African G6PD A and the Mediterranean variants; several variants are also present in Southeast Asia. All of these variants cause acute intermittent hemolysis. African G6PD A and the Mediterranean variant of G6PD deficiency have been particularly well-studied. G6PD A+, another well-studied isoenzyme variant, is associated with no obvious hematological phenotype and has a gene frequency similar to that of G6PD A among African Americans.[139] The G6PD A mutation (G202A) arose on a G6PD A+ chromosome (A376G).[140]

Epidemiology

G6PD deficiency is one of the most prevalent disease-causing mutations worldwide, affecting hundreds of millions of people. [137] [141] Most of the G6PD isoenzymes with decreased activity are associated with only moderate health risks without a significant effect on longevity. [142] [143]

In the United States, G6PD deficiency is seen frequently among African Americans (G6PD A), affecting about 10% of males. The Mediterranean variant of G6PD deficiency is common in the southern part of Italy, Greece, Spain, and Corsica, and among Arabs and Kurdish Jews. In some populations of Kurdish Jews the gene frequency exceeds 50%. This variant is heterogeneous at the nucleotide level and is composed of several distinct mutations. [144] [145] Several variants are pandemic in Asia. G6PD Mahidol is common in Thailand and India; [146] G6PD Chinese-1, G6PD Chinese-2, G6PD Chinese-3, and G6PD Canton are frequent in China and Southeast Asia.[147] [148] [149] [150] It is assumed that malaria provided a positive selection pressure accounting for the high gene frequency of these G6PD variants (see discussion following), whereas mutations that arose in parts of the world not plagued by malaria are sporadic.

Acute Hemolysis and G6PD Deficiency

Hemoglobin is maintained in solution in a high concentration in the cytoplasm of the erythrocyte. Oxidant damage leads to the oxidation of free -SH groups of hemoglobin, forming disulfide bridges that in turn lead to decreased hemoglobin solubility. The precipitated hemoglobin may be morphologically recognized as Heinz bodies. The high ratio of reduced-to-oxidized glutathione represents the major defense against oxidative damage of hemoglobin. The enzymatic activity of G6PD generates NADPH that is utilized for the glutathione reduction (see Fig. 32-6). Reduced glutathione (GSH) reconstitutes SH groups of hemoglobin, maintaining the solubility of hemoglobin.

In G6PD deficiency, this process is variably impaired depending on the type of the G6PD mutation. In a subject with an acute hemolytic G6PD deficient variant, there is no clinical or laboratory evidence of hemolysis unless the individual is exposed to certain clinical situations. However, in subjects with a chronic hemolytic G6PD variant, the same clinical situations

lead to an acute hemolytic deterioration of a pre-existing chronic hemolytic anemia.

An acute insult, most commonly *drugs, infections,* or *fava bean ingestion,* typically precipitates hemolysis. In spite of continuation of the drug or persistence of infection, hemolysis is short-lasting, presumably due to the elimination of a subpopulation of red cells with very low G6PD activity. The younger red cells and reticulocytes, which have higher G6PD activity, are typically not hemolyzed.

Pharmaceutical agents are the best-defined precipitants of hemolysis. Although many drugs have been alleged to precipitate hemolysis in G6PD-deficient subjects, relatively few have withstood scrutiny.[108] Many of these agents are now obsolete and unlikely to be used. However, some newer chemotherapy agents, such as Adriamycin,[151] can precipitate a hemolytic episode. A selected number of these agents follow.

Substances to Be Avoided in G6PD Deficiency

Acetanilid

Doxorubicin [151]

Isobutyl nitrite[152]

Methylene blue

Naphthalene[153]

Nitrofurantoin (Furadantin)

Phenazopyridine (Pyridium)[154]

Phenylhydrazine

Primaquine

Sulfacetamide

Sulfamethoxazole (Gantanol)

Sulfanilamide

Sulfapyridine

Methylene blue administration to subjects with acute toxic methemoglobinemia is a well-known cause of severe hemolysis [108] that may be life-threatening in a subject with already compromised oxygen delivery due to methemoglobinemia (see section on methemoglobinemia earlier in this chapter).

Infections have been widely recognized as a cause of hemolysis in G6PD-deficient subjects. It is assumed that diffusion of oxidants from neutrophils undergoing oxidative bursts leads to the formation of disulfide bridges of hemoglobin.

Fava beans are a staple food in many parts of the world where G6PD deficiency is found at a high gene frequency. The hemolysis precipitated by fava bean ingestion, favism, has been widely recognized in the Mediterranean region [155] [156] and occurs only in subjects who are also G6PD deficient. However, not all G6PD-deficient variants are prone to favism. Subjects with the G6PD A variant are typically not susceptible (although a rare exception to this rule was reported) [157] and not all subjects with the more severely deficient Mediterranean variant of G6PD deficiency are sensitive. It is assumed that the hemolytic risk of fava beans depends on the source and preparation of the beans [158] as well as individual variation due to an additional genetic component that has not yet been characterized. [159] Two fava bean metabolites, divicine and isouramil, are presumed oxidants and have been reported as possible causes of favism. [158]

Evolutionary Benefit of G6PD Deficiency

Shortly after the discovery of G6PD deficiency it became apparent that the geographic distribution of populations with a high gene frequency of deficient variants overlapped closely with the prevalence of malaria. Based on this association, it was suggested that G6PD deficiency might be protective against malaria. [160] [161] Unexpectedly, no protective effect of the G6PD deficiency was found for hemizygous G6PD-deficient males. [162] However, an apparent protection was found for heterozygous females[162] who, because of X-chromosome inactivation, are mosaics for deficient and nondeficient cells. While the malaria parasite does not initially thrive in a G6PD-deficient environment, [142] it adapts after several days of residence in a G6PD-deficient erythrocyte by increased production of malarial G6PD. [163] [164] This strategy counteracts the evolutionary defense of G6PD deficiency in males; however, when the parasites infect the variably deficient and nondeficient erythrocytes of heterozygous females, malarial G6PD production is not efficient. [164]

Diagnosis

The diagnosis of G6PD deficiency is based on the generation of NADPH from NADP as detected by either quantitative spectrophotometric analysis [110] or, more conveniently, by a rapid fluorescent screening test. [165] However, false negative results are not unusual, especially if enzymatic analysis is performed shortly after resolution of acute hemolytic episodes. [115] After acute hemolysis, reticulocytes and young erythrocytes, which have much higher enzymatic activity, predominate. These false negative tests are more likely to occur when a screening test rather than a quantitative spectrophotometric analysis of the enzyme activity is used. Furthermore, a high proportion of young red cells can be conveniently estimated by concomitant spectrophotometric analysis of hexokinase, another red cell enzyme whose activity is markedly dependent on red cell age.

Because of the natural mosaicism for X-chromosome enzymes present in females (G6PD-deficient erythrocytes of heterozygous females are also prone to hemolysis), females heterozygous for G6PD deficiency are particularly difficult to diagnose. [115] In populations of African ancestry, the faster electrophoretic mobility of G6PD A discriminates it from the wild-type G6PD B isoenzyme, but electrophoresis does not differentiate G6PD A from the other African polymorphic nondeficient isoenzyme G6PD A+.[115] However, now that the nucleotide substitutions of many G6PD-deficient isoenzymes have been established, molecular diagnostic methods can be more reliably used for the accurate diagnosis of females who are heterozygous for G6PD deficiency. [143] [166]

Therapy

Drugs that are known to precipitate hemolysis in G6PD-deficient subjects should be avoided. In subjects with G6PD A-deficiency, hemolysis is typically short-lasting in spite of continuous use of the offending agent. This is not always the case in the more severe Mediterranean variant of G6PD deficiency and the precipitating agent should be always be withdrawn. When anemia is severe and symptomatic, blood transfusion may be necessary.

-Glutamyl Cysteine Synthase Deficiency

-Glutamyl cysteine synthase catalyzes the first metabolic step of glutathione synthesis. Only two families with a defect of this enzyme have been reported. [167] [168] The first family had hemolytic anemia and progressive neurological defects; the other family had hemolytic anemia but was neurologically normal. [168]

GSH Synthase Deficiency

More than a dozen families with GSH synthase deficiencies have been diagnosed. There are at least two phenotypes. In one phenotype, hemolytic anemia is the only clinically relevant defect. [169] However, in the more common phenotype both hemolytic anemia and severe metabolic acidosis [170] due to the accumulation of 5-oxoproline (see Fig. 32-6) are present. Deficiency of this enzyme in neutrophils has also been alleged to

cause intermittent neutropenia in some families. [171] One affected African American was also an albino, [172] suggesting the participation of this enzyme in melanin

metabolism. Although therapy with vitamin E has been reported to be beneficial in one patient with this disorder, [171] it was not confirmed in another study of a different family.[172]

Glutathione Reductase Deficiency

Glutathione reductase requires the riboflavin-derived co-factor FAD for full activity. Its in vitro activity with and without exogenously added FAD can be conveniently used for diagnosing riboflavin deficiency. [110] The only reported case of an inherited deficiency of this enzyme was a Dutch family with two affected siblings who had unstable GSH and developed a hemolytic crisis after eating fava beans. [173] Acquired deficiency of this enzyme secondary to riboflavin deficiency does not appear to have any hematological phenotype.

Glutathione Peroxidase Deficiency

Glutathione peroxidase contains selenium. Selenium deficiency is particularly common in New Zealand where multiple individuals with decreased enzyme activity have been found.[174] These acquired decreased activities were not associated with a recognizable phenotype; no clear-cut congenital deficiency of this enzyme has been reported.

Enzymopathies of the Glycolytic Pathway

The enzyme deficiencies of glycolytic pathway differ from those enzyme abnormalities of glutathione pathway metabolism in several ways: (1) they do not have any characteristic morphological abnormalities such as Heinz bodies, (2) they are not subject to hemolytic crisis after exposure to oxidants, and (3) their mechanism of hemolysis is not clearly understood. Furthermore, the clinical phenotype of each of these disorders differs and is unpredictable; the phenotype appears to be specific for each enzymatic defect. The diagnosis of these disorders depends on the quantitation of enzyme activity in a hemolysate prepared from leukocyte- and platelet-depleted washed red cells.[110]

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is the most common erythrocyte enzyme defect causing congenital chronic hemolytic anemia. Although this disorder is far less common than G6PD deficiency, the vast majority of patients with G6PD deficiency never suffer an acute hemolytic episode and those G6PD variants associated with chronic hemolytic states are rare.

PK Isoenzymes and Molecular Biology

The pyruvate kinase (PK) isoenzymes, M_1 , M_2 , L, and R, are products of two distinct genes. The PK M gene, which is expressed in muscle, leukocytes, platelets, brain tissue and other cells, is located on chromosome 15q22; [175] M_1 and M_2 isoforms result from differential processing of a single transcript of this gene. [176] PK-M_2 is the dominant fetal form of PK. In adult life it is largely replaced in muscle and brain by PK-M_1 but persists in leukocytes, platelets, and early erythroid progenitors. [177]

A gene on chromosome 1q21 encodes the L and R PK isoenzymes.[178] This gene utilizes two different tissue-specific promoters initiating transcription at different exons.[179] The L isoform is unique to hepatocytes and is 33 amino acids smaller than the R form, which is unique to erythrocytes. The R isoform gradually replaces the M_1 isoform as erythroid cells mature. The complexity of PK isoforms is further accentuated by the fact that the functional enzyme is a tetramer.

An allosteric enzyme with one substrate-binding site, PK converts phosphoenol pyruvate to lactate, generating ATP in the process. PK also interacts with fructose diphosphate (FDP). Similar to the interaction of hemoglobin with 2,3-BPG, this interaction changes the conformational structure of PK and decreases its Michaels enzymatic constant (K_M) for its substrate phosphoenol pyruvate, thus dramatically increasing the activity (V_{Max}) of the enzyme.[180] [181] PK-M_1 is the only isoform that does not allosterically interact with FDP. The PK M variants also have quite different kinetic properties.

Mechanism of Hemolysis and Physiologic Implications

The mechanism of hemolysis is not clear. Although it has been postulated that the defect in ATP generation contributes to the hemolytic process, [182] this explanation is insufficient because ATP deficiency is difficult to demonstrate in many patients, and other disorders with more severe ATP deficiency are not associated with significant hemolysis.[183]

It has been suggested that the anemia of PK deficiency is better tolerated than a comparable level of anemia seen in hexokinase deficiency, since the block in glycolysis occurs after the Rappaport-Leubering shunt (see section in this chapter on 2,3-BPG deficiency). The accumulation of 2,3-BPG in this downstream glycolytic defect leads to higher 2,3-BPG concentrations and thus better oxygen delivery to the tissue and superior tolerance of anemia. [184]

Patients with hemolytic anemia who undergo splenectomy, with a resultant decrease in the hemolytic process and improvement of anemia, have a higher number of reticulocytes than they did before the splenectomy. [185] [186] This perplexing observation indicates that our knowledge of the regulation of erythropoiesis and reticulocyte kinetics remains incomplete. It has been suggested that process of neonacytolysis [187] influences the premature destruction of reticulocytes and young red cells in patients with significant pyruvate kinase deficiency [186] by an as yet unknown mechanism.[187]

Clinical Presentation and Therapy

The severity of hemolysis in PK-deficient patients is highly variable. It ranges from life-threatening transfusion-requiring hemolytic anemia present at birth to a mild fully compensated hemolytic process without anemia. As would be expected with multiple mutations causing the PK deficiency, the degree of severity is similar within a given family. Affected individuals are either homozygous for the same mutation or doubly heterozygous for two different PK defects. PK deficiency is distributed worldwide, but it has been reported that the gene is more common among people of northern European extraction [188] and perhaps Chinese[189] and certain other ethnic and racial groups. In these populations, the frequency of heterozygosity may exceed 1%. [188] [189]

Patients with severe hemolysis may be chronically jaundiced, and the clinical complications of hemolytic states, including gallstones, aplastic anemia (often due to parvovirus infection), folate deficiency, and, infrequently, skin ulcers, have been all observed. As with any autosomal recessive disorder, the defect is more common in a group with a history of inbreeding or consanguinity. A high frequency of this disorder has been well-documented among Pennsylvania Amish. [190]

Splenomegaly is frequently seen but not invariable. The beneficial effect of splenectomy on hemolysis is well-documented; typically, the degree of hemolysis and anemia is ameliorated and in severe cases the transfusion requirement is generally abolished. However, as stated above, reticulocytes invariably rise postsplenectomy. Unless the patient is transfusion dependent, it is advisable to delay splenectomy until after the age of three years when the risk of pneumococcal, *Hemophilus influenzae,* and meningococcal infections declines. Although folic acid

replacement is frequently used, it may not always be necessary; however, it is inexpensive and safe.

Diagnosis

There are no specific clinical findings or morphological abnormalities in PK deficiency. No routinely available laboratory measurements aid in diagnosis, although it was previously proposed that the autohemolysis test might be helpful in the diagnosis of PK deficiency. This test does not have any physiological basis and should not be used in modern hematology practice.[109]

A screening test, utilizing crude hemolysate with one concentration substrate, has been employed for detection of pyruvate deficiency. [110] However, this screening test

misses the PK variants characterized by increased K_M and those with abnormal FDP interaction. Specialized laboratories that can perform quantitative PK enzyme analysis with various concentrations of substrate with and without FDP (the native FDP must first be removed by dialysis) may be required. [110] The mutant enzyme can be further analyzed by comprehensive kinetic and electrophoretic studies of the partially purified enzyme. [191] However, these studies have now been largely replaced by the detection of specific mutations of the enzyme at cDNA or genomic level. [192] Single nucleotide substitutions have been described as well as intronic mutations, deletions, and insertions. [193] The 1529A PK mutation appears to be particularly common even in unrelated individuals. [194]

Glucose Phosphoisomerase (GPI) Deficiency

GPI deficiency is either the second or the third most common red cell enzyme defect causing chronic hemolytic anemia (following pyruvate kinase deficiency and rare sporadic severe variants of G6PD). More than 100 families have been described. In some families, the hemolysis is severe enough to necessitate chronic blood transfusions. [195] Neonatal jaundice is common in this disorder [196] and hydrops fetalis has also been reported. [197] Although no specific therapy is available, it has been suggested that splenectomy may provide a moderate benefit. [198]

Hexokinase Deficiency

Hexokinase catalyzes the initial step of glycolysis and produces glucose 6-phosphate, which is utilized in both glycolysis and the pentose pathway (see Fig. 32-1). Fewer than 50 cases have been reported. Most are of individuals of northern European extraction, [199] although one case was found in a Chinese individual. [200] Since the metabolic defect is proximal to the generation of 2,3-BPG, it has been suggested that the resultant decreased level of 2,3-BPG leads to a left-shifted hemoglobin-oxygen dissociation curve and a more symptomatic anemia than comparable levels of anemia seen in other red cell disorders. [201] Some families have transfusion dependent hemolysis; it has been reported that splenectomy results in partial amelioration of hemolysis. Postsplenectomy, most patients required no transfusions; however, the hemolysis continued in all reported cases.

Phosphofructokinase and Aldolase Deficiencies

Deficiencies of phosphofructokinase and aldolase are rare causes of glycogen storage disease and chronic nonspherocytic hemolytic anemia. As in other rare autosomal recessive disorders, consanguinity is frequent.

Phosphoglycerokinase Deficiency

Deficiency of this X-chromosome encoded enzyme is associated with hemolytic anemia, mental retardation, and myoglobinuria. The cDNA for the phosphoglycerokinase gene has been cloned [202] and several mutants described.

Triosophosphate Isomerase Deficiency

Triosophosphate isomerase deficiency is a rare red cell defect reported to cause congenital hemolytic anemia and other severe organ dysfunctions, including progressive neurological abnormalities and early death. [203] An increased susceptibility to bacterial infections has also been described. [204] No specific therapy for this disorder is available. In a single reported case, splenectomy did not ameliorate hemolysis.

Pyrimidine 5 Nucleotidase Deficiency

Pyrimidine 5 nucleotidase participates in RNA degradation in reticulocytes. The accumulation of pyrimidines in the red cells is presumed to be toxic and a cause of hemolysis. Pyrimidine 5 nucleotidase deficiency is the only congenital hemolytic anemia due to a red cell enzyme deficiency that has a specific, consistent morphological abnormalitybasophilic stippling. [205] Thus, morphologic examination of the peripheral blood smear provides simple and inexpensive screening. Basophilic stippling is also found in hemolytic anemia due to acute lead toxicity. Lead is a powerful inhibitor of pyrimidine 5 nucleotidase [206] and determination of lead levels should be included whenever the constellation of hemolytic anemia, pyrimidine 5 nucleotidase deficiency, and basophilic stippling is found. Lead-induced acquired pyrimidine 5 nucleotidase deficiency is treatable, unlike the congenital deficiency for which no therapy is available.

POLYCYTHEMIA DUE TO CONGENITAL RED CELL ENZYME DEFICIENCY

The polycythemias (also known as erythrocytosis) comprise a group of etiologically different disorders. [207] Absolute polycythemias may be primarily due to an intrinsic defect of hematopoietic progenitors or, more commonly, secondary due to stimulation of normal hematopoietic progenitors by extrinsic factors such as erythropoietin. While most polycythemias are acquired, some are congenital. [208] One rare cause of congenital secondary polycythemia is familial 2,3-bisphosphoglycerate (2,3-BPG, previously known as 2,3-DPG) deficiency, which results from a deficiency of the red cell enzyme bisphosphoglyceromutase (BPGM). Present in a very high concentration in red blood cells, 2,3-BPG binds hemoglobin, allosterically changing hemoglobins conformation and modulating its ability to bind oxygen. Thus, a decreased 2,3-BPG level shifts the hemoglobin oxygen dissociation curve to the left (increases hemoglobin affinity for oxygen), resulting in decreased delivery of oxygen into the peripheral tissues and compensatory polycythemia.

Biochemistry

The formation of 2,3-BPG constitutes the Rapoport-Luebering shunt, [209] which is often called an energy switch because it bypasses the formation of ATP in the reaction mediated by the glycolytic enzyme phosphoglycerate kinase (Fig. 32-7). A single multifunctional enzyme, bisphosphoglyceromutase (BPGM), with both synthase and phosphatase activity controls this shunt. BPGM is a homodimer of two identical 258-amino-acid subunits. The BPGM gene has been mapped to 7q34-7q22; transcripts of the gene have been detected in higher levels in erythroid cells than in nonerythroid cells, although no erythroid-specific promoter region has been identified. [210]

The conversion of 1,3-bisphosphoglycerate to 2,3-BPG is catalyzed by the synthase activity of BPGM. 2,3-BPG is then metabolized to 3-phosphoglycerate (3-PGA), an intermediate of the glycolytic pathway, by BPGM-phosphatase activity residing in the same protein molecule. [211] [212] [213] [214] [215] The synthase activity of BPGM is activated by alkalosis, while the phophatase activity of BPGM is enhanced by acidosis. [216]

Figure 32-7 Rapoport-Luebering shunt. 2,3-BPG metabolism is regulated by a multifunctional enzyme, bisphosphoglycerate mutase, with both synthase (BPG synthase) and phosphatase (BPG phosphatase) activity. This reaction bypasses the formation of ATP in the glycolytic pathway. G-3-P, Glyceraldehyde-3-phosphate; 1,3-BPG, 1,3-Bisphosphoglycerate; 3-PG, 3-Phosphoglycerate; 2,3-BPG, 2,3-Bisphosphoglycerate; Pi, Inorganic phosphate.

Clinical Manifestations and Inheritance

Deficiency of BPGM leads to a marked decrease in 2,3-BPG levels. The resultant increased hemoglobin oxygen affinity decreases the amount of oxygen released peripherally, leading to a compensatory polycythemia. One family with this deficiency was comprehensively studied; the proband with polycythemia had severely decreased enzyme activity and 2,3-BPG levels while his children had partially reduced enzyme activity and mildly decreased 2,3-BPG levels reflected in a decreased P_5 but were not polycythemic. [217] These findings suggested an autosomal recessive disease. When the family was restudied, the propositus and two of his sisters had complete deficiency of the synthase activity of BPGM and an affected sisters child had partially decreased enzyme activity. [218] One of the sisters and the propositus were more recently found to be compound heterozygotes for two different BPGM mutations. [219] [220] The heterozygous progeny of the enzyme-deficient subjects were subsequently found to have a moderate polycythemia, [218] [220] and similar observations of polycythemia in heterozygous subjects have been reported by others. [79] [221]

Other reports [221] [222] [223] [224] [225] of reduced BPGM activity and decreased 2,3-BPG levels are difficult to interpret or do not pass rigorous biochemical and molecular biologic scrutiny. In some of these reports, the phenotype included hemolysis; however, other causes of hemolysis were not definitively excluded.

Because of the rarity of complete BPGM deficiency, it is not possible to predict the phenotype of heterozygous individuals; however, it is likely that many individuals heterozygous for this enzyme deficiency will have a mild to moderate polycythemia and in these families an apparent autosomal dominant pattern of inheritance may be observed. [79] [218] [220] [221]

Diagnosis and Therapy

The determination of hemoglobin oxygen association kinetics is the best initial-screening laboratory test for congenital secondary polycythemia. If a co-oximeter is not available, the P_{50} can be estimated from a venous blood gas measurement by a simple mathematical formula, [226] providing that both the venous PaO_2 and the hemoglobin oxygen saturation are measured. A decreased P_{50} usually results from a mutant hemoglobin. Once a hemoglobin mutant has been excluded, a biochemical assay of freshly obtained erythrocytes may be used to detect decreased erythrocyte 2,3-BPG. [110] If 2,3-BPG deficiency is found, it should be followed by an assay of BPGM activity and, if desired, analysis for the gene mutation. Because inheritance of this defect may in some families be autosomal recessive, a family history of this rare deficiency may not be present and, as in all rare recessive disorders, consanguinity should be suspected.

Only limited clinical experience with this disorder is available; the polycythemia would be expected to compensate fully for the decreased tissue oxygen delivery and no significant health impairment would be foreseen. However, a superimposed anemia, such as that caused by blood loss or nutritional deficiency, would be expected to be more symptomatic than the same level of anemia seen in subjects with normal enzyme activity and normal levels of 2,3-BPG.

DIAGNOSTIC AND OTHER USES OF RED CELL ENZYMOPATHIES

Deficiencies of some erythrocyte enzymes, such as LDH or catalase, have no discernible phenotypes. Other red cell enzymopathies do not cause abnormalities of the erythrocyte, but easily obtainable red cells serve as a convenient source of material for diagnosing systemic diseases. The red cell is capable of metabolizing galactose, but abnormalities of galactose metabolism do not have any hematological phenotype. Galactose kinase deficiency is associated with cataracts, and galactose uridinyl-1-transferase is associated with classic galactosemia (i.e., cataracts, congenital deafness, and mental retardation). Adenosine deaminase deficiency is associated with profound immunological disturbance, but no red cell abnormalities. Measurement of adenosine deaminase in erythrocytes is a convenient diagnostic tool. The activity of erythrocyte glutathione reductase, which requires the riboflavin-derived co-enzyme-FAD, can be measured with and without FAD, serving as a convenient indicator of riboflavin deficiency.

Chapter 33 - Red Cell Membrane Disorders

Patrick G. Gallagher
Petr Jarolim

INTRODUCTION

Progress in the characterization of the structure and function of red cell membrane proteins and their genes (Table 33-1) has led to considerable advances in the understanding of the molecular pathology of red cell membrane disorders. This, in turn, has led to the definition and characterization of mutations of membrane proteins as a well-defined cause of hereditary hemolytic disease. Likewise, knowledge of the molecular mechanisms underlying changes in red cell deformability, structural integrity, and shape has advanced. Importantly, red cell shape abnormalities often provide a clue to the pathobiology and diagnosis of the underlying disorder. Consequently, this chapter categorizes red cell membrane disorders according to the following morphologic and clinical phenotypes: (1) hereditary spherocytosis (HS); (2) hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), and related disorders; (3) Southeast Asian ovalocytosis (SAO); (4) hereditary and acquired acanthocytosis; and (5) hereditary and acquired stomatocytosis. Some hypotheses attempting to explain the molecular basis of these shape abnormalities are outlined in the following sections. The structure and function of the normal red cell membrane are described in Chapter 4 ; a review of that chapter will facilitate understanding the material in this chapter.

Vertical and Horizontal Interactions of Membrane Proteins and Disorders of Red Cell Shape

Palek and colleagues[1] [2] first proposed dividing membrane proteinprotein and proteinlipid interactions into two categories, vertical and horizontal interactions. Vertical interactions, which are perpendicular to the plane of the membrane, stabilize the lipid bilayer membrane. These interactions include spectrin-ankyrin-band 3 interactions, the protein 4.1-glycophorin C linkage, and the weak interactions between the skeletal proteins and the negatively charged lipids of the inner half of the membrane lipid bilayer. Horizontal interactions, which are parallel to the plane of the membrane, support the structural integrity of erythrocytes after their exposure to shear stress. Horizontal interactions involve the spectrin heterodimer site, where spectrin heterodimers assemble into tetramers, the principal building blocks of the membrane skeleton, and the contacts of the distal ends of spectrin heterodimers with actin and protein 4.1 within the junctional complex (Fig. 33-1). The interplay between proteins of the erythrocyte membrane is certainly more complex than can be classified by this model of horizontal and vertical interactions. [3] [4] However, the model serves as a useful starting place for understanding erythrocyte membrane protein interactions, particularly in reference to membrane-related disorders.

According to the vertical/horizontal model, HS is considered a disorder of vertical interactions. Although the primary molecular defects in HS are heterogeneous (including deficiencies or dysfunctions of - and -spectrin, ankyrin, band 3, and protein 4.2; see following), one common feature of HS red cells is a weakening of the vertical contacts between the skeleton and the overlying lipid bilayer membrane together with its integral proteins. Consequently, the lipid bilayer membrane is destabilized, leading to release of bilayer lipids from the cells in the form of skeleton-free lipid vesicles. [5] [6] This lipid loss, in turn, results in membrane surface area deficiency and spherocytosis.

In most patients with HE or the closely related disorder, HPP, a severe hemolytic anemia with marked microspherocytosis, poikilocytosis and fragmentation, the principal lesion involves horizontal membrane protein associations, primarily spectrin dimer-dimer interactions. In a smaller subset of HE patients with a deficiency or a dysfunction of protein 4.1 or glycophorin C, the horizontal defect resides in the junctional complex, where the distal ends of spectrin tetramers connect to

Data from Palek and Jarolim.[1]

Figure 33-1 (Top right) Vertical and horizontal interactions of membrane proteins and the pathobiology of the red cell lesion in hereditary spherocytosis and ellipto-poikilocytosis. **(Left)** A defect of vertical interactions as exemplified by the red cell membrane lesion in HS. Partial deficiencies of spectrin, ankyrin, or band 3 protein lead to uncoupling of the membrane lipid bilayer from the underlying skeleton (arrow), followed by a formation of spectrin-free microvesicles of about 0.20.5 mm in diameter (arrowheads). These vesicles can be visualized by transmission electron microscopy, but they are not seen on examination of a peripheral blood film. The subsequent loss of cell surface area and a decrease in the surface/volume ratio lead to spherocytosis. For further details, see Figure 33-3 . **(Bottom right)** Defect of horizontal interactions of skeletal proteins as exemplified by the membrane lesion in hemolytic forms of HS associated with a defect of spectrin heterodimer self-association. The molecular lesion involving a weakened self-association of spectrin heterodimers to tetramers (SpT) represents a horizontal defect of the shear stress-resisting protein interactions. It leads to a disruption of the membrane skeletal lattice and, consequently, to destabilization of the whole cell, followed by cell fragmentation, as seen on peripheral blood films. *(Modified from Palek and Jarolim,[1] with permission.)*

actin, with the aid of the 4.1 protein. In patients with severely dysfunctional spectrin mutations, the weakened spectrin dimer-dimer self-association disrupts the skeletal lattice, leading to a marked skeletal instability and cell fragments. In patients with mildly dysfunctional spectrins, red cell shape is that of biconcave elliptocytes. It is speculated that elliptocytes are permanently deformed cells because the weakened horizontal interactions facilitate a shear stress-induced rearrangement of skeletal proteins, precluding recovery of the normal biconcave shape (for details, see the discussion under Hereditary Elliptocytosis and Related Disorders). This hypothesis is not applicable to all forms of elliptocytosis. For example, in SAO, the elliptocytic/ovalocytic cells containing mutant band 3 protein are rigid and hyperstable rather than unstable. Further details are discussed in the following sections.

Acanthocytosis, Stomatocytosis, and the Bilayer Couple Hypothesis

The mechanism of acanthocytosis and stomatocytosis associated with defects of membrane proteins is much less clear. Most forms of acanthocytosis are associated with either acquired or inherited abnormalities of membrane lipids (e.g., acanthocytosis in end-stage liver disease or abetalipoproteinemia). In rare subjects with acanthocytosis, membrane protein abnormalities have been detected, but the mechanism whereby they lead to acanthocyte formation is unknown. These abnormalities occur in the McLeod phenotype, the chorea-acanthocytosis syndromes, and rare examples of acanthocytosis associated with abnormalities of the band 3 protein. In all forms of acanthocytosis studied to date, the acanthocytic shape is normalized by agents that interact with the lipids of the inner lipid bilayer leaflet. [7] These studies suggest that the shape abnormalities reflect an asymmetry in the distribution of membrane lipids between the two halves of the red cell lipid bilayer as predicted by the bilayer couple hypothesis (Fig. 33-2).[8] [9] [10] [11] This hypothesis is based on the well-established idea that the lipid bilayer is

Figure 33-2 Bilayer couple hypothesis and the discocyte-echinocyte-stomatocyte transformation. Red cell shape is determined by the ratio of the surface areas of the two hemileaflets of the lipid bilayer. Compounds (black triangles) that preferentially accumulate in the outer hemileaflet produce its expansion, followed by red cell crenation (echinocytosis or acanthocytosis). In contrast, expansion of the inner lipid bilayer leaflet leads to a cup shape (stomatocytosis) and surface invaginations. AB

highly asymmetric, with phosphatidylcholine and sphingomyelin the main phospholipids of the outer face of the bilayer leaflet. [12] According to the bilayer hypothesis, red cell shape reflects the ratio of the surface areas of the two hemileaflets of the bilayer. The preferential expansion of the outer leaflet leads to red cell crenation (echinocytosis or acanthocytosis), while expansion of the inner lipid bilayer produces a cup shape (stomatocytosis) and surface invaginations.

HEREDITARY SPHEROCYTOSIS

Definition, Prevalence, and History

The typical diagnostic features of HS include a dominantly inherited hemolytic anemia of mild to moderate severity, spherocytosis on the peripheral blood film, and a favorable response to splenectomy. However, the clinical spectrum of HS is variable [13] [14] [15] [16] and includes both mild and asymptomatic forms that may first be diagnosed late in life [17] as well as severe forms that are often inherited in a nondominant fashion. [18] [19] [20] [21] [22] The previously reported HS prevalence in Western populations of 1 in 5,000 persons [23] may be an underestimation, because milder forms of HS may be asymptomatic. [24] [25] HS has also been reported in Japanese and African populations, [26] [27] [28] [29] but its prevalence in these ethnic groups is unknown.

HS was first described in 1871 by Vanlair and Masius [30] and rediscovered 20 years later by Wilson [31] and Minkowski. [32] The next major contributions were (1) Chauffards description of increased osmotic fragility, [33] (2) reports of correction of hemolysis by splenectomy, [34] [35] and (3) the studies by Ham and Castle [36] implicating the spleen in the conditioning of hereditary spherocytes. Soon thereafter, HS membranes were found to be leaky to sodium [37] [38] and to exhibit a loss of lipids, leading to surface area deficiency. [39] [40] An abnormality of membrane skeleton was suspected; [41] subsequently several distinct molecular defects of both skeletal and transmembrane proteins have been identified (Table 33-2). [42] [43] [44] [45] [46] [47] [48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] [66] [67] [68] [69] [70] [71] [72] [73] [74] [75] [76] [77] [78] [79] [80]

Etiology and Pathobiology

Two major factors are involved in HS pathophysiology: (1) an intracorpuscular red cell defect, and (2) an intact spleen that selectively retains the intrinsically abnormal HS cells. [13] [81] [82] The accelerated red cell destruction in HS is now recognized to be a multistep process resulting from an inherited deficiency or dysfunction of one of the proteins of the erythrocyte membrane. The ensuing destabilization of the lipid bilayer facilitates a release of lipids from the membrane, leading to surface area deficiency and formation of poorly deformable spherocytes that are selectively retained and damaged in the spleen (Fig. 33-3).

Molecular Pathology

The molecular basis of HS is heterogeneous (Table 33-2). Based on a densitometric quantitation of membrane proteins separated by polyacrylamide gel electrophoresis (PAGE), HS can be divided into the following subsets: (1) isolated partial deficiency of spectrin, (2) combined partial deficiency of spectrin and ankyrin, (3) partial deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) other less common defects. [83]

Isolated Partial Spectrin Deficiency

The reported mutations of isolated spectrin deficiency include defects of both - and -spectrin. Mutations of the -spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency (Table 33-2). With one exception, -spectrin ^{Houston} , a frameshift mutation identified in several kindreds, [45] these mutations are private,

Figure 33-3 Pathobiology of the lesion in hereditary spherocytosis. The principal abnormality in hereditary spherocytosis (HS) is the deficiency of membrane surface area leading spherocytic erythrocytes. Two distinct pathways lead to reduced membrane surface area. **(A)** Primary defects of spectrin, ankyrin or protein 4.2 lead to reduced density of the membrane skeleton (solid rectangles). This causes destabilization of the lipid bilayer with the resultant loss of band 3-containing microvesicles. **(B)** Primary defects of band 3 (black ovals) result in band 3 deficiency. This leads to the loss of the lipid-stabilizing effect of band 3 with the release of band 3-free microvesicles from the membrane. Both pathways ultimately result in the loss of membrane material with a reduction in membrane surface area. The ensuing decrease in membrane surface area with formation of spherocytes is paralleled by a decrease in erythrocyte deformability that predisposes the cells to splenic entrapment and conditioning. The spleen plays a secondary, but important, role in the pathobiology of HS. Splenic destruction of abnormal erythrocytes with decreased deformability is the primary cause of hemolysis experienced by HS patients.

i.e., they are unique to individual kindreds, and they may be associated with decreased -spectrin mRNA accumulation. -Spectrin ^{Kissimmee}, a point mutation located in the highly conserved region of -spectrin involved in the interaction with protein 4.1, is dysfunctional in its in vitro binding to protein 4.1 and thereby the linkage of spectrin to actin.[46] [84] However, correction of the binding defect by reducing agents suggests that in circulating red cells, which are rich in reduced glutathione, this spectrin/4.1 protein-binding defect is not functionally expressed. [85]

In nondominantly inherited HS associated with isolated spectrin deficiency, the reported defects involve -spectrin. In normal erythroid cells, -spectrin is synthesized in large excess of -spectrin.[86] Thus, subjects with one normal and one defective -spectrin allele are expected to be asymptomatic, because -spectrin production remains in excess of -spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. [87] Patients who are homozygotes or compound heterozygotes for -spectrin defects will suffer from severe HS. Wichterle et al. described a patient with severe HS who was a compound heterozygote for two different -spectrin gene defects: in one allele, there was a splicing defect associated with an upstream intronic mutation, ^{LEPRA}; in the other allele there was another mutation, ^{PRAGUE}.[42] The ^{LEPRA} allele produces approximately six times less of the correctly spliced -spectrin transcript than the normal allele. Further studies have shown that in many patients with nondominant, spectrin-deficient HS, including a number of the patients originally described by Agre et al., [19] [20] [22] ^{LEPRA} is in linkage dysequilibrium with $^{Bug\ Hill}$, an amino acid substitution in the II domain.[88] [89] Thus it appears that the combination of the ^{LEPRA} allele with other defects of -spectrin in trans leads to significant spectrin-deficient spherocytic anemia.

In a report of a lethal and near lethal HS associated with dramatic (26% of normal) spectrin deficiency, pulse labeling studies of burst-forming uniterythroid-derived erythroblasts revealed a marked decrease in -spectrin synthesis.[90] Although the underlying molecular basis of this defect is unknown, a family history of a mild dominantly inherited HS in the mother and the finding of slightly increased osmotic fragility in the hematologically normal father suggest that the proband inherited at least two genetic defects that in a simple heterozygote have either minimal or no adverse consequences.

Combined Partial Deficiency of Spectrin and Ankyrin

The biochemical phenotype of combined partial deficiency of spectrin and ankyrin, originally described by Coetzer et al., [21] is the most common abnormality found in the erythrocytes of HS patients.[91] [92] [93] Ankyrin represents the principal binding site for spectrin on the membrane; thus it is not surprising that ankyrin deficiency is accompanied by a proportional decrease in spectrin assembly on the membrane despite normal spectrin synthesis. [92] Typically, like HS associated with -spectrin mutations, most ankyrin defects are private point mutations that are frequently associated with decreased mRNA accumulation (Table 33-2). One frameshift mutation associated with severe HS, ankyrin ^{Florianopolis}, is an exception; it has been identified in HS patients from three different kindreds from different genetic backgrounds. [53] Approximately 1520% of ankyrin gene mutations reported are de novo mutations. Varying clinical severity among affected members of the same HS kindred has been reported, resulting from parental mosaicism for ankyrin mutations in two families. [55]

A number of patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus have been described. In one patient, the underlying molecular defect involved an absence of the entire ankyrin gene on chromosome 8 due to a large interstitial deletion. [94] Ankyrin deletions may be part of a contiguous gene syndrome with the clinical manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.

Partial Deficiency of Band 3 Protein

Partial deficiency of band 3 protein is found in a subset of HS patients who present with a phenotype of a mild to moderate dominantly inherited HS with mushroom-shaped or pincered red cells.[83] [95] Most, if not all, of these patients also have concomitant protein 4.2 deficiency. Nearly 50 different band 3 mutations associated with HS have been reported (Table 33-2). These mutations are spread throughout band 3, occurring in both the cytoplasmic domain as well as in the

membrane spanning domain.[72] Lethal and near lethal HS associated with fetal hydrops fetalis, metabolic acidosis, and severe anemia with complete deficiency of band 3 and protein 4.2 from erythrocyte membranes have been reported in members of a kindred homozygous for a band 3 mutation, band 3 ^{Coimbra} .[96] Alleles have been identified that influence band 3 expression and that, when inherited in trans to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of disease.[63] [65]

In some band 3-deficient HS subjects, the deficiency is considerably greater in the dense reticulocyte-poor cells than in the light reticulocyte-rich cells. This finding, in conjunction with the report of normal band 3 synthesis and normal mRNA levels in one patient, is consistent with the idea that in some patients the band 3 protein is unstable and is susceptible to accelerated release from the cells. The mechanism of such accelerated band 3 loss is unknown, and the hypothetical molecular mechanisms include a weakened binding of band 3 protein to ankyrin as a result of a primary defect of either band 3 protein or ankyrin or as a result of a defective assembly of band 3 on the membrane. In some band 3-deficient HS patients, band 3 gene expression may be reduced or a band 3 mutation may interfere with the proper co-translational insertion of band 3 into membranes of the endoplasmic reticulum or translocation of band 3 to the plasma membrane.

A number of band 3 mutations clustered in the membrane spanning domain that replace highly conserved arginines have been described. [70] These arginines, which are all located at the cytoplasmic end of a predicted transmembrane helix, are thought to aid in maintaining the orientation of transmembrane spanning segments. In these cases, the hypothesis that the mutant band 3 does not fold and insert into the endoplasmic reticulum and ultimately into the erythrocyte membrane after synthesis appears likely.

Finally, three HS kindreds with rapidly migrating band 3 as studied by SDS-PAGE, due to a post-translational defect of band 3 glycosylation, have been described. [97] There was also a more rapidly migrating glycophorin A, which is known to be involved in band 3 glycosylation, in gels of erythrocyte membranes from these patients. The precise molecular defect(s) and its role in the pathogenesis in these patients is unknown.

Deficiency of Protein 4.2

Recessively inherited HS due to mutations in protein 4.2 is relatively common in Japan (Table 33-2).[26] [27] In these cases there is almost total absence of protein 4.2 from the erythrocyte membranes of affected homozygous patients. Protein 4.2-deficient erythrocytes may also be deficient in ankyrin and band 3 protein.

Several reports have identified protein 4.2 deficiency due to reduced membrane binding of protein 4.2 as a result of mutations in the cytoplasmic domain of band 3. [60] [66] Presumably, these mutations involve sites of protein 4.2band 3 interactions. In one report, there was partial band 3 deficiency and total protein 4.2 deficiency in the erythrocyte membranes of an HS patient who was a compound heterozygote for two different band

3 defects. Presumably, one mutant band 3 protein, band 3 ^{Okinawa} , binds all the available protein 4.2 in erythrocyte precursors because the other mutant band 3, band 3 ^{Fukuoka} , contains a mutation in a region of band 3protein 4.2 interaction. Because band 3 ^{Okinawa} cannot be inserted into the membrane, the band 3 ^{Okinawa} protein 4.2 complex is degraded, leading to the observed phenotype.

Molecular Basis of Surface Area Deficiency

Hereditary spherocytes are intrinsically unstable, releasing lipids under a variety of in vitro conditions, including adenosine triphosphate (ATP) depletion or exposure of cells to shear stress. The loss of membrane material occurs through the release of 0.2- to 0.5-m vesicles containing integral proteins devoid of spectrin. [5] [98] [99] During in vitro incubation, the loss of membrane material is of sufficient magnitude to augment the surface area deficiency, as evidenced by increased osmotic fragility of the cells after incubation.[40] [100] [101] It is generally assumed that a similar process takes place in vivo, but its experimental verification has yet to be provided.

Insofar as the molecular basis of HS is heterogeneous, it is likely that surface area deficiency is a consequence of several distinct molecular mechanisms that share a weakening of the vertical connections between the skeleton and the lipid bilayer membrane. Three distinct hypothetical pathways that may lead to surface area deficiency are depicted in Figure 33-3 . In patients with isolated spectrin deficiency or a combined deficiency of spectrin and ankyrin, the surface area deficiency may involve an uncoupling of the lipid bilayer membrane from the underlying skeleton (Fig. 33-3). In normal red cells, the skeleton forms a nearly monomolecular submembrane layer occupying more than one-half the inner surface of the membrane. Consequently, spectrin deficiency leads to a decreased density of this network (Fig. 33-4). As a result, areas of the lipid bilayer membrane that are not directly supported by the skeleton are susceptible to release from the cells in the form of microvesicles.

In HS associated with a deficiency of band 3 protein, two hypothetical pathways may lead to a loss of surface area (Fig. 33-3). One mechanism may involve a loss of band 3 protein from the cells.[95] Since band 3 protein spans the lipid bilayer membrane many times, it is likely that a substantial amount of boundary lipids are released together with the band 3 protein, thus leading to surface area deficiency. Another possible mechanism may involve a formation of band 3-free domains in the membrane, followed by the formation of membrane blebs, which are subsequently released from the cells as microvesicles. Such a hypothesis is based on the observation that aggregation of intramembrane particles (composed principally of the band 3 protein) in ghosts leads to the formation of particle-depleted domains from which membrane lipids bleb off as microvesicles. Additional evidence supporting the latter model comes from the band 3 knockout mouse model. [102] Erythrocytes lacking band 3 spontaneously shed membrane vesicles, leading to severe spherocytosis and hemolysis.

Alterations in Cation Content and Permeability

HS red cells, particularly those collected from the spleen, are somewhat dehydrated [103] [104] and abnormally permeable to monovalent cations,[105] [106] presumably as a consequence of the underlying skeletal defect. The cellular dehydration may be due to activation of pathways causing a selective loss of potassium and water, such as the K^+ , Cl co-transporter, which may be stimulated by the relatively low pH of the spleen or by oxidative damage, [107] [108] possibly in sites at which red cells are in contact with macrophages producing oxygen radicals. Furthermore, the Na^+ /K^+ pump that regulates the intracellular sodium and potassium content is hyperactive in HS cells, compensating for the increased sodium leak into the cells. Increased activity of this pump could lead to red cell dehydration, since for every two atoms of potassium transported inward, three sodium atoms are extruded from the cell. Protein 4.2-deficient HS erythrocytes have increased anion transport, whereas HS erythrocytes deficient in spectrin, ankyrin, or band 3 have normal or decreased anion transport. [106]

Entrapment of Nondeformable Spherocytes in the Spleen

The importance of the spleen in the pathophysiology of hemolysis in HS was appreciated in the original description of the disease

Figure 33-4 Ultrastructure of the membrane skeleton in normal red cells and in red cells from a patient with severe HS associated with a combined deficiency of spectrin and ankyrin. Hemoglobin-free ghosts were sonicated to open a window that allows us to see the intact skeleton at the inner membrane surface. The ghosts were fixed and negatively stained. The skeleton is preferentially stained under these conditions. **(A)** In ghosts from normal red cells, the individual skeletal proteins are in close apposition to each other and form a monomolecular layer. **(B)** In contrast, the HS skeleton is considerably less dense with the individual proteins separated by skeleton-free areas. *(Courtesy of S.C. Liu.)*

and has been substantiated by subsequent studies.[36] [81] Two factors participate in the selective destruction of the HS cell in the spleen: (1) poor deformability of HS red cells[109] [110] [111] and (2) the unique anatomy of the splenic vasculature, which acts as a microcirculation filter. [112] [113]

The poor red cell deformability is principally a consequence of a decreased cell surface/cell volume ratio resulting from the loss of surface material. [109] [114] In contrast to normal discocytes, which have an abundant surface, allowing the cells to deform and pass through narrow microcirculation openings, HS red cells lack this extra surface. Their poor deformability may be further impaired by cellular dehydration. [109] [115] [116] Interestingly, in contrast to the deformability of the intact cell, the

deformability of the HS red cell membrane is normal or even increased.[109] [117]

The principal sites of red cell entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation.[112] [113] In the rat spleen, the length and width of these fenestrations (23 m and 0.20.5 m, respectively) are about one-half the red cell diameter. Electron micrographs of spleen specimens show that very few HS red cells traverse these slits. [118] [119] [120] Consequently, the nondeformable spherocytes accumulate in the red pulp, which becomes grossly engorged, as seen in anatomic sections of the spleen obtained after splenectomy. [118] [119] [120] [121] [122]

Splenic Conditioning and Destruction

Once trapped in the spleen, HS red cells undergo additional damage marked by further loss of surface area and an increase in cell density, as is evident in cells removed from the spleen at splenectomy.[36] [82] [124] [125] In part, these conditioned red cells re-enter the systemic circulation, as revealed by the tail of the osmotic fragility curve (see later), indicating the presence of a subpopulation of cells with a markedly reduced surface area. [82] [123] [124] [125] After splenectomy, this red cell population disappears.

Earlier studies attempted to simulate splenic conditioning of HS red cells by in vitro incubation. [121] The possible conditioning factors may include a relatively low pH in the spleen[126] [127] as well as in the sequestered red cells that may further compromise the poor HS red cell deformability, [126] [127] and a contact of red cells with macrophages that may inflict additional damage on the red cell membrane.[108] [128] [129] Glucose deprivation and the ensuing intracellular ATP depletion do not appear to be significant factors, because cells collected from the spleen at splenectomy have a normal ATP content.

The conditioning effect of the spleen appears to represent a cumulative injury. The average residence time of HS red cells in the splenic cords is between 10 and 100 minutes, and only 110% of blood entering the spleen is temporarily sequestered in the congested cords, while the remaining 90% of blood flow is rapidly shunted into the venous circulation.

Although most HS red cells are eventually sequestered and destroyed in the spleen, HS cells that have been most severely damaged in the spleen can be destroyed outside this organ as well. The HS red cell surface alterations that trigger red cell phagocytosis by tissue macrophages are unknown. One possible pathway may involve alterations in phospholipid distribution within the two leaflets of the lipid bilayer, leading to the exposure in the external hemileaflet of phosphatidylserine, which promotes red cell attachment to macrophages and phagocytosis in vitro. Although the distribution of phospholipids in the two lipid hemileaflets is normal in most HS patients, altered phospholipid distribution has been demonstrated in red cells from patients with severe forms of HS. It is possible, but not proved, that similar changes in phospholipid asymmetry take place in the end-stage HS cells that are repeatedly conditioned in the spleen. Unlike senescent normal red cells and some abnormal erythrocytes, HS red cells have normal amounts of surface-associated IgG. Thus, it is unlikely that the HS erythrocytes undergo surface alterations leading to an exposure of new antigenic sites on their surface (the senescent red cell antigen).

HS and Nonerythroid Manifestations

In most HS cases, the clinical manifestations are confined to the erythroid lineage, probably because many of the nonerythroid counterparts of the red cell membrane proteins (e.g., spectrin and ankyrin) are encoded by separate genes or because some proteins (e.g., protein 4.1, -spectrin, ankyrin) are subject to tissue-specific alternative splicing. However, there are notable exceptions. Several HS kindreds have been reported with a co-segregating neurologic or muscular abnormality such as a degenerative disorder of the spinal cord, cardiomyopathy, or mental retardation. The observation that both erythrocyte ankyrin and -spectrin are also expressed in muscle, brain, and spinal cord raises the possibility that these HS patients may have a defect in one of these proteins. [130] [131] [132] This hypothesis is further supported by studies of a mouse model of HS, the *nb* mutation. [133] [134] Homozygous *nb*/*nb* mice have severe HS with spectrin and ankyrin deficiencies attributable to a primary molecular defect of ankyrin. They develop a neurologic syndrome whose progression coincides with the degeneration of Purkinje cells in the cerebellum. Purkinje cells normally express erythroid ankyrin, which is absent in *nb*/*nb* mice.[134] [135]

Defects of band 3 have been described in patients with autosomal dominantly inherited distal renal tubular acidosis. [136] [137] Unlike in most patients with heterozygous mutations of band 3, who have normal renal acidification and abnormal erythrocytes, two band 3 mutations, R589H and S613F, have been associated with renal acidification defects and normal erythrocytes. In addition, two kindreds with co-inherited HS and renal acidification defects due to band 3 mRNA processing mutations, band $3^{Pribram}$ and band $3^{Campinas}$, [64] [138] have been described. In all of these cases, the precise pathogenesis of the renal tubular acidosis is unknown.

Inheritance

Because of the heterogeneous molecular basis of HS, the putative HS genes can be assigned to several chromosomes, including chromosome 1 (-spectrin), chromosome 8 (ankyrin), chromosome 14 (-spectrin), chromosome 17 (band 3 protein), and chromosome 15 (protein 4.2) (Table 33-1). In most HS patients (75%), inheritance is autosomal dominant.[13] [14] [15] In the remaining patients, inheritance is nondominant. In these patients, HS is due to a de novo mutation, [15] [51] [52] [54] [139] which tends to occur at CpG dinucleotides and is associated with small deletions or insertions. It may also be inherited in an autosomal recessive fashion. [20] [22]

A number of cases of recessively inherited HS manifesting with severe hemolytic anemia have been reported. The majority of the affected patients were found to be severely deficient in red cell spectrin, and the putative defect has been assigned to -spectrin. [140] [141] [142] The remaining cases characterized by a recessive inheritance pattern are due to a defect in protein 4.2. [74] [76] [80] This deficiency is associated with relatively mild hemolysis, and the red cell morphology reveals the presence of stomatocytes and ovalocytes, which are not seen in other patients with HS.

Only a few cases of homozygous HS have been reported. These patients have a severe hemolytic anemia, while their parents have a very mild form of the disease. [19] [20] In contrast, the homozygous state for the more typical hemolytic form of HS appears to be lethal. [96] In one such kindred, both consanguineous parents and three offspring (presumably HS heterozygotes) had moderately severe HS, one offspring was normal, and there

were two miscarriages, a frequency consistent with the predicted homozygosity for the HS gene.

Although the clinical severity of HS is highly variable among different kindreds, in general, it is relatively uniform within a given family, in which HS is typically inherited as an autosomal dominant disorder.[15] [23] However, HS has been identified in one or more siblings whose parents had no identifiable abnormalities or only slightly abnormal osmotic fragility after incubation. In addition, HS kindreds have been described in which there was great variability in the clinical severity of affected family members.[13] [14] [16] [143] [144] A number of explanations may account for these observations: (1) There may be variable penetrance of the genetic defect. (2) There may be a de novo mutation or possibly a mild form of recessively inherited HS in the kindred. (3) Modifier alleles that influence the expression of a membrane protein leading to the variability in clinical expression may exist in the family. (4) There may be tissue-specific mosaicism of the defect.

Clinical Manifestations

Typical Forms

A typical HS patient is relatively asymptomatic. As noted in the earliest descriptions of HS, mild jaundice may be the only symptom of the disease. Splenomegaly is present in most patients,[13] [16] with the spleen occasionally reaching large dimensions. Anemia, which is usually mild to moderate, may be absent in some cases because of compensatory bone marrow hyperplasia.

Mild Forms and HS Carrier State

In some patients, anemia is absent, the reticulocyte count is normal or only minimally elevated, laboratory evidence of hemolysis is minimal or absent, [13] [14] [15] and the changes in red cell shape may be mild, escaping detection on the peripheral blood film. The presence of HS is detected only by osmotic fragility testing or during evaluation of a relative with a more symptomatic form of the disease. Some patients are first diagnosed during transient infections such as infectious mononucleosis

or parvovirus infection,[145] [146] during pregnancy, or even in the seventh to ninth decades of life as the bone marrows ability to compensate for the hemolysis wanes.

Severe and Atypical Forms

The relatively uncommon patients with spectrin-deficient, nondominant forms of HS may present with a severe life-threatening hemolysis early in life. [18] [19] [20] [21] In one report the parents, who were distant cousins, were asymptomatic HS carriers and their offspring (presumed HS homozygotes) presented in infancy with a life-threatening hemolytic anemia that was only partially improved by splenectomy. Some patients may be transfusion dependent during early infancy and childhood.

Laboratory Evaluation

Most HS patients have either a mild to moderate anemia or no anemia at all, reflecting the facts that the hemolytic rate may be very mild and that the hemolysis is fully compensated for by increased red cell production, as evidenced by reticulocytosis. Some patients, however, particularly those with nondominantly inherited HS, are severely anemic, with a hemoglobin concentration of 46 g/dl.

Despite the increased percentage of reticulocytes, which have a larger volume than mature red cells, the mean corpuscular volume (MCV) of HS red cells is often low normal or even slightly decreased, a finding that, together with a slight increase in mean corpuscular hemoglobin concentration (MCHC), reflects mild cellular dehydration. The finding of an elevated MCHC combined with an elevated erythrocyte distribution width, as determined by automated cell counters, has been found to be an excellent predictor as a screening test for HS. Another screening method utilizes the Technicon H1 counter (Tarrytown, NY) and its successors. These counters, which measure MCV by light scattering, provide a histogram of MCHCs that has been claimed to identify nearly all HS patients. [147] [148] [149] [150]

Evidence of accelerated red cell destruction, as indicated by increased lactate dehydrogenase and unconjugated bilirubin levels and decreased haptoglobin levels, as well as by reticulocytosis, is present in most patients. However, these abnormalities may be absent in individuals with a mild form of the disease.

Blood Film

In typical HS, spherocytes are readily identified by their characteristic shape on the peripheral blood film (Fig. 33-5A). They lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinized. The hemoglobinized appearance reflects both altered red cell geometry and increased cell density. In a three-dimensional view, some spherocytes have a spherostomatocytic shape that is occasionally appreciated on the peripheral blood film. In mild forms of the disease,

Figure 33-5 Blood films from patients with HS of varying severity. **(A)** Two blood films of typical moderately severe HS with a mild deficiency of red cell spectrin and ankyrin. Although many cells have a spheroidal shape, some retain a central concavity. **(B)** HS with pincered red cells (arrows), as typically seen in HS associated with band 3 deficiency. Occasional spiculated red cells are also present. **(C)** Severe atypical HS due to a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. **(D)** HS with isolated spectrin deficiency due to a -spectrin mutation.[85] [151] Some of the spherocytes have prominent surface projections resembling spheroacanthocytes. *(Blood film D was provided courtesy of D.L. Wolfe.)*

the peripheral blood smear may appear normal because the loss of surface area may be too small to be appreciated by blood smear evaluation; the cells appear as fat disks rather than as true spherocytes.

Additional morphologic features have been described in some HS patients. A subset of HS patients whose red cells are deficient in band 3 protein have some pincered red cells (Fig. 33-5B) on the peripheral blood film, a finding that is both sensitive and specific for this HS subset. [62] [95] However, pincered cells disappear after splenectomy. Cells with irregular contour were found in two patients with severe combined spectrin and ankyrin deficiency (Fig. 33-5C). Surface spiculations or acanthocytic spherocytes have been described in a number of cases of HS associated with defects in -spectrin (Fig. 33-5D). Another atypical phenotype involves the presence of sphero-ovalocytes and stomatocytes, as reported in Japanese patients with protein 4.2 deficiency.

Osmotic Fragility

The osmotic fragility test (Fig. 33-6) measures the in vitro lysis of red cells suspended in solutions of decreasing osmolarity. The normal red cell membrane is unstretchable and is virtually freely permeable to water. [151] Thus the cell behaves as a nearly perfect osmometer in that it increases its volume in hypotonic solutions progressively until a critical hemolytic volume is reached. At this point the red cell membrane ruptures and hemoglobin escapes into the supernatant solution through a hole. As a result of the loss of membrane and the ensuing surface area deficiency, the critical hemolytic volume of spherocytes is considerably lower than that of normal red cells. Consequently, these cells hemolyze more than normal red cells when suspended in hypotonic NaCl solutions. However, a finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis on the peripheral blood film.

The slight dehydration of hereditary spherocytes (which in other conditions is associated with decreased osmotic fragility) has no appreciable effect on HS osmotic fragility because of the overriding effect of the markedly diminished cell-surface area. In fact, the densest, most dehydrated cells exhibit the greatest increase in osmotic fragility. [13] [152] The osmotic fragility curve often

Figure 33-6 Characteristic osmotic fragility curves in hereditary spherocytosis. The typical curve of increased osmotic fragility is the most common finding. The tailed curve reveals a second population (a tail) of very fragile erythrocytes conditioned by the spleen. This tail disappears after splenectomy. The diagonal curve is seen in patients with severe HS. *(Modified from Dacie,[16] with permission.)*

reveals uniformly increased osmotic fragility (Fig. 33-6). In addition, in nonsplenectomized HS subjects, a tail of the osmotic fragility curve may be present, indicating a subpopulation of particularly fragile red cells conditioned by splenic stasis. [13] [82] This subpopulation of cells disappears after splenectomy. In subjects with mild HS, osmotic fragility may be normal and abnormalities can be found only after incubation that further augments the loss of surface area; however, the sensitivity of the incubated osmotic fragility test may be outweighed by a loss of its specificity. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ectacytometry, available only in specialized laboratories.

Autohemolysis and Other Tests

Red cell autohemolysis, the spontaneous hemolysis of red cells incubated under sterile conditions without glucose, was previously advocated as a sensitive test for the detection of HS. This test is being used less frequently and is probably no more sensitive than the incubated osmotic fragility test. Other tests described in the literature are not widely used (e.g., the glycerol lysis test, [25] [153] [154] [155] the pink test,[156] [157] and the skeleton gelation test [158] [159]). The former two tests, which employ glycerol to retard the osmotic swelling of red cells, are preferred in some laboratories because they are easy to perform and can be adapted to microsamples.

Detection of the Underlying Molecular Defect

Because the most common finding in erythrocytes of patients with HS is a deficiency of one or more of the membrane proteins, initial studies often include polyacrylamide gel electrophoresis of sodium dodecyl sulfate-solubilized red cell membrane proteins (SDS-PAGE) in gel systems of Laemmli and Fairbanks et al., followed by densitometric quantitation. [160] [161] This technique reveals abnormalities in 7080% of patients, defining the distinct biochemical phenotypes discussed previously. Direct quantitation of membrane proteins by classic radioimmunoassay is more sensitive than the densitometric quantitation and permits accurate measurement of the copy number of the individual proteins per red cell. The importance of the latter approach is heightened by the fact that densitometry may underestimate spectrin and ankyrin deficiencies because it involves a normalization to the band 3 protein (i.e., spectrin/band 3 ratio), the loss of which, together with

membrane lipids, may spuriously normalize the spectrin/band 3 ratio. Consequently, the spectrin/band 3 ratio is lower after splenectomy.

Subsequent strategies to search for the underlying defect are complex. Studies of protein function, which remain the reference standard in the detection of spectrin mutations in HE and HPP (see below), have been disappointing in detecting abnormalities in HS, with the exception of HS characterized by a weakened -spectrinprotein 4.1 interaction. Studies of membrane protein synthesis and assembly, using either reticulocytes or erythroblasts derived from peripheral blood burst-forming units in vitro, have been used to detect two defects: (1) a marked decrease in -spectrin synthesis in lethal HS, and (2) a primary defect involving reduced synthesis and expression of ankyrin in HS with a combined spectrin and ankyrin deficiency. [87] [90] However, these tests are likely to be insensitive in detecting mild to moderate abnormalities in membrane protein synthesis and assembly and are technically cumbersome to perform.

Another approach to beginning to identify the precise molecular defect in HS employs genetic linkage analysis. These studies, which are typically PCR-based, employ highly informative markers in or nearby the HS genes either for linkage exclusion or linkage verification. [162] [163] Disadvantages of linkage analysis include the need to study large kindreds to achieve significance and its lack of utility in studying patients with de novo mutations.

The identification of candidate genes, either by biochemical or genetic techniques, is followed by mutation detection. The most widely employed screening technique to rapidly identify candidate mutations is single-strand conformational polymorphism (SSCP) analysis. SSCP analysis identifies candidate regions in HS genes that can then be subjected to direct nucleotide sequence analysis for detection of the precise genetic defect.

Complications

Gallstones

Bilirubin stones are found in 50% of patients with HS, often even in those with a very mild form of the disease. Gallstones have occasionally been detected during infancy, but they are uncommon in very young children. [164] In a study of gallstones in HS that was conducted before the routine availability of ultrasound, approximately half of HS patients developed gallstones between 10 and 30 years of age. [165] Because of their high incidence, HS patients should be periodically examined by ultrasound for the presence of gallstones.

Crises

True hemolytic crises are relatively rare and only occasionally reported in association with infections. [164] [166] Aplastic crises during viral infections are largely attributable to infection by parvovirus B19. [145] [146] [167] [168] [169] [170] [171] This infection (erythema infectiosum, fifth disease [169] [171]) manifests with fever, chills, lethargy, malaise, nausea, vomiting, abdominal pain with occasional diarrhea, respiratory symptoms, muscle and joint pains, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities. [167] [168] [169] [170] The virus selectively infects erythroid precursors and inhibits their growth, [165] [165] [170] and the ensuing anemia, often profound, may be the first manifestation of HS. [145] [146] Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time. This has led to the description of HS outbreaks or epidemics.

Parvovirus infection has also been associated with neutropenia and thrombocytopenia. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

Rarely, patients may present with megaloblastic crises because of folate deficiency. This typically occurs in patients with increased folate demands, i.e., those recovering from an aplastic crisis, pregnant women, and the elderly. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS.

Other Complications

In patients with more severe forms of HS, other complications include leg ulcers and/or dermatitis that heal after splenectomy [172] and symptoms of expanded erythroid space, including paravertebral masses of extramedullary hematopoiesis, which may raise the possibility of an underlying neoplasm. [173] [174] Several cases of hemochromatosis in HS patients have been reported. In some, iron overload resulted from repeated transfusions; in others, the patients had two genetic defects, one involving HS and the other involving a hemochromatosis carrier state. [175] [176] [177] [178]

Over a dozen cases of HS and hematologic malignancy, including myeloproliferative disorders and leukemia, have been reported. [179] [180] It is unknown if long-standing hematopoietic stress predisposes to the development of these secondary disorders or if they occurred randomly.

Differential Diagnosis

Because of the relatively asymptomatic presentation of HS, this diagnosis should be considered during an evaluation for unexplained splenomegaly, unconjugated hyperbilirubinemia of unknown cause, gallstones at a young age, severe anemia during pregnancy, or transient anemia during acute infections. The diagnosis of HS can be missed in mild forms of the disease, because spherocytosis may not be apparent on the peripheral blood film. However, an osmotic fragility test of incubated red cells usually provides a diagnostic answer. It should be noted that spherocytosis is transiently improved and both the osmotic fragility and hemolysis are normalized in patients in whom obstructive jaundice develops. This is due to an expansion of red cell surface area that follows an increased uptake of phospholipids and cholesterol from the abnormal plasma lipoproteins. In normal red cells, this leads to target cell formation; in HS, spherocytes are transformed to discocytes. Spherocytosis and the increased osmotic fragility of HS red cells are likewise improved by iron deficiency, but the red cell life span remains shortened. In addition, coexistence of -thalassemia trait and HS partially corrects the HS phenotype.

More typical forms of HS, characterized by relatively uniform spherocytosis with increased MCHC, are usually easily distinguished from other disorders manifesting with spherocytosis, such as immune hemolytic anemias and unstable hemoglobins. In some patients, the spherostomatocytes in the rare Rh deficiency syndrome and the intermediate syndromes of hereditary stomatocytosis may be confused with HS red cells.

Therapy and Prognosis

Splenectomy

Splenectomy is curative in patients with typical forms of HS. Although red cell survival may remain slightly shortened in some patients, hyperbilirubinemia, anemia, and reticulocytosis are no longer present. Spherocytosis and the increase in osmotic fragility persists, but the tail of the osmotic fragility curve, indicating the presence of a subpopulation of cells conditioned by the spleen, disappears. [13] [82] [125] In patients with severe, nondominantly inherited HS, splenectomy produces a dramatic clinical improvement, but hemolysis is only partially corrected. [18] [20] [21]

Indications for Splenectomy

Risks and benefits should be considered carefully in HS patients before splenectomy is performed. A multitude of factors influence the decision for splenectomy in HS patients, including the risk of overwhelming postsplenectomy infection and the emergence of penicillin-resistant pneumococci. Indications for splenectomy include growth retardation, skeletal changes, symptomatic hemolytic disease (e.g., severe constitutional symptoms), anemia-induced compromise of vital organs, the development of leg ulcers, or the appearance of extramedullary hematopoietic tumors. Whether to perform splenectomy in patients with moderate HS without any of the above factors remains controversial. Because of an increased frequency of postsplenectomy infection in young children, splenectomy should not be performed earlier than 35 years of age. Rarely, a child with severe HS and growth retardation and skeletal deformities may need splenectomy earlier. Based on the recent finding that partial splenectomy improves the hemolytic rate while maintaining splenic phagocytic function, this procedure has been proposed for consideration in transfusion-dependent HS infants. In light of the high regenerative potential of splenic tissue, the long-term benefits of this procedure are uncertain.

Several weeks before splenectomy, patients should be immunized with polyvalent vaccine against *Pneumococcus* as well as vaccines against *Hemophilus influenzae*

type b and *Meningococcus*. After splenectomy, prophylactic antibiotics (penicillin V, 125 mg orally twice daily [<7 years of age] or 250 mg orally twice daily [<7 years of age, including adults]) have been recommended for at least 5 years by some, and for life by others. The duration of prophylactic antibiotic therapy after splenectomy

---

is unknown. Before splenectomy and, in some cases, after splenectomy, HS patients should take folic acid (1 mg/day orally) to prevent folate deficiency.

Early complications of splenectomy include local infection or bleeding and pancreatitis. When splenectomy is warranted, laparoscopic splenectomy is becoming the procedure of choice in many centers. Laparascopic splenectomy has been associated with less postoperative discomfort, a quicker return to preoperative diet and activities, a shorter hospitalization time, decreased costs, and smaller scars. [181] [182] [183] In general, the morbidity of splenectomy is lower in HS than in other hematologic diseases. However, the benefits of surgery must be weighed against possible complications, such as postsplenectomy infections, including the postsplenectomy sepsis syndrome.[184] [185] [186] [187] Although these complications are rare and their frequency is likely to diminish further with appropriate vaccinations, the indiscriminate performance of splenectomy in all HS patients with splenomegaly is unwarranted. [188] The risk/benefit ratio and the changing trends in indications for splenectomy have recently been reviewed. [189]

Postsplenectomy Failures

Postsplenectomy failures are due either to the presence of an accessory spleen missed during surgery (accessory spleens may be present in 39% of all patients [190] [191]) or to the presence of another superimposed red cell disorder such as pyruvate kinase deficiency. The recurrence of hemolytic anemia several years after splenectomy should raise the suspicion of development of splenunculi, resulting from autotransplantation of splenic tissue during surgery. [18] The presence of an accessory spleen or splenunculus is suggested by the absence of both Howell-Jolly bodies and the pitted cells with crater-like surface indentations readily seen by interference contrast microscopy.[192] [193] A definitive confirmation of splenosis is made by a radiocolloid liver-spleen scan or by a scan using Cr-labeled heated red cells, which are taken up by the ectopic splenic tissue. [194] [195] Spontaneous regression of HS, presumably as a result of development of hyposplenism, has been observed in two family members who had both HS and sickle cell trait.

Other Therapies

HS erythrocytes may lose additional membrane, even under optimal storage conditions, suggesting that preoperative autologous erythrocyte transfusion may be of little benefit to HS patients scheduled to undergo surgery. [196]

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

Definition, Prevalence, and History

Hereditary elliptocytosis designates a group of inherited disorders that have in common the presence of elliptical red cells on peripheral blood films. Elliptocytosis was first described by Dresbach[197] in 1904, and its heritability was firmly established by Hunter. [198] [199] Subsequent reports have revealed a considerable heterogeneity of clinical expression and have defined several distinct syndromes, including hereditary pyropoikilocytosis (HPP) and Southeast Asian ovalocytosis (SAO). [200] [201] [202]

HE is common in people of African and Mediterranean ancestry. In the U.S. population, the prevalence of HE is about 35 per 10,000. [203] [204] [205] The true incidence of HE is unknown because its clinical severity is heterogeneous and many patients are asymptomatic and without anemia. HE is considerably more frequent in areas of endemic malaria. In equatorial Africa, the prevalence of common HE has been estimated at between 0.6% and 1.6%. Worldwide, HE appears to be more common among blacks, particularly those of African origin. In Southeast Asian populations, the prevalence of SAO is as high as 30%. [200] [206] [207] [208]

The molecular basis of HE remained obscure until 15 years ago, when a defect of skeletal proteins was suggested. [209] [210] [211] [212] [213] [214] Subsequently many erythrocyte skeletal protein defects have been described, some characterized at the level of amino acid and DNA sequence.

On the basis of red cell morphology, HE can be divided into three major groups. Common HE, a dominantly inherited condition, is morphologically characterized by biconcave elliptocytes and, in some patients, rod-shaped cells. The clinical severity of common HE is highly variable, ranging from an asymptomatic condition to a severe recessively inherited hemolytic anemia, designated HPP, in which the blood film reveals numerous red cell fragments, microspherocytes, and poikilocytes. Spherocytic HE, also called hemolytic ovalocytosis, is a rare condition in which both round fat ovalocytes and spherocytes are present on the blood film. SAO, a disorder highly prevalent in the malaria-infested belt of Southeast Asia and the Pacific, is characterized by rigid, spoon-shaped cells that have either a longitudinal slit or a transverse ridge (Fig. 33-7).

Figure 33-7 Blood films of subjects with various forms of HE. **(A)** Simple heterozygote with mild common HE Sp I/65. Note the predominant elliptocytosis with some rod-shaped cells (arrow) and virtual absence of poikilocytes. **(B)** Simple heterozygote with severe common hemolytic elliptocytosis (HE Sp I/74). Note the numerous small fragments and poikilocytes. **(C)** Homozygous common HE due to doubly heterozygous state for two mutant -spectrins, Sp I/74 and Sp I/65. Both parents have mild HE. Note the many elliptocytes as well as numerous fragments and poikilocytes. **(D)** HPP, Sp I/74. The patient is a double heterozygote for mutant -spectrin (Sp I/74) and a presumed synthetic defect of this protein. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only few elliptocytes are present. Some poikilocytes are in the process of budding (arrow). **(E)** Spherocytic HE (hereditary ovalocytosis). Most red cells are oval rather than truly elliptical. Many oval cells are fat, lacking a central concavity, the feature distinguishing spherocytic HE from common HE. **(F)** Southeast Asian ovalocytosis (Melanesian). Most cells are oval, some containing either a longitudinal slit or a transverse ridge (arrow). All blood smears were photographed at the same magnification (× 1,000).

Common Hereditary Elliptocytosis

A possibility that the primary lesion of HE and HPP erythrocytes resides in the proteins of the red cell membrane skeleton was first raised by the findings of thermal instability of HPP spectrin, [209] [210] retention of the elliptical shape in HE membrane skeletons, disintegration of membrane skeletons after exposure to shear stress, defective self-association of spectrin dimers to tetramers, [212] [213] altered susceptibility of spectrin to tryptic digestion, and a deficiency of the skeletal proteins spectrin and protein 4.1. A large number of reports followed that documented either dysfunction or deficiencies of several membrane skeletal proteins. In many cases, the underlying genetic defect has now been defined.

Etiology

Spectrin Mutations

The most common defects in HE, found in about two-thirds of all patients, are mutations of - or -spectrin. [215] [216] Both - and -spectrin are elongated flexible molecules consisting of triple helical repeats connected by nonhelical segments. [217] [218] These polypeptides are associated side to side in an antiparallel position, forming a flexible, rodlike heterodimer (Fig. 33-8) in which the N-terminus of -spectrin and the C-terminus of -spectrin form the head region of the heterodimer. Spectrin heterodimers associate head to head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers, in turn, are interconnected into a highly ordered two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1. [219] [220]

The contact site between the - and -spectrin chains of the opposed heterodimers is a combined triple helical repetitive segment in which the first two helices are contributed by the C-terminus of -spectrin, while helix 3 is the first helical segment of -spectrin (Fig. 33-9).[221] The spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers. Most -spectrin defects described to date reside at or near the N-terminus of -spectrin, which is involved in the heterodimer contact (the so-called I domain defined by limited tryptic peptide mapping; see the discussion under Laboratory Evaluation and Fig. 33-8). Consequently, these mutations impair the self-association of spectrin into tetramers. Most -spectrin mutations reported are point mutations (Fig. 33-9). These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Most of the reported elliptocytogenic -spectrin mutations are C-terminal point mutations or truncations (Fig. 33-9) that disrupt the formation of the combined triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers. All of these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, which gives rise to a 74-kd I peptide.

Although most spectrin mutations reside in the vicinity of the -spectrin self-association site, several mutations residing in the II domain have been described. [222] [223] [224] These mutations are asymptomatic in the simple heterozygous state but cause elliptocytic hemolytic anemia, which may be severe, in homozygous patients.

Protein 4.1 Mutations

Another group of elliptocytogenic mutations, although less common than spectrin mutations, are quantitative or qualitative defects of protein 4.1. Protein 4.1 is a

multifunctional protein that contains several important functional sites, including the

Figure 33-8 Schematic representation of the molecular assembly of the membrane skeleton and the molecular defects in HE and HPP. Spectrin is composed of -spectrin and -spectrin heterodimers (SpD) that associate in their head regions into tetramers. At their distal ends, SpD bind to the junctional complexes of oligomeric actin (band 5) and protein 4.1. Additional proteins found in the junctional complex, such as adducin, tropomyosin, and protein 4.9, are shown in the lower enlarged area. The membrane skeleton is attached to transmembrane proteins by interactions of -spectrin with ankyrin (protein 2.1; black arrow designates the ankyrin-binding site in -spectrin), which in turn binds to the cytoplasmic domain of band 3, and by linkage of protein 4.1 to glycophorin C. The known protein dysfunctions in HE and HPP include (1) defects of the SpD head region due to a mutation of either - or -spectrin, causing impaired assembly of SpD into tetramers, and (2) defects of proteins of the junctional complex such as a qualitative or quantitative defect of protein 4.1 or glycophorin C.

spectrin-binding domain, where 4.1 binds to the distal end of the spectrin heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and a basic N-terminal domain, where 4.1 interacts with glycophorin C, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.[225] [226] [227] [228]

Studies of 4.1 mRNA from normal red cells revealed multiple 4.1 isoforms resulting from alternate mRNA splicing. Alternate translation initiation sites are present in the protein 4.1 mRNA. When an upstream AUG is utilized, isoforms greater than 80 kd are synthesized. During erythropoiesis, this upstream AUG is spliced out and a downstream AUG is utilized, leading to the production of the 80-kd mature erythroid protein 4.1 isoform. [229] On SDS-PAGE, protein 4.1 is resolved into two bands of different sizes: 4.1a and 4.1b. The larger band, 4.1a, is typically found in normal red cells, while the shorter one, 4.1b,

Figure 33-9 Mutations of - and -spectrin affecting the association of spectrin dimers into tetramers. Schematic representation of the self-association site between the - and -spectrin chains into heterodimers. Full circles denote point mutations and open circles denote deletions and insertions, all of which affect self-association of spectrin heterodimers into tetramers. The position of open circles corresponds to the last normal amino acid preceding the mutation. The numbering of amino acids and the respective codons of -spectrin is based on the cDNA sequence, including the first six amino acids not detected by protein sequencing.[239] [240] Most mutations either increase tryptic cleavage at normal sites or open new tryptic cleavage sites (short arrows), giving rise to abnormal tryptic peptides. Their sizes are indicated next to the short arrows. The size of these abnormal peptides provides a basis for designation of some of these mutations (e.g., Sp I/46). The tryptic cleavage site creating the normal 80-kd I peptide is denoted by the long arrow. The spectrin repetitive segments are phased according to conformation, rather than sequence homology, e.g., repetitive segment I is formed by helices 1, 2, and 3. Correspondingly, the atypical repeat at the contact site of self-association contains part of an -spectrin repeat (helix 3) and part of a -spectrin repeat (helices 1 and 2). Note that most spectrin mutations are located within helix 3 of each repetitive segment. *(From Palek and Jarolim,[1] with permission.)*

represents the major isoform of reticulocytes. The 4.1b isoform is converted into the 4.1a isoform by deamidation of Asn 502.

A partial deficiency of protein 4.1 is associated with mild dominantly inherited HE, [230] [231] [232] [233] [234] while a complete deficiency (a homozygous state) leads to a severe hemolytic disease.[234] [235] Homozygous 4.1() erythrocytes fragment more rapidly than normal at moderate sheer stresses, an indication of their intrinsic instability.[236] Membrane mechanical stability can be restored by reconstituting the deficient red cells with protein 4.1 or the protein 4.1/spectrin/actin-binding site. [237] Homozygous protein 4.1() erythrocytes also lack p55 and have only 30% of the normal content of glycophorin C. These homozygous 4.1() erythrocytes, as well as glycophorin C() Leach erythrocytes, demonstrate decreased invasion and growth of *Plasmodium falciparum* in vitro.[238]

Most patients with protein 4.1-associated elliptocytosis are of North African descent. [215] [241] Mutations associated with protein 4.1 deficiency have included a deletion that includes the exon encoding the erythroid transcription start size and mutations of the transcription initiation codon. [242] [243] [244] [245] Qualitative defects of protein 4.1 protein include deletions and duplications of the exons encoding the spectrin-binding domain, leading either to truncated or elongated forms of protein 4.1. [233] [246] [247] Electron microscopic studies of homozygous 4.1() erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1 plays an important role in maintenance not only of the skeletal network, but also of the integral proteins of the membrane structure.[248]

Glycophorin C Deficiency

Glycophorin C has been found absent due to a variety of molecular defects. In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal red blood cell morphology, and homozygous subjects have no anemia and only mild elliptocytosis apparent on the peripheral blood film.

Glycophorin C deficiency with elliptocytosis, the so-called Leach phenotype, [249] [250] caused by reduced expression of glycophorin C, should be distinguished from the immunochemically defined phenotypes Gerbich and Yus, in which abnormal glycoproteins are formed that can functionally substitute for normal glycophorin C and preserve the normal red cell shape.[251] [252] The Leach phenotype is usually due to a large deletion of genomic DNA (7 kb) that removes exons 3 and 4 from the GPC/GPD locus.[253] [254] The genetic basis of the Leach phenotype in one patient has been reported to be due to a nucleotide deletion leading to frame shift with premature chain termination.

Glycophorin C-deficient subjects are also partially deficient in protein 4.1 and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane.[255] [256] It has been speculated that the protein 4.1 deficiency

in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, subjects deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Pathobiology of the Red Cell Lesion

Most of the elliptocytogenic mutations of spectrin reside within, or in the vicinity of, the spectrin heterodimer self-association site, disrupting this region and consequently disrupting the two-dimensional integrity of the membrane skeleton. These horizontal defects are readily detected by ultrastructural examination of membrane skeleton, which reveals disruption of a normally uniform hexagonal lattice (Fig. 33-10).[99] Consequently, membrane skeletons are mechanically unstable, as are whole cell membranes and the cells.[6] [257] In patients with severely dysfunctional spectrin mutations, or in subjects who are homozygous or doubly heterozygous for such mutant proteins, this membrane instability is sufficient to cause red cell fragmentation with hemolytic anemia under conditions of normal circulatory shear stress.

The pathobiology of the elliptocytic shape is less clear. Red cell precursors in common HE are round, and the cells become progressively more elliptical as they age in vivo.[203] [258] [259] Red cells subjected to shear stress in vitro, or red cells flowing through microcirculation in vivo, have an elliptical or parachute-like shape, respectively. [260] It is possible that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape because the weakened spectrin heterodimer contacts facilitate skeletal reorganization, which follows axial deformation of cells resulting from application of a prolonged or excessive shear stress. This reorganization is likely to involve breakage of the unidirectionally stretched protein connections followed by the formation of new protein contacts that preclude the recovery of a normal biconcave shape.[257] This process has recently been shown to account for permanent deformation of irreversibly sickled cells. [261]

In HPP, the recessively inherited form of HE characterized by severe hemolysis, red cells have two abnormalities. They contain a mutant spectrin that characteristically disrupts spectrin heterodimer self-association, and they are also partially deficient in spectrin, as evidenced by a decreased spectrin/band 3 ratio. [216] [262] In some HPP cases, this biochemical phenotype is a consequence of a double heterozygous state for an elliptocytogenic -spectrin mutation and a defect involving reduced -spectrin synthesis. [87] [263] [264] Such synthetic defect of -spectrin is fully asymptomatic in the heterozygous carrier, because under normal conditions, the synthesis of -spectrin is about three to four times greater than that of -spectrin.

Figure 33-10 Electron micrographs of negatively stained, artificially extended membrane skeletons from **(A)** a control subject, **(B)** a patient with moderately severe HS with partial spectrin deficiency, **(C)** a subject with mild heterozygous HE with a mutant spectrin characterized by a defective self-association of spectrin dimers to tetramers, and **(D)** an HPP subject carrying a severely dysfunctional mutant spectrin. The skeletons were uniformly stretched so that their major protein components and their connections are visible. Only one skeletal layer is exposed. Note the uniform, largely hexagonal lattice in the control sample **(A)**. The globular structures represent junctional complexes (JC) composed of oligomeric actin, while the interconnecting fibers represent spectrin tetramers (Sp). **(B)** The skeletons from an HS patient with a mild spectrin deficiency. The skeleton appears morphologically intact, because spectrin is largely in a tetrameric form. **(C)** A carrier of the spectrin mutation having a mild increase in unassembled dimeric spectrin in the crude spectrin extract and a mildly disrupted skeletal lattice. **(D)** The skeleton from the HPP patient is grossly disrupted. This disruption presumably underlies the marked membrane instability of red cells and red cell fragmentation. The junctional complexes are clustered and only few interconnecting spectrin tetramers can be seen. Membranes from this patient have a marked increase in unassembled (dimeric) spectrin and their spectrin content is reduced to about 70% of normal. *(Courtesy of S.C. Liu.)*

When present in conjunction with an elliptocytogenic mutation of -spectrin, such a synthetic defect augments the expression of the mutant spectrin. Because the elliptocytogenic -spectrin mutants are often unstable, [87] [262] the combination of the two defects leads to spectrin deficiency in the cells. Other HPP subjects are homozygous or doubly heterozygous for one or two elliptocytogenic spectrin mutations, respectively. [87] [263] In such cases, the spectrin deficiency may be a consequence of spectrin instability that reduces the amount of spectrin available for membrane assembly. Furthermore, in red cells containing a high fraction of unassembled dimeric spectrin, the spectrin deficiency may in part be related to the stoichiometric ratio of one ankyrin copy per one spectrin tetramer (i.e., two spectrin heterodimers). Consequently, only about one-half of spectrin heterodimers succeed in attaching to the ankyrin-binding sites. The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of red cell surface area deficiency (as reflected by the presence of microspherocytes on the peripheral blood film), suggests that the membrane dysfunction involves both vertical interactions (a consequence of spectrin deficiency, see above) and horizontal interactions involving the elliptocytogenic spectrin mutation.

The red cell lesion in protein 4.1 deficiency shows similarities in regard to cell shape and membrane stability to the above elliptocytogenic mutations of spectrin, [257] suggesting that the deficiency principally affects the spectrin-actin contact (i.e., a horizontal interaction) rather than the skeleton attachment to glycophorin C via protein 4.1 (a vertical interaction).

The molecular basis of elliptocytosis and the mechanical instability of glycophorin C-deficient red cells is not fully understood. However, recent studies suggest that the deficiency of glycophorin C is not directly responsible for the altered mechanical properties. Instead, the mechanical instability appears to be related to a concomitant partial deficiency of protein 4.1, as evidenced by a full correction of membrane instability by introduction into the cells of protein 4.1 or its spectrin-binding peptide, which facilitates the contact of -spectrin to actin. The superimposed deficiency of protein 4.1 is likely to be related to the fact that glycophorin C serves as an attachment site for protein 4.1 to the membrane, recruiting protein 4.1 to the red cell membrane. The effects of the above defects on the mechanical stability of glycophorin C-deficient cells appear relatively minor, because glycophorin C-deficient subjects have no detectable hemolytic anemia and the mechanical properties of the red cells are normal when tested by micropipette aspiration.

Previous studies of HE red cells revealed increased utilization of ATP and 2,3-diphosphoglycerate, [265] presumably due to increased transmembrane sodium movements.[266] As a result of the underlying skeletal defect, HE and HPP red cells also exhibit an abnormally increased Na, K, and Ca permeability. [267] [268] The latter defect was proposed to represent the primary molecular lesion in a case of severe microcytic hemolytic anemia associated with thermal instability of red cells, but subsequent studies of this patient identified a spectrin mutation. [267] [268]

Inheritance

In most patients, HE is inherited as an autosomal dominant disorder. The clinical severity is highly variable both among different kindreds (reflecting heterogeneous molecular lesions[219] and, to a lesser extent, within a given kindred, presumably because of other genetic or acquired defects that modify disease expression. [269] [270] [271] Occasionally, HE is inherited as an autosomal recessive condition from an asymptomatic parent who carries the same molecular defect of spectrin as the HE offspring. HE is linked to blood group antigens Rh and Duffy, the genes of which are located on chromosome 1, the Duffy blood group locus being close to the gene for -spectrin,[272] [273] while the Rh gene locus (1p 33) is close to the gene for protein 4.1 (Table 33-1). [205] [274] [275]

The inheritance of HPP, a disorder closely related to HE, is autosomal recessive: one of the parents carries the -spectrin mutation and either is asymptomatic or has mild HE, while the other parent is fully asymptomatic and has no abnormalities detectable by current biochemical approaches. [2] [219] However, several HPP patients have recently been studied who were doubly heterozygous for two -spectrin mutations; in the heterozygous parents, these mutations were either silent or expressed as mild HE.[276]

Clinical Manifestations

In view of the striking molecular heterogeneity of common HE, it is not surprising that the clinical spectrum of this disorder is variable, ranging from an asymptomatic trait without hemolysis to a life-threatening hemolytic anemia.

Mild Hereditary Elliptocytosis and Asymptomatic Carrier State

In most of these subjects, HE is found accidentally during evaluation of the peripheral blood film. Although some HE subjects have a mild compensated hemolytic anemia,[271] [277] [278] others do not have any evidence of hemolysis, their red cell survival is normal, and the peripheral blood film may reveal only modest (15%) elliptocytosis;[2] [279] they even may be blood donors. The molecular basis of mild HE is heterogeneous, and the reported molecular defects include both - and -spectrin mutations, partial deficiency of the 4.1 protein, and the absence of glycophorin C. Some individuals carrying the spectrin mutation are completely asymptomatic, including normal red cell morphology; this is often the case in one of the parents of a patient with HPP. [2] [279] [280] [281]

Hereditary Elliptocytosis with Sporadic Hemolysis

Worsening of hemolysis together with the appearance of poikilocytes on the peripheral blood film has been reported in patients with hypersplenism, infections, or vitamin B_{12} deficiency,[2] as well as in those with microangiopathic hemolysis such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura.[282] In the latter two conditions, worsening hemolysis may be due to microcirculatory damage superimposed on the underlying mechanical instability of the red cells.

Hereditary Elliptocytosis with Neonatal Poikilocytosis

Neonatal offspring of parents with mild HE present with symptomatic hemolytic anemia and a marked poikilocytosis. During the first year of life, the hemolysis and poikilocytosis abate, and the clinical picture transforms into that of mild HE. [283] [284] [285] Such patients typically carry one mutant -spectrin allele. [2] [279] The severity of the molecular defect, in terms of the percentage of spectrin dimers and the amount of mutant spectrin in the cells, is the same in the neonatal period as it is later in life. The worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG).[286] The ensuing elevation of free 2,3-DPG levels has a marked destabilizing effect on the spectrin-protein 4.1-actin interaction, [286] [287] thereby further destabilizing the membrane skeleton.

Hereditary Elliptocytosis with Chronic Hemolysis

Patients with HE with chronic hemolysis present with moderate to severe hemolytic anemia with elliptocytes and poikilocytes on peripheral blood film; some require splenectomy.[269] [270] [271] [288] [289] In some of the kindreds, the hemolytic HE has been transmitted through several generations. [290] [291] In two families, the affected individuals carried a severely dysfunctional spectrin, Sp I/74. In some kindreds, not all of the HE subjects have chronic hemolysis;

some have a mild hemolysis only, presumably because of another genetic factor modifying the disease expression. [269] [271]

Homozygous and Compound Heterozygous Hereditary Elliptocytosis

Several HE individuals have been described who were apparent homozygotes for the HE gene. [2] [279] [292] More recently, these individuals were found to be either homozygotes or compound (double) heterozygotes for one or two - or -spectrin mutations. [263] [293] [294] [295] The clinical severity is variable, depending on the severity of the underlying molecular defect; patients homozygous for the mildly dysfunctional Sp I/65 have a relatively mild hemolytic anemia that does not require splenectomy, while other homozygous or doubly heterozygous patients, such as those with the Sp I/74 mutation, have a severe, life-threatening disease. [263] [293] [296] In addition, peripheral blood films of some homozygous HE subjects (e.g., Sp I/74) contain numerous very small microspherocytes, and the red cells are partially deficient in spectrin. Thus, their clinical presentation is indistinguishable from that of patients with HPP.

Hereditary Pyropoikilocytosis

Under the term HPP, Zarkowsky et al. described an autosomal recessive severe hemolytic anemia with striking micropoikilocytosis and thermal instability of red cells.[297] It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of both HE and HPP in the same family and by the presence of the same molecular defect of spectrin. Unlike HE subjects carrying the spectrin mutation, the red cells of HPP subjects are also partially deficient in spectrin.[216] [262] Typically, one parent of the HPP offspring carries an -spectrin mutation while the other parent is fully asymptomatic and has no detectable biochemical abnormality. In many such patients, the asymptomatic parent carries a silent thalassemia-like defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP offspring. [2] [279] Some HPP subjects inherited two -spectrin mutations; either their parents were hematologically normal or one had mild HE.[263] [276] [279] In these HPP subjects, spectrin deficiency may be related to instability of the mutant spectrin. In one such doubly heterozygous proband, the red cell spectrin content (spectrin/band 3 ratio) was normal, the hemolysis was mild, and the peripheral blood smear resembled that of hemolytic HE (poikilocytes and elliptocytes) rather than HPP, further highlighting the overlap between these two disorders. [298] The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder; it is also found in HE subjects carrying this -spectrin mutation, both in the homozygous and in the heterozygous state.[263] HPP is seen predominantly in black subjects, but it has also been diagnosed in Arabs and whites. [215] [299] [300] [301]

Molecular Determinants of Clinical Severity

The severity of hemolysis in common HE often varies not only among different kindred but within a given family as well. The two principal determinants of severity of hemolysis are the spectrin content of the cells and the percentage of dimeric spectrin in the crude spectrin extract. [5] The fraction of dimeric spectrin in such extracts in turn depends on several factors. The first of them is the degree of dysfunction of the mutant spectrin. Typically, mutations that are either within or near the combined triple helical repetitive segment representing the spectrin heterodimer self-association site produce a more severe clinical phenotype and a more severe defect of spectrin function than are seen with point mutations in the more distant triple helical repeats. [264] Second, the percentage of the dimeric spectrin depends on the fraction of the mutant spectrin in the cells, which in turn is determined by the gene dose (e.g., simple heterozygote versus homozygote or double heterozygote) or the presence of other genetic defects such as the presence, in trans, of a defect leading to a reduced -spectrin synthesis in some subjects with HPP.

The low-expression -spectrin allele ^{LELY} is the best-characterized abnormality affecting spectrin content and clinical severity. Initially, a polymorphism of the V domain, $^{V/41}$, was identified in HE patients who, when they inherited $^{V/41}$ in trans, had more severe HE than expected. Subsequently an amino acid substitution of exon 46, Leu1857Val, and partial skipping of exon 46, linked to the $^{V/41}$ polymorphism, were identified as the characteristics of the ^{LELY} allele. These abnormalities are located within the site at which spectrin monomers assemble into heterodimers (the spectrin heterodimer nucleation site). [264] [302] [303] In vitro studies suggest that the inability of -spectrin chains to assemble into the mature membrane skeleton is due to a combination of decreased dimer-binding affinity and increased proteolytic cleavage of the mutant -spectrin chains.[304] The presence of ^{LELY} in trans diminishes the propensity of the otherwise normal allele to associate with the corresponding -chain, favoring the attachment of the elliptocytogenic -spectrin allele. Conversely, coexistence of the -spectrin mutation in cis and the mutation involving the -spectrin nucleation site diminishes the propensity of the mutant allele to be incorporated into the spectrin heterodimer, thereby ameliorating the clinical severity of this mutation. [264] [303] The ^{LELY} allele is clinically silent by itself, even when inherited in the homozygous state, probably because -spectrin is normally synthesized in three- to fourfold excess.

Certain acquired factors may affect the clinical severity of HE. In neonatal red cells, the weak binding of 2,3-DPG by fetal hemoglobin leads to an increase in free 2,3-DPG, which in turn induces a superimposed destabilization of the spectrin-actin-protein 4.1 interaction. [286] [287] Lastly, hemolytic anemia can be worsened by several acquired conditions, including those that alter the microcirculatory stress to the cells. [282]

Laboratory Evaluation

Blood Film and Laboratory Evidence of Hemolysis

A careful blood smear evaluation is essential both for the diagnosis of HE and for the classification of the disorder into the three major subtypes outlined earlier (Fig. 33-8). In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is characteristically minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of round fat ovalocytes is associated with accelerated red cell destruction. In patients with hemolytic forms of common HE, poikilocytosis is characteristically found on the blood film. In severe forms of HE, particularly in homozygous HE, many red cells circulate as cell fragments, producing a marked decrease in MCV. The finding of red cell fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP (Fig. 33-7).

Osmotic, Thermal, and Mechanical Fragility

Osmotic fragility is increased in HPP, in spherocytic elliptocytosis, and in HE subjects with poikilocytosis apparent on the peripheral blood film. [2] [305] In patients with a mild common HE without poikilocytosis on the peripheral blood film, osmotic fragility is normal. [306]

Thermal instability of red cells was originally reported by Zarkowsky et al. as a characteristic feature of HPP. [297] It reflects thermal instability of the mutant spectrin: in normal red cells, spectrin is denatured and red cells fragment at 50°C. HPP red cells fragment and their spectrin denatures at 41°C. However, the diagnostic value of this test is limited, because thermal instability

of red cells is also noted in HE red cells containing mutant spectrin. [263] In contrast, an occasional patient with otherwise typical HPP may have normal thermal stability of both red cells and spectrin. Red cells in common HE have unstable membranes and membrane skeletons when subjected to shear stress. [2] [236]

Electrophoretic Separation of Solubilized Membrane Proteins

In HE and HPP, SDS-PAGE may reveal proteins of abnormal mobility, the origin of which can be subsequently identified by Western blotting (e.g., truncated - or -spectrins in HE and HPP, or elongated or truncated forms of the 4.1 protein, and a partial or, rarely, complete deficiency of the 4.1 protein in HE) (Fig. 33-11A). In HPP, SDS-PAGE reveals a partial deficiency of spectrin, as indicated by a decreased spectrin/band 3 ratio. [216] [262] Spectrin deficiency, in conjunction with an elliptocytogenic spectrin mutation affecting the spectrin heterodimer contact, is invariably found in HPP.

In a rare subject with a mild recessive HE, it is useful to stain the gels with the periodic acid-Schiff reagent. This approach may reveal a deficiency of glycophorin C. Glycophorin C deficiency is also found in patients deficient in the 4.1 protein, possibly because the latter protein plays a role in the recruitment of glycophorin C on the membrane.[242]

Nondenaturing Gel Electrophoresis of Low Ionic Strength Spectrin Extract

Analysis of the ratio of tetrameric and dimeric spectrin in the low ionic strength extracts reveals the most common functional abnormality in HE (i.e., weakened

self-association of spectrin heterodimers into tetramers) (Fig. 33-11B). Because the spectrin dimer-tetramer interconversion has a high activation energy, it is kinetically immobilized at near 0°C. [308] Consequently, the percentage of spectrin dimers and tetramers in the 0°C crude spectrin extract reflects the relative distribution of these species in the red cell membrane in situ. [309] Mutations of - or -spectrin residing within or near the -spectrin heterodimer self-association site invariably lead to an increase in the fraction of dimeric spectrin (normal range, 5 ± 5%) in the crude 0°C spectrin extract. [264] [310]

Tryptic Peptide Mapping of Spectrin and the Detection of the Underlying DNA Defect

As reviewed elsewhere, [264] [310] [311] tryptic digestion of spectrin under controlled conditions followed by electrophoretic separation gives rise to highly reproducible tryptic peptide patterns (Figs. 33-11C and D). Among these peptides, the 80-kd I domain peptide representing the self-association site of the normal

Figure 33-11 Evaluation of defects of the membrane skeleton in HE and HPP. **(A)** Membrane proteins from control red cells (lanes 1 and 3) and red cells of the two patients (lanes 2 and 4) were solubilized in sodium dodecylsulfate and electrophoresed in a Fairbanks nonlinear 3.517% polyacrylamide gradient gel (first two gels) and Laemmli gel (last two gels). Note excellent resolution of -spectrin, -spectrin, and ankyrin bands in the modified Fairbanks system. In the Laemmli system, -spectrin and ankyrin bands overlap. However, the Laemmli system resolves band 4.1 into two bands (4.1a, 4.1b). In lane 2, a truncated -spectrin mutant with abnormal mobility (spectrin Nice) associated with HE was identified in the Fairbanks gel. In lane 4, both protein 4.1 bands are absent from the erythrocyte membranes of a homozygous individual with 4.1() HE as seen in a Laemmli gel. **(B)** Nondenaturing polyacrylamide gels of crude spectrin (Sp) extracts. The extracts in lane 1, from a normal control, are tetrameric (SpT) and oligomeric (SpO). The extracts in lane 2, from one of two parents who both have common HE, exist as dimers (SpD), tetramers, and oligomers. The extracts in lane 3, from a homozygous HE offspring, exist almost exclusively as dimerics. **(C** & **D)** SDS-PAGE of tryptic digests of Sp from members of the same family followed by Coomassie blue staining **(C)** or immunoblotting with an anti-I spectrin antibody **(D)**. Note that the immunoblot from the HE parent (lane 2) contains both normal 80-kd and abnormal 74-kd I domain peptides, implying that the parent is heterozygous for the Sp I/74 mutant. The immunoblot from the homozygous offspring contains only the abnormal 74-kd mutant I domain peptide; no normal 80-kd peptide is present. *(From Palek and Lambert, [307] with permission.)*

-spectrin is the most prominent one. Nearly all - or -spectrin mutations reported are associated with a formation of tryptic peptides of abnormal size and mobility that are generated instead of the normal 80-kd I domain peptide. The cleavage sites of the most common abnormal tryptic peptides were mapped and found to reside in the third helix of a given triple helical repetitive segment (Fig. 33-9). The reported mutations reside in the vicinity of these cleavage sites either in the same helix or, less commonly, in helix 1 or 2 of a given repetitive segment. Consequently, tryptic peptide mapping remains a powerful tool with which to map the site of the underlying spectrin mutation, which can be subsequently defined by polymerase chain reaction amplification and sequencing of the respective region of the genomic DNA or cDNA.

Differential Diagnosis

Various acquired and inherited conditions can be associated with elliptocytosis and poikilocytosis, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. The percentage of elliptocytes in these conditions is seldom >60%.[258] [312] [313] However, this is not diagnostically useful, since some HE subjects may have a relatively low percentage of elliptocytes. [2] [279] In normal subjects, the percentage of elliptocytes is not >5%, [2] although in earlier reports it was listed as high as 15%. [203] [278] Previous diagnostic criteria of HE, based on the percentage of elliptocytes, such as 25%, [205] 33%, [314] or 40%, [203] and their axial ratio, [271] do not appear useful. [307] The most reliable differentiation of HE from the above conditions is based on a positive family history rather than on the percentage of elliptocytes. [307]

Treatment and Prognosis

As in the case of HS, red cells from patients with more severe forms of HE are retained by the spleen, producing a marked engorgement of splenic pulp. [119] [315] Consequently, patients with symptomatic hemolysis benefit from splenectomy. [305] [306] This procedure is virtually never indicated in heterozygotes with autosomal dominant HE because most do not have clinically significant hemolytic anemia. In contrast, splenectomy is required in most patients with homozygous HE and HPP. If hemolysis is still active after splenectomy, folate should be administered daily. Recommendations for antibiotic prophylaxis, immunizations, and monitoring for intercurrent illnesses are similar to those noted earlier for HS patients before and after splenectomy. Serial interval ultrasound investigations to detect gallstones should be performed in patients with significant hemolysis.

Spherocytic Elliptocytosis

Spherocytic elliptocytosis, which shares features of both HS and HE, has been designated spherocytic HE, HE with spherocytosis, or hereditary hemolytic ovalocytosis. [279] [306] [307] [316] The diagnosis is based on the simultaneous presence of elliptical red cells and spherocytes or fat, round sphero-ovalocytes in the peripheral blood film (Fig. 33-7). In contrast to common HE, cells of other shapes, such as rod-shaped cells, poikilocytes, and fragments, are absent. Importantly, hemolysis, despite relatively mild alterations in red cell morphology, and increased osmotic fragility are the main diagnostic features distinguishing this disorder from common HE.

The molecular basis of classic spherocytic HE is unknown. However, patients with mutations, particularly truncations at the C-terminus of -spectrin, have many of the clinical features of spherocytic HE and are probably an example of this disorder. Patients who lack glycophorin C have rounded, smooth elliptocytes and could be classified as having a mild, recessively inherited variant of spherocytic HE. Finally, some patients with recessively inherited defects of protein 4.2 may display some features of spherocytic HE, particularly mild ovalostomatocytosis. However, the erythrocyte morphology and pathophysiology associated with protein 4.2 deficiency more closely resemble HS; thus it is better classified as a variant of HS than HE.

Southeast Asian Ovalocytosis

SAO is characterized by the presence of oval red cells, many containing one or two transverse ridges or a longitudinal slit (Fig. 33-7). The condition is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia. [317] [318] [319] Numerous functional abnormalities of ovalocytes have been reported, including increased red cell rigidity, decreased osmotic fragility, increased thermal stability, resistance to shape change by echinocytogenic agents, and a reduced expression of many red cell antigens. [202] [320] [321] [322] [323] [324] [325] A remarkable feature of ovalocytes is their resistance to in vitro invasion by several strains of malaria parasites, including *Plasmodium falciparum* and *Plasmodium knowlesi*. [323] [324] [326] Moreover, in areas of endemic malaria, the ovalocytic subjects have reduced numbers of intracellular parasites in vivo. [206] In these regions, there is a decrease in the prevalence and in the disease severity of malaria in patients with SAO compared to controls. [327] [328]

The finding of a tight linkage of the abnormal proteolytic digest of erythrocyte band 3 protein to the SAO phenotype has led to the detection of the underlying molecular defect. [320] All carriers of the SAO phenotype were found to be heterozygotes, with one band 3 allele normal and the other containing two mutations in cis: the deletion of 9 codons encoding amino acids 400408 from the boundary of the cytoplasmic and membrane domains of band 3, and the 56 Lys to Glu substitution. [329] [330] [331] The 56 Lys to Glu substitution represents an asymptomatic polymorphism known as band 3 Memphis. [332] [333] [334] The SAO phenotype is associated with a tighter binding of band 3 to ankyrin, [320] increased tyrosine phosphorylation of the band 3 protein, [335] [336] [337] inability to transport sulfate anions, [338] [339] and a markedly restricted lateral and rotational mobility of band 3 protein in the membrane. [320] [330]

Laboratory Evaluation

The finding of 30% of oval red cells on the peripheral blood film, some containing a central slit or a transverse ridge, in the context of a notable absence of clinical and laboratory evidence of hemolysis in a subject from the above-noted ethnic groups is highly suggestive of the diagnosis. A useful screening test is the demonstration of the resistance of ovalocytes or their ghosts to changes in shape produced by treatments that produce spiculation in normal cells, such as metabolic depletion or exposure of ghosts to salt solutions. [320] [322] [326] [329] In contrast to normal red cells, which form spicules in response to such stimuli, SAO red cells or ghosts do not change shape after these treatments. The mechanism of this resistance to changes in shape is not clear, and it may reflect the high rigidity of the red cell membrane.

Since the underlying cause of SAO is the deletion of 27 bases from the band 3 gene, isolation of genomic DNA or reticulocyte cDNA with subsequent amplification of the deletion-containing region appears to be the most specific test for establishing the diagnosis of SAO. This amplification produces a single band in control cells and

a doublet with the second band shorter by 27 base pairs in the SAO cells. [329] [330] [340] Interestingly, this mutation appears to be lethal in the homozygous state, as large screens of individuals from indigenous areas have only identified heterozygotes. [328] [341]

Molecular Basis of SAO Membrane Rigidity and Malaria Resistance

SAO red cells are unique among axially deformed cells in that they are rigid and hyperstable rather than unstable. [321] The SAO mutation is the first example of a defect of an integral membrane protein leading to red cell membrane rigidity, an observation previously attributed to properties of the membrane skeleton. [110] Exposure of red cells to various ligands that bind to glycophorin A has been found to decrease membrane deformability. [342] [343] In both conditions, conformational changes of the cytoplasmic domain of the respective proteins may preclude lateral movement (extension) of the skeletal network during deformation. [110] Another putative mechanism of the high SAO membrane rigidity is increased binding of band 3 to ankyrin and thus to the underlying skeleton, or increased propensity of the band 3 protein to aggregate into higher oligomers with increased band 3-ankyrin stoichiometry, which in turn can facilitate band 3 attachment to ankyrin. [320] [344] Yet another proposed mechanism involves a nonspecific adherence of the SAO band 3 to the skeleton, possibly due to denaturation of the membrane spanning domain. [345]

The molecular basis of malaria resistance of SAO red cells is likely related to altered properties of the band 3 protein, which serves as one of the malaria receptors, as evidenced by the inhibition of in vitro invasion by band 3-containing liposomes. [346] In normal red cells, the invasion process is associated with a marked membrane remodeling that involves redistribution of intramembrane particles that contain band 3 protein. [347] Such particles cluster at the site of parasite invasion, forming a ring around the orifice through which the parasite enters the cell. The invaginated red cell membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO red cells [320] [330] may preclude band 3 receptor clustering, thereby preventing the attachment of the parasites to the cells. Decreased exchange of anions across the red cell membrane has also been proposed to contribute to the resistance of ovalocytes to malaria invasion. [338] [339] In addition, SAO red cells also consume ATP at a higher rate than normal cells, and the partial depletion of ATP levels in ovalocytes has been suggested to account, at least in part, for the resistance of these cells to malaria invasion in vitro. [348]

ACANTHOCYTOSIS AND RELATED DISORDERS

Acanthocytes (from the Greek *acantha*, thorn) or spur cells are red cells with prominent thornlike surface protrusions that vary in width, length, and surface distribution. Spur cells must be distinguished from echinocytes (Greek *echinos*, urchin) or burr cells, characterized by multiple small projections that are uniformly distributed throughout the cell surface (Fig. 33-12 (Figure Not Available)). [349] Acanthocytes should also be distinguished from keratocytes (horn red cells) that have few massive protuberances.

Acanthocytosis was first described in abetalipoproteinemia [350] [351] and subsequently in severe liver disease, [352] [353] the chorea-acanthocytosis syndrome,[354] [355] the McLeod blood group phenotype,[356] and other conditions.[357] [358] [359] [360] [361] The molecular mechanisms leading to acanthocytosis in abetalipoproteinemia and severe liver disease have been extensively studied and have been attributed to changes in composition of membrane lipids and their altered distribution between the two hemileaflets of the lipid bilayer.

Spur Cell Hemolytic Anemia of Severe Liver Disease

Spur cell hemolytic anemia is an uncommon ominous complication of severe liver disease that is manifested by rapidly progressive

Figure 33-12 (Figure Not Available) Morphologic differences between **(A)** acanthocytes and **(B)** echinocytes as demonstrated by scanning electron microscopy. *(Adapted from Bessis,[349] with permission.)*

hemolytic anemia and acanthocytes on the peripheral blood smear. [352] [353] [362] [363]

Pathobiology

The human red cell membrane contains nearly equal amounts of free (unesterified) cholesterol and phospholipids. The free cholesterol in the plasma readily equilibrates with the red cell membrane cholesterol pool. [364] This is in contrast to esterified cholesterol, which cannot be transferred from plasma into the red cell membrane. The plasma of patients with severe liver disease contains abnormal lipoproteins that have a high free cholesterol/phospholipid ratio. [363] The excess free cholesterol readily partitions into the red cell membrane, leading to a marked increase in free cholesterol in the cells. [363] [364] Consequently, normal cells can develop a spur cell shape after their transfusion into a patient with severe liver disease [362] or after incubation with the liver disease patients plasma or cholesterol-enriched liposomes.[365]

Spur cell formation involves two steps (Fig. 33-13). The first step is evident in red cells of splenectomized subjects with spur cell hemolytic anemia: red cells have an expanded surface area with irregular contour and targeting, [98] reflecting accumulation of free cholesterol in the membrane. This extra cholesterol accumulates preferentially in the outer bilayer leaflet, as suggested by findings of increased accessibility of cholesterol to cholesterol oxidase and a selective decrease in lipid fluidity of the outer hemileaflet of the lipid bilayer. [7] [339] [366]

The second step in acanthocyte formation involves red cell remodeling by the spleen. [99] As a result, red cells become spheroidal and the surface projections are considerably longer and more irregular (Fig. 33-13). The end result of these processes is poorly deformable red cells with long bizarre projections that are readily trapped in the spleen,[353] [367] which is often markedly enlarged because of passive congestion due to underlying portal hypertension. Cholesterol also alters membrane permeability and interacts with several membrane skeletal proteins, but the role of these changes in spur cell lesions is unclear. [368] [369]

Clinical Manifestations

Most patients with chronic liver disease have a mild to moderate anemia related to gastrointestinal blood loss, iron and folic acid deficiencies, hemodilution, or as a direct effect of alcohol on red cell precursors. [364] [370] [371] Peripheral blood smears from these patients often reveal target cells that are particularly prominent in obstructive jaundice.

In some patients, particularly those with end-stage liver disease, anemia rapidly worsens and spur cells appear in high percentage in the peripheral blood. [352] [353] [362] [365] This is accompanied by worsening jaundice, rapid deterioration of liver function, hepatic encephalopathy, and hemorrhagic diatheses. A similar clinical syndrome has been described in patients with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease. [372] The development of spur cell hemolytic anemia is an ominous sign in most patients, predicting a survival seldom exceeding weeks to months. [354] In theory, splenectomy could provide a marked improvement, since the spleen is the major sequestration site of nondeformable acanthocytes; in reality, splenectomy is seldom considered because of severity of the underlying liver disease. [98]

Spur cell hemolytic anemia of liver disease must be distinguished from other hemolytic syndromes of liver disease, including (1) transient hemolysis associated with fatty metamorphosis of the liver and hyperglycemia (Zieve syndrome),[364] [373] (2) transient hemolytic anemia with stomatocytosis,[252] [374] (3) hemolytic anemia with rigid spiculated red cells (echinocytes), which can be seen in malnourished patients with severe hypophosphatemia and hypomagnesemia, [375] and (4) a mild hemolysis with some spherocytes, seen in patients with congestive splenomegaly. [364]

Abetalipoproteinemia

Definition and History

Bassen and Kornzweig first described an association of acanthocytosis with atypical retinitis pigmentosa, progressive ataxic neurologic disease, and a celiac disease later attributed to fat malabsorption. [350] [351] Subsequently, several investigators reported a congenital absence of -lipoprotein, accounting for the diverse manifestations of the disorder. [376]

Pathobiology

This autosomal recessive disorder has been detected in people of diverse ethnic backgrounds. [376] The primary molecular defect involves a congenital absence of

-apolipoprotein in plasma.[376] [377] [378] The B apoproteins (B100 and B48) are generated by alternate transcription of a single gene residing on the short

Figure 33-13 Blood film of a patient with liver cirrhosis and spur cell anemia **(A)** before and **(B)** after splenectomy. The latter smear demonstrates the effect of cholesterol acquisition leading to both targeting (indicating increase in surface area) and irregularities in cell contour. The conditioning effect of the spleen (smear A) is demonstrated by the spheroidal shape of the cells and the remodeling of the spicules. *(From Cooper RA, Kimball DB, Durocher JR: The role of the spleen in membrane conditioning and hemolysis of spur cells in liver disease. N Engl J Med 290:1279, 1974, with permission.)*

arm of chromosome 2.[376] Their deficiency is secondary to defective cellular secretion of the apoprotein by liver cells, caused either by aberrant post-translational processing or by defective aposecretion.[376] In some patients, this is due to qualitative or quantitative defects in the microsomal triglyceride transfer protein (MTP), which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces. [379] [380] [381] [382] MTP is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B-containing lipoproteins. [383] As a result, apoprotein B is absent in plasma, as are the individual lipoprotein fractions that contain this apoprotein. [377] [378] These lipoprotein fractions include chylomicrons and very-low-density lipoproteins that transport triglycerides, as well as the low-density lipoproteins that are products of very-low-density lipoproteins and transport cholesterol. Consequently, preformed triglycerides are not transported from the intestinal mucosa,[377] [384] and they are nearly absent in the plasma. Plasma cholesterol and phospholipids are markedly reduced, with a relative increase in sphingomyelin at the expense of lecithin. [385] [386] [387]

As is the case in acanthocytosis of liver disease, the acanthocytic lesion is acquired from the plasma. Erythrocyte precursors are of normal shape, and the acanthocytic lesion develops as the cells mature and age in the circulation. [377] [388] Normal cells acquire this shape when transfused into the recipient.

The most striking abnormality of red cell membrane lipids involves a net increase in sphingomyelin. Because plasma lipids readily exchange with the lipids of the red cell membrane,[368] it is likely that this change simply mirrors the alterations in plasma lipid composition. In contrast to red cells in spur cell anemia of severe liver disease, the content of membrane cholesterol is normal or only slightly increased. [367] [369] [387] [389]
