Therefore, determining the optimal management for a particular patient remains problematic. In a young patient, who potentially will have a more prolonged course lasting several decades, it appears best to treat with phlebotomy and low-dose aspirin if possible. In patients with serious hemorrhagic or thrombotic complications, however, this may not be possible. This situation warrants supplemental therapy with interferon-, anagrelide, or hydroxyurea. Concern over the potential leukemogenic activity of hydroxyurea is warranted because we are only now becoming aware of the true leukemogenic potential of this drug. [183] [188] [241] [242] [245] In some patients, the effectiveness of hydroxyurea in reducing the incidence of thrombotic complications might, however, outweigh the enhanced risk of leukemic transformation experienced by hydroxyurea-treated patients. In elderly patients, who have a more limited survival because of their age, the use of either ^{32}P or hydroxyurea appears warranted.

FUTURE DIRECTIONS

Future directions in the treatment of patients with polycythemia vera are highly dependent on a more comprehensive understanding of the pathophysiology of this clonal neoplastic disorder. Further definition of oncogenic alterations in intracellular signaling within these malignant cells should permit the development of more specific therapies. Further definition of risk factors for the development of fatal thrombotic and hemorrhagic events will be important for the rational design of therapeutic

interventions to prevent these complications. [96] Completion of the large randomized trial testing the ability of low-dose aspirin to reduce the incidence of thrombotic complications in patients treated with phlebotomy will be of major importance. [115]

Chapter 62 - Chronic Myelogenous Leukemia

Helen Enright
Philip McGlave

INTRODUCTION

Chronic myelogenous leukemia (CML) is a clonal expansion of hematopoietic progenitor cells characterized clinically by myeloid hyperplasia, leukocytosis with basophilia, and splenomegaly. An initial chronic phase of expanded clonal myelopoiesis is followed by inevitable progression to accelerated phase and, finally, to fatal blast crisis. The characteristic Philadelphia chromosome translocation, t(9;22)(q34;q11), juxtaposes the c- *abl* oncogene from chromosome 9 with the breakpoint cluster region (*bcr*) on chromosome 22 resulting in the generation of aberrant *bcr/abl* transcripts. The abnormal *bcr/abl* tyrosine kinase gene product has enhanced activity compared to the wild type c-*abl* tyrosine kinase and is believed central to the pathogenesis of CML.

In 1960, Nowell and Hungerford described the characteristic Philadelphia chromosome associated with CML, the first recurrent chromosomal abnormality associated with a specific human malignancy.[1] They reported that myeloid cells from patients with CML showed a deletion of the long arm of chromosome 22. Subsequently, the translocation t(9;22)(q34;q11) was defined and the abnormal *bcr/abl* gene product identified.[2] [3] [4] [5] This highly consistent genetic abnormality provides a marker for the study of the disease and may provide a target for specific therapy.

The incidence of CML is 1/100,000 population, accounting for 1520% of all leukemias in adults. [6] [7] [8] The peak incidence occurs between the fifth and sixth decades, with a male:female ratio of 1.4:1.[6] [8] The increased incidence of subsequent development of CML in persons exposed to the atomic bomb at Hiroshima and Nagasaki implicates radiation as a potential contributory cause in the etiology of CML. [9] [10] The later development of CML has also been described in patients undergoing radiation therapy for ankylosing spondylitis and for cervical cancer. [11] [12] However, there are usually no predisposing factors identified in individual patients presenting with CML.

PRESENTATION AND CLINICAL MANIFESTATIONS OF CHRONIC PHASE CML

Clinical Features

Traditionally, CML is described as a phasic disease with most patients presenting in chronic or stable phase, the median duration of which is 34 years. Chronic phase disease then progresses to accelerated phase and subsequently to blast crisis. In symptomatic patients presenting in chronic phase, the most common presenting features are anemia, splenomegaly, bleeding, and constitutional symptoms such as fatigue, lethargy, weight loss, or low-grade fever [13] [14] (Table 62-1). However,

TABLE 62-1 -- Clinical Features at Presentation of CML

Splenomegaly	Constitutional symptoms
Asymptomatic	Fatigue
Left upper quadrant discomfort/pain	Anorexia/weight loss
	Sweats/low grade fever
Early satiety	Bone pain[a]
Anemia	Hyperleukocytosis
Hepatomegaly	Priapism
Purpura	

[a]Uncommon in chronic phase CML.

2040% of patients with CML present with asymptomatic leukocytosis, thrombocytosis, or splenomegaly discovered on routine investigation. [14] [15]

Splenomegaly is present at diagnosis in 8590% of patients. Patients may also present with symptoms due to splenic enlargement such as satiety, left upper quadrant pain or discomfort, and abdominal swelling or bloating. Mild to moderate hepatomegaly is frequent but lymphadenopathy is uncommon. In recent years, there has been an increase in the proportion of patients presenting with lower white blood cell (WBC) counts and a lesser degree of splenomegaly. However, male patients may present with higher WBC counts and larger spleens, [14] and priapism secondary to hyperleukocytosis may be the presenting feature. Generally, there is no increased risk of infections in chronic phase CML, although abnormal neutrophil and natural killer cell function are described. [16] [17]

Laboratory Features

Peripheral blood leukocytosis is characteristic of chronic phase CML (Table 62-2). Generally the WBC count is >25 × 10^9 /L and is not uncommonly 100300 × 10^9 /L. The differential WBC count shows granulocytes at all stages of maturation and peripheral blood basophilia with or without eosinophilia. Mild anemia is common. Although thrombocytosis is present at presentation in 3050% of patients, thrombotic complications are unusual, [14] in contrast to thrombocytosis associated with polycythemia rubra vera or essential thrombocytosis. [14] [18] Indeed, purpura may be the presenting feature of CML, occurring in 15% of patients despite normal or increased platelet counts, and abnormal platelet function is described. [14] [18] [19] Thrombocytopenia is unusual, occurring in <10% of patients at presentation.

The marrow is hypercellular due to extreme myeloid hyperplasia with a differential WBC count showing a biphasic peak of myelocytes and mature neutrophils. The myeloid:erythroid ratio is increased (1030:1). The blast percentage in the bone marrow is <10% and myeloid maturation appears morphologically normal with little or no dysplasia. There may be absolute monocytosis but the monocyte percentage is usually <3%. Megakaryocytes may be increased with megakaryocyte dysplasia. Pseudo-Gaucher cells or sea-blue histiocytes may be present. [20] The bone marrow biopsy confirms the myeloid hyperplasia and there may be an increase in reticulin fibrosis. Occasionally, moderate or even severe myelofibrosis is present.

The leukocyte alkaline phosphatase (LAP) score is almost uniformly low in chronic phase CML but may increase with therapy or with progression of disease. Serum lactic dehydrogenase and uric acid levels may be elevated. There are increased serum levels of vitamin B_{12} and transcobalamin. Although clinically

TABLE 62-2 -- Laboratory Features at Presentation of CML

Peripheral Blood	**Bone Marrow**
Neutrophil leukocytosis with left shift	Myeloid hyperplasia
	Blasts <10% in chronic phase
Basophilia/eosinophilia	
Thrombocytosis	Minimal/no dysplasia
Anemia	Increased megakaryocytes
Blasts <10% in chronic phase	Myelofibrosis (mild/moderate)
	Monocytes usually <3%
Leukocyte alkaline phosphatase (LAP) score	
Lactic dehydrogenase	
Uric acid	
Vitamin B_{12} /transcobalamin	

	Partial thromboplastin time
Cytogenetic analysis	Philadelphia chromosome positive (9095%)
Molecular analysis	*bcr/abl* positive (>95%)

significant coagulopathy is unusual, the partial thromboplastin time may be prolonged.

Differential Diagnosis

At presentation, the differential diagnosis of chronic phase CML most often involves distinction from reactive leukocytosis or a leukemoid or leukoerythroblastic reaction due to infection, inflammation, or metastatic carcinoma. The presence of more than sparse erythroblasts in the peripheral blood is unusual in CML. Likewise, tear-drop poikilocytes are not characteristic of CML and may indicate myelofibrosis or bone marrow infiltration. An absolute basophilia is characteristic of CML. [21] The LAP score may help distinguish CML from reactive states. This score is almost uniformly low in CML and is usually increased in other myeloproliferative disorders and in reactive leukocytosis. It may, however, also be low in paroxysmal nocturnal hemoglobinuria and in hypophosphatasia, although these conditions are not difficult to differentiate from CML. A definitive diagnosis may be made by the demonstration of the characteristic 9;22 chromosomal translocation by cytogenetic or molecular analysis of the peripheral blood or marrow.

Thrombocythemic presentation of CML (57% of cases) should be considered in the evaluation of patients presenting with unexplained thrombocytosis, especially in the presence of splenomegaly.[22] Atypical cases of CML may occasionally be difficult to distinguish from myelodysplastic syndromes, especially chronic myelomonocytic leukemia (CMML).[23] The French-American British Cooperative Leukaemia Group has published guidelines for distinguishing CML from CMML and atypical CML.[24] CMML is characterized by the presence of an absolute monocytosis with marrow trilineage dysplasia and absence of the Philadelphia chromosome.

Chronic neutrophilic leukemia is a rare myeloproliferative disorder characterized by neutrophil leukocytosis and an indolent course. The LAP score is normal or high and there is no basophilia. Splenomegaly, if present, is mild to moderate. Recently, the *bcr/abl* breakpoint in chronic neutrophilic leukemia has been defined. [25] The clinical course of chronic neutrophilic leukemia is more benign than that of typical CML, and treatment is usually not required.

Juvenile CML and CMML

Juvenile CML should be distinguished from juvenile CMML.[26] Juvenile CML usually presents at the ages of 1014, and the clinical features are similar to the adult form of the disease. In most cases of juvenile CML the Philadelphia chromosome can be detected. Juvenile CMML is characterized by splenomegaly, fever, hepatomegaly, generalized lymphadenopathy with eczematoid rashes, leukocytosis with prominent monocytosis, anemia, and thrombocytopenia. The marrow shows myeloid hyperplasia with monocytosis and dyserythropoiesis. The karyotype is usually normal. Serum fetal hemoglobin levels are markedly increased and serum muramidase levels are raised. Most patients are under 2 years of age at presentation and the response to treatment is poor, with survival usually <2 years.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACCELERATED PHASE CML

Survival in patients with CML is usually determined by the time to progression to accelerated phase (usually 34 years from presentation) and subsequent blast crisis. Accelerated or advanced phase CML is characterized by progressive myeloid maturation arrest, increasing resistance to therapy, an increase in bone marrow and peripheral blood blasts and basophils, clonal cytogenetic evolution, extramedullary disease,

TABLE 62-3 -- Features of Advancing CML

WBC count difficult to control with conventional chemotherapy [a]
Anemia or thrombocytopenia unresponsive to chemotherapy
Increasing splenomegaly
>10% blasts in the peripheral blood or bone marrow
>20% blasts plus promyelocytes in the peripheral blood or bone marrow
>20% basophils plus eosinophils in the peripheral blood or bone marrow
Persistent thrombocytosis
Additional clonal chromosomal changes [b]
Extramedullary disease
Myelofibrosis

[a] The relevance of this feature in patients treated with interferon is uncertain.
[b] See text for discussion of the significance of additional clonal cytogenetic abnormalities.

thrombocytosis or thrombocytopenia, myelofibrosis, and increasing splenomegaly despite therapy. Many patients with advancing CML remain asymptomatic until the late stages of disease, but some experience fever, night sweats, weight loss, and symptoms of splenomegaly, bone pain, or anemia.

Criteria for defining acceleration of CML have been proposed by the International Bone Marrow Transplant Registry but a consensus has not been reached [27] [28] (Table 62-3). In addition, the applicability of such criteria in the era of interferon therapy and stem cell transplantation has not been established.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BLAST CRISIS

Blast crisis, resembling acute leukemia, develops in 7585% of patients with CML and is associated with an extremely poor prognosis. Survival averages only 36 months. The presence of >30% blasts in the bone marrow or peripheral blood is generally accepted as evidence of transition to blast crisis. Others accept a definition of >30% blasts plus promyelocytes in the bone marrow or peripheral blood as blast crisis. [29]

During blast crisis, constitutional symptoms such as bone pain, sweats, fever, weight loss, and anorexia are more prominent than in the chronic or accelerated phases of CML.[14] Complications of blast crisis include infection, anemia, thrombocytopenia, and extramedullary disease. The most common sites of extramedullary disease are lymph nodes, skin, bone, and the central nervous system. Occasionally, extramedullary disease may be the first manifestation of blast crisis, without evidence of progression in the bone marrow. However, it almost invariably heralds the onset of blast crisis in the marrow within a short period of time.

In 50% of cases the leukemic cells in blast crisis show morphologic and immunophenotypic characteristics of myeloblasts. Occasionally, erythroblasts or immature basophils or eosinophils predominate. In 25% of cases, the blasts are lymphoid, with immunophenotypic characteristics of pre-B lymphoblasts, and a further 25% are undifferentiated or biphenotypic. [30] Thus, for patients presenting in blast crisis the differential diagnosis includes Philadelphia chromosome-positive acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL). In addition 20% of adults and 4% of children presenting with ALL and rare patients with AML have the Philadelphia chromosome detected on cytogenetic testing or DNA analysis. Occasionally, patients with presumed Philadelphia chromosome-positive ALL revert to chronic phase CML with persistent Philadelphia chromosome positivity following induction chemotherapy, and the diagnosis of lymphoid blast crisis of CML is made retrospectively.

PROGNOSTIC EVALUATION

A number of studies have identified prognostic factors in patients with CML. The International Chronic Granulocytic Leukemia Prognosis Study Group examined presenting features in 678 cases of CML and established age, splenic size, platelet count, percentage of blasts, and percentage of basophils in the peripheral blood or bone marrow as significant factors influencing survival. The presence at diagnosis of peripheral blood blasts 15%, peripheral blood blasts plus promyelocytes 30%, peripheral blood basophils 20%, thrombocytopenia $<100 \times 10^9$ /L or of myelofibrosis has been identified as features with independent adverse prognostic significance.[14] [27] Models have been generated defining high-, medium-, and low-risk patients with significant differences in survival based on the various prognostic features.[31] [32] [33] [34] [35] The Sokal score has gained wide acceptance.[34] However, the relevance of such classifications in the era of interferon therapy is as yet undefined, and it may be more useful to define prognosis on the basis of individual features of advancing disease. [36] For patients treated with interferon, a response to therapy is an important prognostic factor.

The site of the breakpoint in the *bcr* region has been suggested to have prognostic significance,[37] [38] but this has not been confirmed.[39] The significance of clonal cytogenetic evolution is discussed below.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

CYTOGENETIC FINDINGS IN CML

Cytogenetic analysis reveals the classical 9;22 translocation in 9095% of patients with CML. A variant form of this translocation is identified in 5%. The most commonly identified variant translocations involve the distal part of chromosome 22 but without involvement of chromosome 9. Complex translocations involving chromosomes 9 and 22 and a third chromosome may also occur.

In many Philadelphia chromosome-negative patients (as assessed by conventional cytogenetic methods), the characteristic *bcr/abl* translocation can be demonstrated by molecular analysis.[40] [41] [42] [43] The presentation, clinical features, prognosis, and response to therapy of these patients do not differ from those with typical Philadelphia chromosome-positive disease. A small number of patients with CML are *bcr/abl* negative on molecular analysis. These patients are typically older, have a higher incidence of thrombocytopenia, lower WBC counts, and less prominent basophilia than patients with typical Philadelphia chromosome or *bcr/abl* positive disease.[41] The prognosis for this group of patients is poorer than that for typical CML, with a reported median survival of 25 months. [40]

Additional chromosomal abnormalities are present in advanced phase CML in 80% of cases. These typically involve duplication of the Philadelphia chromosome translocation, isochromosome 17, trisomy 8, or trisomy 19.[27] [44] The relationship of clonal evolution to disease progression in the absence of other clinical or laboratory features of acceleration remains a subject of debate. Traditionally, clonal cytogenetic abnormalities in addition to the 9;22 translocation have been considered to be independently associated with a worse prognosis. [34] [35] [45] More recently, however, it has been recognized that clonal evolution in chronic phase without other features of acceleration may not necessarily be associated with an adverse prognosis. [46] The significance may depend somewhat on the specific additional chromosomal abnormality, the proportion of metaphases that are abnormal, and the time of appearance of the additional abnormality. Isochromosome 17 is almost always associated with disease evolution to accelerated phase and a poor prognosis. However, loss of the Y chromosome may be associated with improved prognosis.[47] In one study, the appearance of an additional chromosomal abnormality >25 months after diagnosis, its presence in >25% of metaphases, and other concomitant features of advancing disease indicated a poorer prognosis. [46]

PATHOGENESIS OF CML

Molecular Genetics

The cytogenetic hallmark of CML, a reciprocal translocation between chromosomes 9 and 22 (t(9;22)(q34;q11)), results in the juxtaposition of the c- *abl* oncogene on chromosome 9 with the *bcr* region of chromosome 22 and the resulting formation of a chimeric *bcr/abl* gene. In most cases of CML, this chimeric gene expresses an 8.5-kb hybrid mRNA transcript giving rise to a 210-kd fusion protein (p210 *bcr/abl*) with transforming activity for hematopoietic cells and the ability to cause CML-like myelopoiesis in mice.[5] [48]

The human *abl* proto-oncogene, a large gene (approximately 225 kb in length) located on 9q34 contains sequences homologous to the v- *abl* sequences in the Abelson murine leukemia gene associated with its transforming activity. [49] [50] At transcription, exon 1a is spliced out, resulting in fusion of exon 1b to exon 2 (the first common exon).[51] Two mRNA species are normally generated, resulting in two proteins differing by 19 amino acids at the amino terminal. Both are known as p145 and have intrinsic tyrosine kinase activity. The precise breakpoint on the *abl* gene in CML is variable and is distributed over an area >200 kb between exon 1b and exon 2.[49] The translocation results in most of the *abl* gene (exons 211) being translocated to chromosome 22.[3] [4] [5] [50]

The *bcr* region on chromosome 22 spans approximately 135 kb containing 23 exons. Two *bcr* proteins are encoded and are widely expressed in normal tissues. In CML, the fusion protein product of *bcr/abl* varies in size, depending on the site of the *bcr* breakpoint. Three breakpoints are described, M- *bcr*, m-*bcr*, and -*bcr* (Fig. 62-1). The breakpoint is usually within a 5.8-kb segment, the major breakpoint cluster region (M- *bcr*), either between *bcr* exons b2 and b3 or between exons b3 and b4.[52] [53] As a result, the *bcr/abl* translocation leads to the production of two different fusion gene protein products, that is, two variant 210 kd proteins compared to the normal c-*abl* product (145 kd). In 40% of CML patients, the mRNA transcript has a b2a2 junction, and in 40% it is b3a2. [54] Alternative splicing in 20% of patients results in the presence of both fusion proteins, b2a2 and b3a2. [51] When the breakpoint is within the minor breakpoint cluster region (m- *bcr*), p190*bcr/abl* is produced. Here the breakpoint is in the first intron of the *bcr* gene between exons e1 and e2, resulting in fusion of the first exon of *bcr* (e1) to a2.[55] This 190-kd variant *bcr/abl* protein, usually associated with ALL, is present in low amounts in some CML patients and in rare cases is the predominant mRNA expressed.[54] Recently, co-expression of p210 and low levels of p190 have been shown to be more common than previously recognized in CML.[54] [56]

Figure 62-1 Structure of the normal *bcr* and *abl* genes. The three named breakpoints in *bcr* associated with CML are indicated by arrows. The lower part of the figure shows the structure of the possible *bcr-abl* mRNA fusion transcripts. (*Courtesy of Dr. J. M. Goldman.*)

A third breakpoint cluster region, downstream of M- *bcr*, has also been described, -*bcr*, which results in a protein of 230 kd.[57] Novel variants of *bcr/abl* continue to be described, including one joining exon e6 of *bcr* to exon a2 of *abl*,[58] associated with Philadelphia chromosome-negative CML and a further variant joining exon e2 to a2.[59]

Clinical and Molecular Correlations

Strong evidence suggests that the position of the breakpoint in the *bcr* region influences the disease phenotype in CML. [55] In rare cases of CML, p190 is the predominant gene product. These patients have a prominent monocytic component, are generally older, have no palpable splenomegaly and only moderate leukocytosis.[60] It has also been suggested that co-expression of p210*bcr/abl* and p190*bcr/abl* might correlate with disease progression, and the appearance of m-*bcr/abl* mRNA in patients with M-*bcr* expression may be associated with progression to lymphoid blast crisis. [60] [61] [62] However, it has now been recognized that co-expression of p210*bcr/abl* and p190*bcr/abl* is much more common than previously recognized and is not necessarily associated with disease progression. [54]

The -*bcr* breakpoint is present in rare instances, and some cases resemble chronic neutrophilic leukemia rather than typical CML. [57] The *bcr/abl* breakpoint in chronic neutrophilic leukemia has also been described between exons c3 and c4 of *bcr*, resulting in a c3/a2 junction [25] and is associated with a more benign course than typical CML. Presentation of CML with very high platelet counts (1,0002,000 × 10^9 /L) and only moderate leukocytosis is associated with the b3a2 type of *bcr/abl* mRNA transcript.[22]

bcr/abl Expression and Regulation

The functions of the normal *abl* and *bcr* genes are not well understood, and, consequently, the molecular events causing the disordered proliferation and differentiation and clonal expansion of hematopoietic cells characteristic of CML are poorly delineated. However, evidence strongly suggests that the *bcr/abl* fusion gene product is directly involved in leukemogenesis. The *abl* gene is normally located in the nucleus and has low tyrosine kinase activity. Overexpression of p145 *abl* results in inhibition of cell cycle progression at the G_1/S interphase. The activity and intracellular localization of *abl* is regulated by integrins, and it has been postulated that the normal role of *abl* is in transmission of integrin signals involved in cell cycle control to the nucleus. [63] In CML, the fusion of the first exon of *abl* with the first exon of *bcr* leads to relocation of the fusion protein to the cytoplasm with markedly increased tyrosine kinase activity. Up-regulation of *abl* kinase activity in CML is mediated through binding of the first exon of the *bcr* molecule (essential for transforming activity) to the SH2 regulatory domain of *abl*, the major tyrosine phosphorylation site.

Both the p210 and p190*bcr/abl* gene products have enhanced tyrosine kinase activity compared with the normal c- *abl* product (P145)[64] and there is increasing evidence that the abnormal protein is directly involved in cellular transformation to the CML phenotype. [48] [65] The introduction of a retrovirus vector expressing p210*bcr/abl* into human factor-dependent cell lines can result in the generation of factor-independent cells. [66] In addition, the expression of an activated tyrosine kinase in multipotent hematopoietic progenitors causes a delay in maturation, altered responsiveness to growth factors, and a delay in apoptosis induced

by the absence of growth factor.[67] [68] Thus, *bcr/abl* can induce cell proliferation and transformation of immature hematopoietic cells and suppress apoptosis in vitro. Most importantly, a disease resembling CML has been observed in mice transplanted with hematopoietic stem cells containing a *bcr/abl* construct, and the resulting experimental leukemia can be transplanted to secondary recipients. [48]

bcr/abl Substrates

Current investigation of the mechanisms underlying the development of CML include attempts to identify molecules that interact with *bcr/abl* and the signal-transduction pathways by which *bcr/abl* proteins, which are primarily cytoplasmic, can transduce signals to the nucleus to exert transforming activity. In addition to increased autophosphorylation activity of *abl*, the fusion protein appears to change the normal pattern of phosphorylation of key regulatory proteins. [69] [70] [71] Such *bcr/abl* substrates may act as intermediates in tyrosine kinase signaling cascades regulating expression of genes affecting cell growth and differentiation. Putative targets for *bcr/abl* include important regulatory factors such as Grb-2, Shc, p21*ras*, p120GAP, ph-P53, p160*bcr*, CRKL, c-*myc*, c-*myb*, p120CBL, *bcl*-2, and P1-3 kinase.

Many of these proteins are involved in pathways that lead to the activation of the *ras* oncogene. Activated (GTP-bound) p21*ras* has an established role in signal transduction and growth regulation and is required for the proliferation of CML cells. Expression of p210 *bcr/abl* in fibroblasts simultaneously activates p21*ras* and inhibits the GTPase-promoting activity of p120GAP; down-regulation of p210 *bcr/abl* in CML cells with *bcr/abl* antisense oligonucleotides abrogates these effects. [72] Thus, p210*bcr/abl* activity is necessary for the maintenance of p21*ras* in the active GTP-bound form, regulated by the GTPase-activating protein, p120GAP. [70] The SH2 phosphorylation domain of p210*bcr/abl* may also link p210*bcr/abl* to the adaptor protein Grb-2, also leading to *ras* activation. [73]

Other potentially important substrates for p210 *bcr/abl* include ph-P53, which complexes with *bcr/abl* in K562 cells, the *bcr* protein itself, and the phosphorylated adaptor protein CRKL, which is phosphorylated by and also forms specific complexes with p210 *bcr/abl*, [74] [75] [76] although its role, if any, in transformation is unknown. p120CBL is bound by p210*bcr/abl*-bound CRKL and appears to be an important substrate of *bcr/abl* forming complexes with CRKL and phosphatidylinositol-3 kinase (p-13-kinase). [77] [78] This kinase has been suggested as an important downstream effector of *bcr/abl* tyrosine kinase in CML cells, is regulated by *bcr/abl*, and has been demonstrated to be important for proliferation of Philadelphia chromosome-positive cells in vitro. [79]

Although little is known regarding control of p210 *bcr/abl* expression, its transcriptional regulation may be important in the pathogenesis of CML. [80] This is supported by evidence that Philadelphia chromosome-positive colonies arising from hematopoietic progenitors may transcribe the aberrant *bcr/abl* mRNA to a variable degree or express normal *abl* mRNA. [81] The function of the reciprocal fusion gene *abl/bcr* (expressed in 60% of CML patients) is unknown. [82]

Apoptosis in CML

Growing evidence suggests that regulation of hematopoietic cell survival by programmed cell death or apoptosis may play an important role in normal erythroid and myeloid differentiation. Thus, abnormalities in the regulation of cell death may lead to disordered hematopoiesis, contributing to the development of malignancy. It is postulated that the *abl* kinase is normally involved in regulation of apoptosis. Expression of *bcr/abl* in CML appears to confer resistance in vitro to chemotherapeutic and other DNA-damaging agents and prolongs the growth factor-independent survival of CML progenitors by inhibition of apoptosis. [83] [84] [85] Additionally, *bcr/abl* expression may influence hematopoietic cell cycle distribution following DNA damage with delayed transition through G2/M, perhaps allowing time for DNA repair. [85]

Further information regarding the role of p210 *bcr/abl* in leukemogenesis has been generated using antisense oligonucleotides specific for *bcr/abl* sequences. Antisense oligonucleotides can down-regulate *bcr/abl*, suppress Philadelphia chromosome-positive leukemia cell growth in mice, specifically reduce colony formation of early hematopoietic progenitors from CML patients, and decrease cell proliferation in CML-like lines, perhaps by rendering the cells sensitive to apoptosis. [84] [86] [87] [88] A relationship between *bcr/abl* function and *bcl*-2 has been suggested. Transformed, factor-independent and tumorigenic murine hematopoietic cells expressing *bcr/abl* are rendered resistant to apoptosis by virtue of increased *bcl*-2 expression. [89] Furthermore, when *bcl*-2 expression is suppressed, *bcr/abl*-positive cells revert to factor dependence and nontumorigenicity.

These studies have led to the hypothesis that the *bcr/abl* gene serves an anti-apoptotic function resulting in an expanded myeloid population without stimulation of proliferation. However, the importance of p210-mediated suppression of apoptosis in the pathogenesis of CML is uncertain and inhibition of apoptosis alone is unlikely to account for the characteristic clonal expansion. [90] Furthermore, conflicting results are reported. Despite reports of defects in cell cycle control and apoptosis, other studies have failed to identify differences in survival of normal and CML progenitors following exposure to apoptotic stimuli. [91]

The Bone Marrow Milieu and the Pathogenesis of CML

Current evidence suggests that CML is a disease of the primitive pluripotent stem cell with megakaryocytes, erythroid precursors, monocytes, macrophages, eosinophils, basophils, at least some B lymphocytes, and (in some cases) T lymphocytes involved in the malignant clone. [92] [93] During the chronic phase the leukemic myeloid cells mature normally and have a near-normal life span. However, assays of the peripheral blood reveal a significant increase in erythroid, megakaryocytic, and pluripotent progenitors. These are actively cycling, in contrast to the quiescent population of progenitors present in normal blood. [94] These abnormalities may reflect either an expansion of the progenitor cell population or abnormal trafficking and release of progenitors from the marrow.

Long-term marrow cultures have been used to study the relationship between hematopoietic precursors and the marrow microenvironment and to characterize very primitive benign and malignant cells in normal and CML hematopoiesis. In patients with CML, the marrow mononuclear cell population contains both Philadelphia chromosome-negative and -positive primitive progenitors, both of which can give rise to granulocyte/macrophage progenitors in long-term culture. [94] [95] [96] In vitro culture studies have identified abnormalities in the proliferation and differentiation of CML progenitors, their interactions with marrow stroma, and their requirements for and responsiveness to growth factors and negative growth regulators, although the significance of many of these observations remains uncertain. [97] [98] [99]

Progenitor Cell/Stroma Interactions

Abnormalities of stromal/progenitor cell interaction may be central to the pathogenesis of the leukemic hematopoiesis in CML. [97] [98] Specifically, abnormal cytoadhesion or anchorage properties of malignant progenitors is hypothesized to contribute to the disorderly maturation and proliferation of CML progenitors.

[100] [101] [102] CML progenitor cells display defective adherence to normal marrow stroma and to purified fibronectin, perhaps due to adhesion receptor abnormalities, although benign Philadelphia-negative progenitors in CML retain their ability to adhere to stroma. [103] -1-Integrin receptor-mediated adhesion mechanisms especially are defective in CML. [104] [105] In addition, CML progenitors have decreased expression of the adhesion molecule lymphocyte activation antigen-3. [106] The cytoplasmic distribution of the p210 *bcr/abl* fusion protein is hypothesized to be directly involved in these adhesion abnormalities, perhaps by inducing phosphorylation of the intracytoplasmic domains of integrins or other adhesion molecules. [99] [104] [105] These abnormalities in hematopoietic progenitor cell adhesion may, at least in part, contribute to the abnormal proliferation, egress from the marrow, and trafficking of cells in CML.

The CML progenitors may show different growth patterns and responsiveness to humoral factors. Although in vitro observations have uncertain relevance to in vivo growth patterns, differential responses are seen to a number of cytokines including stem cell factor and macrophage inflammatory protein 1-. [95] [105] [107] Further characterization of the complex interactions between marrow stroma and both leukemic and normal progenitor cells and the function and substrates of the *bcr/abl* gene products will be required to enhance our understanding of the pathogenesis of leukemic hematopoiesis in CML.

MOLECULAR ASPECTS OF DISEASE EVOLUTION

Although additional cytogenetic changes are commonly identified as CML progresses, the molecular events responsible for the transition to the accelerated and blastic phases are unknown. It is believed that the inevitable evolution of CML into accelerated phase and blast crisis is a multistep process involving sequential genetic events. Abnormalities of the tumor suppressor gene, p53, are detectable in 1015% of patients with myeloid blast crisis, [108] [109] and introduction of mutant p53 into hematopoietic progenitor cells from patients with CML can promote their proliferation in vitro and can even lead to the growth of factor-independent colonies, suggesting a potential role for p53 in the evolution to accelerated phase of CML in at least some cases. [110] Changes in the retinoblastoma and *ras* genes have also been described in a small number of cases. [111] [112] However, alterations in tumor suppressor genes or in specific oncogenes appear to be uncommon. New evidence suggests that genomic instability or spontaneous errors in DNA replication, as demonstrated by the detection of microsatellite instability, may play a role in disease evolution. [113]

Most patients with phenotypical lymphoid blast crisis have clonal rearrangement of the immunoglobulin genes and some also have rearrangement of the T-cell receptor genes. [114] [115] More recently, homozygous deletion of the p16 tumor suppressor gene has been identified in 4050% of lymphoid blast crises of CML, but not in myeloid blast crisis. [116] [117] p16 (also known as the CDKN-2 gene) inhibits a critical cycle-dependent kinase (CDK-4), which in turn regulates a primary cell cycle checkpoint before cells are committed to DNA synthesis. Sequential studies have shown homozygous deletion of p16 is acquired in association with progression to blast crisis in at least some cases. [117] A defect in cell cycle regulation (involving G_2/M arrest or the inhibition of apoptosis following DNA damage) may allow the accumulation of additional cytogenetic events and survival of damaged cells, thus contributing to disease evolution. [85]

THERAPY OF CML

The first chemotherapeutic agent widely used for the therapy of CML was busulfan. [118] The effectiveness of this agent was confirmed in 1968 in a randomized trial. [119] The use of hydroxyurea was first reported in 1966 [120] and both agents are still widely used for control of chronic phase CML. Interferon, introduced in the mid-1980s, [121] [122] was the first agent shown to prolong survival, delay the transition to accelerated phase, and achieve cytogenetic remission in a proportion of patients. During the same decade, allogeneic stem cell transplantation (SCT) became established as the treatment of choice for younger patients with a matched sibling donor and remains the only proven curative treatment. Recently, autologous transplant using chemotherapy-primed peripheral blood stem cells has been performed. Despite these advances, treatment of the accelerated and blast crisis phases of CML remains unsatisfactory, with most patients dying from CML. A treatment pathway is outlined in the box and accompanying algorithm.

Conventional Cytotoxic Chemotherapy

Single-agent therapy with hydroxyurea or busulfan can control chronic phase CML and maintain normal WBC counts but is unlikely to significantly prolong survival. In many centers, hydroxyurea has replaced busulfan for initial control of CML, due to the potential for prolonged bone marrow hypoplasia associated with busulfan, and the superiority of hydroxyurea over busulfan has been demonstrated. [123] Hydroxyurea inhibits the enzyme ribonucleotide reductase, interfering with DNA synthesis. The usual starting dose is 2 g/day, although higher doses (34 g/day) can be used for short periods in patients presenting with very high WBC counts. The dose is titrated in the individual patient to the WBC count. Aplasia, if it occurs, is transient and usually reversible within days of discontinuation of the drug, unlike that associated with busulfan. Allergic reactions may rarely occur. Other complications include oral aphthous ulceration and nail dystrophy. At higher doses, nausea, vomiting, and diarrhea may occur. Teratogenicity has been reported in patients taking hydroxyurea during the first trimester of pregnancy.

Therapy with busulfan is usually commenced at 46 mg/day. Close monitoring of the WBC count is essential and it is advisable to discontinue therapy when the WBC count reaches 2030 × 10^9 /L, because the count will continue to fall for 23 weeks following discontinuation. When the WBC count stabilizes, busulfan therapy may be reinstituted at lower doses (13 mg/day) or intermittent courses may be used. Prolonged and occasionally irreversible aplasia may complicate busulfan therapy. Other toxicities include aspermia, amenorrhea, and a late pulmonary syndrome characterized by cough, fever, pulmonary infiltrates, and respiratory failure. A wasting syndrome similar to Addisons disease may also occur.

Other chemotherapeutic agents have also been investigated for the therapy of CML. Homoharringtonine has shown activity in some patients, including some hematologic and cytogenetic responses in accelerated phase disease. [124] However, complete elimination of Philadelphia chromosome-positive cells from the marrow using conventional chemotherapy is unusual, occurring in only 25% of patients. [125] [126] [127] Intensive chemotherapy similar to induction therapy for AML has been used in CML. Although complete hematologic responses and major cytogenetic responses can be achieved in some patients, these have generally been transient. [125]

Interferon Alpha

Interferon- is now considered standard therapy for most newly diagnosed patients with chronic phase CML. Initial reports indicated that interferon- therapy results in hematologic control in approximately 7080% of patients in chronic phase with a complete cytogenetic response in 1015% of patients and suggested that time to development of blast crisis and overall median survival could be prolonged. Achievement of a major

A TREATMENT PATHWAY FOR PATIENTS WITH CML

Numerous approaches to the therapy of newly diagnosed chronic phase CML are available, ranging from use of hydroxyurea as a single agent until disease progresses to aggressive use of allogeneic transplantation shortly after presentation. The use of interferon- is associated with low early mortality and prolonged survival in a subset of recipients, but arguably may jeopardize efficacy of subsequent allogeneic stem cell transplantation. On the other hand, early use of hematopoietic stem cell transplantation may be curative but is associated with hospitalization and a high incidence of early morbidity and mortality. Of course, the therapeutic decision-making process should include the wishes of a well-informed patient. A description follows of one approach to the treatment of CML drawing on our current understanding of the therapeutic options.

Patients presenting with CML receive leukapheresis or hydroxyurea or both to lower the WBC count, if necessary. Selected patients seeking the potential advantages of early transplantation may wish to proceed directly to allogeneic or autologous transplantation without a trial of interferon- (*dashed line*). Other patients wishing to pursue an initial nontransplant approach (*solid line*) receive a trial of high-dose interferon- (5 million units/m^2 /day) with appropriate dose modification. Cytosine arabinoside may be used as an adjunct to interferon-. Patients who achieve a major or complete cytogenetic remission (66% Philadelphia chromosome-negative metaphases in the bone marrow) by 1 year and who tolerate interferon- without major side effects remain on this therapy. Patients who fail to achieve major or complete cytogenetic remissions as well as patients with clinical or hematologic evidence of advancing disease and patients who cannot tolerate interferon- become eligible for alternative therapeutic approaches. Transplant approaches include allogeneic stem cell transplantation for patients with a suitably HLA-matched related or unrelated donor and autologous transplantation. Nontransplant approaches include hydroxyurea, interferon-, or novel chemotherapy.

cytogenetic response, defined as <35% Philadelphia chromosome-positive cells in the marrow, was associated with a statistically significant improvement in survival. [15] [128]

Randomized trials have compared interferon- with conventional chemotherapy for patients with chronic phase CML [126] [127] [129] [130] (Table 62-4). Most of these have shown a survival advantage for patients treated with interferon-. [126] [127] [129] The Italian Cooperative Study Group on CML reported results of therapy in 322 chronic phase patients randomly assigned to receive conventional chemotherapy (hydroxyurea or busulfan) or interferon- $_{2a}$. Therapy with interferon- induced more karyotypic responses than conventional chemotherapy (30% compared with 5%). A complete cytogenetic response was achieved in 8% and a partial cytogenetic response in

11% of interferon--treated patients. Interferon- therapy was associated with a longer time to progression to accelerated phase or blast crisis (median >72 months compared with 45 months) and with longer survival (median 72 compared with 56 months)[126] (Fig. 62-2 (Figure Not Available)).

Similarly, in the multicenter Medical Research Councils study of 527 chronic phase patients randomized to receive either interferon- or chemotherapy (busulfan or hydroxyurea) survival was significantly improved for patients treated with interferon-. Patients with a cytogenetic response to interferon- survived significantly longer than those not responding. In addition, a survival benefit was seen in the interferon- group even in the absence of a cytogenetic response. [129] [131]

TABLE 62-4 -- Randomized Studies of Interferon in Chronic Phase CML Patients

Reference	Randomization	n	Complete Hematologic Response	Major Cytogenetic Response	Median Survival	Cytogenetic Response Associated with Increased Survival
[130]	Interferon vs hydroxurea or busulfan	513	31%	10%	66 mo	No
[126]	Interferon vs hydroxurea or busulfan	322	62%	19%	72 mo	Yes
[129]	Interferon vs hydroxurea or busulfan	527	68%	11%	61 mo	Yes
[127]	Interferon vs busulfan	117	39%	7.5%	65 mo	Yes
[134]	Interferon/cytarabine vs interferon	721	66%	41% (12 mo) 54% (24 mo)	86% 3-y survival	Yes

However, the German CML Study Group, in a randomized trial of 513 patients receiving interferon-, hydroxyurea, or busulfan, failed to demonstrate an overall survival advantage for patients treated with interferon- compared with those receiving hydroxyurea (median survival 5.5 years compared with 4.7 years). Survival was improved compared to patients treated with busulfan (median survival 3.8 years). Patients with a complete hematologic response to interferon- had a survival advantage compared to partial responders or nonresponders. In contrast to other reports, achievement of a complete cytogenetic response to interferon- was not associated with improved survival.[130] It has been speculated that differences in dosing regimens may partly explain these discrepancies. [132] [133]

More recently, the use of interferon- in combination with other agents has been explored. [134] [135] Previous data suggested that cytarabine (cytosine arabinoside) given subcutaneously could reduce the number of Philadelphia chromosome-positive cells in the bone marrow. [136] [137] In the largest study reported to date, a multicenter trial conducted by the French Chronic Myeloid Leukemia Study Group, 721 chronic phase patients were randomized to receive either interferon- (5 million units/m [2] /day) and hydroxyurea or interferon-, hydroxyurea, and cytarabine (20 mg/m[2] /day subcutaneously for 10 days each month). The rate of hematologic response was greater in the interferon-cytarabine group (66% compared to 55%). Major cytogenetic responses were observed 12 months after randomization in 41% of patients in the interferon-cytarabine group compared with 24% in the interferon alone group. In patients receiving interferon- with cytarabine, cytogenetic response was complete in 15% compared with 9% for those receiving interferon- alone. At 24 months, a major cytogenetic response had been achieved in 54% compared with 41%. In both groups, landmark analysis showed a significant survival advantage for patients with a cytogenetic response (complete or partial) compared to those with no response or a minor response.[134] Low-risk patients by the Sokal score had a greater probability of cytogenetic response. Overall survival after 3 years was significantly greater (86%) for patients treated with interferon- and cytarabine compared with 79% for those treated with interferon- alone.

These studies have had a major impact on the approach to therapy of patients with CML. A recent meta-analysis confirms the survival advantage for patients with chronic phase CML treated with interferon-.[138] In summary, treatment with interferon- in chronic phase CML can result in hematologic responses in 7080% of patients. Cytogenetic responses, either partial or complete, occur in up to 50% of patients and these may be major and durable in 1530% with prolonged high-dose therapy. In most studies to date, achievement of a major cytogenetic

Figure 62-2 (Figure Not Available) Survival of CML patients randomly assigned to receive conventional therapy (hydroxyurea or busulfan) or interferon- $_{2a}$. (*From Italian Cooperative Study Group on Chronic Myeloid Leukemia,[126] with permission. Copyright 1994, Massachusetts Medical Society. All rights reserved.*)

response is associated with improved outcome, with survival of up to 90% in patients with a complete cytogenetic response.

Despite its demonstrated value for patients with chronic phase CML, interferon- therapy may be up to 200 times more costly than conventional chemotherapy [126] and up to 25% of patients discontinue therapy as a result of toxicity. [130] Side effects of interferon- include myalgia, arthralgia, impotence, weight loss, headache, and fever. Most patients experience an influenza-like syndrome at the onset of therapy. Gradually escalating doses over a number of weeks, premedication with acetaminophen, and administration of interferon- in the evening may alleviate these side effects significantly. Neurologic toxicity may occur, usually manifested by memory loss and depression, and is more prominent in older patients. Autoimmune phenomena including immune thrombocytopenia, autoimmune hemolysis, Raynauds phenomenon, lupus erythematosus, and hypothyroidism are also described. Up to 22% of patients develop anti-interferon antibodies, and neutralizing antibodies may be associated with a poor response to therapy.[139] Although interferon- therapy results in equivalent response rates in older patients, toxicity may be increased in this group. [140] Toxicity may also be increased if interferon- is combined with other agents. [130] [134] Thus, patient tolerance and compliance remain significant problems.

The optimal dose for interferon- therapy in CML has not yet been established but is currently being addressed in randomized trials. [131] [141] The most commonly used dose in clinical trials is 5 million units/m [2] /day. It has been argued that administration of lower daily doses of interferon- or use of thrice weekly interferon- dosing can be effective. Such regimens would probably reduce the toxicity of interferon-; however, their efficacy has been called into question. The median time to hematologic response is 68 months (many centers combine interferon- with hydroxyurea for initial control of disease) and to cytogenetic response is 2224 months. [126] [142]

Debate also continues regarding the precise role of interferon and its interaction with other therapies including SCT, where interval between diagnosis and transplant may be a critical prognostic factor for both survival and relapse. Some studies have suggested that prior interferon- therapy may adversely affect post-transplant outcome, although this remains controversial.[143] [144] [145] [146] In addition, even chronic phase patients with a complete cytogenetic response to interferon- usually have residual *bcr/abl*-positive cells detectable by reverse transcriptase-polymerase chain reaction (RT-PCR). [147] Thus, interferon- is unlikely to lead to continuing complete molecular remission, and its curative potential is not yet established.

Mechanism of Action of Interferon Alpha

The mechanism of action of interferon- remains unclear. There is evidence in vitro for antiproliferative effects, normalization of adhesion, progenitor/stroma interactions, and promotion of natural killer cell cytotoxic activity. [104] [105] [106] Interferon- causes a dose-dependent increase in adhesion of primitive long-term culture-initiating cells and committed colony-forming cells from CML marrow to normal stroma, possibly mediated by restoration of normal -integrin function. [104] [105] Interferon- may also modulate local paracrine release of growth factors in the stromal environment, with an increase in inhibitory cytokines such as the interleukin-1 receptor antagonist, transforming growth factor, and MIP-1. There may also be increased T-cell reactivity, although specific anti- *bcr/abl* T-cell reactivity induced by interferon remains unproven. Prevention of transcription of p210 *bcr/abl* mRNA and hence expression of the p210*bcr/abl* tyrosine kinase has also been suggested as a possible mechanism of action.[148] Others have implicated induction of apoptosis of Fas-positive CML progenitors via up-regulation of the Fas-receptor/Fas-ligand system by interferon.[149] [150] However, the relevance of these findings to the restoration of normal hematopoiesis in CML by interferon remains undefined.

TREATMENT OF THE ACCELERATED PHASE OF CML

With the onset of disease acceleration, increasing doses of hydroxyurea or interferon- are typically required for control, and median survival is 818 months. Interferon- may be combined with hydroxyurea, although the impact of this approach to treatment has not been addressed by randomized trials. Almost all of the large studies to date have examined the role of interferon- in patients early in the course of disease and in chronic phase. Factors influencing the response to therapy with interferon- are poor performance status, splenomegaly, anemia, and the presence of symptoms at diagnosis as well as elevated WBC count, bone marrow basophil percentage, or blast percentage in the peripheral blood. [128] A complete hematologic response is seen in <40% of patients in accelerated phase and major cytogenetic responses are rarely achieved.[15] [151] Thus, interferon- may not play a major role in the treatment of patients with accelerated phase disease, and the predominant cause of death remains blast transformation. Aggressive combination chemotherapy similar to that used in acute leukemia may result in complete hematologic remission in 2530% of patients, but is not associated with significant prolongation of survival. [152]

The complications of accelerated phase disease may require attention. Splenic pain may respond to splenic irradiation, although neither irradiation nor splenectomy prolong survival in most cases. In patients with thrombocytosis, Anagrelide may be useful to control the platelet count without affecting the WBC count. [153] Hyperviscosity symptoms due to hyperleukocytosis may be treated in urgent cases with leukapheresis. Therapy of priapism is difficult and surgical intervention is often complicated by impotence.

TREATMENT OF BLAST CRISIS

With the development of blast crisis, survival is usually limited to weeks or months. Most patients develop myeloid blast crisis (with occasional basophil, eosinophil, or erythroid predominance) that responds poorly to a combination chemotherapy regimen similar to that used for AML. Occasionally a lasting second chronic phase can be established using aggressive combination chemotherapy.[154] However, complete remission is achieved in <20% of patients. The results of SCT in blast crisis are similarly poor.[155] Tumor lysis syndromes may occur during aggressive treatment of blast crisis with associated hypocalcemia, hyperphosphatemia, hyperkalemia, hyperuricemia, renal failure, and acidosis.

In 2535% of cases of blast crisis the blasts show markers of lymphoid or biphenotypic differentiation. Patients with lymphoid blast crisis may respond to chemotherapy regimens containing vincristine and prednisone, similar to those used in ALL, with approximately 60% of patients responding. However, the overall survival of patients with lymphoid blast crisis remains only 46 months.[29]

ALLOGENEIC STEM CELL TRANSPLANTATION

Related Donor Transplantation

Long-term disease-free survival can be anticipated in 4570% of CML patients undergoing related donor SCT in chronic phase. [155] [156] [157] The beneficial effects are most evident in younger patients transplanted early in the course of disease (optimally within 1 year of diagnosis). More than 70% of this good-risk group experiences long-term disease-free survival. [155] [158] Indeed,

Figure 62-3 Probability of hematologic relapse for patients undergoing related donor marrow and unrelated donor marrow transplant for CML. (*Data from the University of Minnesota Bone Marrow Transplant Program,[161] with permission.*)

in some long-term studies, median survival for younger patients following allogeneic transplant for CML now approaches 10 years. [155] [156] [158]

Allogeneic SCT is generally performed following preparation with cyclophosphamide (60 mg/kg/day for 2 days) combined with total-body irradiation (single dose, fractionated or hyperfractionated). [156] Cyclophosphamide (50 mg/kg/day for 2 days) may be combined with busulfan (4 mg/kg/day for 4 days).[159] Alternative regimens that may be equally effective include high-dose etoposide in combination with fractionated total-body irradiation. [160] However, longer-term follow-up of patients transplanted with alternative preparative regimens may be necessary to gauge their effectiveness as it is increasingly recognized that late relapses following related donor SCT are not uncommon.[161] Pretransplant splenectomy does not improve the post-transplant outcome and may be associated with an increased risk of relapse.[162] [163] [164] Splenic irradiation has also been studied in a randomized multicenter study by the European Bone Marrow Transplant Group. No benefit was demonstrated in standard-risk patients. [165]

Pretransplant patient and disease characteristics have been analyzed to determine their association with outcome. Factors independently associated with an increased risk of relapse or death following related donor SCT include increased patient age and a longer interval between diagnosis and transplant. [155] [166] In a study of 137 consecutive related donor SCT recipients with CML at the University of Minnesota, the 5-year disease-free survival for patients undergoing transplant within 1 year of diagnosis was significantly better than that for patients transplanted beyond 1 year from diagnosis. [155] Other factors associated with an adverse outcome include SCT performed in accelerated phase of CML, with long-term survival of only 2040% of patients. [155] [158] [159] [167] [168] The International Bone Marrow Transplant Registry reported 35% survival in accelerated phase patients and 12% for patients undergoing transplant in blast crisis. [168] The recognition of a poor prognosis for patients undergoing transplant late in the course of disease or with advanced disease is of some importance because as many as one-third of patients in economically advanced countries undergo transplant in the less favorable accelerated or blastic phases of CML, and the interval between diagnosis and transplant varies widely.[169] T-cell depletion is associated with a decreased incidence of graft-versus-host disease (GVHD), but an increased risk of graft failure and relapse and is generally not undertaken for patients with a matched sibling donor. [170]

The probability of relapse at 5 years approaches 20% for recipients of unmanipulated, matched sibling donor stem cells, and approximately 10% of survivors free of disease at 5 years may subsequently undergo late hematologic relapse [155] [161] [171] (Fig. 62-3). Pretransplant factors independently predicting increased risk of post-transplant relapse include increased patient age, a prolonged interval between diagnosis and transplant, and prior splenectomy [155] [161] [164] [171] (Table 62-5). The International Bone Marrow Transplant Registry has reported a 40% relapse rate at 3 years in patients with CML receiving syngeneic stem cells compared with 7% in sibling donor transplant recipients. [172] For patients receiving busulfan-containing regimens, low plasma busulfan levels may be associated with an increased risk of relapse.[173] The rate of relapse is higher for recipients of T-cell-depleted marrow and for those receiving non-T-cell-depleted marrow with mixed T-cell chimerism post-transplant.[174] [175] Patients developing GVHD (acute or chronic GVHD) have a decreased risk of relapse. [155] [161] [176]

Unrelated Donor Transplantation

A human leukocyte antigen (HLA)-matched related donor is available for <35% of potential SCT recipients, and unrelated donor SCT should be considered for young patients without a matched sibling donor. This approach can result in successful outcome for patients with CML. Engraftment is achieved in 90% of patients, and overall survival following transplant of unmanipulated, unrelated donor stem cells is approximately 3545% at 2 years. [177] [178] [179] Results are highly correlated with risk factors. Selected patient groups with good risk factors, such as younger age, HLA match, and short interval for diagnosis to transplant in chronic phase, may have a <70% survival rate at 3 years. Recipients of unrelated donor marrow, although having increased transplant-related mortality and poorer overall long-term survival, rarely have hematologic or cytogenetic relapse of CML. This supports the concept that an ongoing graft-versus-leukemia effect related to alloreactivity between donor and host is important in preventing relapse. [161] [180] [181] The University of Minnesota reported a hematologic relapse rate at 5 years of only 3% for recipients of non-T-cell-depleted unrelated donor stem cells compared with a 20% risk of relapse following related donor

TABLE 62-5 -- Risk Factors for Relapse of CML Following Allogeneic Transplantation

Pretransplant Factors	Transplant Characteristics and Peritransplant Factors	Post-transplant Factors
Age	Related donor[a]	Absence of chronic GVHD
Interval from diagnosis to transplant	T-cell depletion[b]	*bcr/abl* positivity >6 mo post-transplant
Splenectomy	Plasma busulfan levels	Persistent *bcr/abl* positivity post-transplant
	Radiation dose	

[a]Compared to unrelated donor recipients.
[b]T-cell depletion is associated with a higher risk of relapse in both related donor and unrelated donor marrow recipients.

transplant[161] [171] (Fig. 62-3). An HLA-A or -B serologic mismatch between donor and recipient has an independent adverse effect on survival. [177] [178] [182] [183] The results of unrelated donor transplantation in children with CML have also been reported. Engraftment is usually successful in this group of patients (>95%). However, transplant-related mortality may be as high as 40%, and the reported long-term event-free survival is only 50%. [184]

In view of the associated toxicity, alternative approaches to unrelated donor transplant are being explored. T-cell depletion of unrelated donor stem cells can result in successful engraftment and perhaps a decreased incidence of GVHD and improved long-term survival. However, this may be achieved at the cost of an increased rate of CML relapse approaching that seen following related donor SCT, especially for patients undergoing transplant with advanced CML. [180] [185]

New Approaches to Allogeneic Transplantation

Recent studies suggest that the use of allogeneic peripheral blood progenitor cells (including cryopreserved peripheral blood cells) may increase the speed of myeloid and immunologic reconstitution following transfusion. [186] [187] Successful and sustained engraftment and similar short-term outcome to patients undergoing transplants with stem cells obtained from marrow have been reported, although the long-term influence of this approach on survival, the incidence of GVHD, and the risk of relapse have yet to be determined. Successful transplants have also been described using umbilical cord blood or placental blood stem cells in both related donor and unrelated donor recipients. Most reported studies describe the use of this approach in children, but successful engraftment in adults also appears possible. [188] [189] Use of nonmyeloblastic-preparative regimen with the potential to spare regimen-related toxicity is being tested and may be particularly applicable to older recipients.

Post-transplant Relapse and the Graft-versus-Leukemia Effect

Studies of minimal residual disease post-transplant have demonstrated that the leukemic clone is not always eradicated by the preparative regimen. It is believed that a continuing graft-versus-leukemia effect related to alloreactivity between donor and host is important. [161] [180] Cells positive for *bcr/abl* are detectable by PCR in many post-transplant patients, with a significantly higher incidence in patients receiving T-cell-depleted stem cell grafts compared with patients receiving unmanipulated stem cell grafts.[190] [191] It has also been demonstrated that *bcr/ abl*-positive cells persisting following transplant have both proliferative and myeloid differentiation capacity in vitro and therefore the capacity to contribute to relapse. [192] There is a lesser incidence and persistence of *bcr/abl*-positive cells in patients who develop either acute or chronic GVHD.[190] [192] Close monitoring of *bcr/abl* post-transplant can provide useful information regarding the risks of subsequent relapse, which may lead to therapeutic intervention. Patients PCR positive for *bcr/abl* 612 months following transplant and those with persistent positivity or rising numbers of *bcr/abl* transcripts have a significantly increased risk of subsequent cytogenetic and hematologic relapse. Earlier or transient positivity may not be associated with an increased risk of relapse compared to PCR-negative patients. [190] [193]

Therapeutic options for patients who relapse following allogeneic transplant have included second transplant, interferon-, and donor leukocyte infusions (DLIs). The graft-versus-leukemia effect, pioneered by Kolb, has been exploited to induce complete molecular remission using DLI and this has become the treatment of choice for most patients with CML who relapse post-transplant.[194] [195] [196] [197] Complete remission can be re-established in up to 75% of patients. In addition, these remissions are durable and the probability of continuing complete remission at 23 years is almost 90%. [194] Collins et al. surveyed results from 25 North American transplant programs regarding the use of and outcome following DLIs in 80 patients. [197] A complete response was observed in 60% of patients with CML. Factors associated with disease response included cytogenetic or chronic phase relapse. Seventy-six percent of patients receiving DLI therapy after molecular only or chronic phase hematologic relapse experienced complete response compared to 33% for patients with accelerated phase relapse and 17% for patients with blast phase relapse. The actuarial probability of remaining in complete remission at 2 years was 90%. Response also correlated with the occurrence of GVHD following the infusion of donor leukocytes. Most studies have shown that patients with cytogenetic or molecular relapse but without hematologic evidence of disease have a higher rate of complete remission compared with those with frank hematologic relapse.[195] [197] Sixty percent of patients develop GVHD and up to 20% of infusions are complicated by marrow aplasia.[197] This often fatal complication is associated with lack of demonstrable residual donor hematopoiesis in the transplant recipient prior to DLI.[198] These risks must be balanced against the potential benefits of re-establishing remission.

The appropriate dose and schedule for DLI infusion, whether a dose response exists, and the specific effector cell subpopulations responsible for the observed graft-versus-leukemia effect have yet to be determined.[199] [200] Future efforts will focus on identification of the effector cell populations that mediate the graft-versus-leukemia effect, particularly those specific subsets that might contribute to graft-versus-leukemia without causing GVHD.

Minimal Residual Disease in CML

The availability of successful therapy for post-transplant relapse of CML and the need to identify complete responders in patients treated with other modalities including interferon have heightened the importance of the wider clinical application of sensitive molecular biologic techniques for detection of minimal residual disease.[201] [202] [203] [204] Fluorescence in situ hybridization (FISH) techniques are especially useful for characterizing Philadelphia chromosome-negative but *bcr/abl*-positive patients.[201] [202] Hypermetaphase FISH allows analysis of greater numbers of metaphases per sample than conventional FISH and may be especially useful for monitoring patients treated with interferon, where large numbers of metaphases may be difficult to obtain. [202] RT-PCR may have increased sensitivity compared to FISH; however, reliable quantitative techniques suitable for general application have not yet been developed. An important limitation to both FISH and PCR techniques is their inability to detect clonal cytogenetic evolution, although increased *bcr/abl* chimeric mRNA expression may precede disease evolution.[193] [203] [205] In addition, the recent demonstration of low levels of *bcr/abl* expression in peripheral blood WBCs from healthy individuals raises concerns regarding the clinical implications of very low levels of *bcr/abl* transcripts post-transplant.[206]

Autologous Stem Cell Transplantation

The marrow in patients with CML contains a primitive population of progenitors that includes both Philadelphia chromosome-negative and -positive cells. [207] Given the unavailability of HLA-matched donors for many patients with CML and the toxicity of unrelated donor transplant in older patients, autologous SCT has been developed as an alternative approach to therapy. [208] [209] [210] [211] [212] [213] Several nonrandomized studies have suggested a survival advantage for patients treated with autologous transplant.[209] [210] [211] Indeed, in a number of studies survival compares favorably with that following allogeneic transplant. [210] [212]

McGlave et al. reported the combined results of autologous SCT for CML from eight transplant centers. Among 200 patients,

median survival was 42 months and the importance of age, interval between diagnosis and transplant, and phase of disease in determining transplant outcome was confirmed.[210] Although autologous SCT can result in (occasionally durable) Philadelphia chromosome-negative hematopoiesis, even patients with cytogenetic complete remission subsequently relapse. [210] [212] [214] [215] [216]

Current efforts are directed toward attempting to enrich the autologous stem cell graft for benign hematopoietic progenitors. In vivo enrichment for benign hematopoietic progenitors can be achieved by treatment with high-dose chemotherapy and granulocyte colony-stimulating factor (G-CSF) followed by collection of peripheral blood stem cells for autologous reinfusion. [211] [217] [218] Major cytogenetic responses (i.e., collections of Philadelphia chromosome-negative peripheral blood stem cells) can be achieved in up to 30% of cases by these means, and Philadelphia chromosome-negative long-term culture-initiating cells are present in such collections.[218] These techniques have resulted in the temporary establishment of benign hematopoiesis following reinfusion. The level of Philadelphia chromosome-positive cells present on hematopoietic recovery depends on the numbers of Philadelphia chromosome positive cells in the infused graft. [211] [217] [219]

There appear to be high numbers of normal, nonleukemic, long-term culture-initiating cells in the peripheral blood early in the course of CML, suggesting that early collection of peripheral blood stem cells for reinfusion may be advantageous. [220] [221] Indeed, recent reports indicate that results are better when peripheral blood stem cell mobilization and infusion are performed early in the course of CML. [222] [223] [224] In view of the potential for associated toxicity and mortality associated with the mobilization of peripheral blood stem cells with high-dose chemotherapy, [217] [224] it is of note that Philadelphia chromosome-negative progenitor cells can be mobilized using recombinant human G-CSF alone in patients treated with interferon. G-CSF mobilized blood cells enriched for the Philadelphia-negative progenitor population have been successfully used in autografting. [225] [226]

NEW STRATEGIES FOR THERAPY OF CML

Selection and Expansion of Benign Progenitors

Future therapy for CML may involve improved selection and expansion ex vivo of benign progenitors for reinfusion. [211] [227] It is known that the CD34+, HLA-DR fraction of resting marrow is enriched for Philadelphia-negative progenitors. It may therefore be possible to identify and isolate sufficient nonleukemic progenitors from the chromosome marrow to use for transplantation on the basis of their lack of HLA-DR expression, especially early in the disease. [94] [220] [227] [228] Alternative approaches include the functional isolation of cells with characteristics of hematopoietic stem cells using differential responsiveness to cytokines, [97] [229] and long-term culture of CML cells on stem cell factor-deficient stroma, which may favor the growth of benign progenitors. [107] The CD34+ populations contain only 15% of long-term culture-initiating cells. This proportion is increased to 40% in stroma non-contact culture conditions, and further enrichment may be achieved by supplementation with macrophage inflammatory protein 1 and interleukin-3. The development of this methodology has implications not only for the in vitro characterization of primitive progenitor cells, but may provide the ability to expand and enrich for Philadelphia chromosome-negative cells in vitro intended for subsequent in vivo infusion. [96] [227]

Antisense Oligonucleotides

Complementary antisense deoxyoligonucleotide sequences can hybridize to target mRNA and inhibit translation either by physical blockade of ribosome function or, following transport to the nucleus, by specific RNA degradation. Antisense oligodeoxynucleotides targeted to *bcr/abl*, which can cause decreased *bcr/abl* transcript levels and decreased CML cell growth in culture (perhaps by inducing apoptosis), are currently undergoing investigation for their potential use as ex vivo purging agents for autologous SCT. [230] [231] It has been suggested, however, that antisense-mediated inhibition of p210 *bcr/abl* mRNA and induction of apoptosis may not occur via sequence-specific mechanisms, [90] [232] [233] and there are a number of technical barriers to their successful therapeutic application. [234] Experimental autografts using in vitro purging with both *bcr/abl* and c-*myb* antisense oligonucleotides (which have been shown in marrow culture to result in the growth of *bcr/abl*-negative colonies) have resulted in successful engraftment and partial cytogenetic remission following reinfusion in patients with CML. [235] Others have investigated the use of antisense oligodeoxynucleotides in combination with chemotherapeutic agents in animal models. In a SCID mouse model of CML, the use of mafosphamide in combination with antisense phosphorothioate oligodeoxynucleotide significantly retarded the development of leukemia. [86] [236]

Tyrosine Kinase Inhibitors

The abnormal *bcr/abl* gene product has enhanced tyrosine kinase activity compared to the wild type c-*abl*. Recently, *abl*-specific tyrosine kinase inhibitors have been identified with the ability to selectively inhibit in vitro proliferation of leukemic colony-forming units-granulocyte/macrophage from CML progenitors (but not their normal counterparts). [237] [238] The tyrosine kinase inhibitor, genistein, can suppress both normal and CML cell proliferation and colony formation in marrow culture, with relative sparing of primitive long-term culture-initiating cells, and a decrease in the percentage of *bcr/abl*-positive progenitors, perhaps by induction of apoptosis. [237] Further preclinical testing is needed before the potential of this and other tyrosine kinase inhibitors for the treatment of CML is defined.

Gene Therapy for CML

Technical advances in gene therapy are likely to lead to novel approaches to stem cell transplant in patients with CML. One approach currently under investigation is the retroviral transduction of normal, Philadelphia chromosome-negative cells in patients with CML with a drug resistance gene linked to a *bcr/abl* antisense gene. [208] [239] [240] Selective therapy could then be applied following autologous transplant to eliminate residual Philadelphia chromosome-positive cells while sparing normal progenitors.

Immunomodulation

The characterization in vitro of apparently leukemia-specific immune responses to CML cells has led to speculation that in vivo immunomodulatory treatment may be possible. [241] Immunogenicity of amino acid peptides representing the p210 *bcr/abl* fusion region and peptide binding to major histocompatibility complex class I alleles have been demonstrated and peptide-specific CD4+ T-cell lines that recognize *bcr/abl*-expressing cells have been generated. [242] [243] [244] The p210 b3a2 gene product can be degraded and expressed for presentation by major histocompatibility complex class II molecules at the surface of leukemic cells, thus acting as a tumor-specific antigen. These observations may lead to therapy of CML using human T-cell-mediated recognition of tumor-associated antigens. [244] [245]

Others have explored the antileukemic potential of interleukin-2-activated natural killer (NK) cells and cytotoxic T cells. [17] [246] [247] Autologous NK cells can suppress progenitor growth from CML but not normal marrows, and large-scale expansion ex vivo of autologous activated NK cells now appears feasible, allowing future use for in vivo immunotherapy or in vitro marrow purging. [248] Recently, generation of dendritic cells in culture from patients with CML with the capacity to stimulate autologous T cells with cytotoxic and antiproliferative activity against CML cells but low activity against normal marrow cells has also been possible. [249] These approaches may lead to the development of adoptive immunotherapy of CML using expanded autologous antileukemic NK or cytotoxic T cells with enhanced activity against CML cells. These in vitro observations may precede the development of new strategies using immune recognition and tumor-specific cytotoxicity for immunotherapy of CML. [241]

THERAPEUTIC OPTIONS FOR PATIENTS WITH CML: SUMMARY

Initial control of the WBC count is most easily achieved using hydroxyurea. For most patients, early institution of therapy with interferon- is appropriate. Recent reports indicate that the use of interferon- in combination with other agents such as cytarabine may result in improved hematologic and cytogenetic responses, and survival may be prolonged. Patients responsive to interferon- may choose to continue interferon- therapy rather than risk the morbidity and mortality associated with allogeneic transplant. However, debate continues regarding the precise role of interferon- and its interaction with other therapies including SCT, where interval between diagnosis and transplant influences both survival and relapse rates. Even chronic phase patients with a complete cytogenetic response to interferon almost all have residual *bcr/abl*-positive cells detectable by RT-PCR, and its curative potential is not established. For younger patients with an available HLA-matched related donor, SCT may be curative and, therefore, early consideration should be given to the patients suitability for allogeneic transplantation. For patients lacking a matched related donor, unrelated SCT or autografting, with or without purging, may also be considered. The use of autologous stem cells may be appropriate for patients without a histocompatible donor who do not achieve a cytogenetic response to interferon, although, as with other approaches to therapy, results are likely to be improved by transplant early in the course of disease. Randomized studies comparing interferon therapy with autografting or allogeneic transplantation may be appropriate for selected groups of patients. Unfortunately, treatment in accelerated phase and blast crisis of CML remains unsatisfactory; for these patients, the predominant cause of death remains blast transformation.

Chapter 63 - Agnogenic Myeloid Metaplasia

Ronald Hoffman

INTRODUCTION

Agnogenic myeloid metaplasia (AMM) is a chronic, malignant hematologic disorder characterized by splenomegaly, a leukoerythroblastic blood picture, teardrop poikilocytosis (dacryocytes), varying degrees of marrow fibrosis, and extramedullary hematopoiesis. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] This disorder was first described in 1879 by Heuck,[11] who reported the presence of marrow fibrosis and extramedullary hematopoiesis in the liver and spleen of two patients. AMM has also been referred to by a variety of other terms, including myelofibrosis, myelosclerosis, idiopathic myeloid metaplasia, and osteosclerosis. [6] Fibrosis of the bone marrow is not unique to AMM and may accompany many other disorders[9] [10] (Table 63-1). In AMM, the marrow fibrosis is thought to be a response to a clonal proliferation of hematopoietic stem cells. This syndrome frequently leads to progressive marrow failure, [12] but whether the marrow failure is a consequence of the excessive marrow fibrosis or of the underlying hematologic malignancy remains unknown. Dameshek[13] in 1951 included AMM among the myeloproliferative disorders. This hypothesis was largely based on clinical observations of patients with polycythemia vera, chronic myeloid leukemia (CML), and primary thrombocythemia who developed marrow fibrosis and a clinical picture resembling AMM. In addition,

TABLE 63-1 -- Conditions Associated with Myelofibrosis Nonmalignant Conditions

Nonmalignant conditions
Infections: tuberculosis, histoplasmosis
Renal osteodystrophy
Vitamin D deficiency
Hypoparathyroidism
Hyperparathyroidism
Gray platelet syndrome
Systemic lupus erythematosus
Scleroderma
Radiation exposure
Osteopetrosis
Paget disease
Benzene exposure
Thorotrast exposure
Gaucher disease
Malignant Disorders
Agnogenic myeloid metaplasia
Other chronic myeloproliferative disorders: polycythemia vera, chronic myeloid leukemia, primary thrombocythemia
Acute myelofibrosis
Acute myeloid leukemia
Acute lymphocytic leukemia
Hairy cell leukemia
Hodgkin disease
Acute myelodysplasia with myelofibrosis
Multiple myeloma
Systemic mastocytosis
Non-Hodgkin lymphoma
Carcinoma: breast, lung, prostate, stomach

Dameshek[13] noted that each of these myeloproliferative disorders frequently terminates in a leukemic phase.

EPIDEMIOLOGY

Few epidemiologic studies are available to estimate the actual incidence of AMM. From an examination of the number of cases encountered at a variety of medical centers, one can arrive at some estimate of the frequency of the disorder. The Mayo Clinic cared for 137 patients with AMM from 19601965; 100 cases were observed at the Ohio State University over a 16-year period; and 65 patients were seen from 19681980 at Barnes Hospital in St. Louis. [1] [5] [6] [8] Recently, the incidence rate of AMM in Olmstead County, Minnesota has been determined to be 1.33 patients/100,000 population/year. [14] The median age at diagnosis was 67.0 years and the Kaplan-Meier survival was 52.4% at three years. [14]

In Japan AMM is considered a rare disorder, with only 84 cases per 100,000 at autopsy. [15] [16] This figure was obtained by monitoring autopsy protocols from all Japanese medical schools, universities, general hospitals, and research institutes over a 10-year period. [15] The autopsy incidence of myelofibrosis among survivors who were 10,000 m from the hypocenter of the atomic bomb explosion at Hiroshima was 18 times the incidence reported from the remainder of Japan. [17] These patients became symptomatic an average of 6 years after the bomb blast. [17] Such data indicate a strong link between excessive radiation exposure and development of AMM, which is further substantiated by the high incidence of myelofibrosis in patients who have received the contrast material Thorotrast (which contains ^{232}Th, a radioactive element with a half-life of 1.41×10^{10} years). [18] Thorotrast is taken up and retained indefinitely by cells of the reticuloendothelial system, which results in continuous irradiation of the liver, spleen, lymph nodes, and bone marrow. Chronic exposure to several industrial solvents, including benzene and toluene, has also been associated with development of AMM. [19] [20] [21] AMM has been reported as a complication of chronic benzene poisoning since the chemical was first used in the leather and shoe industries during the 1930s and 1940s. [19]

The average age at diagnosis of AMM is approximately 60 years, most patients being diagnosed at 5069 years of age. [1] [2] [3] [4] [5] [6] [7] [8] [14] In several series, males have been reported to be affected more frequently than females, but others have failed to confirm this male predominance. [1] [2] [3] [4] [5] [6] [7] [8] [14] Rarely, AMM has been reported in the pediatric age group. [22] In several children, idiopathic myelofibrosis presented in early childhood and in one family, twins were affected. [23] No evidence of genetic transmission exists.

BIOLOGIC AND MOLECULAR ASPECTS

Ward and Block[7] originally proposed that AMM represents a response of an intrinsically normal stem cell to an unidentified stimulus, while Dameshek [13] conjectured that the abnormal fibroblastic proliferation in AMM is not an integral part of the primary disorder.

These conflicting hypotheses were tested in studies using a

variety of genetic markers to define the cellular origin of AMM. Jacobson et al. [12] demonstrated in a black female AMM patient who was heterozygous for glucose-6-phosphate dehydrogenase (G6PD) that circulating hematopoietic cells were derived from a common hematopoietic stem cell and that the bone marrow fibroblasts were nonclonal in origin. Using x-chromosome gene probes, Lucas et al. [24] have confirmed the clonal origin of hematopoiesis in AMM. Furthermore, using a similar molecular biologic approach Anger et al. [25] reported that in each of three cases of AMM suitable for clonal analysis a clear-cut monoclonal X-inactivation pattern was observed. Furthermore, Greenberg et al.[26] studied the cytogenetic composition of bone marrow fibroblasts of an AMM patient who had a clonal cytogenetic abnormality in unstimulated peripheral blood cells, which, however, was absent in the marrow fibroblasts.

The fully developed fibrosis of the bone arrow in AMM is frequently preceded by a hypercellular phase of variable duration. Because characteristic blood cell findings of the cellular phase of AMM do not exist, the diagnosis depends on the demonstration of atypical megakaryocytes and an increase of fibers within marrow biopsies and the exclusion of other myeloproliferative disorders. Kriepe et al. [27] have used an analysis of x-linked restriction fragment length polymorphisms of blood cells of patients at various stages of AMM, to demonstrate clonality of hematopoiesis not only in advanced stages of AMM but also in the cellular phase. In addition, an N- *ras* mutation present in hematopoietic cells in an AMM patient indicated that T and B cells were also involved in the malignant process in some patients, perhaps providing some explanation for the immunologic abnormalities in AMM. [28] These studies indicate that AMM is a clonal hematologic malignancy and that the marrow fibrosis represents a secondary nonneoplastic reaction of marrow stromal cells. [24] [25] [26] [27] [28] [29] If myelofibrosis is truly an epiphenomenon of the neoplastic hematopoietic cell proliferation it may be expected to disappear if this cell population is eradicated. Reversal of myelofibrosis has, in fact, been observed following allogeneic bone marrow transplantation and following long-term administration of chemotherapy or interferon. [30] [31] [32] Such findings indicate that the bone marrow fibrosis in AMM is not irreversible and is clearly a consequence of the neoplastic cellular proliferation.

The concept that the primary defect in AMM resides in hematopoietic stem cells or progenitor cells is further supported by the observations of a number of investigators concerning the number of unilineage and multilineage hematopoietic progenitor cells present in the blood of AMM patients. [33] [34] [35] [36] [37] [38] Circulating assayable progenitor cells are increased from 9- to 20-fold above numbers present in normal peripheral blood. [33] [34] [35] [36] [37] [38] Patients with secondary myelofibrosis have a much smaller (threefold) increase in circulating assayable progenitor cells. [34] Secondary myelofibrosis is thought to result from insults to the marrow microvascular system rather than from an intrinsic hematopoietic cell defect. [9] [10] Erythroid and megakaryocyte colony formation has been observed to occur in the absence of added exogenous cytokines in AMM, a finding common to other myeloproliferative disorders. [33] [34] [35] [36] [37] [38] [39] The hypothesis that marrow fibrosis in AMM is a secondary process is further supported by the work of Castro-Malaspina et al., [40] Wang,[41] and Hirata et al.[42] These groups have each found that fibroblasts derived from marrow explants obtained from AMM patients displayed the same physical and proliferative characteristics as normal marrow fibroblasts. Both AMM and normal marrow fibroblasts exhibited anchorage and serum dependence, contact inhibition of growth, and similar production of hematopoietic colony-stimulating activities. These data suggest that marrow fibroblasts and their precursor cells in AMM patients do not differ from those of normal subjects.

Many of the peripheral blood abnormalities associated with AMM may be attributed to the extramedullary hematopoiesis which is characteristic of this disorder. Extramedullary hematopoiesis had previously been attributed to the reactivation of quiescent hematopoietic stem cells, which are retained at sites of prior embryonic hematopoiesis, especially the spleen.[7] [13] This hypothesis has been recently questioned by the observation that the spleen is not a prominent site of fetal hematopoiesis in humans and by the observation that extramedullary hematopoiesis occurs in a wide variety of sites in AMM that cannot be accounted for by the fetal reversion hypothesis.[43] [44] [45] Intravascular hematopoiesis within the sinusoids of the bone marrow is a conspicuous finding in AMM. [46] It is likely that this finding is the result of marrow fibrosis distorting the marrow sinuses and allowing entrance of hematopoietic precursors or progenitor/stem cells into the sinusoids and access to the circulation.[46] [47] Such cells are normally filtered from the peripheral blood by the spleen and destroyed. If the number of such primitive cells exceeds the capacity of the spleen, these cells are thought to be worked into the peripheral blood, leading to a leukoerythroblastic blood picture, or to lodge in potential sites of extramedullary hematopoiesis.[44] [45] The characteristic changes of the marrow vascular architecture consist of increased quantities of collagen type IV deposits associated with endothelial cell proliferation. [46] [47] Moreover, sinusoidal hyperplasia and hypervascularity, resulting in increased blood flow, occurs. [47] The excessively dilated marrow sinusoids in AMM contain prominent intraluminal foci of hematopoiesis. [47] [48] Thiele et al.[46] pursued a morphometric analysis of marrow vascular structures and collagen type IV deposits in AMM. In comparison to normal controls and patients with polycythemia vera, a significant increase in the number of marrow sinusoids as well as subendothelial collagen type IV in AMM was observed. [46] Furthermore, evolution of the fibro-osteosclerotic changes in AMM was accompanied by a striking accumulation of collagen IV and a marked luminal expansion and irregularity. Thiele et al. [46] have hypothesized that neovascularization of the bone marrow stroma in AMM is likely mediated by megakaryocyte -granule constituents. Transforming growth factor- (TGF-), for instance, has a profound effect on angiogenesis.[49] [50] The evolution of the fibro-osteosclerotic process in AMM appears to be a coordinated process closely related to the vascular proliferation and also modulated by growth factors present within abnormal megakaryocytes.

Groopman [51] first hypothesized that growth factors released from neoplastic hematopoietic cells in AMM were capable of stimulating marrow fibroblast proliferation and suggested that the megakaryocyte was the primary source of such proliferation factors. The role of megakaryocytes in the development of fibrosis in AMM is further supported by (1) the megakaryocytic hyperplasia with dysplastic or necrotic megakaryocytes which characterizes this disorder, (2) increased circulating megakaryocytes and megakaryocyte progenitors that are present in AMM, (3) the association of marrow fibrosis and acute megakaryocytic leukemia, and (4) the presence of myelofibrosis in gray platelet syndrome, an inherited disorder of platelet -granules. [52] [53] [54] Castro-Malaspina et al.[55] subsequently showed that megakaryocyte-enriched marrow cell homogenates and platelet homogenates induced DNA synthesis by human marrow fibroblasts. This group hypothesized that ineffective megakaryocytopoiesis in AMM results in liberation of excessive amounts of such growth factors, leading to marrow fibroblast expansion and collagen synthesis.[55] Platelet-derived growth factor (PDGF), TGF-, and epidermal growth factor (EGF), each of which is contained within platelet and megakaryocyte -granules, are known to stimulate marrow fibroblast proliferation. [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] In fact, TGF- enhances type I and type III procollagen and fibronectin synthesis by marrow fibroblasts.[57] Kimura et al.[59] have presented data to suggest that myeloproliferative disease fibroblasts are more sensitive to human serum mitogens than normal

marrow fibroblasts. The PDGF content of platelets from AMM patients is known to be decreased, indicating that a release or leakage of such growth factors by marrow

megakaryocytes may occur.[58] Burstein et al.[60] were, however, unable to detect any connection between marrow fibrosis and plasma levels or platelet content of platelet factor 4. Their studies indicated that if -granule constituents were important in the development of marrow fibrosis, their release or leakage would likely occur within the marrow cavity. Such local effects could result in fibrosis without leading to increased concentrations of -granule constituents in the general circulation. [60]

Martyré et al.[61] have further examined the possibility that platelet -granule constituents may account for marrow fibrosis in AMM. In these studies, AMM platelet PDGF and TGF- levels were found to be 2.03.0 and 1.53.0-fold higher respectively in AMM than in normal controls while EGF levels in AMM were similar to that of control platelets.[61] The role of PDGF and TGF- in the biogenesis of AMM is likely not restricted merely to promoting fibroblastic proliferation but is also related to the effect of these two growth factors on synthesis, secretion, and degradation of extracellular matrix components. [56] [57] Martyré et al. have presented additional data which strengthens the hypothesis that TGF- plays a role in the development of progressive fibrosis in AMM. [52] [53] [61] This group documented the increased expression of TGF- mRNA in peripheral blood mononuclear cells isolated from AMM patients and localized this to peripheral blood megakaryocytes of AMM patients. [61] These data strongly implicate TGF- as a major player in the biogenesis of fibrosis in AMM. [52] [53] [61]

TGF- enhances fibronectin and collagens type I, III, IV as well as chondroitin/dermatan sulphate and proteoglycan gene expression. [63] [65] TGF- decreases the synthesis of various collagenase-like enzymes that degrade extracellular matrices, while at the same time stimulating the synthesis of protease inhibitors such as plasminogen activator inhibitor I. [66] The net effect of these complex interactions is the accumulation of extracellular matrix, which likely contributes to further progression of fibrosis.[63]

Additional growth factors are likely involved in the development of progressive fibrosis in AMM. Circulating megakaryocytic cells and platelets from AMM patients have been shown to possess high levels of basic fibroblast growth factor (bFGF). [67] [68] Since bFGF is devoid of a secretion peptide signal, bFGF is not present in media conditioned by megakaryocytic cells from AMM patients. Basic fibroblast growth factor is a potent angiogenic factor and is a mitogen for human bone marrow stromal cells.[68] Elevated platelet, megakaryocyte, and serum bFGF levels have been reported in AMM patients with progressive fibrosis. [67] [69] Basic fibroblast growth factor could be released or leaked from dysplastic and necrotic AMM megakaryocytes or platelets. These findings suggest that bFGF might also contribute to the progressive fibrosis and pronounced angiogenesis frequently observed in AMM. [67] [69]

Recently, platelets have been shown to store and release the calcium-binding protein, calmodulin. [67] [69] Extracellular calmodulin is a mitogen for a variety of cells including fibroblasts.[67] [69] Urinary calmodulin excretion has been shown to be significantly elevated in patients with AMM in comparison to other myeloproliferative disorders without fibrosis.[69] These data suggest that abnormal secretion or leakage of calmodulin in addition to bFGF, PDGF, TGF- and EGF from defective megakaryocytes and/or platelets may also be involved in the pathogenesis of bone marrow fibrosis. [67] [69]

The role of the megakaryocyte and platelet in the development of marrow fibrosis was further clarified by the transplantation of marrow cells genetically modified to overexpress thrombopoietin (TPO) into normal mice.[70] [71] These animals possessed increased numbers of platelets and megakaryocytes and developed a syndrome characterized by marrow myelofibrosis, osteosclerosis, extramedullary hematopoiesis, and elevated numbers of circulating hematopoietic precursors. [70] [71] In these mice, TGF- and PDGF levels in platelet-poor plasma were elevated 23-fold higher than that in normal control mice. [70] [71] Retransplantation of these mice with normal marrow cells resulted after 1215 weeks in reduction of platelet and megakaryocyte numbers and reversal of the marrow myelofibrosis and osteosclerosis. [71] These data dramatically demonstrate the role of megakaryocytes and platelets and their intracellular growth factors in the generation of marrow fibrosis. Remarkably, transgenic mice overexpressing TPO in the liver but not the marrow have similar degrees of megakaryocytic hyperplasia and thrombocytosis but do not develop marrow fibrosis.[72] The discrepancy between these two animal models emphasizes the unique consequences that marrow TPO generation might play in the generation of marrow fibrosis. Furthermore, Ozaki et al. have reported recently that TPO was capable of enhancing the production of megakaryocyte PDGF, PF-4 and TGF-.[73] Whether TPO actually serves as an autocrine or paracrine growth factor for megakaryocytes in AMM will likely be the subject of considerable future investigation.

Megakaryocytes are not the only cells capable of releasing cytokines that promote marrow fibrosis. Monocytes/macrophages from patients with AMM have been shown to produce greater quantities of TGF- and interleukin-1 (IL-1) than normal controls. [74] IL-1 and TGF- are both fibroblast mitogens that induce extracellular matrix protein production. Rameshwar et al. have shown that monocyte adhesion to extracellular matrix proteins leads to the overproduction of IL-1 and TGF- by AMM monocytes.[74] The monocyte adhesion molecule CD44 appears to be involved in the induction of fibrogenic cytokines by mediating the interaction between monocytes and accumulated extracellular matrix protein deposits.[74] The relative role of megakaryocyte/platelet or macrophage/monocyte-derived fibrogenic cytokines in the pathogenesis of AMM requires further study.

ETIOLOGY AND PATHOGENESIS

The etiology of AMM remains unknown. In experimental systems the exposure of a variety of animal models to chemical agents, industrial solvents, hormones, viruses, immunologic stimuli, and ionizing radiation have led to the development of AMM. [6] A model of AMM has been established in the rabbit, [75] [76] [77] [78] in which saponin administered intravenously induces extramedullary hematopoiesis and myelofibrosis over a period of weeks. [76] Interestingly, mice and rats fail to respond to the same doses of saponin. [75] Hoshi and Weiss [75] have provided ultrastructural evidence to suggest that saponin causes damage to the endothelium of marrow vascular cells, rendering them incompetent. A series of hemorrhagic events appears to occur, leading to release of normoblasts into the peripheral blood, marrow hypoplasia, fibrosis, and regeneration. [75] This effect is accompanied by the appearance of increased numbers of hematopoietic progenitor cells in the blood and spleen and a simultaneous depletion of such cells in the marrow. [75] Such marrow vascular injury may be a common link leading to the development of myelofibrosis.

Progress has recently been made in defining the nature of the connective tissue matrix present in normal marrow and in patients with AMM. [10] Reticulin fibrosis of the marrow represents an exaggeration of the fibrous pattern of normal marrow. In contrast, collagen fibrosis occurs in primary and secondary AMM and results in the disruption and obliteration of the sinusoidal architecture of the bone marrow. Bone marrow reticulin has been shown to be composed of types I and III collagen and fibronectin. [78] [79] [80] Charron et al. [81] documented a constant increase in marrow collagen content during the course of AMM. The increment in collagen was highest in those patients in whom the

disease was of longest duration. [81] As compared with collagen extracts from normal individuals, AMM extracts showed a moderate increase in neutral soluble collagen and a larger increase in polymeric collagen. [81] Charron et al. [81] also noted changes in the pattern of marrow collagen deposition during the course of AMM. Early in the course there is a higher percentage of newly synthesized fibers, and later more polymeric collagen is present, presumably as a result of progressive cross-linking and insolubilization. Both Charron et al. [81] and Gay et al. [79] claim that type III collagen preferentially increases in the early stages of the disease but that it is subsequently replaced by type I collagen. Serum procollagen NH_2 -terminal peptide III (PC III), which is cleared extracellularly during collagen biosynthesis, is increased in most AMM patients. [82] This finding supports the concept that type III collagen synthesis is increased in AMM. [83] [84] [85] Some investigators have suggested that PC III levels do not reflect the extent of marrow fibrosis in AMM, [83] [84] yet PC III elevation in a longitudinal study of patients with AMM was found to be a sensitive marker of disease activity. [85] [86] PC III levels were observed to fall in patients responding to chemotherapy and to rise 12 weeks prior to elevations in white cell and blast cell counts in patients unresponsive to chemotherapy. [86] Bone marrow fibrosis appears to depend not only on the accumulation of collagen but also on the establishment of an equilibrium between collagen production and destruction. PC III levels would therefore be expected to reflect collagen synthesis more closely than total marrow collagen content.

Extensive deposition of collagen type VI in AMM has been documented. [54] This structural component forms a linkage between individual collagen type 1 and/or collagen type III fibers. In addition, advanced marrow fibrosis is associated with increased deposition of fibronectin, tenascin and citronectin. In normal bone marrow, collagen type IV and laminin are limited to discontinuous sinusoidal membranes while myelofibrotic stroma possesses continuous sheets of both proteins resulting from neovascularization and endothelial cell proliferation. Reilly has suggested that this altered basement membrane structure might facilitate the excessive migration of marrow progenitor/stem cells from the marrow in AMM. [54]

and come to medical attention because of an enlarged spleen detected during routine physical examination or because of an abnormal peripheral blood smear. The most common symptoms in AMM are a result of anemia, which leads to complaints of weakness, fatigue, dyspnea on exertion, and palpitations. With enlargement of the spleen, various syndromes characterized by abdominal discomfort may emerge.[87] Pressure of the spleen on the stomach may lead to delayed gastric emptying and early satiety.[87] Patients may merely complain of a dull, heavy sensation in the left upper quadrant. Splenic infarction may produce pain of extreme severity, simulating an acute abdominal emergency. Severe diarrhea in patients with AMM may be particularly disabling; because studies of gut flora and motility have been unrevealing, it appears that the pressure of the spleen on the colon or small bowel may be responsible for this symptom. Rarely, the development of AMM can be preceded by the appearance of multiple cutaneous edematous plaques and nodules characteristic of Sweet syndrome, a cutaneous process occuring in response to a number of hematologic malignancies.[88] In addition, extramedullary hematopoiesis can rarely occur in the skin, manifesting as nontender, occasionally pruritic red, pink or violaceous plaques, papules, or hemangioma-like nodules. These dermal infiltrates, when biopsied, are composed of combinations of myeloid, erythroid, and megakaryocytic cells.[85] [90]

Bleeding problems may complicate the clinical course of AMM patients. Bleeding may be trivial, as manifested by petechiae and ecchymoses, or may be life-threatening as a result of uncontrollable esophageal bleeding. [1] [2] [3] [4] [5] [6] [7] [8] It may be secondary to thrombocytopenia or to poor platelet function. [1] [2] [3] [4] [5] [6] [7] [8] Bleeding may be only initially encountered during a surgical procedure such as splenectomy; in this case, the bleeding diathesis may be secondary to nonapparent disseminated intravascular coagulopathy (DIC) and has the potential for catastrophic consequences. [6]

In addition to the preceding three major modes of clinical presentation of AMM, occurrence of isolated sites of ectopic myeloid metaplasia has been reported, particularly in the pulmonary, gastrointestinal, central nervous, and genitourinary systems. [1] [2] [3] [4] [5] [6] [7] [8] Such patients present with cough and large lung tumors, headache, or paralysis secondary to brain tumors or spinal cord tumors, urinary tumors present in either the bladder or kidney, small bowel obstruction, or intractable ascites secondary to ectopic implants of hematopoietic tissue in the gut or peritoneum. [1] [2] [3] [4] [5] [6] [7] [8] [91] [92] [93] [94] [95] [96] [97] [98]

Myeloid metaplasia of the renal pelvis, ureters, and bladder, as well as renal parenchymal infiltration, have been observed. In addition, expansion of hematopoietic tissue at the urethral meatus may be confused with a urethral carbuncle. [95] Such strategically localized sites of extramural hematopoiesis may lead to renal failure or obstruction of both kidneys and bladder dysfunction. [95] Ascites occurring in a patient with AMM may result from peritoneal or mesenteric implants of extramedullary hematopoietic tissue and/or from portal hypertension. [96] [97] If the ascites is secondary to peritoneal implants the fluid is always exudative and sterile and frequently contains myeloid, erythroid, and megakaryocytic elements. [97] Such cytologic studies should routinely be performed on ascitic or pleural fluid obtained from patients with AMM.

Nonspecific systems are not infrequent in AMM and include fever, night sweats, anorexia, and weight loss. [5] Table 63-2 lists the prominent physical findings in patients with AMM. [5] [8] Splenomegaly serves as the hallmark of the disease. Its extent may vary, but massive splenomegaly, with the organ occupying the entire left side of the abdomen and extending into the pelvis, may occur in 35% of patients. Hepatomegaly occurs in almost 70% of cases, [1] [2] [3] [4] [5] [6] [7] [8] and lymphadenopathy is observed in 1020%, but the degree of nodal enlargement is frequently only moderate. [5] [8] Other important physical findings include pallor, peripheral edema, jaundice, and bony tenderness. Acute

Figure 63-1 Peripheral blood smear showing normoblasts and teardrop poikilocytes in AMM. (Wright stain, ×700.)

monoarticular inflammation due to secondary gout is seen in 6% of patients. [5] Peritoneal implants of extramedullary tissue may lead to development of ascites. [95] [96] Portal hypertension may occur and is a result of massive increases in hepatic blood flow and intrahepatic obstruction. [3] [5] [6] [7] [87] [98] [99]

Clinical features of portal hypertension, such as ascites or esophageal varices, are known to occur in 918% of patients with AMM. [96] Occasionally, cirrhosis or evidence of thrombosis of the portal or hepatic veins has been reported. [98] [99] The liver histologic findings in AMM have previously been considered normal or to be characterized by minimal portal fibrosis, which has led to the view that the splenomegaly in AMM may be a result of increased hepatic blood flow with resultant portal hypertension. Wanless et al., however, analyzed a large autopsy series of patients with AMM and found frequent thromboses in small or medium-sized portal veins as well as in extrahepatic portal veins in patients with portal hypertension. [98]

LABORATORY EVALUATION

Careful examination of the peripheral blood smear (Fig. 63-1) and bone marrow (Fig. 63-2) permits ready diagnosis of AMM. The presence of a leukoerythroblastic blood picture with teardrop poikilocytosis (dacryocytes) strongly suggests this diagnosis. A leukoerythroblastic blood picture characterized by the presence of nucleated red blood cells and immature myeloid elements is seen in 96% of cases. [1] [2] [3] [4] [5] [6] [7] [8] Megathrombocytes and megakaryocytic fragments are a constant finding. The teardrop erythrocytes (dacryocytes) have been noted to decrease in number following splenectomy or institution of chemotherapy, [100] [101] which has led some to suggest that splenic fibrosis may lead to development of these red cell changes. [100] [101] In approximately 60% of patients, hemoglobin levels drop to <10 g/dl.[1] [2] [3] [4] [5] [6] [7] [8] The degree of anemia is difficult to estimate by hemoglobin or hematocrit determinations, since individuals with large spleens often have expanded plasma volumes. Such alterations in hemodynamics may lead to apparent anemia, which is largely dilutional in nature. Of patients with decreased red cell masses, 95% have normochromic normocytic red cell indices.[102] The anemia is due to both ineffective red cell production and shortened red cell survival. [103] [104] [105] [106] Ineffective red cell production in AMM can be demonstrated by ferrokinetic studies, which are characterized by increased iron turnover but decreased incorporation of radioactive iron into circulating red cells. [103] [104] [105] [106] Silverstein[6] found ineffective iron incorporation into red cells to occur in 90% of patients with AMM. Morphometric analysis of bone marrow

Figure 63-2 Marrow section from a patient with diffuse myelofibrosis and osteosclerosis. (H&E, ×135.) (*From Silverstein,[6] with permission.*)

biopsies have demonstrated a significant reduction of erythroid precursors. Erythroid hypoplasia is more common than previously appreciated. [107]

Fifteen percent of patients have major hemolytic episodes during their clinical course. [6] The cause of the hemolytic anemia is usually multifactorial, with contributions from hypersplenism, a defect in red cells resembling that in paroxysmal nocturnal hemoglobinuria, and antierythrocyte autoantibodies. [103] [104] [105] [106] [107] [108] [109] [110] In one series, 55% of patients with AMM had a positive acid hemolysis or sucrose hemolysis test, or both, and 10% had decreased haptoglobin levels and hemosiderinuria, suggestive of intravascular hemolysis. [109] [110] Hypochromic microcytic anemia resulting from iron deficiency secondary to blood loss may develop in 5% of AMM patients. The etiology of the blood loss may be leaking esophageal varices, duodenal ulceration, gastritis, or intravascular hemolysis. Occasionally, a patient with AMM may develop an occult malignancy or a site of extramedullary hematopoiesis within the gastrointestinal tract, which may serve as a bleeding source.[111] Macrocytic anemia may complicate AMM.[112] Folic acid absorption is normal in these patients, but the folic acid deficiency is probably due to increased utilization.[112]

Leukopenia can occur in 1325% of patients, while leukocytosis is seen in one-third. [1] [2] [3] [4] [5] [6] [7] [8] In one series,[8] the mean white count was 16,600/mm^3 . Occasional blast cells and granulocytes with the pseudo-Pelger-Huët anomaly are frequent findings. [6] The leukocyte alkaline phosphatase score was studied in 78 patients by Silverstein and Elveback [113] and was high in 41 patients (>100), normal in 17 patients (30100), and low in 20 patients (<30). Such a distribution of leukocyte alkaline phosphatase scores has been reported by others. [8]

In the Mayo Clinic series of 169 patients, platelet counts of <100,000/mm^3 were observed in 31% of patients, while platelet counts of >800,000 were observed in 12%.[6] Defective platelet aggregation is common, and platelets frequently do not respond to either collagen or epinephrine. [6] [114] Didsheim and Bunting[114] reported that 5 of 10 patients with AMM had prolonged bleeding times. A variety of qualitative platelet anomalies documented by abnormal in vitro aggregation patterns has been documented in AMM.[115] In 15% of patients, abnormalities suggestive of ongoing DIC are found, including decreased platelet numbers, decreased levels of coagulation factors V and VIII, and increased fibrin-split products. [6] Usually when DIC occurs in AMM, it produces no symptoms and unfortunately may only become clinically apparent following surgical intervention. Associated liver dysfunction may also be a contributory factor to prolongation of the prothrombin time. Additional laboratory abnormalities are quite frequent. In one series lactic acid levels were elevated in 95% of patients, bilirubin levels in 40%, uric acid in 60%, and alkaline phosphate and serum glutamic oxaloacetic transaminase levels in 50%. [8] Patients with AMM have been noted to have decreased levels of total cholesterol. [116] [117] The ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol has been shown to be diminished. [116] [117]

Ferrokinetic and red cell survival studies may be useful in defining sites of extramedullary hematopoiesis and determining the cause of anemia in AMM. [6] [103] [104] [105] [106] Furthermore, the presence of erythroid hyperplasia, intense hemolysis, increased plasma volume, and significant ineffective erythropoiesis appears to define a subpopulation of patients with an especially poor prognosis. [6]

A variety of immunologic abnormalities have been reported in AMM, including the presence of antinuclear antibodies, elevated rheumatoid factor titers, direct Coombs test positivity, lupus-type circulating anticoagulants, hypocomplementemia, marrow lymphoid nodules, and increased circulating immune complexes. [118] [119] [120] [121] [122] In one series of 50 patients with AMM, increased quantities of circulating immune complexes were detected [118] and found to be associated with increased disease activity as manifested by increased transfusion requirements, bone pain, and fever. [118] Some investigators have suggested that abnormalities of the complement system may be important in disease progression of AMM,[121] while others have hypothesized that low levels of C3 may predispose these patients to develop serious bacterial infections.[118] A remarkably high incidence of monoclonal gammopathies has been reported in AMM, with such benign gammopathies occurring in 810% of patients in some series.[123] [124] Ten cases of the simultaneous occurrence of a plasma cell dyscrasia and AMM have been reported. [6] [123] [124]

Successful bone marrow aspiration is unusual, being accomplished in only 6 of 48 cases in one series, with the tap completely dry in 50% of cases. [8] A bone marrow biopsy is necessary in all cases to assess the amount of residual hematopoietic cellular tissue and the degree of marrow fibrosis. Table 63-3 (Table Not Available) summarizes the appearance of bone marrow biopsies in the series of Varki et al. [8] Some caution should be taken in using repeated bone marrow biopsy specimens to diagnose AMM. Cases in which a marrow biopsy was performed at the site of a previous bone injury during the healing process frequently results in confusion because of primary callus formation at that site. [125] Intense myelofibrosis with new bone formation has been noted at such sites. Marrow biopsies performed at the site of previous biopsies or aspirates may potentially lead to an erroneous diagnosis of AMM. It is recommended that marrow biopsies intended for diagnosis of AMM be performed at a site previously spared. [125] Most marrow biopsies in AMM are hypercellular and are remarkable for increased numbers of megakaryocytes (Table 63-3 (Table Not Available)). Bone marrow fibrosis and osteosclerosis were seen in 67% and 54% of cases, respectively. [8] The three characteristic morphologic features include: (1) patchiness of the hematopoietic cellularity and the reticulin fibrosis, some microscopic fields being cellular and others depleted of hematopoietic cells and

TABLE 63-3 -- Bone Marrow Biopsy Findings at Diagnosis of Patients with AMM

(Not Available)

From Varki et al.,[8] with permission.

the amount of reticulin varying from field to field; (2) increased numbers of megakaryocytes, which often are arranged around and within the sinuses and not always clustered in groups. The megakaryocytes are large with irregular, roundish, cloud-like nuclei; [126] [127] and (3) distended marrow sinusoids frequently containing intravascular hematopoiesis.[48] [126] [127] In Wolf and Neimans series, morphologic evidence of progression of fibrosis was present in only 1 of 21 cases in which sequential biopsies were obtained.[48] In addition, no connection was observed between bone marrow cellularity and fibrosis and splenic size. [48] By contrast, Lohmann and Beckman[128] observed progressive fibrosis in 18 of 20 patients who did not have maximal myelofibrosis at the time of the initial biopsy. Thiele et al. [126] presented data to indicate an early hyperplastic subtype of AMM with no or minimal medullary reticulin and another phase with conspicuous fibrosis and osteosclerotic changes of the marrow. They concluded based on a careful histomorphometric evaluation of the bone marrow that in a subset of patients there was a progressive fibro-osteosclerotic process during the evolution of the disease that was paralleled by an increase in small megakaryocytes with irregular perimeters and megakaryocytes with naked nuclei.[126] However, this same group emphasizes that in 25% of the patients, there was no progression in the degree of marrow fibrosis over time.[126]

Morphologic examination of the spleen reveals foci of extramedullary hematopoiesis in the sinusoids of the red pulp, where megakaryocytes, myeloid elements, and nucleated erythroid elements are seen.[48] Follicular atrophy in the white pulp frequently occurs. [48] Pathologic examination of the liver reveals hematopoietic cellular elements within the sinusoids. Sinusoidal dilation is a frequent finding, as well as prominent intrahepatocyte and Kupffer cell hemosiderin deposition. A marked increase in the hepatic reticulin network has also been observed. [48] [98]

Clinical features of portal hypertension such as ascites or esophageal varices are known to occur in 918% of patients with agnogenic myeloid metaplasia. [96] [97] [98] [99] The liver histologic findings have usually been considered normal or to be characterized by minimal portal fibrosis, which has led to the view that the splenomegaly in AMM may be due to increased hepatic blood flow with resultant portal hypertension. Wanless et al., [98] however, analyzed a large series of patients with polycythemia vera and AMM at autopsy. In those patients with portal hypertension, thrombotic lesions in small or medium-size portal veins as well as extrahepatic portal veins were observed. In addition, nodular regenerative liver hyperplasia occurred in 14.6% of cases and correlated closely with the presence of portal vein lesions. They have concluded that thrombosis is the most likely cause of portal venous obliteration and portal hypertension in AMM and that clinically significant thrombosis confined to small intrahepatic veins or large hepatic veins should be considered in any patient with AMM. In this autopsy series portal and hepatic venous disease occurred even in the absence of signs of portal hypertension. Such a finding is consistent with subclinical thrombosis with recanalization occurring fairly commonly in this patient group.[98]

Approximately 3075% of patients with AMM have karyotypic abnormalities at diagnosis. [129] [130] [131] [132] [133] [134] It is important to perform cytogenetic analysis on this patient population in order to discriminate AMM from CML. [135] [136] Detection of a Philadelphia chromosome and/or a *bcr/abl* fusion gene indicates that the myelofibrosis is secondary to CML. [135] [136] In those cases that are Philadelphia chromosome negative, it is prudent to perform a PCR for BCR/ABL to exclude the diagnosis of chronic myeloid leukemia. Chromosomal abnormalities in AMM have been reported to involve chromosomes 1, 2, 513, 15, 17, 18, 20, and 21 and the Y chromosome.[129] [130] [131] [132] [133] [134] In a recent report by Reilly et al., three cytogenetic patterns (del [13q], del [20q] and partial trisomy 1q) were seen in 65% of all cases with an abnormal karyotype.[134] Partial or complete losses of chromosomes, particularly chromosomes 5 and 7, appear to be associated with the use of chemotherapeutic agents for treatment of AMM.[129] [130] [131] [132] [133] [134] An association between erythroid hypoplasia in AMM and a defect on chromosome 11 has been reported.[137] It is not unusual for a leukemic transformation of AMM to be preceded by additional cytogenetic abnormalities; a finding consistent with a multistep process leading to a leukemic transformation.[138]

On radiographic examination the characteristic features of AMM are a diffuse increase in bone density and increased prominence of the bony trabeculae. This increased bone density may be patchy and can produce a mottled appearance. In 2566% of patients with AMM, such abnormalities have been reported. [6]

Magnetic resonance imaging (MRI) is a promising noninvasive means of evaluating the bone marrow status of patients with AMM. MRI can portray the conversion or reconversion of fatty to cellular marrow.[139] [140] Fibrotic marrow is easily distinguished from cellular marrow by its strikingly low signal intensity with all pulse signals. [139] Kaplan et al.[139] reported that marrow patterns in the proximal femurs of AMM patients correlate with the clinical severity of the disease and that MRI of the proximal femurs may be useful in both staging and evaluating the progression of the disease process. Marrow MRI has been successfully used to follow the progression of this disorder.[140]

DIFFERENTIAL DIAGNOSIS

A patient with hepatosplenomegaly, peripheral cytopenias, teardrop poikilocytosis, and leukoerythroblastosis and marrow fibrosis likely suffers from AMM. It must be appreciated, however, that a number of other disorders besides AMM may lead to this clinical picture [9] [10] (Table 63-1). Secondary myelofibrosis frequently occurs in patients with lymphoma or metastatic carcinoma of the stomach, prostate, lung, and breast. [9] [10] [141] [142] [143] [144] Successful treatment of Hodgkin disease or breast cancer has resulted in reversal of such marrow fibrosis. [141] [142] [143] [144] One should be extremely careful of making the diagnosis of AMM in a patient who has a previous history of a primary neoplasm. The demonstration of carcinoma cells in the marrow establishes that metastatic carcinoma is the cause of the marrow fibrosis. Careful breast examination and mammography are indicated in all women suspected of having AMM, in order to rule out the possibility of metastatic breast cancer. The finding of blastic or lytic bone lesions in patients with myelofibrosis suggests the presence of an underlying carcinoma.

Disseminated tuberculosis and histoplasmosis have also been associated with the development of secondary myelofibrosis. [6] [145] Caseating or noncaseating granulomas observed on bone marrow biopsy suggest the presence of these infectious disorders. Identification of the causative organisms by culture techniques should be pursued.

A number of other primary hematologic disorders can also be accompanied by marrow fibrosis. The peripheral blood and marrow findings that allow one to distinguish these disorders have recently been reviewed by Dickstein and Vardiman (Table 63-4).[45] A variant myelodysplastic syndrome with myelofibrosis has been described by Pagliuca et al.[146] These patients frequently present with cytopenias and have cellular dysplastic abnormalities indistinguishable from those of other patients with myelodysplasia. Their marrows, however, are characterized by the presence of marrow fibrosis and a striking megakaryocytic hyperplasia, with a predominance of small hypolobulated forms, in some cases surrounding fibrosis. Reticulocytopenia is characteristic of these patients as well as teardrop red blood cells and a leukoerythroblastic blood picture. [146] Unlike patients with AMM, patients with myelodysplasia and marrow fibrosis do not have hepatic or splenic enlargement extending

beyond 3 cm below the costal margin. [146] The overall survival of patients with this variant of myelodysplasia has been reported to be 30 months, with death resulting from the effects of cytopenias or transformation to acute leukemia. [146] Two additional studies have indicated that the presence of myelofibrosis in patients with myelodysplasia is associated with a particularly short survival (9.6 months) as compared with patients with myelodysplasia without fibrosis (17.4 months). [147] [148]

Hairy cell leukemia can also be confused with AMM. [8] In one study, 5 of 61 patients who had originally been diagnosed as having AMM were shown retrospectively to have had hairy cell leukemia. [8] Hairy cell leukemia can present as pancytopenia with splenomegaly and is associated with a dry marrow tap. In one series, marrow reticulin content was increased in 26 of 29 patients with hairy cell leukemia. [149] The presence of hairy mononuclear cells possessing tartrate-resistant acid phosphatase or the appropriate phenotype in the peripheral blood or marrow should facilitate differentiation of AMM from hairy cell leukemia. This exercise is important because of the different modalities of treatment that can be successfully employed for hairy cell leukemia.

Myelofibrosis can occur in patients with other myeloproliferative disorders, especially polycythemia vera and CML, and less frequently primary thrombocytopenia. [150] [151] [152] [153] In CML, progressive marrow fibrosis may herald the onset of accelerated disease or blast crisis. [150] [151] [152] [153] Myelofibrosis in CML occurs in two distinct patterns, one in which patients present with CML and significant associated marrow fibrosis, and a second in which the myelofibrosis develops late in the course of the CML.[136] The myelofibrosis in this latter group appears at a mean of 36 months after the diagnosis of CML, is associated with a mean survival of 4.9 months from the detection of myelofibrosis, and therefore represents an ominous prognostic sign. [136]

Postpolycythemic myeloid metaplasia occurs in 515% of patients with polycythemia vera. [150] [151] [152] This transition occurs, on average, 10 years after the initial diagnosis of polycythemia vera is made, but in individual cases it may appear after either shorter or longer intervals. [150] [151] [152] AMM is clinically indistinguishable from postpolycythemic myeloid metaplasia except for the previous history of erythrocytosis in the latter group. Of patients with postpolycythemic myeloid metaplasia, 2550% will develop leukemia, and 70% will be dead within 3 years of this transition. [150] [151] [152] Postpolycythemic myeloid metaplasia represents a transitional myeloproliferative syndrome with relatively grave prognostic implications. Myelofibrosis has also been reported following primary thrombocythemia. [153]

Acute myelofibrosis represents a clinical entity distinct from AMM. [154] [155] [156] Patients characteristically present with pancytopenia, fever, absence of clinically significant splenomegaly, minimal or absent teardrop poikilocytosis, and fibrotic bone marrow. [154] [155] [156] The bone marrow is characterized by the appearance of immature myeloid elements, and the blast cells frequently express megakaryocytic phenotypic properties. [154] [155] [156] Although the number of circulating blast cells is frequently low, these cells have been reported to range from 1355% of the total number of leukocytes. [154] [155] [156] Survival ranges from 1 to 9 months following diagnosis. Acute myelofibrosis is a form of acute megakaryoblastic leukemia. Its distinction from AMM is vital, since aggressive chemotherapy and possibly bone

marrow transplantation are the treatments of choice for acute myelofibrosis.

Pacquette et al. have reported that up to 12% of patients who present with myelofibrosis may suffer from an underlying autoimmune disorder such as systemic lupus erythematosus.[157] The appearance of the marrow in autoimmune myelofibrosis is indistinguishable from AMM. Autoimmune myelofibrosis occurs predominantly in females. The clinical spectrum of autoimmune myelofibrosis is broad. Patients may present with myelofibrosis in the setting of established systemic lupus or in patients with minimal manifestations of an autoimmune disorder.[157] [158] The presence of teardrop erythrocytes or a leukoerythroblastic blood picture in a patient with lupus may suggest autoimmune myelofibrosis. Such patients universally have a positive antinuclear antibody (ANA) test or an elevated anti-DNA titer. [157] [158] Since the physical manifestations of autoimmune diseases may not be evident, all patients with myelofibrosis should have an ANA test. This diagnosis is important because the cytopenia and marrow fibrosis in autoimmune myelofibrosis may partially resolve with steroid therapy. [157] [158]

THERAPY

The optimal forms of treatment have not yet been defined. A conservative approach to management is generally accepted, asymptomatic patients being observed and therapeutic intervention being reserved for those patients with symptoms. [159] [160] An alternative approach proposed by Pegrum et al. [161] provides for the institution of single-agent chemotherapy early in the course of the disease. Chemotherapeutic regimens used have included busulfan (24 mg/day), 6-thioguanine (2040 mg/day), and a combination of chlorambucil (15 mg/day) and prednisone (30 mg/day), administered intermittently for a course of 34 weeks with a 2-week rest interval between courses.[1] [2] [3] [4] [5] [6] [7] [8] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168] Such an approach is associated with reduction in spleen size, and some authors have claimed reversal of marrow fibrosis with reduction in the amount of teardrop red cells, poikilocytosis, and leukoerythroblastosis. [98] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168]

Hydroxyurea appears to be a particularly useful agent for the treatment of AMM. Its use has been reported to be associated with significantly reduced platelet production and a

THERAPY FOR AGNOGENIC MYELOID METAPLASIA

When initially encountering a patient with presumed AMM, one must be certain that this process is not secondary to carcinoma invading the marrow or involvement of the marrow with tuberculosis. After a careful history and physical examination, appropriate cultures, chemistries, and radiographic studies should be performed to exclude these secondary forms of myelofibrosis. An antinuclear antibody screen should be performed on all patients with myelofibrosis to avoid missing an immune-mediated myelofibrosis that is treatable with steroids.

The treatment of AMM is dependent on the major manifestations of the disease in the individual patient. One must consider treatment of anemic patients, patients with symptoms resulting from splenomegaly, those with bleeding abnormalities, those with portal hypertension, and those with ascites, bone pain, or symptoms due to hypermetabolism.

Blood volume studies should be performed in mild to moderately anemic patients with symptoms. Those who have normal red cell masses and marked increases in plasma volume have a dilutional form of anemia requiring no treatment. Nutritional deficiencies of iron or folate are easily diagnosed and treated. Treatment for ineffective erythropoiesis includes use of androgens, the androgens of choice being oxymethalone in doses of 50 mg tid or danazol (400600 mg/day). Occasional hypoproliferative anemias may respond to low-dose dexamethasone (2 mg/day). Those patients who demonstrate a shortened red cell survival benefit from addition of prednisone at a dose of 60 mg/day. In patients with iron deficiency anemia, every attempt should be made to determine the underlying etiology of blood loss. If a patient develops esophageal varices or peptic ulcer disease, these lesions must be specifically treated. Occasional patients may develop an underlying occult gastrointestinal carcinoma.

In those patients with symptoms resulting from splenomegaly, treatment will depend on the severity and nature of these difficulties. Various measures to reduce the size of the spleen have been used to alleviate uncontrollable splenic pain; these measures may include the use of radiotherapy, chemotherapy in the form of busulfan or hydroxyurea, or the use of interferon-. Approximately two-thirds of patients treated with these chemotherapy agents or biological response modifiers will have some reduction of spleen size, but on discontinuation of chemotherapy, rapid enlargement of the spleen usually occurs.

Individuals with acute splenic infarction who do not respond to administration of analgesics may gain pain relief from local irradiation over the spleen at doses of 0.250.50 Gy/day for 45 days. Those with huge, painful spleens in whom splenectomy is too risky a procedure may benefit from a cautious trial of radiotherapy. Patients with symptoms resulting from a profoundly enlarged spleen are best treated by splenectomy.

Whenever a patient is considered a candidate for splenectomy, an extensive preoperative evaluation must be pursued. A patient must be considered an acceptable surgical risk in terms of cardiac, hepatic, renal, and metabolic function. All patients must have an extensive preoperative evaluation of the coagulation system, which should include assays for coagulation factors V and VIII, fibrin-split products, platelet count, and bleeding time. Patients with qualitative platelet abnormalities remain candidates for splenectomy, but successful surgical intervention may require use of adrenal steroids before surgery and platelet transfusion at the time of surgery. In patients with nonapparent DIC, surgery is definitely contraindicated. The operation itself must be considered a major procedure. Only a senior staff surgeon who has performed this type of surgery many times should attempt such an operation.

In treating patients with myelofibrosis, one must understand that bleeding may be multifactorial in origin. Invariably, patients with myelofibrosis will have qualitative platelet ab- normalities. In addition, thrombocytopenia and nonapparent DIC may lead to a hemorrhagic diathesis. In those patients who have qualitatively abnormal platelet function, platelet transfusions are suggested for serious bleeding or when preparing a patient for surgery. Patients with thrombocytopenia secondary to marrow failure and hypersplenism can often be managed by administering danazol (600 mg/day). In those patients with life-threatening thrombocytopenia who do not respond to danazol, splenectomy should be seriously considered. Patients with nonapparent DIC require no treatment. In those patients who develop DIC secondary to infection or other identifiable etiologies, treatment is best directed toward controlling the underlying etiology of the coagulopathy and initiating replacement therapy with platelets and fresh frozen plasma.

Portal hypertension may complicate myelofibrosis in 68% of patients. Careful assessment of patients with this potentially catastrophic problem is mandatory. Portal hypertension in AMM may be secondary to increased blood flow from the spleen to the liver (i.e., forward-flow portal hypertension) or secondary to an intrahepatic block due to postnecrotic cirrhosis or intrahepatic extramedullary hematopoiesis. Forward-flow portal hypertensions cause is correctable by splenectomy whereas portal hypertension due to an intrahepatic defect requires some form of portal-systemic shunt procedure. The indications for portosystemic decompression include upper gastrointestinal bleeding and refractory ascites. Some patients can be decompressed with a transjugular intrahepatic portosystemic stent. [230] If portal hypertension secondary to intrahepatic obstruction persists, a splenorenal shunt is the decompressive procedure of choice. [231] Limited survival in patients treated medically with variceal bleeding has been observed but prolonged survival, >3 years, in patients treated surgically has been reported.

Patients with ascites, bone pain, or hypermetabolism present unique problems. If the ascites is due to portal hypertension, management should be directed toward relieving the hypertension. Development of ascites in AMM may also, however, be a result of seeding of the peritoneal cavity with extramedullary hematopoiesis. In all patients with myelofibrosis who develop ascites, paracentesis should be performed and careful study of the ascitic fluid pursued. If megakaryocytes are found in the samples of ascitic fluid, the ascites is likely due to peritoneal implants of myeloid tissue. These implants are treated by intraperitoneal instillation of cytosine arabinoside initially at a dose of 0.77 mg/kg/day which can be advanced to 13.5 mg/kg/day or by abdominal radiation. Administration of fractional doses of radiation

Patients with ascites, bone pain, or hypermetabolism present unique problems. If the ascites is due to portal hypertension, management should be directed toward relieving the hypertension. Development of ascites in AMM may also, however, be a result of seeding of the peritoneal cavity with extramedullary hematopoiesis. In all patients with myelofibrosis who develop ascites, paracentesis should be performed and careful study of the ascitic fluid pursued. If megakaryocytes are found in the samples of ascitic fluid, the ascites is likely due to peritoneal implants of myeloid tissue. These implants are treated by intraperitoneal instillation of cytosine arabinoside initially at a dose of 0.77 mg/kg/day which can be advanced to 13.5 mg/kg/day or by abdominal radiation. Administration of fractional doses of radiation at 0.25 Gy/day with rotation into the four quadrants of the abdomen is also extremely effective. Radiation therapy to a total dose of 510 Gy may be very rewarding.

Patients with myelofibrosis who develop severe bone pain have an extremely guarded prognosis. Treatment with etidronate at a dose of 6 mg/kg per day on alternative months has resulted in complete recovery from bone symptoms in a few patients.[232] This complication frequently represents leukemic transformation in evolution. In these patients, biopsies at sites of pain may reveal pure populations of leukemic blasts. The pain appears to be the result of invasion of the periosteum by blast cells. Bone pain may also be treated with local radiation for several days.

Symptoms resulting from hypermetabolism such as weight loss, sweating, and asthenia are not unusual. Such patients may benefit from low-dose hydroxyurea or interferon- therapy. All patients less than 50 years of age with symptomatic AMM should be evaluated for allogeneic marrow transplantation. Identification of an appropriate donor and rapid referral to an expert stem cell transplant unit should be expedited.

reduction of megakaryocytic abnormalities, as well as a significant reduction of myelofibrosis. [167] [168] Some investigators have hypothesized that hydroxyurea-induced suppression of megakaryocytopoiesis causes a reduction in platelet-derived fibrogenic cytokines resulting in reduced fibroblast proliferation and deposition of reticulin.[166] Manoharan et al.[162] [163] have shown that moderate doses (2030 mg/kg) of hydroxyurea given twice or three times weekly are effective and safe in AMM patients requiring treatment. Furthermore, similar reports have appeared following the use of busulfan; Chang and Gross [168] have, in fact, reported three patients with AMM who responded to daily busulfan therapy with the achievement of hematologic remission and reversal of myelofibrosis and myeloid metaplasia. Not only did hematologic parameters, including the hemoglobin and hematocrit levels, improve, but a reduction of teardrop erythrocytes and lessening of leukoerythroblastosis was noted as well as reversal of myeloid metaplasia and marrow fibrosis. Most importantly the quality of life of these individuals improved. [168] Judicious use of busulfan is recommended in this setting, however, because of its potential for producing delayed marrow suppression. The long-term effects of such early chemotherapeutic intervention on prognosis and frequency of leukemic transformation of AMM remains unknown. Selection of such an aggressive therapeutic approach at present appears unwarranted, but this strategy clearly merits further investigation. A randomized clinical trial comparing early use of chemotherapy with a supportive approach is needed to clarify the merit of these two different strategies.

Interferon- has also been suggested as a drug that might alter the course of AMM. [169] [170] [171] [172] It is useful in suppressing thrombocytosis and inhibiting the activity of PDGF which stimulates the proliferation of fibroblasts. Dalla et al. reported a case of AMM with anemia, thrombocytopenia and hepatosplenomegaly that was treated for over two years with interferon- with remarkable results.[171] The patient became asymptomatic and transfusion-independent, and repeat marrow biopsy revealed no fibrosis. Bourantos et al. have reported the use of the combination of interferon, GM-CSF, and erythropoietin in seven patients with AMM. [172] Each of these patients had an aspirable marrow with megakaryocytic hyperplasia but only mild to moderate deposition of reticulin fibers. [172] Six of seven patients enjoyed marked reductions in spleen size.[172] Each of these patients had a 1g/dl increase in hemoglobin concentration. In one patient the degree of marrow fibrosis was diminished. These authors suggested that interferon might decrease the rate of fibrosis if administered chronically during the early course of this disease. [172] This hypothesis will require careful testing.

Symptomatic therapy is indicated for patients with the following conditions: (1) symptoms attributable to anemia, (2) pressure symptoms related to splenomegaly, (3) bleeding problems or life-threatening thrombocytopenia, (4) significant hyperuricemia, and (5) portal hypertension and life-threatening gastrointestinal bleeding. [6] Hyperuricemia should be aggressively treated in all patients with AMM. Hydration and chronic administration of allopurinol (300 mg/day) are suggested. [6]

Anemia is a common problem in patients with AMM. It is usually multifactorial in origin, contributing factors being folate deficiency, iron deficiency, ineffective erythropoiesis, erythroid hypoplasia, and hemolysis. [103] [104] [105] [106] Kinetic studies and red cell survival studies using radioisotopes can be helpful in defining the etiology of the anemia. It is also important in some instances to directly measure the patients red cell mass to be assured that the low hemoglobin level is not merely dilutional in origin. [103] [104] [105] [106] Transfusion therapy with packed red cells is clearly indicated in those patients who are symptomatic from their anemia. Patients with documented nutritional deficiencies should receive either folate or iron supplementation, or both. Chronic transfusion therapy will frequently be required; one should try to attain a hemoglobin level at which symptoms resolve. Since AMM is a chronic disease, long-term transfusion therapy potentially may lead to development of iron overload syndrome. Serious consideration should be given to early institution of iron chelation therapy. In a handful of patients, a reduction of transfusion requirements was noted following desferrioxamine therapy. This iron chelator can promote transferrin receptor expression on erythroblasts. [173]

The remainder of approaches to the anemic patient deal with therapeutic interventions designed to avoid or diminish the number of transfusions administered. Ineffective erythropoiesis in AMM may be treated with anabolic steroids. [1] [2] [3] [4] [5] [6] [7] [8] [174] [175] [176] [177] [178] Gardner and Nathan[174] have recommended that all patients with AMM and anemia should receive a trial of androgens. A number of preparations have been suggested, including testosterone enanthate (600 mg/wk IM), stanozolol (12 mg/day PO), nandrolone (3 mg/kg/wk IM), fluoxymesterone (10 mg tid PO), and oxymethalone (50 mg qid PO). It is unknown whether any of these preparations is superior to the others, but a good response, as defined by a decrease or total avoidance of transfusion therapy, occurs in about 50% of patients. A course of 36 months of androgen therapy is indicated in order to identify responsive patients, [174] but the development of hepatic dysfunction or virilizing side effects may limit long-term androgen administration. Besa et al.[177] have indicated that patients with associated chromosomal abnormalities are less likely to respond to androgen therapy. Danazol, a synthetic attenuated androgen, has recently been shown to be useful in reducing the requirement for red cell transfusion support and correction of thrombocytopenia. [178] Danazol appears to be potentially effective therapy in AMM which is mainly characterized by marrow failure. [168] In addition, low dose dexamethasone has also been reported to be useful in the treatment of transfusion-dependent AMM. [179] Whether these cases represent steroid responses of autoimmune-induced myelofibrosis and not classical AMM remains unknown. Erythropoietin therapy alone does not appear to improve the anemia associated with AMM.[180] [181]

Corticosteroids (e.g., prednisone 1 mg/kg/day PO) have also been successfully employed for treatment of the hemolytic anemia associated with AMM. [1] [2] [3] [4] [5] [6] [7] [8] [182] Bouroncle and Doan[1] reported favorable results in approximately 25% of patients, while Silverstein [6] reported a 2 g increase in hemoglobin in 29% of men and 52% of women. Folate should be simultaneously administered to all such patients. Bouroncle and Doan [1] reported even more encouraging results with simultaneous administration of busulfan and corticosteroids, with clinical responses lasting 612 months. Once patients have reached a peak response, tapering of prednisone should be initiated to determine an acceptable maintenance dose. Frequently the hemolytic process recurs following such tapering. Appropriate patients should be referred for splenectomy at that time.

Pressure symptoms secondary to splenic enlargement can be treated initially with cytotoxic chemotherapy. Busulfan, chlorambucil and prednisone, 6-thioguanine, radioactive phosphorus, or hydroxyurea (1520 mg/kg three times a week) have been used for this purpose. [1] [2] [3] [4] [5] [6] [7] [8] [161] [162] [163] [164] [165] [166] [167] [168] In the Mayo Clinic series a significant reduction in spleen size with relief of pressure symptoms occurred in 70% of patients receiving chemotherapy. [6] Responses are unfortunately short-lived, lasting a median of only 4.5 months. [6] Only 16% of those patients with long-term maintenance therapy enjoyed sustained relief of symptoms.[6] Hematologic toxicity was not infrequent and often necessitated cessation of therapy.

Splenic irradiation has also been frequently used for treatment of the painful big spleen syndrome. [6] [7] [182] [183] [184] [185] [186] Irradiation in fractions of 0.151 Gy administered either daily or by an intermittent fractionation schedule (two or three times per week) to a total dose per treatment course of 2.56.5 Gy may be effective. [6] [7] [182] [183] [184] [185] [186] Responses are transient, lasting an average of 3.5 months, and hematopoietic toxicity is frequently significant.

Wagner et al.[184] have recommended for this purpose simultaneous treatment with splenic irradiation and oral hydroxyurea and have obtained some promising preliminary results. Silverstein[6] has reported that splenic irradiation is especially useful for treatment of splenic pain of sudden onset and also for treatment of ascites due to implants of hematopoietic tissue. Radiation therapy should be considered as a temporary measure to be employed in patients who are too ill to tolerate splenectomy or chemotherapy. In one series, the median duration of response to radiation was 6 months. [182] The toxicity of splenic irradiation is limited to myelosuppression with significant prolonged cytopenias occurring in 43% of cases. [182]

Radiotherapy offers a viable treatment option and at times may be the therapy of choice for the treatment of peritoneal or pleural implants leading to ascites or pleural effusions and extramedullary hematopoiesis in vital organs leading to organ dysfunction. [186] Because of the inherent sensitivity of myeloid tissue to irradiation and

profound marrow suppression that may occur following irradiation, therapy is usually initiated at low doses (2025 cGy/day) with modification of the dose as the clinical situation dictates.[186] Recently, an alternative approach using intraperitoneal administration of cytosine arabinoside has been used to treat ascites in AMM. [187] Therapy is initiated at 0.77 mg/kg/day to achieve 30 mg/2 liters of peritoneal fluid. The dosage is advanced so that the patient eventually receives 1 gram or 13.5 mg/kg/day. Abdominal pain is the most common adverse effect associated with this approach.[187]

Parmeggiani et al.[188] reported the use of interferon- (IFN-) for the treatment of painful splenomegaly in AMM. [188] Splenic pain and pressure symptoms disappeared with a decrease in splenic size, but peripheral blood counts deteriorated. Gilbert has, however, reported a similar reduction in spleen size with maintenance IFN- therapy but without hematologic compromise.[189] Barosi et al.[190] have suggested that IFN- might be useful in treating thrombocytosis that follows splenectomy in AMM patients. Several investigators have noted, however, that although IFN- has cytoreductive activity in AMM, its use is often limited by debilitating toxic effects such as severe flu-like symptoms. Martyré et al.[191] also reported that IFN- administration results in the reduction of PDGF and TGF- levels present within AMM platelets. These investigators have suggested that such an approach might lead to a cessation or slowing of the marrow fibrosis. [191] The appropriate role of the IFNs in the treatment of AMM as previously mentioned requires further investigation.

The role of splenectomy in the management of AMM remains a controversial issue.[192] [193] [194] [195] [196] Splenectomy is indicated in patients with hemolysis, thrombocytopenia, painful splenomegaly, recurrent splenic infarctions, and traumatic splenic rupture refractory to other therapeutic modalities. [6] Crosby[192] and Mulder et al.[193] have suggested that splenectomy be performed in every patient with AMM immediately after the diagnosis is made. However, Benbassat et al. [194] reviewed the role of splenectomy in AMM by evaluating 321 published AMM splenectomy cases and concluded that this procedure should be considered only in selected individuals for specific indications. Table 63-5 shows the combined results from two representative published series of splenectomized patients. These series indicate that for specific indications splenectomy is an excellent therapeutic choice. [195] [196] It is important to note, however, that 10 of the 72 patients in these series died postoperatively and that significant postoperative morbidity resulting from septicemia and hemorrhage was present. [194] [195] [196] [197] Benbassat et al.[196] further explored the risks and benefits of splenectomy by reviewing and performing a formal decision analysis of 15 reports in the literature dealing with splenectomy in AMM that were published after 1970. They determined that the operative mortality was 13.4% and early morbidity caused by atelectasis, hemorrhage, thromboembolism,

TABLE 63-5 -- Indications for and Responses to Splenectomy in Patients with AMM

Indication	Combined Series	
	No. of Patients	No. of Responders
Painful splenomegaly	40	38
Refractory thrombocytopenia	13	6
Refractory hemolytic anemia	19	11
Portal hypertension	11	9

Data from Silverstein and Remine[195] and Brenner et al. [200]

and subphrenic infections was 45.5%. [196] However, anemia was improved in 70% of patients, painful splenomegaly in 97% of patients, thrombocytopenia in 56% of patients and portal hypertension in 83% of individuals. [196] Splenectomy was not demonstrated to alter survival but was recognized to improve the quality of life. In several series, an extraordinarily high rate of leukemic transformation was noted following splenectomy. [197] [198] [195] Whether this was a function of the absence of the spleen or more likely the consequence of the natural history of the disease is unknown. Splenectomy should be considered for symptomatic patients after they have been informed of the operative mortality and chances of palliation. [196] Ferrokinetic measures of total erythropoiesis and of plasma volume previously claimed to be useful guides for the choice of splenectomy have little value for predicting outcome. [197] [200] [201] The clinician should not agonize over the decision of whether or not to perform splenectomy on a patient with AMM. Splenectomy often results in improved quality of life due to resolution of cytopenias or relief from painful splenomegaly.[194] [195] [196] [197] [198] [199] [200] It is important to be aware that compensatory hepatic myeloid metaplasia may accelerate following splenectomy, leading to rapid enlargement of the liver.[8] [199] [202] [203] Occasionally this massive myeloid metaplasia and sinusoidal dilation can result in liver failure and death. [202] [203] This complication can, however, frequently be treated with chemotherapy.[202] 2-chlorodeoxyadenosine (2-CdA) has been shown to be particularly effective in controlling progressive hepatomegaly or symptomatic thrombocytosis after splenectomy in AMM.[204] This drug has been administered at 0.050.1 mg/kg/day as a 7-day continuous infusion for four to five courses at monthly intervals. This therapy resulted in control of thrombocytosis in 78% of patients and significant reduction in liver size in over 50% of cases for a prolonged period (428 months).[204] Surgical morbidity following splenectomy can be minimized by careful selection of patients with respect to cardiac and renal status, improved surgical technique, aggressive blood bank support with platelet transfusions and early postoperative mobilization of the patient. Platelet transfusions should be administered to the bleeding patient following splenectomy even if the platelet count is normal because AMM is frequently associated with qualitative platelet abnormalities.

Excessive bleeding in patients with AMM can be a result of either thrombocytopenia, qualitative platelet defects, or DIC. [6] Based on his clinical observations, Silverstein[6] [195] has suggested that splenectomy is contraindicated in patients with DIC. Actively bleeding patients with consumption coagulopathy should receive platelet and plasma replacement therapy. Low-dose heparinization has resulted in improvement in occasional patients. [6] Platelet transfusions are suggested in bleeding patients who are thrombocytopenic or have a normal platelet count but who are known to have qualitative platelet abnormalities.

Bone marrow transplantation is a potentially useful therapeutic tool in young patients with AMM who have an appropriate

donor available. [31] [205] [206] [207] [208] Successful transplantation is associated with gradual resolution of marrow fibrosis and normalization of hematopoiesis. [31] [209] [210] Allogeneic bone marrow transplantation offers the best chance for cure and should be seriously considered in all patients <40 years of age. [209] [211] The feasibility of successful bone marrow transplantation was questioned by Rajantie et al. [209] who reported that severe marrow fibrosis can adversely affect post-transplantation hematopoietic reconstitution. Soll et al., however, challenged this conclusion and, after an analysis of 203 patients with marrow fibrosis caused by a variety of hematological malignancies who underwent allogeneic transplantation, concluded that myelofibrosis did not enhance the risk of failure to engraft but merely delayed the time to reach platelet transfusion independence by three days. [210]

Splenectomy before transplantation may hasten hematological reconstitution, but removal of the spleen may not be essential. Although graft failure is not usually a problem following allogeneic transplantation in AMM, splenectomy may be indicated in those patients receiving T-cell depleted grafts. [207] [208] [211] Recently Guardiola et al. has reported on the results of 12 patients with the average age of 40 who received allogeneic transplantation for AMM. [208] Eleven patients engrafted with median times to achieve neutrophil and platelet engraftment of 17 and 29 days, respectively. [208] The four-year overall and event-free rates were 71% and 59%, respectively. [208] Two patients were in complete remission 10 and 5 years following transplantation. [207] Allogeneic marrow transplantation appears to be the only means of curing AMM. This conclusion was confirmed in a larger series of 40 patients with AMM who underwent allogeneic bone marrow transplantation, in whom a three-year survival rate of 60% was observed and four patients were alive more than 10 years following transplantation. [211] This study also emphasized that this patient population is at a high risk for the development of graft-versus-host disease. [211]

PROGNOSIS

The median overall survival from the time of diagnosis of AMM varies from series to series but is approximately 5 years [1] [2] [3] [4] [5] [6] [7] [8] [212] (Fig. 63-3). Individual survival has been reported to range from 1 year to >30 years. [1] [2] [3] [4] [5] [6] [7] [8] Several clinical and biological parameters that are characteristic of patients at diagnosis have been used to identify subgroups of patients with different outcomes. [213] [214] [215] [216] [217] Some authors have suggested that there are two subpopulations of patients in AMM: short-lived and long-lived. Such efforts at developing prognostic parameters have met with conflicting results with the exception that anemia at presentation is consistently associated with short survival. [217] Recently Dupriez et al. have developed an extremely simple scoring system based on two adverse prognostic factors, Hgb <10g/dl and WBC <4,000 or >30,000/mm ^{3} and were able to separate patients into three groups (Table 63-6).[216] The low-risk groups (0 factor), intermediate risk (1 factor), and high-risk (2 factors) were associated with a median survival of 93, 26, and 13 months, respectively. Reilly has demonstrated, in 106 patients with AMM with successful marrow karyotypic analysis, the prognostic significance of cytogenetic abnormalities[134] (Fig. 63-4). Thirty-five percent of cases exhibited clonal abnormalities, and 65% had a normal karyotype in this study. Kaplan-Meiers long-range plot analysis defined age ($P < 0.01$), hemoglobin ($P < 0.001$), white blood cell count ($P < 0.06$), platelet count ($P < 0.0001$), and abnormal karyotype ($P < 0.001$) as adverse prognostic parameters. [134] Reilly was able to define a prognostic schema by combining age, karyotype, and hemoglobin level (Table 63-7).[134] Median survival times varied from 180 months for the good risk group (age < 68 Hgb 10, abnormal karyotype). [134]

Knowledge of the prognosis of an individual patient may be useful in defining high-risk patients in whom experimental forms of therapy might be indicated. In one series of 106 cases of AMM, 62 patients had died after prolonged follow-up. [217] The primary causes of death were determined in 53 cases and included infection (16 cases), leukemic transformation (9 cases), heart failure (9 cases), bleeding (7 cases), hepatic failure due to massive myeloid metaplasia of the liver (5 cases), portal hypertension (4 cases), and renal failure, pulmonary embolism, and post-transplant graft-versus-host disease (1 case each). [217] The incidence of acute leukemia as a terminal event ranges from 522% of patients depending on the series cited. [1] [2] [3] [4] [5] [6] [7] [8] [218] [219] [220] [221] [222] Approximately one-half of the patients who develop acute leukemia have received previous treatment with alkylating agents or radiotherapy, suggesting that the evolution into acute leukemia might be part of the natural history of AMM.[196] [223] [224] [225] The actuarial cumulative risk of death from leukemic transformation at 1 and 5 years following diagnosis has been reported to be 2% and 16% respectively. [216] Immunologic and morphologic characterization of the blast phenotype comprising these leukemias reveals that a typical myeloid phenotype is most commonly detected; other cell lineages, such as megakaryocytic, erythroid, lymphoid, and even stem cell phenotype may also be involved, leading to the existence of both mixed myeloid and hybrid transformations. [222] [223] [224] [225] [226] [227] Megakaryoblastic transformations have been detected in one-third of cases in one series, an incidence clearly higher than that found in de novo acute myeloid leukemia. [225] Survival following these blast transformations is limited, a phenomenon that is probably a result of patient age and the aggressive biology of these leukemias. Successful leukemia induction of these patients is a rare event. [228]

FUTURE DIRECTIONS

Rapid strides have been made in understanding the biosynthesis of collagen in myelofibrosis. If it is indeed true that PDGF and TGF- play a major role in promoting fibroblastic proliferation in patients with AMM, agents capable of neutralizing the biologic functions of such growth factors may be of potential clinical use. This hypothesis was tested in a clinical trial of suramin, an antiparasitic agent that antagonizes the activity of TGF-. [227] In a phase II trial suramin was administered in a 24-hour continuous infusion at dose levels of 280350 mg/m ^{2} for 510 days every 5 weeks. No biologic evidence or clinical evidence of suramin activity in AMM was observed.[229] Instead progressive splenomegaly and severe pancytopenia were observed in all patients. [229] Further exploration of the use of biologic response modifiers or drugs that might alter the fibrotic process in AMM will likely be pursued in the future. In addition, because fibrogenic cytokines that are released from megakaryocytes and platelets play such a critical role in AMM biogenics, it remains possible that suppression of megakaryocytopoiesis in this disorder might alter its natural history.

Chapter 64 - Primary Thrombocythemia

Ronald Hoffman

INTRODUCTION

Primary thrombocythemia is a chronic myeloproliferative disorder characterized by a sustained proliferation of megakaryocytes, which leads to increased numbers of circulating platelets. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] In addition to platelet counts in excess of 600,000/mm ^{3} , this disorder is characterized by profound marrow megakaryocyte hyperplasia, splenomegaly, and a clinical course punctuated by hemorrhagic or thrombotic episodes or both. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Primary thrombocythemia is a clinically heterogeneous disorder with up to two-thirds of patients who meet the criteria for diagnosis being asymptomatic at presentation. [17]

Primary thrombocythemia was first reported in 1934 by Epstein and Goedel, [18] who described a patient with an elevated platelet count who suffered from repeated hemorrhagic episodes. [18] This disease entity has been referred to by a variety of names, including essential thrombocythemia, idiopathic thrombocythemia, essential thrombophilia, and essential thrombocytosis. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17]

Originally, many clinical investigators questioned whether primary thrombocythemia represents a distinct clinical entity. [19] However, extensive descriptions of larger series of patients have provided information to overcome this initial skepticism. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Dameshek [20] in 1951 speculated that primary thrombocythemia may represent one of the myeloproliferative disorders. Subsequent laboratory investigations have confirmed this concept and clearly demonstrated that the disorder is a clonal hematologic malignancy. [21] [22] [23] [24] [25]

EPIDEMIOLOGY

The true incidence of primary thrombocythemia is unknown, because extensive epidemiologic studies are not available. Although many investigators have indicated that this disorder is very rare, information from several institutions suggests that it occurs considerably more frequently than originally believed. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Following the incorporation of a platelet channel in automated complete blood cell counts, extreme thrombocytosis has been shown to be a relatively common occurrence in a general hospital setting. [26] Thus, 94 cases of newly diagnosed primary thrombocythemia were identified from 19611982 at the Saint Louis Hospital in France, while 61 patients with this disorder were discovered from 1974 through 1987 at the Medizinische Poliklinik in Munich. [13] [14] The incidence of primary thrombocythemia in Olmstead County in southeastern Minnesota is reported to be 2.38 patients/100,000 population/year. [27] Primary thrombocythemia and polycythemia vera appear to have approximately a 1:4 relative incidence. [27]

The disorder appears to affect primarily middle-aged people, with an average age at diagnosis of 5060 years. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] In most series, there appears to be no sexual predilection; although in several reports, a higher prevalence in females has been noted. [7] [12] [13] [14] [15] [16] [28] [29] This discrepancy might be due to an equal frequency in older patients of both sexes but to a second peak frequency at around 30 years of age for women. [13] This predisposition of young women to develop primary thrombocythemia has been reported previously. [27] [28] [29] [30] [31]

Genetic transmission of the disorder is unusual, although several families with multiple members having primary thrombocythemia have been described. [32] [33] [34] [35] In two of these families, thrombocythemia occurred in three successive generations, with patients ranging in age from 2 to 62 years. [32] [35] An abnormality of thrombopoietin production or in the thrombopoietin receptor has been suggested as the cause of these inherited disorders. [34] A Dutch family with 11 family members and a Japanese family with 8 family members were reported with a hereditary form of primary thrombocythemia which was inherited in an autosomal dominant fashion. The thrombopoietin receptor in the Dutch family was normal, yet there was a G to C transversion in the splice donor site of intron 3 of the thrombopoietin gene. [36] All of the affected members of both the Japanese and Dutch families were shown to have elevated thrombopoietin levels. In each family, a point mutation in the thrombopoietin gene was thought to lead to systemic overproduction of thrombopoietin, leading to a hereditary form of primary thrombocythemia. [36] Several cases of primary thrombocythemia have also been reported in patients in the pediatric age group, but this is an extremely unusual finding. [37] [38] [39] [40]

ETIOLOGY

The mechanisms leading to thrombocytosis in primary thrombocythemia are poorly understood. Patients with primary thrombocythemia have normal or near-normal platelet survival.[31] [32] The thrombocytosis is due to increased platelet production by megakaryocytes. Effective platelet production is increased as much as 10-fold and is associated with an increase in megakaryocyte clustering, volume, nuclear lobe number, and nuclear ploidy. [41] [42] [43] [44]

Analysis of circulating blood cells of females with primary thrombocythemia who were heterozygotes for isoenzymes of glucose-6-phosphate dehydrogenase has revealed that platelets, erythrocytes, and neutrophils express a single isoenzyme type. [21] [22] [23] [24] In addition, Raskind et al.[24] have presented data to indicate that B cells can also be involved in this neoplastic process. Such findings indicate that primary thrombocythemia is a clonal hematopoietic disorder originating at the level of the pluripotential hematopoietic stem cell. The clonal origin of primary thrombocythemia has subsequently been confirmed using restriction fragment length polymorphisms of X chromosome genes.[25] [45]

Such clonal analyses have revealed that a significant proportion of nonclonally derived leukocytes exist in addition to the clonally derived population of leukocytes in patients with primary thrombocythemia.[25] [45] [46] In one study of 42 patients with primary thrombocythemia, 31 patients exhibited clonality of at least one hematopoietic lineage whereas the remaining 11 patients had polyclonal origins of all lineages studied. [25] The biogenesis of polyclonal primary thrombocythemia remains ill-defined. It is possible that small numbers of normal hematopoietic stem cells persist to account for this admixture of nonclonal populations. Primary thrombocythemia patients with polyclonal hematopoiesis appear to have a clinical picture identical to that of patients with monoclonal hematopoiesis. [25] [46]

In one patient, Anger et al.[45] determined that although the total leukocyte fraction was clonally derived, the T-lymphocyte population was nonclonal in origin. In fact, most studies indicate that T lymphocytes are of polyclonal origin in primary thrombocythemia patients. [25] Interestingly, in some patients, monoclonality of hematopoiesis is restricted to platelets despite the polyclonal origin of the other lineages. Other studies, however, have indicated a common origin of granulocytes, platelets, and B lymphocytes in this disorder. [23] Such studies raise the possibility that the malignant transformation leading to primary thrombocythemia occurs at a number of stages along the hematopoietic cellular hierarchy. [47] Such a model would predict that in some cases a primitive stem cell would be the site of the initial oncogenic event, while in others this event might occur in a more differentiated progenitor cell. Data supporting such a hypothesis were supplied in an analysis of two sisters with primary thrombocythemia.[48] In one sister, granulocytes, monocytes, and T lymphocytes were clonally derived; in the other sister, the granulocytes fraction was monoclonal, but the T lymphocytes were polyclonal in origin. This study confirms the heterogeneity of the affected hematopoietic cell at which primary thrombocythemia might originate.

The biologic behavior of megakaryocyte progenitor cells present either in the marrow or in the peripheral blood of patients with primary thrombocythemia has been extensively studied.[49] [50] [51] [52] [53] [54] [55] [56] [57] [58] In each of these studies, the use of serum-containing culture systems has led to the detection of increased numbers of assayable progenitors. These data support the concept that the principal abnormality is an expansion of the progenitor pool. In addition, colonies were noted to appear in the absence of exogenous cytokines.[48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] A subpopulation of colony-forming unit-megakaryocyte (CFU-MK) assayed from patients with primary thrombocythemia was also shown to remain responsive to addition of cytokines. [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] [66] [67] [68] [69]

Several laboratories have demonstrated that megakaryocyte progenitor cells isolated from primary thrombocythemia patients are hypersensitive to the action of several cytokines including IL-3, IL-6, but not GM-CSF. [58] [59] Furthermore, investigators have explored the possibility that the defect in primary thrombocythemia might actually be due to resistance to inhibitors of megakaryocytopoiesis. [57] Zauli et al. have shown that the primary thrombocythemia CFU-MK have a significantly lower sensitivity to the inhibitory effects of low doses of TGF- and a limited response to the inhibitory effects of high concentrations of autologous platelet lysates. [60] TGF- was shown to be primarily responsible for the inhibitory activity present in such platelet lysates. [69] Some combination of increased sensitivity to growth factors that promote platelet production and disrupted sensitivity to negative regulators of thrombopoiesis at the level of the megakaryocyte progenitor cell might account for the thrombocytosis that is characteristic of primary thrombocythemia.

Using serum-free cultures, a number of laboratories have reported conflicting data about spontaneous megakaryocyte colony formation by CFU-MK from patients with primary thrombocythemia in the absence of the addition of exogenous cytokines.[54] [55] [56] [57] [58] Several groups have attempted to utilize this in vitro characteristic as a diagnostic tool to discriminate between primary thrombocythemia and reactive thrombocytosis. [54] [55] [56] [57] [58] [59] Because there is some degree of spontaneous megakaryocyte colony formation by normal marrow in such serum-free culture systems, these findings remain difficult to interpret. [61] No evidence of an autocrine regulatory defect involving IL-3, IL-6, GM-CSF, or thrombopoietin has been detected to account for the expansion of the megakaryocyte progenitor cell pool in primary thrombocythemia.[58] [62]

Erythroid progenitor cells in primary thrombocythemia can also proliferate in response to the small amount of cytokines present in serum alone. Erythroid colony formation in the absence of exogenous erythropoietin is a hallmark of the proliferative defect that characterizes polycythemia vera. [63] Burst-forming unit-erythroids can be assayed from both marrow and peripheral blood of patients with primary thrombocythemia and form erythroid colonies in the absence of exogenous erythropoietin.[64] [65] [66] [67] Such an abnormality in these nonpolycythemic patients probably indicates an underlying defect shared by progenitor cells in many myeloproliferative disorders.[64] [65] [66] [67] These observations allow one to question the claim that endogenous erythroid colony formation can be useful in discriminating between primary thrombocythemia and masked polycythemia vera.[68] This does not diminish the use of such erythroid colony assays to discriminate between myeloproliferative disorders characterized by extreme thrombocytosis and reactive thrombocytosis.

Careful study of one woman with primary thrombocythemia, who entered a spontaneous clinical remission while pregnant, has indicated the existence of normal hematopoietic progenitor cells in the marrow of patients with primary thrombocythemia. [69] This information suggests the coexistence of normal and neoplastic hematopoietic progenitor cells in primary thrombocythemia.[68] This hypothesis is further corroborated by the finding, in some patients, of polyclonal granulocytes, indicating a normal stem cell population alongside the thrombocythemic stem cell clone. [25] [46] [47] Thus, during active phases of the disease the neoplastic cells apparently predominate over normal progenitor cell populations.

Thrombopoietin is the primary physiological regulator of megakaryocytopoiesis and platelet production. This growth factor acts by binding to its cell surface receptor, c-mpl.[70] The thrombopoietin receptor is expressed by CD34+ hematopoietic progenitor cells, megakaryocytes and platelets. [70] Recently, data have been provided that thrombopoietin and its receptor pathways are not directly linked to the defect that underlies primary thrombocythemia. [71] [72] [73] Normal or slightly elevated thrombopoietin levels have been observed in patients with primary thrombocythemia. [71] [72] [73] Furthermore, expression of the thrombopoietin receptor and its mRNA were shown to be dramatically reduced in the platelets of patients with primary thrombocythemia. [72] In addition, the thrombopoietin receptor-mediated signaling cascade was shown not to be constitutively activated in platelets isolated from patients with primary thrombocythemia. [72] Further studies of the molecular pathology

underlying primary thrombocythemia are needed to gain a better understanding of the origins of this disorder.

PATHOBIOLOGY

Most clinical sequelae of primary thrombocythemia are related to hemorrhagic and thrombotic episodes, which frequently punctuate the clinical course of individual patients.[74] [75] [76] [77] Thrombotic complications occur most frequently in older patients and patients with a previous history of a thrombotic event, whereas hemorrhagic events occur almost exclusively in individuals with high platelet counts (>1000 × 10^9 /l).[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [77] A subset of young patients who are asymptomatic and remarkably free of such complications has also been described.[29] [38] [78] Such age-related differences in the frequency of these events have been attributed to the coexistence of vascular disease in older patients.[79] [80] This hypothesis remains controversial since other studies have described younger patients with a significant incidence of vascular thrombosis.[13] [81] Microvascular thrombosis causing digital or central nervous system ischemia leads to a variety of clinical syndromes closely associated with primary thrombocythemia.[9] [74] [75] [76] [82] [83] [84]

Past studies have concluded that the degree of elevation of the platelet count in primary thrombocythemia is an important determinant of the frequency of thrombotic and hemorrhagic events.[1] [4] [5] These conclusions were, however, based on observations of a limited number of patients. Four different studies have failed to define a relationship between the frequency of thrombotic complications and platelet numbers.[13] [14] [85] [86] The relationship between frequency of bleeding episodes and platelet counts is also cloudy. In two studies, patients with extreme thrombocytosis (>1000 × 10^9 /l) were reported to have a much higher incidence of hemorrhagic events, although such a relationship was not confirmed in a third study.[13] [77] [79] [86]

Recently, some progress has been made in further defining the relationship between platelet numbers and the risk for thrombotic and hemorrhagic events in primary thrombocythemia.[74] [77] [87] [88] [89] [90] Cortelazzo has reported in a randomized trial of patients at high risk of developing a thrombotic event (>60 years of age and/or a previous history of thrombotic episode) that reduction of platelet numbers was highly effective in preventing additional thrombotic events.[87] Furthermore, Cortelazzo et al. have shown that the incidence of thrombotic events is closely correlated with the duration of thrombocytosis.[76]

Several groups have now confirmed that the degree and duration of bleeding in this patient population correlates with the platelet count.[72] [82] [83] [84] Bleeding events appear to occur exclusively when the platelet counts are excessively high and stop when the platelet count falls to normal.[77] [88] [89] [90] The clinical spectrum of bleeding in primary thrombocythemia patients closely resembles that observed in von Willebrand disease.[82] [83] [84] Several groups have now shown that high platelet counts (>1000 × 10^9 /l) are associated with an acquired von Willebrand syndrome and that reduction of platelet numbers is associated with correction of the von Willebrand defect and cessation of bleeding episodes.[88] [89] [90] An increase in the number of circulating platelets appears to favor the adsorption of larger von Willebrand multimers onto platelet membranes, resulting in their removal from the circulation and their subsequent degradation.[89] The laboratory features of acquired von Willebrand syndrome in primary thrombocythemia is characteristic of a Type II deficiency, a prolonged bleeding time, a normal Factor VIII C:VWF Ag ratio, decreased ristocetin cofactor activity, and a decrease or absence of large von Willebrand factor multimers.[90]

Platelets in patients with primary thrombocythemia have been known for a considerable time to be qualitatively abnormal.[4] [7] [74] [75] [76] [77] [88] [90] While both increased and decreased platelet reactivity has been described,these findings have not been definitively associated with thrombohemorrhagic complications with two noteworthy exceptions; erythromelalgia, where the prompt relief of symptoms by cyclo-oxygenase inhibitors provides direct evidence that prostaglandins play a role in the development of vascular occlusion, and acquired von Willebrand syndrome, which is a major cause of bleeding in patients with primary thrombocythemia.[4] [7] [75] [82] [83] [84] [85] [86] [87] [88] [89] [90] Prolongation of the bleeding time has been reported in 719% of newly diagnosed patients with primary thrombocythemia.[77] A close correlation between prolongation of the bleeding time and the occurrence of hemorrhage in primary thrombocythemia patients does not always exist. This is in contrast to correction of the bleeding time in those patients with primary thrombocythemia, extreme thrombocytosis, and acquired von Willebrand syndrome following reduction of platelet numbers to the normal range.[75] [90] It is important to emphasize that aspirin prolongs the bleeding time of patients with primary thrombocythemia to a greater degree than that of normal controls.[77] [79] Abnormal platelet aggregation has been reported in 35100% of patients with primary thrombocythemia.[77] Such abnormal aggregation studies are not related to prolongation of the bleeding time or to the incidence of episodes of hemorrhage or thrombosis. In primary thrombocythemia, platelet aggregation is classically defective in response to epinephrine, ADP and collagen but usually normal with arachidonic acid and ristocetin.[77] Characteristically, in primary thrombocythemia, the first wave of aggregation is diminished and the second wave of aggregation is absent in response to epinephrine.[77] Interestingly, preincubation of primary thrombocythemic platelets with thrombopoietin corrects in part the impaired aggregation in response to epinephrine, ADP, and collagen.[91] Usuki et al. have proposed that circulating thrombopoietin levels in this disorder might regulate platelet function and responses to agonists in vivo.[91] An acquired form of platelet storage pool disease occurs frequently in primary thrombocythemia. Platelet -granule content and release are abnormal resulting in elevated plasma levels of platelet factor-4 and -thromboglobulin.[77] Because the content of -granule constituents has been reported to be normal in megakaryocytes isolated from primary thrombocythemia, the synthesis of these molecules is not thought to be abnormal, but rather, the release of granule constituents is thought to be a consequence of platelet activation.[77] The finding of an acquired storage pool defect again does not correlate with platelet numbers or with the occurrence of clinical symptoms. A variety of individual functional

Figure 64-1 Proposed pathophysiologic mechanisms of platelet-mediated inflammatory ischemic arthrothrombotic processes in primary thrombocythemia. (*From Michiels et al.,*[75] *with permission.*)

platelet abnormalities have been demonstrated.[92] [93] [94] [95] [96] [97] [98] [99] A defect in the metabolism of arachidonic acid by lipoxygenase has been documented, as have decreased numbers of platelet receptors for prostaglandin D_2 and adrenergic receptors for epinephrine.[77] [97] [98] Platelets from patients with thrombotic episodes have been found to be capable of increased generation of thromboxane B_2 and to have an increased affinity for fibrinogen.[99] [100] Elevations in -thromboglobulin and serum thromboxane B_2 levels in primary thrombocythemia patients are suggestive of the presence of enhanced in vivo platelet activation and possibly thrombin generation. These same abnormalities are not detected in patients with secondary thrombocytosis and may provide some explanation for the high incidence of thrombosis associated with primary thrombocythemia.

The survival of platelets in patients with erythromelalgia and thrombosis has been shown to be reduced to 4.2 ± 0.2 days in comparison to normal platelet survivals in asymptomatic thrombocythemia patients (6.6 ± 0.3 days) and patients with reactive thrombocytosis (8.0 ± 0.4 days).[101] Treatment of erythromelalgia with aspirin increased mean platelet survival from 4.0 ± 0.3 days to 6.9 ± 0.4 days and was associated with a significant elevation of platelet numbers.[101] These findings suggest that erythromelalgia results from platelet-mediated thrombosis of the arterial microvasculature of the extremities (Fig. 64-1).[75] [101] Complete correction of this ischemic circulatory defect is associated with the use of platelet cyclo-oxygenase inhibitors such as aspirin and indomethacin.[85] Agents that do not inhibit platelet cyclo-oxygenase, such as coumadin, sodium salicylate, dipyridamole, sulfinpyrazone and ticlopidine are not active in the treatment of this disorder. Dazoxiben is capable of inhibiting platelet malondialdehyde and thromboxane B_2 synthesis but does not correct the symptoms of erythromelalgia.[76] [77] [85] These findings suggest

that prostaglandin endoperoxides play a role in the generation of platelet-associated thrombosis in primary thrombocythemia (Fig. 64-1).[75]

Abnormalities of platelet membrane constituents have also been demonstrated in primary thrombocythemia. Most commonly, decreased concentrations of glycoprotein (GP) Ib and also reduced concentrations of GPIIb and GPIIIa have been reported. [77] A remarkable patient with primary thrombocythemia with a prolonged bleeding time was shown to have an acquired deficiency of glycoprotein Ia-IIa, the putative collagen receptor. Collagen-induced platelet aggregation was totally absent.[93] The mechanisms underlying these acquired membrane defects as well as their clinical significance remain unclear.

One intriguing explanation for the increased risk of thrombosis in patients with primary thrombocythemia has been proposed by Lee and Baglin. [94] These investigators demonstrated that the total amount of thrombin generated on the platelet surfaces of patients with primary thrombocythemia was markedly greater than that generated on the platelet surfaces of normal controls or patients with reactive thrombocytosis. [94] The molecular basis of this abnormality has not been defined, but it remains possible that an abnormal membrane structure of primary thrombocythemia platelets may account for the enhanced thrombin potential that may lead to a relatively high thrombotic risk.

CLINICAL MANIFESTATIONS

The presenting symptoms of patients with primary thrombocythemia are quite variable. Many patients (1267%) reach medical attention fortuitously, as a result of the extreme degree of thrombocytosis detected when obtaining a routine blood cell count. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] In two series, in fact, 7684% of cases were asymptomatic and the diagnosis was made incidentally (Table 64-1 (Table Not Available)). [76] [102] Most patients present with symptoms related to small- or

large-vessel thrombosis or minor bleeding. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Presentation with a major bleeding episode is unusual. [103] After thrombocytosis has been detected, 1337% of patients relate symptoms resulting from hemorrhagic events, while 2284% of patients report thromboembolic complications. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [76] [104] Table 64-1 (Table Not Available) lists the symptoms at diagnosis from one large series of patients. [76] The thrombotic events primarily involved the microvasculature, with thrombosis of large vessels also occurring. Neurologic complications are common: [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [81] [104] [105] [106] Table 64-2 lists representative neurologic complaints, [82] of which headache was the most common, with paresthesias of the extremities a close second. There was an extremely high incidence of transient ischemic attacks involving both the anterior and posterior cerebral circulation. [105] [106] [107] These attacks have a sudden onset, last for a few moments, and are frequently associated with a pulsatile headache. [105] [106] [107] The various symptoms occur sequentially rather than simultaneously and can be preceded or followed by erythromelalgia. Transient neurological symptoms include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and even seizures. [105] The syndrome is caused by platelet-mediated ischemia and thrombosis in end-arterial microvasculature. It is not unusual for these symptoms to eventually progress to definitive cerebral infarcts. [106]

Microvascular occlusions involving the toes and fingers are frequent. [74] [75] [76] Such events can lead to digital pain, enhanced by warmth; distal extremity gangrene, (Fig. 64-2) and classic erythromelalgia. [9] [74] [75] [83] [84] [108] [109] The term *erythromelalgia* refers to a syndrome of redness and burning pain in the extremities. [109] Venous thrombosis is not observed in these patients. Erythromelalgia, which is characterized by a burning pain and a dusky congestion of swollen extremities, is usually preceded by paresthesias. [75] Cold provides relief to these symptoms and heat intensifies the symptoms. Patients prefer to wear shoes or slippers without socks and elevate their feet. [75] These symptoms may progress in intensity and lead to peeling of the skin in affected appendages or affected toes or fingers, which then may become cold and ischemic with a dark purplish tinge. Erythromelalgia symptoms are asymmetric in the majority of cases. [70] Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia. [75] [108] Occasionally, hemorrhagic episodes may occur in patients experiencing erythromelalgia. [75] Platelet counts in patients with erythromelalgia are frequently below 1000×10^9 /l except in those patients with concomitant occurrence of erythromelalgia and hemorrhage. [75] [83] [84] [108] The relief of such pain for several days after a single dose of aspirin is diagnostic of erythromelalgia. [75] [83] [84] The specific microvascular syndrome of erythromelalgia is readily explained by platelet-mediated arteriolar inflammation and occlusive thrombosis leading to acrocyanosis and even gangrene. [75] [83] [84] Skin biopsies from affected sites reveal arteriolar lesions without involvement of venules, capillaries, or nerves. [83] The arteriolar endothelial cells are swollen and the vessel walls thickened by cellular swelling and deposition of

intracellular material. [83] In contrast to atherosclerotic circulatory obstruction, arterial pulses in patients with erythromelalgia remain normal. [83] [84]

Although thrombosis of the microvasculature is generally more frequent, thrombosis of large veins and arteries in patients with primary thrombocythemia still occurs commonly. [13] [14] [110] In one series, 51% of patients had symptoms related to large-vessel thrombosis, mostly in the arteries of the legs (30%), the coronary arteries (18%), and the renal arteries (10%). [14] Involvement of the carotid, mesenteric, and subclavian arteries is not unusual. In the same series, 7% of patients suffered from venous thrombosis involving either the splenic vein, hepatic veins, or veins of the legs and pelvis. [14] Unexplained thrombosis of the hepatic veins leads to Budd-Chiari syndrome, while thrombosis of the renal vein can result in the development of the nephrotic syndrome. [104] [111] Priapism is a rare complication of primary thrombocythemia, presumably caused by platelet sludging in the corpus cavernosum. [105] [112] In addition, myocardial ischemia or infarction, or both, associated with normal coronary angiograms has been reported in patients with primary thrombocythemia, as has a high incidence of anginal symptoms. [113] [114] [115] A high incidence of aortic and mitral valvular lesions has been reported in patients with myeloproliferative disorders, including primary thrombocythemia. [115] These valvular lesions resemble previous descriptions of nonbacterial thrombotic endocarditis and may be the origin of the peripheral arterial emboli observed in these patients. [115] In addition, acute renal failure has been observed after thrombosis of renal arteries and veins in one patient with primary thrombocythemia. [116] Pulmonary hypertension secondary to alveolar capillary plugging by platelets and megakaryocytes has also been reported in two patients with primary thrombocythemia. [117] [118]

Hemorrhagic problems plague many patients with primary thrombocythemia;[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] the primary site of bleeding is the gastrointestinal tract.[5] [74] [75] [79] [90] [119] At least 40% of patients with primary thrombocythemia may have duodenal arcade thrombosis with sloughing of duodenal mucosa, simulating a duodenal ulcer.[5] Other sites of bleeding may be the skin, eyes, urinary tract, gums, tooth sockets (following extraction), joints, or brain. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] Bleeding most often is not severe but occasionally may require red cell transfusion support. [1] [8] [13] The postoperative period appears to be an extremely precarious time, with a high incidence of bleeding episodes following surgical insult. [113] The syndrome of hemorrhagic thrombocythemia is closely correlated with a significant increase of platelet counts in excess of 1000 × 10^{9} /l and is associated with pseudohyperkalemia.[75]

In one large study in which 97 primary thrombocythemia

patients were followed for an average of 7 years, the incidence of thrombohemorrhagic complications was significant, although these complications were rarely life-threatening.[120] Of the 97 patients, 26 had some type of hemorrhage, mostly of gastrointestinal or mucosal origin; 33 of the 97 patients had some form of thrombosis, mainly in the peripheral arteries. Risk factors for atherosclerotic disease, especially cigarette smoking, increased the risk of thrombosis. [80] [120] It is important to emphasize that individual patients can suffer from both thrombotic and hemorrhagic episodes and that patients are not necessarily consistent bleeders or clotters.[74] [75] [79] Constitutional symptoms, such as weight loss, sweating, low-grade fever, and pruritus, can occur in 2030% of patients. [10]

A clinically relevant controversy revolves around the understanding of the risk of thrombohemorrhagic events in asymptomatic patients with primary thrombocythemia who are less than 40 years of age.[29] [31] [38] [78] [82] This group represents 25% of the patients studied in a 13-year period at one institution and 34% of those studied at another institution. [78] In one series of 57 such adults with a mean follow-up period of 4.7 years (range from 5 months to 20 years) 43% remained asymptomatic, whereas thrombotic complications developed in another 43%.[78] Hemorrhagic complications occurred in 11% of the patients and 4% suffered a spontaneous abortion (2 out of the 16 pregnancies).[38] The thrombotic complications were life-threatening in only 5% of the patients, all of whom recovered. The two deaths that occurred were not attributable to primary thrombocythemia.[38] The most common thrombotic complications were migraine headache in 20% of the patients and erythromelalgia in 5% of the patients. None of the hemorrhagic episodes were life-threatening. [38] In this series, young patients enjoyed a low incidence of life-threatening complications and a favorable long-term prognosis, findings confirmed by another large series. [29] [38] [73] However, in another study of 44 patients under the age of 45, serious thrombotic or hemorrhagic complications occurred in 23% of patients and 4% died as a consequence of thrombotic events. [79] In addition, one patient experienced a serious hemorrhagic event associated with the development of acquired von Willebrand syndrome. This group did not consider young age as a favorable prognostic factor and favored treatment of asymptomatic young individuals. [79] It is generally agreed that age >60 years is clearly associated with a greater risk of thrombosis.[76] Management of asymptomatic patients between the ages of 40 and 60 years therefore remains problematic, since there is little question that the symptomatic patient requires some sort of therapeutic intervention.

The outcome of pregnancy in patients with primary thrombocythemia has recently been the subject of intense investigation. [121] [122] [123] [124] In an excellent review of the literature, Greisshammer et al. reported that of 106 pregnancies in 57 women, the rate of spontaneous abortion was 43% in comparison to the 15% rate expected in the general population.[121] Placental thrombosis leading to placental infarction was the most common pathological event leading to placental insufficiency, intrauterine growth retardation, and even fetal death.[121] The platelet count usually remains the same during the pregnancy, although a progressive decline in platelet count, which returns to its previous elevated level postpartum has been reported in 20% of cases. [121] [123] A significant fall in platelet count has been reported to be associated with a successful pregnancy.[124] The basis of the decrease of platelets during pregnancy is unknown, but the decrease is generally greater than the 20% reduction in platelet counts associated with normal pregnancies. [124] In the large majority of cases, the fetal losses occur during the first trimester. [121] [122] [123] [124] In one series, 65% of the miscarriages occurred in 17% of women.[122] Thus, a previous history of spontaneous abortion may be the greatest risk factor for the development of subsequent spontaneous abortions.[122] Excessive bleeding during delivery appeared to be an extremely rare event. [121] [122] [123] [124]

Physical examination is relatively unremarkable in most cases. Most patients are not severely ill at diagnosis, a median Karnofsky score of 90% being reported in one series.[10] [12] Splenomegaly is detectable in 4050% of patients, and approximately 20% have hepatomegaly. [10] [12] During the course of the disorder, a further increase in the degree of hepatosplenomegaly does not appear to occur. [10] [12]

Although splenomegaly is the more common finding in primary thrombocythemia, splenic atrophy due to silent autoinfarction of the spleen may lead to an acquired form of hyposplenism.[6] [7] The appearance of Howell-Jolly bodies and target erythrocytes in the peripheral blood smear suggests the occurrence of splenic autoinfarction.

LABORATORY EVALUATION

The hallmark of primary thrombocythemia is a sustained and unexplained elevation of the platelet count. The level of thrombocytosis required for the diagnosis is arbitrarily determined; the range is 450,0001,000,000/mm^3 , depending on the series cited.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Table 64-3 lists the laboratory findings reported in one large series of patients with this disorder. [13] These findings may be considered representative, as only patients with platelet counts of >600,000/mm^3 were evaluated, and relatively rigorous diagnostic criteria were used. Accompanying leukocytosis was a common finding in this series, as in others reported in the literature.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Occasional immature myeloid precursor cells (myelocytes or metamyelocytes) and nucleated red blood cells can be seen in the peripheral blood of 25% of patients. [10] [12] In one series, mild eosinophilia (>400/mm^3) and basophilia (>100/mm^3) were present in more than one-third of patients.[10] [12]

The most common morphologic abnormalities are variations in red cell size and shape and the presence of megathrombocytes. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] The mean leukocyte alkaline phosphatase activity in one series was 79, with levels below 20 being observed in only three patients. [10] [12] Table 64-4 summarizes the bone marrow biopsy findings.[10] [12] In this careful study performed by the Polycythemia Vera Study Group, marrow cellularity was increased

in almost 90% of patients. In two-thirds of patients, marked megakaryocytic hyperplasia, morphologically bizarre megakaryocytes with nuclear pleomorphism, and clustering of megakaryocytes were frequently present.[10] [12] [28] [32] Enlargement of megakaryocytes with multilobulated nuclei and their tendency to cluster in small groups along sinuses is the hallmark of primary thrombocythemia.[125] Granulopoiesis and erythropoiesis are not remarkable except for increased cell numbers. Reticulin content was increased in 25% of patients, but collagen fibrosis was not evident. [10] [12] In 7080% of patients, iron stores were present in the marrow, albeit at reduced levels.[14] [125] Almost all patients have normal serum ferritin levels.[125] Cervantes et al.[126] have suggested that the absence of iron stores in 30% of patients

may merely be an epiphenomenon of a chronic myeloproliferative syndrome, and not truly reflective of an iron deficiency state. Bleeding times are prolonged in 1020% of patients.[13] [77] Platelet aggregation studies are frequently abnormal, most often demonstrating impaired aggregation in response to epinephrine, ADP and collagen but not to arachidonic acid and ristocetin. [77] Spontaneous platelet aggregation has been reported to occur frequently in such patients, but this has not been a universal finding.[13] [77]

About 25% of patients with primary thrombocythemia have been reported to have elevated uric acid levels at diagnosis. [10] [12] [14] The average value of the serum potassium at diagnosis is usually within the normal range, although 23% of patients have been reported to have pseudohyperkalemia and falsely elevated phosphorus concentrations.[127] [128] The laboratory features of acquired von Willebrand syndrome associated with excessively high platelet count and a bleeding tendency have been previously described in detail. This syndrome in patients with primary thrombocythemia is associated almost uniformly with a platelet count >1000 × 10^{9} /l, a prolonged bleeding time, a normal factor VIII coagulant activity and von Willebrand antigen level but a decreased von Willebrand factor-ristocetin cofactor activity and collagen binding activity as well as a decrease or absence of large von Willebrand factor multimers simulating a type II von Willebrand factor deficiency. [88] [89] [90] An enhanced thrombotic risk in primary thrombocythemia patients has been associated with a reduction in the concentration of one of the natural anticoagulants including protein S, antithrombin III protein C, and resistance to activated protein C resulting from an associated genetic defect in factor V. [128] These studies indicate that such a genetic deficiency of one of the natural anticoagulants may further contribute to the thrombotic tendency of patients with primary thrombocythemia. Pseudohypoxemia has also been observed in primary thrombocythemia patients with extreme degrees of thrombocytosis. [129] The serum B_{12} level can be increased in 25% of cases. [10] [12] [13]

In primary thrombocythemia, marrow karyotypes are characteristically normal.[10] [11] [12] [13] [14] [130] The absence of the Philadelphia chromosome rules out the diagnosis of chronic myeloid leukemia (CML).[131] [132] Aneuploidy is seen in the minority of cases. In fact, analysis of 170 cases of primary thrombocytosis revealed a definite chromosomal abnormality in only 5.3% of cases. Marker chromosomal abnormalities, such as 1q , 20q , 21q , or $1q^{+}$, have been reported, but no consistent chromosomal abnormality has been identified. [10] [11] [12] [13] [14] [130] [131] [132] [133] [134] [135] [136] [137]

DIFFERENTIAL DIAGNOSIS

The diagnosis of primary thrombocythemia is one of exclusion (Table 64-5). Primary thrombocythemia must be distinguished from reactive or secondary forms of thrombocytosis and from other myeloproliferative disorders, such as polycythemia vera, agnogenic myeloid metaplasia, and CML, which are also frequently characterized by thrombocytosis.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] Patients with myelodysplastic syndromes can also present with a moderate or marked degree of thrombocytosis; this is especially true of patients with the 5q syndrome and of patients with idiopathic acquired sideroblastic anemia. [138] [139] The causes of secondary or reactive forms of thrombocytosis are numerous. In a hospital population, patients with extreme thrombocytosis (>1000 × 10^9 /l) are not particularly rare in adult or pediatric patient populations. [26] [140] [141] [142] [143] Examination of the blood smear is important to avoid confusion with so-called pseudothrombocytosis. This occurs in a number of conditions in which platelet-sized particles that are red or white cell fragments (CLL, TTP, Hgb-H disease, microspherocytosis) are erroneously enumerated as platelets by automatic particle counting. [144] Confirmation of increased numbers of platelets by examination of the peripheral smear will

TABLE 64-5 -- Criteria for Diagnosis of Primary Thrombocythemia

1. Platelet count >600,000/mm^3 on two different occasions, separated by a 1-month interval
2. Absence of identifiable cause of reactive thrombocytosis
3. Normal red cell mass, measured red cell mass <25% above the normal predicted value
4. Absence of significant fibrosis of the marrow (>1/3 cross-sectional area of the bone marrow biopsy)
5. Absence of the Philadelphia chromosome and the fusion *bcr/abl* gene by PCR; absence of clonal cytogenetic abnormalities associated with myelodysplastic disorders
6. Presence of splenomegaly by physical examination, ultrasonography, or scan
7. Bone marrow hypercellularity, as shown by a bone marrow biopsy and the presence of megakaryocytic hyperplasia with clusters of multilobulated large megakaryocytes
8. Absence of iron deficiency, as documented by the presence of stainable marrow iron and/or normal serum ferritin
9. In females, demonstration of clonal hematopoiesis by means of restriction fragment length polymorphism analysis of genes present on the X chromosome
10. Presence of abnormal marrow hematopoietic progenitor cells, as determined by the formation of endogenous erythroid and/or megakaryocytic colonies with increased sensitivity to IL-3
11. No elevation of plasma C-reactive protein and IL-6 levels
Patients who meet criteria 15 and 3 of criteria 611 should be considered to have primary thrombocythemia.

avoid misdiagnosis and unnecessary clinical evaluation. In one series of 280 patients with extreme thrombocytosis encountered over a 5-year period at a university hospital, reactive thrombocytosis accounted for 82% of cases of extreme thrombocytosis, whereas thrombocytosis due to myeloproliferative disorders accounted for only 14% of cases.[142] In fact, of the patients with myeloproliferative disorders, primary thrombocythemia accounted for only 29% of the cases. Reactive thrombocytosis was more common in all age groups except those in the eighth decade and higher. The causes of extreme thrombocytosis outlined in this series are listed in Table 64-6 .[142] Importantly, in this series, the mean peak platelet count for patients with reactive thrombocytosis (1,195 × 10^9 /l) was significantly lower than that of patients with thrombocytosis secondary to a myeloproliferative disorder (1,808 × 10^9 /l).[138] This shows that a significant number of patients with reactive thrombocytosis have platelet counts greater than 1,000 × 10^9 /l and that it is impossible to distinguish between reactive thrombocytosis and thrombocythemia caused by a myeloproliferative disorder, based solely on the degree of thrombocytosis. [140] [141] [142] Thrombotic and hemorrhagic events infrequently occur in patients with reactive thrombocytosis.[140] [141] [142] [143] These findings are in contrast to the enhanced risk of these two complications in patients with primary thrombocythemia. This relatively high frequency of extreme thrombocytosis in an acute care hospital emphasizes the need for caution in making a diagnosis of primary thrombocythemia. A number of groups have shown that reactive thrombocytosis may be a consequence of the elaboration of known cytokines in response to the underlying inflammation or neoplastic disorder.[145] [146] [147] [148] Elevated levels of IL-1, IL-6, GM-CSF and G-CSF have been detected in such patient populations but not in individuals with thrombocytosis caused by an underlying myeloproliferative disorder. [72] [73] [145] [146] [147] [148] [149] Elevation of thrombopoietin has not only been found to be elevated in patients with reactive thrombocytosis but also in patients with primary thrombocythemia. [73] C-reactive protein is an acute phase reactant, the hepatic synthesis of which is mediated by IL-6.[141] C-reactive protein levels are high in patients with high levels of IL-6. [145] In one series, 81% of patients with reactive thrombocytosis had elevated IL-6 or C-reactive protein levels, whereas patients with uncomplicated thrombocytosis secondary to a myeloproliferative disorder had undetectable IL-6 levels.[145] Low levels of both IL-6 and C-reactive protein are strongly indicative of the thrombocytosis

being the consequence of an underlying myeloproliferative disorder rather than being reactive thrombocytosis. [145] The clinical and laboratory features useful in distinguishing primary thrombocythemia from reactive thrombocytosis are outlined in Table 64-7 .[150]

A number of investigators have constructed lists of diagnostic criteria useful in identifying individuals with primary thrombocythemia. [10] [13] [29] [30] [150] [151] [152] [153] [154] No such list is infallible. Table 64-5 lists useful diagnostic criteria, but these criteria are arbitrary. Red cell mass and plasma volume studies are frequently necessary to differentiate primary thrombocythemia from polycythemia vera. In males with thrombocytosis and a hematocrit <60% or in a female with a hematocrit <55%, such studies should be performed. Values greater than these values are associated with an elevated red cell mass, and radioisotope studies are unnecessary to document the presence of an elevated red cell mass.[155] Bone marrow karyotypic analysis is imperative in every patient to exclude the diagnosis of CML. [131] [132] This step is necessary because the natural history of these disorders is very different, and early therapeutic intervention with bone marrow transplantation for appropriate patients with CML is potentially curative.[131] [132] In one series, six women presented with the clinical picture of primary thrombocythemia without anemia, marked splenomegaly, or extreme leukocytosis characteristic of CML.[132] Each of these patients was shown to have a Philadelphia chromosome on karyotypic analysis, and five of the six entered the accelerated phase or blast crisis within 57 years of diagnosis. [132]

A highly instructive case was reported by Morris et al. [131] The patient was a 23-year-old woman who presented with a syndrome indistinguishable from primary thrombocythemia.[131] Although no Philadelphia chromosome was detected, the patient did develop blast crisis after four years of follow-up. By Southern blot analysis, she was shown to have the BCR-ABL fusion gene, suggesting that she actually suffered from CML and not from primary thrombocythemia.[132] This case emphasizes the importance of molecular studies when evaluating patients suspected of having primary thrombocythemia. [131]

Blickstein et al., in a large series of patients with Philadelphia chromosome negative primary thrombocythemia, confirmed these findings. [156] They examined the BCR-ABL status using a two-step nested PCR assay of the bone marrow cells in 25 patients with Philadelphia negative primary thrombocythemia and found that 12 were positive for BCR-ABL.[156] The clinical characteristics of these two groups of patients were identical and after a median follow-up of just less than 2 years there had been no cases of leukemic transformation.[156] This high rate of BCR-ABL positivity in this group is surprising, and further

follow-up of this patient population will be required to determine the eventual rate of leukemic transformation. This study does, however, again emphasize the need for molecular diagnostics to exclude the diagnosis of CML in patients with isolated thrombocytosis.

The presence of clonal hematopoiesis at least in one lineage quickly establishes the diagnosis of primary thrombocythemia. [21] [22] [23] Such studies may be particularly useful in young females with thrombocytosis.[25] Probes for a variety of genes on the X chromosome can be informative for clonal analysis of blood cell production in >72% of American females.[25] In such patients, analysis of restriction fragment length polymorphisms can be used to establish a pattern of clonal hematopoiesis, which is indicative of a hematologic malignancy and establishes the diagnosis of primary thrombocythemia in a young female with thrombocytosis. [24] Polyclonal hematopoiesis is found in all cases of reactive thrombocytosis. Polyclonal hematopoiesis, however, does not exclude the diagnosis of primary thrombocytosis because in several series, almost one-third of patients who met the clinical criteria for primary thrombocythemia had polyclonal hematopoiesis in all studied lineages.[25] [45] The biogenesis of this polyclonal form of primary thrombocythemia is poorly understood.

A number of diagnostic tests, including splenic volume estimates using ultrasound evaluations and assays of bone marrow progenitor cells (erythroid or megakaryocyte), have been suggested as useful means of differentiating reactive thrombocytosis from primary thrombocythemia. [54] [55] [56] [57] [58] [157] Insufficient numbers of patients as well as a lack of long-term follow-up make it impossible to assess the clinical value of such tests.

As has been previously discussed, the lack of quality control in many laboratories in the performance of such clonal assays for hematopoietic progenitor cells is of concern and limits the utility of such information gained by their performance. [54] [55] [56] [57] [58] The presence of endogenous erythroid colonies or megakaryocyte progenitors with increased sensitivity to hematopoietic growth factor is, however, helpful in distinguishing reactive thrombocytosis from thrombocytosis due to a myeloproliferative disorder.[54] [55] [56] [57] [58] Such assays are of limited use in distinguishing primary thrombocythemia from the other myeloproliferative disorders. [58]

At times it is impossible to define the cause of an individual patients thrombocytosis. In an asymptomatic patient, the resolution of this problem is easy: one should simply provide follow-up and determine whether the degree of thrombocytosis increases. If additional clues to the cause of the thrombocytosis are subsequently revealed, a diagnosis will become apparent. In a patient with thrombohemorrhagic difficulties, one must make a presumptive diagnosis of the cause of the thrombocytosis and then, after weighing the benefits versus the risks of various treatment plans, determine whether reduction of platelet numbers or simple observation is indicated. Some reassurance is provided by the report of Schilling, who followed a large cohort of patients, each with platelet counts of $>1 \times 10^6/mm^3$, for 18 months. None of the patients with reactive thrombocytosis developed a cerebrovascular accident, thrombophlebitis, or peripheral arterial thrombosis. [140] These findings are consistent with the conclusions of Buss et al. that thrombohemorrhagic complications are rare in patients with secondary thrombocytosis. [86] [142]

THERAPY

The treatment of patients with primary thrombocythemia is controversial and remains largely problematic, yet new insight into the management of such patients has recently been gained. [15] [30] [150] Handling of primary thrombocythemia patients with life-threatening hemorrhagic or thrombotic episodes is more straightforward and is best approached by plateletpheresis in combination with institution of myelosuppressive therapy. [158] [159] [160] [161] Rapid plateletpheresis using continuous or discontinuous flow centrifugation devices has proved effective in preventing additional morbidity in patients with primary thrombocythemia. [158] [159] [160] [161] In this situation, immediate physical removal of large numbers of platelets is preferred. Since chemotherapeutic agents generally require 1820 days before platelet counts can be reduced to normal levels, Taft et al. [158] have recommended reducing the platelet count to 500,000/mm^3 by each plateletpheresis and suggest that achievement of such a goal requires the passage of two blood volumes over a 34-hour period.

Such a therapeutic approach has been employed to treat acutely ill patients with problems such as cerebrovascular accidents, myocardial infarction, transient ischemic attacks, or life-threatening gastrointestinal hemorrhage. [158] [159] [160] [161] Long-term plateletpheresis has proved an ineffective means of controlling thrombocythemia, presumably because of the rapid rate of production of platelets. [159] Therefore, most clinicians begin by administering a chemotherapeutic agent that has a rapid onset of action, such as hydroxyurea, simultaneously with the institution of plateletpheresis. [161] If plateletpheresis is not an available therapeutic option, administration of nitrogen mustard (0.4 mg/kg) is usually effective in lowering the platelet count within several days. [160]

In those patients found to have primary thrombocythemia and who are clearly symptomatic, little controversy exists as to the need for lowering the platelet count. The large number of thrombotic complications that occur in patients with primary thrombocythemia who smoke, point to the urgent need for these patients to stop smoking immediately. [80] Most investigators try to normalize the platelet count or to reach a platelet count at which the patients symptoms resolve. Although major bleeding episodes requiring hospitalization are rare, those patients with extreme thrombocytosis (>1,500 × 10^9 /l), acquired von Willebrand syndrome, and history of hemorrhagic episode are clearly at risk for developing additional bleeding complications. [88] [89] [90] These patients require reduction of the increased platelet counts to the normal range with use of a variety of chemotherapeutic agents, anagrelide or interferon-. Such patients should avoid exposure to aspirin even if they are suffering hemorrhagic complications and thrombotic episodes simultaneously. [88] [89] [90] Thrombotic complications are more frequent, especially when thrombocytosis is less marked. Symptoms of functional ischemia are the most common clinical presentation, although the majority of patients are asymptomatic at diagnosis (Table 64-1 (Table Not Available)). [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [30] [76] Many authors have attempted to identify factors associated with an increased risk of thrombotic complications. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [30] [76] Patients older than 60 years of age or with a previous history of vascular occlusive episode have significantly greater risk of developing additional thrombotic episodes. [76] Such patients define a high-risk population who merit therapeutic intervention. A clear relationship between platelet numbers and the frequency of thrombotic events has never been established. [76] Recently, Cortellazzo et al., in a randomized trial of high-risk patients, reported that cytoreductive therapy (platelet count to 600 × 10^9 /l) with hydroxyurea was effective in preventing additional thrombotic episodes. [87] Another situation that requires treatment is discomfort due to erythromelalgia or progression of erythromelalgia to frank gangrene. [75] Such patients respond within days to low-dose aspirin therapy and/or platelet reduction therapy. [75] The therapeutic strategy to be employed with asymptomatic patients less than 60 years of age remains controversial. The risk of the development of thrombotic events, the leukemogenic potential of chemotherapeutic agents used to treat thrombocytosis, and the ability of cytoreductive therapy or a platelet antiaggregating therapy to reduce the incidence of thrombotic events must be considered before embarking on treatment of the asymptomatic younger (<60) patient with primary thrombocythemia. Groups of patients have

PERSONAL APPROACH TO THERAPY FOR PRIMARY THROMBOCYTHEMIA

The optimal therapy for patients with primary thrombocythemia remains uncertain. Certain concepts, however, apply to all patients. One is that all patients with primary thrombocythemia should stop smoking to minimize the risk factors associated with atherosclerotic disease. Indiscriminant use of high doses of nonsteroidal anti-inflammatory drugs should be avoided because this practice can lead to an increased risk of hemorrhage. Use of such agents is particularly common in the elderly age group in which primary thrombocythemia is common.

In a randomized trial of high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events. High-risk patients include patients older than 60 years of age and patients with a history of a previous thrombotic episode including erythromelalgia, transient ischemic attacks, or large vessel thrombosis. At present, no therapy is indicated in asymptomatic patients less than 60 years of age. If a patient has a platelet count 1,500 × 10^9 /l and the acquired von Willebrand syndrome, platelet reduction therapy is also indicated to avoid the high risk of hemorrhage. Patients with this acquired von Willebrand syndrome should clearly avoid the use of aspirin.

In those patients requiring platelet reduction therapy, the choice between the use of anagrelide, interferon- and hydroxyurea therapy is based upon patient age, ease of administration, and drug-related toxicity. In patients over 60 years of age, hydroxyurea therapy is the treatment of choice, while in younger patients, I prefer to initiate therapy with anagrelide. This choice is based upon the ability to administer anagrelide orally rather than resorting to parenteral administration for interferon-. If a patient cannot tolerate anagrelide, I then start therapy with interferon-. If the patient cannot tolerate interferon- or fails to respond, I feel comfortable treating the symptomatic patient less than 60 years of age with hydroxyurea. Although I remain concerned about the leukemogenic potential of hydroxyurea, this potential danger is far less than that of the alkylating agents or ^{32}P. Those patients who initially receive hydroxyurea and no longer respond to this agent or suffer toxicity and require another agent should not receive long term ^{32}P or melphalan therapy. This sequence of administration is associated with an extremely high risk of leukemic transformation. Those patients who have had a trial of hydroxyurea and require further treatment should receive either anagrelide or interferon-. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level that I hope to achieve. I believe that strict control to a platelet count 350 × 10^9 /l may lead to greater protection from thrombosis than merely reduction to a level 600 × 10^9 /l. I realize that there are no randomized trials to support this approach but the available anecdotal information is compelling. My success in achieving this goal is obviously dependent on the ability of the patient to tolerate the agents used. In the younger patient if such strict control is not achievable due to poor compliance or toxicity associated with anagrelide or interferon- therapy, I am satisfied with continuing therapy and maintaining platelet counts 600 × 10^9 /l. In patients who suffer from thrombotic episodes, especially episodes involving the microcirculation or large vessels, I administer low-dose aspirin (100 mg/day). This dose of aspirin does increase the number of bleeding episodes to a modest degree but is effective in treatment of thrombotic events. This low-dose aspirin therapy is given in addition to an agent which results in platelet reduction.

Hydroxyurea can be started at a dose of 1 g/day and then adjusted to achieve the target platelet count (<350 × 10^9 /l) without developing leukopenia. Anagrelide is initiated at 0.5 mg qid and increased by 0.5 mg/day every 57 days, if platelet counts do not begin to drop. The usual dose, however, is 2.02.5 mg/day. There are patients who do not tolerate either hydroxyurea or anagrelide. In this patient group, interferon- therapy is initiated at 3 million units three times per week subcutaneously. Another choice is busulfan at 4 mg/day for two-week courses every time the platelet count rises above the normal range. Busulfan therapy is reserved for patients older than 60 years of age.

In general, I do not routinely treat patients younger than 40 years of age, unless they have already have had thrombohemorrhagic symptoms or have significant risk factors for atherosclerotic disease. Complications even in young, otherwise healthy, patients with prolonged platelet counts of >2.0 × 10^6 /mm^3 are unusual.

In certain situations, in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis, and use of anti-inflammatory agents can increase the risk of bleeding postoperatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with primary thrombocythemia, low-dose aspirin therapy is the first treatment option. If the patient develops symptoms as a result of thrombosis within the vasculature, platelet reduction therapy is necessary and interferon- therapy is the treatment of choice. Since interferon does not cross the placenta, it likely will not be teratogenic. Both hydroxyurea and busulfan have been successfully used to treat myeloproliferative disorders during pregnancy, but they are probably teratogenic if used during the first trimester. If such agents are needed, they should be instituted after the first trimester.

In a patient with primary thrombocythemia and a serious acute hemorrhagic event, the site of bleeding should be immediately determined, and any antiplatelet aggregating agents stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may be suffering from acquired von Willebrands syndrome. In patients with acquired von Willebrand syndrome, DDAVP or Factor VIII concentrates containing von Willebrand factor can be used immediately as chemotherapy is being administered. If acquired von Willebrands syndrome is not present, the transfusion of normal platelets is suggested. In those patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by plateletpheresis. Hydroxyurea at 24 g/day for 35 days should be administered immediately, then reduced to 1 g/day. Any patient receiving hydroxyurea should be monitored for the onset of granulocytopenia and/or thrombocytopenia. Reduction of platelet counts is usually observed within 35 days of hydroxyurea treatment.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 100 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms following the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and hydroxyurea or with hydroxyurea alone, depending on the severity of the event. If the arterial thrombosis involves the microcirculation and is not life-threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated and platelet reduction therapy (hydroxyurea, anagrelide or interferon-) can be initiated using standard dose and schedule.

been successfully treated with a variety of chemotherapeutic agents, including busulfan, chlorambucil, pipobroman, thiotepa, radioactive phosphorus, hydroxyurea, nitrogen mustard, uracil mustard, and CCNU (lomustine).[6] [7] [8] [9] [10] [11] [12] [25] [30] [162] [163] [164] [165] [166] [167] [168] Many of these agents have been used to treat a variety of myeloproliferative disorders and solid tumors, and their use has been associated with an increased risk of leukemia.[30] [169] Only a few Phase III studies comparing the efficacy of such agents for the treatment of primary thrombocythemia have been completed.

In a study of a small group of patients, the response to either melphalan or radioactive phosphorus therapy was studied during the first year of therapy.[165] The only

conclusion that could be drawn from this study was that time to response as defined by platelet count reduction was considerably shorter for patients receiving melphalan than for those receiving radioactive phosphorus. [165] Intermittent use of busulfan (4 mg/day, until the platelet count fell to 400,000/mm ^{3} , followed by a series of 2-week courses when the platelet count rose to >400,000/mm ^{3}) has proven to be a relatively nontoxic and effective regimen. [157] These conclusions were based on a lengthy examination of the course of 37 patients. [162]

During the 1980s and 1990s, hydroxyurea became the drug of choice for the treatment of primary thrombocythemia. [29] [30] [87] [168] [170] The impetus for this practice was based upon the capacity of ^{32} P and alkylating agents such as melphalan and busulfan to induce acute leukemia. [30] [169] The popularity of the antimetabolite, hydroxyurea, for the management of primary thrombocythemia was due to belief in the early 1970s that it was nonleukemogenic. [29] [30] Hydroxyurea is administered at a dose of 15mg/kg initially with adjustment of the dose in order to achieve a maintenance dose to maintain a platelet count at a level at least below 600 × 10 ^{9} /l. [81] The use of this drug in a high-risk group of patients with reduction of platelet numbers to less than 600 × 10 ^{9} l has resulted in reduction of thrombotic events when compared to a control population. [87] The reduction of platelet numbers to this level did not entirely eliminate the occurrence of additional thrombotic episodes. One center has reported that more aggressive platelet reduction to less than 350 × 10 ^{9} /l was associated with no recurrence of minor or major thrombotic events involving the peripheral, coronary or cerebral circulation. [170] These findings require confirmation in a large well-controlled randomized clinical trial. Hydroxyurea usage is associated with some toxicity including dose-related neutropenia, nausea, stomatitis, and hair loss. [170] Each of these problems resolve with withdrawal of the drug and dose reduction. Hydroxyurea is also not universally successful in controlling the thrombocytosis. Resistance to hydroxyurea has been reported in 1117% of cases. [170] The risk of evolving to acute leukemia is extremely low in untreated patients. [13] [14] [28] [30] [171] Unfortunately, hydroxyurea has not proven to be nonleukemogenic, with over 20 cases of acute leukemia reported in patients with primary thrombocythemia treated with hydroxyurea alone. [30] [166] [171] [172] [173] [174] In fact, some of the strongest evidence for the leukemogenic potential for hydroxyurea has been provided by the Polycythemia Vera Study Group, which had previously been the most vocal advocate of hydroxyurea therapy for the treatment of primary thrombocythemia. [28] [30] A cohort of 29 patients with primary thrombocythemia were treated with hydroxyurea between 1977 and 1982. [30] These patients met the diagnostic criteria for this disorder as established by this cooperative group. [28] Although 5 patients were lost to follow-up, the median follow-up time for the remaining patients was 7.3 years (Table 64-8). Disturbingly, 6 of the 24 patients developed acute leukemia. One patient developed acute leukemia 2.4 years after treatment, whereas other cases occurred after 6.7 to 9.7 years of follow-up. One of these patients was treated with hydroxyurea alone while 5 others were switched from hydroxyurea to either ^{32} P or an alkylating agent. [32] Another group of 62 patients were treated by this group initially with ^{32} P or melphalan. Of these patients, 21 were later switched to hydroxyurea therapy. After the analysis of patients in all of these groups, the predicted probability of developing acute leukemia was determined to be 21.6% at 10 years with the greatest likelihood being between 5 and 10 years after diagnosis. [20] With careful analysis of this data, the subgroup of patients who were initially treated with hydroxyurea but subsequently switched to an alkylating agent or ^{32} P had an incredibly high incidence of acute leukemia (Table 64-9). [30] By contrast, those patients initially treated with ^{32} P or melphalan, whether or not they were eventually treated with hydroxyurea, had a

TABLE 64-9 -- Incidence of Thrombotic and Bleeding Complications in 68 Patients with Primary Thrombocythaemia Who Had Long-term Follow-up According to Treatment Strategy

[d] P = 0.032 (^{2} = 4.6, 1df), for comparison with careful observation (bleeding).
[b] P = 0.014 (^{2} = 6.0, 1df), for comparison with careful observation (thrombosis).
[e] P = 0.92 (^{2} = 0.01, 1df), for comparison with careful observation (bleeding).
[c] P = 0.003 (^{2} = 8.6, 1df), for comparison with careful observation (thrombosis).
[f] P = 0.014 (^{2} = 6.0, 1df), for comparison with careful observation (bleeding).

lower incidence of leukemia (Table 64-9). [30] One can conclude from these studies and those of others that hydroxyurea therapy alone is likely less leukemogenic than alkylating agents or ^{32} P alone, but that its use does present some enhanced risk for the development of leukemia. [28] [30] [166] [175] Also, if several classes of agents are to be used, the sequence of their use appears to be of great significance. Hydroxyurea therapy followed by ^{32} P or an alkylating agent appears to be a highly risky sequence. [30] By contrast, ^{32} P or melphalan followed by hydroxyurea therapy appears to offer far less risk for the development of leukemia. [30] There are no known explanations for these observations. In those patients who cannot tolerate hydroxyurea or cannot be controlled with its continued use, analgrelide or interferon- therapy appears to be a wise choice. [170] When considering the risk-benefit ratio, one can conclude that hydroxyurea therapy is indicated in patients >60 years of age with a previous history of a thrombotic episode with significant cardiovascular risk factors. Such nonleukemogenic drugs as interferon- or anagrelide appear to be good choices in symptomatic patients less than 60 years of age. Whether platelet-reducing agents, such as analgrelide or interferon, will be equally effective in eliminating symptoms in patients less than 60 years of age remains unknown and will require the performance of large randomized trials. These patients are reported to have a typical form of dysgranulopoiesis characterized by hypolobulated polys, small vacuoles in polys, and p53 mutations. [172] A high proportion of the acute myeloid leukemias and myelodysplastic disorders occurring in primary thrombocythemia patients treated with hydroxyurea alone have morphologic, cytogenetic, and molecular characteristics of the 17p syndrome. [172]

Interferon- has been employed to treat the thrombocytosis associated with myeloproliferative disorders with increasing frequency during the last decade. [176] [177] [178] [179] [180] [181] [182] [183] [184] [185] Interferon- acts by directly inhibiting megakaryocyte colony formation and secondarily by inhibiting the expression of thrombopoietic stimulating cytokines such as GM-CSF, G-CSF, IL-3, and IL-11 and by stimulating the production of negative regulators of megakaryocytopoiesis such as IL-1ra (receptor agonist) and MIP-1a. [158] In a total of 212 patients treated in a total of 11 different clinical trials, a response rate of approximately 90% has been reported. [183] Therapy was administered to outpatients, most frequently at an initial dose of 3 million units daily, and usually produced a rapid decrease in platelets within a period of two months. [183] The mean time to complete response with a daily dose of 3 million units daily was about 3 months. [183] Interferon- was effective in patients who had received other chemotherapeutic agents and in patients resistant to conventional cytotoxic drugs. [176] [177] [178] [179] [180] [181] [182] [183] [184] [185] In the majority of patients, the interferon dose required to maintain a normal platelet count during maintenance therapy was lower than the induction dose. [171] [172] [173] [174] [175] [176] [177] [178] [179] [186] [187] In one study, 61% of patients required 3 million units three times a week, 15% once a week and 24% daily. [187] In addition, sustained remissions that persisted for 336 months were achieved with interferon- therapy in 916% of patients. Interferon- is reported to be nonmutagenic and to not cross the placenta, making it a useful drug for the treatment of the symptomatic pregnant patient with primary thrombocythemia. [182] [183] Reduction in platelet numbers with interferon results in a marked improvement in clinical symptoms. Toxicity, especially in older patients, and the need for parenteral administration, limit the utility of interferon-. [184] The side effects are well known. They include flu-like symptoms during induction therapy, including fever, bone and muscle pain, fatigue, lethargy, and depression. Symptoms are frequently controlled with acetaminophen. [176] [177] [178] [179] [180] [181] [182] [183] [184] [185] [187] [188] Long-term administration of interferon- can result in mild weight loss, alopecia, and late development of autoimmune thyroiditis leading to hypothyroidism and autoimmune hemolytic anemia. [176] [177] [178] [179] [180] [181] [182] [183] [184] [185] [187] [188] Patients may develop neutralizing antibodies to recombinant interferon, leading to a concomitant rise in platelet numbers. [185] In such a situation, use of leukocyte interferon- results in an excellent response. [185] In one review, it was reported that 25% of 273 patients failed to continue to receive interferon therapy either because of poor compliance or side effects. [183] In order to gain a more comprehensive evaluation of the clinical utility of interferon- a prospective clinical trial comparing interferon- to hydroxyurea is presently being pursued in patients with primary thrombocythemia. [183] Until the results of this trial are available, interferon- should be considered a reasonable alternative to hydroxyurea in a patient less than 60 years of age who has suffered a previous thrombotic episode. [179] In addition, interferon- is of use in patients who are in the childbearing years. [183]

The use of platelet antiaggregating agents remains an exciting area of investigation. Patients with primary thrombocythemia have an increased predisposition to

hemorrhage, which is likely potentiated by the use of drugs that affect platelet function. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [74] [77] [79] [89] Transient ischemic attacks and erythromelalgia associated with primary thrombocythemia have been reported to respond rapidly to aspirin alone, to aspirin and dipyridamole in combination, or to indomethacin alone. [75] [83] [84] [108] [109] In erythromelalgia, symptoms disappear for 24 days after administration of a single dose of aspirin. [83] Although these agents surely have a role in the treatment of these specific complications, their use should be pursued with extreme caution because of the increased risk of hemorrhage. Kessler et al.[85] have, in fact, determined that 32% of bleeding episodes in patients with extreme thrombocytosis and myeloproliferative disorders occurred concurrently with the use of anti-inflammatory agents. [85] By contrast, Hehlmann et al.[14] have reported the treatment of 46 patients with primary thrombocythemia with 250 mg/day of aspirin without any bleeding complications.

Aspirin, particularly in lower doses, 100 mg/day has been shown to be useful in preventing thrombotic episodes in patients with primary thrombocythemia. [189] Risk for bleeding associated with aspirin can be minimized if it is administered solely to patients with platelet counts <1,000 × 10^9 /l and/or the absence of a bleeding history.[183] Van Genderen et al. have retrospectively analyzed a group of 57 patients receiving aspirin alone or in combination with a chemotherapeutic agent (Table 64-9).[189] Their data suggests that low-dose aspirin 100500 mg/day is not only effective in the treatment of erythromelalgia and transient ischemia attacks but also reduces the recurrence of other thrombotic events in symptomatic patients.[189] Impressively, in this admittedly small population of high-risk patients with a mean follow-up of only 6.2 years, myelosuppressive therapy, plus low-dose aspirin therapy totally eliminated the incidence of thrombotic complications. [189] These findings are encouraging and are supportive of the judicious use of aspirin in patients with a past history of a thrombotic episode. Low-dose aspirin therapy must be restricted to patients with a platelet count <1,000 × 10^9 /l. The diagnosis of an acquired von Willebrand syndrome should be excluded prior to aspirin use and considered a contraindication to the use of aspirin. [77] [189] These recommendations merit testing in a large randomized trial in the future.

Of great interest has been the increased use of a novel drug, anagrelide, for the treatment of primary thrombocythemia. [170] [182] [190] [191] [192] [193] [194] Anagrelide is a member of the imidazo(2,1-b)quinazolin-2-1 series of compounds. During studies in humans, it was noted that anagrelide in small doses produced profound thrombocytopenia. The drug acts primarily by reducing megakaryocyte size and ploidy and at therapeutic doses, it does not have a major antiproliferative effect. [192] Anagrelide, therefore, appears to lower platelet counts primarily by interfering with the maturation of megakaryocytes. [195] A major study of 577 patients treated with anagrelide has confirmed its usefulness.[191] Anagrelide in low doses was effective in lowering the platelet count in 93% of patients. Most importantly, it was effective

despite resistance to previous therapy. Resistance to anagrelide therapy has not been documented. [170] [182] [190] [191] [192] [193] [194] The recommended initial dose is 0.5 mg orally two to four times a day. The dose should be increased by 0.5 mg/week in order to control thrombocythemia. [182] The dose of anagrelide should not exceed 10 mg/day or 2 mg/dose.[182] Excessive use will result in predictable thrombocytopenia. The median maintenance dose in patients with primary thrombocythemia is 2.0 mg/day administered in divided doses.[194] By 1997, data on over 3,000 patients with a variety of myeloproliferative disorders complicated by extreme thrombocytosis were available.[182] In addition, follow-up of over 500 patients for over 5 years had been reported. [194] Anagrelide has been shown to be an effective drug in the treatment of primary thrombocythemia resulting in a median time to response of 2.5 to 4 weeks. An effect on platelet numbers is usually noted in 6 to 10 days. [182] [190] [191] [192] [193] [194] Anagrelide leads to a reduction in hematocrit in 36% of patients but it has no effect on white cell numbers. [176] [182] [183] [184] [185] Most important, the reduction in platelet numbers initiated by anagrelide use has been reported to be associated with a decrease in symptoms attributable to the thrombocythemia. [194] Silverstein reported that anagrelide use in 1,700 evaluable patients reduced the incidence of thrombohemorrhagic episodes due to thrombocytosis associated with myeloproliferative disorders from 0.66 symptoms per patient before therapy to 0.07 symptoms per patient after 2830 months of therapy. [194] The most common side effects of anagrelide resulted from its vasodilatory and positive inotropic actions. These effects resulted in complaints of headache, dizziness, fluid retention, and palpitations.[182] [189] [190] [191] [192] [193] [194] The vasodilatory effect leads to reduced renal blood flow resulting in fluid retention. In addition, gastrointestinal complications such as nausea, abdominal pain, and diarrhea are preeminent. These side effects usually develop within 2 weeks of initiation of therapy and frequently diminish in severity or resolve within 2 weeks of continued therapy. Because of its ability to promote fluid retention and the development of tachyarrhythmias, anagrelide therapy should be avoided in patients with cardiac disease and should be administered carefully to elderly patients. [194] If congestive heart failure or arrhythmias other than tachycardia develop, anagrelide therapy should be discontinued. [194] Dose reduction can be used to lessen the degree of tachycardia or fluid retention. Acetaminophen may be useful for treatment of the headaches. Silverstein claims that patients with nausea, diarrhea, and abdominal pain are usually lactose-deficient and that the use of LactAid results in resolution of such symptoms. [194] Although most adverse effects are mild or moderate, in one series therapy was discontinued in 16% of patients because of intolerable side effects especially headache, nausea, fluid retention, and rarely, frank congestive heart failure. [188] Anagrelide has no mutagenic activity but its use is not currently advised during pregnancy. Because of its small molecular weight, it is believed to be capable of crossing the placenta and eventually to lead to fetal hemorrhage.[195] Anagrelide does not appear to be leukemogenic because no cases of leukemic transformation have been attributed to its use during 54.7 months of observation.[194] In the review of Silverstein, four cases of acute leukemia developed while patients were receiving anagrelide for 73, 189, 276, and 300 days.[194] It is unknown what myeloproliferative disorders these patients suffered from, but the short duration of therapy and the mechanism by which anagrelide acts make it unlikely that these cases of leukemic transformation were anagrelide-related. [194] Anagrelide, therefore, appears to be a highly effective drug for the treatment of young, symptomatic patients with primary thrombocythemia. Anagrelide has also been successfully used to treat children with primary thrombocythemia.[189]

A continuing clinical controversy revolves around the question of whether any treatment is indicated in patients with primary thrombocythemia in whom the platelet count elevation is initially detected fortuitously and who remain largely asymptomatic. Such a decision is particularly important, as the use of most chemotherapeutic agents is associated with an increased risk of the development of leukemia, and the use of platelet antiaggregating agents is not without risk. [169] [170] The need for such treatment can be questioned, since in several studies a relationship between frequency of thrombotic episodes and degree of platelet elevation has not been established.[13] [77] [86] One should not lapse into a false sense of security in deferring therapy, however, since the course of primary thrombocythemia can include infrequent but dangerous thromboembolic complications, and patients may function normally for long periods of time without experiencing a life-threatening event. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] If the clinician feels compelled to use some therapeutic intervention in the young asymptomatic patient, low-dose aspirin (100 mg/day) appears to be effective in the treatment of microvascular complications and its use is associated with limited toxicity. [189] Still, it would seem reasonable to withhold therapy in younger, asymptomatic patients until the development of a clinically significant thrombotic or hemorrhagic event. The elderly patient (>60 years) with other significant risk factors for cardiovascular complications is probably best served by immediate institution of therapy. In addition, platelet reduction therapy is indicated in a patient with excessive thrombocytosis (platelet count >1,500 × 10^9 /l) and a documented acquired von Willebrand syndrome. [90] Such an individual is at a very high risk of suffering a serious hemorrhagic episode.

The management of a pregnant patient with primary thrombocythemia remains problematic.[121] [122] [123] [124] A review of the literature disclosed that of 106 pregnancies in 57 women with primary thrombocythemia, the rate of miscarriage was 43% as compared to an anticipated rate of 15% in a normal control population. [121] The most frequent complication was spontaneous abortion resulting from placental infarction secondary to thrombosis. [121] [122] [123] [124] In one series, 65% of the miscarriages occurred in only 17% of the women at risk.[122] A previous history of spontaneous abortion appears to be the greatest risk factor for the development of subsequent miscarriages. Remarkably, the incidence of maternal hemorrhagic or thrombotic episodes was extremely low. [121] [122] The maternal platelet count frequently is stable throughout the pregnancy or, in a subpopulation, actually falls. This drop in platelet numbers has been associated with a good outcome. [124] The major goal of any therapeutic intervention in a pregnant patient with primary thrombocythemia should be the prevention of the vaso-occlusive events that lead to placental infarction, intrauterine fetal growth retardation and, in some cases, fetal death. In one large series, there was no significant relationship between the fetal outcome and the degree of maternal thrombocytosis or presence of disease complications. [122] In this series, there were no instances of excessive bleeding or other related complications during delivery.[122] This group did not recommend the use of therapeutic plateletpheresis and, in fact, claimed that specific therapy (aspirin, heparin, or plateletpheresis) did not alter the clinical course. [122] However, of the 21 patients reported in the literature who did not receive any therapy, 12 experienced either spontaneous abortion or intrauterine deaths. [121] Low-dose aspirin (100 mg/day), because of its profound effect on events involving the microcirculation, such as erythromelalgia and transient ischemic events, has been used with increasing frequency in pregnant patients during the first and second trimester. [121] [196] It is recommended that aspirin be discontinued at least 1 week before delivery in order to avoid bleeding complications during delivery or during the postpartum period. [121] Because of the high risk of bleeding in patients with platelet counts greater than 1000 × 10^9 /l with acquired von Willebrand syndrome aspirin therapy is contraindicated.[121] There is limited experience reported in the literature with aspirin therapy alone and although the results are promising, the sample size is too small to confirm a beneficial effect.[121] [197] The observed true birth rate, however, was 75% in those receiving aspirin as compared to 43% in the group in the literature who received no therapy.[121] Treatment with low-dose aspirin during

the first trimester combined with subcutaneous heparin during the second and third trimesters has been reported in a small series to be a promising strategy. [194] This regimen requires further evaluation. Chemotherapeutic drugs are to be avoided during the period of conception and especially during the first trimester. [121] Both

hydroxyurea and busulfan are known teratogens in animals.[121] In addition, busulfan and hydroxyurea reduce fertility in males.[121] With the availability of newer agents to treat primary thrombocythemia, it is difficult to justify the use of chemotherapeutic agents during the time of conception or during the first two trimesters of gestation. Interferon- therapy is not known to be leukemogenic or teratogenic, and because it does not cross the placenta, its use may be considered during pregnancy.[178] The manufacturers of interferon- still advise that interferon- not be used during pregnancy because adverse effects on the fetus cannot be ruled out.[184] The effect of interferon- on male infertility remains uncertain. Anagrelide therapy should be avoided in the pregnant patient because of its potential to lead to fetal hemorrhage.[198] Since none of the strategies described above have been tested in large clinical trials, one must develop a therapeutic strategy for an individual patient. In the patient who has no history of spontaneous abortions and is totally asymptomatic but is found to be pregnant, no therapy is presently indicated although low-dose aspirin therapy (100 mg/day) can be initiated without appreciable risk and can be continued throughout the pregnancy. Its use should be discontinued one week before delivery. Aspirin therapy is contraindicated in patients with platelet counts >1,500 × 10^{9} /l and/or patients with acquired von Willebrand syndrome. If a patient is symptomatic from a thrombohemorrhagic episode or if the platelet count is rising to levels above 1,500 × 10^{9} /l, therapy with a platelet-reducing agent is indicated. Plateletpheresis therapy can be attempted but if incomplete control is obtained, interferon- therapy is at this point the best option. Several successful pregnancies have been reported with interferon- therapy.[121] The patient with a history of a previous spontaneous abortion appears to be at a particularly high risk of developing subsequent spontaneous abortions if left untreated.[122] At the minimum, low-dose aspirin therapy in this patient population is a reasonable therapeutic approach.

PROGNOSIS

The probability that a patient with primary thrombocythemia will survive 10 years is within the range of 6480%. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] In a large study from Spain with extensive follow-up, there was no substantial difference between the survival probability of patients with primary thrombocythemia and that of the control population.[199]

Table 64-10 (Table Not Available) presents the causes of death in one series of 61 patients with primary thrombocythemia. [14] Death predominantly ensued from thrombotic complications.[14] Transformation to acute myeloid leukemia has been reported with increasing frequency in patients with primary thrombocythemia and is

TABLE 64-10 -- Causes of Death in Primary Thrombocythemia

an important cause of mortality.[30] [171] [172] [173] [174] [175] [196] [200] The rate of leukemic transformation ranges from 310%.[28] [32] The blast cell phenotype that characterizes this transformation can be either myeloid, myelomonocytic, megakaryocytic, mixed lineage, or even lymphoblastic. [26] [32] [171] [172] [173] [174] [175] [186] [187] [196] [200] [201] [202] A limited number of patients have been reported who developed acute leukemia and who had not been previously treated with chemotherapeutic agents. [30] [171] [172] [201] [202] Many investigators have concluded that the transformation of primary thrombocythemia into acute leukemia is a rare event, which can be accelerated by the administration of chemotherapeutic agents.[32] [171] [172]

Transformation of primary thrombocythemia to a clinical stage that resembles agnogenic myeloid metaplasia with or without myelofibrosis has been well-documented.[9] [30] In fact, 6% of the patients documented unequivocally as having primary thrombocythemia by the criteria of the Polycythemia Vera Study Group went on to develop myelofribrosis.[30] Three additional patients who met these diagnostic criteria went on to develop polycythemia vera. [28] [30] These studies emphasize the potential of primary thrombocythemia to eventually evolve into clinical picture that resembles one of the other myeloproliferative disorders. This does not represent an instance of misdiagnosis but rather the natural evolution of the underlying hematological malignancy. According to the data mentioned above, the risk of transformation into acute leukemia in this patient population is greater than that in normal individuals. This is a phenomenon shared with the other myeloproliferative disorders.

FUTURE DIRECTIONS

Primary thrombocythemia is now firmly established as a hematologic malignancy with its own distinct clinical manifestations and associated complications. Better means of identifying patients at risk for developing fatal thrombotic or hemorrhagic complications are necessary to provide the basis on which to develop the optimal care of such patients. The ability to reduce the incidence of thrombohemorrhagic episodes with cytoreductive therapy in high-risk patients is now well-established. [87]

Multi-institutional comparisons of the efficacy of such promising agents as interferon- and anagrelide for the treatment of young patients with a prior thrombotic episode are needed. The use of low-dose aspirin therapy to reduce the number of episodes of erythromelalgia and transient ischemic attacks is now well-established.[74] Whether such therapy should be used in combination with anagrelide, interferon-, or hydroxyurea remains uncertain. Another pressing question that requires resolution is the degree of platelet reduction that is required for optimal management to be achieved. Whether reduction of platelet numbers below 350 × 10^9 /l rather than using 600 × 10^9 /l as a therapeutic target will further reduce the rate of thrombotic events will require further study. [170]

Chapter 65 - Myelodysplastic Syndromes and Myeloproliferative Syndromes in Children

Cindy L. Schwartz

Myelodysplastic syndromes (MDS) and myeloproliferative syndromes (MPS) are clonal disorders observed only rarely during the childhood years. Unlike acute leukemia, in which abnormalities of both proliferation and differentiation are apparent at diagnosis, MDS and MPS are characterized by abnormalities of differentiation and proliferation, respectively. The propensity of patients with these disorders eventually to acquire acute leukemia, with abnormalities of both proliferation and differentiation, suggests that MPS and MDS represent an initial step in the process of leukemogenesis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MYELODYSPLASTIC SYNDROMES

Myelodysplastic syndromes are characterized by ineffective hematopoiesis (peripheral cytopenia with a hypercellular bone marrow) and morphologic evidence of abnormal differentiation in at least one, and often multiple, cell lines. The likelihood that a patient with an MDS will acquire acute nonlymphocytic leukemia (ANLL) accounts for the commonly used terms preleukemia and smoldering leukemia. Although MDS occur most often in adults, 6 of 37 children with ANLL had an MDS before diagnosis. Thus, MDS may precede ANLL in children as often as in adults. [1]

Five types of MDS are described in the 1982 French-American-British classification. [2] Children, however, usually present with refractory anemia with an excess of blasts (RAEB) or with RAEB in transformation (RAEBt). Although the other forms of MDS seen in adults may progress at a variable rate to ANLL, the two forms seen in childhood, RAEB and RAEBt, progress rapidly to ANLL. The main features of RAEB and RAEBt are anemia and an excessive number of blasts in the marrow. MDS and ANLL have similar abnormalities of differentiation, but the proliferative abnormality is less apparent in MDS. Recent evidence, however, suggests a rapid proliferative rate, counterbalanced by high levels of apoptosis. [3] Rapid turnover thus may increase the likelihood of a second mutagenic event resulting in an overt leukemia.

Biologic and Molecular Aspects

Cells of multiple hematopoietic lineage are involved in MDS, and chromosomal abnormalities have been noted in 5060% of such patients. [4] Complex chromosomal aberrations in MDS have been associated with rapid progression to ANLL and poor prognosis. In one review, 7 of 16 children in whom chromosome studies were performed had detectable chromosomal abnormalities.[5] Children with an MDS and monosomy 7 often appear to have features of an MPS initially (see later). However, at the time of their leukemic conversion, they may be clinically indistinguishable from patients with MDS only.

Monosomy 7 is the most common chromosomal aberration in children with MDS, followed by trisomy 8, deletion 5q, and aberration of chromosome 3.[6] Monosomy 7 may occur in constitutive preleukemic syndromes such as Fanconis anemia and Kostmanns agranulocytosis as they evolve to ANLL. [7] Families with ataxia and monosomy 7 have been described in which the two phenomena do not always coassociate, suggesting a role for this lesion as a second step causing progression rather than initiation of disease. Secondary point mutations in the granulocyte colony-stimulating factor (G-CSF) receptor have been noted in leukemic cells (but not normal tissue) of children in whom ANLL developed while receiving G-CSF for Kostmanns syndrome. [8]

In one study, mutations of the *ras* oncogene were identified in 1530% of childhood MDS.[9] In one patient, such a mutation was detectable during the MDS phase but not the leukemic phase of disease, suggesting a role in the initiation but not the progression of disease.

Assays of hematopoietic progenitor cells, performed in vitro with marrow cells from patients with RAEB and RAEBt, are characterized by increased numbers of abortive clusters of myeloid cells exhibiting defective maturation, similar to that found in ANLL. [10] In acute leukemia, expansion of an abnormal clone proceeds at the expense of normal cells. In the MDS, normal and abnormal cells may coexist for a prolonged period. [11] The abnormal hematopoiesis of MDS may reflect the growth pattern of the abnormal clone itself or its effect on normal progenitors, perhaps mediated by inhibitors of hematopoiesis. Leukemic proliferation in a patient with an MDS may result from a karyotypic change in the original clone or from a subclone of malignant cells, which slowly gains predominance.

Clinical Manifestations

In contrast to adults, who are often asymptomatic initially, most children with an MDS are symptomatic. Fever, pallor, hemorrhage, and infection are most frequently seen.[1] [12] Except in children with monosomy 7, hepatosplenomegaly is not common. Macrocytic anemia and pancytopenia are classically found in adults with an MDS. Children, however, may present with a normocytic, normochromic anemia,[1] with macrocytosis and ovalocytosis appearing later, followed by poikilocytosis and anisocytosis. Nucleated red blood cells (RBCs) and a low reticulocyte count may be seen. White blood cell (WBC) changes, including Pelger-Huet abnormalities, hypersegmentation, and hypogranularity, may be subtle. Peripheral blasts may be seen with a normal marrow examination, and hypogranular platelets are noted.

The marrow of patients with an MDS is often hypercellular, which is indicative of ineffective hematopoiesis. Megaloblastoid changes of erythroid and myeloid precursors are common. Decreased numbers of megakaryocytes have been reported in children, [1] [13] although megakaryocytes are often increased in adults. Auer rods were present in 12 of 21 children in one study. [1]

Vitamin B_{12} levels were increased in six children tested in one study. [1] In another study, three of nine children had decreased leukocyte alkaline phosphatase activity.[5] Other neutrophil abnormalities noted in adults include decreased myeloperoxidase, chemotaxis, phagocytosis, and bactericidal activity. [14] RBC abnormalities include decreased RBC enzymatic activity, abnormal

iron metabolism, increased fetal hemoglobin, and abnormal expression of RBC antigens. [15] [16]

Differential Diagnosis

The myelodysplastic syndromes are characterized by the presence of anemia with or without other cytopenias and a hypercellular, dyserythropoietic marrow. The high likelihood of leukemic transformation in children with classic presentations of MDS justifies the use of the term preleukemia. Two forms of preleukemia occur commonly in children: pre-ANLL and preacute lymphoblastic leukemia (pre-ALL; Table 65-1). As in acute leukemias, the age frequency of pre-ANLL is approximately constant throughout the childhood period, whereas pre-ALL appears most often in children aged 16 years. Symptoms and peripheral blood findings may be similar, but the marrow findings usually differ, marrow hypoplasia being more common in pre-ALL. Although ineffective erythropoiesis and myelopoiesis may occur in either, ineffective megakaryopoiesis is unique to pre-ANLL. The morphology of marrow precursor cells is abnormal in pre-ANLL and normal in pre-ALL, whereas karyotypic abnormalities are common in pre-ANLL and rare in pre-ALL.[12]

A review of 760 pediatric marrow samples identified 7 children with hematopoietic dysplasia, [17] of whom 1 died of hemorrhage and 4, including 2 with family histories of childhood leukemia, acquired ANLL. One child had Shwachmans syndrome, which has a known association with hematopoietic dysplasia and progression to ANLL.[18] Six of the seven children had constitutional abnormalities, including skin abnormalities (five), short stature (four), unusual facies (four), mental retardation (three), and endocrinopathy (two). The otherwise normal child had a hydrocele. The incidence of leukemia is also increased in other constitutional disorders with

hematologic manifestations, including Kostmanns agranulocytosis, Downs syndrome, Blooms syndrome, Diamond-Blackfan syndrome, and Fanconis anemia. [13] [19]

Therapy and Prognosis

Myelodysplastic syndromes of childhood are rapidly progressive; children rarely die of unrelated causes. Of 26 children with MDS, overt leukemia developed in 23, and 3 died in a preleukemic state. [5] The median preleukemic phase in children is short, lasting 12 months. The rapidity of disease progression necessitates consideration of treatment options beyond supportive care.

Maturational therapies have been used primarily in adults with an intent of inducing differentiation of abnormal cells into normally functional cells. Agents used include low-dose cytosine arabinoside (which may actually exert its effect through cytotoxic clonal suppression), retinoic acid, and vitamin D_3. In general, these therapies have been disappointing. Hematopoiesis improved temporarily (327 months) in one half of patients treated with low-dose cytosine arabinoside, but hospitalizations increased and survival was unchanged. [20] [21] Retinoic acid enhanced in vitro granulocyte-macrophage colony-forming unit (GM-CFU) and erythroid burst-forming unit (BFU-E) cloning efficiency and increased the granulocyte count of some patients, but transfusion requirements were unchanged. [22] Our ability to modify the preleukemic disorder by induction of normal cellular maturation appears limited, most likely because the cellular defect is more complex than a simple block of differentiation.

Success has been greater with regimens used for ANLL. Aggressive chemotherapy in adult MDS patients results in prolonged bone marrow aplasia with few responses. [23] Better remission rates have been noted in younger patients. [24] [25] Of 11 children with MDS treated with intensive chemotherapy, 6 achieved complete remission, and 2 of these remained in complete remission at 48 and 69 months (i.e., 18% survived for longer than 2 years). Allogeneic bone marrow transplantation (BMT) from a human leukocyte antigen (HLA)-matched sibling has resulted in long-term survival of 4080% of patients [26] [27] and is the preferred therapy, when feasible. A recent study in children showed a disease-free survival rate of 69% at 4 years. [28] Hasle et al compared outcome after conventional ANLL therapy to outcome after BMT in children with MDS, noting a 3-year survival rate of 35% versus 74%, respectively. [29] This improved outcome suggests that a marrow donor should be sought for all children with MDS. Six of 10 children undergoing unrelated donor transplantation have survived a median of 1.2 years post BMT. [30]

The use of biologic response modifiers such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and the interferons has been studied in patients with MDS in the hope of affecting the control mechanisms that regulate hematopoiesis. [31] [32] [33] [34] [35] [36] Studies of these agents have shown definitive improvement in neutrophil counts in most patients, with occasional improvement in platelet counts and hemoglobin. Concerns regarding the risk of stimulating a leukemic clone limit use of these agents in pediatric MDS to situations of life-threatening risk, such as serious infection.

MYELOPROLIFERATIVE SYNDROMES

Classic MPS, including adult-type chronic myeloid leukemia (ACML), polycythemia vera (PV), essential thrombocythemia (ET), and agnogenic myeloid metaplasia with myelofibrosis (AMMM), are disorders that were initially thought to be pure proliferations of granulocytes, RBCs, platelets, and fibroblasts, respectively. In 1951, they were grouped together as myeloproliferative syndromes by Dameshek, who noted that, to variable degrees, stimulation of all hematopoietic cells occurs. [37] These syndromes are now known to be clonal disorders, with aberrant regulatory control of hematopoietic precursors causing excessive proliferation. [38] [39] [40]

Classic MPS most frequently occur in adults, but MPS

unique to childhood also exist. Such syndromes include juvenile myelomonocytic leukemia (JMML; previously known as juvenile CML), the MPS of monosomy 7 in childhood, familial CML, the transient MPS of infants with trisomy 21, and childhood forms of myelofibrosis. Study of the biology of these syndromes gives clues to the pathogenesis of leukemia. Biologic and clinical features of MPS in children are discussed.

Disorders Characterized by Leukocytosis

Table 65-2 lists the salient characteristics of ACML, JMML, familial CML, and the MPS of monosomy 7.

Adult Chronic Myeloid Leukemias

Biologic and Molecular Aspects

Adult chronic myeloid leukemia is characterized primarily by granulocytosis, often in association with thrombocytosis, marrow hyperplasia, and fibrosis. A reciprocal translocation, with breakpoints involving the *bcr* oncogene of chromosome 22 and the *abl* oncogene of chromosome 9, results in the abnormal Philadelphia chromosome, which encodes for chimeric *bcr*/*abl* mRNA.[41] [42] Two common molecular rearrangements between the *bcr* and *abl* genes occur in adults (*mbcr* exons 2 or 3 are joined to *abl* exon II). Most children have the *bcr* exon 2 joined to *abl* exon II.[40] The translocated chromosome 9 is usually of paternal origin, whereas the translocated chromosome 22 is of maternal origin.[43] The bcr/abl protein product is an abnormal tyrosine kinase [44] that produces clonal expansion by blocking apoptosis (genetically programmed cell death). [45] Occasional patients have variant translocations that may result in the formation of a similar abnormal protein.

Clinical Features

Adult chronic myeloid leukemia accounts for 13% of childhood leukemia and is the most common form of CML in children. [46] [47] It occurs primarily in the older child. Generalized malaise, weakness, weight loss, fever, pallor, and hepatosplenomegaly are frequently the presenting findings. Hyperleukocytosis has been found to be a more prominent feature in patients younger than 20 years of age (median presenting WBC count = 360,000/mm ^{3}) compared with older patients (137,000/mm ^{3}), [48] resulting in an increased incidence of central nervous system, retinal, and pulmonary dysfunction. Arthritis and priapism may occur.

In addition to leukocytosis with a WBC count >100,000/mm ^{3} and the appearance of some immature myeloid elements, such abnormalities as thrombocytosis, erythrocytosis, eosinophilia, and basophilia may be seen. The bone marrow shows myeloid hyperplasia but normal maturation. Other abnormalities include increased vitamin B_{12} levels and decreased leukocyte alkaline phosphatase levels.

The course of ACML is variable, but ultimately blast crisis intervenes within 10 years (median, 23 years), [47] [49] [50] at which time a florid leukemic picture develops. Such a transformation may be heralded by increased fatigue, pallor, and splenomegaly. Although the blast crisis is usually of myeloid origin, lymphoid blast crisis does occur. Responses to standard therapeutic agents are usually brief.

Therapy

The traditional therapy of ACML has been palliative, using agents such as busulfan and hydroxyurea to lower the granulocyte count and prevent complications. More intensive chemotherapy rarely eradicates the abnormal clone, never for more than a short time. Recombinant -interferon induces hematologic and cytogenetic remissions in CML in adults [51] [52] and in children. [53] However, the *bcr*/*abl* rearrangement can usually be detected in such patients if a sensitive assay is used. [54] [55] Combination regimens (e.g., -interferon and low-dose cytarabine) may show improved clinical response rates as well as higher rates of cytogenetic response. [56] Nonetheless, allogeneic BMT remains

the only known curative approach.[57] The outcome of 68 children with CML diagnosed from 1977 to 1994 showed 42% survival after BMT (62% if transplantation occurred within 3 years of diagnosis) versus 10% without BMT (median follow-up, 5.5 years). [58] Although patients may remain clinically well during the chronic phase, it is not possible to predict when blast crisis will intervene. Thus, early BMT is recommended for children with HLA-matched siblings. For those without such donors, transplantation from matched unrelated donors should be sought. A recent cohort of 366 patients with CML (median age, 34 years) showed a 2-year disease-free survival rate of 51% in those transplanted in the first chronic phase. [59] Because results in children are usually better than in adults, the benefit of initiating an early donor search is apparent.

Juvenile Myelomonocytic Leukemia/Juvenile Chronic Myeloid Leukemia

Biologic and Molecular Aspects

In spite of the similarity in nomenclature, ACML and JMML/JCML are very different disorders, both biologically and clinically. Peripheral blood and marrow monocytosis is more characteristic of JMML/JCML, resulting in the now preferred name of juvenile myelomonocytic leukemia (JMML). [60] Colony-forming assays produce large numbers of macrophage colony-forming units (M-CFU) from blood or marrow of patients with JMML without a requirement for exogenous growth factors.[61] Recent evidence indicates that this is attributable to marked sensitivity of JMML cells to GM-CSF as well as to tumor necrosis factor- (TNF-) and interleukin-1B.[62] [63] The primary abnormality may be alteration in *ras* pathways, either mutations in the gene itself or defective regulation of the gene, resulting in proliferation induced by GM-CSF-initiated nuclear signaling. [64] [65] Monocytes in JMML appear to release interleukin-1, [66] which then augments the effects of GM-CSF and TNF-. TNF- may play a role in disease progression by inhibiting normal hematopoietic colony growth. [63] JMML occurs with increased frequency in neurofibromatosis. Neurofibromin, the protein altered in JMML is normally a negative regulator of *ras*; thus, loss of the effect of neurofibromin allows for increased *ras* activity with consequent enhancement of GM-CSF-induced proliferation. [66] [67]

The Philadelphia chromosome is not present in JMML. Other chromosomal abnormalities have been noted in 18% of patients. [68] Monosomy 7 has been reported in a clinical syndrome much like JMML.[69] [70] The course of that disorder appears different, and these patients are probably best categorized as having a distinct MPS. However, the similarity of the disorders has resulted in a tendency to group these patients together, which perhaps accounts in part for the conflicting clinical and biologic information reported.

Clinical Features

Children with JMML are younger than those with ACML. Most are younger than 2 years of age, and 95% are younger than 4 years of age. [47] [49] [71] At the time of presentation, malaise, bleeding, and fever are common. Occasional patients present with cough, tachypnea, and wheezing, with an interstitial pulmonary pattern observed on chest radiography. Leukemic pulmonary infiltrates have been reported. [72] Physical examination shows splenomegaly, pallor, hepatomegaly, and lymphadenopathy. A facial eczematoid rash may occur, particularly in patients with neurofibromatosis (which has been associated with JMML). [47] [72] [73] [74] [75] [76] Biopsy shows a leukemic infiltrate in the dermal layer. The rash may precede the diagnosis of JMML by 1 year.

Laboratory findings include thrombocytopenia, anemia, and an elevated leukocyte count (usually <100,000/mm ^{3}) with a prominent monocytosis. Occasional blasts may be noted in the peripheral blood, but myeloid cells in all stages of development are noted. The bone marrow shows myeloid and erythroid hyperplasia with myeloid/erythroid ratios of 2:1 to 5:1 (lower than in ACML). [49] Dysplastic features are not present. Other laboratory features include increased fetal hemoglobin levels and glucose-6-phosphate dehydrogenase activity levels, and decreased I antigen, carbonic anhydrous activity, and hemoglobin A $_2$, all of which are consistent with an increased number of fetal RBCs. Leukocyte alkaline phosphatase activity is decreased.

Juvenile myelomonocytic leukemia is associated with an acute deteriorating course, with death from bone marrow failure occurring within 9 months. Increasing myeloid blasts appear, and thrombocytopenia with progressive splenomegaly occurs terminally. An increase in pronormoblasts without evidence of leukemic marrow infiltration has been noted in some patients.[47] [49] In patients with JMML in association with neurofibromatosis, deletion of the whole or part of chromosome 7 may be an important step in the evolution of JMML into the accelerated or blast phase. Erythroid progenitor cells remain responsive to erythropoietin, even at this terminal erythroblastic period.[76]

Two patients have been reported with classic features of JMML who remitted spontaneously. They were found to have serologic evidence of persistent Epstein-Barr virus (EBV) infection.[75] Serologic tests should be performed to rule out an EBV infection before chemotherapy is administered. Monosomy 7 has also been noted in patients with persistent EBV infection.[77]

Further biologic studies will be necessary to understand the relationship of monosomy 7 and EBV infection to JMML-like disorders. The association of neurofibromatosis, monosomy 7, and JMML suggests a multistep mechanism of oncogenesis.[78] [79]

Therapy

Early reports suggested that agents active in ACML (e.g., busulfan) were ineffective in JMML, whereas 6-mercaptopurine was efficacious, although not curative. [47] In 1987, an intensive chemotherapeutic regimen used for the treatment of acute myelomonocytic leukemia was reported to induce complete remissions in all four children to whom it was administered.[80] However, all except one child had continued inhibition of normal hematopoietic colony formation and autonomous M-CFU-derived colony formation when marrow cells were assayed in vitro. More recently, 13- *cis*-retinoic acid has been shown be effective with only minimal toxicity in the treatment of JMML by virtue of its ability to reduce both the spontaneous proliferation and the G-CSF sensitivity of JMML cells. [81]

As in myelomonocytic leukemia, more intensive regimens may be necessary to improve survival rates. Allogeneic BMT has resulted in survival of 6 of 14 children with

JMML for more than 0.5 to more than 11.5 years.[82] This is currently the treatment of choice if an acceptable bone marrow donor can be found.

Myeloproliferative Disease of Monosomy 7

Biologic and Molecular Aspects

In patients with ANLL, monosomy 7 suggests involvement by the leukemic process of a pluripotent hematopoietic stem cell. [83] Monosomy 7 has also occurred in some patients who have been reported as having JMML involving a multilineage progenitor. [84] Because the natural history of those with monosomy 7 differs from that of other patients with JMML, the MPS of monosomy 7 is considered here as a distinct disorder.

Clinical Features

Patients have been reported with monosomy 7 with a clinical presentation similar to JMML. [70] [78] [85] Both syndromes present in children younger than 2 years of age. Pallor, lymphadenopathy, hepatosplenomegaly, infection, facial rash, and petechial bleeding are frequently present. The hematologic picture is characterized

by leukocytosis with monocytosis, anemia, and thrombocytopenia. However, leukocyte alkaline phosphatase activity is reduced in JMML, and hemoglobin F levels, which are increased in JMML, are variable in patients with monosomy 7. It is important to distinguish these two disorders because of their different natural histories. The course of JMML is brief, with most patients dying within 9 months. Patients with monosomy 7 often present initially with repeated bacterial infections and acquire ANLL after a latent period of 36 years. Those patients with monosomy 7 who are diagnosed while their disorder is evolving to ANLL may appear clinically identical to patients with RAEBt or chronic myelomonocytic leukemia, and may be classified as such.

Therapy

Patients with the MPS of monosomy 7 eventually acquire ANLL. Chemotherapy has not proved effective. Allogeneic BMT remains the only means of curing such patients.

Familial Chronic Myelogenous Leukemia

In 1965 Randall et al reported a large kindred of nine cousins afflicted with an MPS characterized by early onset (age 5 months to 4 years), hepatosplenomegaly, anemia, thrombocytopenia, and leukocytosis (with a monocytosis documented in some). [86] The marrow, liver, and spleen of these patients showed marked granulocytic and slight erythroid hyperplasia. Leukocyte alkaline phosphatase levels were low in all patients tested as well as in parents and grandparents. Three of these patients died of complications, whereas six eventually improved (up to 14 years from diagnosis). Other sibling groups with JMML-like illnesses have been reported,[87] [88] particularly in association with monosomy 7. [89] Cerebellar ataxia was also noted in two families described with monosomy 7-associated JMML. [90] [91] The genetic predisposition is not limited to chromosome 7. [92] Thus, a multistep mechanism involving another constitutive gene as well as loss of chromosome 7 may result in leukemia. [93] Potential marrow donors for transplantation should be examined for chromosomal abnormalities in addition to other hematologic abnormalities similar to that of their sibling.

Myeloproliferative Syndrome Associated with Trisomy 21

Newborns with trisomy 21 may present with an MPS that appears morphologically identical to ANLL. The WBC count may be as high as 400,000/mm ^{3} , with peripheral myeloblasts accounting for up to 95% of the WBCs. Anemia, thrombocytopenia, hepatosplenomegaly, and skin infiltrates may be seen. [94] Spontaneous remission occurs within a few months in some of these patients, but others have a persistent leukemia. Three female neonates with Downs syndrome and transient MDS have been shown to have clonal disorders by analysis of methylation patterns of the X chromosome by restriction fragment length polymorphism. [95]

Of 15 neonates with transient MPS, all with trisomy 21 as the only abnormality, leukemia later developed in 1 at 18 months of age. [96] At that time, trisomy 8 and another marker chromosome were present. Some patients have been reported to have chromosomal abnormalities other than trisomy 21 that were no longer detectable as the MPS resolved. [97] [98] These findings are suggestive of a clonal leukemic or preleukemic disorder that remits, possibly as regulatory influences allow the normal trisomic hematopoietic cells to gain dominance over the abnormal clone. In one infant with a transient MPS, an extra chromosome C was noted in 6% of his cells. [99] This abnormal clone persisted as a minor cell line until 26 months of age, at which time leukemia appeared, and the extra chromosome was present in 93% of the cells. The extra C chromosome may have caused genetic instability, predisposing the cells to leukemic transformation. Alternatively, the clone may have been a truly leukemic line that was initially suppressed but then expanded. Transient MPS with trisomy 21 in blast cells has occasionally been noted in phenotypically normal infants,[100] suggesting an increased proliferative potential in cells with trisomy 21.

Granulocyte-macrophage colony-forming unit assays have been performed in an attempt to determine whether the transient disorder can be differentiated from persistent leukemia.[101] [102] [103] [104] In several children with the transient form, the GM-CFU cloning efficiency was normal. In one patient, abortive myeloid clusters were observed, a finding common in ANLL. This patient had a persistent leukemia. The numbers of patients who have been studied with such in vitro techniques are too few to permit routine use of hematopoietic colony assays to predict outcome. Children with this disorder should receive supportive care as long as possible to determine whether the abnormality is transient or whether the patient has a true leukemic process.

Disorders Associated with Myelofibrosis

Some characteristics of the three myelofibrosis-associated myeloproliferative disorders are listed in Table 65-3 .

Agnogenic Myeloid Metaplasia with Myelofibrosis

Agnogenic myeloid metaplasia with myelofibrosis is characterized by myelofibrosis, myeloid metaplasia (splenomegaly), and a leukoerythroblastic blood picture. AMMM is virtually unheard-of in children, although there is one published case in which the child clearly fits the criteria for AMMM. [105]

Acute Myelofibrosis

Acute myelofibrosis (AMF) in adults presents as a rapidly fatal disorder with nonspecific symptoms of fatigue and weight loss. Splenomegaly is absent. The peripheral smear shows pancytopenia with morphologically normal cells, but the marrow shows bizarre megakaryocytes with fibrosis. [106] Unclassifiable blast cells may be present. Electron microscopic examination and platelet peroxidase assays reveal features of megakaryoblasts, suggesting that this may be a variant of acute megakaryocytic leukemia. Classic AMF is rare in childhood. [106] However, a number of children have been reported with a similar syndrome characterized by myelofibrosis, unclassifiable blast cells, and bizarre megakaryocytes. [107] [108] [109] [110] [111] [112] [113] Unlike adults with this disorder, children commonly have splenomegaly, and a leukoerythroblastic blood smear may be seen. These children are acutely ill and survival is brief. This childhood form of AMF (C-AMF) occurs most commonly in toddlers (<3 years of age) with trisomy 21 (Table 65-3). Trisomy 21 is also known to be associated with acute megakaryocytic leukemia. Although marrow infiltration with leukemic blasts is less prominent, C-AMF

TABLE 65-3 -- Myelofibrosis

overlaps with childhood acute megakaryocytic leukemia in clinical symptomology, marrow findings, and the population at risk. [114]

Children with C-AMF treated with chemotherapeutic regimens used for ANLL have had prolonged remissions, [114] as did a child who received an allogeneic BMT. [107] This information also suggests that C-AMF is a type of acute megakaryocytic leukemia.

Congenital Myelofibrosis

Two siblings were found to have myelofibrosis and myeloid metaplasia at the ages of 7 and 8 weeks. [115] No evidence of a clonal disorder was present. A constitutional abnormality may have caused abnormal regulation of marrow fibroblast function or megakaryocytic proliferation.

Disorders Characterized by Erythrocytosis or Thrombocytosis

Polycythemia Vera

Biologic and Molecular Aspects

Polycythemia vera is a clonal disorder resulting in an increase in RBC mass. An increased proliferative response to erythropoietin has been noted for the erythroid colony-forming units (CFU-E) and BFU-E of patients with PV, [116] [117] [118] allowing them to establish dominance over normal hematopoietic precursors.

Clinical Features

Polycythemia vera is rarely seen in children, with only 0.1% of patients younger than 20 years of age. [119] Fewer than 20 children have been reported, and not all have clearly been documented to have PV. [120] [121] [122] [123] [124] [125] [126]

During the proliferative phase, hyperplasia of all marrow elements is present, leading to varying degrees of thrombocytosis and leukocytosis. Splenomegaly is common. When making the diagnosis of PV, it is necessary to exclude causes of relative, or spurious, polycythemia and secondary polycythemia. Erythrocytosis may cause plethora, cardiac symptoms (dyspnea and hypertension), and symptoms of disturbed cerebral circulation (dizziness and paresthesias). Thrombosis and hemorrhage are due to the combination of abnormal platelet function and thrombocytosis. Granulocytic proliferation is associated with increased histamine turnover, causing gastrointestinal symptoms and pruritus. Hyperuricemia and hypermetabolic symptoms of weakness and weight loss are common. During this phase, thrombohemorrhagic events are of greatest concern. In children, serious complications have been noted, including hypersplenism, splenic infarction, hypertension, strokes, and hemorrhage.[121]

A minority of patients progress to the stable phase, during which blood counts normalize without therapy. Eventually they enter the spent phase of postpolycythemic myeloid metaplasia, characterized by extensive marrow fibrosis, hepatosplenomegaly, and peripheral cytopenias. [127] Leukemia most often arises in patients with postpolycythemic myeloid metaplasia.

Therapy

Therapeutic modalities used during the proliferative phase in an attempt to decrease the incidence of thrombohemorrhagic phenomena have included phlebotomy, radioactive phosphorus (^{32}P), chlorambucil, and hydroxyurea. [128] Current recommendations by the Polycythemia Vera Study Group are to use hydroxyurea, a nonalkylating myelosuppressive agent, for older patients at risk for thrombosis. Such agents are to be avoided in younger patients and those at low risk for thrombosis.[129] More recently, -interferon has been shown to decrease the need for

phlebotomy,[130] perhaps by inhibiting the production of hematopoietic cytokines and stimulation of negative regulators. [131] Angrelide, an inhibitor of platelet release, has also resulted in disappearance of thrombocythemia-related symptoms in 80% of patients with PV and ET. [132]

Essential Thrombocythemia

Clinical Features

Essential thrombocythemia is a clonal disorder that causes thrombocytosis (Table 65-4 lists causes of thrombocytosis in children). ET is rarely reported in children,[133] [134] although one study claimed that 13 of 94 patients (14%) with ET were younger than 20 years of age. [135] Approximately one third of young patients present with thrombohemorrhagic events, including transient cerebral ischemia, peripheral vascular ischemia, deep vein thrombosis, and priapism. Pruritus, splenomegaly, and hepatomegaly may occur but are less severe and less frequent in ET than in PV. Laboratory abnormalities related to the hyperproliferative hematopoietic state include elevations in granulocyte count, leukocyte alkaline phosphatase activity, and vitamin B_{12}, uric acid, and cholesterol levels. [135] [136] Platelet aggregation is abnormal,[133] [135] [137] and platelet clumps may be seen on the peripheral blood smear, with megakaryocytic hyperplasia in the marrow.

The course of ET in children is relatively benign. Of 10 children described in the literature, 1 died of leukemia after radioactive ^{32}P treatment, [134] [138] and idiopathic myelofibrosis developed in 1.[139] Among adults, 80% survive more than 100 months, with 5 of 95 treated patients experiencing a leukemic conversion. [135] Children

appear to have a more benign course than that of adults, [140] [141] perhaps because they are more tolerant of thrombocytosis regardless of etiology.

Therapy

Asymptomatic children need not be treated. Treatment with hydroxyurea should be considered for those who have had thrombohemorrhagic episodes. -Interferon has been used successfully to control thrombocytosis in ET. [142] Another potentially useful agent for the treatment of thrombocytosis in ET is anagrelide. [132] [143] [144]

CONCLUSION

Myeloproliferative disorders of childhood include those classic for adults (e.g., CML, PV, AMMM, and ET), as well as some unique to childhood. The increased risk of leukemic conversion in these MPS and in the MDS suggests that an abnormality of proliferation or differentiation may be the first in a two-step process of leukemogenesis.[145] Understanding the biologic processes

involved may help improve our ability to treat these patients.

Chapter 66 - Pathobiology of Non-Hodgkin Lymphomas

Gianluca Gaidano
Riccardo Dalla-Favera

The Revised European-American classification of lymphoid neoplasia (REAL classification), introduced in clinical practice in 1994, has provided a new classification of lymphoid malignancies based on the stage of differentiation of the tumor (see Chap. 69). [1] According to this classification, non-Hodgkin lymphomas (NHL) include lymphoid neoplasms derived from mature lymphoid cells. Thus, NHL are distinct from tumors of precursor lymphoid cells, as represented by most acute lymphoblastic leukemias, although NHL do include leukemic disorders, such as chronic lymphocytic leukemia or L3-type lymphoblastic leukemia, which display biologic features consistent with mature lymphoid cells. Some lymphomas, however, such as the lymphoblastic lymphomas, which present predominantly as solid masses but are derived from precursor lymphoid cells, are biologically related to the acute lymphoblastic leukemias.

Despite their common origin from mature lymphoid cells, NHL constitute an extremely heterogeneous group of diseases. [1] First, NHL may be derived from either the B-cell or the T-cell lineage. Second, within each lymphoid lineage, NHL may be derived from cells at different stages of maturation. Finally, NHL differ in terms of pathogenetic pathways and patterns of molecular alterations. This chapter provides an overview of the main biologic mechanisms contributing to lymphomagenesis and summarizes the molecular basis of the clinico-pathologic heterogeneity of NHL. Overall, many advances have been made in the understanding of the pathogenesis of B-cell NHL, whereas, with few exceptions, the molecular basis of T-cell NHL remains relatively undefined.

HISTOGENESIS OF NON-HODGKIN LYMPHOMAS

The histogenesis of NHL can be assessed by identifying the precise cellular subset from which a given NHL category is derived. This is achieved by defining the lineage and the precise differentiation stage of the various types of NHL and by comparing it with the features characteristic of the different maturation stages of normal lymphocytes. In most parts of the world, with the exception of some regions of the Far East and of the Caribbean, B-cell NHL represents 85% of all NHL and thus far exceeds the number of cases of T-cell NHL.[2] This section will focus on current knowledge on the histogenesis of B-cell NHL; relatively little is known concerning most T-cell NHL.

B lymphocytes are generated in the bone marrow as a result of a multistep differentiation process (see Chap. 8).[3] [4] [5] Precursor B cells usually undergo immunoglobulin (Ig) gene rearrangements of the H chain locus followed by rearrangements of the L chain locus. [3] [4] [5] If precursor B cells express a functional surface antibody acting as antigen receptor, they are positively selected into the peripheral B-cell pool comprising naive B cells. [3] [4] [5] Cells failing to express a functional antigen receptor are eliminated within the bone marrow. [3] [4] [5] For many B cells, the subsequent maturation steps are linked to the histological structure of the germinal center (GC) (Fig. 66-1). [3] [4] [5] [6] [7] The GC is characterized by a dark zone, composed of a dominant growth of rapidly proliferating B cells, and a light zone, in which nonproliferating B cells are selected and induced to differentiate through interactions with follicular dendritic cells and T helper cells. Within the GC, antigen-activated B cells accumulate somatic point mutations within their rearranged H and L chain genes (a phenomenon known as somatic hypermutation) which modify the affinity of their surface antibody to the antigen. [3] [4] [5] [6] [7] [8] Only B cells that have acquired mutations leading to high-affinity binding are positively selected and differentiate into memory B cells or plasmablasts; the majority of B cells are eliminated by apoptosis within the GC. [3] [4] [5] [6] [7] [8]

Until recently, only a few markers were available for histogenetic studies of B-cell NHL, and these markers did not allow one to define with certainty the relationship between the GC and a given NHL category. More recently, the use of somatic hypermutation as a specific marker of B-cell transition through the GC has allowed the definition of two broad histogenetic categories of B-cell NHL: (1) NHL devoid of somatic Ig hypermutation, which may be derived either from pre-GC B cells or from B cells that have achieved maturation without transiting through the GC; (2) NHL associated with somatic Ig hypermutation and thus putatively derived from GC or post-GC B cells. NHL generally devoid of somatic Ig hypermutation include mantle cell lymphoma (MCL) and a substantial fraction of B-cell chronic lymphocytic leukemia (B-CLL) (Fig. 66-1).[9] [10] [11] NHL generally associated with somatic Ig hypermutation include follicular lymphoma (FL), B-lineage diffuse large cell lymphoma (B-DLCL), Burkitt lymphoma (BL), lymphoplasmacytoid lymphoma (LPL), mucosa-associated lymphoid tissue NHL (MALT-NHL), splenic lymphoma with villous lymphocytes, and primary effusion lymphoma (Fig. 66-1).[12] [13] [14] [15] [16] [17] [18] Extranodal lymphomas associated with somatic Ig hypermutation are postulated to originate from B cells that have transited through the GC and subsequently migrated to the involved extranodal site.

Figure 66-1 Model of B-cell NHL histogenesis based on the maturation steps of normal B cells. Upon release from the bone marrow, naive B cells migrate to peripheral lymphoid organs, namely the lymph nodes. A lymphoid follicle, composed of the germinal center (GC) and the follicular mantle, is represented together with the surrounding marginal zone. Upon entering the GC, B cells transform into centroblasts, proliferate, and mature into centrocytes. These events are coupled to somatic hypermutation of Ig genes and the isotype switch of the Ig is produced. GC B cells that have accumulated Ig mutations increasing their affinity for antigens, are positively selected by antigen and therefore survive and exit the GC successfully. Conversely, cells that are not positively selected by antigens undergo apoptosis within the GC and are eliminated. Cells that have exited the GC (post-GC B cells) have two fates, differentiation into plasma cells or into memory B cells. Based on the absence or presence of somatic Ig hypermutation, B-cell NHL may be divided into two broad histogenetic categories: (1) B-cell NHL derived from pre-GC B cells and devoid of Ig mutations, exemplified by mantle cell lymphoma (MCL) in the figure; and (2) B-cell NHL derived from B cells that have transited through the GC and harbor Ig mutations, exemplified in the figure by follicular lymphoma (FL), diffuse large cell lymphoma (DLCL), and Burkitt lymphoma (BL).

Little is known concerning the histogenesis of T-cell NHL. Normal T-cell ontogeny, however, has been investigated in detail. [19] T-cell precursors reside in the thymus, where they undergo maturation and selection. They usually are divided into three stages according to the sequential expression of differentiation antigens: stage I and II thymocytes reside in the cortex of the thymus, whereas stage III thymocytes are located in the medulla. [19] Stage III thymocytes are characterized by the mutually exclusive expression of CD4 and CD8, giving rise to $CD4^+$ /CD8 and $CD8^+$ /CD4 mature T cells (post-thymic T cells). [19] At the genetic level, T-cell maturation is accompanied by rearrangement of the and chain genes of the T-cell receptor (TCR), followed by rearrangements of the TCR chain gene, and at a later step, of the TCR chain gene.[20] The different stages of thymocytes give rise to the T-cell lymphoblastic lymphomas, which are biologically related to T-cell acute lymphoblastic leukemias.[1] Mature, i.e., post-thymic, T cells give rise to a variety of peripheral T-cell tumors that are recognized to be histogenetically heterogeneous, although the biologic basis for this heterogeneity remains poorly understood. [1]

GENERAL MECHANISMS OF LYMPHOMAGENESIS

The pathogenesis of NHL is a highly complex process involving genetic alterations in the tumor clone itself as well as biological alterations in the host. Four main mechanisms of lymphomagenesis are recognized. These include (1) accumulation of gene alterations in the tumor genome; (2) infection of the tumor clone by an oncogenic virus; (3) stimulation and selection of tumor cells by an antigen; and (4) immunodeficiency of the host. The precise role of these mechanisms varies substantially in the pathogenesis of different NHL types, and not all mechanisms are operational during the development of a given category of lymphoma. Yet, since NHL are monoclonal processes, it is generally understood that clonal accumulation of genetic lesions is a prerequisite for lymphomagenesis that is involved in the pathogenesis of all categories of NHL. The one exception to this rule may be represented by lymphoproliferative disorders occurring in transplant recipients, which, at least in a proportion of cases, may be a consequence of virus-driven expansions of genetically normal lymphoid cells.

GENETIC LESIONS

As in most human cancers, the genetic lesions involved in NHL include the activation of proto-oncogenes and disruption of tumor suppressor genes. In contrast to many types of epithelial cancers, the genome of lymphoma cells tends to be relatively stable and is not subject to the generalized random instability that characterizes many types of epithelial cancers.[21] In addition, lymphomas generally lack microsatellite instability, which is caused by defects in DNA mismatch repair genes observed in some hereditary cancer predisposition syndromes as well as in a fraction of sporadic solid cancers. [22] [23] Historically, detection of recurrent, non-random chromosomal abnormalities by karyotypic analysis of NHL metaphases has been a major advance in the identification and cloning of most genetic alterations of NHL.[21] [24]

Activation of Proto-oncogenes by Chromosomal Translocation

Chromosomal translocation represents the main mechanism of proto-oncogene activation in NHL. As in most types of hematopoietic neoplasms, chromosomal translocations in NHL are the consequence of reciprocal and balanced recombination events between two specific chromosomal sites. These translocations are frequently characteristic of a specific clinico-pathologic category of NHL and are clonally represented in each tumor case. All NHL chromosomal translocations that have been cloned to date share a common feature, i.e., the presence of a proto-oncogene mapping to the vicinity of one of the two chromosomal recombination sites. In contrast with neoplasms of precursor lymphoid cells, chromosomal translocations associated with NHL do not generally lead to coding fusions between two genes (Fig. 66-2). Rather, chromosomal translocations of NHL juxtapose the proto-oncogene to heterologous regulatory sequences derived from the partner chromosome (Fig. 66-2). The heterologous regulatory regions implicated in NHL translocations may be derived from antigen receptor loci as well as from other loci, which are expressed at sustained levels in normal cells corresponding to the differentiation stage of the lymphoma (Table 66-1). The common consequence of the translocation is the deregulated expression of the proto-oncogene, which may be categorized as homotopic deregulation or heterotopic deregulation. Homotopic deregulation occurs when the proto-oncogene is also expressed by the normal cells giving rise to the lymphoma, although in normal cells the proto-oncogene is expressed in a tightly regulated manner, which contrasts with the deregulated expression found in tumors. Heterotopic deregulation occurs when the proto-oncogene is not normally expressed in the normal cellular counterparts from which the lymphoma is derived. The one exception to the deregulation model of NHL translocations is represented by the t(2;5) of T-cell anaplastic large cell

Figure 66-2 Models of chromosomal translocations in non-Hodgkin lymphoma. The two genes involved in the translocation event are represented by the relative coding sequences, identified by the rectangle, and by regulatory sequences (RS). The two genes are identified by different colors (red boxes and white boxes). Upper panel: germline configuration of the two genes involved in the translocation. The coding sequence of each of the two genes is proximal to its physiologic regulatory sequences, which coordinate the normal expression of the gene. Lower panel: Chromosomal translocations may lead to two different consequences. In the case of transcriptional deregulation, the normal regulatory sequences of the proto-oncogene are removed and substituted with regulatory sequences derived from the partner chromosome. The proto-oncogene coding sequence (red rectangle) is thus juxtaposed to heterologous regulatory sequences (white circle). In NHL, the novel regulatory regions most commonly are derived from the immunoglobulin gene loci which are consistently expressed at high levels in mature B cells. In the case of fusion transcript formation, part of the coding sequence of the two genes involved is fused together, generating a novel fusion protein with biochemical properties distinct from the native proteins.

lymphoma, which causes the fusion of two genes and gives rise to a chimeric transcript (Table 66-1).

The precise genetic mechanisms driving the chromosomal recombination events are poorly understood. It has been proposed that translocations involving antigen receptor loci may constitute errors of the machinery involved in antigen receptor gene rearrangement in normal lymphoid cells. [25] This hypothesis is corroborated by the evidence that, among B-cell NHL, chromosomal breakpoints within the Ig loci are frequently located within joining (J) or switch (S) sequences, which represent the DNA sequences implicated in physiologic Ig gene rearrangements during B-cell development. [26] Based on this hypothesis, translocations would be the consequence of errors in the enzymatic process physiologically mediating the recombination of antigen receptor genes. In pathologic conditions, this same process would join sequences from different chromosomes instead of sequences within the same antigenic receptor locus. This model, though probably valid for a number of NHL translocations, is challenged by the relatively frequent occurrence of chromosomal translocations that do not involve antigen receptor loci and by the absence of Ig signal recombination sequences at the chromosomal breakpoints in a number of cases. [21] [24] [26] At present, it cannot be determined whether the sites involved in such translocations contain sequences that are aberrantly recognized by recombination enzymes or whether they follow a completely independent mechanism.

The pathogenetic role of chromosomal translocations is demonstrated by in vitro transformation studies as well as by tumorigenicity assays in vivo and reconstruction experiments in transgenic animal models. These experimental models have sometimes led to the conclusion that, both in vitro and in animal models, the sole translocation is sufficient to cause neoplasia. [27] [28] [29] [30] In humans, however, the situation is more complex. When investigated with high-sensitivity techniques, chromosomal translocations characteristic of NHL also commonly occur at a certain rate in normal lymphoid cells of individuals without lymphoma and/or with no increased relative risk of developing lymphoma. [31] [32] [33] This observation suggests that, in naturally occurring tumors, chromosomal translocations contribute to but do not necessarily lead to neoplasia, and that a permissive biological environment may also be required.

The detailed molecular characterization of the most frequent chromosomal translocations of NHL is discussed in the section of this chapter dedicated to the pathogenetic overview of each NHL type.

Other Mechanisms of Proto-oncogene Alteration

In addition to chromosomal translocations, other mechanisms of proto-oncogene activation can also occur in NHL. Proto-oncogene amplification is substantially less common than in epithelial cancers, yet it occurs in some cases of high-grade NHL, as exemplified by the instance of REL amplifications in B-DLCL. [34] Amplification may involve many other unknown chromosomal sites, which are likely to be revealed by the extensive use of advanced cytogenetic techniques such as comparative genomic hybridization. Point mutations can alter the coding

TABLE 66-1 -- Chromosomal Translocations of Non-Hodgkin Lymphomas

NHL Histologic Type	Translocation	Proto-oncogene Involved	Mechanism of Proto-oncogene Activation	Proto-oncogene Function
Lymphoplasmacytoid lymphoma	t(9;14)(p13;q32)	*PAX*-5	Transcriptional deregulation	Transcription factor regulating B-cell proliferation and differentiation

Follicular lymphoma	t(14;18)(q32;q21)	*BCL*-2	Transcriptional deregulation	Negative regulator of apoptosis
	t(2;18)(p11;q21)			
	t(18;22)(q21;q11)			
Mantle cell lymphoma	t(11;14)(q13;q32)	*BCL*-1/cyclin D1	Transcriptional deregulation	Regulator of the early phases of cell cycle
B-lineage diffuse large cell lymphoma	t(3;various)(q27;various)	*BCL*-6	Transcriptional deregulation	Transcriptional repressor implicated in formation and function of germinal centers
Burkitt lymphoma	t(8;14)(q24;q32)	c-*MYC*	Transcriptional deregulation	Transcription factor regulating cell proliferation, differentiation, and apoptosis
	t(2;8)(p11;q24)			
	t(8;22)(q24;q11)			
T-cell anaplastic large cell lymphoma	t(2;5)(p23;q35)	*NPM/ALK*	Fusion protein	*ALK* is a tyrosine kinase

sequence of the proto-oncogene, as in the case of c-*MYC* and *BCL*-2, and thus alter the biological properties of the proto-oncogene product. [35] [36] Alternatively, mutations may affect the proto-oncogene regulatory sequences, as in the case of c-*MYC* and *BCL*-6, thus altering their sensitivity to factors normally regulating the expression of the proto-oncogene through binding to its regulatory sequences. [37] [38] Mutations of the *RAS* genes, which represent the most frequent proto-oncogene alteration in human neoplasia, are virtually absent among NHL. [39] Mutations activating unknown oncogenes may be a frequent event in NHL and their identification is the focus of current investigations.

Inactivation of Tumor Suppressor Loci

Disruption of tumor suppressor loci in NHL occurs through mechanisms similar to those associated with other human cancers and generally leads to biallelic inactivation. Biallelic inactivation is most frequently achieved through deletion of one allele and mutation of the other, although variable combinations of allelic deletion, mutation, and methylation may occur in some cases. The tumor suppressor gene most frequently involved in the pathogenesis of NHL is *p53.* [40] Other tumor suppressor genes involved in lymphoproliferative disorders of mature lymphoid cells include *p16,* a regulator of cell cycle, and *ATM* (for *ataxia teleangectasia mutated*), a gene with multiple functional domains which is also responsible for the hereditary immunodeficiency syndrome ataxia-teleangectasia. [41] [42]

In addition to the aforementioned tumor suppressor genes, NHL frequently carry specific chromosomal deletions, which conceivably are the site of tumor suppressor loci that have not yet been identified. [21] [24] The most frequent of these deletions involve the long arm of chromosomes 6 (6q) and 13 (13q). [43] [44] [45] [46] [47] The putative pathogenetic role of 6q deletions in B-cell NHL is suggested by the observation that 6q deletions may occur as the sole cytogenetic abnormality in some cases. [48] In addition, 6q deletions may have prognostic value as markers of poor outcome in these disorders. [24] With respect to del(13q), it represents the most frequent genetic change detected in B-CLL and is likely to be a very early alteration in the pathogenesis of this lymphoproliferative disorder. [45] [46] [47]

INFECTION BY ONCOGENIC VIRUSES

An additional molecular mechanism implicated in NHL development is infection of the tumor clone by oncogenic viruses. Three oncogenic viruses have been associated with NHL development, including two herpesviruses, Epstein-Barr virus (EBV) and human herpesvirus type-8 (HHV-8), and a retrovirus, human T-cell lymphotropic virus-I (HTLV-I).

Historically, EBV was initially identified in cases of endemic BL of African children. [49] The currently known spectrum of EBV-infected NHL, however, also includes sporadic BL (sBL) and AIDS-related NHL, in addition to endemic BL (eBL). [50] [51] [52] [53] Upon infection of a B cell, the EBV genome is transported into the nucleus, where it is predominantly present as an extrachromosomal circular molecule (episome). [50] The cohesive terminal repeats of EBV, constituted of a variable number of tandem repeats (VNTR) sequence, mediate the formation of the circular episomes. [50] Because of the heterogeneity of the EBV termini, the precise number of VNTR sequences enclosed in the newly formed episomes displays a marked degree of variation, thus providing a constant clonal marker of a single infected cell. [54] EBV infection of NHL is generally characterized by a latency pattern, in which the virus is not replicated and expresses a limited subset of viral genes. [50] The pathogenetic relevance of EBV in lymphomagenesis is substantiated by at least two sets of data. First, EBV is able to significantly alter the growth of B cells in vitro and in vivo. [50] Second, EBV-infected NHL generally harbor one single form of fused EBV termini, consistent with the hypothesis that infection has preceded and may thus have contributed to clonal expansion. [51] [53] [54] Finally, a fraction of EBV-infected NHL express the EBV encoded proteins LMP-1 and EBNA-2, which are well-known transforming agents for B cells. [52] [55] [56] Despite this body of evidence, two observations complicate our understanding of the pathogenetic role of EBV in lymphomagenesis. First, most healthy individuals are infected by EBV, although the risk of NHL in the general population is low. [57] Second, some types of EBV-infected NHL, namely BL, fail to express the EBV-encoded transforming proteins LMP-1 and EBNA-2. [52] [55]

HHV-8 is a gamma herpesvirus initially identified in tissues of AIDS-related Kaposi sarcoma and subsequently found in multicentric Castleman disease and a peculiar type of lymphoma known as primary effusion lymphoma (PEL). [58] [59] [60] [61] [62] [63] Phylogenetic analysis has shown that the closest relative of HHV-8 is herpesvirus saimiri (HVS), a gamma-2 herpesvirus of primates associated with T-cell lymphoproliferative disorders. [64] [65] Like the other gamma herpesviruses, HHV-8 is also lymphotropic, since it can be found in lymphocytes both in vitro and in vivo. [59] [60] [61] [62] [66] [67] Lymphoma cells naturally infected by HHV-8 harbor the HHV-8 genome in its episomal configuration and display a marked restriction of viral gene expression, suggesting a pattern of latent infection. [65] HHV-8 carries several genes that may behave as oncogenes, including a gene homologous to the cellular D-type cyclins, a G-protein coupled receptor (GPCR) displaying constitutive activation, and several genes encoding for molecules displaying high homology with cellular cytokines (IL-6) and chemokines (MIP-1, MIP-II). [68] [69] [70] Although several of these genes are expressed by HHV-8 positive lymphoma cells, including viral IL-6 and viral cyclin D, their precise contribution to lymphomagenesis is still under investigation. [68] [69] [71]

HTLV-I is a member of the lentivirus group which can immortalize normal T cells in vitro and can cause adult T-cell leukemia/lymphoma (ATLL). [72] [73] [74] Unlike acutely transforming retroviruses, the HTLV-I genome does not encode a viral oncogene. [72] [73] [74] Furthermore, this retrovirus does not transform T cells by cis-activation of an adjacent cellular proto-oncogene, because the provirus appears to integrate randomly within the host genome. [72] [73] [74] Rather, the pathogenetic effect of HTLV-I seems to result from viral production of a *trans*-regulatory protein (HTLV-I *tax*) that markedly increases expression of all viral gene products and transcriptionally activates the expression of certain host genes, including IL-2, the alpha chain of the IL-2 receptor (CD25), c- *SIS,* c-*FOS,* and GM-CSF. [75] [76] [77] [78] [79] The central role of these genes in normal T-cell activation and growth, coupled with direct experimental evidence, support the notion that *tax*-mediated activation of these host genes represents an important mechanism by which HTLV-I initiates T-cell transformation. [80] In addition, there are suggestions that *tax* may mediate DNA damage as a consequence of either inactivation of the *p53* checkpoint or a repression of DNA repair functions. [81] [82] Recently, it has been shown that *tax* may abrogate a mitotic checkpoint by targeting the TXBP181 cellular gene, a homolog of the yeast mitotic checkpoint MAD1 protein. [83] These features of *tax* are consistent with the fact that ATLL cells are karyotypically abnormal and frequently present as pleomorphic multinucleated giant cells. [84] [85]

Apart from EBV, HHV-8, and HTLV-I, other viruses have been postulated to contribute to lymphomagenesis. These include human immunodeficiency virus (HIV) and hepatitis virus C (HCV). [86] [87] In contrast to EBV, HHV-8, and HTLV-I, however, other viruses do not infect the lymphoma clone, and thus do not contribute directly to lymphomagenesis. Rather, they may be responsible for the hosts conditions, such as immunodeficiency

in the case of HIV, which predisposes the patient to develop lymphoma through indirect mechanisms.

ANTIGENIC STIMULATION AND SELECTION

The role of antigenic stimulation and selection in the pathogenesis of lymphoid malignancies has been investigated in particular depth in the case of B-cell NHL. [88] The survival of normal B cells depends upon the expression and proper function of surface Ig molecules serving as antigen receptors. [3] [4] [5] [6] [7] [8] When a virgin B cell has left the bone marrow and entered the GC, it will die within a few days unless its receptor is engaged by antigen. [3] [4] [5] [6] [7] [8] If antigen receptors are succesfully engaged, B cells residing in the GC will be induced to activate and proliferate. [3] [4] [5] [6] [7] [8] Given the fundamental role played by antigen stimulation in B-cell development and mitogenesis, it is generally agreed that challenging surface Ig by antigenic stimuli may play a role in the development of malignancies of mature B cells. This notion is supported by the following experimental evidence: (1) presence of somatic mutations of Ig genes, typical of the antigen-driven process; (2) biased usage of specific families of Ig genes, consistent with stimulation and selection by specific antigens; (3) identification of antigenic specificity of the antigen receptors expressed by NHL cells.

The mechanism of Ig gene hypermutation leads to introduction of somatic mutations in Ig genes, which can occur either in the complementarity determining region (CDR) or in the framework region (FWR). [8] [88] Because contact with an antigen is mediated primarily by aminoacid residues in the CDR, mutations replacing the aminoacids in the CDR (defined as R mutations) may potentially alter antigen binding and be positively selected in this fashion. As a result of selection, Ig genes for B cells that have been positively selected by antigen often harbor a disproportionate number of R mutations in their CDR. [8] [88] Studies of the distribution of somatic hypermutation of Ig genes throughout the clinico-pathologic spectrum of B-cell NHL have shown that somatic Ig gene hypermutation characterizes several types of B-cell NHL, including FL, B-DLCL, BL, MALT-NHL, and LPL. [12] [13] [14] [15] [16] [17] [88] [89] [90] [91] [92] [93]

Biased usage of Ig genes in B-cell NHL has also been taken to reinforce the concept of antigen stimulation and selection in B-cell NHL pathogenesis. [94] Given the high number of Ig variable gene segments, a randomized rearrangement process would potentially give rise to a diverse heavy chain repertoire with an equal representation of all Ig gene segments. The expressed human Ig repertoire, however, is not an equal representation of all Ig V segments present in genomic DNA. [94] Rather, a biased subset of V_H segments is overrepresented in antibody repertoires of adult B cells, possibly as a result of antigen selection favoring certain classes of V genes. [95] [96] Similarly, a restricted set of V_H genes is frequently expressed by neoplastic and autoimmune B cells. [94] For example, B-cell NHL frequently express Ig genes containing V segments that are frequently implicated in the generation of autoantibodies, indirectly suggesting that selection by autoantigens may have been involved in lymphoma development. [94] [97] [98]

The characterization of the precise nature of the selective force and the antibody reactivity of NHL with given antigens has helped clarify antigen stimulation and selection in lymphomagenesis. These studies have been performed only in a few cases. In the case of FL and BL, the demonstration of expression of Ig with autoantibody reactivity has suggested the possibility that self-antigens may play a role in B-cell NHL growth. [90] [91] [99] [100] [101]

The precise timing and duration of antigen selection during the clonal expansion of NHL has not been clarified. Also, it is not known whether continued antigen binding may be required for tumor cell growth. Although it appears that in some NHL Ig gene hypermutation is an ongoing phenomenon persisting after full neoplastic transformation, other NHL associated with Ig hypermutation no longer express surface antigen receptor molecules. [1] [16] [93] Thus, for some NHL, antigen selection may be required for the maintenance of the tumor clone, whereas in other cases antigen selection may have played a role in the early phases of tumor development and/or in cells representing the precursor population of the tumor.

IMMUNODEFICIENCY

The close relationship between decreased immunosurveillance and NHL is documented by the observation that many immunodeficiency syndromes are associated with a high relative risk for lymphoma, including most congenital immunodeficiencies, acquired imunodeficiency syndrome (AIDS), and iatrogenically induced immunodeficiencies in transplant recipients. [102] [103] [104] [105] [106] [107]

Immunodeficiency-related NHL are represented by high grade lymphomas, which frequently affect unusual extranodal sites, including the central nervous system. [102] [103] [104] [105] [106] [107] The overwhelming majority of lymphomas associated with the hosts immune disruption are of B-cell origin, with the exception of some congenital immunodeficiency conditions, namely ataxia-teleangectasia, which carries a significant risk for T-cell malignancies. Studies in HIV-infected individuals and transplant recipients have determined that at least three factors related to immunodeficiency influence lymphomagenesis: (1) the degree of immunodeficiency; (2) the duration of immunodeficiency; and (3) the specific type of immunosuppression. [102] [103] [104] [105] [106] [107] These observations may explain why immunodeficiency-related lymphomas are highly heterogeneous and why different immunodeficiency syndromes lead to different types of lymphoma. This notion is best exemplified by the differences in the histologic and molecular spectrum of lymphomas arising in the context of AIDS as opposed to lymphoproliferative disorders developing in transplant recipients. [102] [103] [104] [105] [106] [107]

The precise mechanisms by which immunodeficiency causes lymphoma are complex and not well understood. In the context of AIDS, for example, the development of EBV-infected NHL has been partly explained by the fact that one of the AIDS-associated immunologic defects selectively impairs the immunosurveillance against EBV-infected B cells, which are present in increased numbers in the patients blood and lymphoid organs and may be responsible for minor clonal B-cell expansions that precede the neoplastic transformation. [108] [109] Another mechanism that has been deemed relevant in immunodeficiency-related NHL is the focal in situ failure of T-cell response. In fact, immunodeficiency-related B-cell NHL usually display a markedly lower representation of tumor infiltrating T-lymphocytes (T-TIL) when compared to NHL occurring in immunocompetent hosts. [110] The role of T-TIL in tumor containment is well-established and the magnitude of T-TIL response in B-cell NHL biopsies has been suggested to be an independent predictor of clinical outcome. [111]

PATHOGENETIC HETEROGENEITY OF NON-HODGKIN LYMPHOMAS

The clinico-pathologic heterogeneity of NHL is reflected by a high degree of heterogeneity in the molecular pathogenesis of these disorders. This section provides an overview of the molecular pathways associated with B-cell and T-cell NHL classified according to the Revised European-American Lymphoma (REAL) classification of lymphoid neoplasia.[1] Whereas several B-cell NHL and some T-cell NHL types are known to be associated with well-defined genetic alterations in a consistent and selective fashion, the molecular pathogenesis of other lymphomas is less well defined. In some cases, the only available knowledge is based on karyotypic studies revealing recurrent

cytogenetic abnormalities not yet clarified at the molecular level. The following descriptions focus on those NHL categories for which molecular studies have provided a certain amount of knowledge (Table 66-1).

Small Lymphocytic Lymphoma/B-Cell Chronic Lymphocytic Leukemia

The molecular pathogenesis of small lymphocytic lymphoma/B-cell chronic lymphocytic leukemia (SLL/B-CLL) has been elucidated only in part. In particular, none of the cancer-related genes known to date has been shown to be associated consistently and selectively with SLL/B-CLL. [112] Based on karyotypic and deletion mapping studies, it is likely that the 13q14 chromosomal region may harbor a novel tumor suppressor gene that is involved in the pathogenesis of a high frequency of SLL/B-CLL cases.[45] [46] [47] In fact, analysis with sensitive molecular tools has revealed that deletions of 13q14 occur in approximately 60% of cases, but the relevant tumor-suppressor gene has not been identified.[45] [46] [47] Among known cancer-related genes, mutations of *p53* occur in 10% of the cases of SLL/B-CLL.[112] [113] The frequency of *p53* inactivation increases substantially in cases that have evolved to Richter syndrome, suggesting that *p53* may be at least partially responsible for this aggressive clinical transformation.[113] Despite initial suggestions, it is now well established that true cases of SLL/B-CLL (i.e., $CD5^+$, $CD23^+$ according to the REAL classification) are consistently devoid of *BCL*-1 and *BCL*-2 rearrangements.[1] [112] From a diagnostic standpoint, this notion has practical implications. For example, leukemic processes apparently resembling B-CLL, but harboring *BCL*-1 rearrangements, should be classified as MCL (see section later in this chapter).

In addition to del(13)(q14), chromosomal abnormalities associated with SLL/B-CLL include trisomy 12 and deletion of 6q. [114] [115] Trisomy 12 occurs in 3040% of cases and correlates with poor survival, whereas deletions of 6q define a subset of SLL/B-CLL cases displaying prolymphocytic features. [114] [115] The genes involved in trisomy 12 and del(6q) that lead to SLL/ B-CLL are not known.

Lymphoplasmacytoid Lymphoma

Approximately 50% of LPL are associated with a t(9;14)(p13;q32) translocation (Table 66-1).[116] The translocation appears to display a preferential clustering with LPL cases associated with Waldenstrom macroglobulinemia. The chromosomal breakpoints of t(9;14)(p13;q32) involve the Ig_H locus on chromosome 14q32, and, on chromosome 9p13, a genomic region containing the *PAX*-5 (Paired Homeobox-5) gene.[117] *PAX*-5 encodes a B-cell-specific transcription factor involved in the control of B-cell proliferation and differentiation. [118] Presumably, the juxtaposition of *PAX*-5 to the Ig_H locus in NHL carrying t(9;14)(p13;q32) leads to deregulated expression of the gene, thus contributing to tumor development. Apart from t(9;14)(p13;q32), no other genetic lesion has been detected at significant frequencies in LPL.

Mantle Cell Lymphoma

MCL is typically associated with t(11;14)(q13;q32) (Table 66-1).[111] The translocation juxtaposes the *BCL*-1 locus at 11q13 with the Ig_H locus at 14q32.[119] [120] [121] The t(11;14)(q13;q32) consistently leads to homotopic deregulation of *BCL*-1 (also known as *CCND*1 or *PRAD*1), a gene located in proximity to the breakpoint and encoding for cyclin D_1 , a member of the D-type G_1 cyclins, which regulate the early phases of cell cycle. [122] [123] [124] [125] [126] The consistent and selective clustering of *BCL*-1 overexpression with NHL carrying t(11;14)(q13;q32) strongly suggests that this gene is indeed the critical component of the translocation.

The precise contribution of cyclin D_1 to cell cycle regulation is still under investigation. Like other D-type cyclins, cyclin D_1 is thought to act primarily as a growth factor sensor integrating extracellular signals with the cell cycle machinery. [127] The pathogenetic role of *BCL*1 activation in human neoplasia is suggested by the ability of cyclin D_1 overexpression to transform cells in vitro and contribute to B-cell lymphomagenesis in transgenic mice. [128] [129] [130]

The application of strict phenotypic criteria to the classification of B-cell lymphoproliferations has revealed that the distribution of *BCL*-1 rearrangements, and consequent cyclin D_1 overexpression, are selectively restricted to MCL throughout the clinico-pathologic spectrum recognized by the REAL classification (70% of the cases).[1] [11] [131] [132] Because the diagnosis of MCL may be difficult on pure histologic grounds, the frequency and specificity of this genetic alteration provide excellent markers for diagnosis of MCL. In particular, because cyclin D_1 is not generally expressed by normal B cells, positive expression of cyclin D_1 in the context of a lymphoproliferative disorder has come to represent a highly specific marker for MCL in the clinical practice. [132] The precise identification of MCL among non-follicular small B-cell lymphomas is clinically relevant, since MCL is a far more aggressive disease and displays a significantly shorter survival than other histologically related forms.[133] [134]

Other genetic alterations may be also involved in MCL. Inactivation of *p53* occurs in a subset of cases and is a marker of poor prognosis.[135] Inactivation of *p16,* by deletion, mutation, or hypermethylation, is detectable in approximately half of the cases belonging to an aggressive MCL variant characterized by a blastoid cell morphology.[136]

FOLLICULAR LYMPHOMA

The genetic hallmark of FL is represented by chromosomal translocations of *BCL*-2 which are detected in 8090% of the cases independent of cytologic subtype. [1] Other genetic lesions may also occur, especially in FL cases that have undergone histologic progression to a high grade NHL.

Chromosomal Translocations Involving the *BCL*-2 Gene

Translocations involving 18q21 are the most common translocation in human lymphoid malignancies. Typically, these translocations juxtapose 18q21 to Ig_H [t(14;18)(q32;q21)], although occasionally 18q21 is translocated to Ig [t(2;18)(p11;q21)] or Ig [t(18;22)(q21;q11)] (Table 66-1). Breaks at 18q21 are present in virtually all FL and approximately 30% of B-DLCL. In t(14;18), the rearrangement joins the *BCL*-2 gene at its 3 untranslated region to an Ig_H J segment (Fig. 66-3).[137] [138] [139] [140] [141] Each of these translocations leads to deregulated expression of *BCL*-2, and, consequently, constitutively high levels of *BCL*-2 protein within the cells.[142] [143] Two main breakpoint cluster sites are known in t(14;18)(q32;q21). [137] [138] [139] [140] [141] Approximately 70% of the chromosome 18 breakpoints cluster within the major breakpoint region, conventionally known as MBR. The remaining cases usually break in the more 3 distant minor cluster region of *BCL*-2, known as mcr. Rare cases break in an alternative cluster region known as the 5 breakpoint cluster. [144]

The *BCL*-2 gene encodes a 26-kDa integral membrane protein that has been localized to mitochondria, smooth endoplasmic reticulum, and perinuclear membrane. [145] Whereas most proto-oncogenes of lymphoid noplasia directly enhance cell growth, *BCL*-2 has no ability to promote cell cycle progression or cell proliferation but rather controls the cellular apoptotic threshold by preventing programmed cell death. [145] [146] [147] [148] In normal cells, the topographic restriction of *BCL*-2 expression to GC zones of surviving B cells suggests that *BCL*-2 drives the emergence of long-lived memory B cells.[149] Indeed, *BCL*-2 transgenic animals show

Figure 66-3 Schematic representation of *BCL*-2 translocations. The germline configuration of the *BCL*-2 gene, mapping to 18q21, is shown in the upper panel of the figure. In its germline configuration, *BCL*-2 is composed of three exons with a large intron between exon 2 and exon 3. The coding region of the *BCL*-2 gene is indicated by red boxes, whereas non-coding exons (or portions of exons) are indicated by white boxes. The location of the major breakpoint region (MBR), where most *BCL*-2 breakpoints fall, is indicated by an arrow. The bottom panel of the figure depicts the molecular consequences of t(14;18)(q32;q21), which causes the juxtaposition of *BCL*-2 to the Ig_H locus. Both the genomic configuration of a representative translocated *BCL*-2 allele and the resulting cDNA are shown. The translocation breakpoint within *BCL*-2 most frequently involves the MBR (as in the case of the figure), although approximately 20% of cases break within a region located 3 of the MBR, and designated as minor cluster region (MCR; not shown in the figure). Within the Ig_H locus, the breakpoint involves J_H sequences. Notably, the *BCL*-2 coding sequence of the translocated *BCL*-2 allele is intact. The resulting cDNA is represented by the fusion of *BCL*-2 exons 13 (at the 5 side of the transcript) with J_H and C exons derived from Ig_H (at the 3 side of the transcript). Since the *BCL*-2 coding region is preserved, the hybrid *BCL*-2/Ig_H transcript gives rise to a wild type and normally sized *BCL*-2 protein.

markedly protracted secondary immune responses and an extended lifetime for memory B cells in the absence of antigen. [150]

BCL-2 is only one member of a family of apoptotic regulators, which also includes *BAX* and *BCL*-X.[145] It is now clear that *BCL*-2 exists as part of a high molecular weight complex generated through heterodimerization with *BAX.*[151] [152] The inherent ratio of *BCL*-2 to *BAX* determines the functional activity of *BCL*-2. When *BAX* is in excess, *BAX* homodimers dominate and cell death is accelerated; conversely, when *BCL*-2 is in excess, as in NHL carrying *BCL*-2 rearrangements, *BCL*-2/*BAX* heterodimers are the prevalent species and cell death is prevented. The fine biochemical pathways through which *BCL*-2 exerts its anti-apoptotic function involve activation of an antioxidant pathway at sites of free radical generation and/or regulation of endoplasmic reticulum-associated Ca^{++} fluxes.[153] [154]

The precise contribution of *BCL*-2 deregulation to FL development is complex. The translocation is thought to occur early in ontogeny in a pre-B cell representing a precursor of FL.[89] In contrast to other genetic lesions occurring in pre-B cells and leading to B-cell lineage acute lymphoblastic leukemia by providing a differentiative block of the target cells, *BCL*-2 rearrangements are permissive of B-cell maturation at the stage of $sIgM^+/sIgD^+$ B cell. The pathogenicity of *BCL*-2 lesions in the context of FL is substantiated by the ability of *BCL*-2-specific antisense oligonucleotides to inhibit the growth of human B-cell NHL bearing *BCL*-2 translocations.[155] In vivo, however, the *BCL*-2 transgene leads to a pattern of polyclonal hyperplasia of mature, long-lived B cells resting in G_0, which, despite morphologic similarities, contrasts with the consistent monoclonality of human FL. [156] Hence the view that *BCL*-2 activation is not sufficient for FL development, and that other genetic lesions or host factors are required. A strong candidate for a second event is chronic antigen stimulation and selection that would synergize with *BCL*-2 in driving FL expansion.[88] [89] With time, and similar to what is observed in the human disease, a fraction of *BCL*-2 transgenic mice progress to develop aggressive, clonal large cell lymphomas that have acquired additional genetic lesions. [157]

Other Genetic Lesions

Other proto-oncogenes involved in lymphomagenesis, such as c-*MYC, BCL*-6, or *BCL*-1, are not involved in FL. Deletions of chromosome 6 at 6q27 occur in approximately 20% of cases.[43] Over time, a significant fraction of FL evolves into an aggressive lymphoma with a diffuse large cell architecture. This histologic shift is almost consistently accompanied by the accumulation of *p53* mutation and deletion in addition to the pre-existent *BCL*-2 lesion.[158] In some cases, transformation is accompanied by inactivation of *p16* by deletion, mutation, or hypermethylation. [136] In very rare cases, the histologic progression of FL involves c-*MYC* rearrangements or 6q deletions.[158] [159]

Mucosa-Associated Lymphoid Tissue (MALT) NHL

Understanding of the molecular pathogenesis of MALT-NHL is still in its early stages. In the case of gastric MALT-NHL, the majority of tumors are associated with *Helicobacter pylori* (*H. pylori*) infection.[160] It has been suggested that gastric MALT-NHL may be dependent upon antigen stimulation by *H. pylori,* because malignant lymphoid cells respond to *H. pylori* antigens and the lymphoma may regress upon eradication of infection. [160] The potential role of antigen in MALT-NHL pathogenesis is further supported by the observation that MALT-NHL cells harbor the genotypic clue of antigen-experienced B cells, i.e., somatic hypermutation of Ig genes. [15] [161] [162] Whether the development of MALT-NHL arising in body sites other than the stomach is also dependent upon antigen stimulation and selection remains an open question. In this respect, it is remarkable that thyroid MALT-NHL is generally a sequela of Hashimoto thyroiditis, an autoimmune process causing the exposure of B cells to thyroid-derived autoantigens. [163]

Among genetic alterations commonly involved in other NHL types, only *BCL*-6 rearrangements and *p53* mutations have been detected in MALT-NHL, though at low frequency.[164] [165] Cytogenetic studies, however, have pointed to several abnormalities recurrently involved in these tumors. The most frequent of these abnormalities

are trisomy 3 and t(11;18).[166] [167] The genes implicated in these aberrations have not yet been identified.

B-Lineage Diffuse Large Cell Lymphoma

According to the REAL classification, the term B-lineage diffuse large cell lymphoma (B-DLCL) includes more than one disease entity, consistent with the striking heterogeneity of morphology, clinical presentation, and response to treatment. [1] Part of this heterogeneity may reflect the heterogeneous natural history of the disease, which may arise de novo or, alternatively, may develop from the histologic transformation of an FL. [1] Molecular investigations have confirmed the heterogeneity of B-DLCL at the genotypic level.[168] All B-DLCL represent clonal expansions of mature B cells reflecting features of GC centroblasts. [1] Because of the extreme complexity of the biological interactions regulating the physiologic proliferation and differentiation of mature B cells residing in the GC, it is likely that B-DLCL development is influenced by a multitude of events regulating GC function

and development. [4] [6] [7] As in most other types of NHL, however, it is now clearly established that development of B-DLCL is associated with specific molecular lesions involving proto-oncogenes and tumor suppressor genes.

Chromosomal Translocations Involving *BCL*-6

Cytogenetic studies of NHL have demonstrated that chromosomal alterations affecting band 3q27 are a frequent recurrent abnormality in B-DLCL (Table 66-1).[169] [170] These alterations are predominantly represented by reciprocal translocations between the 3q27 region and several alternative partner chromosomes, including, though not restricted to, the sites of the Ig genes at 14q32 (Ig_H), 2p11 (Ig), and 22q11 (Ig) (Fig. 66-4). [169] [170] The variability of the partner chromosomes juxtaposed to 3q27 in B-DLCL translocations suggests that these abnormalities belong to the group of promiscuous translocations, which involve a fixed chromosomal breakpoint, on one side, and, on the other side, different chromosomal partners in different cases.

Cloning of the 3q27 chromosomal breakpoints revealed that the *BCL*-6 gene is involved in the overwhelming majority of B-DLCL cases harboring 3q27 breaks irrespective of the partner chromosome participating in the translocation. [171] [172] [173] [174] [175] The *BCL*-6 gene is a transcriptional repressor belonging to a family of transcription factors containing zinc fingers, a protein sequence motif that is able to mediate the protein binding to specific DNA sites. [176] [177] The aminoterminal region of the *BCL*-6 protein contains a domain, termed *POZ,* which is homologous to domains found also in several other zinc-finger transcription factors. [178] Apparently, the *POZ* domain acts as a protein-protein interface implicated in homo/hetero-dimerization processes. [178] These structural features of the *BCL*-6 protein are consistent with functional studies indicating that *BCL*-6 can indeed function as a transcriptional repressor that inhibits the expression of genes carrying its specific DNA-binding motif.[179]

The pattern of *BCL*-6 protein expression in human tissues is highly specific and high levels are specifically found in B cells. [180] In particular, *BCL*-6 expression is topographically restricted to

Figure 66-4 Chromosomal sites implicated in der (3)(q27) and leading to rearrangement of *BCL*-6. The variability of the partner chromosome juxtaposed to 3q27 in B-DLCL suggests that these chromosomal abnormalities belong to the group of promiscuous translocations. The thick arrows point to some sites that are involved more frequently than others. (In many cases, indicated by ?der(3)(q27) in the figure, the partner chromosomal site cannot be identified with precision by conventional cytogenetics.)

Figure 66-5 Schematic representation of genetic lesions affecting the *BCL*-6 gene in B-DLCL. In its germline configuration, the *BCL*-6 gene is composed of 10 exons. The coding region of *BCL*-6 is indicated by color boxes, and the noncoding exons (or portions of exons) are indicated by white boxes. The physiologic *BCL*-6 promoter is indicated by an arrow. Rearrangements of *BCL*-6 by chromosomal translocation occur in approximately 35% of B-DLCL cases and cause substitution of the BCL-6 promoter with heterologous promoters derived from the chromosomal partner. The breakpoint sites (indicated by arrows) span the *BCL*-6 first exon and its adjacent sequences on both sides. The majority of breakpoints map to 3 sequences in the immediate vicinity of the *BCL*-6 first exon (indicated by thick arrow). In addition to rearrangements, *BCL*-6 may be also affected by small mutations clustering in the proximity of the *BCL*-6 first exon/first intron border.

the GC, where *BCL*-6 is expressed by both centroblasts and centrocytes, whereas expression of *BCL*-6 is absent in pre-GC B cells (virgin B cells) and post-GC B cells (memory B cells and plasma cells).[180] The observation that *BCL*-6 is expressed within the GC, but not before entry into or following exit from the GC, led investigators to postulate that *BCL*-6 may be needed for GC development and survival, whereas its downregulation may be necessary for further differentiation of B cells. [180] [181]

Clarification of the precise role of *BCL*-6 in physiologic immune processes has been further clarified by knock-out animal models carrying biallelically disrupted *BCL*-6 genes.[182] [183] Mice carrying the *BCL*-$6^{/}$ phenotype consistently fail to form GC. Consistent with the lack of GC formation, *BCL*-$6^{/}$ mice also display impaired T-cell dependent antigen-specific IgG responses. Overall, these animal models unequivocally demonstrate that *BCL*-6 is a key regulator of GC formation and B-cell immune response.

Chromosomal translocations involving band 3q27 truncate the *BCL*-6 gene within its 5 flanking region, within the first exon or within the first intron (Fig. 66-5), making these alterations readily detectable as rearrangements by Southern blot hybridization analysis of tumor DNA. [171] [172] [173] [174] [175] In conventional molecular assays, *BCL*-6 rearrangements are detectable in 35% of cases of B-DLCL and in a small fraction of FL. [165] [184] [185] Conversely, with the exception of a tiny fraction of FL and MALT-NHL, *BCL*-6 rearrangements are consistently absent in all other types of lymphoid neoplasms. [184] [185] The coding domain of the *BCL*-6 gene is left intact in all cases displaying *BCL*-6 rearrangements, whereas the 5 regulatory sequences, which contain the *BCL*-6 promoter, are either truncated or, alternatively, completely removed.[171] [172] [173] [174] [175] In all *BCL*-6 rearrangements, the entire coding sequence of *BCL*-6 is juxtaposed downstream to heterologous sequences which, based on cytogenetic data, may originate from different chromosomal sites in different patients (Fig. 66-4). The common functional consequence of *BCL*-6 translocations is the juxtaposition of heterologous promoters to the *BCL*-6 coding domain, a mechanism called promoter substitution (Fig. 66-5). [186] [187] The substitution of the *BCL*-6 promoter by heterologous regulatory sequences causes deregulated *BCL*-6 expression in B-DLCL carrying *BCL*-6 rearrangements. One feature shared by

the heterologous promoters linked to rearranged *BCL*-6 alleles is that they are physiologically active in normal B cells and are not downregulated during the late stages of B-cell differentiation. [181] [186] [187] Thus, *BCL*-6 rearrangements may prevent downregulation of *BCL*-6 and, in turn, block the differentiation of GC B cells toward plasma cells. According to this model, B-DLCL cells carrying *BCL*-6 rearrangements would thus be frozen at the stage of GC cells.

In addition to rearrangements, the *BCL*-6 gene may be altered by other mechanisms in B-DLCL as well as in other types of B-cell NHL. In approximately 70% of B-DLCL and 50% of FL, the *BCL*-6 gene is affected by multiple, often biallelic, mutations that selectively cluster within the 5 non-coding regions of the gene (Fig. 66-5).[38] [188] The DNA sequences most frequently affected by mutations lie in close proximity to the *BCL*-6 promoter region and overlap with the major cluster of chromosomal breaks at 3q27, suggesting that mutations and rearrangements may be selected by their ability to alter the same region which conceivably regulates the normal expression of *BCL*-6. The cumulative frequency of mutations and rearrangements approaches 100% of B-DLCL cases, indicating that structural alterations of the 5 non-coding regions of *BCL*-6 might be a sine qua non for the development of these lymphomas.[38] [188]

Other Genetic Lesions in B-DLCL

Several other genetic lesions have been detected in B-DLCL. In contrast to *BCL*-6 rearrangements, however, these additional lesions are either not specific for B-DLCL, being detected also in other NHL types, or occur at low frequencies in B-DLCL cases. Approximately one third of B-DLCL cases display chromosomal rearrangements of *BCL*-2.[24] [165] [189] These translocations are entirely similar to the ones associated with FL and lead to the deregulated expression of *BCL*-2. [137] [138] [139] [140] [141] These alterations appear to be mutually exclusive with *BCL*-6 rearrangements, and tend to associate with B-DLCL cases that are derived from the histologic transformation of FL.[158] [165] *REL,* a member of the NF-kB/REL family of transcription factors, also appears to be involved in the pathogenesis of B-DLCL. [34] Activation of *REL* occurs through gene amplification and appears to be a relatively frequent event, occurring in 20% of B-DLCL cases, preferentially in those with

extranodal involvement.[34]

Among tumor suppressor genes, inactivation of *p53* frequently associates with cases resulting from the histologic transformation of FL. [158] In these cases, mutations of *p53* are acquired during the transformation from FL to B-DLCL. [168] Given the role of *p53* in controlling cell proliferation and genomic stability, it is likely that disruption of normal *p53* functions may contribute to tumor progression directly, by providing FL cells with a high proliferative rate, or indirectly, by allowing the accumulation of additional genetic lesions. Deletions of the long arm of chromosome 6 are also frequently detected in B-DLCL, although the gene(s) involved is not known. [43]

Based on the knowledge outlined here, a pathogenetic model for explaining B-DLCL heterogeneity is proposed in Figure 66-6 .

Burkitt Lymphoma

Burkitt lymphoma (BL) is classified into two main epidemiologic variants, including sporadic BL (sBL) and endemic BL (eBL). [1] Cases of sBL occur in North America and Europe, whereas cases of eBL occur primarily in Equatorial Africa and Papua New Guinea. Some BL cases present with massive involvement of the bone marrow and peripheral blood. Such cases, though traditionally termed acute lymphoblastic leukemia L3-type (L3-ALL), should be classified as BL because of their biologic features and their response to therapy. In 1994, the REAL classification of B-cell neoplasia formally acknowledged

Figure 66-6 Model of molecular pathways in B-DLCL development. Three main pathogenetic pathways may be recognized in B-DLCL. The first two molecular pathways are designated de novo pathways since, in these instances, B-DLCL develops without a pre-existent follicular lymphoma. One de novo pathway implicates the *BCL*-6 gene and occurs in approximately 35% of B-DLCL. The second de novo pathway involves presently unknown genetic lesions (indicated by the question mark), although some cases may harbor alterations of *REL.* The third pathway, designated as a transformation pathway, implicates the transformation of a pre-existing follicular NHL to a B-DLCL histology. Cases of B-DLCL belonging to this pathway harbor rearrangements of *BCL*-2 and mutations of *p53.* Whereas the *BCL*-2 rearrangement is already present in the follicular NHL phase, *p53* mutations are gained during histologic transformation.

that L3-ALL and classical BL represent different manifestations of the same disease. [1]

Despite the epidemiologic and clinical heterogeneity of BL, all BL variants, including sBL, eBL, and L3-ALL, consistently share a common genetic background represented by chromosomal translocations between c-*MYC* and one of the Ig loci. Other genetic lesions associate at variable frequencies with cases of BL and include infection of the tumor clone by EBV, inactivation of *p53* and *p16,* and mutations of *BCL*-6 5 noncoding regions.

Breaks at 8q24 and c-*MYC*

Chromosomal breaks at 8q24 are found in 100% of sBL, eBL, and L3-ALL (Table 66-1).[1] Historically, translocations of 8q24 have provided the first example of the involvement of proto-oncogenes in tumor-associated chromosomal abnormalities and have thus constituted the paradigm for the study of other chromosomal translocations involving antigen receptor loci. [190] In BL, all 8q24 breaks lead to a common final consequence, deregulated expression of the c-*MYC* proto-oncogene.[190] [191] [192] [193] [194] [195] Depending on the Ig locus involved, the c-*MYC* gene may be involved in three distinct translocations. In 80% of cases the translocation involves Ig_H , leading to t(8;14)(q24;q32) (Fig. 66-7).[190] [191] [192] [193] [194] [195] In the remaining 20% of cases, c-*MYC* juxtaposes either to Ig , leading to t(2;8)(p11;q24) (15% of cases), or to Ig , leading to t(8;22) (q24;q11) (5% of cases). Breaks at 8q24 selectively cluster with all BL variants throughout the spectrum of B-cell neoplasms recognized by the REAL classification. [1]

The product of the c-*MYC* proto-oncogene is a ubiquitously expressed nuclear bHLH-LZIP phosphoprotein that functions as a transcriptional regulator controlling cell proliferation, differentiation, and apoptosis. [190] [196] Expression of c-*MYC* is rapidly induced in quiescent cells upon mitogenic induction, suggesting that c-*MYC* plays a role in mediating the transition from quiescence to proliferation. [196] In addition to mediating cell

Figure 66-7 Schematic representation of chromosomal translocations involving the c-*MYC* gene. In its germline configuration (upper panel), c-*MYC* is composed of three exons. The coding region of c-*MYC* is indicated by red boxes, and noncoding exons (or portions of exons) are indicated by white boxes. The c-*MYC* promoters are indicated by arrows. The molecular consequences of the most frequent c-*MYC* translocation, i.e., t(8;14), are depicted in the middle and lower panels. Two molecular subtypes of t(8;14) are recognized, which tend to associate with sBL (middle panel) and eBL (lower panel), respectively. For each molecular subtype of t(8;14), both the genomic configuration and the resulting cDNA of a representative translocated c-*MYC* allele are shown. In the case of t(8;14) of sBL (middle panel), the chromosome 8 breakpoint involves sequences within c-*MYC,* which is deprived of its exon 1. Since the physiologic promoters are removed by the translocation, transcription is driven by an otherwise silent promoter located within c-*MYC* intron 1 (indicated by an arrow in the figure). On chromosome 14, the breakpoint maps in the proximity of the switch (S) region. Notably, the translocation leaves intact the gross configuration of the coding sequence of c-*MYC.* However, at the nucleotide level, c-*MYC* translocated alleles frequently harbor point mutations within the exon 2 coding sequence, leading to amino acid substitutions in the c-*MYC* protein. The cDNA encoded by translocated c-*MYC* alleles includes the exons 2 and 3 of the gene, as well as an abnormally transcribed sequence of intron 1 starting from the novel transcriptional initiation site within c-*MYC* intron 1. Because the c-*MYC* coding region is intact, a normally sized c-*MYC* protein is translated by t(8;14) of sBL. In the case of t(8;14) of eBL (lower panel), the c-*MYC* breakpoint involves sequences on chromosome 8 at an undefined distance (>100 kb) 5 to c-*MYC* and sequences on chromosome 14 within or in proximity to the Ig J_H region. The internal genomic configuration of the translocated c-*MYC* allele is thus apparently preserved. However, c-*MYC* alleles involved by t(8;14) of eBL consistently harbor small mutations mapping to the exon 1/intron 1 border, where c-*MYC* regulatory regions are located. In addition, point mutations within exon 2 coding sequence are also present. The cDNA transcribed by translocated c-*MYC* alleles of eBL includes c-*MYC* exons 13 and gives rise to a normally sized c-*MYC* protein.

proliferation, c-*MYC* is also implicated in blocking differentiation. [196] In the absence of a supportive microenvironment providing adequate concentrations of growth stimuli, however, proliferation and/or block of differentiation are replaced by cellular apoptosis. [197] [198] [199] [200] The biochemical mechanisms by which c-*MYC* achieves its various functions have been clarified to a certain extent. In physiologic in vivo settings, c-*MYC* is mainly engaged in heterodimeric complexes with the related protein *MAX* which stimulates transcription and cell proliferation. [201] [202] [203] [204] [205] [206] In addition to c-*MYC, MAX* can also form homodimers as well as heterodimers with *MAD* and *MXI*1, two bHLH-LZIP proteins that act as negative regulators of transcription. [207] [208] Because the levels of *MAX* tend to be stable throughout the cell cycle, the ratio of c-*MYC*/*MAX* heterodimers is controlled by the relative abundance of c-*MYC, MAD,* and *MXI*1.[201] [202] [203] [204] [205] [206] [207] [208] As the ratio of c-*MYC* to *MAD* or *MXI*1 varies, the promoter activity of target genes is expected to be modulated in either a positive (when c-*MYC* levels are high) or negative (when *MAD* or *MXI*1 levels are high) fashion. Therefore, in lymphoid tumors associated with c-*MYC* deregulation, it is conceivable that constitutive expression of c-*MYC* leads to the predominance of *MYC*/*MAX* heterodimers, thus inducing positive growth regulation.

Although fairly homogeneous at the microscopic level, c-*MYC* translocations display a high degree of heterogeneity when dissected at the molecular level (Fig. 66-7). The t(8;14) breakpoints are located 5 and centromeric to c-*MYC,* whereas they map 3 to c-*MYC* in t(2;8) and t(8;22).[190] [191] [192] [193] [194] [195] In the instance of t(8;14), the exact location of the breakpoint sites of chromosomes 8 and 14 contributes further heterogeneity. [209] [210] In eBL, the breakpoint sites on chromosome 8 preferentially involve sequences at an undefined distance (>200 kb) 5 to c-*MYC,* whereas on chromosome 14, the breakpoints fall within or in proximity to the Ig JH region. In sBL, the t(8;14) breakpoints fall within or immediately 5 (<3 kb) to c-*MYC* on chromosome 8 and within the Ig S regions on chromosome 14.

The common functional effect of t(8;14), t(2;8), and t(8;22) is that c-*MYC* translocated alleles undergo constitutive expression in tumor cells, whereas under physiologic conditions c-*MYC* levels are tightly regulated during B-cell proliferation and differentiation. [211] [212] [213] Chromosomal translocations cause c-*MYC* deregulation by at least two distinct mechanisms. First, translocated c-*MYC* alleles are juxtaposed to heterologous regulatory elements derived from Ig loci. [190] [191] [192] [193] [194] [195] Second, the 5 regulatory regions of c-*MYC* are consistently affected by structural alterations

that are supposed to modify their responsiveness to cellular factors regulating c-*MYC* expression (Fig. 66-7). In the case of sBL and L3-ALL, the t(8;14) chromosomal translocation depletes the c-*MYC* gene of its first exon.[190] Conversely, in cases carrying breakpoints located either 5 or 3 to the c-*MYC* gene, such as eBL harboring t(8;14) and all cases carrying t(2;8) or t(8;22), a 400-bp region spanning the first exon/first intron junction, and containing several potentially relevant regulatory domains, is consistently mutated in translocated c-*MYC* alleles.[37]

In addition to transcriptional deregulation, oncogenic conversion of c-*MYC* is also thought to stem from amino acid substitutions in c-*MYC* exon 2 affecting the N-terminal transcriptional activation domain of the gene (Fig. 66-7).[36] [214] The high prevalence of these mutations suggests a biologic role for these alterations in lymphomagenesis. Although under normal conditions the activity of the c-*MYC* transactivation domain is suppressed by protein-protein interactions with the pRB-related protein p107, c-*MYC* proteins carrying exon 2 mutations are able to escape the p107-mediated modulation. [215] [216] The mechanism of resistance of mutant c-*MYC* proteins to p107-mediated suppression is not known, although it is not caused by the disruption of the physical interactions between c-*MYC* and p107.[216] Rather, c-*MYC* exon 2 mutations may confer resistance to p107-mediated phosphorylation, which is essential for the p107 suppression effect. [216] [217]

Several lines of experimental evidence document that the deregulated expression of c-*MYC* can influence the growth of B cells in vitro and in vivo. In vitro, the expression of c-*MYC* oncogenes transfected into EBV immortalized human B cells, a potential natural target for c-*MYC* activation in EBV positive BL, leads to their malignant transformation.[28] In addition, antisense oligonucleotides directed against translocated c-*MYC* alleles are able to revert the tumorigenicity of BL. [218] [219] In vivo, the targeted expression of c-*MYC* oncogenes in the B-cell lineage of transgenic mice leads to the development of B-cell malignancies at a high rate. [27]

Other Genetic Lesions in Burkitt Lymphoma

In addition to c-*MYC* translocations, the molecular pathogenesis of BL also involves infection of the tumor clone by EBV, inactivation of the *p53* and *p16* tumor suppressor genes, mutations of the 5 noncoding regions of *BCL*-6, and deletions of 6q. Infection by EBV occurs in virtually all cases of eBL and in approximately 30% of cases of sBL.[49] [50] [51] [52] The consistent monoclonality of EBV infection in BL, as assessed by molecular analysis of EBV terminal repeats, suggests that infection precedes clonal expansion of the tumor, consistent with a pathogenetic role of the virus. [49] [50] [51] [52] [54] Notably, however, BL cells fail to express the EBV transforming antigens LMP-1 and EBNA-2, rendering the role of EBV infection unclear. [50] [52] Inactivation of *p53* is detected in approximately 3040% of BL cases, independent of their geographic origin or the presence of EBV infection. [113] Inactivation of *p16* occurs in 3040% of BL through mutation, deletion or hypermethylation. [220] Mutations of the *BCL*-6 5 noncoding regions occur in approximately 40% of BL, confirming the histogenetic derivation of the disease from GC B cells. [221] As in many other NHL types, BL is also associated with deletions of 6q.[43] In vitro models indicate that accumulation of genetic lesions follows a temporal order in BL pathogenesis. [222] Thus, translocations of c-*MYC* and mutations of *BCL*-6 represent early events, whereas *p53* mutations occur late in BL pathogenesis. [222]

Immunodeficiency-Related NHL

AIDS-Related Lymphomas

AIDS-related non-Hodgkin lymphomas (AIDS-NHL) are invariably derived from B cells and are primarily classified into three main clinicopathologic categories, including AIDS-related Burkitt lymphoma (AIDS-BL), AIDS-related diffuse large cell lymphoma (AIDS-DLCL), and AIDS-related primary effusion lymphoma (Table 66-2).[86] [103] [104] [107] Based on the presence or absence of immunoblastic features, AIDS-DLCL may be further categorized as large noncleaved cell lymphoma (LNCLL) or immunoblastic lymphoma plasmacytoid (IBLP).[86] [103] [104] [107] Based on the site of origin, AIDS-NHL are generally grouped into systemic AIDS-NHL and AIDS-related primary central nervous system lymphoma (AIDS-PCNSL).[86] [103] [104] [107] Systemic AIDS-NHL may be either AIDS-DLCL or AIDS-BL. Conversely, AIDS-PCNSL display a uniform morphology consistent with an architecture of diffuse large cells.

The different categories of AIDS-NHL are associated with distinctive molecular pathways (Table 66-2).[86] [104] [107] [223] Cases of AIDS-BL consistently display activation of c-*MYC* by chromosomal translocations that show structural similarities to those found in sBL patients. [53] Rearrangements of *BCL*-6 are consistently absent in this AIDS-NHL type. [224] AIDS-BL also frequently harbor mutations of *p53* (60%), mutations of *BCL*-6 5 noncoding regions (60%), and, in 30% of cases, infection of the tumor clone by EBV.[53] [188] The EBV-encoded antigens LMP-1 and EBNA-2 are not expressed by AIDS-BL.[55] [225] In addition to genetic lesions and EBV infection, stimulation and selection by antigens, frequently represented by autoantigens, appear to be a prominent feature of AIDS-BL. [90] [91] [107] [223] One puzzling feature of AIDS-BL is that AIDS is the only immunodeficiency syndrome associated with this type of lymphoma. In fact, patients affected by other types of immunodeficiency syndromes, such as congenital or iatrogenically induced immunodeficiencies, do have a high relative risk of NHL development, but these NHL

TABLE 66-2 -- Clinical and Biological Heterogeneity of AIDS-NHL

Histology[a]	Occurrence[b]	Immunodeficit	Predominant Genetic Lesion	EBV		HHV-8 Infection
				Infection	LMP-1 Status	
AIDS-BL	Early	Mild	c-*MYC*	30%		
AIDS-DLCL						
AIDS-LNCCL	Late	Marked	*BCL*-6	30%		
AIDS-IBLP	Late	Marked	?	90%	+	
AIDS-PCNSL	Late	Very marked	?	100%	+	
AIDS-PEL	?	Marked	?	90%		100%

[a]AIDS-BL, AIDS-related Burkitt lymphoma; AIDS-DLCL, AIDS-related diffuse large cell lymphoma; AIDS-LNCCL, AIDS-related large noncleaved cell lymphoma; AIDS-IBLP, AIDS-related immunoblastic lymphoma plasmacytoid; AIDS-PCNSL, AIDS-related primary central nervous system lymphoma; AIDS-PEL, AIDS-related primary effusion lymphoma.
[b]Time of lymphoma occurrence since HIV infection.

are consistently B-DLCL or PCNSL, and not BL. In this respect, it is intriguing that AIDS-BL may also develop in the presence of relatively normal numbers of CD4 cells.

AIDS-DLCL display several genotypic differences compared to AIDS-BL.[86] [104] [107] [223] First, the most frequent genetic alteration detected in AIDS-DLCL is infection by EBV, which occurs in approximately 6070% of the cases and associates frequently, though not always, with expression of LMP-1. [53] [55] [225] Second, AIDS-DLCL displays rearrangements of *BCL*-6 in 20% of cases.[224] Mutations of *BCL*-6 5 noncoding regions occur in 70% of AIDS-DLCL.[188] AIDS-DLCL can be segregated into two distinct histogenetic categories based on the expression pattern of the *BCL*-6 protein: the CD138/syndecan-1 antigen and the EBV-encoded LMP-1. [55] [226] AIDS-DLCL associated with the *BCL*-6^{+} /syndecan-1 /LMP-1 phenotype tend to display a LNCCL morphology and closely reflect the phenotype of GC B cells. [55] [226] Conversely, *BCL*-$6^{/}$ syndecan-1^{+} /LMP-1^{+} AIDS-DLCL are morphologically IBLP and reflect a post-GC stage of B-cell differentiation. [55] [226]

All AIDS-PCNSL harbor EBV infection.[56] [227] However, only a fraction of AIDS-PCNSL, namely those with IBLP morphology, express the LMP-1 transforming protein of EBV.[56] Both systemic AIDS-DLCL and AIDS-PCNSL may be divided into two phenotypic categories, based on the expression pattern of *BCL*-6, syndecan-1, and LMP-1.[56] Apart from EBV infection, AIDS-PCNSL are also characterized by mutations of *BCL*-6 in 60% of cases.[56] Although some reports have suggested that HHV-8 may be related to PCNSL pathogenesis in immunocompromised patients, extensive analysis of AIDS-PCNSL has unequivocally ruled out this hypothesis. [56] [228]

The last type of AIDS-NHL that has been characterized at the molecular level is primary effusion lymphoma (PEL), also termed body cavity-based lymphoma. [59] [60] [61] [62] [229] This is a novel lymphoma characterized by HHV-8 infection and clinically presenting as effusions in the serosal cavities of the body (pleura, pericardium, and peritoneum) in the absence of solid tumor masses.[59] [60] [61] [62] [229] PEL is consistently derived from B cells that reflect a pre-terminal stage of B-cell differentiation. [55] [60] [61] [62] [229] [230] Infection of the tumor clone by HHV-8 occurs in 100% of cases and is a sine qua non for diagnosis of the disease. [59] [60] [61] [104] [107] [223] [229] In addition to HHV-8, cases of PEL frequently carry co-infection of the tumor clone by EBV. [55] [60] [61] [104] [107] [223] [229]

Post-transplant Lymphoproliferative Disorders

Post-transplant lymphoproliferative disorders (PTLPD) are a major cause of morbidity and mortality among transplant recipients. [102] [103] [106] [231] [232] The occurrence of

PTLPD depends substantially upon the type, degree, and duration of immunosuppressive therapy administered. PTLPD frequently involve multiple sites in the same patient, are characterized by frequent extranodal location, and have a rapid course and a high mortality rate. [231] [232] [233] [234] [235] The precise histologic classification of PTLPD is a matter of current debate.[235] It is generally agreed that PTLPD are highly pleomorphic proliferations of large cells frequently resembling immunoblasts. [105] [106] [233] [235] Upon reduction of immunosuppressive therapy, a fraction of PTLPD will regress, questioning the truly malignant nature of the disease. [105] [106] [233] [235]

Because PTLPD are virtually always derived from B cells, immunogenotypic studies of Ig genes have allowed the definition of their clonality status. [106] [233] [234] [236] Many PTLPD are monoclonal B-cell proliferations. Multiple, separate PTLPD from different sites in the same patient, even when arising in the same organ, may display different Ig gene rearrangement patterns. A fraction of PTLPD is constituted of oligo- or polyclonal proliferations throughout the entire course of the disease.[233] [234] [235] [236] Molecular genetic analysis has established that PTLPD of organ transplant recipients are generally of host origin. [237] Conversely, PTLPD arising after allogenic bone marrow transplantation originate from donor cells. [106] Defining the donor-versus-recipient origin of PTLPD is a fundamental requirement in view of the progressively larger clinical use of adoptive immunotherapy strategies based on infusion of cytotoxic T-lymphocytes directed against EBV antigens expressed by PTLPD.[238]

The molecular pathogenesis of PTLPD is poorly understood. In virtually all PTLPD, there is evidence of EBV infection as demonstrated by expression of LMP-1 and EBNA-2.[106] [233] [234] [236] Monoclonal PTLPD generally display a monoclonal pattern of EBV infection, whereas oligo- and polyclonal PTLPD are associated with polyclonal infection by the virus. Mutations of *p53* and N-*RAS,* as well as rearrangements of *BCL*-6 and c-*MYC,* have been reported in scattered cases of PTLPD characterized by a monoclonal proliferation pattern, but are absent in oligo- and polyclonal PTLPD. [106] [233] [234] [236] Overall, oligo- and polyclonal PTLPD are generally regarded as lymphoproliferative disorders solely driven by EBV in the context of immunodeficiency. The genotypic nature of PTLPD has been proposed to influence the disease prognosis.[106] [233] [234] [236] Monoclonal PTLPD cases containing genetic lesions other than EBV infection usually progress in spite of reduced immunosuppression. Conversely, oligo- or polyclonal PTLPD devoid of genetic lesions may regress by simply decreasing the level of immunosuppression.

T-Cell Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma (ALCL) is a specific category of T-cell NHL composed of large pleomorphic cells that usually express the CD30 antigen. [1] ALCL is characterized by frequent cutaneous and extranodal involvement. [1] Conventional karyotypic analyses of ALCL cases have shown a unique translocation involving bands 2p23 and 5q35 in a substantial fraction of ALCL cases. [21] The cloning of the t(2;5)(p23;q35) translocation has demonstrated that it involves the fusion of the nucleophosmin/B23 (*NPM*) gene on 5q35 to a novel anaplastic lymphoma kinase (*ALK*) on 2p23.[239] As a consequence of this translocation, the *NPM* and *ALK* genes are fused to form a chimeric transcript that encodes a hybrid protein (p80) in which the aminoterminus of *NPM* is linked to the catalytic domain of *ALK*.[239] Two distinct oncogenic effects are thought to be caused by the t(2;5) translocation. First, the *ALK* gene, which is not physiologically expressed in normal T lymphocytes, undergoes heterologous expression in lymphoma cells, conceivably because of its juxtaposition to the promoter sequences of *NPM,* which are physiologically expressed in T cells. Second, based on the activation model of other tyrosine kinase oncogenes, one would predict that the truncated *ALK* constitutively phosphorylates intracellular targets to trigger malignant transformation.

The pathogenic role of *NPM/ALK* rearrangements is supported by studies in vitro and in vivo. First, overexpression of p80 in in vitro models induces neoplastic transformation of target cells, substantiating the notion that the p80 kinase is in fact aberrantly activated. [29] Second, retroviral-mediated gene transfer of *NPM/ALK* in vivo causes T-cell lymphoid malignancies in mice. [30] In such animal models, *NPM/ALK* selectively transforms lymphoid cells of T-cell origin, whereas the growth properties of other hematopoietic cells remain unaffected. [30]

The distribution of *NPM/ALK* rearrangements throughout the spectrum of NHL is highly selective, being virtually restricted to T-cell lineage ALCL. [240] [241] [242] Within this category, *NPM/ALK* rearrangements seem to be preferentially associated with cases occurring during childhood (88% positivity), although they are also detected in a large fraction of adult cases (60%). [240] [241] [242] Despite initial suggestions, *NPM/ALK* rearrangements are consistently negative in HD. [240] [242]

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is associated with HTLV-I infection of the tumor clone in 100% of cases. [72] [73] The

period between infection and onset of clinical disease is generally quite long, varying between 10 to 40 years. [72] [73] The pathogenetic effect of HTLV-I in ATLL appears to be due to the viral production of a *trans*-regulatory protein (*tax*) that markedly increases expression of all viral gene products and transcriptionally activates the expression of certain host genes, including IL-2 and the chain of the IL-2 receptor. [72] [73] [74] [75] [76] [77] [78] [79] [80] Indeed a property of ATLL cells is the constitutive high levels of expression of IL-2 receptors, which are known to mediate growth signals to T cells. [80]

The consistent monoclonality of ATLL, the long latency period between HTLV-I infection and the development of disease, as well as the small proportion of HTLV-I-infected individuals developing ATLL (<5% lifetime risk), have led to the notion that HTLV-I alone is not sufficient for ATLL development and that other genetic alterations may be required for the biogenesis of this disease. [72] [73] This concept has been validated by the observation that ATLL cells frequently carry *p53* mutations as well as a number of other cytogenetic abnormalities.[85] [243] On these grounds, it has been proposed that tumor development begins with an initial phase of polyclonal T-cell proliferation, conceivably mediated by the *tax*-induced overexpression of IL-2 and IL-2R. This proliferative process then predisposes the infected T-cell population to the accumulation of additional genetic events leading to the monoclonal outgrowth typical of ATLL patients.

T-Cell Prolymphocytic Leukemia

T-cell prolymphocytic leukemia (T-PLL) frequently carries cytogenetic abnormalities of chromosome 11, the most common abnormalities being monosomy 11, partial or terminal deletions of 11q, and unbalanced translocations involving the 11q arm. [21] The gene relevant to these abnormalities has been recently identified and has been shown to correspond to *ATM* (for *ataxia teleangectasia mutated*), a gene that is also responsible for the hereditary disorder ataxia-teleangectasia. [41] [244] [245] Whereas *ATM* is mutated in the germline of ataxia-teleangectasia patients, it is altered somatically in cases of T-PLL. [244] [245] Mutations of *ATM* in T-PLL associate with deletion of the other allele and lead to the absence, premature truncation, or alteration of the *ATM* gene product, consistent with the inactivation model of tumor suppressor genes.[244] [245] Substantial evidence suggests that *ATM* might be involved in cell cycle regulation and DNA repair, which in fact have been shown to be defective in cells with biallelic *ATM* inactivation.[41]

CLINICAL IMPLICATIONS OF GENETIC LESIONS OF NON-HODGKIN LYMPHOMAS

The use of genetic lesions as clinical tools has been well-established in at least three settings. First, genetic lesions integrate morphologic and immunohistochemical diagnosis of lymphoma. Second, genetic lesions may allow follow-up of minimal residual disease by highly specific and highly sensitive technologies. Third, genetic lesions may provide the rationale for designing novel therapeutic strategies directly aimed at correcting the molecular defect of the lymphoma.

Genetic lesions may serve as markers for NHL diagnosis because of their selective association with specific clinicopathologic categories of lymphoma. Examples include the selective association between rearrangements of *BCL*-1/cyclin D_1 and MCL, *BCL*-6 and B-DLCL, c-*MYC* and BL, and *NPM/ALK* and $CD30^+$ T-cell ALCL, as well as HHV-8 infection and PEL. [1] [229] The use of genetic markers may be particularly valuable in classifying traditionally difficult cases displaying doubtful morphologic features. Thus, for example, the detection of *BCL*-1/cyclin D_1 activation in non-follicular small-cell NHL is considered the most specific indicator in the diagnosis of MCL. [132] Similarly, infection by HHV-8 is the most reliable marker of PEL in the differential diagnosis of lymphomatous effusions. [229] The widespread use of molecular diagnostics for NHL is likely to substantially refine classification of these disorders. Ideally, NHL should be grouped into homogeneous categories displaying the same pattern of molecular lesions. At the same time, some genetically distinct NHL categories may represent distinct diseases that may require distinct therapeutic options. The REAL classification represents a major advance toward this aim, and all future proposals for NHL classification should consider tumor genotype among the leading criteria for diagnosis. [1] Furthermore, it is conceivable that advanced cytogenetic techniques, such as fluorescent in situ hybridization (FISH) and comparative genomic hybridization (CGH), may reveal novel genetic alterations of lymphoma, which will help further refine future lymphoma classifications.

The second well-established application of molecular diagnosis to NHL management relies on the fact that genetic lesions constitute a specific and sensitive marker for evaluation of minimal residual disease. At present, the availability of PCR strategies for large-scale analysis of minimal residual disease is restricted to rearrangements of *BCL*-1, *BCL*-2, and *NPM/ALK.* [246] The development of routine PCR assays for rearrangements of *BCL*-6 and c-*MYC* is in progress. Several factors account for the difficulties in developing PCR assays for minimal residual disease evaluation in NHL as compared to acute leukemias, such as the lack of chromosomal clustering in many NHL translocations (e.g., c-*MYC* translocations) and/or the heterogeneity of chromosomal partners juxtaposing the involved oncogene (e.g., *BCL*-6 translocations).

In addition to the contribution to the diagnosis and molecular follow-up of lymphomas, the study of the molecular pathogenesis of these disorders may provide other potential applications in the future. One such application lies on the fact that subtle differences in the tumor genotype may influence the prognosis of NHL belonging to the same histologic category. [114] [247] [248] A further implication is the possibility of developing therapeutic strategies targeted at the very genetic lesions that are responsible for tumor development. Such therapy should, by definition, be largely specific for the lymphoma cells, and hence devoid of the major side effects presently encountered with antineoplastic therapy. Preliminary reports from in vitro studies do substantiate the validity of gene targeting in controlling the tumorigenic behavior of NHL. [155] [218] [249]

Chapter 67 - Pathology and Histogenesis of Hodgkin Disease

Marshall E. Kadin

The nature of the Reed-Sternberg (RS) cell and the cellular origin of Hodgkin disease (HD) have been an enigma for more than 150 years. Some authorities have doubted that HD represents a malignant process, in part because of its variable clinical behavior and multiple histologic types. Recent progress in immunology, cell culture, and the molecular biology of isolated RS cells has helped identify the RS cell as a part of the malignant cell population. The remaining cell types, which comprise the bulk of the HD lesion, appear to represent a combination of RS cell precursors, host inflammatory cells, and cells recruited to the site in response to cytokines liberated by RS cells. Somehow the mixture of these cell types and stromal elements determines the natural history of HD, thereby influencing the treatment and prognosis of the disease. This chapter re-evaluates the

morphologic hallmarks of HD in light of new knowledge about the RS cell and its cellular immunology. Immunopathologic methods for the more accurate diagnosis of HD are emphasized. Recent information regarding the role of Epstein-Barr virus (EBV) in HD is presented. Finally, cytogenetic abnormalities and non-Hodgkin lymphomas (NHL) associated with HD are discussed in the context of the histogenesis of HD.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

HISTOPATHOLOGY

The histopathology of HD is more complex and variable than that of the NHL. To simplify the histopathologic interpretation of HD and make it clinically relevant, Lukes et al[1] formulated a histopathologic classification of HD based on six different types: (1) lymphocytic or histiocytic (L&H), nodular; (2) L&H, diffuse; (3) nodular sclerosis; (4) mixed cellularity; (5) diffuse fibrosis; and (6) reticular (cellular) types. At the Rye conference on HD, [2] the nodular and diffuse subtypes of L&H were included under a single heading of lymphocyte predominance type; the diffuse fibrosis and reticular types were combined under the heading of lymphocyte depletion. In 1989, Wright[3] argued that clinicopathologic correlations since the late 1960s justify a return to the subtypes of HD proposed originally by Lukes and co-workers.

Recently, hematopathologists have noted that lymphocyte predominance HD includes two major types, one corresponding to the original lymphocyte predominance nodular type that contains L&H variants of RS cells, and a second type corresponding to lymphocyte-rich classic HD; in this latter, lymphocyte-rich type, the RS cells and natural history more closely resemble those of mixed cellularity and nodular sclerosing types. [4]

A definite relationship among histologic types, clinical stages, and survival has been demonstrated. [1] Nodular sclerosis is associated with a good prognosis and a marked propensity to involve the mediastinum, and is often limited to stage I or II disease. Lymphocyte predominance, nodular, has an excellent prognosis and is commonly restricted to localized stage I disease in the neck or inguinal areas. Lymphocyte predominance, diffuse, also has a strong tendency for presentation with limited-stage disease and a recurrence rate that may be significantly lower than that for patients with a nodular histologic type, when strict morphologic and immunophenotypic criteria are used for diagnosis. [5] Lymphocyte depletion has a poor prognosis and usually presents with advanced stage III or IV disease and a high frequency of bone marrow and abdominal lymph node disease. Some cases originally classified as lymphocyte depletion type, on review with immunohistochemical studies, have been reclassified as large cell lymphoma, which may account for their poor outcome. Nevertheless, there remain cases with numerous RS cells or diffuse fibrosis, particularly in older male patients or immunosuppressed patients, including those with human immunodeficiency virus (HIV) infection, which are bona fide HD. Mixed cellularity has an intermediate prognosis, commonly presenting with abdominal disease and relatively infrequently being associated with mediastinal disease.

These relationships were confirmed and extended in a study of 719 patients with HD who underwent staging laparotomy with splenectomy between April, 1969 and December, 1986 at the Harvard Joint Center for Radiation. Mauch et al[6] showed that the mediastinum and left and right sides of the neck are the most common sites of involvement in patients with nodular sclerosis or mixed cellularity types, each site being involved in 60% of cases. By contrast, the mediastinum was involved in only 8% of patients with lymphocyte predominance. Nodular sclerosis and mixed cellularity appeared to spread by contiguity, whereas lymphocyte predominance was limited to one site of involvement in approximately 50% of patients and was least likely to spread in a contiguous fashion.

A review of 9,418 microscopically confirmed HD cases accessioned from 1973 to 1987 by the Surveillance, Epidemiology and End Results (SEER) program of the National Cancer Institute revealed a dramatic increase in the incidence of nodular sclerosis, particularly in adolescents and young adults, whereas mixed cellularity remained stable. The incidence of HD in the elderly decreased, most likely because of improved ability to recognize many cases of NHL that would have been misclassified as HD.[7]

Histologic Types

Nodular Sclerosis

In most series, nodular sclerosis is the most frequent type of HD [1] [6] [7] [8] [9] (Plate 67-1). It is characterized by interconnecting, dense bands of collagen that circumscribe abnormal lymphoid nodules. As a result, the cut surface of lymph nodes show tan nodules of lymphoid tissue bulging out from gray-white connective tissue. This gross appearance should lead to a high suspicion of nodular sclerosing HD, which can sometimes be confirmed in the surgical suite by demonstrating RS variants in touch imprints of the lymph node. In permanent tissue sections stained with hematoxylin and eosin, eosinophilic collagen bands of varying width surround blue lymphoid nodules, a pattern that can be recognized with the naked eye by holding the slide up to the light. The collagen is birefringent in polarized light, which may aid in its recognition and quantitation. It appears to emanate from a thickened capsule or from the adventitia of blood vessels, or both. [1] [8] Microscopically, there are large spaces around the RS variants, called lacunar cells. The lacunar artifact, best seen in formalin-fixed tissue, results from retraction of cytoplasm of the RS cells from surrounding tissues (Plate 67-1). The lacunar cells appear distinctive by virtue of pale, sometimes transparent cytoplasm and relatively small nuclei and nucleoli compared with diagnostic RS cells. The nucleoli may be basophilic, in contrast to the eosinophilic nucleoli of RS cells. Lacunar cells may have one, two, or many nuclear lobes. Usually only an occasional lacunar cell closely resembles an RS cell.

The amount of collagen sclerosis may vary considerably from marked (visible to the naked eye) to minimal, in which case the diagnosis is suspected mainly from the presence of distinctive lacunar cells. This latter type, with minimal or absent sclerosis, has been referred to as the cellular phase of nodular sclerosis. [8] [10] The frequent finding of typical sclerotic lesions elsewhere in the same patient seemed to justify recognition of the cellular phase as part of the spectrum of nodular sclerosis.[8] This concept was supported by the study conducted by Strum and Rappaport,[11] who observed progression from the cellular phase to advanced sclerosis in serial biopsies from five of seven patients. Colby et al [9] found that patients with the cellular phase of nodular sclerosis had clinical features and overall survival rates similar to those of patients with mixed cellularity HD, but a relapse-free survival rate similar to that of nodular sclerosis patients. Recognizing that sampling sometimes demonstrates lymph node involvement in the cellular phase without collagen bands, Lukes [10] recommended that for reproducibility, the diagnosis of nodular sclerosis should be made only when the two criteria of collagen band formation and lacunar cells are met.

Colby et al[9] described a fibroblastic variant of nodular sclerosis. They found the number of fibroblasts to be prognostically more significant than the number of lymphocytes; numerous fibroblasts correlated with a shorter relapse-free survival. This grading system is not in widespread use. Dorfman [12] has indicated that mediastinal biopsies from patients with the fibroblastic variant of nodular sclerosis may be misinterpreted as malignant fibrous histiocytoma.

In 1986, Strickler et al[13] described a syncytial variant of nodular sclerosis in which cohesive clusters or sheets of RS cells are

found (Plate 67-2). Syncytial foci may be found anywhere in the node, but often occur in interfollicular areas and in the trabecular sinuses of the lymph node. The atypical HD giant cells often surround zones of necrosis and may be associated with numerous granulocytes. This histologic picture may be mistaken for metastatic carcinoma, malignant melanoma, thymoma, and large cell NHL.[10] The distinction of nodular sclerosing HD can be confirmed by immunophenotypic studies, as described later in this chapter.

The British National Lymphoma Investigation (BNLI) recognized that within the spectrum of nodular sclerosis there is wide variation in the relative numbers of

pleomorphic HD giant cells and small lymphocytes.[14] The BNLI subclassified nodular sclerosis into grades I and II; grade II shows areas of lymphocyte depletion or numerous pleomorphic HD giant cells. Grade II, which accounts for 2030% of all cases of nodular sclerosis, has a significantly worse prognosis than that of grade I. The prognostic significance of this grading of nodular sclerosis has been confirmed in a multivariate analysis. [15] Patients with nodular sclerosis grade I who relapse have a more successful salvage and longer period of survival than do patients with grade II nodular sclerosis. [16] Histologic subclassification of nodular sclerosis therefore appears to be clinically relevant and important in planning therapy. Subclassification of nodular sclerosis into grades I and II was found to be reproducible at a rate of 81.6% by a panel of 4 experienced pathologists reviewing biopsy results of more than 1,000 patients in the German National Trial on Hodgkin disease. [17]

Nodular sclerosis occurs most often in women, a predilection that is present across all age groups. The prognostic advantage of nodular sclerosing HD is largely restricted to patients in clinical stages I and II. There is no survival advantage of patients with nodular sclerosis in stages III and IV, with the possible exception of patients with stage IV disease on the basis of contiguous spread to the lung or anterior chest wall. [18]

Lymphocyte Predominance

Lymphocyte predominance occurs in both diffuse and nodular forms[1] (Plates 67-3 and 67-4). The cut surface of the lymph node has a diffuse or faintly nodular fish-flesh appearance. Both nodular and diffuse types consist primarily of small lymphocytes and of benign epithelioid histiocytes. Other cellular elements, such as eosinophils and plasma cells, are rare or absent. Necrosis and fibrosis are also negligible, and diagnostic RS cells are rare (Plate 67-3). There are, however, distinctive variants of RS cells, which have large folded, twisted, or multilobated nuclei and relatively small nucleoli (Plate 67-4). These variants of RS cells have become known as L&H cells or, because they resemble popcorn, as popcorn cells. L&H/popcorn variants are sufficiently distinctive that some authorities rely on their appearance to make a diagnosis of HD with lymphocyte predominance (LPHD) in the absence of diagnostic RS cells.

Because of the rarity of diagnostic RS cells, the diffuse form of LPHD can be mistaken for well differentiated lymphocytic lymphoma or chronic lymphocytic leukemia.[10] When histiocytes predominate, the differential diagnosis includes lymphoepithelioid lymphoma (Lennerts lymphoma) and granulomatous inflammation. Lennerts lymphoma can be distinguished by a spectrum of atypical lymphoid cells and clustering of histiocytes. Diffuse LPHD differs from nodular LPHD mainly in having a much smaller amount of follicular dendritic cells. [19] Granulomatous inflammation is often accompanied by necrosis not found in LPHD. In nodular LPHD, epithelioid histiocytes may be numerous within the nodules or surrounding them in a wreathlike arrangement. The diagnosis of LPHD is made when there are L&H/popcorn variants of RS cells. LPHD can occasionally present at extranodal sites, particularly Waldeyers ring, spleen, liver, or bone marrow; in such instances, confusion with low-grade NHL or T-cell-rich B-cell lymphoma may occur. [20]

Nodular LPHD is often found in association with progressively transformed germinal centers (PTGC) [21] [22] [23] [24] (Plate 67-5), which occur in follicular hyperplasia when secondary follicles become large and the border between the germinal center and lymphocytes of the mantle zone becomes indistinct. In PTGC, the small lymphocytes of the mantle zone appear to infiltrate and gradually overrun the germinal centers. PTGC may precede, follow, or coexist with nodular LPHD, but the condition is not sufficient for a diagnosis of LPHD. [23] [24] It is essential that the diagnosis of nodular LPHD not be made unless diagnostic RS cells or their L&H/popcorn variants, or both, are found in some of the lymphoid nodules. Indeed, the only difference between PTGC and the nodules of nodular LPHD is the absence of L&H/popcorn cells in PTGC.[25]

Regula et al[26] emphasized clinical differences between the nodular and diffuse subtypes of LPHD. Patients with the diffuse form tend to have a course similar to that of the mixed cellularity and nodular sclerosing types of HD. By contrast, patients with nodular LPHD have significantly more relapses, independent of stage or treatment and occurring continuously for many years after initial therapy. Trudel et al [27] noted differences in the clinical presentations of diffuse and nodular LPHD: nodular LPHD usually involves a single anatomic site, whereas the diffuse form often presents with more extensive disease. These differences were not confirmed when immunophenotypic criteria were used to confirm the diagnosis of the diffuse type.[5]

Nodular LPHD sometimes progresses to large cell NHL.[21] , [28] [29] [30] Miettenen et al[28] reported that 5 of 51 patients with nodular LPHD acquired large cell NHL 411 years after the diagnosis of nodular LPHD, and that only 1 of these patients had received radiation therapy. Hansmann et al [29] observed the simultaneous presence of (n = 11) or subsequent transition into (n = 3) a large B-cell lymphoma in 14 nodular LPHD cases. Retrospective follow-up of these secondary large cell lymphomas in patients with nodular LPHD revealed a longer survival time than that of primary B-type large cell lymphomas and other secondary large cell lymphomas. Sundeen et al[30] described seven cases of nodular LPHD in which mononuclear (L&H) RS cell variants occurred in large confluent sheets resembling large cell lymphoma. These findings were interpreted as histologic progression of nodular LPHD, with uncertain biologic significance. Six of these patients were in complete remission after radiation or chemotherapy, suggesting a good prognosis for large cell lymphomas occurring in patients with LPHD.

In a study of 2,836 cases of LPHD, the German Hodgkin Study Group found that immunohistochemistry disproved the expert panels morphologic diagnosis of LPHD in 25 of 104 cases. Moreover, 13 cases originally not classified as LPHD had an LPHD-like immunophenotype. Immunohistochemically confirmed LPHD cases showed a significantly better freedom from treatment failure and survival than classic HD ($P = 0.033$). Significance of survival for LPHD cases improved from $P = 0.047$ (morphologic classification) to $P = 0.0071$, when classified by immunohistochemistry. The authors concluded that immunohistochemical analysis should be mandatory for HD biopsies suspected of being LPHD when a modified therapy protocol, different from that used for classic HD, is used to treat LPHD. [31]

Lymphocyte Depletion

Lymphocyte depletion HD includes two major types: diffuse fibrosis and reticular[1] (Plate 67-6). Both types are characterized by a depletion of lymphocytes, and focal necrosis is common. The diffuse fibrosis type is characterized by amorphous proteinaceous material or disorderly fibrils without mature birefringent collagen, or both, whereas the reticular type shows numerous diagnostic RS cells (Plate 67-6) or RS cell variants of the

pleomorphic and sarcomatous types. When the pleomorphic variants predominate, the process may be mistaken for a poorly differentiated nonlymphoid neoplasm. A morphologic distinction between the reticular type of lymphocyte depletion HD and Ki-1 (CD30)+ anaplastic large cell lymphoma (ALCL) can be difficult and is aided by application of immunohistochemical techniques. [32] [33]

Neiman et al[34] noted that 13 patients with lymphocyte depletion had a distinctive clinicopathologic syndrome of rapidly fatal disease with fever, pancytopenia, lymphocytopenia, and abnormal hepatic function, often without peripheral lymphadenopathy. In patients with the diffuse fibrosis type, the diagnosis was commonly made by bone marrow examination, at laparotomy, or at autopsy. Patients with the reticular type more often had peripheral lymphadenopathy. Lymphocyte depletion HD is predominantly subdiaphragmatic, with extensive involvement of liver, spleen, retroperitoneal lymph nodes, and multiple bone marrow sites, often accompanied by bone marrow hypoplasia and pancytopenia. Thus, multiple bone marrow biopsies and liver biopsies can frequently establish the diagnosis of lymphocyte depletion HD.

Bearman et al[35] found no clinical or survival differences between reticular and diffuse types of lymphocyte depletion HD. However, Greer et al [36] reported that patients with diffuse fibrosis more often had bone marrow involvement and less frequently had peripheral lymphadenopathy than patients with the reticular type. Among patients who received chemotherapy, median survival was longer for patients with diffuse fibrosis.

Kant et al[37] found that of 39 patients treated for lymphocyte depletion HD at the National Cancer Institute between 1964 and 1976, 10 actually had large cell NHL and 13 had nodular sclerosing HD. Only 3 of 10 patients with NHL experienced complete remissions, and their median survival was only 7 months. Complete remissions were attained by 67% and 85% of patients with lymphocyte depletion and nodular sclerosing HD, respectively, and the median survival had not been reached in either group with a median follow-up of 14 years. These results suggest that more accurate diagnosis and classification of HD is needed not only for proper care of individual patients but for accurate analysis of new treatment protocols.

Mixed Cellularity

Mixed cellularity is the second most common histologic type of HD and shows a relatively high frequency of abdominal involvement. [6] [38] Reactive histiocytes, eosinophils, neutrophils, plasma cells, and small lymphocytes are numerous, and small foci of necrosis are common. Among the benign cellular elements are numerous diagnostic RS cells (Plate 67-7). In diffusely involved lymph nodes, the architecture is usually obliterated, and the capsular and subcapsular sinuses are compressed. In focally involved lymph nodes the sinuses may remain patent. Mixed cellularity HD comprises a heterogeneous histologic group representing the

center of a spectrum of lesions whose appearance ranges from that of lymphocyte predominance on one extreme to that of lymphocyte depletion on the other. Lukes[10] intended mixed cellularity also to serve as a catch-all classification for those lesions that lack typical features of the remaining types. For example, HD in which lymph nodes are focally or partially involved and lack characteristics of nodular sclerosis are included in the mixed cellularity type. A morphologic variant of mixed cellularity with numerous epithelioid histiocytes has been described. [39] Awareness of this morphologic variant helps to distinguish it from lymphoepithelioid (Lennerts) lymphoma, angioimmunoblastic T-cell lymphoma, and granulomatous inflammation.

Reed-Sternberg Cells

Diagnostic RS cells have two or more nuclear lobes and huge, inclusion-like nucleoli (Plate 67-8). The classic RS cell has a symmetric mirror-image nucleus. Other RS cells have multiple separate nuclei or an elongated and often twisted nucleus, which, when cut in thin tissue sections, simulates a multinucleated cell. Some RS cells are truly multinucleated. RS cell nucleoli are of relatively uniform density and eosinophilic to amphophilic in staining quality. Nuclear chromatin is condensed to the nuclear membrane, resulting in a clear halo around the nucleolus. The cytoplasm is variable in appearance but is usually abundant and eosinophilic to amphophilic in staining quality.

Reed-Sternberg cell variants are associated with the different histologic types of HD (see Table 67-1 and Plates 67-1 , 67-4 , and 67-6). The L&H/popcorn variant is characteristic of the lymphocyte predominance type, the lacunar variant is typical of nodular sclerosis, and the pleomorphic or sarcomatous variant is found in lymphocyte depletion.

In general, the number of diagnostic RS cells is inversely proportional to the number of small lymphocytes; hence, diagnostic RS cells are rare in lymphocyte predominance, frequent in lymphocyte depletion, and easily found in mixed cellularity types. In nodular sclerosis, the number of diagnostic RS cells is quite variable and may be low. This is rarely a problem for diagnosis, because lacunar variants in a background of collagen sclerosis are virtually diagnostic of nodular sclerosis HD.

Diagnostic Problems

Because of wide variation in the character and frequency of RS cells, HD may sometimes be confused with benign lymphadenopathies,

TABLE 67-1 -- Summary of Morphology and Phenotype of Reed-Sternberg Cells in Different Histologic Types of Hodgkin Disease

Histologic Type	Reed-Sternberg Cell Variant	Appearance	Pattern	Phenotype
Mixed cellularity	Classic	Bilobed or multilobed nucleus, huge, inclusion-like, eosinophilic nucleoli	Diffuse or interfollicular	CD30+, CD15+, CD45
Nodular sclerosis	Lacunar cells	Pale, retracted cytoplasm	Nodular with collagen bands	CD30+, CD15+, CD45
Lymphocyte predominance	Popcorn cells	Wrinkled, twisted nuclei, small nucleoli	Nodular, rarely diffuse	CD30+/, CD15, CD45+, CD20+, EMA+
Lymphocyte depletion	Sarcomatous	Pleomorphic hyperchromatic nuclei, nucleoli often indistinct	Diffuse with fibrosis	CD30+, CD15+, CD45

with NHL, and even with epithelial and soft tissue malignancies. [9] , [40] ,[41] Lukes et al[40] reported cells indistinguishable from RS cells in infectious mononucleosis. Strum and Rappaport[41] expanded the list of conditions containing RS-like cells to include rubeola, myositis, thymoma, anticonvulsant-induced lymphadenopathy, carcinomas of the lung and breast, malignant melanoma, malignant fibroxanthoma, and various hematopoietic neoplasms. Colby et al [9] added angioimmunoblastic lymphadenopathy, toxoplasmosis, and malignant histiocytosis to the list of disorders mimicking HD.

Coppleson et al[42] found a high degree of interobserver and intraobserver disagreement in the histologic classification of HD. These investigators recommended the use of a panel of pathologists for the reproducible classification of HD.

In an expert hematopathology panel review of initial diagnostic material from a Southwest Oncology Group trial of advanced HD, Miller et al [43] found that 13% of 287 cases had been misdiagnosed as HD. The most common error was to confuse other malignant lymphomas with HD (14 of 21 patients), particularly in the case of large cell lymphomas with pleomorphic features and RS-like cells. Lennerts lymphoma and angioimmunoblastic lymphadenopathy were also confused with HD. Mixed cellularity and lymphocyte depletion HD were the types most frequently diagnosed incorrectly (14 of 21), and nodular sclerosis was least frequently mistaken for other disorders (2 of 21). One of the two patients mistakenly diagnosed as having nodular sclerosing HD actually had a sclerosing carcinoma; the other had a dermatopathic lymphadenopathy with multinucleate cells, which on review were found not to be RS cells. Atypical clinical presentations, particularly unusual extranodal sites of disease, characterized the group most often incorrectly diagnosed as HD. Overdiagnosis of HD is particularly common in elderly patients. [44]

Should We Continue to Subclassify HD?

Advances in treatment have diminished the earlier prognostic significance of the histologic subtypes of HD, and the question has been raised: Should we bother subclassifying HD?[45] For now, the answer seems to be yes. Histologic classification continues to identify subcategories at greater or lesser risk of relapse. Classification also helps to predict the most likely sites and extent of disease, and in so doing influences decisions about staging and therapy. Correlations of HD histology with new biologic markers will likely provide new insights into the etiology and pathophysiology of HD.

Pathologic Staging

Improved therapy protocols have placed greater emphasis on more accurate staging of HD. Staging considerations include recognition of early or focal involvement of abdominal lymph nodes, distinction of HD from nondiagnostic granulomas, and recognition of HD in the spleen and at extranodal sites, usually the liver and bone marrow.[46] In addition, HD may present at unusual extranodal sites such as the skin in patients with acquired immunodeficiency syndrome (AIDS), and at various sites, including body fluids, in patients who relapse from HD.

Clinically occult lymph node involvement is most often found in splenic hilar and celiac lymph nodes. [8] [38] Early microscopic involvement of abdominal lymph nodes typically occurs in the interfollicular areas (Fig. 67-1), where it resembles the pattern described as interfollicular HD, sometimes encountered in initial biopsy specimens.[47] At least one diagnostic RS cell or variant thereof should be found before a staging lymph node is considered to be involved by HD. Occasionally, prominent immunoblasts in a perifollicular location may cause confusion with HD.

Splenic involvement almost always is apparent on gross inspection of the spleen sliced at thin (34-mm) intervals. The number of splenic nodules should be noted because patients with five or more nodules may have a more unfavorable prognosis. [48] Splenic lesions begin in the white pulp and appear as more prominent than usual malpighian corpuscles. Microscopically, the lesions of HD are first evident near the central artery in the periarterial lymphatic sheath [49] (Plate 67-9). Usually inflammatory cells are increased; patients with nodular sclerosis are commonly found to have bands of collagen.

Liver involvement histologically begins in the portal areas, where increased numbers of small lymphocytes, inflammatory cells, and occasional, often infrequent, HD giant cells are present. It is generally accepted that once the diagnosis of HD has been established, a mononuclear variant of the RS cell with a huge nucleolus is sufficient to confirm HD in the liver and other extranodal sites. [10]

Liver involvement almost never occurs in the absence of splenic HD, except in patients with AIDS in whom HD develops. [50]

Figure 67-1 Splenic hilar lymph node: interfollicular Hodgkin disease.

Liver function tests are poor predictors of hepatic involvement. The frequency of positive liver biopsies is doubled by performing laparotomy or peritoneoscopy after negative percutaneous biopsy.[51]

Bone marrow involvement occurs in no more than 10% of untreated patients with HD.[52] It is almost always detected in the biopsy and only rarely in the aspirate. This result is most likely due to the focal nature of bone marrow involvement and the increase in reticulum fibers in areas of HD. Bone marrow involvement is probably never recognized as isolated RS cells. Consequently, it can usually be detected at low and medium microscopic magnifications as nodular aggregates of inflammatory cells or fibrosis (Plate 67-10). RS cells or their variants may be confirmed at medium and high power (Plate 67-11). They must be distinguished from megakaryocytes, which lack large, inclusion-like nucleoli. Confirmation of the presence of RS cells may be possible by use of immunohistochemical stains that detect Ki-1 (CD30) antigen (Plate 67-12).

In a patient with HD, bone marrow fibrosis is presumptive evidence of marrow involvement by HD. Further sections of the biopsy should be made until RS cells or their variants can be found. Bone marrow fibrosis is usually not related to previous treatment, which more often causes bone marrow hypoplasia.

Isolated sarcoid-like granulomas may occur in any of the staging sites and should not be considered evidence of HD unless accompanied by RS cells. [53] These granulomas most often occur in a perivascular location (Plate 67-13). In one study, they were found to be associated with a more favorable prognosis and are thought to represent a host immune response to HD.[54] Isolated granulomas in HD seldom contain areas of necrosis, but probably should be stained for acid-fast bacilli and fungi to exclude opportunistic infection, which can occur with higher incidence in immunocompromised patients with HD than in the normal population.

HISTOGENESIS

Nature of the Malignant Cell

Origin of RS Cells from Germinal Center B Lymphocytes

Molecular genetic studies support an origin of the RS cell from crippled germinal center B lymphocytes, particularly

centroblasts. RS cells from HD tissues of 10 untreated patients were isolated and studied by polymerase chain reaction (PCR) amplification of immunoglobulin (Ig) genes by Rajewskys group.[103] Clonally related rearrangements of Ig V_H genes were found in 9 of the 10 cases of mixed cellularity and nodular sclerosis. Rearranged V_H genes from RS cells carry a high load of somatic mutations. Stop codons in some in-frame V_H gene rearrangements suggest that RS cell precursors are derived from germinal centers where they have acquired crippling mutations that prevent antigen selection, but escape apoptosis, possibly through a transforming event such as that mediated by EBV LMP1 (see following). B cells normally are selected for expression of high-affinity antibodies. Only cells that fulfill this criterion are allowed to persist and leave the germinal center to become memory B cells.[104] Because B cells that bear V_H gene rearrangements that render them nonfunctional by somatic hypermutation can occur only within the germinal center, it is likely that RS cells that carry such rearrangements originate from precursor cells that had undergone a transforming event before entry into, or within, the germinal center, enabling them to escape apoptotic death in the absence of antigenic selection. Two other groups found that RS cells could be either monoclonal or polyclonal with respect to Ig genes or X-chromosome inactivation. [105] [106]

Studies of L&H variants of RS cells in nodular LPHD are consistent with a germinal center origin for these cells as well. Sixteen cases of nodular LPHD were found to contain L&H cells with molecular features of clonal B lymphocytes. L&H cells with identically rearranged V_H genes were isolated from the same or different nodules in nodular LPHD, [107] [108] and from different lymph nodes from the same patient,[108] supporting the hypothesis that nodular LPHD is a clonal B-cell lymphoproliferative disorder.

These recent studies using single-cell PCR amplification of Ig genes are consistent with the original observation of Weiss et al, who reported that HD tissues frequently contain clonal immunoglobulin gene rearrangements.[109] The recent PCR results are also in agreement with the earlier finding that the frequency of Ig gene rearrangements detected in HD is higher in cell suspensions enriched for RS cells. [110] Thus, both earlier studies on whole HD tissues and single-cell PCR amplification of Ig genes indicate that RS cells are derived from germinal center B lymphocytes in most cases of HD.

Possible Origin of RS Cells from Other than B Lymphocytes

Several lines of evidence suggest that RS cells are not derived from germinal center B cells in all cases of classic HD. Clonal Ig rearrangements have not been found in all HD cases.[103] In 1015% of classic HD cases, RS cells express T-cell differentiation antigens (CD3, T-cell receptor-f1, CD4), [56] [57] [69] [70] [71] or protein products (granzyme B or perforin) of cytolytic T lymphocytes or natural killer cells. [72] [73] [74] RS cells also can express antigens associated with granulocytes or monocyte/macrophages.[111] [112] [113] It is possible that these antigens or cytolytic proteins are acquired from surrounding inflammatory cells in the microenvironment of RS cells. However, this hypothesis would not explain the expression of such antigens on tumor cell lines derived from HD. [114] [115] [116] [117] [118]

Some studies [58] [119] [120] [121] [122] have shown similarities between RS cells and interdigitating reticulum cells, which are antigen-presenting cells in interfollicular regions of lymph nodes. The L428 cell line has been shown to be capable of antigen presentation. [114] RS cells express antigens shared with activated interdigitating reticulum cells,[120] and both cell types have similar reactivities with CD15 antibody and peanut agglutinin. [111] Pinkus et al showed similar expression of fascin by RS cells and interdigitating reticulum cells.[58] Moreover, RS cells closely resemble interdigitating reticulum cells in their cytomorphology and location in affected lymph nodes. [58] [121] [122] Fascin expression can be induced in B cells by EBV, [123] but this does not explain the high levels of fascin expression by RS cells in cases of HD where EBV is not detected.

Delsol et al [124] hypothesized derivation of RS cells from follicular dendritic reticulum cells (FDRC). Delsol and co-workers supported this hypothesis by observations of the intimate association of RS cells with the lymph node FDRC network, expression of CD21 antigen by both FDRC and RS cells, expression of IgG Fc receptors, and the presence of polyclonal IgG and IgE in the cytoplasm of both FDRC and RS cells.

Epstein-Barr Virus

An association between EBV and HD has been suggested by epidemiologic and serologic studies that reveal an increased risk of HD in patients with a history of infectious mononucleosis, elevated EBV antibody titers, and an altered serologic pattern of antibody response to EBV, before and after diagnosis of HD. [125] EBV was first demonstrated directly in HD tissues by immunoperoxidase staining of EBV nuclear antigen in RS cells in a single case of mixed cellularity HD after a chronic EBV infection.[126] Subsequently, EBV genomes have been demonstrated in RS cells in approximately one half of HD cases.[127] [128] [129] There is evidence that EBV is clonally integrated into RS cells, which indicates that infection occurred before or at the time of malignant transformation, and thereby implicates EBV directly in the pathogenesis of these cases of HD. Using a combined approach of slot blot, Southern blot, and in situ hybridization, Weiss et al [126] and Anagnostopoulos et al[129] demonstrated monoclonality of EBV-infected cells and localization of EBV nucleic acid to RS cells and their variants. EBV is associated at highest frequency with the mixed cellularity histologic type, less often with nodular sclerosis, and only infrequently with LPHD. [130] EBV is most commonly found in HD of children and older patients, only rarely in young adults, [131] [132] and occurs at highest frequency in HD of underdeveloped countries. [133]

Reed-Sternberg cells commonly express the EBV gene product LMP1,[134] which can confer a growth advantage on these cells. [135] LMP1 up-regulates expression of both CD40 and *bcl*-2, which prevent apoptosis of germinal center cells, and this could be the transforming event that confers immortality on precursors of Hodgkin/RS (H/RS) cells in germinal centers.[136] In HD, EBV infection is more highly associated with expression of *bcl*-x, a *bcl*-2-related protein.[137] *Bax*, a cell death-inducing gene, is frequently expressed in H/RS cells, but usually is expressed together with *bcl*-2, *bcl*-x, or *mcl*-1, another antiapoptotic protein.[138] Frequent expression of *Bax* may explain the relatively good therapeutic responses usually obtained in HD.

Latent membrane protein 1 engages signaling proteins of the TNF receptor superfamily. [139] Transfection of LMP1 into cell lines promotes multinuclearity of the EBV-negative HD cell line L428, and this effect appears to be mediated by NF- B activation. [140] LMP1 is recognized by cytotoxic T cells, which normally limit the growth of EBV-infected cells.[141] This could explain the better overall survival of HD patients whose tumor cells express LMP1. [142] Somewhat unexpectedly, increased numbers of cytotoxic T cells in HD tissues, identified by expression of granzyme B and CD8, has been associated with an unfavorable clinical outcome of HD

patients.[143] This may reflect impaired ability of cytotoxic T cells in HD patients to kill H/RS cells. Frisan et al found an inverse correlation between the presence of EBV in H/RS cells and EBV-specific cytotoxic lymphocytes in HD nodes.[144] Although EBV-specific cytotoxic T cells were detectable in three EBV-negative HD cases, none of six EBV-positive cases had detectable EBV-specific cytotoxic activity. One patient with EBV-positive HD from whom peripheral blood was available had circulating EBV-specific cytotoxic T cells. These observations suggest that local factors in the lymph node environment

of H/RS cells can suppress virus-specific immunity. Indeed, T cells in patients with HD have a defect in cytolytic function associated with down-regulation of the T-cell receptor chain, possibly in response to transforming growth factor-.[145] Failure of H/RS cells to express major histocompatibility class I antigens may also contribute to defective immune surveillance by cytotoxic T cells in HD.[146] There is also evidence for a genetic defect in immunity,[147] so that HD could result from the inability of certain affected people to control an EBV infection that in others of normal immunocompetence would go unnoticed or produce only a benign syndrome of infectious mononucleosis. An exaggerated defect in T-cell immune surveillance contributes to the high frequency of advanced HD in patients with AIDS.[148] Immunotherapies with bispecific monoclonal antibodies that bridge human effector cells to H/RS cells deserve evaluation as a means to overcome the impaired immune surveillance in HD.[149]

CYTOGENETICS

Chromosome analyses of fresh HD tissue have usually revealed two populations of cells, one having a diploid modal chromosome number that is thought to represent the nonmalignant small lymphocyte population, and the other having a pseudodiploid or often hypotetraploid number that appears to represent the malignant cells. Seif and Spriggs[150] were the first to demonstrate marker chromosomes as evidence of a clone of malignant aneuploid cells in HD. Subsequent studies confirm that HD cells are usually aneuploid and frequently clonally related. [151] By use of simultaneous fluorescence immunophenotyping and interphase cytogenetic analysis, Weber-Matthiesen et al have shown that numeric chromosome abnormalities are present in CD30+ H/RS cells in all cases of HD. [152] In each case, there is considerable variability in chromosome numbers, demonstrating that karyotype instability is a characteristic of malignant cells in HD. Cytogenetic markers are consistent with a lymphocytic origin of HD. [153] The most common breakpoints found by Cabanillas et al[153] were at 11q23, 14q32, 6q11-q21, and 8q22-q24, which are also common breakpoints in B- and T-cell lymphomas. Moreover, the 11q23 breakpoint is also seen in a type of childhood B-cell acute lymphocytic leukemia characterized by the presence of aberrant myeloid and monocytic antigens, [154] a possible similarity to HD. Tilly et al [155] found that some of the chromosome regions involved in HD are shared with NHL of either B-cell (e.g., 14q32, 8q24, 6q, and 11q21-q23) or T-cell origin (e.g., 4q28, 7q31-q35, and 3q27), and demonstrated that significant differences occurred more often between HD and diffuse B-cell NHL than between HD and T-cell NHL. Schouten et al [156] found recurrent breakpoints at 4q32-q34, 6q24, 12q13, 12q23-q24, and 13p11-q13; three patients had two or more clones, and one had subclones. In HD cell lines, Fonatsch et al [157] found nonrandom marker chromosome abnormalities that are frequently associated with proto-oncogenes and other genes. Among the frequently involved sites are 1p21-p22, associated with N-*ras*, B-*lym*, and L-*myc*; 7q11.2-q36, associated with *met* and the T-cell receptor -chain gene; 11q21-q23, associated with c-*ets*1, CD3, , and epsilon chains; 14q32, associated with immunoglobulin heavy-chain gene; 15p12, associated with the nucleolus organizing region; and 21q21-q22, associated with c-*ets*2.

Rearrangement of *bcl*-2 can occur as a result of translocations involving chromosomes 14 and 18. [158] Rearrangements of the *bcl*-2 gene have been detected in approximately 40% of HD cases, and it has been suggested that these rearrangements may be involved in the pathogenesis of HD. [159] To determine whether the presence of translocations between chromosomes 14 and 18 explain the observed *bcl*-2 rearrangements in HD, Poppema et al[160] performed cytogenetics and *bcl*-2 gene rearrangement analyses on biopsy specimens from 28 consecutive untreated patients with HD. Although 11 patients had chromosome abnormalities in the chromosome 14q region, and 6 of these had involvement of the 14q32 region that comprises the gene encoding for immunoglobulin heavy chain, only 1 patient had a t(14;18) translocation, whereas almost 40% of these 28 patients showed *bcl*-2 rearrangements by a PCR method. Thus, although most cases of HD contain a clonal population with an abnormal karyotype, comprising RS cells, and the 14q32 region is frequently involved, a t(14;18) is extremely infrequent in HD.

ASSOCIATION OF HODGKIN DISEASE WITH NON-HODGKIN LYMPHOMAS

Hodgkin disease can follow, coexist with, or precede a variety of lymphocytic malignancies. [30] [161] [162] [163] This interrelationship has stimulated the hypothesis that both HD and NHL can be derived from a common stem cell. Validation of this hypothesis would support a lymphoid origin for RS cells. Among the lymphocytic malignancies repeatedly associated with HD are chronic lymphocytic leukemia (CLL), follicular lymphoma, diffuse large cell or immunoblastic lymphoma, and mycosis fungoides. The most common association between HD and NHL is that of nodular LPHD and B-cell large cell lymphoma. This association is consistent with a B-cell origin for L&H cells in nodular LPHD, and suggests that the diffuse large cell component represents a form of histologic progression of nodular LPHD. [30] Meittenen et al[28] described five cases of diffuse large cell lymphoma in 51 patients, occurring 411 years after the diagnosis of non-LPHD. Sundeen et al [30] described seven cases of localized large cell lymphoma that were coexistent with nodular LPHD.

Momose et al[162] described 13 cases of CLL/small lymphocytic lymphoma in which RS cells were present. The RS cells in 12 of 13 cases contained EBV RNA, but the surrounding neoplastic lymphocytes were negative for EBV RNA. In each of these cases, the NHL was of B-cell phenotype. Weisenberg et al described eight additional cases of HD associated with CLL, including two of the lymphocyte predominant type. [164] Ohno et al showed identical sequences of the Ig heavy chain complementarity region III in H/RS cells and leukemic cells in two cases of HD arising in patients with CLL, supporting the concept that H/RS cells arising in classic HD often are derived from transformed B cells.[165]

Some cases of nodular LPHD are associated with the development of a T-cell lymphoma. [166] A report from the British National Lymphoma Investigation indicates that 2.2% of nodular LPHD cases are associated with B-cell lymphomas and 1.6% are associated with T-cell lymphomas. [167]

More than 20 cases of HD associated with mycosis fungoides, a T-cell malignancy, have been reported. [161] [168] In one such case, molecular genetic and immunophenotypic studies indicated that the RS cells and mycosis fungoides cells were derived from a common T-cell clone. [163] Together, these studies of HD and NHL or CLL in the same individual support the hypothesis that the RS cell of HD is most often derived from a B lymphocyte and less frequently from a T lymphocyte.

CYTOKINES

It has been hypothesized that the different histologic types of HD, and systemic symptoms, are a consequence of cytokines secreted by the malignant RS cells. [55] [169] [170] IL-1 and granulocyte colony-stimulating factor have been demonstrated in culture supernates of HD cell lines. [171] [172] Eosinophilia may occur in response to IL-5 secreted by RS cells.[173] Nodular sclerosis may be explained by the stimulation of collagen synthesis by transforming growth factor- secreted by RS cells [174] [175] and eosinophils.[176] IL-6, which stimulates growth of B cells and plasma cells, was found in cell cultures and tissue sections of HD but did not correlate with the intensity or number of RS cells stained

---

or degree of plasma cell infiltration.[177] IL-9, which stimulates T-cell proliferation, appears to be uniquely associated with RS cells and tumor cells in CD30+ ALCL. [178] Kretschmer et al[179] demonstrated synthesis of both TNF- and TNF- (lymphotoxin) by HD cell lines, and TNF- protein and mRNA directly in HD tissue specimens. Sappino et al[180] demonstrated high levels of lymphotoxin mRNA in Northern blots of tissue extracts from LPHD. TNF- and lymphotoxin have a broad range of biologic activities, which include neutrophil and eosinophil recruitment, [181] macrophage activation,[182] stimulation of fibroblast growth,[183] and endothelial cell/leukocyte interactions, [184] each of which can contribute to the pathologic features and symptoms of HD. Interferon (IFN)- mRNA and protein are produced by the HD cell line SUP-HD1 derived from a patient with nodular sclerosing HD.[185] IFN- causes fever and chills, which are symptoms of HD. IFN- also induces lymphocyte proliferation, activation of phagocytes, recruitment of monocytes and T lymphocytes, and formation of multinucleated giant cells, which may account for some histologic features of HD.[186]

Hodgkin/RS cells express several members of the TNF receptor superfamily, including CD30, CD40, CD95, CD120a, CD120b, and 4-1BB, [187] and the corresponding ligands are produced by surrounding inflammatory cells. [188] CD30 antigen is expressed preferentially, if not exclusively, on activated lymphocytes, supporting the hypothesis that RS cells are derived from activated lymphocytes.[55] The normal counterparts of CD30+ cells are found around, between, and at the inner margin of germinal centers.[55] [189] Stein et al[55] and Froese et al[190] have shown that CD30 can be induced, together with the IL-2 receptor (CD25), on normal B and T cells by exposure to phytohemagglutinin, human T-leukemia viruses, EBV, or *Staphylococcus aureus*. [55] [190] The 120-kd CD30 antigen develops from an intracellular precursor of 90 kd by N- and O-glycosidic glycosylation, and can be shed from the cell surface as a soluble CD30 antigen of approximately 90 kd. [191] CD30 antigen expression appears to represent a late event in lymphocyte activation. [45] [192]

CD30L and CD40L are expressed as membrane-bound proteins by activated T cells. CD30L has been localized to T cells and granulocytes that surround H/RS cells.[193] Recombinant CD30L and CD40L enhance release of IL-6, TNF-, and lymphotoxin from cultured H/RS cells. [194] CD40L, but not CD30L, induces IL-8 secretion and enhances expression of costimulatory molecules, intercellular adhesion molecule (ICAM)-1 (CD54) and B7-1 (CD80), by cultured H/RS cells. [60] CD40L is also a critical signal for T-cell-dependent activation of B cells. CD30L was found to enhance proliferation of T-cell-like HD cell lines HDLM-1, -2, and -3, and L540) but not B-cell-like HD cell lines KMH2 and L428.[195] CD30L expressed by eosinophils stimulates the proliferation of the HD cell line HDLM-2. [196]

The cytokine hypothesis does not appear to provide an adequate explanation of the influence of environmental factors and patient age on the relative frequency of the different types of HD. For example, lymphocyte predominance and nodular sclerosis are more common in children from developed countries, whereas the less favorable mixed cellularity and lymphocyte depletion types are relatively more common among older patients and among children from underdeveloped countries. [197] [198] [199] These observations suggest that nutrition and host immune factors may also contribute significantly to the histopathology of HD.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

SUMMARY

Hodgkin disease is a malignant disorder in which the proportion of RS cells and their variants in affected tissues correspond to the clinical grade of malignancy. RS cells have a distinctive immunologic profile that is characteristic of activated lymphocytes and allows distinction of HD from NHLs with overlapping morphologic features but different natural histories and therapeutic responses. Recurrent chromosomal abnormalities and clonal relationships between HD and NHL are both consistent with a lymphocytic origin for the malignant cell in HD. In most cases, H/RS cells are derived from crippled germinal center B cells (centroblasts) that are rescued from apoptosis by a transforming event, possibly induced by EBV-LMP1, which up-regulates antiapoptotic proteins. Although LMP1 is a target for cytotoxic T cells, the latter are defective in their ability to respond to H/RS cells because of genetic and local microenvironmental factors in HD tissues. Cytokines released by H/RS cells and surrounding inflammatory cells are responsible for the different histologic types of HD and symptoms experienced by patients with HD.

Chapter 68 - Hodgkin Disease: Clinical Manifestations, Staging, and Therapy

Carol S. Portlock
John Glick

INTRODUCTION

Hodgkin disease (HD) is a unique malignancy of uncertain etiology and cell type that has become a prototype for curable neoplasms. Although the disease may involve the entire lymphoid system, the pattern of presentation and spread is usually predictable and initially localized, lending itself to the successful use of extended field radiotherapy. Since the first description of this disorder by Thomas Hodgkin in 1832, there has been much conjecture as to its nature and, in fact, whether it represents a true malignancy at all.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

INCIDENCE AND EPIDEMIOLOGY

In the United States, the number of new HD cases in 1997 was estimated to be 7,500.[1] The median age of diagnosis is 2631

years. A bimodal pattern of age distribution frequency for HD has been characteristically seen in the United States, with one peak at 2029 years, followed by a trough at 4059 years and a second peak at 60 years. It is now recognized that the second bimodal frequency peak was the result of pathologic misclassification. [2] The most recent data from the National Cancer Institutes Surveillance, Epidemiology, and End Results Program (SEER) indicate that these cases were largely aggressive non-Hodgkin lymphomas (NHL), rather than HD, mixed cellularity or lymphocyte depletion subtypes, as often reported. The nodular sclerosis (NS) subtype is the most common diagnosis overall, with >75% of cases occurring at <40 years of age and without a second peak thereafter. The other histologic subtypes, lymphocyte predominance (LP), mixed cellularity (MC), and lymphocyte depletion (LD), occur with low but gradually increasing frequency in all age groups. [3]

The incidence of HD is approximately 1.4-fold-greater in males. A male predominance has been noted in children <10 years old and again >50 years of age. Between the ages of 10 and 40 years, the ratio is reversed, with females predominating. This corresponds to the peak incidence of NSHD, which is more frequent in females. HD is primarily a malignancy of the white population in the United States, with whites accounting for more than 90% of all cases. In addition, the incidence is associated with small family size and a high standard of living in childhood, as well as a high level of maternal school education. [4] [5] Other possible risk factors include human immunodeficiency virus (HIV)[6] infection, Epstein-Barr virus (EBV) [7] infection, genetic predisposition, [8] [9] environmental exposure to herbicides, and certain occupations (woodworking, livestock, and meat processing). [10]

The etiology of HD remains uncertain (see Chap. 67). Both a possible genetic susceptibility and an infectious agent, particularly EBV, have been considered. Recent epidemiologic data support both. However, each may play a role in different subsets of disease.

Twin studies have demonstrated that the risk of HD is significantly increased among identical twins as compared to fraternal twins. [8] However, overall, familial HD occurs in less than 5% of all HD patients. In reviewing 328 patients with familial HD, only one major incidence peak was identified between ages 1534 years as compared to the broader incidence of sporadic HD.[9] A study of 60 patients from such HD families revealed no excess positive concordance for the presence of EBV in tumor tissue or in EBV serologies of patients from the same family.[11] Moreover, only 1 of 10 monozygotic twin pairs was concordant for EBV. These data suggest that EBV does not play an important role in familial HD.

On the other hand, EBV is consistently identified in the majority of HD cases occurring in developing countries. In developed countries, EBV is seen in pediatric and older adult cases and less frequently in young adults with nodular sclerosing histology. For example, in Kenya, 100% of pediatric cases were EBV Latent Membrane Protein-1 (LMP-1) positive, and 25 of these cases had type 1 and/or type 2 EBV strains documented. [12] In this same study, only 63% of Kenyan adults were LMP-1 positive. A recent epidemiologic analysis of 1546 HD cases with known EBV tumor status revealed an increased odds ratio for EBV in mixed cellularity versus nodular sclerosis; children versus young adult males versus females; and Hispanics versus whites. [7]

When EBV is present in HD, the monoclonal EBV genome is detectable in all tumor cells. Why it is not consistently identified in all HD and what role the virus plays in lymphomagenesis remain to be elucidated.

CLINICAL MANIFESTATIONS

HD usually presents with supradiaphragmatic lymph node involvement and only later with generalized lymphatic and extralymphatic disease. Regional disease presenting below the diaphragm is distinctly unusual (<10% of all cases). [13] Lymph node involvement above the diaphragm frequently includes the anterior mediastinum and may become very large (>10 cm) without causing major symptoms. Complaints of dry nonproductive cough, substernal discomfort, and decreased exercise tolerance are common in this situation. Enlarged lymph nodes in the supraclavicular, cervical, and/or axillary regions are typically noted. Occasionally infraclavicular, submandibular, or even preauricular disease may be present. Waldeyers ring adenopathy is distinctly unusual and suggests a NHL. Lymph nodes are characteristically firm and rubbery and are often bulky. Local inflammation or erythema is uncommon, although lymphadenopathy will occasionally wax and wane spontaneously or appear to respond partially to antibiotic therapy.

Mauch et al[14] performed a detailed analysis of the initial sites of anatomic involvement, histopathologic findings, and clinical features in 719 patients with HD who underwent staging laparotomy and splenectomy. Table 68-1 (Table Not Available) presents the initial sites of involvement above the diaphragm, with the mediastinum, left side of neck, and right side of neck each present at diagnosis in >50% of patients with NSHD and MCHD. One of these sites of involvement was present in 92% of their patient population. The spleen was involved in 27% of patients (documented by splenectomy), while upper and lower abdominal nodes were found in 14% and 11% of patients, respectively. A strong association between splenic involvement and upper and lower abdominal disease was found. Only 5% of patients without splenic involvement had abdominal lymph node involvement. By contrast, 61% of patients with splenic involvement had abdominal lymph node disease. [14]

Bulky lymph node disease may result in certain regional complications. For example, tracheal or bronchial compression by massive mediastinal disease can result in complaints of cough or shortness of breath, often made worse in a supine rather than an upright position; obstructive pneumonia may also develop with hilar nodal compression. Extension of mediastinal and hilar adenopathy into adjacent lung, pericardium, chest wall, and pleura may be identified on chest radiograph and by computed tomography (CT) scanning. Pericardial and pleural fluid collections are usually asymptomatic, and cytologic examination rarely reveals Reed-Sternberg cells. Chest wall extension may be so great that adjacent sternal or rib destruction occurs, and palpable parasternal disease may be appreciated on physical examination.

In spite of bulky intrathoracic disease presentations, it is rare

TABLE 68-1 -- Presenting Sites of Involvement Above the Diaphragm in Descending Order of Prevalence

(Not Available)

From Mauch P, Kalish L, Kadin M et al: Patterns of presentation of Hodgkins disease: implications for etiology and pathogenesis. Cancer 71:2062, 1993. Copyright 1993 by the American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

for patients with HD to have superior vena cava syndrome, upper-extremity venous thrombosis, or phrenic nerve or recurrent laryngeal nerve entrapment. These clinical manifestations are more likely found in patients with NHLs.

Bulky intra-abdominal lymph node involvement is less common in HD and, when identified, is often associated with regional presentations (inguinal and iliac nodes) below the diaphragm. Ureteral obstruction, lower-extremity lymphedema, and venous thrombosis are rare complications and again suggest a NHL. Moreover, lymph node involvement rarely occurs in the mesentery or as isolated retroperitoneal adenopathy.

The spleen is often an occult site of HD spread (see the Staging section of this chapter). Massive splenomegaly is rare, as are such complications as splenic infarct or hypersplenism. In addition, clinical and radiologic evidence of splenomegaly does not always indicate disease involvement.

Extranodal spread of HD may occur by two separate means: (1) direct extension from a nodal mass (e.g., hilar adenopathy extending into lung parenchyma) and (2) hematogenous dissemination (e.g., bone marrow disease). Regional extranodal extension usually occurs in the presence of local bulky adenopathy. For example, in the lung this may lead to a confusing picture of obstructive pneumonia and infiltrative pulmonary HD. Along the lumbosacral spine, the epidural cord or nerve root may be compressed in addition to direct invasion of one or more vertebral bodies.

Hematogenous spread may be manifested by such findings as multiple pulmonary nodules or diffuse infiltrative disease of the liver and/or bone marrow. Extranodal sites that are rarely involved in HD include skin, the gastrointestinal tract, and the central nervous system. Although recognized more often in patients with the acquired immunodeficiency syndrome (AIDS) and HD, [6] [15] these extranodal disease sites suggest a NHL. The presence of disseminated extranodal disease is generally accompanied by generalized lymphadenopathy and splenic involvement. Because all such presentations are uncommon, it is important to document these extranodal sites pathologically, which usually requires a cutting-needle or open biopsy, since aspiration cytology is rarely if ever positive. Clinical judgment must be used in assessing the risk versus benefit of performing an extranodal site biopsy. For example, in a patient with multiple pulmonary nodules and mediastinal and hilar adenopathy, lung biopsy is rarely indicated.

HD may have associated systemic symptoms such as unexplained fever of greater than 101°F, drenching night sweats, and/or weight loss of >10% body weight during the previous six months. Such B symptoms correlate with disease stage, increasing in frequency with extent and bulk of tumor, and also correlate with overall prognosis. Other systemic manifestations of HD without known prognostic significance include generalized pruritus (often severe and difficult to treat symptomatically without control of the HD) and lymph node pain after ingestion of alcoholic beverages. These systemic complaints may be the first indication of active HD, but more often they are elicited after the diagnosis has been established.

Patients with HD will often be anergic to skin test antigens at first diagnosis. Hyporesponsiveness increases with increasing disease stage. In addition, T-cell number, T-cell helper (CD4)/suppressor (CD8) ratio, and T-cell in-vitro response to antigen may be altered. Although cell-mediated immunity may be mildly abnormal, patients with HD rarely develop opportunistic infections prior to treatment. An exception, however, is the increased frequency of herpes zoster, seen in previously untreated as well as in treated patients. [16]

B-cell function appears to be normal in HD at diagnosis. Pneumococcal vaccination, for example, results in normal antibody response as long as subsequent treatment is delayed 1014 days. Splenectomy does not interfere with an adequate antibody rise. In contrast, overwhelming bacterial sepsis with encapsulated

organisms is still a potential risk among patients with HD after splenectomy or irradiation to the spleen. [17] [18]

STAGING

Clinical and Pathologic Staging

Once a diagnosis has been established with an adequate biopsy and hematopathologic interpretation, systematic clinical staging should be initiated (Table 68-2). During a complete history and physical examination, the presence of systemic symptoms and the extent of lymph node involvement can be assessed. A chest radiograph will define the bulk of intrathoracic adenopathy and the possible presence of pulmonary extension, postobstructive pneumonia, or rarely, disseminated lung disease. CT scanning of the chest, abdomen, and pelvis will identify enlarged lymph nodes and their relationship to normal anatomic structures (e.g., pericardium, chest wall, kidney). Possible extranodal involvement (e.g., lung, liver, bone) may also be imaged. Although hepatosplenomegaly may be identified, its presence does not necessarily confirm disease involvement since nonspecific enlargement of these organs may occur.

The lymphogram complements the negative or equivocal

TABLE 68-2 -- Clinical Staging Evaluation

1. Detailed history for unexplained fever, weight loss, night sweats, and pruritus
2. Physical examination to document all areas of lymphadenopathy; size of liver and spleen; bony tenderness; neurologic evaluation
3. Laboratory studies
a. CBC, differential and platelet count, erythrocyte sedimentation rate
b. Serum alkaline phosphatase, lactate dehydrogenase
c. Renal function, including uric acid
d. Liver function tests
4. Radiologic studies
a. Chest radiograph
b. Bipedal lymphogram
c. Computed tomography of the chest and whole abdomen, including the pelvis
d. Gallium scan
e. Bone scan/bone radiographs obtained when areas of bone pain or tenderness are present
5. Biopsy studies
a. Diagnostic biopsy of lymph node: review with experienced hematopathologist
b. Bone marrow biopsy
c. Biopsy of suspicious disseminated extranodal sites (i.e., pulmonary or liver lesions), if clinically indicated
6. Under special circumstances
a. Magnetic resonance imaging
b. Ultrasound

abdominal and pelvic CT scan, since it may identify abnormal lymph nodes of borderline size, as well as identifying intranodal architecture. The lymphogram is more sensitive in detecting para-aortic disease (8598% rate of true-positive results as compared with 4065% for CT). [19] [20] However, the lymphogram is not accurate above L2L3 and is therefore unable to assess celiac axis, porta hepatis, or mesenteric (rare in HD) adenopathy; CT scanning is more accurate in assessing these nodal areas. Thus, both abdominal CT scanning and a bipedal lymphogram are recommended as part of the initial staging procedures.

Although uncommon at diagnosis, bone marrow involvement should be excluded before regional therapy is initiated. Percutaneous bone marrow biopsies are indicated as part of routine clinical staging. They are more likely to be positive in patients with B symptoms, clinical stage III or IV disease, or mixed cellularity Hodgkin disease (MCHD) or lymphocyte depletion Hodgkin disease (LDHD) and in patients with leukopenia or thrombocytopenia. Routine laboratory blood work may reveal leukocytosis, often with eosinophilia, a mild thrombocytosis, and/or anemia with a reactive bone marrow picture. The alkaline phosphatase may be elevated nonspecifically or in association with bone and/or bone marrow or liver involvement. Elevation of lactate dehydrogenase is an indication of bulky disease and appears to have prognostic significance at high levels.

Other staging studies that are often used include gallium scanning and magnetic resonance imaging (MRI). Gallium scanning is most useful in the anterior mediastinum and chest when evaluating treatment outcome of bulky disease.[21] If initial and post-treatment studies indicate gallium avidity with a persistent mediastinal mass, the possibility of residual HD mandates biopsy confirmation. The gallium scan is less useful in the abdomen because of bowel uptake, although SPECT (Single Photon Emission Computed Tomography) imaging will often clarify the uptake. MRI of the bone marrow in relapsed HD may be a particularly useful method of detecting occult disease.[22] Although MRI may provide excellent imaging of nodal and extranodal sites, its superiority to CT scanning has not been proven nor shown to be cost-effective. A new imaging technique that appears to hold promise is PET (positron emission tomography) scanning. [23]

The Ann Arbor staging classification[24] for HD represented an important step in therapeutic decision making in the treatment of HD. The Cotswolds modification [25] of the Ann Arbor staging method, which recognizes both a clinical and a pathological stage, is presented in Table 68-3 . Staging designations are determined according to the number of lymph node regions (not sites) involved and whether there is disease on one or both sides of the diaphragm. Systemic or B symptoms include fever, night sweats, and weight loss. The E lesion is defined as a direct extranodal extension of lymph node disease that can potentially be encompassed in radiation portal, such as hilar node extension in lung parenchyma.

Clinical staging includes the initial biopsy site and all other abnormalities detected by noninvasive methods, including physical examination and radiologic studies. Pathologic staging requires biopsy confirmation of potentially abnormal sites (e.g., liver or bone). In the past, pathologic staging also referred to findings at staging laparotomy, performed in those patients with clinically limited supradiaphragmatic disease. This latter procedure required biopsy of para-aortic, celiac, porta hepatis, and other suspicious lymph nodes, and splenectomy (with placement of clips on the splenic pedicle), liver wedge and needle biopsies, and bone marrow biopsy (if not done prior to laparotomy). Pneumococcal vaccine is routinely administered prior to surgery.

Although staging laparotomy has been widely applied in HD, its indications have decreased significantly in recent years, and it is now rarely indicated. Successful treatment of many clinically staged patients has become feasible with the use of combination chemotherapy to treat uncertain intra-abdominal sites, plus limited radiotherapy fields to known disease above the diaphragm. Moreover, very favorable subsets of patients with early-stage HD may be identified in whom the risk of intra-abdominal disease is <510% and in whom primary irradiation may be considered without laparotomy confirmation and without the need for combination chemotherapy.

Historically, following complete clinical and pathologic staging, the distribution of patients with HD is as shown in Table 68-4 .[26] Prognostic factors not reflected in the Ann Arbor staging system that may influence treatment decisions and outcome include bulk of disease, site and number of nodal regions involved, distribution of intra-abdominal stage III adenopathy, extent of splenic involvement, and blood tests such as erythrocyte sedimentation rate (ESR) or lactic dehydrogenase (LDH).

In 1989, an international multidisciplinary committee[27] recommended

TABLE 68-3 -- Cotswolds Staging Classification of Hodgkin Disease

Classification	Description
Stage I	Involvement of a single lymph node region or lymphoid structure
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is considered as a single site, whereas hilar lymph nodes are considered bilaterally); number of anatomic sites should be indicated by a subscript (e.g., stage II_3)
Stage III	Involvement of lymph node regions or structures on both sides of the diaphragm
III_1	With or without involvement of the spleen, splenic, hilar, celiac, or portal nodes
III_2	With involvement of para-aortic, iliac, and mesenteric nodes
Stage IV	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used (see the following designations)
	Designations applicable to any disease stage
A	No symptoms
B	Fever (temperature, >38°C), drenching night sweats, unexplained loss of >10% body weight within the preceding 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third or the presence of a nodal mass with a maximal dimension of >10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site
CS	Clinical stage
PS	Pathologic stage (as determined by laparotomy)

Adapted from Lister and Crowther,[25] with permission.

TABLE 68-4 -- Clinical Characteristics of Patients Treated for Hodgkin Disease at Stanford (19681988), According to Histologic Subtype

	Lymphocyte Predominance	Nodular Sclerosis	Mixed Cellularity	Lymphocyte Depletion

Data from Hoppe.[26]

further modifications in the Ann Arbor staging classification to reflect changes in clinical staging criteria, the increased use of new diagnostic tests such as CT scanning, newly recognized prognostic factors, and their impact on therapeutic decisions. Table 68-5 summarizes the Cotswolds Staging Classification recommendations for clinical imaging criteria.[25] [27] This staging system acknowledges the value of CT and other imaging modalities in defining disease extent. However, it was again emphasized that biopsy confirmation is required if treatment recommendations might be altered by an equivocal study. This new staging system also clarified issues of disease distribution and bulk. In regional disease, the number of involved sites is denoted by a subscript (e.g., stage II_3). For stage III presentations, anatomic extent of intra-abdominal adenopathy is defined and denoted by subscript, with stage III_1 assigned to patients with spleen or splenic hilar, celiac, or portal node involvement; and stage III_2 to those with para-aortic, iliac, inguinal, or mesenteric involvement. Bulky disease is defined by maximum dimension (>10 cm) or by at least one-third mass/thorax ratio, designated by the subscript X. In the setting of bulky intrathoracic disease, contiguous spread to adjacent extranodal tissues is clearly distinguished from disseminated extranodal involvement (e.g., multiple pulmonary nodules). This common clinical stage II presentation would be designated with the subscript X for bulky or E for extranodal extension of lymph node disease into adjacent tissues (e.g., chest wall, pericardium, and sternum) and with a numerical subscript for the number of nodal sites involved above the diaphragm.

TABLE 68-5 -- Cotswolds Meeting Recommendations for Clinical Imaging Criteria

1. Lymph node involvement
CT size criteria of >1.5 cm for a positive study
2. Spleen involvement
Requires unequivocally palpable spleen or equivocally palpable spleen plus radiologic enlargement or splenic defects
3. Liver involvement
Multiple focal defects confirmed by two imaging modalities
4. Definition of bulky dimension

	10 cm in largest dimension
	Mediastinal mass greater than one-third of the internal transverse diameter of the thorax at T5T6 [a]

From Lister et al,[27] with permission.

[a]Although the Cotswolds definition of a bulky mediastinal mass uses the internal transverse diameter of the thorax at T5T6, most investigators define a large mediastinal mass as greater than one-third of the maximal intrathoracic diameter.

Staging Laparotomy: Is This Procedure Still Indicated?

The Ann Arbor and Cotswolds staging systems are based on both clinical and pathologic staging. The extent to which disease is pathologically confirmed depends on the suspected sites involved and whether that information would influence treatment decisions. Most HD patients have involvement limited to lymph node areas. Therefore, suspected stage IV sites should be pathologically confirmed (e.g., liver lesions) if these sites are not unequivocally involved by disease (e.g., multiple obvious lung nodules or a positive bone radiograph with blastic involvement).

Moreover, the anatomic distribution of lymph node involvement in HD is not random. Supradiaphragmatic disease with or without intra-abdominal involvement is the rule, and regional disease limited to subdiaphragmatic sites is uncommon. During the 1960s, the extent of intra-abdominal involvement was recognized to be underestimated in many cases, since the disease status of the spleen could not be reliably assessed by clinical means alone. Staging laparotomy was introduced to more adequately evaluate the suspected clinical findings and to determine whether radiation alone could be used for treatment.

Surprisingly, the accuracy of clinical abdominal disease assessment was often poor in spite of CT and lymphogram imaging. [13] [28] More than 40% of clinical stage IIIA patients were downstaged (negative laparotomy findings), and the extent of inaccuracy rose to 68% for patients <40 years of age with LPHD or NSHD. Likewise, for patients whose disease was classified as clinical stage I and II, staging laparotomy yielded evidence of intra-abdominal disease in approximately one-third of patients. Those factors most likely to be associated with upstaging include male sex, presence of B symptoms, and two or more sites of disease involvement above the diaphragm.

Of equal importance, however, was the observation that certain subgroups had a very low likelihood of change in stage with laparotomy. Those with clinical stage IA disease presenting in the mediastinum had virtually no risk of intra-abdominal involvement. Females with clinical stage IA at other supradiaphragmatic sites had a 6% risk, whereas males with similar clinical characteristics were at an equally low risk only if they had LPHD or interfollicular HD. Other histologic subtypes were associated with positive laparotomy findings in up to one-third of clinical stage IA males. [28]

For clinical stage II patients, female sex conferred a significantly lower risk of intra-abdominal disease (22% vs. 36%) than for males. Moreover, a favorable subset (females 26 years of

Data from Leibenhaut et al[13] and Mauch et al.[26]

age with fewer than three disease sites) was identified by the Stanford group; [13] laparotomy is positive in <10% of this subset. Such laparotomy data make it possible to identify subsets of patients in whom there is good correspondence between clinical and pathologic staging; these subsets are summarized in Table 68-6 .

For patients with favorable clinical stage I and II presentations, a correspondence of 90 with pathologic staging suggests that primary irradiation without staging laparotomy may be administered. This approach is valid if other treatment parameters are satisfactory for primary irradiation (i.e., no bulk disease at any site). [29] Similarly, for patients with clinical stages IIIB and IVB, correspondence is 8090%, suggesting that few if any of these patients would be downstaged with complete staging laparotomy evaluation. In this situation, combination chemotherapy with or without irradiation would be the primary treatment approach chosen.

For all other presentations of clinical stages I and II as well as equivocal clinical stage IIIA, it has been previously recommended that staging laparotomy be performed, if primary irradiation alone was to be used. [30] [31] [32] [33] In these situations, the correspondence was low enough (80%) that many patients would be inaccurately staged and treated with primary irradiation if the clinical stage was not pathologically confirmed.

As discussed below, however, the recommendation of staging laparotomy is no longer made in those instances of low correspondence. Instead, such patients are managed with combination chemotherapy and limited irradiation, obviating the need to accurately stage the abdomen.

In summary, the concept of clinical and pathologic staging in HD remains a valid tool in selecting curative treatment strategies. By keeping in mind the likelihood of clinical and pathologic stage correlations, an accurate definition of subsets of patients is possible.

For limited disease with high correspondence, primary irradiation may be considered based on clinical stage. For advanced disease and high correspondence, combination chemotherapy is recommended. For patients diagnosed with early stage disease by clinical staging, but whose disease has uncertain correspondence with historical laparotomy data, combined modality therapy is indicated.

THERAPY

The prognosis for patients with all stages of HD has improved dramatically since 1960 as a result of advances in precise staging, knowledge of important prognostic factors, the development of supervoltage radiotherapy, and the use of effective combination chemotherapy. The improved results achieved with modern therapy after accurate staging are possible only with experienced teams of pathologists, surgeons, radiotherapists, hematologists, and oncologists working closely together. This approach can produce the excellent cure rates now possible, while minimizing acute and long-term morbidity from treatment. It should be emphasized that the goal of treatment is to obtain the highest overall possible cure rate for all patients, minimizing side effects whenever feasible. Thus, freedom from first or even second relapse must be considered in the evaluation of both disease-free and overall survival when the results of past and current trials are analyzed. For example, an early-stage patient who has relapsed after radiation therapy alone may be cured with chemotherapy administered at relapse. The challenge for physicians caring for patients with all stages of HD is to weigh carefully the toxicity/benefit ratio for each treatment regimen and to design a treatment strategy that maximizes the overall survival rate.

Radiotherapy for Early-Stage Disease

The long-term survival of patients with early-stage HD is >85% in multiple studies using various staging techniques and treatment modalities. [34] [35] [36] [37] [38] [39] [40] [41] [42] Definitive radiotherapy has long been considered standard treatment for the vast majority of patients with stage III HD because of the excellent long-term survival with minimal complications. The results of radiotherapy for laparotomy-stage I and II patients are dependent on close attention to important technical considerations for radiotherapy, including total radiation dose per field; size, shape, and number of treatment fields and careful definition of involved sites; use of appropriate voltage devices (e.g., linear accelerators); treatment simulation with individually shaped blocks for careful protection of normal tissues, such as the lungs and heart; equal doses from anterior and posterior fields; and use of cone-down fields and careful matching techniques with appropriate cord blocks. [35] [43] [44] [45] [46] [47]

Kaplan[47] provided the critical data to indicate that radiotherapy of HD follows a dose-response curve. Permanent eradication of any given known site of involvement is achieved in the vast majority of cases with doses of 3,6004,400 cGy delivered at a dose rate of 1,000 cGy/wk. Prophylactic radiation to a total dose of 3,0003,600 cGy is delivered to apparently uninvolved areas treated for subclinical disease. Use of a linear accelerator in the 48 MeV range provides the advantage of precise beam margins with reduced lateral scatter, increased depth-dose, and improved skin tolerance. [46] It is important to define carefully the extent of disease and fields to be treated, using appropriate treatment simulators. Proper technique also includes the use of carefully shaped lead blocks to protect such vital structures as the lungs, heart, and spinal cord; frequent port films; and dose verification using precise dosimetry.

Current radiotherapy practice continues to emphasize the treatment of multiple lymph node chains within a few very large, carefully shaped fields. Figure 68-1 illustrates the radiation fields most frequently delivered in clinical practice. The mantle field treats the cervical, supraclavicular, infraclavicular, axillary, hilar, and mediastinal lymph nodes to the level of the diaphragm in one contiguous treatment volume. Prophylactic whole lung irradiation to a dose of 1,5001,650 cGy in 150-cGy fractions is administered by some radiotherapists when the ipsilateral hilum is involved with HD. [44] [46] Although this technique decreases relapse in the treated fields for patients with hilar disease, the routine use of whole-lung irradiation remains controversial. The para-aortic field covers the splenic pedicle, the spleen (if not removed at laparotomy), and the celiac and para-aortic lymph nodes from the diaphragm to the level of the aortic bifurcation. The mantle (M) and para-aortic fields are frequently referred to as extended-field (EF) or subtotal nodal (or lymphoid) irradiation (STNI). The radiotherapy approach known as total nodal irradiation (TNI) or total lymphoid irradiation, involves treating the mantle, para-aortic, and pelvic fields.

Figure 68-1 Radiotherapy fields commonly used for HD. Total nodal irradiation consists of **(A)** a mantle and an inverted Y or **(B)** three fields. **(C)** Subtotal nodal irradiation after splenectomy consists of a mantle and para-aortic fields. (*From Rosenberg,[43] with permission.*)

As discussed in the following sections, inclusion of pelvic irradiation as part of TNI has disappeared. In addition, pelvic irradiation affects large amounts of bone marrow and therefore may subsequently preclude the use of full-dose chemotherapy. Pelvic radiotherapy may also increase the risk of infertility.

Delivering radiotherapy to apparently uninvolved lymph node regions has long been advocated because of the orderliness and contiguity of spread for patients who present with early stage disease. [48] [49] [50] [51] [52] This approach is based on the knowledge of sites of relapse of HD when treated only with involved field radiotherapy, the limitations of our diagnostic techniques in discovering minute or microscopic foci of subclinical disease, and the advantage of avoiding overlapping fields. In the initial Stanford trials, [37] patients with stage I and IIA disease were randomly assigned to involved field (IF) irradiation, EF irradiation, or TNI. A highly significant difference in disease-free survival was observed in favor of either EF irradiation or TNI, although overall survival was similar (80% at 15 years). The studies from the Joint Center for Radiation Therapy (JCRT) in laparotomy stage IIIA HD have been reviewed by Mauch et al [34] At a median follow-up of 9 years, review of the 315 patients treated with mantle and para-aortic irradiation (M + PA) revealed a freedom from relapse of 82% and an overall survival of 90%. These results are illustrated in Figure 68-2 . More than 80% of patients treated with mantle and para-aortic irradiation have been continuously relapse-free and therefore have not required the use of salvage chemotherapy. Pelvic recurrences were noted in only 3% of cases, indicating that it is reasonable to omit the pelvic field from the radiotherapy port. Other investigators using comparable staging and radiotherapy techniques have reported similar results, which are summarized in Table 68-7 .

In the JCRT series, mediastinal size was the only factor that significantly predicted freedom from relapse. [34] Patients with large mediastinal masses were significantly less likely to have freedom from relapse than were those with less or no mediastinal involvement (53% vs. 83%, respectively). However, the survival of these two groups of patients was not significantly different. The approach to patients with large mediastinal masses is discussed in a subsequent section.

Gospodarowicz et al[40] reported the long-term results of treating 521 clinical stage I and II patients with radiation alone at the Princess Margaret Hospital (Table 68-7). The overall actuarial survival for all irradiated patients was 78% at 10 years and 63% at 20 years, while the cause-specific survival was 87% and 83%, respectively. The use of mantle radiotherapy rather than IF radiotherapy was associated with a significant improvement in the 10-year relapse-free survival (RFS) (M = 66%, IF = 51%) and in the 10-year actuarial survival (M = 80%, IF = 59%). There was further improvement in the 10-year RFS with the use of EF

Figure 68-2 Actuarial freedom from relapse (FFR) and survival for stage IA and IIA patients treated initially with mantle and para-aortic irradiation. Actuarial survival curves are shown censored for unrelated deaths (marked HD) and for survival, including deaths from all causes. (*From Mauch et al, [34] with permission.*)

radiotherapy (76%), but this effect was not statistically significant when EF was compared with mantle radiotherapy alone in a multivariate analysis adjusting for other prognostic features. In a low-risk or very favorable cohort of patients (defined as clinical stage I and IIA, <50 years of age, with LP or NS histology, erythrocyte sedimentation rate (ESR) <40, no large mediastinal mass, and no E lesion), the 10-year survival rate was 91%, with an RFS of 77%. The 10-year RFS for patients in this favorable subgroup was 80% for mantle radiotherapy, compared with 87% for EF radiotherapy (not statistically significant). The overall conclusions reached by Gospodarowicz et al[40] were that the role of laparotomy and splenectomy in defining a favorable group of patients for treatment with radiotherapy alone may be offset by patient selection, using multiple clinical prognostic factors and by employing EF radiotherapy.

An alternative approach to the staging and treatment of early stage HD was proposed by Cosset et al, [39] reporting for the European Organization for the Research and Treatment of Cancer (EORTC). In the EORTC H2 trial, NSHD patients were randomized to either staging laparotomy and splenectomy followed by mantle and para-aortic radiotherapy, or to clinical staging and STNI plus splenic irradiation (Table 68-7). At 12 years, RFS was 68% for STNI alone and 76% for laparotomy-STNI. Overall survival was virtually identical. In the subsequent H5 trial, a favorable prognostic group was defined with all the following characteristics: no B symptoms, age <40 years, ESR <70, LP or NS histology, and either clinical stage I or II without mediastinal involvement. All patients in this favorable group first underwent laparotomy and splenectomy. If negative, patients were randomly assigned to mantle irradiation alone or to mantle plus para-aortic radiotherapy. There was no difference in either RFS or overall survival between the two arms (Table 68-7). Therefore, in patients with all these initial favorable prognostic factors and with no infradiaphragmatic extension (i.e., negative laparotomy), the addition of para-aortic irradiation did not yield any benefit. The EORTC H6 trial then addressed the need for laparotomy in the favorable subgroup: patients in the first arm of the study underwent laparotomy with treatment adapted to the pathology findings; if the laparotomy was negative, mantle radiotherapy was given (plus para-aortic field for MC or LD histology); if the laparotomy was positive, combined-modality treatment was administered. Patients in the second arm of the study without laparotomy directly received mantle, para-aortic, and spleen radiotherapy (STNI + spleen). In this trial, the end point was survival and not RFS. At 5 years, RFS was significantly lower in the STNI group than in the laparotomy (plus adapted treatment) patients, as expected. However, because of the efficacy of salvage chemotherapy, 5-year overall survival was similar (Table 68-7). [39] Based on these studies, the EORTC decided to give up staging laparotomy for supradiaphragmatic disease and subsequently used clinical staging. On the basis of their data, they also defined a small cohort of patients who could be safely treated with a mantle field alone without laparotomy. This subgroup is very restrictively defined and only includes female NSHD or LPHD patients with clinical stage I, <40 years of age, without B symptoms, with an ESR of <50, and without bulky mediastinal involvement. [39]

Similar results were reported by Fuller et al [50] for the M.D. Anderson group in a small number of prognostically favorable patients, who had supradiaphragmatic disease with either no mediastinal disease or limited mediastinal disease without hilar involvement and no B symptoms. These patients were treated with mantle radiotherapy alone. The British National Lymphoma Investigational Trials [49] as well as Mauch et al[52] have confirmed the equal effectiveness of more limited radiotherapy fields (i.e., mantle) for favorable subsets of stage IIIA patients.

Thus, laparotomy-staged patients with pathologic stage IIIA supradiaphragmatic disease of the NS or LP histology who do not have mediastinal involvement can be treated with mantle radiotherapy alone. Stage I patients with these histologies and a small mediastinal mass may also be treated with a mantle field. However, for pathologic stage IIIA patients not meeting these criteria, mantle and para-aortic fields should be used. In clinically staged patients (i.e., no laparotomy), the risk of undetected intra-abdominal disease may be up to 3050%. Except in very favorable subgroups, as defined by Gospodarowicz et al, [40]

Abbreviations: FFP, freedom from progression; RFS, relapse-free survival; M, mantle radiotherapy; PA, para-aortic radiotherapy; sTNI, subtotal nodal irradiation; TNI, total nodal irradiation; lap, staging laparotomy and splenectomy; ESR, erythrocyte sedimentation rate; SMM, small mediastinal mass; LMM, large mediastinal mass; NS, nodular sclerosis; LP, lymphocyte predominance; MC, mixed cellularity; LD, lymphocyte depletion; NA, results not available.

[a]Very favorable: clinical Stage IA or IIA with age <50, or lymphocyte predominance, ESR <40, no LMM, and no E lesion.
[b]Favorable: age <40, ESR <70, NS or LP histology, clinical stage IA or clinical stage IIA without mediastinal involvement. Unfavorable: one or more of the following: age 40, ESR 70, MC or LD histology, clinical stage II with mediastinal involvement.

SUMMARY OF INITIAL THERAPY RECOMMENDATIONS BY STAGE OF HODGKIN DISEASE

The recommended therapy for a patient with HD must be individualized. Advances in histopathologic classification, precise staging procedures, and selection of appropriate aggressive therapy have led to continuous improvement in both failure-free survival and overall survival. Any treatment recommendations must be viewed with the understanding that the management of HD is dynamic, constantly undergoing change and refinement. The goal is to provide each patient with the best probability of cure and the least possibility of long-term toxicity.

With an early stage presentation one must first consider whether the disease presentation is associated with a low likelihood of occult intra-abdominal involvement. Staging laparotomy is no longer indicated because historical data is adequate to define clinically favorable and unfavorable subsets. For very favorable subsets of clinical stage IA and selected IIA patients, primary irradiation, either a mantle field, or mantle, para-aortic, and splenic fields, depending on their clinical prognostic factors may be administered. For other favorable and unfavorable subsets with clinical stage I and IIA disease, ABVD and limited irradiation is indicated. For early-stage asymptomatic patients with bulky mediastinal masses, radiotherapy alone is not an acceptable option. A combined modality approach is appropriate, and treatment is initiated with one of the currently accepted regimens for advanced-stage disease. In this situation chemotherapy is given to maximal tumor response, which is then followed by limited-field radiotherapy.

Stage IIIB disease, with or without bulky mediastinal mass, should be treated with combined modality therapy.

Patients with subdiaphragmatic early stage HD are generally treated with combined modality therapy since the risk of intra-abdominal disease is high and a favorable subset is not defined for primary irradiation of clinically staged patients.

Combined modality therapy is an attractive alternative for the management of early- and intermediate-stage disease, particularly with the use of short-course ABVD or other chemotherapy and limited field irradiation. Future investigation will clarify the role of chemotherapy alone in these settings.

For patients with clinical stage IIIA disease, combined modality therapy or chemotherapy alone should be used. From the limited data available, it would appear that chemotherapy alone using any one of the accepted combinations for advanced disease is as effective as combined modality therapy for most patients with extensive stage IIIA disease. Although the results with combined modality therapy for IIIB and IV disease are excellent in terms of freedom from progression and overall survival, they do not appear significantly different from the results obtained with chemotherapy alone. Thus, for the vast majority of patients with stage IIIB or IV disease, chemotherapy alone is recommended as initial treatment.

For many years, MOPP remained the standard of care for the treatment of patients with stage IIIB or IV disease. However, data from recent randomized trials indicate that ABVD should now be considered the standard drug combination for treatment of Hodgkins disease. In advanced disease, other alternating regimens such as MOPP/ ABVD and MOPP/ABV hybrid have not been shown to be superior and may have significantly greater acute and late toxicity. Administration of radiotherapy to all sites of pretreatment involvement, once a complete remission has been obtained with chemotherapy for advanced disease, does not result in improved failure-free or overall survival and cannot be recommended. Limited-field irradiation to initial sites of bulky disease may be used in selected clinical situations.

The treatment of HD remains one of the great triumphs of cancer therapy since the middle 1960s. The overall 5-year survival rate for all patients has increased to 75% today. Thus, a treatment strategy for each patient should be designed to provide the highest probability of overall cure, while limiting late toxicities when possible. Moreover, it is important to counsel patients regarding secondary cancer and cardiac prevention (e.g., to stop smoking, to modify diet, and to exercise) and detection (mammography).

the EORTC,[39] Liebenhaut et al,[13] Mauch et al[28] and others, it is now recommended that most clinical Stage I and IIA patients receive combination chemotherapy and limited field irradiation. Similarly, for clinically staged IIIA patients with large mediastinal masses, combined modality therapy should be used as initial treatment.

The presence of constitutional or B symptoms has long been recognized as an important prognostic factor in HD. This observation is based primarily on data from patients with advanced disease, since patients with early-stage disease rarely present with B symptoms. In the past, this has led to different treatment recommendations for surgically staged patients with supradiaphragmatic stage IIIB disease. Investigators now recommend the routine use of combined modality therapy without laparotomy for these patients,[34] [51] [53] [54] [55] and this approach is no longer considered controversial.

In one of the few randomized trials for this subset of patients, the Stanford investigators treated laparotomy staged IBIIB patients with either TNI alone or TNI followed by six cycles of adjuvant MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) chemotherapy.[35] This small controlled trial showed no difference in either freedom from progression or overall survival, with 78% of all patients surviving >10 years from initial treatment. Crnkovich et al [53] reviewed the treatment records of 180 patients with pathologic stage IBIIB HD treated at Stanford and the JCRT. In this retrospective review, the two most important disease characteristics predictive of relapse were the number and type of B symptoms and the presence of a large mediastinal mass. Patients with both fever and weight loss had a 7-year freedom from relapse of 48% and an overall survival of only 57%. The poor prognosis in this subset was apparent for treatment either with radiation alone or with combined modality therapy. The presence of night sweats alone had no adverse effect on outcome. Among patients treated with radiation alone, there was similar freedom from relapse and overall survival irrespective of whether pelvic irradiation was included in the initial treatment fields. Combined modality therapy improved the 7-year freedom from relapse when compared with radiotherapy alone (86% vs. 74%, $P = 0.02$), whereas overall survival in the two treatment groups was virtually identical (88% and 89%, respectively). It was concluded that the presence of B symptoms was not necessarily a poor prognostic factor in patients with pathologically staged IAIIB HD, since their overall survival approached that of surgically staged IAIIA patients.[53] Thus, patients with stage IB or IIB disease can be treated effectively with either combined modality therapy or, after staging laparotomy, with mantle and para-aortic radiotherapy alone. The presence of both fever and weight loss and/or

a large mediastinal mass requires initial combined modality therapy. As previously emphasized, staging laparotomy and primary irradiation is no longer recommended as the best alternative since combination chemotherapy has proven to be well tolerated and spares the patient a major surgical procedure. Moreover, as the Stanford study demonstrated, combined modality therapy resulted in superior disease-free survival for stages IBIIB.

Radiation and Combined Modality Therapy for Large Mediastinal Masses

It is now well-recognized that a subgroup of stage I and II patients with large mediastinal masses have a significantly greater risk of relapse than patients with little or no mediastinal disease when treated with radiotherapy alone.[56] The most commonly accepted definition of a large mediastinal mass is a mass greater than one-third of the maximal intrathoracic diameter. However, this measurement alone is not a sufficient criterion for selecting which patients should be treated by definitive irradiation alone rather than by combined modality therapy. Other important selection criteria that should be considered in the evaluation of patients with a large mediastinal mass include (1) location of the mass: wide versus long, anterior and superior mediastinum versus mid-mediastinum; (2) involvement of multiple E sites; and (3) estimated volume of normal tissue that would need treatment with shrinking radiation fields. Treatment of all patients with a large mediastinal mass with initial radiotherapy alone results in a RFS of approximately 50%. However, in 1990 Hoppe and Behar reported a Stanford study [57] of a small series of selected patients with bulky mediastinal disease, who were carefully staged with CT scans to determine tumor volume, and then were laparotomy-staged (some patients were irradiated before surgery). These patients were treated with aggressive mantle radiation, which often included prophylactic treatment to the lungs. This treatment resulted in a 7-year freedom from relapse in 80% of patients and an overall survival of 100%. Careful monitoring of the tumor response during radiotherapy and the use of a shrinking field technique helped the Stanford group keep complications to a minimum. However, radiotherapy alone is inappropriate for most patients with early-stage HD who present with large mediastinal masses. Treatment with initial radiotherapy in these patients often requires extensive irradiation of the heart and lungs in order to include the large mediastinal mass in the radiotherapy port, which causes significant subsequent morbidity.

Although it must be recognized that patients with early-stage HD and large mediastinal masses treated with initial combined modality therapy achieve significantly better freedom from relapse at 10 years (83%) than do those treated by radiotherapy alone (49%), overall survival is virtually identical (8283%). [34] Despite the similarity in overall survival, most investigators concur that a 50% risk of relapse is too high, and therefore recommend combined modality therapy as the initial approach. Patients treated with radiotherapy alone tend to relapse in the initially irradiated field, as well as in adjacent untreated lymph nodes, while extranodal

relapses are seen primarily in the lung.

Therefore, for patients with large mediastinal masses, a combined modality approach is recommended. In the subgroup of patients who will receive initial combined modality therapy, staging laparotomy is not indicated, and treatment is initiated with ABVD (Adriamycin, bleomycin, vinblastine, dacarbazine) or one of the other regimens commonly used for advanced disease. Chemotherapy is given to maximal tumor response, as judged by chest radiographs and CT scans, after which two additional cycles of consolidation chemotherapy are given. Once maximal benefit from chemotherapy has been obtained, limited radiation therapy (generally to the mediastinum alone or to a mantle field) is used. With this combined modality approach, approximately 80% of patients will remain disease-free beyond 5 years. The medical and psychological advantage to this approach, with its high rate of RFS, cannot be underestimated. One unresolved question is whether patients with stage III and IV disease who have large mediastinal masses at presentation and in whom initial chemotherapy is the treatment of choice should receive consolidation radiotherapy to the mediastinum to decrease the risk of relapse in this one particular site. [58]

It is also important to recognize that most patients with large mediastinal masses treated either with radiation therapy or with chemotherapy plus radiation will have a residual mediastinal abnormality after treatment. Jochelson et al [59] noted that mediastinal abnormalities were common at the end of radiation or combined modality therapy for HD, and that they did not necessarily indicate persistent active disease or an increased risk of relapse. Persistent radiologic abnormalities may continue to improve in up to one-half of patients for >1 year after therapy. The use of high-dose gallium scanning may be particularly helpful when a residual mediastinal mass is documented, especially if the gallium scan is positive before treatment and reverts to normal following the completion of radiotherapy or combined modality treatment.[60] On the other hand, a persistently positive gallium scan after treatment is associated with a high likelihood of relapse and indicates the need for biopsy. [61] In young patients (<25 years old), a regenerating thymus during the 6 months after treatment may present as an enlarging anterior mediastinal mass. [33] This can be a diagnostic problem, as this mass may be gallium-positive.

Radiation and Combined Modality Therapy for Subdiaphragmatic Early-Stage Disease

HD below the diaphragm is a relatively rare clinical presentation, occurring in <5% of patients. Patients with early-stage subdiaphragmatic presentation tend to be older men with MC pathology.[13] [62] [63] Overall freedom from relapse and survival are similar to those of patients with supradiaphragmatic presentations, if compared stage for stage.[62] [63] [64] However, relapses tend to occur later in subdiaphragmatic presentations.

Historically, clinically staged IIIA patients with negative para-aortic nodes on lymphangiogram had a 10% incidence of splenic involvement at laparotomy, as compared with a 52% incidence of splenic involvement when the para-aortic nodes were positive. [13] [62] In subdiaphragmatic clinical stage IIB disease, risk of splenic disease was even higher (89%).

The M.D. Anderson group [65] treated 60 patients with infradiaphragmatic presentations. In 22 patients with inguinal/femoral or pelvic disease who were treated with irradiation alone, the 10-year freedom from progression and overall survival were 86% and 90%, respectively. In this retrospective analysis, the small numbers of patients with abdominal disease who were treated with radiotherapy plus MOPP fared better than did similar patients treated with radiotherapy alone. Patients with subdiaphragmatic pathologic stage IA were generally treated with inverted Y radiotherapy that included the splenic pedicle. In patients with pathologic stage IIA and II_S A with limited splenic involvement, TNI (including the mediastinum) and combined modality therapy appeared to be of comparable efficacy on the basis of limited data.[13] [62] [65]

For all subdiaphragmatic clinical stage I and II presentations, the incidence of possible intra-abdominal involvement is high enough to recommend combined chemotherapy and limited irradiation. Although results with primary irradiation appear similar, this approach requires staging laparotomy, which is no longer warranted.

Complications of Radiotherapy

Complications of radiotherapy are related to the technique employed, dosage administered, and irradiated volume. [43] [46] Mantle

and para-aortic radiotherapy or TNI is technically difficult and potentially hazardous. The complications of radiation are also directly related to the skill and experience of the radiotherapist. The acute side effects of radiotherapy include transient nausea and vomiting, dysphagia, and marrow suppression. These side effects subside shortly after radiotherapy is completed. Temporary alopecia may be expected in the occipital regions on either side of the mantle field. Late potential side effects of radiation include elevation of thyroid-stimulating hormone in 2550% and clinical hypothyroidism in 1020% of patients; [66] [67] symptomatic radiation pneumonitis in <5%; transient myelitis (generally manifested as electric-like shocks in limbs on neck flexion, known as Lhermitte sign); and rarely, radiation pericarditis or chronic restrictive fibrosis. Persistent myelosuppression is also a rare late complication. Radiation-induced decrease in bone growth has been noted in children. Radiotherapy appears to accelerate coronary artery disease.[68] [69] [70] The Stanford group has reported a 3.1 increased relative risk of death, primarily from late fatal myocardial infarction.[70] Variables affecting risk included: radiation dose (3000 cGy, no increased risk; >3000 cGy, relative risk was 3.5), lack of cardiac shielding, young age at radiotherapy (particularly younger than 20), and increasing duration of follow-up. Of 49 patients dying of myocardial infarction, 53% had a documented smoking history. The incidence of second neoplasms following radiotherapy alone or combined modality therapy is discussed in a separate section.

Combined Modality Therapy or Chemotherapy Alone for Early- and Intermediate-Stage Disease

Combinations of radiotherapy and chemotherapy in the treatment of early-stage HD have been used since about 1970, with the goal of increasing the cure rate. It is reasonable to assume that chemotherapy, effective in curing most patients with advanced disease, should be even more effective for subclinical disease that might be present after radiotherapy. Relapses after radiotherapy frequently occur in areas of extranodal disease, whereas relapses after chemotherapy most frequently occur in sites of pretreatment involvement, including bulky lymph node areas.

Combined Modality Therapy

Combined modality therapy for clinical stage I and II HD is shown in Table 68-8 . Randomized trials conducted at Stanford[37] [41] in pathologic stage I-IIA HD demonstrated that adjuvant chemotherapy could replace prophylactic irradiation to areas of occult subclinical disease. IF radiotherapy followed by MOPP or phenylalanine mustard, Alkeran, vinblastine (PAVe) chemotherapy achieved freedom from relapse and overall survival results comparable to those of TNI or STNI. [37] [41] [71] In a small study from Stanford,[41] [72] asymptomatic patients with pathologic stage I, II, and IIIA HD were randomly assigned to involved field radiotherapy plus vinblastine, bleomycin, methotrexate (VBM) chemotherapy versus STNI. Initially, there was no difference in either freedom from relapse or overall survival. However, follow-up results of that study[73] reveal freedom from progression at 10 years of 98% for VBM + IF vs. 78% for STNI. Overall survival of all patients, regardless of treatment arm, is 100% at 10 years. The VBM combination was empirically developed because of its presumed lower long-term morbidity (i.e., less effect on fertility and lower risk of leukemia). However, pulmonary toxicity is a potential risk in this bleomycin- and methotrexate-containing regimen. Although less toxic than either adjuvant MOPP or PAVe, the VBM combination is untested in large numbers of patients with advanced HD. A randomized study by the Stanford group [73] comparing sTNI vs. VBM plus IF in 78 clinically staged patients has again demonstrated comparable outcomes at 4 years median follow-up, freedom from progression was 92% for radiation alone and 87% for the combined modality regimen. These excellent results will need confirmation in a larger prospective study before VBM + IF can be considered an effective alternative in favorable presentations of early stage HD.

More recent trials confirm the data that combined modality therapy may substitute for primary irradiation. The EORTC [74] has compared a novel chemotherapy regimen of epirubicin, bleomycin, vinblastine, prednisone (EBVP) for six cycles plus IF versus STNI in 333 clinically staged favorable HD patients. This H7 study revealed a 5-year event-free survival of 90% versus 81% in favor of combined modality therapy.

The Milan group[75] has confirmed that IF irradiation is adequate as consolidative irradiation following ABVD. Santoro et al treated 103 clinical stage I and II patients with four cycles of ABVD followed by either IF or sTNI irradiation. With median follow-up of 38 months, freedom from progression was 95% versus 94%, with 100% of patients surviving.[75]

Cosset et al[39] reported the updated EORTC results in clinical stage III patients classified as having any one or more of the following unfavorable prognostic factors: B

symptoms, age 40 years, ESR 70, MC or LD histology, and/or clinical stage II with mediastinal involvement. In these patients, laparotomy was not performed. Patients were randomly assigned to either TNI or three cycles of MOPP, followed by mantle radiotherapy

TABLE 68-8 -- Clinical Stage I and II Hodgkin Disease: Combined Modality Therapy

	#	FFP	DFS	OS	Actuarial Analysis	Median Follow-up
Stanford[73]						
PS I-IIIA	72					9 yrs
sTNI vs.		78%		100%	10 yrs	
VBM + IF		98%		100%	10 yrs

VBM + IF		87%			5 yrs	
Milan[75]						
CS I-IIA	103					38 mos
ABVD + sTNI vs.		94%		100%	4 yrs	
ABVD + IF		95%		100%	4 yrs	
EORTC[74]						
CS I-II	333					6 yrs
favorable sTNI vs.			81%	95%	5 yrs	
EBVP + IF			90%	98%	5 yrs	

and a further three cycles of MOPP (Table 68-7). There was a significant difference in freedom from relapse at 9 years in favor of combined modality treatment (83% versus 66%), but overall survival showed only a borderline advantage for the combined modality patients (Table 68-7). In patients <40 years of age, no difference in long-term survival could be detected between the two forms of treatment.

A second EORTC trial in this unfavorable cohort randomized patients to MOPP for three cycles, mantle radiotherapy, MOPP for three cycles; or to ABVD for three cycles, mantle radiotherapy, ABVD for three cycles. At 5 years, RFS was significantly lower in the MOPP group (79%) than in the ABVD group (89%), but no difference in overall survival was noted (groups were virtually identical at 89%). [39] The M. D. Anderson group[50] [76] reported similar results with combined modality therapy using two cycles of MOPP and IF radiotherapy.

The obvious conclusion can be drawn from these studies that staging laparotomy is unnecessary if combined modality treatment is to be used as initial therapy. Moreover, when treatment is selected on the basis of prognostic factors in stage I and II disease, virtually all patients can be managed without staging laparotomy, using primary irradiation for very favorable disease settings and combined modality therapy for all other presentations. Questions remaining in this patient group include: which combination chemotherapy regimen should be utilized (ABVD as standard vs. others, such as VBM, [72] [73] EBVP,[74] EVA,[77] and NOVP[78]); what should be the duration of chemotherapy (short course, 34 cycles, vs. full course, 6 cycles); and finally, is the adjuvant regional irradiation necessary?

Less conclusive prospective data is available regarding combination chemotherapy alone in early stage Hodgkins disease. The National Cancer Institute (NCI) has conducted a pilot study in patients with pathologic stages IBII and IIIA, comparing IF radiotherapy followed by six cycles of MOPP, as compared to MOPP alone. [79] The small number of patients in each stage precludes definitive conclusions from this study. However, to date, there are no significant differences in either disease-free survival, freedom from relapse, or overall survival among these two groups.

Pavlovsky et al[80] reported the results of a randomized trial of cyclophosphamide, vinblastine, procarbazine, prednisone (CVPP) chemotherapy for six monthly cycles versus the same chemotherapy plus IF radiotherapy (3,000 cGy) in 277 patients with clinical stage III HD (Table 68-7). One or more of the following factors were considered prognostically unfavorable: age >45 years, more than two lymph node areas involved, or bulky disease. In the favorable group without any of these adverse prognostic factors, disease-free survival (77% vs. 70%) and overall survival (92% vs. 91%) were similar at 7 years for CVPP versus radiotherapy plus CVPP. These results are similar to comparable series of patients treated with mantle and para-aortic radiotherapy alone. Among patients in the unfavorable prognostic subgroup reported on by Pavlovsky et al[80] those treated with radiotherapy plus CVPP had a longer disease-free survival (75% vs. 34%) and overall survival (84% vs. 66%) than those patients treated with CVPP alone. However, the results with CVPP chemotherapy alone in this subgroup appear distinctly inferior to those reported in a small series of early stage patients treated with MOPP at the NCI. [81]

Longo et al[81] recently reported the updated results of a randomized trial of MOPP chemotherapy alone versus mantle and para-aortic radiotherapy in 106 patients with surgically staged IA, IB, IIA, IIB, and III_1 A disease (Table 68-7). With a median follow-up of 7.5 years, 96% of MOPP-treated patients achieved complete remission, with 7 (13%) relapses. Of the radiotherapy-treated patients, 96% achieved a complete response, but 17 (35%) relapsed. However, the radiotherapy arm of the study contained more patients with large mediastinal masses than did the chemotherapy arm. Four MOPP-treated patients (7%) and 10 radiotherapy-treated patients (20%) have died. Although the curves of complete response duration significantly favor MOPP, overall survival is not significantly different. [81] When patients with either large mediastinal masses or stage III_1 A are excluded from the analysis, there are no significant differences in either disease-free survival (67% for radiation vs. 82% for MOPP) or overall survival (85% for radiation vs. 90% for MOPP). Patients treated with MOPP had significantly more hospital admissions, episodes of febrile neutropenia, and documented infections and received more blood transfusions. The results from this study do not permit one to conclude that MOPP alone can be safely substituted for mantle and para-aortic radiotherapy for early-stage HD.

Biti et al[82] updated the results of a small randomized trial comparing MOPP alone with mantle and para-aortic radiotherapy for 89 patients with pathologic stage IIIA disease (Table 68-7). Complete remission was obtained in all radiotherapy patients compared with 40 of 44 (91%) of the MOPP patients. With a median follow-up of 8 years, overall survival was significantly higher in the radiation therapy group (93%) as compared to 56 percent in the MOPP group ($P < 0.001$), whereas freedom from progression and disease-free survival were similar. Relapsing patients had a much higher salvage rate in the radiotherapy group, reflected in the significantly improved overall survival. True recurrences (in sites of initial presentation) were significantly more frequent in the chemotherapy patients than in those treated with radiotherapy, who relapsed mainly in previously uninvolved sites. Early relapses (within 1 year from the end of treatment) were also more frequent in the chemotherapy group. Moreover, treatment-related complications were more severe in the chemotherapy group. [83] These data suggest that curative radiotherapy may achieve better local control of HD than does MOPP chemotherapy. Whether combined modality therapy is better than chemotherapy alone when utilizing regimens not containing MOPP, is the important question today in early stage Hodgkin disease. This answer must await future prospective study.

The role of primary irradiation in stage IIIA HD has previously been controversial. Table 68-9 summarizes the treatment results with either radiotherapy alone (generally mantle plus para-aortic irradiation or TNI), combined modality therapy, or chemotherapy alone. The use of combined radiation therapy and chemotherapy is associated with both a lower risk of relapse and improved survival for most patients with stage IIIA disease, as compared with radiation therapy alone. [84] [85] Previously, it has been reported that pathologic stage III_1 A (pathologic involvement of the spleen and/or upper abdominal nodes) and minimal splenic involvement could be successfully treated with either mantle and para-aortic radiotherapy or with TNI alone. [86] However, even in such patients, Marcus et al have recently reported a significant survival advantage for combined modality therapy. [31] Overall, among 93 patients with PS III_1 A retrospectively analyzed, freedom from relapse at 10 years was 39% for STLI, 55% for TNI, and 94% for MOPP plus STLI. Ten-year actuarial survival was 89% for combined modality patients versus 78% for STLI and 70% for TNI. Therefore, primary irradiation alone is no longer indicated in any subset of stage IIIA HD.

The most important question pertaining to the treatment of stage IIIA patients today is whether combined modality therapy is superior to chemotherapy alone.

Investigators from the NCI reported a 94% 10-year disease-free survival in a small number of stage IIIAIVA patients treated with MOPP alone. [87] Lister et al[88] reported a 10-year freedom from relapse rate of 85% in patients treated with mechlorethamine, vinblastine, procarbazine, and prednisone (MVPP) chemotherapy alone, as compared to 60% with TNI. However, there were no significant differences in overall survival between these two modalities. Crowther et al [89] compared MVPP chemotherapy alone with the same

Abbreviations: XRT, radiotherapy (either mantle and para-aortic or TNI); TNI, total nodal irradiation; STLI, subtotal lymphoid irradiation; CMT, combined modality therapy (generally extended field radiotherapy + MOPP); MVPP, nitrogen mustard, vinblastine procarbazine, prednisone; MOPP, nitrogen mustard, vincristine, procarbazine, prednisone; ABVD, Adriamycin, bleomycin, vinblastine, decarbazine; NS, not stated; FFR, freedom from relapse.

[a] III_1 , pathologic involvement of any of the following sites: spleen; splenic hilar, celiac, porta hepatis nodes.

[b] III_2 , pathologic involvement of para-aortic nodes, iliac, or inguinal nodes with or without involvement of the spleen and upper abdominal nodes.

[c] Minimal splenic involvement: <5 splenic nodules.

[d] Extensive splenic involvement: 5 splenic nodules.

chemotherapy regimen plus radiotherapy. There were no significant differences in either disease-free survival or overall survival between these two arms. Thus, it appears that MOPP- based chemotherapy alone is as effective as combined modality therapy for patients with stage IIIA disease.

In a small randomized study from Milan of 63 stage IIIA patients treated with three cycles of either MOPP or ABVD followed by extensive irradiation and then in some cases by three additional cycles of the same chemotherapy, the 7-year results indicated both improved complete response rates and freedom from progression with ABVD plus RT.[90] Moreover, it was reported that irreversible gonadal dysfunction as well as acute leukemia occurred only in patients subjected to MOPP, while cardiopulmonary studies failed to document a significant laboratory difference between the two treatment arms. These results suggest that ABVD as part of a combined modality therapy program is at least as effective as MOPP, with decreased morbidity.

The radiation dose and field size employed in combined modality therapy of bulky and intermediate stage Hodgkins disease continues to be defined. Low-dose RT (20002400 cGy) combined modality regimens have been utilized in pediatric patients and in adults with advanced stage disease. A recent prospective comparison of 2000 cGy versus 4000 cGy RT as extended field adjunctive therapy following combination chemotherapy of Stages IIIIA (bulky mass, E lesion, or massive splenic involvement) has revealed no significant differences in failure-free or overall survival at 5 years. [91] The bulky site was always treated with 4000 cGy. Among 26 relapsing patients, 18 failed in the bulky site or in extranodal sites. Acute toxicities were greater in the 4000 cGy group. Loeffler et al have concluded that 2000 cGy is sufficient as adjuvant RT in nonbulky sites, as part of a combined modality regimen. [91] This important report will require confirmation in larger studies before this dose schedule can be considered standard.

Patients with clinical or pathologic stage IIIB disease are generally treated with combination chemotherapy alone, as described in subsequent sections. However, selected small series suggest a possible role for combined modality in these patients. Mauch et al [92] treated 43 stage IIIB patients with combined modality therapy (IF radiotherapy plus MOPP). At 12 years they observed excellent freedom from relapse (79%) and overall survival (76%). Rosenberg and Kaplan, [37] reporting for the Stanford group, performed a series of prospective trials in pathologic stage IIIB disease, in which, again, small numbers of patients were treated with each combined modality therapy regimen. TNI plus MOPP resulted in only a 51% freedom from progression rate and 52% overall survival at 10 years. The Stanford investigators then proceeded to use two courses of initial chemotherapy, followed by TNI, followed by four cycles of the same chemotherapy (split-course technique). In this series of 42 patients, freedom from relapse of 82% and overall survival of approximately 72% at 8 years were observed. [37] Henkelmann et al[93] treated 26 patients with pathologic

stage III_1 B disease with two cycles of MOPP and TNI. They reported 78% freedom from progression and 91% overall survival at 10 years. In the randomized study conducted by Santoro et al,[90] a total of only 28 patients were treated with three cycles of either MOPP or ABVD, followed by IF radiotherapy, and then with three cycles of the same drug regimen. In this series, 78% of IIIB patients achieved complete remission with MOPP, as compared to 94% with ABVD. Freedom from progression also favored the ABVD patients (92% at 7 years), as compared with MOPP (65%).

Chemotherapy of Advanced Disease

MOPP-Containing Regimens

Since the late 1960s, a dramatic improvement has been observed in the prognosis of patients with advanced HD resulting from the development of curative combination chemotherapy. Until recently, MOPP represented the standard against which all alternative chemotherapy or combined modality regimens were judged. The landmark studies of DeVita et al[87] [94] at the NCI demonstrated that >50% of patients with advanced HD are cured with chemotherapy alone. An update of the NCI data has been reported by Longo et al, [95] who reanalyzed 188 of the original NCI patients after a median of 14 years of follow-up. A complete remission rate of 84% was reported; also, 66% of the complete responders had remained disease-free for>10 years. Thus, 54% of patients were continuously free of disease, and 48% were alive between 9 and 21 years from the end of treatment. It is important to note that 19% of the complete responders died of intercurrent illnesses while free of HD.

The major factors adversely affecting complete response rate in the NCI-MOPP trials were B symptoms, male sex, advanced-stage disease, and lower than projected rate of vincristine administration. [95] The most important factors predicting duration of complete response were B symptoms, age, rapidity of complete response (patients requiring five cycles or less had significantly longer remissions), number of extranodal sites of disease, and liver or pleural involvement. Maintenance chemotherapy after achieving complete remission had no influence on either disease-free or overall survival.

In the NCI-MOPP trials, most patients required six cycles of chemotherapy, but approximately 2025% of patients required two or more additional cycles. Restaging studies were generally performed after the fourth cycle, and if they were negative, two more cycles were administered. However, if continued tumor response was observed between cycles 4 and 6, two additional cycles of chemotherapy were administered followed by repeat staging studies. [33] Thus, it is current practice to administer six to eight cycles of chemotherapy, using the general guideline of treating to clinical or pathologic complete response (usually reassessed first after four cycles) plus two additional cycles. In the case of a stable residual mass that is unchanged by radiography or CT scan after two or more additional cycles of chemotherapy, the patient is classified as a clinical complete responder and chemotherapy is stopped. Further evidence for complete response in this situation is gained if the tumor mass went from gallium scan-positive before chemotherapy to gallium scan-negative after chemotherapy. These same principles apply to the duration of therapy for the newer drug combinations described later in this section.

The NCI-MOPP trials and subsequent studies over the next decade continued to use the end points of complete response, disease-free survival, and overall survival as measures of efficacy. However, determination of complete response may be difficult and ambiguous in the setting of advanced HD. This is particularly true in bulky disease, where a residual mass on radiography is frequently observed after six to eight cycles of combination chemotherapy. Disease-free survival refers only to patients who achieve a complete remission and does not reflect the outcome of the whole population of patients treated. Moreover, some investigators censor out patients who die from causes other than HD from their disease-free survival curves, artificially improving their results. Therefore, the most accurate and definitive end point for determining the effectiveness of any chemotherapy regimen is failure-free survival, also referred to as freedom from progression. Failure-free survival is defined for the entire group of patients treated and therefore counts as an event the following parameters: progressive disease, relapse from complete or partial remission, and death from any cause. Overall survival remains the most important end point and reflects not only the effectiveness of the primary chemotherapy regimen but also the efficacy of any secondary or salvage treatments.

Although MOPP revolutionized the treatment of advanced HD, there is ample opportunity for improvement in these results, since 1530% of patients do not achieve initial complete remission, and 3040% of complete responders eventually relapse. Although multiple studies with MOPP confirmed its efficacy in the treatment of advanced HD, numerous investigators attempted to design alternative combinations aimed at improving the therapeutic index of MOPP by reducing toxicity and attempting to improve the cure rate. These trials are described in detail in several reviews, [33] [46] [96] and selected alternative chemotherapy regimens are listed in Table 68-10 . For example, the BCVPP (BCNU [carmustine], cyclophosphamide, vinblastine, procarbazine, prednisone) regimen adds BCNU (carmustine or 1,3 bis[2-chloroethyl 1]-1-nitrosourea), while substituting cyclophosphamide for nitrogen mustard and vinblastine for vincristine. In a prospective controlled trial conducted by the Eastern

TABLE 68-10 -- Selected Chemotherapy Regimens for Advanced Hodgkin Disease

ABVD
Doxorubicin (Adriamycin) 25 mg/m^2 IV, days 1, 15
Bleomycin 10 U/m^2 IV, days 1, 15
Vinblastine 6 mg/m^2 IV, days 1, 15
Dacarbazine 375 mg/m^2 IV, days 1, 15
MOPP (NCI)
Nitrogen mustard 6 mg/m^2 IV, days 1, 8
Vincristine (Oncovine) 1.4 mg/m^2 IV, days 1, 8
Procarbazine 100 mg/m^2 PO, days 114
Prednisone 40 mg/m^2 PO, days 114
MOPP/ABVD
Month 1
Nitrogen mustard 6 mg/m^2 IV, days 1, 8

Procarbazine 100 mg/m^2 PO, days 114
Prednisone 40 mg/m^2 PO, days 114
Month 2
Doxorubicin (Adriamycin) 25 mg/m^2 IV, days 1, 15
Bleomycin 10 U/m^2 IV, days 1, 15
Vinblastine 6 mg/m^2 IV, days 1, 15
Dacarbazine 375 mg/m^2 IV, days 1, 15; alternate one cycle of monthly MOPP with one cycle of monthly ABVD
MOPP/ABV hybrid
Nitrogen mustard 6 mg/m^2 IV, day 1
Vincristine (Oncovine) 1.4 mg/m^2 IV (max = 2 mg/dose)
Procarbazine 100 mg/m^2 PO, days 17

Prednisone 40 mg/m^2 PO, days 1–14
Doxorubicin (Adriamycin) 35 mg/m^2 IV, day 8
Vinblastine 6 mg/m^2 IV, day 8
Bleomycin 10 U/m^2 IV, day 8, repeat every 28 days

Cooperative Oncology Group (ECOG), Bakemeier et al [97] compared BCVPP directly with MOPP. Although the complete response rates were virtually identical, the duration of complete response and the overall survival of the complete responders were significantly longer with BCVPP. Moreover, despite inclusion of the additional myelosuppressive agent BCNU, there were no significant differences in hematologic toxicity. Both severe and life-threatening neurotoxicity and gastrointestinal toxicity were significantly reduced on the BCVPP arm. Reporting for the Southeast Oncology Group, Gams et al [98] achieved similar results with BCVPP.

Several other alternatives to MOPP that are considered useful under specific circumstances emerged during the mid- to late 1970s. The MVPP combination substitutes vinblastine for vincristine (Oncovin) and has been used for patients who cannot tolerate the neurotoxicity of vincristine. [99] The LOPP regimen substitutes chlorambucil (Leukeran) for nitrogen mustard. A controlled trial compared LOPP with MOPP and achieved equivalent results with less toxicity for LOPP. [100] However, the results with both arms are inferior to other reports. The ChlVPP protocol [101] [102] substitutes chlorambucil for mustard and vinblastine for vincristine. Nausea, vomiting, and neurotoxicity are substantially reduced with ChlVPP, which makes it a valuable regimen, particularly for elderly patients. Selby et al [101] updated the British experience with ChlVPP in 229 previously untreated patients, 85% of whom entered complete remission. The disease-free survival of complete responders was 71% at 10 years,

and the 10-year overall survival for all patients was 65%. Acute toxicity was mild, and the 10-year actuarial risk of leukemia was 2.7%. Reporting for four research groups that pooled their data on the use of ChlVPP, Anderson et al [102] observed an 89% and 72% complete response rate in stage IIIA and IIIB/IV patients, respectively. Failure-free survival and overall survival at 5 years were 67% and 78%, respectively, for the stage IIIA patients. For the IIIB/IV group, 5-year failure-free survival was 51%, and 5-year overall survival was 63%. Patients aged 50 years with all stages of disease did especially poorly on ChlVPP therapy, making this less-toxic regimen much less useful in the older age population. [102] Although the BCVPP, MVPP, and ChlVPP regimens are attractive alternatives to MOPP, these combinations are generally no longer recommended as initial therapy.

The identification of the ABVD regimen as an active non-cross-resistant combination in relapsed HD led to the investigation of this new and important regimen in the previously untreated patient. In the original comparison of MOPP and ABVD as initial treatment, [103] the complete response rate with MOPP was 63%, as compared to 72% with ABVD. In addition, disease-free and overall survival were similar. Bonadonna et al [104] then proceeded with a controlled randomized trial in which 88 patients with stage IV HD previously untreated by chemotherapy were treated in a 12-month cycle with either MOPP alone or MOPP alternating every month with ABVD (Table 68-11). Although the complete remission rate with MOPP/ABVD was 89% compared to 74% with MOPP, this difference was not statistically significant, undoubtedly because of the small number of patients entered in this trial. The 8-year actuarial results also indicated that MOPP/ABVD was superior to MOPP in terms of freedom from progression (64% vs. 36%, respectively) as well as disease-free survival of the complete responders (73% vs. 45%). Tumor mortality (only deaths from HD included) was also significantly reduced on the MOPP/ABVD arm. However, the overall survival (including deaths from all causes) at 8 years was 76% on MOPP/ABVD versus 62% on MOPP. This difference is not statistically significant, but again this may be due to the small sample size in this study. Favorable prognostic factors in this trial include the fact that 28% of patients relapsed after radiotherapy alone and 30% were asymptomatic. Although this study has been criticized for the lower-than-expected freedom from progression and disease-free survival in the MOPP-alone arm, it is interesting to note that there were no differences in the overall survival rate between MOPP results seen in this study and the MOPP results from the NCI. However, a larger patient population and confirmatory clinical trials were clearly required before the apparent superiority of MOPP/ABVD could be accepted.

Two confirmatory trials have been completed and the results reported (see Table 68-11). Canellos et al [105] described the 5-year results of the Cancer and Acute Leukemia Group B (CALGB) controlled trial comparing MOPP, ABVD, and MOPP/ABVD in 361 eligible patients with HD stage III $_2$ AIVB. Patients received a minimum of six cycles of treatment with either MOPP or ABVD, which included two additional cycles after complete remission was obtained; MOPP/ABVD patients received six cycles of each combination for a total of 12 cycles. While this study has been criticized for the reduced doses of MOPP administered, doses were adjusted on the basis of observed toxicity and were not arbitrarily reduced. The complete response rate for MOPP/ABVD was 83%, compared with 67% for MOPP. However, the complete response rate for ABVD of 82% was similar to that with MOPP/ABVD. With a median follow-up of >4 years, these data have been reported in terms of 5-year actuarial results. Failure-free survival reported with MOPP/ABVD (65%) was significantly improved as compared to MOPP (50%) but was similar to that obtained with ABVD alone (61%). The overall 5-year survival for the treatment groups was similar and was not statistically significant: MOPP 66%, ABVD 73%, and MOPP/ABVD 75%. To date there is no advantage of MOPP/ABVD over ABVD alone. The ABVD regimen is attractive because of its relative lack of gonadal toxicity and absence of acute leukemia. However, on the question of ABVD or MOPP/ABVD versus MOPP, the CALGB trial clearly showed the superiority of MOPP/ABVD or ABVD alone.

The ECOG compared the MOPP/ABVD regimen with BCVPP alone and with BCVPP followed by low-dose consolidation radiotherapy administered to sites of pretreatment involvement in patients achieving a complete response. [106] In this protocol, each of the three chemotherapy regimens was administered for a minimum of eight cycles (or to complete response plus two cycles). Since there were no differences in complete response rate, failure-free survival, or overall survival at 6 years between the two BCVPP arms, they have been combined and compared directly with MOPP/ABVD. The complete response rate on MOPP/ABVD of 80% was significantly better than the 69% complete response rate on the combined BCVPP arms. Although there are no significant differences in complete response duration, both failure-free survival and overall survival were

Abbreviations: N, number of eligible patients; CR, complete response rate; FFS, failure-free survival for all eligible patients entered in study; OS, overall survey for all patients; RT, radiotherapy. See Tables 68-9 and 68-10 for definitions and doses of the chemotherapy regimens.

[a]P 0.05 for the comparison of the experimental arm compared with the MOPP-type regimen.

significantly improved on MOPP/ABVD. At 6 years, the failure-free survival on MOPP/ABVD was 59% versus 47% on the combined BCVPP arms. At 6 years, 73% of the MOPP/ABVD patients were alive, compared with 63% of those receiving either of the BCVPP regimens. Importantly, the MOPP/ABVD data from ECOG [106] are virtually identical to those reported by CALGB [105] and by Bonadonna et al[104] All three of these prospectively randomized trials provide strong evidence of the superiority of MOPP/ABVD over MOPP.

The MOPP/ABVD regimen was based on clinical empiricism (i.e., the therapeutic limitations of MOPP and the apparent effectiveness of ABVD as salvage therapy in MOPP-refractory patients) and preceded the mathematical model proposed by Goldie et al [107] The Goldie-Coldman hypothesis predicts that the efficacy of treatment will be enhanced by the earliest introduction of the most rapid alternation of all active single agents in a chemotherapy regimen to decrease drug resistance. Klimo and Connors[108] [109] [110] reported the updated results of a MOPP/ABV hybrid regimen (Tables 68-8 and 68-11) designed to test the Goldie-Coldman hypothesis prospectively. In this regimen, decarbazine is omitted, the adriamycin dose is increased, prednisone is administered for 14 days, and MOPP is given on day 1, while ABV is given on day 8. Treatment is administered for a minimum of six courses of therapy, with patients in complete remission at that time receiving two additional courses. In patients who have a partial response limited to a single nodal area, local radiotherapy is administered, whereas for more extensive residual disease further MOPP/ABV is given. In the original report, of the 76 evaluable patients, 97.5% achieved complete remission, 84% on chemotherapy alone and 13% with IF radiotherapy. In Klimo and Connorss 1988 report,[109] only seven patients (9.5%) relapsed, most of these patients being males with large mediastinal masses and B symptoms. Actuarial RFS of the 74 complete responders was 94% with a median follow-up of almost 4 years; overall survival for all patients was 79%. The toxicity of this regimen was acceptable, with only one death from toxic effects and <10% of patients requiring hospitalization for a suspected or proven systemic infection. In this study, 40% of patients were asymptomatic, 17% had stage II disease, and the very high complete response rate included patients who received radiotherapy for residual disease. Nonetheless, the results with the MOPP/ABV hybrid regimen represented a potential increase in the cure rate for advanced HD. In addition, it remained to be determined whether the MOPP/ABV hybrid was equivalent or superior to alternating monthly MOPP/ABVD.

Three confirmatory trials have now been reported (Table 68-11). The Intergroup trial led by ECOG compared the MOPP/ABV hybrid regimen to sequential MOPP followed by ABVD, in which MOPP alone is administered to the point of complete remission or stable partial response followed by three cycles of ABVD in consolidation.[111] No radiotherapy was administered in either arm of the Intergroup trial. The complete response rate on the MOPP/ABV hybrid was 83%, compared with 79% on the sequential regimen ($P < 0.02$). The 8-year failure-free survival (FFS) of 64% on the hybrid program was also superior to the 54% 8-year FFS on the sequential arm ($P = .01$). Moreover, the 8-year overall survival of 79% for MOPP/ABV hybrid was significantly better than the 71% overall survival on the sequential MOPP followed by ABVD ($P = 0.02$). There was no difference in the incidence of severe or very severe leukopenia between the two arms, while significantly more patients on the sequential MOPP/ABVD arm had thrombocytopenia. Infectious and pulmonary complications were greater on the hybrid arm, whereas there was no difference in neurotoxicity. Myelodysplasia or acute myelogenous leukemia was documented in nine patients receiving sequential MOPP/ABVD and in one patient receiving MOPP/ABV hybrid. ($P = 0.01$) Thus, the Intergroup trial provides definitive evidence for the superiority of MOPP/ABV hybrid over MOPP, even when MOPP is augmented by ABVD given as late consolidation to complete responders.

The NCI of Canada has compared the MOPP/ABV hybrid regimen with Bonadonnas alternating monthly MOPP/ABVD, with radiotherapy administered in both arms to selected patients with residual nodal disease. [110] [112] The most recent analysis at 5 years reveals that the complete response rates were similar: 83% on the hybrid and 76% on MOPP/ABVD.[112] At 5 years, the FFS for both regimens is not significantly different (Table 68-11). This important trial demonstrates the equivalence of the MOPP/ABV hybrid regimen and alternating monthly MOPP/ABVD. In an earlier report from the NCI of Milan, Viviani et al [113] also compared alternating half-cycles of MOPP and ABVD with their original MOPP/ABVD program and found no significant differences between these two eight-drug regimens (see Table 68-11).

ABVD as Standard Chemotherapy

Thus, the cumulative results of prospective trials comparing MOPP or MOPP-containing regimens with ABVD alone (as described previously and as outlined in Table 68-11) have demonstrated that ABVD must now be considered the standard drug combination for advanced HD. The first report suggesting ABVD superiority was by the Milan group comparing MOPP with MOPP/ABVD. The CALGB subsequently compared MOPP versus MOPP/ABVD versus ABVD, confirming the superiority of the ABVD-containing regimens and demonstrating the equivalence of MOPP/ABVD and ABVD. MOPP/ABVD was then compared to MOPP/ABV hybrid by the NCI Canada and found equivalent.

Finally, the most recent pivotal intergroup study is that led by CALGB comparing ABVD versus MOPP/ABV hybrid in which the outcomes of 856 prospectively randomized patients were reported with three-year median results. [114] Although follow-up is still short, outcomes were equivalent between the two regimens (complete response 73% vs. 71%; FFS 67% vs. 65%; and overall survival, 85% vs. 87%). However, toxicity was significantly greater with the MOPP-containing hybrid regimen for pulmonary, hematologic, and infectious complications. Moreover, secondary malignancies were significantly more frequent with the hybrid regimen.

A summary algorithm of Table 68-11 may be outlined as
ABVD MOPP/ABV hybrid = MOPP/ABVD > MOPP
The selection of ABVD as the standard regimen is based on equivalent, or better, complete response rates, failure-free survival and survival as compared with MOPP-containing regimens. Moreover, toxicities of infertility, secondary leukemia, and complications of myelosuppression are significantly reduced. ABVD is not without serious potential toxicity, however, and must be used with caution.

Unfortunately, ABVD does not cure all patients with advanced HD, and new strategies are clearly needed. One approach is a short-course, dose-intense regimen such as Stanford V[115] or BEACOPP (see Table 68-12).[116] Both combination programs utilize involved field adjuvant irradiation. Preliminary results have been encouraging, and BEACOPP has been prospectively compared with COPP/ABVD in 321 patients revealing significant improvement in CR (89% vs. 76%), with decreased progression (7% vs. 16%), and death rate (5% vs. 13%). Neither BEACOPP nor Stanford V has been compared to date with ABVD.

Autologous stem cell transplantation has an important place in the standard management of relapsed and refractory HD. Its role in upfront management of poor risk subsets is yet to be defined. The first question is whether a poor risk group can be identified that justifies no initial trial of standard therapy. As

reported by Hasenclever and Diehl, [117] prognostic factors that have been reported as adversely affecting outcome in advanced HD include age 45 years, male gender, Stage IV presentation, albumin <4.0 mg/dl, hemoglobin <10.5 gm/dl, white blood cell count 15,000/l and lymphocyte count <600/l or <8%. In this prognostic model, the cumulative number of factors correlates well with 5-year failure-free survival. For example, FFS at five years is 84% in patients with no poor risk factors, 60% for those with 3 factors, and 42% for those with five or more factors. Such predictive modeling may assist in the design of future clinical trials comparing ABVD with dose-intense regimens.

A pilot study by Carella et al has reported 22 patients experience with MOPP/ABVD induction followed by ASCT consolidation in high-risk HD. [118] A historical comparison with MOPP/ABVD has revealed an improved outcome in the high risk ASCT-treated patients (77% disease free at 86 months as compared to 33% at 89 months for MOPP/ABVD alone). This important question will require a prospective randomized trial with long-term follow-up, as it can be anticipated that ASCT may produce a greater frequency of immediate and late effects that could negatively influence survival outcome in otherwise cured patients.

Since it is well known that most relapses following chemotherapy for advanced HD occur in nodal sites, other investigators have evaluated the additive role of low-dose radiotherapy administered following chemotherapy to sites of pretreatment involvement. Prosnitz et al [119] updated their combined modality results for 102 previously untreated patients with stage IIIBIV disease and for 82 patients who relapsed after initial treatment with radiotherapy. During the initial years of their studies, induction chemotherapy with mechlorethamine, vincristine, vinblastine, procarbazine, prednisone (MVPP) for 6 months was followed by low-dose radiotherapy (1,5002,500 cGy) to all disease sites present prior to chemotherapy. Subsequently, induction chemotherapy for poor-risk advanced-stage patients was changed to MOPP/ABVD and ultimately to a randomization between MVVPP and MOPP. The results of the three induction chemotherapy regimens were similar. The overall

complete response rate was 82%, with a 5-year relapse-free survival rate of 70%. However, the 15-year actuarial overall survival of all treated patients was 54%, which is not significantly different from that reported by the NCI for MOPP alone. Of the 184 patients, 17 died of causes other than HD, 11 with secondary malignancies.[119]

ECOG attempted to reproduce the results reported by Prosnitz et al in two separate controlled studies, reported by Glick et al [106] [120] [121] In the first of these trials, sequential bleomycin-MOPP (Bleo-MOPP) followed by ABVD was compared with the same induction chemotherapy with Bleo-MOPP followed by low-dose radiotherapy administered according to the technique used by Prosnitz et al [119] The overall complete response rate in both arms was identical (75%), but the 8-year freedom from progression on the sequential Bleo-MOPP/ABVD arm was 62%, compared with 44% on the Bleo-MOPP/radiotherapy arm.[121] This difference is statistically significant. In addition, the 8-year overall survival rate of 78% for all patients on the sequential Bleo-MOPP/ABVD arm was significantly better than that achieved on the radiotherapy arm (65%). These results were not known at the time a second ECOG study was initiated in 1981. The Prosnitz radiotherapy technique was again used in an ECOG protocol in which alternating monthly MOPP/ABVD was compared with BCVPP alone or followed by low-dose radiotherapy. Again, no differences in complete response rates, disease-free survival, or overall survival were noted in the two BCVPP arms. [106] The German Hodgkins Study Group has also reported a prospective comparison of consolidative combination chemotherapy (COPP/ABVD) versus low-dose involved field RT (2000 cGy) in 100 complete responders to COPP/ABVD.[122] Involved field RT resulted in no significant improvement of failure-free survival or survival in patients with advanced Hodgkins disease. Thus, three large-scale randomized trials have failed to confirm any significant benefit for administration of low-dose radiotherapy to sites of pretreatment involvement once a complete remission has been obtained with chemotherapy.

Salvage Therapy for Advanced Disease

The choice of salvage therapy for HD relapsing after initial treatment is one of the most difficult challenges and must be individualized to the clinical circumstances of the relapse. Four broad categories of treatment failures after initial therapy have been identified: (1) patients with early-stage disease relapsing from primary radiotherapy; (2) patients whose initial complete response to front-line chemotherapy lasted >1 year; (3) patients whose initial complete response to chemotherapy lasted <1 year; and (4) patients who fail to achieve a complete remission with initial chemotherapy. The treatment of choice for the first category is one of the accepted chemotherapy regimens used as initial treatment for stage III or IV disease. Thus, ABVD, MOPP/ABVD, or the MOPP/ABV hybrid regimen should be used in full doses with the realistic expectation of achieving complete response rates, failure-free survival, and overall survival as good as, or better than, that achieved with initial chemotherapy for stage IIIB and IV disease. Although the risk of significant myelosuppression is recognized under these circumstances, salvage chemotherapy results in the cure of 50% of patients who relapse after radiotherapy alone. [46] [123] As the risk of secondary leukemia will approach 10% at 10 years in patients receiving MOPP salvage regimens, ABVD is the first choice, if possible. However, patients relapsing after receiving mantle radiotherapy may experience an increased risk of cardiac or pulmonary toxicity when ABVD is used alone as a salvage treatment. Therefore, close cardiac and pulmonary monitoring is warranted.

Even for patients whose initial complete response to chemotherapy lasted >1 year, retreatment with the same or a cross-over regimen (e.g., MOPP-treated patients receiving MOPP a second time or crossing over to ABVD at relapse) will result in a durable remission in only one-third or less of cases. [124] [125] [126] [127] [128] [129] [130] The NCI recently updated their experience using retreatment with MOPP in patients with recurrent HD who had previously achieved complete remission with the same initial chemotherapy.[124] Among patients with long initial remissions (>1 year), RFS at 10 years was 45%, but the development of second neoplasms and other treatment-related mortality reduced the overall survival to 24%. Among patients with a short (<1-year) initial remission, only 11% survived >10 years. The follow-up results from the Milan group on long-term salvage therapy with ABVD are similar to the NCI data. [125] Those patients whose initial response to chemotherapy lasted <1 year or who fail to achieve a complete response with initial chemotherapy represent a very poor risk group. Although complete response rates ranging from 1372% have been reported with a variety of standard dose salvage regimens, prolonged disease-free survival is achieved in significantly <20% of patients. [124] [125] [126] [127] [128] [129] [130]

High-dose combination chemotherapy with autologous bone marrow or peripheral stem cell transplantation (ASCT), or both, has become the standard salvage approach for most patients relapsing after initial chemotherapy. This recommendation is based on (1) high rates of durable complete remission with ASCT regimens; (2) low rates of morbidity and mortality in selected patients with the availability of growth factors to hasten nadir myelosuppression recovery; and (3) poor outcomes in most patients treated with standard-dose salvage chemotherapy regimens.

ASCT in relapsed or refractory HD has several technical

components that can influence outcome. These include timing of the intervention (first or later relapse); type of stem cell rescue product (bone marrow or peripheral blood stem cells, or rarely allogeneic bone marrow); type of cytoreductive induction chemotherapy prior to ASCT to demonstrate chemoresponsive disease (e.g., ifosfamide/cisplatin-based regimens); type of preparative regimen (e.g., CBV [cyclophosphamide, BCNU, VP-16]; or BEAM [BCNU, VP-16, cytosine arabinoside, melphalan]); the use of consolidative irradiation; and the use of growth factors and other supportive care measures.

The Stanford group has recently summarized their experience with ASCT in recurrent/refractory HD. A case-matched comparison with conventional salvage therapy revealed significant benefit of ASCT at 4 years, in terms of failure-free progression, 62% versus 32%, although overall survival was not yet significantly improved (54% vs. 47%). [131] Among 119 patients transplanted,[132] adverse prognostic factors prior to ASCT included systemic symptoms, disseminated lung or bone marrow disease, and incomplete response to re-induction chemotherapy prior to ASCT. At four years, patients without adverse factors had an 85% freedom from progression as compared to 41% for those with one or more poor prognostic factors. Survival outcomes were not significantly affected by the kind of conditioning regimen employed, whereas involved field irradiation appeared to improve freedom from relapse in those with nodal involvement prior to ASCT. [133]

The University of Nebraska and M.D. Anderson groups have identified the number of prior chemotherapy regimens (two or fewer vs. three or more) and the absence of bone marrow disease as important prognostic variables in predicting significantly improved survival. Among 128 patients, failure-free survival at 4 years (37%, 31%, 10%) significantly favored patients who had failed one (35 patients), two (45 patients), or three or more (48 patients) chemotherapy regimens, respectively. [134] The Nebraska group has also reported their results of ASCT in 85 patients in first relapse of HD. [135] An overall failure-free survival of 40% at 5 years was reported. The 5-year failure-free survival was 32% for patients relapsing at <18 months after initial diagnosis compared to 47% for those with a relapse of >18 months after diagnosis. An early death was reported in 4% of patients, and overall survival at 5 years was 44%. It was concluded that ASCT should be considered in any patient relapsing after initial chemotherapy, regardless of the remission duration.

Most investigators agree that autologous transplantation is the standard salvage therapy, when possible, for refractory Hodgkin disease and for those patients relapsing within one year of conventional chemotherapy. The small randomized trial of the British National Lymphoma Investigation group [136] has conclusively demonstrated significantly improved event-free survival (at 3 years, 53% vs. 10%) among 40 patients randomized to ASCT with BEAM vs. Mini-BEAM without ASCT, respectively. All patients had refractory or early relapsing disease. Nevertheless, even in this study, overall survival was not yet significantly better for the ASCT group.

For relapses beyond one year, the question is somewhat more difficult as elucidated by Lohri and Connors. [137] However, as the acute toxicities of ASCT are better managed and mortality rates decline, ASCT has emerged as the standard, potentially curative, treatment option for the vast majority of refractory and relapsed patients.

For patients ineligible for ASCT, or in selected patients with very long first remissions, retreatment with the initial drug regimen or a second non-cross resistant conventional drug combination may be utilized. In addition to those listed in Table 68-12 , regimens developed by the Milan group such as lomustine or 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU), VP-16, and prednimustine (CEP) or ifosfamide/etoposide regimens may be considered. Following CEP, an ifosfamide/etoposide-containing regimen, or retreatment with MOPP/ABVD in

TABLE 68-12 -- New Short-Course Regimens in Hodgkin Disease

BEACOPP[116]		
Bleomycin	10 mg/m^2	day 8
Etoposide	100 mg/m^2	day 13

Doxorubicin	35 mg/m^2	day 1
Cyclophosphamide	650 mg/m^2	day 1
Vincristine	1.4 mg/m^2	day 8
Procarbazine	100 mg/m^2 PO	day 17
Prednisone	40 mg/m^2 PO	day 114
Repeat cycles every 3 weeks for 8 cycles		
Stanford V[115]

Etoposide	60 mg/m^2 IV	day 15, 16
Prednisone	40 mg/m^2 PO	QOD
Repeat cycles every 28 days for 3 cycles		

those with initial CR greater than 12 months, Bonfante et al have reported a second complete remission was achieved in 89% and, at 8 years, the freedom from progression was 44%, with overall survival of 54%.[138] These results appear to compare favorably with that of ASCT in second remission and further challenge the question of ASCT timing. The salvage chemotherapy regimen of etoposide, vinblastine, and doxorubicin (EVA) has also shown significant activity in recurrent HD. [139] Forty-five patients who were refractory or in relapse following MOPP as the only prior therapy were treated. The complete response rate was 40%. The median time to treatment failure was 10 months, with 31% progression-free at 42 months.

Thus, the treatment of choice for patients failing to achieve complete remission with initial chemotherapy alone or relapsing after an initial complete remission to chemotherapy for advanced disease is high-dose chemotherapy (e.g., CBV) plus ASCT. Since ASCT appears to be more effective in a setting of low-volume chemotherapy-responsive disease, it would appear that the optimal approach to these subgroups of patients would be to use a conventional-dose chemotherapy regimen to maximum clinical response (with or without involved field radiotherapy to the sites of residual disease) before employing ASCT. With this approach, a significant survival advantage and a realistic increase in the long-term cure rate may be expected.

Although salvage chemotherapy with non-cross-resistant regimens, combined modality therapy, or high-dose chemotherapy with ASCT is generally recommended for relapse from a chemotherapy-induced complete remission, extended-field radiotherapy alone may be curative in a small subset of this population. Several retrospective and selected series have been reported, [140] [141] from which it has been concluded that comprehensive salvage radiotherapy is of benefit for patients who have long disease-free intervals after initial chemotherapy and who have relapsed only in nodal sites without systemic dissemination of their disease. High-dose extended-field radiotherapy in this situation generally included the areas of nodal recurrence as well as covering adjacent nodal sites in the same manner as would be used in treating patients with early-stage HD. Therefore, most patients received either mantle and para-aortic radiotherapy or TNI. All patients in these trials had relapsed or had failed to obtain a complete remission after combination chemotherapy. The 5-year disease-free survival in these three series ranged from 25% to 48%, and the 5-year overall survival ranged from 30% to 70%. [140] [141] These results are not significantly different from those obtained with salvage chemotherapy alone in

patients who had had a complete remission of >1 year with initial chemotherapy. However, for selected patients with nodal disease at recurrence, who have had prolonged initial remission with chemotherapy and for whom either salvage chemotherapy with a non-cross-resistant regimen or high-dose cytoreductive chemotherapy plus ASCT is not an option, extended-field radiotherapy alone may be curative.

Complications of Chemotherapy

A major complication of combination chemotherapy is bone marrow suppression, with increased risk of infection and, rarely, hemorrhage. Peripheral blood counts are monitored carefully during chemotherapy, and drug doses are adjusted according to the degree of myelosuppression. However, with the availability of growth factor support, dose modification may not be necessary. As a cautionary note, drug dose reductions made simply for the purpose of decreasing subjective toxicity are inappropriate. Significant myelosuppression is seen with all the chemotherapy regimens commonly used for advanced disease or as part of combined modality programs.

Treatment-induced sterility, more commonly seen in males, is a frequent and often permanent side effect of chemotherapy. This is of particular importance because long-term survival is observed in most patients treated for advanced disease with combination chemotherapy. Irreversible sterility in males after treatment with MOPP and MOPP-containing regimens has been reported in a high percentage of patients, regardless of age, whereas drug-induced ovarian failure among females, resulting in premature menopause, is much more common in older patients. [142] [143] [144] The ABVD combination produces significantly less infertility than does MOPP. Children conceived after treatment for Hodgkins disease appear normal without increased rates of stillbirth, congenital malformation, or cancer. [144]

The incidence of congestive heart failure does not appear to be significantly increased with ABVD, but the dose of adriamycin is frequently limited to 300 mg/m ^{2} . Patients treated with ABVD and mantle radiotherapy have a significantly higher incidence of post-irradiation paramediastinal fibrosis; persistent dyspnea on exertion has been observed in a small number of these patients at 3 years after completion of therapy. [90] [145] Significant nausea and vomiting may occur with MOPP and with the MOPP-containing and ABVD regimens. The use of selective 5-HT3 (hydroxy tryptamine) receptor antagonists such as odansetron or granisetron has diminished, but not fully eliminated, these toxicities. These drug programs may produce serious psychological problems that require effective counseling as well as antiemetic agents. Mild to moderate peripheral neuropathy is commonly seen with vincristine, and muscular weakness is an indication to discontinue this drug. Aseptic necrosis of the femoral heads and rarely, the humeral heads, is an unusual late complication related to corticosteroid therapy. [43]

SECOND PRIMARY NEOPLASMS

Patients cured of HD are at an increased risk of the development of second primary cancers. The most widely reported neoplasm is acute myeloid leukemia, generally thought to result from combination chemotherapy or from treatment with both chemotherapy and radiation. An increased risk of solid tumors, usually attributed to irradiation, is emerging as a significant problem, as patients cured of HD are being followed for longer times. [41]

Tester et al[146] reviewed the NCI experience in 473 previously untreated patients, among whom 34 subsequent second malignant neoplasms were observed. At 10 years of follow-up, these investigators reported no increased risk of the development of leukemia in patients treated with radiotherapy alone. The estimated risk of leukemia following MOPP chemotherapy alone was 2%, and that following initial planned combined radiotherapy and MOPP chemotherapy was 6%, increasing to 9% in patients treated initially with radiotherapy who received MOPP chemotherapy at relapse. The 10-year estimated risk of solid tumors was 7% overall, with all treatment groups having similar risks. In contrast to other reports,[147] a greater risk of leukemia in patients who began treatment for HD at 40 years of age was not found. No case of acute leukemia occurred at >11 years after treatment. Actuarial analysis showed a peak onset of leukemia-related complications between 3 and 9 years after first treatment.[146]

Valagussa et al,[148] reporting for the Milan group, retrospectively reviewed the records of 1,329 patients, in whom a total of 68 new cancers were documented. None of the 19 cases of acute myeloid leukemia reported was observed in patients treated with radiotherapy alone. The 12-year estimate of leukemia development by treatment was 1.4% for chemotherapy alone, 10.2% for radiotherapy plus MOPP, 0% for radiation plus ABVD, and 4.8% for radiation plus other drug regimens. The incidence of leukemia was particularly high in patients who received salvage MOPP after relapse from radiotherapy. Valagussa and co-workers [148] also noted a positive association between increasing age and the risk of second malignancies, especially leukemia, which had been reported initially by the Southwest Oncology Group.[147] The overall risk of NHL in the Milan series was only 1.3%, and that of solid tumors, excluding basal cell carcinomas, was 6.7%. The failure to document an increased risk of leukemia in patients treated with ABVD chemotherapy alone or with radiotherapy plus ABVD is an important observation, since it appears that ABVD is more effective than MOPP in its ability to achieve long-term disease-free survival as initial chemotherapy for advanced disease. [105]

In a case-controlled study of 163 cases of leukemia following treatment for HD, Kaldor et al [149] observed that the use of chemotherapy alone to treat HD was associated with a relative risk of leukemia of 9.0, as compared with the use of radiation alone; patients treated with both modalities had a relative risk of 7.7. After treatment with more than six cycles of combination chemotherapy including nitrogen mustard and procarbazine, the risk of leukemia was 14 times as high as after radiotherapy alone. The use of radiotherapy in combination with chemotherapy did not increase the risk of leukemia above that produced by the use of chemotherapy alone. The peak in leukemia risk came approximately 5 years after the start of chemotherapy, and a large excess risk as compared with other treatment modalities persisted for 8 years after its discontinuance. Patients who had undergone splenectomy had at least twice the leukemia risk of patients who had not undergone this surgical procedure. Interestingly, Tura et al [150] have confirmed the observation that splenectomy, in addition to exposure to MOPP chemotherapy, increases the risk of secondary leukemia. In their study of 503 patients treated with MOPP plus irradiation, only 1 of 145 without splenectomy developed leukemia as compared to 21 of 358 splenectomized patients (5.9%). Moreover, an increasing number of MOPP cycles correlated with increasing risk of secondary leukemia, as reported by other groups.

A review by Tucker et al[151] of the Stanford series of 1,507 patients treated since 1968 indicated that 83 second cancers occurred >1 year after diagnosis. The mean 15-year actuarial risk was 18% for all second cancers, of which 13% were solid tumors. The risk of leukemia appeared to reach a plateau level of 3.3% at 10 years, whereas NHL continued to increase to 16% by the end of the follow-up period. Although these investigators noted that there was no increased risk of leukemia after radiotherapy alone, the risk of leukemia was significantly higher after either adjuvant chemotherapy or chemotherapy alone. The risk of a second solid tumor did not vary significantly according to treatment category, but the data did suggest that the risk of solid tumors after therapy for HD continues to increase with time.

The Stanford group has recently updated this data base, examining the risk of breast cancer in a cohort of 885 women with a mean follow-up of 10 years. [152] The overall relative risk (RR) of breast cancer was 4.1, and age at irradiation was a significant prognostic factor. For girls treated before age 15, RR was 136; at 1524 years, RR was 19; at 2429 years, RR was 7; and interestingly, at >30 years, RR was not elevated (0.7). Length of follow-up was also correlated with RR: <15 years, RR was 2.0; >15 years, RR was 13.6. This finding explains the lack of significant breast cancer risk observed in the earlier Stanford analysis by Tucker et al [151] Most breast cancers occurred within, or adjacent to, prior irradiation portals. Yahalom et al [153] from Memorial Sloan-Kettering also confirmed the increased risk of breast cancer in patients irradiated for HD. In this series, patients in whom breast cancer developed were more likely to be younger (median age 43 years) and to have bilateral disease, and involvement of the medial half of the breast was more frequent. The median interval from the treatment of HD to the diagnosis of breast cancer was 15 years.

Van Leeuwen et al[154] assessed the risk of second cancers in 744 patients admitted to the Netherlands Cancer Institute from 1966 to 1983. Among the 69 second cancers observed were lung cancer (14 cases), leukemia (16 cases), myelodysplastic syndrome (6 cases), and NHL (9 cases). The overall relative risk of the development of lung cancer was 4.9%. Excess lung cancer risk was noted only in treatment regimens including radiotherapy, and all lung cancers arose in irradiation fields. Kaldor et al[155] reported the results of a collaborative group of population-based cancer registries and major treatment centers using a case-control study. Patients treated with chemotherapy had about twice the risk of the development of lung cancer than that of patients treated with radiotherapy alone or both modalities. Among patients treated with radiation alone, the increased risk was related to estimated radiation dose to the lung. There was also a strong association between cigarette smoking in this population and the risk of lung cancer.

Mauch et al have reported the relative risks of second solid tumors in 794 patients with Pathologic Stage IAIIIB disease treated with radiotherapy alone or RT plus chemotherapy.[156] Risk increased with number of years post-treatment (3.7 at <5 years; 7.4 at 15 years) and was greater in patients treated at a young age (absolute excess risk at age of therapy: 69.6 if <17 years; 49.9 if 1739 years; and 5.7 if >40 years at age of therapy). Solid tumor sites included breast, gastrointestinal tract, lung, head and neck, and melanoma.

It is evident from these studies and others in the literature that treated HD patients have an increased risk of second neoplasms. The incidence of leukemia appears lowest in patients treated with radiotherapy and/or ABVD, whereas the development of solid tumors increases significantly over time in those receiving RT. The risk of leukemia is seen in patients treated with chemotherapy alone using a MOPP-containing regimen, with initial combined modality therapy using adjuvant MOPP, and with salvage alkylating agent-based chemotherapy following radiotherapy relapse. The peak risk of leukemia occurs at 58 years after initiation of chemotherapy, and no cases of leukemia have been observed at >10 years after the end of treatment. The risks of the development of solid tumors or acute leukemia must be taken into consideration in planning the initial treatment for an individual patient. Any predicted improvement in disease-free survival from initial therapy must be balanced against the possible risk of a second neoplasm at a later date.

It is reasonable to attempt to diminish the late treatment-associated risks of HD therapy with the following preventive strategies: counsel patients to stop smoking, encourage exercise and a cardiac prevention diet, monitor females for breast cancer with annual mammography beginning approximately seven years after RT (particularly important in women under age 30 at the time of irradiation) decrease sun exposure, monitor thyroid status yearly if patients have been exposed to prior neck irradiation, and suppress chemical hypothyroidism.

Chapter 69 - The Pathologic Basis for the Classification of Non-Hodgkin Lymphomas

William C. Pugh
J. Adelia McBride

INTRODUCTION

The histogenetic principles upon which the classification of human neoplasia has traditionally been predicated dictate that the malignant lymphomas, as neoplastic derivatives of the immune system, be classified in conformity with our understanding of the functional heterogeneity of lymphoid cells that make up the normal immune system. In view of the rapidity with which our understanding of immune system biology has grown in recent decades, it is not surprising that the evolution of lymphoma classifications has been swift and somewhat turbulent. In the span of some 40 years, these classifications have progressed from schemes recognizing only two essential cellular components (lymphocytes and histiocytes) to ones that now distinguish immature (precursor) from mature (peripheral) cells of B-, T-, and natural killer (NK) cell lineage, with additional phenotypic heterogeneity defined within each of these categories. The conjoint influences of monoclonal antibody technology and molecular biology have been largely responsible for these refinements, and it has been gratifying to note that neoplastic cells do indeed recapitulate the functional attributes of their presumptive normal cellular counterparts, thereby validating such an approach to tumor classification. However, our knowledge of the origin and function of certain specific constituents of the immune system, and of their neoplastic derivatives, remains rudimentary at best. In particular, the / T-cell and cytotoxic T-cell and NK cell malignancies, as well as lymphomas deriving from the whole of the extranodal immune system, have only recently become the objects of clinical investigation, in part because of their relative rarity and in part because of the lack, until recently, of the tools for their recognition. Our ability to classify these neoplasms has not progressed apace with the much more common node-based peripheral B-cell neoplasms.

In this chapter a very brief appraisal of the evolutionary history of lymphoma classifications, followed by a discussion of the normal developmental and functional anatomy of the immune system, will serve as a prelude to a review of the cardinal morphologic, immunophenotypic, and molecular genetic characteristics of the non-Hodgkin lymphomas.

HISTORICAL PERSPECTIVE ON LYMPHOMA CLASSIFICATIONS

The optimal classification of lymphoid neoplasia has been the focus of one of the most contentious debates in the history of nosology since the mid-1960s. While all could agree that a valid classification should be easily taught, readily learned, scientifically valid, and clinically relevant, a consensus as to how this might best be achieved proved elusive. The Rappaport scheme, initially introduced by Henry Rappaport in 1956, subdivided tumors with respect to growth pattern (nodular vs. diffuse), cell type (lymphocytic vs. histiocytic), and degree of differentiation (well differentiated vs. poorly differentiated vs. undifferentiated) and gained wide acceptance in the United States by both clinicians and pathologists. [1] The principal competing classifications were those of Karl Lennert, which became known as the Kiel classification and gained equally widespread endorsement in Europe, [2] and the Lukes and Collins classification, proposed by Robert Lukes and Robert Collins in the United States. [3] These classifications differed from the Rappaport classification in advocating a more rigorous reliance on the principles of cellular immunology as the conceptual basis for lymphoma classification. In the Kiel schema of 1974, which antedated the advent of monoclonal antibody technology, lymphoid tumors were related to discrete stages of lymphoid differentiation on the basis of their characteristic morphologic features. [4] [5] [6] [7] Each of these classifications spawned various congeners, rapidly leading to a surfeit of nomenclatures without any readily apparent intercorrelation. This awkward situation eventually led to an unprececented retrospective collaborative project between hematopathologists and oncologists treating lymphomas. This initiative culminated in the publication of the Working Formulation for Clinical Usage in 1982 (Table 69-1). [8] In essence the Working Formulation represented a modification of the Rappaport scheme, adapting some terminology from the immunologically based scheme of Lukes and Collins. Although it was intended only as a compendium of equivalencies among the various prevailing classification schemes and had been designed with the primary purpose of facilitating interinstitutional clinical dialogue, the Working Formulation quickly gained de facto acceptance as a classification and was favored by oncologists, who appreciated its grouping of lymphoid neoplasia into three clinically prognostic grades. The Working Formulation, like the Rappaport scheme, eschewed any formalized reliance on immunology or the then developing monoclonal antibody technologies, maintaining that tumor classification should be accomplished on a purely morphologic basis. The Kiel classification, in contrast, persisted in its pursuit of a precise histogenetic classification in accordance with the emerging principles of immune biology and was quick to embrace immunohistochemistry as an adjunctive tool in that quest. [9] These refinements were incorporated in the updated Kiel classifications of 1988 and 1992 (Table 69-2), as well as in later updates. [10] [11] [12] [13] Thus, the polyglot prehistory of lymphoma classifications became distilled over the past decade and a half into a largely bilingual era, which nonetheless preserved the essential dichotomies and controversies of the earlier period. More recently, as monoclonal antibody technology and molecular biology have contributed steadily to our understanding of lymphoid biology, the argument for an immunologically and genetically based classification of lymphoid neoplasia has become more and more compelling. Indeed, the nascent but certain prospect of specific, genetically based therapies virtually mandates such a classification. In accordance with these goals and the desire for a single consensus classification of lymphoid neoplasms, a proposal was recently offered by an international group of 19 hematopathologists under the rubric of the Revised European-American Lymphoma (REAL) classification (Table 69-3). [14] Unlike the Working Formulation, this project was undertaken without any systematic review of clinical data, and the resulting proposal was stated merely to reflect a listing of those entities which the participating pathologists considered to be well-defined pathologic or clinical entities that

TABLE 69-2 -- Updated Kiel Classification of Non-Hodgkin Lymphomas (1992)

B Cell	T Cell
Low-grade Malignant Lymphomas	
Lymphocytic	Lymphocytic
Chronic lymphocytic leukemia	Chronic lymphocytic leukemia
Prolymphocytic leukemia	Prolymphocytic leukemia
Hairy cell leukemia	Small cell, cerebriform
Lymphoplasmacytic/cytoid (immunocytoma)	Mycosis fungoides/Sézary syndrome
Plasmacytic	Lymphoepithelioid (Lennert lymphoma)
Centroblastic-centrocytic (follicular ± diffuse; diffuse)	Angioimmunoblastic
Centrocytic (mantle cell)	T-zone lymphoma
Monocytoid, including marginal zone cell	Pleomorphic, small cell (HTLV-I±)
High-grade Malignant Lymphomas	
Centroblastic	Pleomorphic, medium-sized, and large cell (HTLV-I±)
Immunoblastic	Immunoblastic (HTLV-I±)
Burkitt lymphoma	Large cell anaplastic (Ki1+)
Large cell anaplastic (Ki1+)	
Lymphoblastic	Lymphoblastic
Miscellaneous	
Other rare types of lymphoma may be separately identified for T-cell and B-cell lymphomas, respectively.	

TABLE 69-3 -- Revised European-American Lymphoma Classification (1994)

B-Cell Neoplasms
Precursor B-cell neoplasm
Precursor B-lymphoblastic leukemia/lymphoma
Peripheral B-cell neoplasms
B-cell chronic lymphocytic leukemia/prolymphocytic leukemia/small lymphocytic lymphoma
Lymphoplasmacytoid lymphoma/immunocytoma
Mantle cell lymphoma
Follicle center lymphoma, follicular
Provisional cytologic grades: I (small), II (mixed), III (large)
Provisional subtype: diffuse, predominantly small cell
Marginal zone B-cell lymphoma
Extranodal (MALT type ± monocytoid B cells)
Provisional subtype: nodal (± monocytoid B cells)
Provisional entity: splenic marginal zone lymphoma (± villous lymphocytes)
Hairy cell leukemia
Plasmacytoma/myeloma
Diffuse large B-cell lymphoma
Subtype: primary mediastinal (thymic) B-cell lymphoma
Burkitt lymphoma
Provisional entity: high-grade B-cell lymphoma, Burkitt-like
T-Cell and Putative NK Cell Neoplasms
Precursor T-cell neoplasm
Precursor T-lymphoblastic lymphoma/leukemia

Peripheral T-cell and NK cell neoplasms
T-cell chronic lymphocytic leukemia/prolymphocytic leukemia
Large granular lymphocyte leukemia
T-cell type
NK-cell type
Mycosis fungoides/Sézary syndrome
Peripheral T-cell lymphomas, unspecified
Provisional categories: medium, mixed, large, lymphoepithelioid
Provisional subtypes: hepatosplenic T-cell lymphoma subcutaneous panniculitic T-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Angiocentric lymphoma (nasal T/NK cell lymphoma)
Intestinal T-cell lymphoma (± enteropathy)
Adult T-cell lymphoma/leukemia
Anaplastic large cell lymphoma (T/null)
Provisional: anaplastic large cell lymphoma, Hodgkin-like
Hodgkin Disease
Lymphocyte predominance (nodular ± diffuse)
Nodular sclerosis
Mixed cellularity
Lymphocyte depletion
Lymphocyte-rich classic Hodgkin disease (provisional subtype)

could be recognized with reasonable reproducibility by experienced hematopathologists. [15] This proposal is, in essence, the Kiel classification, modified to incorporate extranodal lymphomas and Hodgkin disease, as well as a different conceptual approach to the still challenging classification of postthymic and extrathymic T-cell and NK cell lymphomas.[16] The REAL classification of 1994 is used as a structural framework for this chapter. The reader is advised, however, that classifications are constantly evolving, and the REAL classification is already undergoing further modifications, to be published as the WHO classification of lymphoid neoplasia.

LYMPHOPOIESIS AND THE FUNCTIONAL ANATOMY OF THE IMMUNE RESPONSE

Lymphoid cells of all lineages derive from a common progenitor cell that differentiates into precursor cells of B-, T-, and NK cell lineage. In fetal life, hematopoiesis is initiated in blood islands, followed shortly by the liver and spleen. This function is gradually transferred to the primary, or generative, lymphoid organs of the adult, where precursor lymphoid development proceeds. These generative organs are the bone marrow and, in the instance of T cells, the thymus as well. The precursor stage of lymphoid ontogeny is antigen independent, that is, it takes place in the absence of antigenic stimulation. During this early phase of differentiation B and T cells rearrange antigen receptor genes and ultimately express on their surface a functional and clonally specific immunoglobulin or T-cell receptor. [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] [44] This process is mediated by the concerted activities of several lymphocyte-specific recombinases. Recombinatorial diversity is further enhanced by the enzyme terminal deoxynucleotidyl transferase (TdT), which has the capability of randomly adding nucleotide bases to the newly formed genetic recombination sites in the absence of substrate direction. [45] Expression of TdT thus constitutes a highly useful marker for precursor lymphocytes without respect to lineage and is a definitive marker of precursor cell neoplasiathat is, lymphoblastic lymphoma/leukemia. The antigen receptor proteins, though membrane spanning, consist of only rather short intracytoplasmic tails, and must become associated with an appropriate membrane signal transducer, CD79a in the case of B cells and CD3 (aided by the proteins) in the case of T cells. [45] [46] [47] [48] [49] [50] [51] [52] [53] It is likely that these transducer proteins are expressed on the cell surface prior to the expression of the respective antigen receptors and are, in fact, requisite for the transport of the antigen receptor proteins to the cell surface. The subset antigens, CD4 and CD8, additionally form part of the T-cell receptor complex and define MHC class II and MHC class I restriction, respectively. [54] [55] [56] [57] [58] [59] [60] Although most CD4+ T cells function as helper cells and the majority of CD8+ T cells are functionally cytolytic or suppressor, there are exceptions in both directions.[61] [62] [63] Once a viable antigen receptor complex has been expressed by the developing cell, thereby rendering it capable of antigenic interaction, the cell acquires resistance to programmed cell death through the cellular expression of bcl-2 and related proteins and migrates to the secondary, or peripheral, lymphoid organs as a TdT naive (i.e., non-antigen-primed) B- or T-lymphoid cell. [64] [65] Those cells that express either nonfunctional or self-reactive antigen receptors are eliminated in the primary lymphoid organs through apoptosis. [66] [67] [68] [69] [70] [71]

Peripheral B cells comprise two principal populations of cells, distinguished by their expression of the CD5 antigen. [72] CD5+ B cells are rare in the adult, accounting for less than 510% of B cells, but they are the predominant B-cell population in the fetus, in which they appear to constitute a rather primitive but effective first line of defense against foreign antigens.[73] The immunoglobulin receptors of these naive cells are of IgM or IgD type (or both) and are characterized by highly selective utilization of a few variable region genes that have not yet undergone the mutational process of affinity maturation, with the result that these cells express only a limited antibody repertoire of broad specificity but low affinity. [74] In the adult these cells recirculate and, in tissues, home to the primary follicle and follicular mantle zone.[75] CD5+ B cells are implicated in autoimmune disease, in which they are frequently numerically expanded, [76] and are the presumptive precursors of the two common CD5+ B-cell malignancies, B-cell chronic lymphocytic leukemia (B-CLL, also known as small lymphocytic lymphoma/leukemia) and mantle cell lymphoma. [77]

The second, numerically preponderant, population of peripheral B cells is characterized by lack of CD5 antigen expression. This group includes a subpopulation of naive B cells as well as follicle center B cells and post-germinal center effector and memory B cells. With the exception of the naive B-cell subgroup, and in contrast to the CD5+ B-cell population, these cells generally show evidence of positive germinal center selection in the form of affinity maturation of immunoglobulin receptors with or without heavy chain class switch. This large family of B cells constitutes the precursors of virtually all B-cell lymphomas other than B-CLL and mantle cell lymphoma.

Peripheral T and NK cells, like their B-cell counterparts, can be segregated into families based on functional differences as well as differences in immunophenotypic profiles and T-cell receptor expression. [78] T cells are distinguished from NK cells by the presence of a functional surface T-cell receptor complex, including CD3, and absence of (or infrequent) expression of NK antigens. Mature T cells are further subdivided into two populations by virtue of their expression of either the / or the / heterodimeric T-cell receptor. Commercially available monoclonal antibodies to the and chains now readily permit this distinction to be made without resort to more complicated molecular analyses.[79] In lymphoid development, the process of T-cell receptor rearrangement is initiated by recombination of the / receptor genes. [80] The signals through which certain T cells remain permanently committed to / lineage, while the vast majority of precursor T cells undergo subsequent rearrangement of the / T-cell receptor genes to become / T cells, are presently unknown. [81] Indeed, it remains a matter of conjecture whether rearrangement of the / and / receptor genes occurs serially or in parallel in T-cell populations. It is evident, however, that, like CD5+ B cells, / T cells manifest very selective variable region gene usage and that the pattern of gene usage is correlated with specific patterns of tissue tropism. [82] Moreover, / T cells exhibit a remarkable propensity for extranodal localization, a property that appears to be recapitulated by their malignant counterparts. In the human adult, / T cells constitute fewer than 5% of peripheral lymphoid cells. Whereas in mice, / T cells compose the majority of intraepithelial T cells in the gut and a significant proportion of intraepidermal T cells, this does not appear to be the case in humans, in whom CD8+ / T cells predominate in these sites. [83] / T cells appear to mediate non-MHC-restricted immune interactions, largely of a cytotoxic nature, mediated by perforin and serine esterases. [84]

The much larger population of MHC-restricted / T cells can be further segregated based on patterns of expression of the subset antigens, CD4 and CD8. CD4+/CD8+ and CD4/CD8 phenotypes are largely thymic, or precursor, phenotypes and are rarely encountered in normal peripheral T cells, except for / T cells, which are typically double negative but may occasionally express CD8 or, very exceptionally, CD4. Cells expressing a CD4+/CD8 phenotype predominate over those with the inverse phenotype and are the precursors of the majority of node-based peripheral T-cell lymphomas. Normal CD4+ helper T cells function largely through lymphokine secretion, a property reflected in the polymorphous morphology of their derivative neoplasms (e.g., histiocyte aggregation and activation, vascular proliferation, eosinophil attraction). In contrast,

normal CD4/CD8+ T cells generally subserve a suppressor or cytotoxic function. Some, known as NK-like T cells, express NK cell antigens in addition to a surface T-cell receptor complex and possess perforin and granzyme-containing cytoplasmic granules that mediate cytolysis, analogous to the situation in NK cells. True NK cells lack both a T-cell receptor and surface CD3 but may express the CD3epsilon chain within the cytoplasm and usually express the CD56 NK-associated antigen. NK and NK-like T cells, both benign and malignant, can be recognized morphologically by their distinctive cytoplasmic azurophilic granules, which house the cytolytic proteins perforin and granzymes. NK cell lymphomas, like / T-cell lymphomas and / T-cell lymphomas that manifest a cytolytic phenotype, tend to localize to extranodal sites.

The secondary lymphoid organs constitute the lymph nodal network, the spleen, and various extranodal immune systems, including the mucosal and cutaneous lymphoid tissues. These organs collectively represent the principal sites of antigen concentration and are the preferential homing targets for naive lymphoid cells. Each of these organs is characterized by a functional anatomy that (1) allows for the constant sampling of lymph or blood (or both) for the presence of foreign antigens and (2) optimizes B-, T-, and accessory cell interactions in response to these challenges. Whereas T lymphocytes for the most part constitute a recirculating pool of cells that continually traffic between extranodal sites and lymph nodes and exert their influences locally via cytokines and cytolytic granule-associated proteins, B cells are largely confined to the secondary lymphoid organs, whence they exert their effector function remotely via secreted antibody molecules. T cells respond only to protein antigens, with a further requirement that these proteins be processed into short peptides and be presented on the surface of an appropriate

antigen-presenting cell (including macrophages, B cells, and dendritic cells) in conjunction with MHC molecules. [85] [86] [87] In contrast, B cells have the capacity to engage both protein and nonprotein antigens, which may be soluble, that is, non-cell-associated.

In the lymph node, the cortex, with its component primary and secondary lymphoid follicles, represents the principal B-cell region. The primary follicle is composed of small lymphocytes, predominantly naive B cells, with lesser numbers of memory B cells and small numbers of T lymphocytes and follicular dendritic cells. This structure thus represents both the precursor and the residuum of the germinal center reaction. The T-cell- and antigen-dependent phase of the immune response is initiated when a naive B cell, with its primitive (i.e., nonmutated) clonal antigen receptor, encounters antigen and, prompted by T-cell help, transforms into a primary B-cell blast (possibly the normal cellular counterpart of Burkitt lymphoma), which migrates into the B-cell follicle and there undergoes massive clonal expansion, giving rise to the secondary follicle center, or so-called germinal center. [88] [89] [90] In so doing, this cell down-regulates its expression of the bcl-2 protein and becomes susceptible to programmed cell death. In the basal, darkly staining zone of the germinal center, this primary B-cell blast differentiates into the cell morphologists recognize as the centroblast, characterized by a vesicular chromatin pattern, membrane-associated nucleoli, and basophilic cytoplasm. It is at this stage of transformation that the process of somatic mutation of immunoglobulin variable region genes occurs, resulting in affinity maturation of the primitive immunoglobulin receptor.[91] Heavy chain class switch is also initiated at this time, producing B cells of differing isotype but identical antigen specificity. The centroblast eventually transforms into the cell known as the centrocyte, recognized by its angulated nuclear contour, inconspicuous nucleoli, and scant cytoplasm, and migrates into the apical, lightly staining zone of the germinal center. This region is rich in follicular dendritic cells, which bind, immobilize, and retain immune complexes via complement and Fc receptors and in this form present antigen to follicle center B cells. It is at this stage that the process of antigen selection occurs, ensuring (1) the survival of those centrocytes in which somatic mutation has yielded an antibody of appropriate high affinity and (2) the elimination of other B cells. [92] If a centrocyte can sustain a stable interaction with antigen as a consequence of a high-affinity receptor, the centrocyte then ingests and processes that antigen and, in turn, presents the modified antigen on its surface in relation to MHC molecules. This composite antigen is in turn recognized by helper T cells, which respond by expressing a variety of surface determinants and secreted factors, including the CD40 ligand, that collectively induce the centrocyte to increase the density of its surface immunoglobulin expression and to up-regulate bcl-2 protein expression, which is under post-transcriptional control in the cell. This latter event effectively rescues the cell from apoptotic degradation and allows it to further differentiate into an effector cell of either plasmacytic or memory type. Plasma cells are terminally differentiated B cells in which alternative splicing of primary RNA transcripts of immunoglobulin receptor genes has resulted in loss of hydrophobic transmembrane domains, causing a switch from membrane-bound immunoglobulin to cytoplasmic and secreted immunoglobulin. Those cells that are not positively selected in the germinal center succumb to programmed cell death and phagocytotic elimination by the so-called tingible body macrophages of the germinal center.

The T-cell-rich zone of the lymph node is termed the paracortex. This region is composed predominantly of small T lymphocytes, most of which are CD4+ helper cells and are associated with a specific form of antigen-presenting cell referred to as the interdigitating reticulum cell. The latter cell is closely related to the Langerhans cell of the epidermis and performs two functions critical to T-cell activation. First, it is responsible for the proteolytic conversion of native protein antigens into MHC-associated peptide fragments, which are then presented to T cells for cognate interaction (essentially the same function performed by centrocytes in the germinal center reaction, as discussed above). Second, the antigen-presenting cells express and/or secrete a number of co-stimulatory molecules that maximize the T-cell response. Naive T cells enter lymph nodes either from afferent lymphatics or from the bloodstream. The latter route of access is mediated by specific homing receptors (selectins) for cuboidal endothelial cells that line specialized paracortical venules known as high endothelial venules. Similar venules are present in the mucosal immune system. Thus, particular patterns of adhesion molecule expression determine the preferential homing of naive T cells to lymph nodes, where the recognition and activation phases of the primary immune response take place with the aid of antigen-presenting cells. [93] [94] Following activation, altered profiles of adhesion molecule expression diminish the affinity of T cells for nodal endothelium, resulting in the displacement of activated T cells to sites of inflammation, where endothelial cell expression of ligands for activated T-cell integrins has been amplified by inflammatory cues. If activated T cells encounter antigen in these sites, adhesion molecule interaction is further strengthened and T cells are retained locally, where they accomplish the effector phase of the T-cell immune response. [95] [96] [97]

Whereas the lymph node system is the primary venue for immune responses to lymph-borne antigens, the spleen functions as the major site for immunologic responses to blood-borne antigens, and this function is reflected in its structure. The splenic arterioles terminate in a vast meshwork of red pulp sinusoids and cords, through which the blood is filtered prior to gaining re-entry into the venous circulation. This sojourn provides ample opportunity for the detection of foreign antigens by splenic lymphoid tissue, known as the splenic white pulp. The white pulp comprises T- and B-cell-rich sectors, just as in the lymph node, but with some differences. The periarteriolar

lymphoid sheath constitutes the principal T zone of the spleen and is composed of CD4+ and CD8+ / T cells in a ratio of approximately 2:1, in addition to antigen-presenting cells, including dendritic cells and macrophages. B-cell follicles, which may demonstrate germinal center formation, are situated adjacent to the periarteriolar lymphoid sheath and are in most respects analogous to their nodal counterparts. Surrounding both sectors is a specialized zone of B cells, macrophages, and helper T cells termed the marginal zone.[98] This zone, which is normally present only in the spleen, mesenteric lymph nodes, and other components of the mucosal immune system, appears to be particularly important in the immunologic response to nonprotein antigens, notably bacterial cell wall polysaccharides.[99] [100] Humoral immunity affords the only substantive host defense against such antigens, as these antigens cannot be recognized by T cells. Marginal zone B cells are distinguished by their surface expression of IgM in the absence of IgD. The splenic red pulp, in contrast to the white pulp, is selectively populated by cytotoxic T cells and contains a resident population of / T cells.

The mucosal immune system is most fully developed in the gastrointestinal tract, where it comprises the Peyers patches of the distal ileum, intraepithelial lymphocytes throughout the length of the intestine, and lymphoid cells distributed in the lamina propria of the entire gastrointestinal tract. Remote components of this system include the mesenteric lymph nodes and the spleen. The lymphoid follicles of the Peyers patches exhibit a functional organization similar to that of the spleen, with central germinal centers surmounted by a marginal zone, which intervenes between the germinal center and the overlying dome epithelium. Intraepithelial lymphocytes in the dome epithelium constitute an admixture of B- and T-lymphoid cells, the former tending to occur in small aggregates and the latter as singly distributed cells. T cells surrounding the lymphoid follicle are largely CD4+ helper cells. When protein antigen reaches the Peyers patches, B and T lymphocytes are stimulated to respond as in other lymphoid tissues. Two cytokines, TGF- and IL-5, both secreted by T cells, are implicated in mediating IgA isotype switch in activated B cells. The greater numbers of IL-5-producing T cells in Peyers patches as compared with other lymphoid organs and selective homing of IgA-producing B cells to Peyers patches account at least in part for the concentration of IgA-expressing B cells in this site. Intraepithelial lymphocytes elsewhere in the gastrointestinal tract are predominantly of T-cell lineage, with CD8+ cells predominating. Approximately 10% of intraepithelial lymphocytes in humans are of / lineage. Regardless of receptor class, intraepithelial T cells display restricted usage of variable region gene families with resultant limited diversity of antigen receptors, presumably reflecting an evolutionary origin to deal with commonly encountered luminal antigens. [101] [102] Cytolytic granule-associated proteins have been demonstrated in intraepithelial lymphocytes.[103] Finally, lymphoid cells of the lamina propria consist largely of CD4+ T cells that most probably home to this site following antigen recognition and activation in mesenteric lymph nodes. Lesser numbers of activated B-lymphoid cells and polytypic plasma cells, as well as eosinophils, mast cells, and macrophages, are also present in the lamina propria.

NON-HODGKIN LYMPHOMAS

Neoplasms of Precursor B and T/NK Cells

Precursor B-Lymphoblastic Leukemia/Lymphoma

The vast majority of cases of precursor B-cell neoplasia manifest an acute leukemic presentation with preferential involvement of peripheral blood and bone marrow. However, a small proportion of cases, perhaps 510%, present as solid tumors with a predilection for skin, bone marrow (osteolytic lesions), and lymph nodes. [104] This disease is most common in children and young adults, with a mean age at onset significantly less than that of precursor T-lymphoblastic lymphoma/leukemia, but may be observed in older adults as well. Although aggressive, this disease is frequently curable by existing therapeutic modalities. Approximately 80% of cases of acute lymphoblastic leukemia (ALL) and 1520% of cases of lymphoblastic lymphoma are of precursor B lineage.

The neoplastic cells of precursor B-lymphoblastic leukemia/lymphoma infiltrate in a diffuse pattern and exhibit an immature cytology, characterized by intermediate size, finely stippled chromatin, inconspicuous nucleoli, and scant cytoplasm. Nuclear contours may be either round or convoluted (Fig. 69-1A). The mitotic rate is high, consonant with developmental stage. The distinction between precursor B- and precursor T-cell neoplasms cannot be established on histologic grounds and must be supported by immunophenotypic studies. Differential diagnostic considerations based purely on morphologic observations include acute myelogenous leukemia (AML)/granulocytic sarcoma (extramedullary myeloid cell tumor) and blastic variants of mantle cell lymphoma. Immunophenotypic analysis may be required for distinction.

Precursor B-lymphoblastic leukemia/lymphoma, like its normal cellular counterpart, demonstrates consistent immunoreactivity for early B-cell antigens such as CD19, CD79a, and CD10, as well as nuclear positivity for the enzyme TdT. [105] Surface immunoglobulin expression is uniformly lacking, whereas heavy chains may be demonstrable in the cytoplasm. The stem cell antigen CD34 is often detectable, and the myeloid markers CD13 and CD33 may be infrequently encountered. Immunoglobulin heavy chain gene rearrangements are detectable in a majority of cases; light chain rearrangement is less frequent. [106] Incomplete rearrangements of the T-cell receptor genes may also be observed. [107]

Cytogenetic analysis may provide prognostic information. Karyotypic alterations associated with an unfavorable outcome include t(1;19), t(9;22), and abnormalities of 11q13. Cases with more than 50 chromosomes, in contrast, appear to have a favorable prognosis. Immunophenotypic profiles have also been correlated with outcome. In particular, myeloid antigen expression is said to confer an unfavorable prognosis, [108] as is lack of expression of the CD10 or CD34 antigens.

Precursor T-Lymphoblastic Lymphoma/Leukemia

Neoplasms of precursor T-cell lineage constitute roughly 15% of cases of ALL and 8085% of cases of lymphoblastic lymphoma, in contrast to precursor B-cell neoplasia, as discussed above. [109] These are tumors of adolescents and young adults, with a male preponderance. The disease typically presents as a bulky mediastinal mass, often attended by supradiaphragmatic lymphadenopathy, and is usually disseminated at diagnosis, with frequent involvement of the bone marrow, central nervous system, and gonads. The distinction of leukemic from lymphomatous disease is arbitrary, generally based on a threshold of 25% marrow blasts, but is now of lesser therapeutic importance, as most patients are currently treated on leukemia protocols.

The histologic and cytologic features of precursor T-lymphoblastic lymphoma/leukemia are identical to those described for neoplasms of precursor B lineage (Fig. 69-1B). Involvement of the nodal paracortex may be exceedingly subtle. Evidence of early nodal infiltration is often best sought in the trabecular structures and capsule of the node, where it is more readily appreciated by virtue of its striking single file pattern. A subset of cases of T-lymphoblastic lymphoma/leukemia distinguished by marked eosinophil infiltration has been associated with the subsequent development of AML or myeloproliferative

Figure 69-1 Lymphoblastic lymphoma/leukemia. **(A)** An example of cutaneous precursor B-cell lymphoma is composed of primitive intermediate-sized cells with convoluted nuclear contours. **(B)** Cytologic features in **(A)** are indistinguishable from those of the nodal precursor T-cell lymphoma shown here.

disease. The t(8;13)(p11;q12) and t(8;13)(p2123;q14) translocations appear to represent recurring abnormalities in such cases. [110] [111] [112]

Immunophenotypic studies are requisite for lineage assignment in lymphoblastic lymphoma/leukemia. In concert with its precursor B-cell counterpart, precursor T-lymphoblastic lymphoma/leukemia displays consistent immunoreactivity for the intranuclear enzyme TdT, which is now readily demonstrable using monoclonal antibodies in paraffin sections. Apart from this, the neoplastic cells may manifest an immunophenotypic profile corresponding to any discrete stage of thymic maturation, with leukemic cases tending to be less phenotypically mature than cases with a lymphomatous presentation. [113] [114] [115] [116] [117] The early T-cell differentiation antigen CD7 is almost uniformly present. Cytoplasmic CD3, with or without surface CD3, is often detectable, while the CD2 and CD5 antigens are less commonly observed. [118] CD1a is variably expressed, and the subset antigens CD4 and CD8 are expressed either in concert (double positive) or not at all (double negative), in contrast to tumors of peripheral T-cell lineage, in which the subset antigens have segregated. The CD10 antigen is present in about one-third of cases. NK-associated antigens (CD16 and CD57) are rarely encountered but have been associated with clinically aggressive disease in the small number of cases reported. [119] [120] [121] [122] [123] [124] [125] [126] [127]

T-cell receptor genes show an inconstant pattern of rearrangement. Neoplastic cells may express either the / or the / T-cell receptor or may fail to express T-cell receptors altogether. [128] Immunoglobulin gene rearrangements are variable and often incomplete. [129]

Cytogenetic abnormalities are common and typically involve T-cell receptor gene loci, in particular 14q11 (TCR-), 7q34 (TCR-), and 7p15 (TCR-). With the possible exception of t(9;17)(q34;q23), which was associated in one study with mediastinal disease and a rapidly progressive clinical course without leukemic conversion, and of the translocations associated with eosinophilia and subsequent transversion to myeloid disease, none of the karyotypic abnormalities appears to have prognostic relevance.

Neoplasms of Peripheral B and T/NK Cells

Peripheral B-Cell Lymphomas

CD5+ B-Cell Lymphomas

B-Cell Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma/Prolymphocytic Leukemia

This category comprises a group of related disorders distinguished histologically by a preponderant proliferation of small lymphocytes and prolymphocytes, admixed in varying proportion.[130] [131] [132] The disease affects older adults and is usually leukemic at presentation, often with concomitant involvement of lymph nodes, spleen, and liver; in this circumstance the term B-cell chronic lymphocytic

leukemia (B-CLL) is preferred. When the clinical presentation is nonleukemic, a diagnosis of small lymphocytic lymphoma is made and is understood to connote a B-cell neoplasm having all of the morphologic and immunophenotypic attributes of B-CLL. Approximately 10% of cases of B-CLL/small lymphocytic lymphoma manifest a terminal high-grade histologic transformation, referred to as Richter syndrome. [133] [134] This most often takes the form of a large B-cell or immunoblastic lymphoma, but may also evince paraimmunoblastic[135] or lymphoblastic morphology. A Hodgkin-like transformation, associated with Epstein-Barr virus (EBV), has also been described and appears to be less clinically aggressive. [136] [137] Alternatively, the disease course may be attended by a progressive increase in prolymphocytes in the peripheral blood, a phenomenon termed prolymphocytoid transformation. Prolymphocytic leukemia, by contrast, is a disease that typically presents de novo and manifests with splenomegaly, minimal lymphadenopathy, and very high white cell counts, with prolymphocytes constituting at least 55% (and usually a very much higher proportion) of lymphoid cells. [138] [139]

A definitive morphologic diagnosis of B-CLL leukemia and small lymphocytic lymphoma is most readily established in tissue biopsies, preferably lymph nodes. Despite the nomenclatural emphasis on the small lymphocyte, which generally exhibits a round nuclear contour and mature condensed chromatin pattern, the most characteristic and diagnostically reliable feature of these tumors is the invariant presence of prolymphocytes and paraimmunoblasts, frequently aggregated in proliferation centers. [140] The paraimmunoblasts are activated and proliferating cells, distinguished from small lymphocytes by their larger size, vesicular nuclear chromatin, and single, usually central nucleoli (Fig. 69-2). So characteristic are these cells that alternative diagnoses should be entertained if they cannot be identified in a reasonably representative biopsy specimen. Plasmacytoid differentiation is evident in a minority of cases and may be accompanied by a paraprotein. If proliferation centers are identified in such cases, they should nonetheless be classified as B-CLL (i.e., not as lymphoplasmacytoid lymphoma/immunocytoma) and will most often exhibit an immunophenotypic profile and clinical evolution typical of this disease.

The diagnosis of prolymphocytic leukemia, on the other hand, generally requires the availability of cytologic preparations such as peripheral blood and bone marrow aspirate smears or imprint preparations of lymph nodes or spleen. As previously stated, the diagnosis is based on the identification of a preponderant population of prolymphocytes, which display a less condensed chromatin pattern than small lymphocytes and small but definite single nucleoli (Fig. 69-3). This disease pursues a much more accelerated clinical course than that of the other indolent diseases included in this category. Indeed, a strong argument can be advanced for its separation from this grouping, as has been the case historically and as has been proposed in the WHO classification of lymphoid neoplasia.

The immunophenotype of this family of diseases is highly constant. B-CLL/small lymphocytic lymphoma expresses low-density monotypic surface immunoglobulin of IgM type, with or without IgD. Cytoplasmic immunoglobulin detection is variable and correlates with plasmacytoid differentiation. B-cell antigens such as CD19 and CD20 are expressed in association with both CD5 and CD23, in contradistinction to mantle cell lymphoma, which manifests a CD5+, CD23 phenotype. Neoplastic cells are nonimmunoreactive for the CD10 antigen and for FMC7, the latter commonly expressed in a host of other low-grade B-cell lymphomas. Expression of the CD11c antigen is variable and may identify a clinically distinctive subset. Prolymphocytic leukemia differs from this classic phenotype by a higher density surface immunoglobulin, variable CD5 expression, and more consistent expression of the CD22 antigen.

Cytogenetic studies have revealed the presence of trisomy

Figure 69-2 Small lymphocytic lymphoma. Note the distinctive admixture of small lymphocytes, prolymphocytes (medium-sized cells with small nucleoli), and paraimmunoblasts (large cells with prominent central nucleoli) that is the diagnostic sine qua non of this entity.

Figure 69-3 Prolymphocytic leukemia. A peripheral blood smear demonstrates the dominant population of prolymphocytes that characterizes this clinically aggressive B-cell leukemia. Neoplastic cells have a relatively mature chromatin pattern, but nucleoli are uniformly discernible.

12 in about one-third of cases, and abnormalities of 13q in roughly one-quarter. [141] [142] The t(11;14) is occasionally but infrequently encountered in the morphologic setting of B-CLL/small lymphocytic lymphoma.

Mantle Cell Lymphoma

The entity now termed mantle cell lymphoma [143] was initially described as centrocytic lymphoma in the Kiel classification and as intermediate lymphocytic lymphoma or mantle zone lymphoma in the United States. The characterization of this disease as a clinicopathologic entity proceeded more rapidly in Europe than in the United States.[144] However, the entity has now gained widespread acceptance through substantiating immunophenotypic and molecular genetic data and mounting evidence of a distinctly poor clinical outcome not predicted by its low-grade histology. Mantle cell lymphoma is largely a disease of adults, like other malignant lymphomas of small B lymphocytes, from which it differs by showing a distinct predilection for males and an aggressive clinical course with a median survival of approximately 3 years.[145] [146] [147] The disease is typically disseminated at presentation and has a propensity to involve Waldeyers ring and the gastrointestinal tract, where it accounts for most cases of lymphomatous polyposis.[148] Roughly 25% of cases are overtly leukemic at diagnosis. The disease is currently believed to arise from a small population of CD5+ peripheral B cells that selectively home to the follicular mantle. Transformation to large cell lymphoma is exceedingly rare, if it occurs at all.

Universal recognition of mantle cell lymphoma as a morphologic entity was delayed in part because of its rather subtle and occasionally deceptive cytological and architectural attributes. The disease most commonly demonstrates a diffuse growth pattern, but may also grow in a mantle zone configuration surrounding reactive germinal centers,[149] [150] and may even manifest a purely nodular or follicular pattern devoid of benign germinal centers, mimicking that of follicular lymphoma. [151] The neoplastic cells in the usual case are slightly larger than small lymphocytes and exhibit irregular nuclear contours, a less condensed chromatin pattern, indistinct nucleoli, scant cytoplasm, and a variable mitotic rate. At one extreme of the cytologic spectrum, so-called lymphoblastoid variants are composed of somewhat larger cells with stippled chromatin and a high mitotic rate, whereas at the opposite extreme, rare examples may closely simulate small mature lymphocytes. [152] [153] [154] A cardinal feature of mantle cell lymphoma regardless of cytologic or architectural pattern is the virtual absence of large transformed cells having features of centroblasts, immunoblasts, or paraimmunoblasts. Epithelioid histiocytes are often singly distributed among the neoplastic cells and may further aid in the recognition of this disease (Fig. 69-4).

Neoplastic mantle cells are characterized immunophenotypically by the presence of moderate-density monotypic surface immunoglobulin of IgM type, usually with coexisting IgD. In contrast to most other B-cell lymphomas, light chains are expressed in the majority (at least 65%) of cases. The tumor cells co-express B-cell antigens and CD5 but do not express the CD10 antigen. CD23 is not expressed, a feature of utility in the distinction from B-CLL/small lymphocytic lymphoma. Staining for the cyclin D1 protein, deregulated as a consequence of the t(11;14) observed in the majority of cases of mantle cell lymphoma, provides a highly specific marker for this disease, as this protein is not known to be expressed by any normal lymphoid population and is only very exceptionally detected in lymphomas of other histologic types.[155]

The translocation t(11;14)(q13;q32) characterizes the vast majority of cases of mantle cell lymphoma and results in overexpression of the cyclin D1 protein, which is involved in the complex regulatory mechanism of cell cycle progression. [62] [156] [157] [158] [159] [160] [161] [162] [163] [164] [165] [166] The breakpoints in this translocation are widely dispersed over a considerable nucleotide span, rendering this rearrangement less susceptible to polymerase chain reaction (PCR) detection than other recurring chromosomal translocations in hematolymphoid malignancies. [167]

CD5 B-Cell Lymphomas

Lymphoplasmacytoid Lymphoma/Immunocytoma

Lymphoplasmacytoid lymphoma, or immunocytoma, is largely a disease of older adults, usually associated with a serum paraprotein of IgM type and variably accompanied by the clinical syndrome of Waldenströms macroglobulinemia. The spleen, lymph nodes, and bone marrow are frequent sites of disease; extranodal involvement may also be seen. An absolute lymphocytosis is less a feature of this disease than of B-CLL. [168] [169]

The criteria currently proposed for a diagnosis of lymphoplasmacytoid lymphoma or immunocytoma are more restrictive than hitherto and rely to a certain extent on the rigorous exclusion of other entities (small lymphocytic lymphoma, follicle center lymphoma, marginal zone B-cell lymphoma, mantle cell lymphoma) that may on occasion be associated with plasmacytoid differentiation. [170] Thus defined, this entity most closely approximates the lymphoplasmacytic type of immunocytoma as elaborated by Lennert. These tumors are composed of a spectrum of small lymphocytes, plasmacytoid cells, and plasma cells and do not manifest any of the histologic hallmarks of other specific types of B-cell lymphoma (Fig. 69-5). The growth pattern is diffuse and often interfollicular. Lymph node sinuses often remain patent or even ectatic.

Lymphoplasmacytoid lymphoma is characterized by the simultaneous presence of surface and cytoplasmic immunoglobulin of the same isotype, most commonly IgM without IgD. The neoplastic cells express B-cell antigens but generally fail to co-express CD5. CD10 is not expressed, and expression of CD23 is variable. [7]

The t(9;14)(p13;q32), with breakpoints involving the *pax-5* gene on the short arm of chromosome 9, has recently been reported in cases diagnosed as plasmacytoid variants of small lymphocytic lymphoma. [171] [172] The *pax-5* gene encodes a transcription factor known as B-cell-specific activator protein (BSAP), which is normally expressed throughout B-cell development, but not in terminally differentiated plasma cells. [173] [174] [175] [176] [177] It is unclear whether such cases correspond to what would be classified as lymphoplasmacytoid lymphoma in the REAL classification.

Follicle Center Lymphoma, Follicular

Follicle center lymphoma and large B-cell lymphoma are the most frequently diagnosed lymphoma subtypes in the United States, each accounting for approximately one-third of all cases. Follicle center lymphomas are largely diseases of adults, having a peak incidence in the fifth and sixth decades. Exceedingly rare cases are observed in teens and young adults. The clinical presentation is usually nodal, and bone marrow involvement is documented at diagnosis in the majority of patients. The natural history of

Figure 69-4 Mantle cell lymphoma. **(A)** A typical example is composed of a diffuse proliferation of highly monotonous angulated cells with scant cytoplasm and a virtual absence of blasts. **(B)** A lymphoblastoid variant exhibits a more primitive nuclear chromatin. **(C)** Cyclin D1 staining highlights a mantle zone configuration in this mantle zone variant. Non-neoplastic germinal centers are negatively stained and are surrounded by a collar of dark-staining tumoral cells. **(D)**. In contrast is the nodular variant shown here, in which the neoplastic population has effaced the central germinal centers, leaving only vestiges focally discernible (unstained) in this cyclin D1 stain. This pattern is easily mistaken for follicle center lymphoma.

Figure 69-5 Lymphoplasmacytoid lymphoma/immunocytoma. A bone marrow aspirate smear contains small lymphocytes, plasmacytoid cells, and plasma cells. Mast cells (arrows) are often conspicuously increased in this lymphoma.

this disease is characterized by a continuous risk of histologic progression or transformation, usually to diffuse large B-cell lymphoma. Extranodal presentations, though infrequent, appear to be most common in the skin, with a particular predilection for the scalp. Molecular genetic evidence suggests, however, that fundamental biologic differences exist between primary cutaneous follicle center lymphoma and nodal follicle center lymphoma, despite their apparent morphologic similarities.

Histologically this disease is easily recognized as a consequence of its characteristic follicular growth pattern in lymph nodes. It must be emphasized, however, that tumors deriving from any of the zones of the B-cell follicle (e.g., mantle cell lymphoma, marginal zone B-cell lymphoma, nodular lymphocyte-predominant Hodgkin disease) may exhibit a nodular pattern, and thus it is imperative that the diagnosis be based on an assessment of the cytologic composition of the neoplastic follicles. Follicle center lymphomas invariably display the full spectrum of follicle center differentiation and are composed of a polymorphous admixture of centrocytes and centroblasts in varying proportion (Fig. 69-6). [178] [179] Several schemes for grading follicle center lymphomas, based on estimates of the relative or absolute numbers of centrocytes and/or centroblasts, have been proposed but have generally proved to be poorly reproducible and of questionable clinical utility. [180] [181] [182] [183] The follicular growth pattern may be accompanied by a component of diffuse growth. [184] [185] Rarely, the pattern may be entirely diffuse; follicle center origin is more difficult to establish in such cases. Sclerosis may be a prominent feature of this disease and is especially common in retroperitoneal presentations.

Follicle center lymphomas usually express surface immunoglobulin, which may be of any isotype, reflecting the phenomenon of heavy chain class switch that normally occurs during germinal center differentiation. Approximately 10% of cases are surface immunoglobulin negative but express other B-cell-associated antigens, confirming their B-cell lineage. These tumors typically express the CD10 antigen but are CD5 and CD23 variable. Staining for the *bcl*-2 protein, which is constitutively expressed in most follicle center lymphomas as a consequence of the t(14;18), is useful in distinguishing malignant from benign follicle centers but is of no utility in differentiating follicle center lymphoma from other types of low-grade B-cell lymphoma, many of which also express the protein. [186] [187] [188] [189] It should also be borne in mind that a fraction of follicle center lymphomas, particularly those of large cell type, cannot be demonstrated to express the *bcl*-2 protein, and nonimmunoreactivity for *bcl*-2 should not therefore exclude a diagnosis of follicle center lymphoma if all other features are typical. This pattern of more frequent *bcl*-2 expression by centrocytes than centroblasts recapitulates the normal process of germinal center differentiation and may perhaps indicate intrinsic biologic differences between low- and high-grade follicle center lymphomas. [190]

The cytogenetic and molecular genetic hallmark of follicle center lymphoma is the t(14;18)(q32;q21), which is observed in at least 85% of cases and leads to overexpression of the anti-apoptosis protein, *bcl*-2. [31] [191] [192] The practical consequence of this event is to confer a survival advantage on the cell, resulting in the steady accumulation of long-lived cells that are at risk for secondary genetic events. [193] [194] These secondary events, particularly those inducing cellular proliferation (e.g., c-*myc* activation), may correlate with histologic progression and disease acceleration. [195] [196] [197] [198] [199] [200] Bcl-2 breakpoints are highly clustered into two breakpoint regions, termed the major breakpoint region and the minor cluster region, facilitating detection by simple PCR strategies. [201] Accumulating evidence suggests that clinical outcome may correlate with the specific breakpoint site.

Marginal Zone B-Cell Lymphoma

As presently conceived, this category encompasses two closely related disorders that are distinguished on the basis of their patterns of clinical disease. By far the more frequent is the extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type (Fig. 69-7). This disease, initially characterized by Isaacson, represents the neoplastic derivative of the mucosal immune system, whose cytologic and homing properties it recapitulates. [202] [203] The stomach and salivary glands are the most frequent sites of involvement, although disease may be encountered in any extranodal site distinguished by the presence of a columnar or cuboidal epithelium. [204] [205] [206] [207] The disease is strongly associated with *Helicobacter pylori* infection in the stomach and with autoimmune manifestations in other

sites (Sjögren syndrome, Hashimoto thyroiditis).[208] [209] MALT lymphoma is a disease of adult life and is characterized by an exceptionally indolent clinical course, which, in conjunction with certain histologic features, delayed its recognition as a clonal lymphoid neoplasm. The disease is most often localized at presentation, although simultaneous or sequential involvement of multiple mucosal sites is often observed. [210] [211] The frequency of nodal dissemination is difficult to evaluate, as nodal disease may remain clinically silent for protracted periods and may be difficult to distinguish from a reactive process on a purely histologic basis. Marrow infiltration is uncommon. The demonstration that some gastric MALT lymphomas can be induced to regress in response to antibiotic therapy directed at *H. pylori*, coupled with the association with autoimmune disease, has led to the hypothesis that continued antigenic stimulation is critical to both the development and the maintenance of these distinctive tumors.[212] [213]

Figure 69-6 Follicle center lymphoma. **(A)** The follicular growth pattern is easily recognized, but can be closely simulated by lymphomas deriving from any of the zones of the B-cell follicle. **(B)** Neoplastic follicles invariably comprise an admixture of centrocytes and centroblasts.

The second disease included in this category is nodal marginal zone B-cell lymphoma, also referred to as monocytoid B-cell lymphoma. [214] [215] [216] [217] [218] [219] It now appears that the majority of these tumors represent nodal dissemination of underlying extranodal MALT lymphomas, which may not be clinically evident at the time of lymph node biopsy.[220] [221] [222] Nonetheless, occasional cases of apparently primary nodal marginal zone B-cell lymphomas are encountered and are histologically indistinguishable from low-grade B-cell lymphomas of MALT type with secondary nodal involvement (Fig. 69-8). Nodal involvement may be either

Figure 69-7 Gastric marginal zone B-cell lymphoma of MALT type. **(A)** The neoplastic proliferation consists of pale-staining cells of small to intermediate size that infiltrate in a marginal zone pattern around reactive-appearing germinal centers. Note the greatly attenuated rim of darkly stained apparent mantle zone lymphocytes that separates the neoplastic cells from the germinal centers. **(B)** A hallmark lymphoepithelial lesion shows partial destruction of a gland by clusters of neoplastic B cells, which in this instance evince plasmacytic differentiation.

Figure 69-8 Nodal marginal zone B-cell lymphoma. The cytologic composition and pattern of infiltration are indistinguishable from secondary nodal involvement by an extranodal marginal zone B-cell lymphoma of MALT type. Compare with Figures 69-7 and 69-9 .

localized or generalized, and marrow involvement may be seen.[223] Finally, it should be noted that focal monocytoid B-cell differentiation may be observed in other forms of low-grade B-cell lymphoma, most commonly follicle center lymphoma.

The unifying cytologic feature of both diseases is the marginal zone B cell, a small to medium-sized cell with abundant pale cytoplasm, which is commonly admixed in varying proportion with monocytoid B cells (similar-appearing cells with distinctly reniform nuclear contours), small lymphocytes, and plasma cells. [224] [225] [226] [227] Large transformed cells are commonly present, and overt large cell transformation may occur. The neoplastic proliferation is almost invariably attended by reactive follicle centers, about which tumor cells infiltrate in a marginal zone pattern, often with secondary involvement of the follicle centers themselves (so-called follicular colonization).[228] In lymph nodes, the pattern of infiltration may as well be sinusoidal or parafollicular. Lymphoepithelial lesions, consisting of epithelial units partially or entirely disrupted by discrete islands of small lymphoid cells, are a consistent finding in mucosal sites. Isotypic plasmacytic differentation may be extensive, causing diagnostic confusion with plasmacytoma.[229] The latter, however, consistently lacks a significant B-lymphocytic component and is not characterized by the presence of reactive germinal centers.

Marginal zone B-cell lymphomas express monotypic surface immunoglobulin, which may be of IgM, IgG, or IgA type. Cytoplasmic immunoglobulin is detectable in close to one-half of cases, reflecting plasmacytoid differentiation. There is no expression of CD5, CD10, or CD23, and expression of CD11c and CD43 is variable.

Karyotypic data are available in only a small number of cases because of the difficulty in obtaining analyzable metaphases. The translocations t(11;18)(q21;q21) and t(1;14)(p22;q32) have both been reported in extranodal cases, [230] [231] [232] [233] [234] as have a variety of numerical abnormalities, with trisomy 3 being most frequent. [235]

Splenic Marginal Zone Lymphoma (+/ Villous Lymphocytes)

In common with the marginal zone B-cell lymphomas of nodal and extranodal sites, these tumors present in adult life, with a slight female predominance. Patients exhibit little lymphadenopathy, but in contrast to patients with nodal and extranodal marginal zone tumors, frequently manifest marrow involvement and low-degree peripheral blood dissemination. Peripheral blood manifestations closely simulate those of so-called splenic lymphoma with villous lymphocytes; the precise histogenetic relation between these two entities remains uncertain. [236] [237] [238] As in other marginal zone B-cell lymphomas, plasmacytoid differentiation may occur and may be accompanied by a serum paraprotein. This disease pursues an indolent clinical course, with sustained remissions reported after splenectomy.

Involved spleens demonstrate white pulp expansion with selective involvement of the marginal zone. [239] Neoplastic cells resemble normal marginal zone B cells in possessing round to mildly irregular nuclear contours and relatively abundant pale cytoplasm (Fig. 69-9). Not infrequently, the neoplastic marginal zone is separated from a central reactive germinal center by what appears to be a preserved rim of small mantle zone B cells with scant cytoplasm. Immunophenotypic characterization, however, reveals that these apparent mantle zone cells lack IgD expression and may, therefore, represent a differentiated marginal zone population. [240] Just as in nodal and extranodal marginal zone B-cell lymphomas, the neoplastic proliferation may eventually infiltrate and obscure the follicle center, making recognition of the tumors marginal zone origin less apparent histologically. Concomitant red pulp involvement is usual, though of a variable degree.

The immunophenotype is similar to that described for nodal and extranodal marginal zone B-cell lymphomas. Cytogenetic reports are generally lacking.

Plasmacytoma/Plasma Cell Myeloma

These tumors are defined as being of purely plasmacytic origin, i.e., lacking a discernible lymphoid component as detected either morphologically or immunohistochemically. The majority of such tumors correspond to the clinical definition of plasma cell myeloma, or so-called multiple myeloma. A minority, however, arise as solitary bone or extranodal tumors, or less commonly as nodal neoplasms (Fig. 69-10). This disease may progress to overt myeloma, the incidence appearing to be greatest in patients with osseous involvement.

The majority of plasmacytomas are composed of well-differentiated plasma cells and are clinically low-grade tumors. [241] A small number of cases exhibit immature or plasmablastic cytomorphology, characterized by prominent nucleoli, variable pleomorphism, and a high mitotic rate. Such cases may be impossible

Figure 69-9 Splenic marginal zone lymphoma. The spleen shows selective involvement of the white pulp, with secondary infiltration of the red pulp. The white pulp infiltrate surrounds atrophic germinal centers in a marginal zone pattern, as in Figures 69-7 and 69-8 . A narrow rim of small, darkly staining cells is interposed between the germinal center and the neoplastic population. Although these cells appear morphologically to represent mantle zone B cells, their immunophenotype is not typical and suggests that they may rather represent a differentiated population of marginal zone B cells.

Figure 69-10 Plasmacytoma. The lymph node is diffusely infiltrated by mature-appearing plasma cells. An isotypic B-lymphocytic component is not observed.

to differentiate from immunoblastic lymphoma,[242] and may pursue a more aggressive clinical course.

Like their benign counterparts, the neoplastic cells express monotypic cytoplasmic immunoglobulin without surface immunoglobulin and do not express B-cell antigens.[243] [244]

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphomas as presently defined collectively account for approximately one-third of adult non-Hodgkin lymphomas. This likely reflects our current ignorance of the biologic diversity of these lymphomas, as many as 40% of which arise in extranodal sites. There is mounting evidence, best exemplified at present by primary mediastinal large B-cell lymphoma, that extranodal lymphomas are not in any simple way analogous to their morphologic counterparts in lymph nodes. Additionally, diffuse large B-cell lymphoma represents the common morphologic expression of a variety of transformed low-grade B-cell lymphomas, including small lymphocytic lymphoma, follicle center lymphoma, marginal zone B-cell lymphoma, and nodular lymphocyte-predominant Hodgkin disease (nodular paragranuloma). [245] [246] It is likely that the next decade will see considerable progress in the recognition of clinically relevant subsets of diffuse large B-cell lymphoma. [247] [248] Although generally a disease of adult life, large B-cell lymphomas may occur in childhood. Untreated, the disease is aggressive, but contemporary chemotherapeutic regimens now yield complete remissions in 7580% of cases, with durable relapse-free survival rates approximating 50%.

As defined by the REAL classification, this category encompasses both the diffuse large cell and large cell immunoblastic categories of the Working Formulation, which had been separately distinguished as intermediate- and high-grade tumors, respectively, in the Working Formulation (Fig. 69-11). There remains considerable controversy regarding the appropriateness of this decision, as some data from European groups suggest that immunoblastic lymphoma, when defined by the Kiel criterion of greater than 90% immunoblastic composition, is indeed a more clinically aggressive disease than centroblastic lymphoma. Also included in the single category of diffuse large B-cell lymphoma for the time being are tumors composed of large cleaved cells (large centrocytes), multilobated cells (many of such tumors arise in extranodal sites),[249] [250] and anaplastic B cells. Large B-cell lymphomas may be infiltrated by substantial numbers of non-neoplastic T lymphocytes or histiocytes (T-cell or histiocyte-rich large B-cell lymphoma, respectively), giving rise to diagnostic confusion with both peripheral T-cell lymphoma and Hodgkin disease.[251] [252] [253] [254] [255] [256] [257]

The majority of diffuse large B-cell lymphomas express monotypic surface immunoglobulin, an important exception being primary mediastinal large B-cell lymphoma (discussed later). Cytoplasmic immunoglobulin is detectable in a minority of cases. Expression of either the CD5 or the CD10 antigen is exceptional. [258]

Chromosomal alterations involving the 3q27 locus of the *bcl*-6 gene are strongly associated with diffuse large B-cell lymphoma, occurring in approximately 40% of cases.[198] [259] [260] [261] [262] [263] [264] [265] [266] [267] The

Figure 69-11 Diffuse large B-cell lymphoma. **(A)** B-immunoblastic lymphoma is composed of a uniform population of immunoblasts having prominent central nucleoli and plasmacytoid cytoplasm. **(B)** T-cell-rich large B-cell lymphoma is readily identified in sections stained for CD20 (L26), which strongly and uniformly marks the minor population of neoplastic large B cells. **(C)** Intravascular large B-cell lymphoma is shown here involving a lesion of Kaposi sarcoma in a patient with AIDS.

-6 protein functions as a transcription factor[268] [269] [270] [271] and is normally expressed exclusively on follicle center B cells. [272] [273] Constitutive expression of the protein is induced during lymphomagenesis by heterologous promoters juxtaposed to the *bcl*-6 coding sequence as a consequence of chromosomal translocation.[274] Neoplastic cells are thereby arrested at a germinal center stage of development. Other molecular abnormalities in diffuse large B-cell lymphoma include rearrangement of the *bcl*-2 gene in roughly 2530% of cases.[275] [276] [277] [278] [279] [280] These alterations are entirely analogous to those seen in follicle center lymphomas and presumably identify cases that have transformed from follicular histology. Interestingly, rearrangements of *bcl*-2 and *bcl*-6 appear to be mutually exclusive, suggesting that these represent distinct transformation pathways. Available clinical data tend to substantiate this interpretation, indicating a favorable prognosis for *bcl*-6-associated disease and an unfavorable prognosis for *bcl*-2-associated disease.

Primary Mediastinal Large B-Cell Lymphoma

This variant of large B-cell lymphoma is thought to derive from a minor population of B cells that normally reside in the thymus. [281] [282] [283] [284] Although certain morphologic attributes have been proposed as characteristic of this variant, the histologic features are inconstant and the disease is therefore largely defined by clinical parameters. Like other diffuse large B-cell lymphomas, it is composed of large transformed B cells, which may resemble centroblasts, immunoblasts, large centrocytes, multilobate large cells, or even Reed-Sternberg cells. Typically the cytoplasm is pale-staining, and the tumor is often accompanied by fine comparmentalizing sclerosis (Fig. 69-12). [285] [286] [287] [288] This disease exhibits a striking predilection for women in the fourth decade of life, who commonly present with superior vena cava syndrome. Curiously, this syndrome is exceedingly rare in Hodgkin disease, even in the setting of bulky mediastinal disease. Chemotherapy now produces cure rates similar to those for other forms of large B-cell lymphoma.[289] Relapse patterns, however, are distinctive, with a high incidence of visceral dissemination involving the kidneys, adrenals, liver, ovaries, and central nervous system.

In contrast to other diffuse large B-cell lymphomas, this variant commonly fails to express surface immunoglobulin while retaining expression of other pan-B-cell antigens, such as CD19, CD20, and CD22.[290] Recurring chromosomal translocations have not been described, although abnormalities of the c- *myc* locus have been reported.

Burkitt Lymphoma

Burkitt lymphoma is the most common pediatric non-Hodgkin lymphoma in the United States, accounting for roughly 35% of cases. [291] The disease is less frequent in adults, in whom it is often encountered in the setting of immunodeficiency. The clinical presentation is generally extranodal, with a predilection for the jaw in African subjects and for the ileocecal region and mesentery in non-African subjects. Leukemic presentations with involvement of peripheral blood

and bone marrow (ALL, French-American-British [FAB] L3 type) are relatively infrequent. Burkitt lymphoma is the most highly proliferative of all non-Hodgkin lymphomas and is clinically aggressive, but curable with appropriate multiagent chemotherapy. [292]

The morphologic features of Burkitt lymphoma are highly distinctive. The tumor is composed of a monomorphous population of intermediate-size cells with round nuclear contours, multiple nucleoli, and moderately abundant basophilic cytoplasm. Imprint preparations reveal prominent cytoplasmic lipid vacuoles. The classical starry sky pattern is conferred by the presence of numerous macrophages ingesting apoptotic debris resulting from the high rate of programmed cell death (Fig. 69-13).

Burkitt lymphoma cells express surface immunoglobulin of the IgM type, in conjunction with pan-B-cell antigens, and additionally express the CD10 antigen. [293] CD5, CD23, and the *bcl*-2 protein are not expressed.

Translocations involving the c-*myc* gene on chromosome 8q24 are observed in virtually all cases of Burkitt lymphoma, although both the precise breakpoint and the reciprocal chromosome may vary.[294] The most frequent translocation, t(8;14) (q24;q32), occurs in approximately 80% of cases and juxtaposes the c- *myc* gene with

immunoglobulin heavy chain regulatory loci on chromosome 14. Variant translocations involve the light chain genes on chromosomes 2 and 22 in the remainder of cases.

Figure 69-12 Primary mediastinal large B-cell lymphoma. These tumors cannot be reliably distinguished from other forms of large B-cell lymphoma on purely morphologic grounds, although the pattern of compartmentalizing sclerosis seen here is typical.

Figure 69-13 Burkitt lymphoma. The distinctive starry sky pattern reflects the presence of numerous phagocytic histiocytes ingesting apoptotic debris in this most rapidly proliferating of all lymphomas.

In cases of endemic (African) Burkitt lymphoma, the heavy chain breakpoint lies within the joining region gene cluster, suggesting an early differentiational event, whereas the breakpoint in nonendemic disease occurs in the switch regions, implicating a later transformation event. [295] [296] A further difference in the biology of endemic versus nonendemic disease relates to the frequency of detection of EBV genomes in neoplastic cells. EBV genomes are present in nearly all cases of endemic Burkitt lymphoma but in only 1520% of cases of sporadic disease, with an intermediate incidence in AIDS-related Burkitt lymphoma. [297] Finally, mutations of *p53* are frequently encountered in Burkitt lymphoma.[133]

High-grade B-Cell Lymphoma, Burkitt-like

This category is afforded provisional recognition in the REAL classification pending further study of criteria for its recognition and the systematic analysis of clinical outcome. It corresponds in large part to those lymphomas classified as small non-cleaved cell lymphoma, non-Burkitt type, in the Working Formulation and is defined loosely as a lymphoma whose morphologic attributes are intermediate between those of Burkitt lymphoma and diffuse large B-cell lymphoma. [298] [299] The immunophenotype differs from that of classic Burkitt lymphoma in that cytoplasmic immunoglobulin may be expressed, while the CD10 antigen is typically not expressed. The molecular profile of these tumors in one study suggested a closer relation to large B-cell lymphoma than to Burkitt lymphoma, in that c- *myc* rearrangements were

not identified, whereas *bcl*-2 rearrangements were found in about 30% of cases.[300] [301] [302]

A special form of high-grade B-cell lymphoma, strongly AIDS associated, has been recently described under the terms body cavity-based lymphoma and primary effusion lymphoma. As the names imply, these lymphomas are characterized clinically by presentation as effusions involving serosal cavities, without concomitant solid tumors.[303] These lymphomas are invariably of B-cell lineage, as confirmed by antigen receptor gene rearrangement analysis, but typically fail to express common pan-B-cell antigens. Virtually all cases show evidence of HHV-8 infection, [303] [304] [305] [306] often with EBV co-infection. Abnormalities of known B-cell lymphoma-associated oncogene loci are not detected.

Peripheral T- and NK Cell Lymphomas

/ T-Cell Lymphomas

T-Cell Chronic Lymphocytic Leukemia/Prolymphocytic Leukemia

This rare variant of peripheral T-cell neoplasia is characterized clinically by a leukemic presentation, often with a very high white cell count, splenomegaly, and hepatomegaly. Lymphadenopathy is variable; primary nodal presentations are unusual. Cutaneous and mucosal manifestations are not infrequent. The disease pursues a moderately aggressive course and is not generally curable with existing regimens. [307] [308]

Neoplastic cells are of small to medium size and, in most instances, demonstrate at least some nuclear irregularity, prominent nucleoli, and relatively abundant cytoplasm. In lymph nodes the pattern of infiltration is paracortical or diffuse. Proliferation centers, typical of B-CLL, are not observed. High endothelial venules may be prominent and are commonly infiltrated by neoplastic cells (Fig. 69-14). Splenic red pulp and hepatic sinusoids are selectively involved, and the marrow tends to be diffusely involved.

The immunophenotype is that of a mature T cell; loss of pan-T-cell antigens is unusual. Thus, most cases express CD2, CD3, CD5, and CD7. The majority of cases express the CD4 subset antigen. Occasional cases are double positive (i.e., CD4+ and CD8+). CD25 is not expressed, in contrast to adult T-cell lymphoma/leukemia.

Karyotypic analysis has shown a striking correlation between this histology and inv14(q11;q32). This abnormality has been reported in as many as 75% of cases. An association with trisomy 8q has also been noted.

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides and Sézary syndrome are primary cutaneous T-cell lymphomas that differ in their propensity for peripheral blood dissemination. These entities tend to be disorders of adults and are typified by the presence of multiple cutaneous plaques or by diffuse exfoliative erythroderma. Nodal involvement is rare in the early stages of disease and, when it develops, usually heralds a terminal phase. [309] [310] [311] Histologic progression to large cell lymphoma, frequently with anaplastic morphology, may occur late in the disease course.

In the skin, mycosis fungoides is recognized by its characteristic bandlike distribution in the superficial dermis. Epidermotropism, with formation of so-called Pautrier abscesses, is the histologic hallmark (Fig. 69-15). Spongiosis is absent. Neoplastic cells are predominantly of small size and exhibit cerebriform nuclear contours. A minor population of larger, hyperchromatic cells is often admixed; transformed cells with vesicular nuclei and prominent nucleoli are less commonly observed. Nodal involvement, when seen, is paracortical and the neoplastic infiltrate is invariably accompanied by a proliferation of CD1a+ interdigitating reticulum cells. [312]

Neoplastic cells typically express the CD2, CD3, and CD5 antigens but fail to express CD7 in at least two-thirds of cases.

Figure 69-14 T-cell chronic lymphocytic leukemia/prolymphocytic leukemia. The neoplastic population consists of small lymphoid cells with small but conspicuous nucleoli. High endothelial venules are prominent and are permeated by neoplastic cells.

The vast majority of cases demonstrate CD4 subset restriction, though rare CD8+ cases are encountered. [313] CD25 is not expressed.

Peripheral T-Cell Lymphoma, Unspecified

As currently formulated, this represents the largest single category of peripheral T-cell lymphomas in the REAL classification, reflecting not

Figure 69-15 Mycosis fungoides. Cerebriform cells exhibit pronounced epidermotropism, with formation of Pautrier microabscesses.

a homogeneous disease entity but rather the difficulty in defining morphologic, immunophenotypic, or genetic parameters that would allow for precise and reproducible subclassification of these tumors. This category encompasses all of the pleomorphic subtypes of the updated Kiel classification, as well as T-zone lymphoma, lymphoepithelioid cell lymphoma (Lennert lymphoma), and T-immunoblastic lymphoma of that scheme. A number of clinical studies have now documented the generally more aggressive nature of peripheral T-cell lymphomas as compared to lymphomas of B-cell derivation and have shown stage to be a more accurate predictor of outcome than morphologic subtype.[314] [315] [316] [317] [318] [319] [320] As a whole, patients with these diseases are adults who present with generalized lymphadenopathy. Cutaneous involvement is not uncommon, and visceral involvement is found with some frequency. Peripheral blood manifestations include the presence of circulating lymphoma cells and eosinophilia. Collectively, patients with peripheral T-cell lymphomas appear more prone to disease relapse than do patients with B-cell tumors of comparable grade. Histologic progression may occasionally be observed in sequential biopsies, though this appears less frequent than in B-cell lymphomas. Hemophagocytic syndromes producing profound cytopenias may supervene as terminal events.[321] EBV has been etiologically associated with a variable proportion of peripheral T-cell lymphomas but is most strongly correlated with angiocentric T/NK cell lymphomas of nasal type.

As might be expected of such a heterogeneous group of disorders, the morphologic manifestations are highly varied, although with some points of commonality.[322] Peripheral T-cell lymphomas as a group tend to be characterized by both pleomorphism (cytologic variability among cells of the same lineage or clone) and polymorphism (intermingling of cells of different lineage), the latter apparently the consequence of lymphokine secretion by neoplastic T cells. Most of the unspecified peripheral T-cell lymphomas are composed of pleomorphic lymphoid cells of intermediate to large size, admixed with varying numbers of eosinophils, plasma cells, histiocytes, and epithelioid cells (Fig. 69-16A). Cells closely resembling the Reed-Sternberg cell of Hodgkin disease may be seen. High endothelial venules may be a prominent feature of these proliferations, and interdigitating reticulum cells are often increased in number. Lymphoepithelioid cell lymphoma (Lennert lymphoma) is composed of small lymphoid cells with minimal pleomorphism and is distinguished by the presence of small multifocal aggregates of epithelioid cells (Fig. 69-16B).[323] [324] Thus, neoplastic expansions of post-thymic T cells simulate in all respects the biologic and morphologic aspects of the normal T-cell immune response. Nodal involvement is either diffuse or interfollicular. Marrow involvement is relatively frequent.

The immunophenotype is that of a post-thymic T cell, with variable loss of T-cell antigens, most commonly CD7. The majority of cases exhibit CD4 subset restriction. Occasional cases are CD8 subset restricted; rare cases may be either double negative or double positive.

T-cell receptor genes are rearranged in the vast majority of cases. Incomplete rearrangements of immunoglobulin heavy

Figure 69-16 Peripheral T-cell lymphoma, unspecified. **(A)** This typical example demonstrates a pleomorphic spectrum of lymphoid cells in a polymorphous milieu of histiocytes, plasma cells, and eosinophils. **(B)** Lymphoepithelioid cell lymphoma (Lennert lymphoma), in contrast, is characterized by a minimally pleomorphic proliferation of small T lymphocytes associated with multifocal aggregates of epithelioid histiocytes.

and occasionally light chain genes may additionally be seen. Most cases express the / T-cell receptor, as detected by the antibody F1; a minority express the / receptor, identified by the antibody TCR-. Cytogenetic abnormalities involving the T-cell receptor gene loci are frequent.[325] [326] [327] [328]

Subcutaneous Panniculitis-like T-Cell Lymphoma

This variant of peripheral T-cell lymphoma describes a distinctive clinical syndrome and has been provisionally recognized in the REAL classification. Patients with this disease present with numerous subcutaneous nodules, generally distributed over the extremities and unassociated with lymphadenopathy.[329] The disease does not appear to be EBV related and manifests a particularly high incidence of terminal hemophagocytic syndromes, which are the usual cause of death in fatal cases.

Biopsy specimens demonstrate a panniculitic pattern of disease in which atypical lymphoid cells infiltrate between adipocytes of the subcutis in a manner reminiscent of that seen in panniculitis (Fig. 69-17). The dermis is usually uninvolved. Destruction of adipocytes may produce fat necrosis and a foreign body giant cell reaction. In contradistinction to simple panniculitis, however, the lymphoid population is cytologically malignant, mitotically active, and shows prominent karyorrhexis. Most cells are of medium size and exhibit irregular nuclear contours and hyperchromasia. Large cells may be admixed. Angioinvasion is usually not a salient feature, although necrosis is frequent.

The neoplastic cells have a mature T-cell phenotype and may express either CD4 or CD8 subset antigens. EBV sequences are not identified in neoplastic cells. T-cell receptor genes are consistently rearranged. Rare cases of / T-cell lymphoma may present with a similar clinical and morphologic picture.

Angioimmunoblastic T-Cell Lymphoma

Initially described as an abnormal immune response under a variety of names (angioimmunoblastic lymphadenopathy with dysproteinemia, immunoblastic lymphadenopathy, lymphogranulomatosis X), this condition appears in most cases to represent a bona fide T-cell lymphoma with distinctive clinical and morphologic features.[330] Patients typically present with generalized lymphadenopathy, constitutional symptoms, a skin rash, and polyclonal hypergammaglobulinemia. Although prolonged remissions may be obtained in some cases with steroids, intensive chemotherapy is typically required for disease control. Histologic progression to large cell (immunoblastic) lymphoma, which may be of either T or B lineage, may occur.[331] Molecular or karyotypic analyses of sequential biopsies or of simultaneous biopsies from different sites have revealed unstable and fluctuating clonal expansions, lending some credence to the notion that these proliferations may indeed arise out of the background of an abnormal immune response.

The morphologic features are highly characteristic. Involved lymph nodes appear lymphoid depleted at low magnification and consistently demonstrate a marked proliferation of high endothelial venules.[332] The venules are often surrounded by a cuff of hyaline material, which can be highlighted by PAS staining. The neoplastic proliferation comprises small lymphocytes, immunoblasts, and a distinctive population of pale-staining or clear cells, which tend to aggregate along vessel walls (Fig. 69-18). Plasma cells, eosinophils, and histiocytes may be interspersed in varying number. Germinal centers are typically absent or inconspicuous. Irregularly expanded aggregates of follicular dendritic cells, recognized by immunohistochemical staining with appropriate antibodies (e.g., CD21 or CD35), constitute a consistent and relatively specific immunologic lesion in angioimmunoblastic T-cell lymphoma.

The immunophenotype is that of a post-thymic T-cell, usually CD4+, without other distinguishing characteristics except for the expanded follicular dendritic cell aggregates previously mentioned. EBV sequences are detectable in a high percentage of cases.[333] [334]

Molecular analysis of antigen receptor gene configuration reveals the presence of clonally rearranged T-cell receptor genes in the majority of cases.[335] Immunoglobulin gene rearrangements are encountered in a smaller percentage of cases, with or without corresponding T-cell receptor rearrangement.[336] Numerical abnormalities, particularly trisomy 3 and trisomy 5, have been noted in cytogenetic studies.[337] [338]

Intestinal T-Cell Lymphoma

This highly aggressive, primary intestinal form of T-cell lymphoma afflicts adults, many of whom have a history of gluten-sensitive enteropathy. In some cases, however, it constitutes the initial manifestation of enteropathy, whereas in others an association with enteropathy is never established.[339] [340] [341] Presenting complaints include abdominal pain and weight loss. The jejunum is the most frequent site of disease, with multifocal ulceration, often with perforation, being typical. Mass lesions are not always discernible. Regional lymph node involvement is common. The disease typically pursues an accelerated and intractable course.

Biopsies and resected specimens demonstrate constant infiltration

Figure 69-17 Subcutaneous panniculitis-like T-cell lymphoma. **(A)** The interstitial pattern of neoplastic infiltration between subcutaneous adipocytes simulates panniculitis. Tumoral cells, however, are cytologically atypical and often show karyorrhexis. **(B)** Terminal hemophagocytic syndromes are particularly common in this form of T-cell lymphoma. A bone marrow biopsy from such a patient shows hypocellularity with prominent phagocytosis of erythrocytes and hematopoietic precursors by benign-appearing histiocytes.

Figure 69-18 Angioimmunoblastic T-cell lymphoma. **(A)** Relative lymphoid depletion and a conspicuous haphazard vascular proliferation are the cardinal low-power attributes of this lymphoma. **(B)** Aggregates of clear cells, often perivascular, are frequently observed.

of the mucosa and variable degrees of infiltration of the bowel wall by an atypical lymphoid population that may range from small to large in size. Anaplasia may be observed. Small intraepithelial T cells are usually prominently distributed in the adjacent mucosa, which may or may not show changes of villous atrophy (Fig. 69-19). [342]

Figure 69-19 Intestinal T-cell lymphoma. An ulcerated, transmural tumor in the jejunum is associated with prominent atrophy and blunting of adjacent villi.

Neoplastic cells express T-cell antigens, including CD3. The mucosal lymphocyte antigen CD103 is consistently expressed. [343] [344] [345] T-cell subset antigens are variably expressed, with most cases exhibiting a CD4/CD8 or a CD4/CD8+ phenotype. TCR- genes are clonally rearranged.

Adult T-Cell Lymphoma/Leukemia

The clinical and morphologic profiles of this disease are protean, and thus the disease is defined serologically by the presence of antibodies to HTLV-I. The disease is endemic in southwestern Japan and the Caribbean basin and occurs most commonly in an acute form characterized by lymphadenopathy, hepatosplenomegaly, cutaneous disease, and peripheral blood involvement. [346] [347] [348] [349] [350] [351] [352] In this form the disease is frequently accompanied by hypercalcemia and lytic bone lesions. Median survival does not exceed 1 year. A lymphomatous variant is characterized by lymphadenopathy or by tumor formation in visceral sites, whereas chronic and smoldering forms are manifest by lesser degrees of lymphocytosis, often accompanied by a skin rash. [353] These variant forms of disease generally follow a more protracted disease course.

The most characteristic and easily recognizable manifestation of adult T-cell lymphoma/leukemia occurs in the peripheral blood, where neoplastic cells stand out by virtue of their multilobate nuclei (so-called cloverleaf or flower cells) and basophilic cytoplasm. In lymph nodes the infiltration is diffuse and may be composed of cells of small, intermediate, or large size, often in combination (Fig. 69-20). Reed-Sternberg-like cells may be present. [354] Cutaneous infiltrates frequently show epidermotropism, making distinction from mycosis fungoides difficult or impossible on morphologic grounds. Bone marrow

Figure 69-20 Adult T-cell lymphoma/leukemia. A pleomorphic infiltrate of medium-sized to large cells infiltrates the paracortex and surrounds a benign germinal center. Neoplastic cells expressed a CD4+, CD7, CD25+ immunophenotype.

involvement is diffuse and may be discordantly sparse in relation to the level of lymphocytosis observed in the peripheral blood. Biopsy of lytic lesions typically reveals only increased bone resorption in the absence of significant tumoral infiltration; it appears to represent a remote effect.

Tumor cells exhibit a T-cell phenotype but generally lack the CD7 antigen and, in contrast to other peripheral T-cell lymphomas, express high levels of the CD25 antigen (IL-2 receptor). Most cases are CD4+, though rare CD8+ cases have been reported. [355]

T-cell receptor genes are clonally rearranged. All cases show clonal integration of HTLV-I genomes. [356] [357]

Anaplastic Large Cell Lymphoma

Two distinct clinical syndromes are included in this category and likely represent different disease entities, as evidenced by their differing clinical behavior, immunophenotypes, and genetic features. [358] [359] [360] The classic form is a systemic disease manifested by lymphadenopathy, with or without cutaneous involvement. The disease may affect any age group, but a strong predilection for onset in childhood and adolescence is evident. In this form, anaplastic large cell lymphoma corresponds to most cases previously described as malignant histiocytosis. In addition, many cases formerly classified as lymphocyte-depletion Hodgkin disease would now be categorized as anaplastic large cell lymphoma. The clinical outcome following intensive therapy appears to be more favorable than that for other forms of peripheral T-cell lymphoma, with survival rates not differing substantially from those of other types of large cell lymphoma. [361] [362] The second form of anaplastic large cell lymphoma is a primary cutaneous lymphoproliferation that is cytologically malignant but pursues an indolent clinical course, frequently punctuated by spontaneous remissions. This disease overlaps considerably with, and is often indistinguishable from, the syndrome described as lymphomatoid papulosis. [363] [364] [365] It is primarily a disease of adults and carries an attendant risk of transformation to a disseminated lymphomatous phase of disease, currently placed at about 20%.

The morphologic picture of anaplastic large cell lymphoma does not differ appreciably in the two variants. The neoplastic population comprises a pleomorphic spectrum of large cells, many with horseshoe- or wreath-shaped nuclei, prominent nucleoli, and abundant, rather basophilic cytoplasm. Cells closely resembling Reed-Sternberg cells may be found. [366] In lymph nodes, the infiltrate assumes a cohesive pattern with a predilection for sinusoidal involvement (Fig. 69-21 A, B). [367] These features not infrequently lead to a diagnosis of metastatic disease. Variant morphologies have been described and include a monomorphous type with minimal anaplasia, a small cell variant, and the so-called lymphohistiocytic variant in which a characteristic plasmacytoid-appearing histiocyte overwhelmingly predominates and obscures the minor population of anaplastic large cells (Fig. 69-21 C, D). [368] [369]

The immunophenotype of these tumors is distinctive. [370] The CD30 antigen, which initially defined these lymphomas, is almost always expressed, but it may be expressed by other lymphomas of both B- and T-cell type. [371] [372] [373] [374] [375] Leukocyte common antigen (CD45) and epithelial membrane antigen are variably expressed, [376] [377] whereas the CD15 (LeuM1) antigen is infrequently expressed. [378] The vast majority of cases exhibit either a T-cell or null phenotype and genotype and express cytolytic granule-associated proteins, indicative of cytolytic T-cell function. Histiocyte-specific markers are not expressed. [379] It remains controversial whether rare cases with a B-cell phenotype exist; at present the REAL classification recommends that only cases with a T- or null cell phenotype be classified as anaplastic large cell lymphoma. [380] Cases with anaplastic morphology and a B-cell phenotype are classified simply as diffuse large B-cell lymphomas.

Cytogenetic studies of anaplastic large cell lymphoma and of cases earlier classified as malignant histiocytosis [381] [382] have shown a strong association with the t(2;5)(p23;q35), particularly in pediatric populations. [383] [384] [385] [386] [387] [388] [389] Molecular studies in several laboratories have since confirmed the highly selective nature of this association. The t(2;5) translocation yields a chimeric p80 protein in which the amino-terminus of nucleophosmin (NPM) on 5q35 is fused to the catalytic domain of anaplastic lymphoma kinase (ALK) on 2p23. [390] This translocation is readily detected by DNA-based PCR strategies, [391] [392] and antibodies are now available that permit detection of the p80 protein. [393] [394]

A primary cutaneous form of CD30+ lymphoproliferative disorder with anaplastic large cell morphology is recognized under the clinical term lymphomatoid papulosis. Although morphologically indistinguishable from anaplastic large cell lymphoma, this disease is characterized by the presence of one or several cutaneous nodules, rarely exceeding 2 cm in size, that exhibit the remarkable property of spontaneous regression, often followed by similar episodes of recurrence and spontaneous remission. Up to 20% of patients may eventually develop disseminated lymphoma. These lesions differ immunophenotypically from classic anaplastic large cell lymphoma by their expression of the cutaneous lymphocyte antigen and lack of expression of epithelial membrane antigen. Cytolytic granule-associated proteins, as

observed in most cases of anaplastic large cell lymphoma, have recently been demonstrated. Cytogenetic and molecular studies to date have shown these cases to lack the t(2;5)(p23;q35) typical of anaplastic large cell

Figure 69-21 Anaplastic large cell lymphoma. **(A)** Neoplastic cells, here stained for CD30 (BerH2), exhibit a striking propensity for sinusoidal infiltration. **(B)** Parenchymal involvement is often syncytial, composed of anaplastic cells with horseshoe-like and otherwise bizarre nuclear contours. **(C)** Malignant cells are inconspicuous in the so-called lymphohistiocytic variant of anaplastic large cell lymphoma. In such cases a cytologically distinctive histiocyte with plasmacytoid morphology predominates, conferring a deceptively benign appearance. The *NPM/ALK* rearrangement was detected in this case by PCR. **(D)** CD30 staining in the same case revealed the presence of rare malignant cells with anaplastic morphology.

lymphoma. Thus, despite considerable morphologic similarity, these appear to represent distinctive clinical entities that mandate different therapeutic approaches.

/ T-Cell Lymphomas

Hepatosplenic / T-Cell Lymphoma

The function of / T cells remains poorly understood, but there is good experimental evidence in mice suggesting that / and / T cells represent distinct cell lineages. / T cells are the first to develop ontogenetically and exhibit highly selective utilization of variable region genes, limited diversity, and a remarkable predilection for localization to particular anatomic sites (often epithelial) that appears to correlate with variable region gene usage. [395] TCR- knockout mice develop normal numbers of / T cells; and, conversely, normal numbers of / T cells are found in TCR- knockout mice. Moreover, molecular analysis of /-expressing T cells has shown a high frequency of out-of-frame rearrangements of region genes and germline region sequences in deleted DNA loops, indicating that such cells could not have expressed a functional / receptor. [396] The / receptors associate with the CD3 transmembrane signaling complex but, unlike their / counterparts, are only infrequently coupled with either the CD4 or the CD8 antigen. Although the antigenic specificity of / T cells is unknown, it appears that these cells have a non-MHC-restricted cytolytic capability that may have evolved to recognize a limited number of high-frequency antigens encountered at epithelial surfaces and to provide a first line of defense against microbial organisms at these sites prior to the recruitment of a more specific immune response. [397] Interestingly, while / T cells constitute the majority of intraepithelial and intraepidermal lymphocytes in mice, they appear to represent less than 10% of such cells in humans. [398] [399]

The classification of lymphomas derived from cytolytic or NK-like T cells, true NK cells, and / T cells will surely undergo significant revision in the coming years. As a group these

Figure 69-22 Hepatosplenic / T-cell lymphoma. Sinusoidal infiltration by rather featureless small to medium-sized cells is the hallmark of this disease in the spleen, as well as in the liver and bone marrow.

lymphomas are distinguished by their propensity to involve extranodal sites and, with a few exceptions, to pursue an aggressive clinical course. As is evident from the schema proposed by the International Lymphoma Study Group, the morphologic, immunophenotypic, and other criteria that have historically been well suited to the classification of B-cell lymphomas have proved disappointing in the study of T-cell lymphomas, with the result that new entities have been accorded provisional recognition on the basis of what appear to be reproducible clinical patterns of disease. As additional immunophenotypic and molecular data accrue, it is likely that these disease boundaries will shift or be largely redrafted.

The so-called hepatosplenic / T-cell lymphoma has become the prototype of the / T-cell lymphomas. [400] This is a disease predominantly affecting young men, who present with massive hepatosplenomegaly and insignificant lymphadenopathy. [400] [401] [402] [403] The clinical course is abbreviated, despite initial response to chemotherapy, with median survival not exceeding a few years.

Morphologically, the disease is recognized by its distinctive pattern of infiltration in splenic and hepatic sinusoids (Fig. 69-22). [404] [405] Bone marrow involvement is common but may be subtle, requiring immunohistochemical staining to highlight its sinusoidal predilection. The neoplastic cells are most commonly of small to intermediate size, although some variation from this spectrum may be seen in individual cases. The chromatin is less condensed than that of a mature lymphocyte, and nucleoli are inconspicuous. The tumoral cells are otherwise generally featureless, with round or minimally irregular nuclear contours and a small amount of cytoplasm. [406]

The immunophenotypic profile of the neoplastic population is that expected of / T cells, with positivity for the TCR- protein. Tumoral cells most commonly express a CD4/CD8 phenotype, as is typical of the vast majority of normal / T cells, but may occasionally exhibit a CD4/CD8+ phenotype. Cytolytic proteins such as those identified by TIA-1 are often demonstrable, and NK-associated antigens may also be detected.

Molecular studies confirm clonal rearrangement of the TCR- and TCR- genes in most cases. Karyotypic analysis has identified the isochromosome 7q as a recurring chromosomal aberration in a high percentage of cases. [407] [408]

/ T-cell lymphomas with a predilection for cutaneous rather than hepatosplenic presentation have now been well characterized. [409] [410] [411] [412] [413] [414] These lymphomas closely mimic in morphologic terms the disease described above as subcutaneous panniculitis-like T-cell lymphoma and differ from the hepatosplenic variant of / T-cell lymphoma in utilizing V2 rather than V1 genes. The latter feature recapitulates the pattern observed in normal / T cells, in which the V1 subset shows selective homing to spleen and thymus, while the V2 subset homes to lymph nodes, peripheral blood, tonsils, and skin. [415] In addition, a clinically and histologically identical form of hepatosplenic T-cell lymphoma has been shown recently to express the / T-cell receptor, to harbor the i7q cytogenetic abnormality, and to be characterized by an equally aggressive clinical course. [416] Thus, it must be conceded that, for the moment, a rational classification of many of the peripheral T-cell lymphomas, whether on clinical, morphologic, or immunologic grounds, remains elusive.

NK Cell Lymphomas

Large Granular Lymphocyte Leukemia

The indolent clinical syndrome connoted by the term large granular lymphocyte leukemia is shared by two morphologically indistinguishable variants of this disease, one derived from CD8+ T cells and the other from cells of NK type. [417] [418] Patients affected by these diseases are generally adults, with a roughly equal sex distribution. Peripheral blood smears typically demonstrate a mild to moderate lymphocytosis with a discernible increase in large granular lymphocytes, characterized by their small to intermediate size, oval nuclei, and abundant pale blue cytoplasm containing coarse or fine azurophilic granules (Fig. 69-23). Neutropenia is a consistent hallmark of the T-cell variant and may be seen as well in the NK form, in which it tends to be less pronounced. [419] Bacterial infections, consequently, may pose a recurring clinical problem in these patients. Anemia may additionally be seen in the T-cell form. Hepatosplenomegaly is almost always present, whereas significant lymphadenopathy is infrequent. Various autoimmune manifestations may accompany the disease, with rheumatoid arthritis being especially common. Bone marrow disease is interstitial in distribution and may be subtle. Splenic involvement is localized to the red pulp and may be difficult to identify in routine preparations. Imprints are helpful in recognizing the cytoplasmic azurophilic granules, which are not identifiable in tissue sections. Liver biopsies reveal

Figure 69-23 Large granular lymphocyte leukemia. A peripheral blood smear shows a mild lymphocytosis consisting of small cells with relatively abundant pale cytoplasm containing prominent azurophilic granules. Neutropenia is additionally evident.

a sinusoidal pattern of infiltration. [420] The disease course is stable and prolonged in most instances, although aggressive evolution has been reported on occasion and appears particularly common in EBV-associated Asian cases. [421]

Immunophenotypic and molecular studies are useful adjuncts in the diagnosis of these lymphoproliferative disorders. The T-cell variant exhibits a CD3+, CD8+, CD16/57 variable +, CD56 immunophenotype and has productively rearranged T-cell receptor genes, usually /. In contrast, the NK form of disease fails to express surface CD3 (but may express cytoplasmic CD3), uniformly expresses CD56, and has not undergone productive T-cell receptor gene rearrangement. T subset antigens are usually not expressed in this variant, although CD8 may be detectable in a fraction of cases. [422] [423]

Angiocentric (Nasal-Type) T/NK Cell Lymphoma

This disease was known historically by the names lethal midline granuloma and polymorphic reticulosis, and was initially included in the spectrum of diseases conceptualized under the rubric of angiocentric immunoproliferative lesion, which included so-called lymphomatoid granulomatosis. [424] [425] [426] As now more rigorously defined, this disease is considered to represent a neoplastic proliferation of NK or related T cells. [427] [428] [429] [430] It is the most strongly EBV associated of all peripheral T-cell lymphomas[431] [432] [433] and is endemic to Asia and certain parts of Latin America. [434] The disease may affect any age group, and demonstrates a particular predilection for the nose and palate. Other extranodal sites, including the skin and testis, may be primarily involved. [435] [436] [437] [438] The clinical course is variable and difficult to predict. [439] [440] At least some cases previously diagnosed as angiocentric immunoproliferative lesion in the lung (lymphomatoid granulomatosis) have since been shown to represent EBV-associated large B-cell lymphomas with a marked T-cell response, and are excluded from the category of angiocentric T/NK cell lymphoma.[441]

The cytologic spectrum observed in this lymphoma is broad, ranging from cases composed predominantly of intermediate-sized cells to cases with large numbers of immunoblasts. Plasma cells are often interspersed; other inflammatory components, including eosinophils, may be seen as well. Regardless of cytologic composition, these cases exhibit in common a distinctive angiocentric and angiodestructive pattern of growth, resulting in large geographic zones of necrosis, which may prove diagnostically frustrating in small biopsy specimens (Fig. 69-24).

The typical immunophenotypic profile includes immunoreactivity for CD2 and CD56, with variable positivity for CD5 and nonimmunoreactivity for surface CD3 as its most salient features.[442] Cytoplasmic positivity for the CD3epsilon chain may, however, be detected. The molecular configuration of the T-cell receptor genes is almost invariably germline.[443]

Aggressive NK Cell Lymphoma/Leukemia

Rare cases of NK cell neoplasia phenotypically indistinguishable from nasal-type angiocentric lymphoma have been reported in young adults presenting with fever, cytopenias, mild lymphocytosis, and hepatosplenomegaly. These cases demonstrate significant

Figure 69-24 Nasal angiocentric T/NK cell lymphoma. **(A)** Extensive necrosis, displayed here, is a common finding in these tumors. **(B)** Angiodestructive growth is characteristic, but may be focal and difficult to demonstrate in small biopsies.

morphologic overlap with indolent large granular lymphoproliferative disorders, including the presence of cytoplasmic azurophilic granules, but are characterized by a highly aggressive clinical course and poor therapeutic response. [444] [445] [446] [447] [448] [449] [450] They are variably EBV associated.

Chapter 70 - Clinical Manifestations, Staging, and Treatment of Non-Hodgkin Lymphoma

Koen van Besien
Fernando Cabanillas

INTRODUCTION

The term non-Hodgkin lymphoma (NHL) encompasses all malignancies originating from the lymphoid system with the exception of classic Hodgkin disease. The lymphoid system is extremely complex. Cells belonging to it are located in highly specialized organs such as the lymph nodes, but also are distributed throughout practically every organ in the body, with some exceptions such as the central nervous system (CNS) and stomach. The three major cell typesnatural killer (NK) cells, B cells, and T cellscan undergo expansion, maturation, and selection on exposure to an appropriate antigen. Expansion of abnormal clonogenic cells can occur in any of these cell types, in different subtypes of cells, and at different stages of maturation. It is therefore not surprising that NHL has many different subtypes with different behavior, and can be localized in or spread to any organ. In many respects, NHL is not one but many different disorders, each as dissimilar from the others as Hodgkin disease is from other NHLs. Also, some forms of NHL defy classification schemes and straddle the border between different disease categories. Burkitt lymphoma and T-cell lymphoblastic disease may be appropriately called mature B-cell acute lymphocytic leukemia (ALL) and T-cell ALL, respectively. There is very little difference between small lymphocytic lymphoma and chronic lymphocytic leukemia (CLL); and the entity termed Waldenström disease may be interchangeable in many cases with immunocytoma. Some lymphomas are difficult to categorize as either Hodgkin disease or NHL. Finally, some disorders may be at the border between lymphoid malignancy and inflammatory disorders. This is true for some cases of indolent NK cell proliferation and for some cases of severe gluten enteropathy, in which a clonal T-cell proliferation can be noted, or for Sjögren syndrome, in which a clonal B-cell proliferation is commonly found.

Despite the extreme variability in clinical presentation, some clinical and pathologic features are common to practically all lymphoid malignancies. These features include the frequent localization to the principal lymphoid organsthe lymph nodes, bone marrow, and blood. Although NHL does not always originate in these organs, it almost always involves them at some time during the course of the disorder. Other common features include a particular morphology, the expression of a lymphoid immunophenotype (either NK, B, or T cell), and T-cell receptor or immunoglobulin gene rearrangement. Importantly, almost all NHLs are sensitive to commonly used chemotherapeutic agents or radiation therapy (or both).

Because of the diverse subentities, many of which are clinically relevant, the classification of NHL is a challenge for the practicing physician. A number of classifications have been proposed over the years, leading to considerable confusion. The Working Formulation was an attempt by the National Cancer Institute to provide common ground in classification and reporting. [1] It continues to represent a useful scheme for the majority of cases. The Working Formulation was based on purely morphologic criteria and clinical outcomes. The immunophenotype was not used at all because the technique was not widely available in the 1970s. The Working Formulation formed the basis for a number of large cooperative studies and was widely accepted. Our knowledge of the pathogenesis of NHL, however, has progressed rapidly over the past decade. Advances in immunology, molecular biology, cytogenetics, and immunophenotyping have been applied to the characterization of lymphomas and have profoundly influenced our thinking. New entities are recognized that do not have a place in the Working Formulation. Furthermore, some recognized morphologic entities were found to include heterogeneous disease subgroups, such as diffuse small cleaved cell lymphoma, which includes what is now recognized as mantle cell lymphoma as well as some cases of peripheral T-cell lymphoma. A new classification of NHL, the Revised American-European Lymphoma (REAL) classification, was proposed in 1994. [1] It provides a framework for understanding currently recognized lymphoma subtypes and allows the design of specific treatment strategies for a number of newly recognized disorders. [2] The REAL classification will be used throughout this chapter. It represents, as its authors acknowledge, a work in progress. [3] Since its application, additional proposals have been published for the classification of skin lymphomas,[4] and important new insights have been gained regarding angiocentric lymphomas. [5] [6] A classification of NHL for clinical use is provided in Table 70-1 . It is derived from the REAL classification but attempts to arrange the disorders

TABLE 70-1 -- Clinical Classification of Lymphoid Malignancies

Indolent B-cell lymphomas
Chronic lymphocytic leukemia
Lymphoplasmacytoid lymphoma/immunocytoma/Waldenström macroglobulinemia
Hairy cell leukemia
Marginal zone B-cell lymphoma
Nodal: Monocytoid B-cell lymphoma
Extranodal: MALT lymphoma
Spleen/peripheral blood: Splenic lymphoma with villous lymphocytes or splenic marginal zone lymphoma
Follicle center lymphoma, grade I and II
Mantle cell lymphoma of mantle zone type
Primary cutaneous follicle center lymphoma
Aggressive B-cell lymphomas (intermediate risk)
Prolymphocytic leukemia
Mantle cell lymphoma (diffuse, nodular, and blastic variants)
Follicle center lymphoma grade III
Diffuse large B-cell lymphoma

Primary mediastinal large B-cell lymphoma
Primary cutaneous large cell lymphoma
Lymphomatoid granulomatosis
Immunoproliferative small intestinal disease
Plasmacytoma/plasma cell leukemia
Very aggressive B-cell lymphoma
Precursor B-lymphoblastic lymphoma/leukemia
Burkitt lymphoma/B-cell ALL
Plasma cell leukemia
Indolent T-cell and NK cell lymphomas
T-cell large granular lymphocyte leukemia
Chronic NK cell lymphocytosis
Mycosis fungoides/Sézary syndrome
Smoldering and chronic adult T-cell leukemia/lymphoma, HTLV-1 related
Aggressive T-cell and NK cell lymphomas (intermediate risk)
T-cell prolymphocytic leukemia
Peripheral T-cell lymphoma, unspecified
Angiocentric sinonasal lymphoma
Intestinal T-cell lymphoma
Anaplastic large cell lymphoma (T- and null cell type)
Hepatosplenic T-cell lymphoma.
CD56+ T-cell large granular lymphocyte leukemia
Very aggressive T-cell and NK cell lymphomas
Adult T-cell lymphoma/leukemia (HTLV-1 related)
Precursor T-lymphoblastic lymphoma/leukemia
Aggressive NK cell lymphoma
CD3+, CD33, DR+, promyelocyte-like NK cell leukemia
ALL-like NK cell leukemia
Undifferentiated myeloid/NK cell leukemia
Note: Disorders that are not discussed in this chapter are in *italic*.
Adapted from Hiddemann,[2] with permission.

according to their expected clinical behavior. More recently, essentially the same group of pathologists who devised the REAL classification has proposed several modifications in a new scheme that is known as the World Health Organization (WHO) classification.

In many cases, especially for extranodal lymphomas, patient management is influenced not only by stage and histology, but also by the site of disease. The second part of this chapter provides an overview of the differential diagnosis and management of specific types of extranodal lymphoma.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 50,000 cases of NHL are diagnosed yearly in the United States, representing 4% of all cancers, and NHL causes 4% of all cancer deaths annually. The incidence of NHL has been increasing steadily over the past decades, in part in relation to the AIDS epidemic but also for other unknown reasons. [7] [8] In the United States, NHL is more common in men than in women and among whites than in other racial groups, for reasons that are unknown but may in part be genetic. The racial differences are more pronounced for some subsets of the disease, such as follicular lymphoma, which constitutes a large percentage of cases in Western countries but is relatively rare in developing countries. Genetic features may also be important in other lymphoid disorders, such as CLL, which is virtually absent in Asian populations, and multiple myeloma, which is increased in African Americans. On the other hand, some entities that are particularly common in specific countries appear to be related to viral infections such as Epstein-Barr virus (EBV; e.g., NK-cell lymphomas in South America and Asia, or Burkitt lymphoma in Africa), HTLV-1 (e.g., adult T-cell leukemia/lymphoma in some Caribbean countries and Asia) or hepatitis C (e.g., B-cell lymphoma, especially immunocytoma in northern Italy and Japan).

In most cases NHL is a sporadic disease without specific etiologic factors. Epidemiologic studies have, however, revealed important environmental and dietary risk factors.

The incidence of NHL is higher among agricultural workers than among the general population. [9] [10] A number of studies have implicated the use of pesticides and especially the herbicide 2,4-D in the increased risk for NHL. [9] The use of pesticides has increased steadily in the United States over the past 40 years, with extensive exposure through use in homes, gardens, and lawns, as well as indirectly through food and water. [11] It is conceivable that the increasing incidence of NHL may be related to such increased exposure to pesticides. In addition to exposure to pesticides, nitrate contamination of the groundwater is a significant problem in some parts of the country that is related to an increased incidence of NHL and that affects both farmers and the general population. [12]

In addition to farming, employment in other occupations has been linked to an increased risk for NHL. [13] These occupations include professions with exposure to chemicals such as chemists, dry cleaners, printing workers, wood workers, beauticians, and cosmetologists. Exposure to phenoxyacetic acid, chlorophenols, and solvents, particularly benzene, has been associated with an increased

risk. The use of hair dyes, especially permanent hair color products, has been associated with an increased risk of NHL among users of dark colors. [14] [15] [16] [17] In one study, the use of hair dyes was estimated to account for 20% of the cases of NHL. [15] Dietary factors such as an increased intake of proteins or a decreased intake of vitamins and vegetables have sometimes been associated with the development of NHL. The strongest dietary association was described in two European studies that found a correlation between milk intake and an increased incidence of NHL. A high intake of milk (>2 glasses per day) was associated with a twofold greater risk of NHL. [18] [19] In one study from Nebraska this risk was restricted to men. [20]

Blood transfusion has been associated with a 1.5- to 2.5-fold increased risk for NHL. [21] [22] [23] This increased risk may be related to the transmission of infectious agents or to an immunosuppressive effect of transfusion. Exposure to radiation has not generally been thought to be a major risk factor for NHL, [24] but exposure to some chemotherapeutic agents is. [13] Familial cases of NHL have been observed and are sometimes associated with inherited immunodeficiency. [13] The risk for indolent lymphoma is 3.3 times increased in persons with a family history of leukemia or lymphoma. [25]

Immunosuppression is associated with an increased incidence of NHL. This is best exemplified by the increased incidence of NHL in AIDS (see Chap. 75). Other situations of relative immune deficiency such as rheumatoid arthritis, Sjögren syndrome, and organ transplantation are associated with an increased risk of NHL. In many cases the increased risk is related to reactivation of EBV.

Some infectious agents are associated with a great increase in risk for NHL. Some agents are associated with various types of NHL, while others are associated with one specific subtype. The most widely implicated organism in lymphomagenesis is EBV, which is associated with many different types of NHL in immunocompetent as well as immunocompromised subjects, and with Hodgkin disease. Infection with HTLV-1 can cause a specific form of lymphoma/leukemia; HTLV-1 may also be implicated in other forms of NHL. *Helicobacter pylori* is probably the etiologic agent leading to gastric mucosa-associated lymphoid tissue (MALT) lymphoma, and infection with *Borrelia burgdorfferi*, the etiologic agent of Lyme disease, is associated with some forms of skin lymphoma. Recently, infection with hepatitis C virus (HCV) has been associated with an increased risk for B-cell NHL. These and other infectious associations with and causes of NHL are discussed later in the chapter.

CLINICAL PRESENTATION

Many subtypes of NHL are recognized (Table 70-1), often associated with specific clinical features. In general, the signs and symptoms of NHL are dependent on the rate of tumor cell proliferation and on the initial localization. For clinical purposes, therefore, the division into indolent, aggressive, and very aggressive lymphoma continues to apply.[2]

Patients with nodal indolent lymphoma often present with widespread central and peripheral adenopathy, including involvement of unusual sites such as epitrochlear nodes. Some subtypes, the MALT lymphomas, have typically extranodal localizations. A third group of indolent lymphomas is characterized by peripheral blood involvement and splenomegaly. Patients with indolent lymphoma may have few or no symptoms and may seek medical attention because they have noticed a lump or because of mild discomfort. In cases of indolent nodal lymphoma, a prolonged history of waxing and waning adenopathy can often be elicited. A staging workup will frequently reveal bone marrow involvement and sometimes involvement of the peripheral blood. Constitutional symptoms (night sweats, fever, or >10% weight loss), elevations in lactate dehydrogenase (LDH) levels, or anemia are distinctly uncommon in indolent NHL. When these symptoms occur, the possibility of disease transformation should be entertained.

Extranodal indolent lymphomas of the MALT type are commonly located in the stomach, parotid gland, thyroid, or lung. In contrast to nodal disease, they often represent localized (i.e., stage I-II) disease. Lymphoproliferative disorders with a leukemic picture often have limited lymph node involvement but pronounced splenomegaly. If symptoms occur they are due to splenomegaly (e.g., abdominal discomfort) or to hypersplenism. Sometimes there is neutropenia or thrombocytopenia without splenomegaly. Such patients usually come to medical attention because of infection related to neutropenia, or because abnormal cells are detected on routine examination of the peripheral blood smear.

In contrast to indolent lymphomas, aggressive lymphomas are commonly symptomatic at diagnosis and affected patients have a relatively short disease history. They commonly present with pain, obstructive symptoms (swelling of legs or the superior vena cava syndrome) or constitutional symptoms. Patients with T-cell lymphoma more commonly present with extranodal involvement and severe constitutional symptoms. Sometimes T-cell NHL is associated with hemophagocytosis. Peripheral adenopathy can occur but is not usually widespread, and involvement of epitrochlear or occipital nodes is uncommon. Many patients do not have peripheral adenopathy, but radiologic examinations may reveal extensive retroperitoneal adenopathy or sometimes anterior mediastinal adenopathy. Disease localization is frequently suggestive of specific histologies, although the diagnosis ultimately depends on biopsy. Lymphoma of the nasopharyngeal area with destruction of midline facial structures (so-called lethal midline granuloma) is often due to an EBV-associated T-cell or NK cell lymphoma. Pulmonary or skin involvement may be due to lymphomatoid granulomatosis. Small intestinal involvement in a patient with a history of gluten enteropathy is almost certainly due to T-cell lymphoma. The laboratory and radiologic workup of patients with aggressive NHL can reveal various stages of disease. More extensive disease is associated with a worse prognosis.

Mantle cell lymphoma is somewhat different from other aggressive lymphomas in that it is often widespread at the time of diagnosis and fairly reminiscent of follicle center lymphomas at presentation. In contrast to what is seen in follicle center lymphomas, involvement of the intestine (lymphomatous polyposis) is common.

The very aggressive (high-grade) lymphomas are typically disorders of young adults and children, although older patients are occasionally seen. Burkitt lymphoma is one of the most rapidly proliferating malignancies known. Patients typically present with rapidly enlarging abdominal masses. In African Burkitt lymphoma, jaw masses are common. Symptoms such as pain, fever, or sweats are common. In American Burkitt lymphoma abdominal masses are common and such a mass can often be palpated in the abdomen. Bone marrow and peripheral blood involvement is extremely common, and examination of the bone marrow and blood may permit the diagnosis to be made. Serum LDH levels can be extremely elevated. Levels 510 times normal are not unusual. These extreme levels are rarely seen in other lymphomas. Uric acid may be elevated at diagnosis, and renal function may be impaired owing to ongoing spontaneous tumor lysis. CNS involvement at diagnosis is not uncommon but is not per se an adverse prognostic feature.

Lymphoblastic lymphoma of T-cell origin also occurs in young adults who present with rapidly enlarging mediastinal masses. As in Burkitt disease, the diagnosis can often be made by examination of the bone marrow and blood, thus allowing expedited treatment.

STAGING AND RESTAGING OF NHL

History and Physical Examination

The staging of NHL begins with a thorough history in which such symptoms as fever, weight loss, night sweats, and painful areas are reviewed. Any remote history of adenopathy should also be recorded, because indolent lymphomas frequently are associated with a several-year history of waxing and waning nodes. The physical examination should emphasize the cervical, supraclavicular, axillary, inguinal, and epitrochlear nodes, as well as the abdominal cavity, liver, and spleen. The epitrochlear nodes are occasionally involved by indolent NHLs, whereas such involvement is uncommon in aggressive disease. The size of these nodes must be measured and recorded to aid in post-therapy follow-up. Other areas of emphasis in the history and physical examination depend on the particular presentation of the disease.

Biopsy and Invasive Procedures

Adequate tissue sampling is required for the correct diagnosis of NHL and should include enough material for immunophenotyping, cytogenetic studies, and molecular studies. Immunophenotyping is essential for correct assignment of diagnosis according to the REAL classification. In some cases, however, such as T-cell-rich B-cell lymphoma or lymphomatoid granulomatosis, an excess of reactive T cells may obscure a minority of malignant B cells. In other situations an inflammatory process

may be confused with NHL. Therefore, in difficult cases the diagnosis may depend on demonstration of clonality in the B or T cells. This may require studies of immunoglobulin gene or T-cell receptor gene rearrangement. In addition, in a number of diseases the demonstration of oncogene rearrangement such as that of *bcl-2* (follicular lymphoma) or of *bcl-1* (mantle cell lymphoma) helps in establishing a diagnosis. Cytogenetic analysis of the lymph nodes or bone marrow can also be helpful. Some NHLs are associated with typical cytogenetic abnormalities (e.g., t(8;14) in Burkitt lymphoma, t(14;18) in follicular lymphoma, t(2;5) in anaplastic large cell lymphoma, t(11;14) in mantle cell lymphoma, and trisomy 3 or trisomy 18 in marginal zone lymphoma).

In some cases, especially when patients have abdominal tumors, an incisional or excisional biopsy, which provides the ideal material for diagnostic purposes, may require laparotomy. Core needle biopsy has been used in lieu of a lymph node biopsy in such cases. These biopsies provide sufficient information in certain cases, but adequate assessment of lymph node architecture is not always possible and may occasionally lead to an erroneous diagnosis. [26] [27] [28] Fine needle aspiration (FNA) is also an alternative, but only an expert cytologist with experience in the cytologic diagnosis of NHL should attempt this for the establishment of a primary diagnosis. Total reliance on FNA for the diagnosis of NHL is risky and frequently leads to erroneous diagnosis. Some tumor types, such as Burkitt lymphoma and lymphoblastic lymphomas, with very well defined cytologic, cytogenetic, molecular, and immunophenotypic features lend themselves more to this approach than do others. FNA is more commonly used for the diagnosis of recurrent or persistent disease after therapy and to rule out transformation of indolent lymphoma.

In general, the analysis of peripheral blood or bone marrow that is involved does not allow complete assessment of lymphoma, and biopsy of lymph nodes or tumor masses, if present, should be pursued as well. There are, however, some exceptions: (1) In CLL and in other lymphomas characterized by a leukemic picture, the diagnosis can be made by immunophenotyping of cells in the peripheral blood. Lymph node biopsy is not warranted unless mantle cell lymphoma or disease transformation is suspected. (2) Burkitt disease and lymphoblastic lymphoma often manifest as abdominal or mediastinal masses, respectively. These diseases require immediate treatment, and an accurate diagnosis can often be established from examining the bone marrow or peripheral blood, or both. No further staging beyond a chest radiograph, computed tomography (CT) of abdomen and pelvis, bone marrow aspirate, lumbar puncture, and routine blood tests is required in these disorders. In fact, unnecessary attempts at invasive diagnostic procedures may lead to significant delays and compromise the patients ability to tolerate chemotherapy. In the presence of a rapidly growing tumor mass in the characteristic clinical context of Burkitt or lymphoblastic lymphoma, whenever possible minimally invasive procedures, including FNA with morphologic, flow cytometric, and cytogenetic analyses of tissue, should be used to allow prompt initiation of therapy.

Bone marrow biopsy provides valuable staging information and should be performed routinely in NHL. The yield of bilateral bone marrow biopsies is 15% higher than that of a unilateral biopsy in indolent NHL, and such biopsies are routine practice in several institutions. In many cases of large cell lymphoma, an indolent histology is encountered in the bone marrow, leading to the diagnosis of discordant (divergent) lymphoma, which has important therapeutic implications. [29] [30] The distribution of marrow involvement can be very irregular or patchy. In some cases, magnetic resonance imaging (MRI) can be useful in detecting occult marrow involvement.

Diagnostic lumbar puncture is part of the diagnostic workup of patients with highly aggressive lymphomas or blastic variants of mantle cell lymphoma. It should also be considered for patients with aggressive histologies and high-risk factors for CNS relapse (such as high LDH levels or involvement of multiple extranodal sites) or specific localizations, such as testicular lymphoma, and for those with large cell lymphoma involving the bone marrow.

Gastrointestinal (GI) workup and evaluation of Waldeyer ring may be useful in patients with lymphoma that has a high propensity to disseminate to these areas, specifically MALT and mantle cell lymphomas. Liver biopsy is needed only when liver involvement is suspected on the basis of laboratory or radiologic test results.

Imaging Studies

Chest radiography and CT of the abdomen, and pelvis are a routine part of the workup of a patient with NHL. Chest CT should be performed in cases in which the chest x-ray findings are questionable or whenever a mediastinal mass is detected. In the latter instance, occult pulmonary or pleural disease is common and can be detected with CT. Ultrasound (US) of the liver should be considered for patients with abnormal results on liver function tests and a normal CT scan, because US occasionally has greater sensitivity than CT. Lymphangiography is more sensitive in demonstrating lower abdominal and pelvic adenopathy than CT and should be considered in the treatment planning for patients with indolent NHL if total lymphoid irradiation is considered for the treatment.

The gallium scan is increasingly used in the staging of patients with aggressive histologies, who will commonly have residual changes on CT after completion of treatment. It is abnormal at the time of diagnosis in the large majority of patients. Persistent gallium positivity in a residual mass after completion of treatment indicates a high risk of persistent disease. [31] [32] [33] False positive results occur commonly in the pulmonary hilar areas after therapy and in areas where previous involvement of bone existed. The latter are due to inflammatory changes. Hence, interpretation of gallium scans in bone is not reliable. The pulmonary hilar changes must be interpreted in conjunction with the chest radiograph, which will not show hilar enlargement in cases of false positivity on gallium studies. On the other hand, the absence of gallium uptake in residual masses is not a sensitive predictor of prolonged remission. Gallium scanning has also been used in indolent lymphoma and

appears to be useful in indicating persistent disease, although its role in these histologic types is less established. [34]

Because of its ability to discriminate to some extent between benign and malignant tissue, MRI has been used in a fashion similar to gallium scanning to detect residual lymphoma in persistent masses after completion of chemotherapy.[35] It appears to have a sensitivity similar to that of gallium scanning. MRI is also used to detect marrow involvement that cannot be demonstrated by biopsy because of inhomogeneous distribution of the marrow involvement. [36]

Blood Tests

In addition to routine blood tests, it is essential to measure serum LDH and $_2$ -microglobulin levels. These values are indirect indicators of tumor burden and proliferative activity and important indicators of disease prognosis. HIV or HTLV-1 serology, hepatitis B and C, and EBV serology should be considered in the workup for many patients because of their association with NHL and because of implications for treatment. Serum levels of -fetoprotein or -human chorionic gonadotropin are necessary in the evaluation of young males with an isolated mediastinal mass. Markedly elevated levels of either of these markers indicate the presence of a mediastinal germ cell tumor and may obviate thoracotomy.

Evaluation of Response to Therapy

In aggressive lymphomas the rate of response to treatment is an important prognostic feature.[33] [37] Disease progression or lack of response are extremely poor prognostic features, as is the commonly observed kinetic failure, in which progression occurs after an initial response but before administration of the next cycle of chemotherapy. It is therefore customary to repeat abnormal staging studies after the first two cycles of chemotherapy. Restaging involves the repetition of any tests that yielded abnormal results at baseline, including physical examination, radiologic examination, bone marrow biopsies, and blood tests. If there is a change in clinical status, earlier restaging may be indicated. After treatment is completed, complete restaging is usually repeated. If the gallium scan became normal earlier during treatment, there is no need to repeat it. MRI could constitute an alternative to gallium scanning, especially if the initial gallium scan was normal. FNA can also be used to evaluate residual masses after therapy. It is customary to repeat staging procedures at regular intervals after treatment is completed. Although restaging after treatment is useful for reassurance of the patient and for evaluation of clinical studies, it has not been shown to be helpful in detecting most instances of recurrence of large cell lymphoma before the development of other signs such as an elevated LDH level or symptoms. [38] The gallium scan may be a useful adjunct in routine follow-up to detect recurrence of large cell lymphoma.

In indolent lymphomas, the rate or rapidity of the response to chemotherapy is usually slower, and therefore restaging is needed at less frequent intervals. We usually perform restaging after three to four cycles of treatment in patients with indolent follicle center lymphomas.

PROGNOSTIC FACTORS

The histologic type is a major determinant of prognosis in patients with NHL. The implications of histology for the treatment and prognosis of NHL are discussed in conjunction with each of the different subtypes. But factors other than disease histology and treatment play a major role in determining the prognosis for an individual patient. It is extremely important to recognize these prognostic factors in order to determine the optimal management, predict outcome for an individual patient, and interpret and design clinical studies. Diffuse large B-cell lymphoma is the subtype of lymphoma in which the impact of prognostic factors has been studied most thoroughly, and to a certain degree it has served as a paradigm for the study of prognostic factors in other types of NHL.

Prognostic Factors in Diffuse Large Cell Lymphoma

Prognostic factors in diffuse large cell lymphoma can be divided into those that are related to the disease and those that are related to the patient or the patients interaction with the disease.[39] [40] Factors related to the patient include advanced age and poor performance status, which are adverse prognostic factors. The poor prognosis related to age may be due to a lesser tolerance for chemotherapy or perhaps to increasing immunocompromise with advancing age. Even when adequate chemotherapy is administered, the complete remission rate and survival rate in older patients are less than in younger cohorts. [41] Performance status is related in part to the patients disease and may be an indicator of the degree of tumor bulk and proliferation. In part it is related to the patients general health and appears to correlate with the patients ability to tolerate treatment.

A number of parameters related to the bulk and proliferative capacity of the lymphoma are also predictive of outcome. They include Ann Arbor stage, size of tumor masses, number of extranodal sites, and LDH and $_2$ -microglobulin levels. Such parameters are only surrogates for important biologic differences between different NHL patients. Recently there has been interest in defining more exactly the biologic determinants of disease that may relate to prognosis. The presence of certain molecular or cytogenetic abnormalities in the genome of the lymphoma cells or the expression of certain adhesion molecules may be related to prognosis. Such abnormalities, while not routinely determined in the assessment of NHL patients, provide insight into the pathogenesis of the disorder and may ultimately provide valuable leads for treatment. Some of the newly defined prognostic parameters are shown in Table 70-2 . The recognition of certain histologic subtypes that are commonly included in studies of aggressive lymphoma may also add further prognostic information. Ki-1-positive anaplastic large cell lymphoma is associated with an improved prognosis in recent studies, while other subtypes of T-cell lymphoma are associated with a worse prognosis. Similarly, immunoblastic lymphoma, although often grouped with diffuse large cell lymphoma, may have a worse prognosis.

In addition to prognostic factors that can be recognized prior to initiation of treatment, some prognostic information becomes available only after treatment has started. The response to chemotherapy is a very important feature. A slow response to chemotherapy predicts a poor outcome. [33] [37] If a patient with an aggressive histologic type fails to achieve a complete remission after two or three cycles of chemotherapy, the chance for long-term disease-free survival is decreased. A source of confusion in evaluating response is the presence of a residual mass after therapy. Therefore it is helpful to evaluate those cases with gallium scan, MRI, or biopsy, either FNA or incisional. [31] [35]

Prognostic Models

Prognostic models are developed with the intent of predicting the prognosis of a patient prior to initiating treatment. A good prognostic model should satisfy a number of criteria. The most important ones are (1) by dividing instances of disease into favorable and unfavorable categories, it should facilitate therapeutic decisions, and (2) it should be simple and reproducible.

The International Prognostic Index (IPI) and the Age-Adjusted International Index result from an international cooperative effort and have become increasingly accepted as the tool to determine prognosis in patients with large cell lymphoma. [42] The International Prognostic Index was devised using a very large database of patients treated with standard doxorubicin-containing regimens. It is based on five parameters: age, performance status, serum LDH, involvement of more than one extranodal site, and stage of disease (the mnemonic is APLES). A point is assigned for each of the following characteristics: (1) age >60, (2) performance score of 2, (3) increased serum LDH level, (4) involvement of more than one extranodal site, and (5) Ann Arbor stage III or stage IV disease. In principle, the International Prognostic Index applies only to patients with aggressive NHL. It has also been applied to patients with other types of NHL and appears to provide information in those subtypes as well. [43] [44] [45] [46] The major limitation of the IPI is that approximately one-half of patients fall into an intermediate-prognosis category. In these patients only very limited prognostic information is gained, and therapeutic decisions are not facilitated (Table 70-3).

Another index, called the tumor score, was developed at M.D. Anderson Cancer Center. [47] It is a simple system based on five reproducible parameters. One point is assigned for each of the following: (1) the presence of constitutional symptoms, (2) stage III or IV disease, (3) any tumor mass >7 cm, (4) LDH >1.10 over the normal level, and (5) $_2$ -microglobulin increased >1.5 above the normal level. This system divides the patients in two prognostic groups. All patients with a tumor score of

TABLE 70-2 -- New Prognostic Parameters in Aggressive NHL

Prognostic Feature	Author, Year	Method	Comments
Abnormalities in chromosomes 7 and 17	Cabanillas et al., 1989[530]	Cytogenetic analysis	Poor prognosis associated with abnormalities of chromosome 7 and chromosome 17. No multivariate analysis
Ki-67	Miller et al., 1994[531]	Monoclonal antibody, detects nuclear antigen associated with cell proliferation	High Ki-67 is associated with 18% 1-year survival. Independent factor in multivariate analysis of small patient sample[a]
bcl-2 protein expression	Hermine et al., 1996; [532] Hill et al., 1996[533]	Immunohistochemical staining for expression of *bcl-2* protein	High expression of *bcl-2* is associated with reduced disease-free survival and overall survival in diffuse large B-cell lymphoma; also associated with an increased risk for relapse. Independent factor in multivariate analysis [a]
Ploidy and proliferative activity	Winter et al., 1996[534]	Flow cytometric analysis	No association between aneuploidy and outcome in aggressive NHL. Increased mitotic index is associated with decreased survival but is not an independent predictor[a]

CD44v	Stauder et al., 1995[535]	Variant isoform of adhesion protein, immunohistochemical analysis	Expression of variant isoform of CD44 is associated with decreased survival in aggressive lymphoma. Independent predictor in multivariate analysis[a]
Plasma level of TNF and TNF receptor p55 and p75	Warzocha et al., 1997[536]	ELISA	High levels of TNF, p55, and p75 are associated with decreased survival and freedom from progression in aggressive lymphomas. Independent predictor in multivariate analysis[a]
Rearrangement of *bcl-6*	Offit et al., 1994[537]	Southern blot	Improvement in survival and disease-free survival in aggressive lymphomas with rearranged *bcl-6*. Independent predictor in multivariate analysis[a]
Mutation of *p53*	Ichikawa et al., 1997[559]	Polymerase chain reaction	Mutations of *p53* are associated with decreased rate of complete responses and decreased overall survival. Independent predictor in multivariate analysis[a]
Serum level of $_2$ -microglobulin	Preti et al., 1993[514]	Radioimmunoassay	Increased level of $_2$ -microglobulin is associated with a worse prognosis. Independent predictor in multivariate analysis[a]
Serum level of interleukin-6	Preti et al., 1997[538]	ELISA	Increased level of interleukin-6 is associated with decreased complete response rate and survival. Independent predictor in multivariate analysis[a]
ICAM-1 expression	Terol et al., 1998[539]	Immunostaining	Increased expression of ICAM-1 is associated with lymphoma dissemination and decreased survival. Independent predictor in multivariate analysis[a]

[a]Multivariate analysis incorporates the parameters evaluated in the International Prognostic Index, in addition to the one studied.

>3 have a very poor prognosis when treated with CHOP-bleomycin and are currently treated on investigational protocols. Those with tumor scores of <3 have a disease-free survival rate of 80% when treated with conventional regimens. Therefore, the prognostic information gained from this model is in general greater than that obtained with the IPI.

The same prognostic parameters that apply in aggressive lymphoma are usually found to be valid in indolent lymphomas, [48] and therefore the IPI has been applied to indolent malignancies. [43] [45] [46] In indolent lymphomas, however, the IPI lacks sufficient sensitivity to predict the majority of failures. When the index is used, only 812% of cases will be assigned to a high-risk subgroup. [43] [45] [46] [48] The vast majority of patients will fall into favorable and intermediate-favorable subgroups. Several groups have proposed other prognostic models. [49] [50] [51] A simple model based on serum LDH and $_2$ -microglobulin levels has been found to be useful. It divides patients into three prognostic groups according to whether serum levels of neither, one, or both factors are elevated. [49] It has excellent discriminatory power and was confirmed in an independent population to be easily applicable and predictive of outcome. [48] As in other types of lymphoma, further research is needed to identify parameters that can accurately predict the prognosis in indolent lymphomas.

TABLE 70-3 -- Prognostic Indices in Large Cell Lymphoma[a]

Risk Category	Score	Patients in Risk Group (%)	Complete Responses (%)	5-Year Disease-Free Survival for Patients with Complete Responses (%)	5-Year Survival (%)
International Prognostic Index[42]					
Low	0 or 1	35	87	70	73
Low-intermediate	2	27	67	50	51
High-intermediate	3	22	55	49	43
High	4 or 5	16	44	40	26
Age-Adjusted International Index[42]					
Low	0	22	92	86	83
Low-intermediate	1	32	78	66	69
High-intermediate	2	32	57	53	46
High	3	14	46	58	32
Tumor score[47]					
Low	02	61	91	92[b]	83[b]
High	3	39	46	46[b]	24[b]

Age-Adjusted International Index: one point each is assigned for performance status <1, elevated lactate dehydrogenase level, stage III or stage IV disease.

Tumor score: one point each is assigned for elevated lactate dehydrogenase level >110%, elevated $_2$ -microglobulin >3, presence of constitutional symptoms, stage III or stage IV disease, each mass >7cm.

[a]International Prognostic Index: one point each is assigned for age >60, performance status <1, elevated lactate dehydrogenase level, involvement of more than one extranodal site, stage III or stage IV disease.
[b]3-year survival.

PRESENTATION AND MANAGEMENT OF B-CELL LYMPHOMAS

Management and Diagnosis of Burkitt Lymphoma and High-grade B-Cell Burkitt-like Lymphoma

In the Working Formulation three disease entities were included among the high-grade lymphomas: lymphoblastic lymphoma, immunoblastic lymphoma, and diffuse small noncleaved cell lymphoma. Lymphoblastic lymphoma is usually of T-cell type and will be discussed later. The term immunoblastic lymphoma is not used in the REAL classification. Immunoblastic lymphoma of B-cell origin is currently thought to be closely related to diffuse large cell lymphoma and is treated similarly. A recent report from the Kiel group suggests that immunoblastic B-cell lymphomas have a worse prognosis than other diffuse B-cell large cell lymphomas. [52] This may prompt re-evaluation of this issue. A number of subtypes of T-cell immunoblastic lymphoma are currently classified as anaplastic T-cell lymphoma or as angioimmunoblastic T-cell lymphomas.

Three variants of Burkitt disease are recognized. The endemic (African form) is closely associated with EBV infection, in which patients often present with jaw or abdominal masses.[53] [54] The sporadic (American) form is infrequently associated with EBV infection. Patients with sporadic Burkitt disease often present with abdominal disease and bone marrow involvement.[55] A third variant, AIDS-related Burkitt lymphoma, is discussed in Chapter 75 , which deals with AIDS-associated lymphomas.

Diffuse small noncleaved cell lymphoma has been subdivided in the REAL classification into Burkitt lymphoma and high-grade B-cell lymphoma, Burkitt-like. [55] The latter includes some cases that might have been classified as large cell lymphoma in the past. The clinical significance of this distinction is unclear. The morphology of Burkitt lymphoma cells is very typical and is similar to the L3 subtype of ALL. The cells are mature B cells with expression of surface immunoglobulin. The disease is associated with chromosomal translocations involving the c-*myc* oncogene and immunoglobulin genes.[56] Some cases of Burkitt-like NHL lack these rearrangements and may have rearrangements of *bcl-2.*[60]

Burkitt lymphoma is more common among children and young adults. Patients present with rapidly proliferating tumors, and frequently with bone marrow and peripheral blood involvement. CNS involvement at diagnosis is not uncommon. The serum LDH level is often extremely elevated, and hyperuricemia and renal impairment may be found at diagnosis. Staging should be limited to allow expedited treatment. [55] [56] In addition to a diagnostic biopsy with cytogenetic studies and immunophenotyping, staging studies should always include a bone marrow biopsy and lumbar puncture, as these two tests have both prognostic and therapeutic implications. Cytogenetic and molecular analysis as well as immunophenotyping allow one to establish the diagnosis with certainty and to rule out alternative diagnoses such as aggressive NK cell leukemia. If the bone marrow or peripheral blood sample is diagnostic, a biopsy of tumor masses should generally be avoided. It is unnecessary and may lead to considerable delay in initiating treatment. If the bone marrow examination is negative, diagnostic FNA should be considered in cases with a typical presentation. Surgical resection used to be recommended as part of the treatment of patients with Burkitt disease. [57] [58] Currently, given the high efficacy of intensive chemotherapeutic regimens, surgical debulking is in general not indicated. [59]

The curative treatment of endemic Burkitt disease with cyclophosphamide represented one of the first successes of chemotherapy. [61] This single-agent treatment resulted in cure for a minority of patients and is no longer used. For patients without bone marrow or CNS involvement, cure can often be achieved with regimens that include both alkylating agents and antimetabolites and that were designed for large cell lymphoma, [62] [63] [64] but patients with extensive disease usually do not benefit from such approaches. Burkitt disease is very closely related to B-cell ALL. A number of intensive treatment regimens designed for pediatric B-cell ALL have now been used in adult Burkitt lymphoma. Successful regimens include high doses of cyclophosphamide (13 g/m ^{2} per course) or ifosfamide combined

MANAGEMENT OF VERY AGGRESSIVE LYMPHOMA IN THE ADULT

The large majority of very aggressive lymphomas are either T-cell lymphoblastic or B-cell (Burkitt) lymphoma. The differential diagnosis between the two entities is usually obvious from the clinical picture. T-cell lymphoblastic lymphoma presents with a mediastinal mass, whereas Burkitt lymphoma often presents with large abdominal masses or other more peripheral masses; mediastinal masses are rare in Burkitt lymphoma. The staging workup should be expedited. Often examination of the peripheral blood or bone marrow, or both, can provide the diagnosis. Immunophenotyping and molecular and cytogenetic analyses of the bone marrow or peripheral blood, or both, are essential. Burkitt lymphoma is characterized by an L3 morphology, a mature B-cell phenotype (with expression of surface immunoglobulin), and t(8;14), t(2;8), or t(8;22). Lymphoblastic lymphoma has an L1 morphology, a T-cell phenotype, is TdT positive, and usually has diploid cytogenetics. The differential diagnosis includes other forms of very aggressive lymphoma, such as NK cell lymphoma or adult T-cell lymphoma, or different types of ALL. In cases without bone marrow involvement, the diagnosis may require a surgical procedure. In some cases with a suggestive clinical picture, FNA is preferred, as it is less invasive and provides adequate tissue for diagnosis in this disorder. The staging workup is completed with a laboratory workup that includes determinations of serum LDH (often very elevated) and $_2$ -microglobulin levels, liver and kidney tests and coagulation tests. Chest radiography and CT of the abdomen are usually performed. A lumbar puncture is also essential.

Other tests can be considered if clinically indicated, but their performance should not delay the initiation of treatment.

A central line is placed and D5W + 100 mEq sodium acetate at 100150 ml/hour is administered to alkalinize the urine. Allopurinol, 600 mg, is given PO daily for 2 days; thereafter it is continued at 300 mg/day PO until the tumor lysis syndrome has resolved. The chemotherapy regimen used at M.D. Anderson consists of the hyper-CVAD regimen.

The first cycle consists of cyclophosphamide, 300 mg/m^2 given IV over 3 hours every 12 hours for six consecutive doses (total dose 1,800 mg/m^2); Mesna, 600 mg/m^2 given by continuous IV infusion over 24 hours per day for 3 consecutive days (Mesna is started 1 hour before cyclophosphamide and continued for 12 hours after the last dose); adriamycin, 25 mg/m^2 given by continuous IV infusion over 24 hours for 2 days (total dose, 50 mg/m^2); and vincristine, 1 mg given by continuous IV infusion over 24 hours for 2 days (total dose, 2 mg). Vincristine and adriamycin are started after the last dose of cyclophosphamide. Vincristine, 2 mg by IV push, is repeated on day 11. Decadron, 40 mg/day PO, is given on days 14 and 1114. G-CSF, 5 g/kg, is given daily starting 24 hours after the last dose of adriamycin. It is continued until granulocytes are >30,000/l or until day 21 (whichever comes first).

This regimen is very effective in inducing remissions in high-grade NHL. Tumor lysis, especially in patients with Burkitt lymphoma, is very common, and in the first days of treatment the patient should be monitored extremely closely. Electrolyte abnormalities should be corrected, and if renal failure ensues, dialysis should be initiated. In our experience the acute renal failure associated with tumor lysis is usually profound but rapidly and completely reversible. To avoid opportunistic infection, ciprofloxacin, acyclovir, and fluconazole can be given preventatively.

One day after completion of G-CSF therapy, and provided a complete remission is achieved, we proceed with the next cycle of treatment. This consists of methotrexate, 200 mg/m^2 given IV over 2 hours, then 800 mg/m^2 given IV over 22 hours on day 1. Leucovorin, 50 mg IV or PO, is given 12 hours after the completion of methotrexate, followed by 15 mg IV or PO every 6 hours for 8 doses. Ara-C, 3 g/m^2 IV over 2 hours, is given every 12 hours for four doses on days 2 and 3. At the end of the methotrexate infusion, 24 hours and 48 hours after completion, the methotrexate level is checked. If the level is >1 M at 24 hours or >0.1 M at 48 hours, the leucovorin dose is increased to 50 mg IV every 6 hours until the level is <0.1 M. G-CSF, 5 g/kg, is given starting on day 1 until the ANC is >30,000/l or until day 21 (whichever comes first). Then it is held for 1 day and the next cycle is started. Alkalinization with D5W and sodium acetate, steroid eye drops, and prophylactic antibiotics are used in this regimen.

These cycles are alternated every 3 weeks (or faster if possible) for eight cycles. Intrathecal prophylaxis consists of methotrexate, 12 mg on day 2, and Ara-C, 100 mg on day 7. This is continued for four cycles (total of eight injections). Patients with CNS involvement at diagnosis receive intrathecal treatment with alternating methotrexate and Ara-C twice a week until the CSF clears. Then they receive prophylaxis during all cycles of their treatment (total of 16 injections). Cranial radiation therapy is not routinely used in this protocol.

Maintenance treatment is offered to patients with lymphoblastic lymphoma, but it is omitted in Burkitt disease. It consists of 6-mercaptopurine, 50 mg PO t.i.d. one-half hour before meals daily; methotrexate, 20 mg/m^2 IV weekly; vincristine, 2 mg IV monthly; and prednisone, 100 mg daily for 5 days every month. This treatment is continued for 24 months. Doses are adjusted for myelosuppression, mucositis, liver dysfunction, neuropathy, or steroid side effects.

with vinca alkaloids, steroids, and anthracyclines. They also include drugs with good CNS penetration such as Ara-C and high-dose methotrexate, as well as intrathecal chemotherapeutic prophylaxis. Radiation treatment to the brain is not used in most protocols, except on occasion in patients with CNS involvement at diagnosis. Treatment is extremely intensive, with a rapid succession of myelosuppressive regimens. Maintenance treatment is considered unnecessary, and treatment is usually completed within 3 months. The prognosis has steadily improved even for patients who present with CNS involvement. [65] [66] [67] [68] [69] [70] [71] [72] [549] A number of recently reported trials in adults and treatment outcomes are summarized in Table 70-4 . The trials that include higher doses of alkylating agents appear to be associated with a somewhat superior outcome. The outcomes are also better in those trials that include a large proportion of patients without bone marrow involvement (i.e., the outcomes for patients with mature B-cell leukemia are inferior to the outcomes for patients with classic Burkitt lymphoma) and for younger patients.

High-dose chemotherapy followed by autologous transplantation has been successful in children and young adults with persistent or recurrent Burkitt lymphoma. [73] [74] [75] This has prompted the use of autologous bone marrow transplantation during the first remission. [75] Given the excellent results of modern

[b] Seven of 12 are disease free.
[c] Four treatment-related deaths were related to autologous bone marrow transplantation.
[a] Thirteen patients received autologous bone marrow transplants during the first complete response.
[d] Treatment regimen included ifosfamide and prophylactic cranial irradiation.
[e] Six patients received bone marrow transplants during the first complete response, with two treatment-related deaths.
[f] CNS involvement is not an adverse prognostic factor.

chemotherapy in this disorder, consolidation with high-dose chemotherapy may be unnecessary in the large majority of patients during first complete remission and is generally not recommended any longer except as salvage treatment.

The induction treatment of Burkitt lymphoma is frequently complicated by massive tumor lysis syndrome and requires special precautions. Patients should receive allopurinol and should undergo hydration and alkalinization. Electrolyte abnormalities such as hyperkalemia, hyperphosphatemia, and hypocalcemia should be monitored and aggressively corrected. Some groups prefer to give an initial low-dose cytoreductive treatment, to prevent tumor lysis. [69] [72] This is followed 1 week later by more intensive chemotherapy.

Presentation and Management of Aggressive B-Cell Lymphomas

The most common variant of aggressive NHL is diffuse large B-cell lymphoma. It accounts for 40% of all B-cell lymphomas. [76] Diffuse large cell lymphoma and a small subset of follicle center lymphoma, the so-called follicle center grade III histology, are aggressive disorders and will be discussed together.

Diffuse Large B-Cell Lymphoma and Follicle Center Lymphoma Grade III

These entities roughly correspond to the intermediate grade histologies in the Working Formulation and also to some cases of immunoblastic lymphoma. They have a fairly similar natural history, have often been grouped together for the purpose of prospective studies, and are usually treated in a fairly uniform fashion. Within the category of diffuse large cell lymphoma, several disease entities have been recognized with particular clinical, histologic, immunophenotypic, or cytogenetic characteristics. Some histologic variants such as T-cell-rich B-cell lymphoma have an outcome similar to that of diffuse large cell lymphoma and are similarly treated.[77] [78] Another entity, primary mediastinal B-cell large cell lymphoma, has a somewhat different natural history and will be briefly discussed. It is likely that further progress will lead to the recognition of other subtypes with clinical relevance.

Clinical Presentation and Natural History

The median age of patients presenting with aggressive B-cell lymphoma is 60 years, but it is considerably lower for some subgroups, such as those with primary mediastinal B-cell lymphoma. Large cell NHL can arise de novo or as a transformation of (sometimes undiagnosed) low-grade lymphoma. Nearly half of patients present with localized nodal disease (stage I or II disease) and half with widespread disease. Many patients are symptomatic at the time of diagnosis, and with increasing tumor bulk constitutional symptoms develop. B-cell large cell lymphoma is usually a nodal disease, but it can also occur in extranodal organs such as the skin, stomach, or CNS. Such extranodal presentations may have a somewhat different biology and require specific consideration for their treatment. They are discussed in another section. The lymphadenopathy in cases with nodal disease is often localized to the retroperitoneum or mediastinum, rendering a diagnostic biopsy difficult. Untreated, the disease has a poor prognosis and leads to death within 1224 months. The diagnosis of this disorder depends on an adequate biopsy. Treatment planning requires rigorous staging and assessment of prognostic factors. With appropriate treatment, 40% of patients can be cured. [79] The mainstay of treatment is combination chemotherapy, but radiation therapy has a role in selected patients. The treatment of elderly patients, of patients with recurrent disease, and of those with adverse prognostic features presents specific problems and is discussed separately.

Chemotherapy in Diffuse Large B-cell Lymphoma

The alkylating agents, corticosteroids, and vincristine were the first effective agents for the treatment of aggressive NHL. [80] The CHOP regimen, in which doxorubicin is added to the combination, was then shown to result in improved survival.[81] [82] The 1970s and early 1980s saw the testing of numerous third-generation regimens built on the CHOP backbone but with the addition of other drugs. A number of these regimens are shown in Table 70-5 . Encouraging results were reported in pilot studies that included predominantly young patients. Unfortunately, four large randomized multicenter studies failed to show in a more representative population a significant advantage for any of these regimens (Table 70-6). [83] [84] [85] [86] Similarly, increments in the dose of doxorubicin, [87] or the infusional administration of etoposide and doxorubicin (the EPOCH regimen), could not be shown to result in improved disease-free or overall survival. [88] On the other hand, two recent reports indicated a statistically significant benefit for the second-generation regimens. [89] [90] In one study, MACOP-B was compared with CHOP and no difference was detected at the time of initial publication. [86] A later analysis of the same patient population did detect a benefit in both survival and disease-free survival for patients receiving MACOP-B.[89] A second study with a median follow-up of 10 years indicated benefit of a six-drug regimen over a four-drug regimen (Table 70-6).[90] Although the latter two studies indicate that there may be some benefit to second-generation regimens, any such benefit is likely to be influenced by the selection of patients participating in the study and is unlikely to be very large.

MANAGEMENT OF AGGRESSIVE NHL IN THE ADULT

The modern management of aggressive NHL begins with an accurate diagnosis, which should include a review by an expert hematopathologist as well as immunophenotyping and, if possible, cytogenetic assay. Aggressive NHL includes the cell types indicated in Table 70-1 . The treatment strategy for these disorders is similar, with the exception of mantle cell lymphomas and immunoproliferative small intestinal disease, which are unique entities and require different management.

Once a diagnosis is firmly established and other staging studies have been completed, it should be determined whether there is a reasonable chance for cure with the CHOP regimen and whether the patients cardiac function is adequate for the administration of anthracyclines. Determination of the chance for cure with CHOP can be made using the prognostic models already discussed. Most clinicians use the IPI to determine this, but the inclusion of $_s$ -microglobulin as used in the tumor score model can add discrimination to this model.[514] For these purposes we use the M.D. Anderson tumor score system as previously described.

If the chance for cure with CHOP is >75%, this regimen should be used if at all possible because it is well tolerated and simple to administer. For patients whose cardiac function is compromised, the decision is more difficult. Possible alternatives in these cases include the use of non-anthracycline-containing regimens such as ESHAP or IMVP-16, or both, given in alternating fashion.

MANAGEMENT OF PATIENTS WITH A FAVORABLE RISK PROFILE

Within this category are included only those cases with favorable prognostic features such as a tumor score of 02 (or IPI of 01). In general, these patients are treated with the CHOP regimen, but they can be divided into two subsets: those who had localized disease on presentation (i.e., Ann Arbor stages III) and those with more advances stages (IIIIV). The length of treatment may vary accordingly. Localized disease can be considered an ultrafavorable presentation, with a cure rate of 85%. Treatment may be very brief and consist of only three courses of CHOP followed by involved-field irradiation. [91] [93] [550] Patients with advanced Ann Arbor stage disease (the second subset) can be treated with six courses of CHOP without radiation therapy. Their prognosis is also excellent with this approach.

MANAGEMENT OF PATIENTS WITH AN UNFAVORABLE RISK PROFILE

These patients include anyone with a tumor score >2 (or anyone with an IPI score >3). The outcome for patients with disease with adverse prognostic features when managed with the classic CHOP regimen is poor, and their cure rate is <30%. [42] [47] There is no standard regimen that has been tested in a randomized setting and shown to be more effective than CHOP for these patients. We have used the alternating triple-therapy or ATT regimen, consisting of alternating courses of ASHAP, M-BACOS, and MINE for a total of nine cycles. Patients with bulky disease received consolidative radiation to areas of bulky involvement. This regimen, when compared with the historical experience with CHOP, showed a statistically significant benefit for patients <61 years old. [515] Although this study was not randomized, we used prognostic factor analysis to compare the two protocols, thus adjusting for potential bias in patient selection. Others have used intensive chemotherapy and autologous stem cell transplantation for patients with unfavorable risk factors. Currently we are comparing, in a randomized study, the ATT regimen with an intensive chemotherapy regimen followed by autologous stem cell transplantation.

Those patients with an adverse prognostic profile (i.e., tumor score >2) and >60 years old represent the most challenging group. When these patients were treated with ATT they did not show any benefit as compared with CHOP. Their cure rate as well as their 3-year survival rate has been only 28%. [513] [515] Recently the substitution of idarubicin for doxorubicin in a randomized study using the ATT regimen has been associated with a 50% 3-year survival in older patients with a tumor score >2, compared with 35% for doxorubicin.[115] This is currently our standard treatment in older patients with poor prognostic features.

All randomized studies antedated the routine use of prognostic models, and therefore their conclusions may not apply to the current treatment of patients. It is now well established that CHOP is highly effective in subsets of patients with so-called good prognostic features, which includes those aged <60 years with an Age-Adjusted International Prognostic Index of 0 or 1. For such patients the expected complete response rate with a conventional anthracycline-containing regimen is at least 80%, and two-thirds of the remissions are durable.[42] Their expected survival at 5 years is 69%. An alternative treatment strategy for patients with good-prognosis stage I or II disease consists of the administration of three to four cycles of CHOP or other anthracycline-based chemotherapy, followed by radiation treatment of the involved field. This strategy, when tested in a randomized study, has yielded superior long-term disease control with minimal toxicity. [91] [92] [93] [550] It is unlikely that second- or third-generation regimens will further improve the prognosis in those groups, and CHOP chemotherapy can continue to be used. By contrast, among patients with several adverse prognostic features, neither CHOP nor any of its derivatives is likely to result in high durable remission rates. Whenever possible, such patients should be enrolled in investigational protocols.

Treatment of Aggressive, Poor-Prognosis NHL with High-Dose Chemotherapy

CHOP chemotherapy or any of its derivatives is unlikely to be beneficial in patients with an IPI of >2. One of the most interesting avenues of research, at least for younger patients with poor-prognosis NHL, is that of high-dose chemotherapy and autologous bone marrow

TABLE 70-5 -- Commonly Used Anthracycline-Containing Chemotherapy Regimens for Aggressive NHL[a]

Name	Frequency of Administration	No. of Cycles	Cyclophosphamide	Adriamycin	Vincristine[b]	Prednisone	Methotrexate[c]	Bleomycin	Etoposide	Cytarabine	Procarbazine
CHOP[82]	21	68	750 mg/m^2	50 mg/m^2	1.4 mg/m^2	100 mg for 5 days					
CAP-BOP[555]	21	68	650 mg/m^2	50 mg/m^2	1.4 mg/m^2 on day 15	100 mg for 7 days (days 1521)		10 U/m^2 on day 15			100 mg/m^2 for 7 days
m-BACOD[556]	21	68	600 mg/m^2	45 mg/m^2	1 mg/m^2 on day 8	Decadron, 6 mg/m^2 for 5 days	200 mg/m^2 on days 8 and 15	4 mg/m^2			
MACOP-B[557] [d]	14	6	350 mg/m^2	50 mg/m^2	1.4 mg/m^2	75 mg for 14 days	400 mg/m^2 on day 8 (every other cycle)	10 U/m^2 on day 8 (every other cycle alternates with methotrexate)			
ProMACE CytaBOM[541]	28	68	650 mg/m^2	25 mg/m^2	1.4 mg/m^2 on day 8	60 mg/m^2 for 14 days	120 mg/m^2 on day 8	5 U/m^2 on day 8	120 mg/m^2	300 mg/m^2 on day 8	
LNH-84 induction[100] [e]	14	4	1,200 mg/m^2	75 mg/m^2		60 mg/m^2 for 5 days		5 U/m^2 on days 1 and 5			
EPOCH[135] [f]	21	68	750 mg/m^2 on day 6	10 mg/m^2 on days 15	0.4 mg/m^2 on days 14	60 mg/m^2 on days 14			50 mg/m^2 on days 14		

Hyper-CVAD, first cycle[540] [549]	21	6	300 mg/m^2 q 12 hr for 6 doses with mesna	25 mg/m^2 IV on days 4 and 5	0.1 mg on day 4, 1 mg on day 5, and 2 mg on day 11	Decadron, 40 mg on days 14, 1114						

Note: This table does not provide all details regarding supportive care for the regimens described. See specific references.

[a] All drugs are administered on day 1, unless otherwise specified.
[b] The dose of vincristine in most regimens is limited to 2 mg total dose.
[c] Regimens containing methotrexate commonly include leucovorin rescue.
[d] MACOP-B requires antifungal and *Pneumocystis carinii* prophylaxis.
[e] Consolidation LNH-84: methotrexate, 3 g/m^2 during weeks 1 and 3; ifosfamide, 1,500 mg/m^2, and etoposide, 300 mg/m^2, during weeks 5 and 7; asparaginase, 5,000 IU/m^2 during weeks 9 and 10; and cytarabine, 100 mg/m^2 for 4 days during weeks 11 and 13.
[f] EPOCH is given as infusional therapy over 96 hours.

transplantation. A number of prospective studies have established the feasibility of this approach and reported encouraging response rates. [94] [95] [96] [97] [98] [99] Several randomized prospective studies of high-dose chemotherapy have been recently completed. They are summarized in Table 70-7 .

In a large French study,[100] patients with poor prognostic features who achieved complete remission after four induction cycles of conventional chemotherapy were randomized to intensification or sequential chemotherapy. The 3-year disease-free survival rate was 52% (4559%) in the sequential chemotherapy arm and 59% (5266%) in the autologous bone marrow transplantation arm ($P = 0.46$). When the International Index was applied, approximately 50% of patients were found to be in a high-intermediate or high-risk category. For these patients, the 5-year disease-free survival rate was 39% after conventional chemotherapy, versus 59% for those in the autologous bone marrow transplantation arm ($P = 0.01$).[101]

Gianni et al. reported a comparison between MACOP-B and an innovative high-dose sequential chemotherapy program, supported by growth factors and autografting for patients with bulky or advanced stage diffuse large B-cell lymphoma but without bone marrow involvement. [102] They found an improved survival rate and disease-free survival rate in patients who received high-dose chemotherapy.

Martelli et al. randomized 49 patients whose response to front-line treatment was only a partial remission to receive either DHAP chemotherapy or high-dose chemotherapy and autologous stem cell transplantation. [103] The complete response rate was significantly higher for patients who received high-dose chemotherapy (96% vs. 59%, $P < 0.001$). The disease-free survival rate at 3 years was 73% in the autologous bone marrow transplantation group versus 52% in the DHAP group (P = NS). The difference was not statistically significant because of the small numbers of patients randomized.

In a Dutch study, [104] patients with stages IIIV lymphoma who had a partial remission after three induction cycles of CHOP chemotherapy, but no bone marrow involvement, were randomized to either three additional cycles of CHOP or to autologous bone marrow transplantation after conditioning with cyclophosphamide and total body irradiation. Sixty-nine patients were randomized, 34 to autologous bone marrow transplantation, 35 to CHOP chemotherapy. In this study no benefit in either survival rate or disease-free survival rate could be shown for autologous bone marrow transplantation. Because neither a biopsy nor a gallium scan was required at the time of randomization, it is likely that many of the so-labeled partial responses were actually complete responses with residual fibrotic masses.

These data and others[97] [98] [105] suggest that high-dose chemotherapy improves the outcome of younger patients with NHL and some adverse prognostic features, such as bulky disease, by approximately 1020%. In the absence of a study protocol, consolidation with high-dose chemotherapy appears justified in younger patients with adverse prognostic features. It should be acknowledged, however, that the studies on which such recommendations are based used rather stringent selection criteria. These criteria often included good performance status, young age, and absence of bone marrow involvement. The subset of patients with the most adverse prognostic features was therefore almost certainly excluded from such studies. Improved supportive care and blood stem cell support have dramatically decreased the morbidity and mortality of high-dose chemotherapy, and it is now possible to evaluate this technology in less selected and older patients. Whether any benefit will be achieved in such patients remains to be demonstrated.

Radiation Therapy in the Treatment of Large Cell Lymphoma

Radiation treatment was the first effective treatment approach for NHL and was also the first approach to be studied systematically. [106] Response rates correlate with the dose of radiation and are optimal with doses of at least 40 Gy. At these doses, response rates of up to 80% are observed, and some of the responses, especially among patients with localized disease, are durable. [107] Currently, the use of radiation therapy as a sole treatment modality in aggressive lymphoma has been abandoned because of the high recurrence rates both in and outside the radiation field; however, in nonbulky limited-stage disease, the most effective approach is that of combining three or four cycles of chemotherapy with localized radiation. [91] [92] [93] [550]

In some studies, radiation to bulky tumor masses has also been used as consolidation treatment after chemotherapy in patients with widespread disease. This practice is based on the observation of frequent recurrence in sites of bulky disease but has never been evaluated in a randomized study. Only one randomized study, reported in abstract form, has evaluated the use of adjuvant radiation therapy in patients with bulky stage I and stage II disease. [108] All patients were treated with eight cycles of CHOP. Those who achieved a complete response were then randomized to receive or not to receive 3,000 cGy of radiation to areas of previously involved disease. With a median follow-up of 6 years, the disease-free survival was 58% for those receiving CHOP, versus 73% for those receiving CHOP plus radiation ($P < 0.04$). The overall survival rate was 70% versus 84% ($P = 0.06$).

Treatment of Older Patients with Aggressive Non-Hodgkin Lymphoma

Half of the patients with aggressive lymphoma are >60 years old. There are specific challenges in treating these older patients. The mainstay of treatment has been the CHOP regimen. The outcome of CHOP chemotherapy is worse with increasing age, in part because of decreased tolerance, a high frequency of intercurrent infections, and perhaps differences in disease biology and a higher incidence of tumor resistance. Because of concerns over toxicity, a number of alternative regimens have been designed with an intent to reduce toxicity. In general they incorporate either no anthracyclines, or different or reduced doses of these agents. [109] [110] [111] However, four prospective randomized studies specifically designed for older patients clearly indicate that anthracyclines are an essential component for the treatment of NHL in the elderly, and that not all anthracyclines are equivalent in their activity. Bastion et al. reported the results of a French randomized study of chemotherapy for patients over the age of 68 with aggressive NHL.[41] The median age was 75. Patients were randomly assigned to cyclophosphamide, 750 mg/m^2 , teniposide, 75 mg/m^2 , and prednisone, 40 mg/m^2 , for 5 days (CVP), or to the same regimen with added pirarubicin, an anthracycline derivative (CTVP). Two hundred twenty patients received CVP and 233 received CTVP. The complete remission rate and progression-free survival rate were significantly better with the CTVP regimen. The 5-year survival rate was 26% with CTVP versus 19% with CVP ($P < 0.05$). The treatment-related mortality was 13% overall. This treatment-related mortality was higher than would be expected in a younger age group, but there were no significant differences in treatment-related mortality between the treatment groups.

Sonneveld et al. compared, in patients older than 59, CHOP chemotherapy with CNOP, in which doxorubicin, 50 mg/m^2, was replaced with mitoxantrone (Novantrone), 10 mg/m^2.[109] The complete remission rate, survival rate, and disease-free survival rate were significantly better with CHOP chemotherapy, indicating that mitoxantrone in the doses used in this study is less effective than doxorubicin for the treatment of NHL. The severity of toxicity was similar in both arms of the study.

In a cooperative study from the European Organization for the Research and Treatment of Cancer (EORTC), patients aged 70 years and older were randomized to receive six cycles of CHOP or six cycles of a regimen consisting of etoposide, prednimustine, and mitoxantrone (VMP).[112] Sixty patients in each arm were assessable for response. Response rates and complete remission rates were higher for patients receiving CHOP. The number of treatment-related deaths in both treatment groups was comparable. At 2 years the progression-free survival rate was 25% with VMP versus 55% with CHOP ($P = 0.002$). The overall survival rate was 30% with VMP versus 65% with CHOP ($P = 0.004$). Finally, in a small prospective study from Canada, weekly one-third-dose chop was not

found to be less toxic than full-dose CHOP and was possibly less effective.[113]

These studies and a number of smaller studies indicate that despite lower response rates than in younger patient populations, a significant proportion of older patients derive prolonged benefit from anthracycline-based chemotherapy. In a report from the Cancer Center of British Columbia, Vancouver, 80% of older patients were in good enough condition to receive chemotherapy and derive benefit from it.[114] By far the major reason for mortality in older patients with aggressive NHL is disease progression. Reducing the intensity of chemotherapy regimens does not have a major effect on toxicity but does reduce efficacy. Hence, more effective regimens, rather than attenuated regimens, need to be explored. In this regard, the use of growth factor support may allow further dose intensification, which may conceivably result in higher remission rates and longer durations of remission. Such a strategy will need to be explored in prospective trials. Other new approaches include the use of shortened, 8-week treatment regimens that have been well tolerated and result in response rates that are comparable to those obtained with CHOP,[109] [110] [114] or the use of new, potentially more effective drug combinations. In one study, the use of idarubicin-containing regimens in older patients was shown to result in higher response rates and reduced toxicity compared with doxorubicin-based regimens.[115]

For patients with limited disease, short courses of chemotherapy followed by radiation therapy to the involved field represent an attractive, nontoxic, and highly effective option.[91] [92] [93] [550] For patients with recurrent disease after conventional chemotherapy, options such as high-dose chemotherapy with stem cell transplantation have become possible with the availability of growth factors and the reduced risk associated with these treatments.[116]

Primary Mediastinal Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma is a subset of diffuse large cell lymphoma with a specific biology and age distribution. The disease usually affects patients in their 20s and 30s, and women are more frequently affected than men. Patients with primary mediastinal large B-cell lymphoma represent a fairly large percentage of the younger patients with diffuse large B-cell lymphoma. Patients present with large anterior mediastinal masses, often extending into the pulmonary parenchyma or associated with pleural effusions, or both.[117] [118] [119] [120] Initially the disease is often limited to the thorax or supraclavicular lymph nodes (Fig. 70-1). The differential diagnosis includes Hodgkin disease, lymphoblastic lymphoma, thymoma, and, in males, germ cell tumor. Disseminated disease is characterized by infiltration of parenchymal organs such as the liver and kidney and frequent CNS involvement. Spread to other lymph node areas, on the other hand, is uncommon. Histologically, a diffuse infiltrate of large lymphoid cells is present, often in a background of fibrosis. Immunophenotyping reveals a B-cell phenotype. Expression of CD21 and of surface immunoglobulins is absent. In contrast to other types of aggressive NHL, serum levels of $_2$-microglobulin are rarely elevated.[121] The International Prognostic Index is not very useful for predicting outcome in this disorder.[122] [123] Recognized adverse prognostic features are (1) extrathoracic disease, (2) a mediastinal mass >10 cm, (3) in some series, the presence of a pleural effusion, and (4) a partial response to initial treatment, as evidenced by residual gallium positivity or histologic evidence of residual disease.

The disease is usually treated with anthracycline-containing regimens followed by radiation therapy to the involved field.[122] [124] In most large series, the disease-free survival rate is approximately 50%. In some series an improved survival rate has been attributed to the use of third-generation regimens such as MACOP-B,[125] [126] or other more intensive treatment regimens.[123]

Figure 70-1 Primary mediastinal large B-cell lymphoma. **(A)** On CT, a large anterior mediastinal mass with necrosis is noted. This radiologic picture can be confused with Hodgkin disease, mediastinal germ cell tumor, or rarely thymoma. Lymphoblastic lymphoma is usually associated with a more symmetric mass. **(B)** Chest radiograph shows widening of the mediastinum with a large mass extending more to the left lung.

High-dose chemotherapy and autologous stem cell transplantation have also been used with good success as consolidation of initial response in this disorder.[99] Patients with recurrent or refractory primary mediastinal lymphoma have a relatively favorable outcome with autologous stem cell transplantation.[127] [128] Radiation treatment is ineffective if used as the only salvage treatment, even in cases with recurrences localized to the mediastinum.[122]

Treatment of Patients with Recurrent or Refractory Large Cell Lymphoma

Forty percent of patients with aggressive NHL fail to achieve remission with conventional chemotherapy, and half of those who achieve remission will relapse. Salvage chemotherapy regimens

TABLE 70-8 -- Non-Anthracycline-Containing Regimens Used in the Treatment of Large Cell Lymphoma

DHAP:[129]	Cisplatin, 100 mg/m^2 by IV continuous infusion over 24 hours on day 1
	Ara-C, 2g/m^2 IV q 12 hr × 2 doses on day 2
	Dexamethasone, 40 mg IV × 4 doses on days 14
	Repeat q 21 days
MIME:[132]	Methyl-gag, 500 mg/m^2 IV on days 1 and 14
	Ifosfamide, 1 g/m^2 /day IV on days 15
	Methotrexate, 30 mg/m^2 IV on day 3
	Etoposide, 100 mg/m^2 /day × 3 days
	Mesna
	Repeat q 21 days

MINE:[134]	Ifosfamide, 1.3 g/m^2 /day IV on days 13
	Mitoxantrone, 8 mg/m^2 IV on day 1
	Etoposide, 65 mg/m^2 IV on days 13
	Mesna
	Repeat q 21 days
ESHAP:[130]	Etoposide, 60 mg/m^2 /day IV on days 14
	Methylprednisolone, 500 mg/day IV on days 14
	Cisplatin, 25 mg/m^2 /day IV on days 14
	Ara-C, 2 g/m^2 IV on day 5
	Repeat q 21 days
CEPP(B):[558]	Cyclophosphamide, 600 mg/m^2 IV on days 1 and 8
	Etoposide, 70 mg/m^2 /day IV on days 13
	Procarbazine, 60 mg/m^2 PO on days 110
	Prednisone, 60 mg/m^2 PO on days 110
	(Bleomycin, 15 U/m^2 on days 1 and 15)
	Repeat q 21 days
LNH-84 Induction (see Table 70-5), followed by: LNH-84 consolidation:[100]	
	Methotrexate, 3 g/m^2 during weeks 1 and 3 (with leucovorin rescue)
	Ifosfamide, 1,500 mg/m^2 (with Mesna), and etoposide, 300 mg/m^2 IV during weeks 5 and 7
	Asparaginase, 5,000 IU/m^2 IV weeks 9 and 10
	Cytarabine, 100 mg/m^2 /day × 4 days during weeks 11 and 13
Hyper-CVAD, second[540] [549]	Methotrexate, 1 g/m^2 IV on day 1
	Cytarabine, 3 g/m^2 IV q 12 hr on days 2 and 3

are therefore of major importance. A number of consecutive trials of salvage chemotherapy, which were mainly based on the use of non-cross-resistant chemotherapeutic agents, have been reported (Table 70-8). The DHAP regimen resulted in response rates in 60% of patients. [129] Subsequently ESHAP was developed, which has a superior outcome but less toxicity. [130] [131] Regimens combining ifosfamide and etoposide with methyl-GAG (MIME) or with methotrexate (IMVP-16) are also active salvage regimens. [132] [133] Alternating an ifosfamide/etoposide regimen with a platinum/cytarabine regimen, as in the combination of MINE (Mesna-ifosfamide-etoposide-Novantrone) and ESHAP, appears superior to either regimen alone. [134] The M.D. Anderson regimens are designed for patients who have been previously exposed to anthracyclines. Others have utilized anthracycline-containing regimens with different infusion schedules, such as EPOCH. [135]

A number of newer salvage regimens utilize higher-dose chemotherapy with growth factor support. They include the high-dose ifosfamide/VP-16 regimen or regimens utilizing cyclophosphamide and carboplatin. [136] [137] These regimens result in somewhat higher response and complete remission rates and are often used at the same time for stem cell mobilization. At present it is unclear which, if any, of the commonly used salvage regimens is superior. In any case, patient characteristics such as age and performance status and disease characteristics such as stage, response to initial treatment, and duration of initial remission are more important determinants of response than the salvage chemotherapy regimen used. For patients with disease that is truly refractory to anthracycline-containing regimens (i.e., patients who fail to achieve a partial remission in response to initial treatment or those whose disease progresses during treatment), the rates of response to salvage regimens are low. [132] [138]

Patients with chemotherapy-sensitive recurrences, i.e., those whose disease is responsive to salvage chemotherapy, are usually offered consolidation with high-dose chemotherapy and autologous stem cell transplantation. [79] [139] [140] A randomized study (Parma study) has indicated that durable remissions can be obtained in 50% of such patients, which is significantly better than the rate of durable remissions obtained with conventional doses of DHAP chemotherapy. [141] The treatment options for patients with truly refractory disease are limited. With the possible exception of primary mediastinal B-cell lymphoma, autologous stem cell transplantation is often followed by rapid recurrence. The use of allogeneic transplantation in a subset of younger patients with HLA-compatible donors has been explored. [142] [143] [144] [145] It appears that durable remissions can be obtained in a substantial fraction of such patients and that treatment-related morbidity and mortality can be decreased by improvements in supportive care. The majority of patients, however, do not qualify for allogeneic transplantation because of age, performance status, or lack of a donor. They should be considered for investigational treatments. Paclitaxel is a drug with limited toxicity that can induce transient responses. [146] Nucleoside analogs such as fludarabine or 2-CDA have little or no effect on aggressive lymphomas. Interferon, commonly used for patients with indolent lymphoma, is used only rarely for those with aggressive lymphoma, mainly because of low response rates when it is used as a single agent.

Mantle Cell Lymphoma

Mantle cell lymphoma was first recognized as a separate entity in the Kiel classification. In Europe it was known as centrocytic lymphoma, and in the United States as lymphocytic lymphoma of intermediate differentiation or as mantle zone lymphoma. [147] The description of an association with t(11;14)(q13;q32) in a large percentage of these cases led to the recognition of mantle cell lymphoma as a unique biologic entity. [148] [149] [150] In the REAL classification the term mantle cell lymphoma was proposed, indicating the close relationship with the normal counterpart, the B cell of the mantle zone. [1]

The clinical features of mantle cell lymphoma have been described only recently. [147] [151] [152] [153] [154] [155] [156] The usual age of patients with mantle cell lymphoma is 5070 years. Patients often present with widespread disease; bone marrow involvement and peripheral blood involvement are common, but the lymphocyte count usually does not exceed 20,000/l. The spleen is often involved. Liver involvement occurs, and diffuse GI involvement is fairly typical for mantle cell lymphoma. Sometimes this form of lymphoma presents as multiple lymphomatous polyposis. Waldeyers ring involvement also occurs frequently.

MANAGEMENT OF RECURRENT OR REFRACTORY NHL

GENERAL PRINCIPLES

Management of the patient with relapsed NHL should begin with a repeat biopsy, which is meant not only to establish objectively the existence of a relapse but also to determine the disease histology. It is not uncommon for indolent NHL to relapse with a large cell lymphoma. On the other hand, the large cell lymphomas can also relapse with an indolent cell type, which most likely occurs because at diagnosis there might have been divergent histologic types present that could have gone undetected until a relapse occurred. [518]

Once the cell type is determined, a thorough staging evaluation is performed. This is necessary in order to determine the response to salvage therapy later on. The same tests are performed as in the initial staging of the disease. Cardiac function tests are important in determining whether anthracyclines can be used again and whether high-dose cyclophosphamide can be utilized. Laboratory tests such as serum creatinine determinations will also help to decide whether platinum can be used as part of the salvage regimen. Serum LDH and $_2$ -microglobulin levels can also be used as predictors of prognosis in the salvage setting. [134] The bone marrow biopsy, platelet count, and WBC count predict the patients tolerance of intensive therapy.

Management depends on various factors. In addition to the histologic type and extent of disease, these factors include the history of prior therapy, the quality of the response to front-line therapy, and the patients age, performance status, cardiac function, renal function, and bone marrow function. In general, salvage chemotherapy regimens for patients with disease relapse should include active agents that were not used in the front-line combination. However, patients with NHL that relapses more than a year after completion of frontline treatment can still respond to the same chemotherapy regimen. [518] Cytarabine/platinum-based combinations (e.g., ESHAP) are effective in patients with both indolent and aggressive NHL who have received initial CHOP therapy.

MANAGEMENT OF RECURRENT AGGRESSIVE AND HIGHLY AGGRESSIVE NHL

The easiest to manage category comprises younger patients who have received only limited treatment and have chemotherapy-sensitive disease. For cases in this category, an attempt at salvage with a conventional dose regimen such as ESHAP (etoposide, Solumedrol [methylprednisolone], high-dose Ana-C, and platinum), MINE (Mesna, ifosfamide, Novantrone [mitoxantrone], and etoposide), ICE, EPOCH,[130] [134] [135] or a variant of these has a reasonable chance of producing a second remission, especially if favorable prognostic factors are present, such as low LDH and $_2$ -microglobulin levels. Once a response has been achieved, the current consensus is to proceed with harvesting of either stem cells or bone marrow, followed quickly by high-dose chemotherapy with a regimen such as BEAM that includes BCNU, etoposide, Ara-C, and melphalan.[137] [141] The latter is preferred over BEAC (same regimen but with cyclophosphamide instead of melphalan) because it avoids exposure to high-dose cyclophosphamide, which is potentially cardiotoxic. [280] Stem cells can be harvested at the time of recovery from myelosuppression from the conventional dose regimen or after chemotherapy mobilization. We have used intermediate-dose ifosfamide and intermediate-dose etoposide plus G-CSF with great success to generate stem cells.[137] High-dose chemotherapy with autologous peripheral blood stem cell rescue can yield cure rates in the range of 3050% for those with disease sensitive to the conventional dose salvage regimen that pre- cedes the high-dose chemotherapy. [128] [137] [141] Some disease subsets, in particular primary mediastinal lymphoma, may be more sensitive to chemotherapy dose escalation. [127] [128] Those with disease that fails to respond to a conventional dose salvage regimen have experienced a poor outcome with high-dose chemotherapy regimens. [128] [139] Their management remains in the realm of clinical research. Allogeneic bone marrow transplantation might have a role in these cases because of the decreased recurrence rate associated with this procedure and a potential graft-versus-lymphoma effect. [142] [143] [144] [145] [519] [520]

Older patients who have received only one prior regimen and who do not have chemotherapy-refractory disease can usually be treated for salvage with a conventional dose regimen. DHAP is the most commonly used combination.[129] [131] ESHAP has been found to be less toxic and more effective in a series of sequential salvage regimens tested at the M.D. Anderson Cancer Center.[131] A newer regimen, MINE-ESHAP, has been the most active of all the salvage combinations tested at the M.D. Anderson Cancer Center.[134] It starts with MINE, which is consolidated with ESHAP. Mitoxantrone has moderate cardiotoxicity, especially in elderly patients who have received a significant amount of anthracyclines in the past. In addition, the ESHAP regimen is nephrotoxic. Candidates for this treatment should therefore undergo a cardiac scan and their kidney function should be reasonable (serum creatinine <2 mg/dl is a minimum requirement). Consolidation with high-dose chemotherapy should be considered in selected patients who are in good general condition. Given the improvements in supportive care, it can be used even in some patients in their early 70s.

The most difficult to treat are patients who have received extensive prior therapy and who have disease refractory to front-line therapy. Usually their response to salvage regimens is also poor, irrespective of the dose intensity. [133] [134] Such patients are seldom able to mount any type of significant response to salvage treatment, and consequently other novel treatment strategies are necessary.

Newer agents with moderate activity in recurrent aggressive NHL include paclitaxel (Taxol) [146] [521] and topotecan.[522] More recently, the monoclonal antibody rituximab, directed against the CD20 antigen, which is expressed in the vast majority of B-cell NHLs, has produced a 37% response rate as a single agent in relapsed large cell lymphoma.[523] In selected patients allogeneic transplantation may have a role, [142] [145] [519] [520] and autologous transplantation may have a role in some patients with primary mediastinal B-cell lymphoma.[127] [127]

MANAGEMENT OF RECURRENT INDOLENT LYMPHOMAS

Salvage therapies for relapsed indolent lymphoma span many options, including high-dose chemotherapy with autologous peripheral blood stem cell rescue, allogeneic bone marrow transplantation in young patients with a matched sibling donor, monoclonal antibody treatments, purine analog-based therapy, or other active chemotherapy regimens, including Ara-C and cisplatin combinations, as well as the watch-and-wait strategy.

Because of the indolent nature of these disorders and the wide disparity of available alternatives, selection of the best option becomes difficult. The patient, aided by the physician, must assume an active role in the decision-making process. In reaching this decision, two chief factors must be considered: the patients age and the expected survival if the

disease is managed with conventional dose therapy. The choice of a treatment alternative associated with a high mortality and morbidity, such as allogeneic bone marrow transplantation in a patient whose expected survival is long even when the disease is managed conservatively, has to be weighed against the potential for cure. Despite evidence suggesting a graft-versus-lymphoma effect, the potential for cure at this point remains to be proved. [143] [265] [266] [267] [268] [269] [270] The expected survival after relapse is a function of various prognostic factors. In one study, the median survival of patients with indolent lymphoma after a first or second relapse was 36 months, and after a third relapse it was 14 months.[524] Features associated with a short median survival after relapse were the presence of constitutional symptoms, a bulky tumor mass, more than two relapses, LDH >400 mg/ml (normal, 225 mg/ml), and hemoglobin <10 g/dl. Whenever one of these variables was present, the median survival was 28 months, and when two or more were present, it was 8.5 months. On the other hand, when none of these adverse features was present at relapse, the median survival still had not been reached at 6 years.

Management of Patients Less Than 65 Years Old

The most difficult decision in treating patients <65 years old is whether to proceed with an experimental and risky approach such as allogeneic bone marrow transplantation, should an HLA identical donor be available. Other alternatives include an aggressive approach such as high-dose chemotherapy with autologous peripheral blood stem cell rescue, conventional dose regimens (with higher-risk strategies for the future), or the watch-and-wait posture. The use of allogeneic bone marrow transplantation in recurrent indolent NHL is usually reserved for patients <55 years old because they better tolerate this treatment.

Whenever a donor is not available, the possibility of high-dose chemotherapy with autologous peripheral blood stem cell rescue has to be considered. This approach is experimental, because there are no solid data to prove that it prolongs survival or results in cures. Available data show that at 4 years, the failure-free survival of relapsed patients treated with high-dose chemotherapy is 45%. [257] [525] [526] Although this rate appears at first glance to be superior to the rate achieved with standard management, these studies did not control for patient selection. Further, there is no clear plateau in the failure-free survival curve to indicate a likelihood of cure in these cases. One of the major limitations of this strategy is the potential for transplanting tumor cells. Purging with antibodies directed against B-cell antigens can reduce this risk but is not always totally effective in removing malignant cells. [261] [264]

Whenever a donor is not available, the possibility of high-dose chemotherapy with autologous peripheral blood stem cell rescue has to be considered. This approach is experimental, because there are no solid data to prove that it prolongs survival or results in cures. Available data show that at 4 years, the failure-free survival of relapsed patients treated with high-dose chemotherapy is 45%. [257] [525] [526] Although this rate appears at first glance to be superior to the rate achieved with standard management, these studies did not control for patient selection. Further, there is no clear plateau in the failure-free survival curve to indicate a likelihood of cure in these cases. One of the major limitations of this strategy is the potential for transplanting tumor cells. Purging with antibodies directed against B-cell antigens can reduce this risk but is not always totally effective in removing malignant cells. [261] [264]

The use of conventional dose regimens includes anything from single-agent chemotherapy with drugs such as fludarabine to combinations such as the FMD (fludarabine, mitoxantrone, Decadron) regimen (Table 70-11), Ara-C/platinum combinations, or ifosfamide-based regimens, [130] [134] [235] [242] [527] [528] [529] all of which have significant activity but none of which has been demonstrated to be curative in recurrent indolent lymphomas. The new monoclonal anti-B-cell antibody rituximab has added another treatment option for these patients. [248] [249] [250] [251]

Patients More Than 65 Years Old

The choice of treatment for patients >65 years old is simpler because it only involves selecting among the different standard dose regimens available. The introduction of the therapeutic anti-CD20 monoclonal antibody rituximab is an important advance for this age group, whose tolerance of chemotherapy is frequently compromised by decreased bone marrow function. [251] The FMD combination has also been used sucessfully in all age groups and has shown a 94% response rate (Table 70-11). Future trials will likely involve the use of rituximab in combination with chemotherapy regimens.

Abnormalities in serum immunoglobulin levels (either hypo- or hypergammaglobulinemia) can be detected in a large percentage of the patients. Monoclonal gammopathy, mainly of the IgM type, was reported to occur in 25% of patients. [157]

Morphologically, the lymphoma cells are usually small cleaved cells with a pattern of differentiation that is intermediate between that of CLL and follicle center lymphomas. [1] [147] Blastoid and pleomorphic variants are recognized as well. [158] The growth pattern is either nodular, diffuse, or mantle zone. [151] [152] The experienced hematopathologist can often make the correct diagnosis by recognition of the typical cleaved cells in the blood smear or from the lymph node histology. [147] [159] The immunohistology reveals a typical CD5+, CD19+ phenotype like B-cell CLL, which is crucial for the diagnosis. The cells express sIgM and often sIgD. In contrast to CLL, they lack expression of CD23 and have more intense sIG and CD20 staining. Immunoglobulin gene rearrangement is consistently present. [1] [147] Although *bcl-1* rearrangements are present in at most two-thirds of cases, [160] [161] [162] [163] [164] overexpression of cyclin D1 (*PRAD* oncogene) and the presence of t(11;14) by fluorescence in situ hybridization (FISH) can often be demonstrated. [162] [165] [166] [167] Mutations in the *p53* oncogene have also been described in a subset of patients and are associated with a worse prognosis. [168] [169] [170]

The prognosis of mantle cell lymphoma is worse than that of CLL or follicular lymphoma, and in general the responses to chemotherapy are less durable than those achieved in other types of diffuse lymphoma. [151] [152] [153] [154] [155] The estimated 10-year survival in a recent series was only 8%. [153] One subset, the mantle zone variant (i.e., proliferation of disease limited to the mantle zone of the follicle) is characterized by an indolent behavior, a good response to conventional chemotherapy, and a prolonged survival. [147] [151] Bone marrow involvement is less common in this subtype than in the diffuse and nodular variants of mantle cell lymphoma. The diffuse and nodular variants respond poorly to conventional anthracycline-containing regimens and are associated with a median survival of 3 years. [151] Blastoid and pleomorphic variants as well as those with mutations of the *p53* gene have an even worse prognosis, [153] [168] [169] [170] and patients may be at high risk for CNS recurrence. [171] Treatment with platinum-containing regimens or fludarabine has also been disappointing. [147] [172] Recently the hyper-CVAD regimen (see box on management of very aggressive lymphoma) as originally proposed for the treatment of childhood ALL has been applied to the treatment of mantle cell lymphoma. This regimen has resulted in encouraging response rates of good duration. [173] Similar results have been reported with VAD plus chlorambucil by Gressin et al. [174] Preliminary results indicate that maintenance therapy with interferon may have a role in the treatment of this disorder. [172]

Many centers have recommended autologous or allogeneic transplantation as consolidation of remission. [147] [175] [176] Future follow-up is needed to clarify whether this tactic will result in improvement in long-term outcome. [172] A high recurrence rate was reported in one recent series. [177] [178]

Follicle Center Lymphoma, Grade I or II, and Small Lymphocytic Lymphoma

Several subtypes of indolent B-cell non-Hodgkin lymphomas are recognized. Their immunophenotypic, cytogenetic, and clinical characteristics are summarized in Table 70-9 . The majority of cases belong to the group of follicle center lymphomas and to the small lymphocytic lymphomas. [3] These entities were grouped in the Working Formulation as low-grade NHL. They are usually considered to have a similar prognosis and may benefit from the same treatments. Follicle center lymphoma grade I, as defined by the REAL classification, corresponds to follicular small cleaved cell lymphoma of the Working Formulation. Follicle center lymphoma grade II corresponds to follicular mixed cell lymphoma and to some cases of follicular large cleaved cell lymphoma. Follicle center lymphoma grade III corresponds to the majority of cases of follicular large cell lymphomas and has a more aggressive behavior. [179] [180] Usually there is at least partial follicular architecture in follicle center lymphomas, but diffuse areas may be present, and occasionally the entire biopsy specimen shows a diffuse pattern. This finding may connote a somewhat worse prognosis. The follicle center lymphomas are characterized by the presence of t(14;18), leading to rearrangement of the *bcl-2* oncogene in the majority of cases. Small lymphocytic lymphoma is a variant of chronic lymphocytic leukemia and has similar morphologic, immunophenotypic, and cytogenetic characteristics. It presents almost always with bone marrow involvement but has by definition no involvement of the peripheral blood. The treatment of indolent non-Hodgkin lymphomas is one of the more controversial

MANAGEMENT OF B-CELL INDOLENT NHL

As with any other NHL, management of the indolent forms should begin with a careful review of the biopsy slides by an experienced hematopathologist. The indolent NHLs include the cell types listed in Table 70-1 . Among these, the follicular types and the small lymphocytic lymphomas are the most common, but recently marginal zone lymphomas have been added to this group of disorders. They share the indolent behavior of the former, but their clinical presentation and management may be very different. This discussion addresses only the follicle center grade I and II lymphomas and small lymphocytic lymphomas.

The single most important factor in determining the management of an indolent NHL is the Ann Arbor disease stage. For this reason, thorough staging is critical. Of all the staging tests, the bone marrow biopsy is the most important because the skeleton is the most commonly involved extranodal organ in these disorders. For this reason, many investigators prefer to perform bilateral bone marrow biopsies. Once the Ann Arbor stage is determined, the patients can be divided into those with stage IV disease, which is the most common presentation, versus all others.

MANAGEMENT OF EARLY STAGES

Early-stage indolent NHL refers to Ann Arbor stages IIII presentations. Some investigators have traditionally managed the Ann Arbor stage III presentations the same way as the stage IV cases. There is enough information, however, to suggest that stage III presentations should be treated more like the early stage III cases because their prognosis is superior to that of the stage IV presentations; furthermore, in contrast to stage IV, there seems to be a potential for cure with standard therapy.

For patients with stage III disease we use COP-Bleo chemotherapy (cyclophosphamide, 100 mg/m^2 IV on day 1; vincristine, 2 mg IV on day 1; and prednisone, 100 mg PO daily × 5; plus bleomycin, 15 units IV). This regimen is administered for ten cycles. After the third cycle, radiation is administered to involved fields. In general, we use a dose of 45 Gy for the upper torso, 30 Gy for the lower torso and the abdominal sites. For patients with high-risk disease (high LDH levels, bulky disease, extranodal involvement) and for patients with small lymphocytic lymphomas, adriamycin, 50 mg/m^2 IV, is given with every cycle to a total dose of 450 mg/m^2 (CHOP-bleomycin). In patients >60 years old, no bleomycin is administered. [201]

For patients with stage III disease we use CHOP-bleomy- cin for eight cycles (adriamycin is capped at 400 mg/m^2), plus two courses of COP. Bleomycin is not given to patients >60 years old. After cycle 2, cycle 4, and, if needed, after cycle 6, radiation therapy is administered to all involved lymph node areas. [203] After radiation to the abdomen, doses of CHOP-bleo are reduced by 20%. This regimen has resulted in prolonged disease-free survival in 50% of patients.

MANAGEMENT OF ADVANCED DISEASE

The optimal management of patients with advanced disease (i.e., stage IV indolent lymphoma) is controversial. Treatment options range from watchful waiting to intensive chemotherapy and autologous bone marrow transplantation. No treatment option has been convincingly shown to improve survival, and the treatment options for specific patients are dictated by patient and physician preference or by investigational protocols. All treatment options are discussed in the text of this chapter. Here we detail the investigational approach that is pursued at the M.D. Anderson Cancer Center.

In an attempt to obtain durable remissions, an intensive chemotherapy regimen was designed that incorporates three different alternating non-cross-resistant regimens. The first combination, CHOP-bleomycin, is based on doxorubicin and cyclophosphamide. This is followed by an Ara-C-platinum-based regimen (ESHAP). The third combination, NOPP, consists of mitoxantrone, 10 mg/m^2 IV on day 1; oncovin, 2 mg IV on day 1; procarbazine, 100 mg/m^2 PO daily for 14 days; and prednisone, 100 mg PO daily for 5 days. This regimen is administered at approximately monthly intervals for a total of 12 cycles and is followed by maintenance treatment with interferon for 1 year. In a series of 138 patients treated with this regimen, approximately two-thirds achieved complete remission, and by PCR analysis, 13 of 19 patients achieved PCR-negative status in the blood. [516] PCR negativity had seldom been observed after CHOP-bleomycin therapy in stage IV follicular lymphoma, and achievement of PCR negativity may correlate with long-term failure-free survival. [517] Prolonged follow-up will be necessary to demonstrate any impact of this regimen on overall survival. More recently, we have compared this regimen in a randomized study with the fludarabine-mitoxantrone-dexamethasone regimen (FMD).[242] In a preliminary analysis, clinical and molecular response rates were equivalent with both regimens, but the toxicity of FMD was much less than that of ATT.[560] The FMD regimen currently constitutes our standard of care.

TABLE 70-9 -- Differential Diagnosis and Characteristics of Indolent B-Cell Lymphoma

Lymphoma	Peripheral Blood Involvement	Paraprotein	Bone Marrow Involvement	Lymph Node Involvement; Histology	Phenotype[c]	Typical Cytogenetic and Molecular Abnormalities
B-CLL/SLL	Common; WBC: 10,000200,000/mm^3	Rare	Common	Common; diffuse	SIG+, CIG±, **CD5**+, CD10, **CD23**+, CD43+	Trisomy 12 (30%)
Lymphoplasmacytoid lymphoma	Rare	IgM	Common	Common; diffuse	SIG+, **CIG**+, CD5, CD10, CD23, CD43±	NA
Mantle cell lymphoma	Common; WBC 10,00030,000/mm^3	Rare[b]	Common	Common; mantle zone, nodular, or diffuse	SIG+, CIG, **CD5**+, CD10±, **CD23**, CD43+	t(11;14), *bcl-1* rearrangement
Follicle center lymphoma	Rare	Rare	Common	Common; follicular, diffuse areas	SIG+, CIG, CD5, CD10±, CD23, CD43	t(14;18), *bcl-2* rearrangement
Monocytoid B-cell[a]	Rare	IgM or IGD similar to monocytoid B cell	Common	Common; diffuse, interfollicular, marginal zone, occasionally follicular colonization	SIG+, CIG±, CD5, CD10, CD23±, CD43±	Trisomy 3, trisomy 18, rearrangement 1q21 or 1p34
Splenic lymphoma with villous lymphocytes[a]	Common; WBC: 10,00025,000/mm^3 , villous lymphocytes	IgM or IGD similar to monocytoid B cell	Common	Unusual; for pattern, see monocytoid B-cell lymphoma

[a]Subtypes of marginal zone lymphoma.

issues in hematology. The controversy can be attributed to the rather prolonged natural history of this disease entity and the difficulties associated with demonstrating the impact on survival of most of the available treatment strategies.

Natural History

Patients with low-grade follicular lymphomas or small lymphocytic lymphomas typically present with widespread lymphadenopathy and bone marrow involvement in 75% of cases. The median age is 60, but there is a wide age range. [181] [182] [183] [184] Patients are often relatively asymptomatic at presentation and may come to medical attention because of a lump or because of vague complaints. Despite its rather benign clinical presentation, most patients affected by indolent lymphomas will die from the disease and not from other causes. There is a mortality rate of 8% per year associated with this disorder and the median survival is 9 years. [185] Disease transformation to a more aggressive histologic type is the most common terminal event. [186]

Differential Diagnosis

Follicular lymphomas should be differentiated from mantle cell lymphomas, especially from the nodular and mantle zone variants. Lymphocytic lymphoma may pose differential diagnostic confusion with other diffuse lymphomas of small cells, such as diffuse mantle cell lymphoma, marginal zone lymphoma, and immunocytoma. (Marginal zone lymphomas are discussed in detail later.) Immunocytoma in many cases represents Waldenström macroglobulinemia or is closely related to it. It is considered in more detail in Chapter 76 . Whenever a biopsy specimen reveals a diagnosis of immunocytoma, serum and urine electrophoresis are indicated. Even in the absence of a monoclonal spike, treatment similar to that for Waldenström disease should be considered. Low-grade lymphoma should also be differentiated from polyclonal lymphoproliferative disorders and from inflammatory and infectious conditions. Expert histopathologic analysis that includes immunophenotyping, cytogenetic analysis, and occasionally molecular analysis can be extremely helpful in the differential diagnosis of these disorders.

Treatment of Stages I and II Follicle Center Lymphomas

Approximately 20% of patients with follicle center lymphoma present with stage I or II disease. Such patients tend to survive longer than those with more advanced disease. They are frequently treated with radiation therapy to the involved field, and a considerable fraction obtain durable remissions. [184] [187] [188] [189] [190] [191] [192] [193] [194] In contrast to more advanced disease, the curability of these disorders is accepted and treatment is generally recommended.

The treatment alternatives for stage III presentations include radiation therapy alone and combined modality using chemotherapy and radiation. [195] Radiation, when used alone, has ranged from involved-field irradiation to treatment of more extensive fields, such as by total nodal or central lymphatic radiation techniques. [184] [187] [188] [189] [190] [191] [192] [193] [194] [196] [197] [198] [199] [200] The latter encompasses all lymph node-bearing areas, including the mesenteric nodes. No comparative trials have been conducted to determine which of these radiation therapy techniques is superior, but the published literature suggests that techniques that involve more extensive radiation fields are associated with a better failure-free survival rate. [196] The use of combined modality therapy with COP-bleomycin and radiation to involved fields (or CHOP-bleomycin and radiation to involved extranodal sites) has been associated with an outcome similar to that with total nodal radiation. [201] At this time it is not known whether radiation alone or combined modality management is superior because no prospective studies have compared these two modalities directly. Although long-term disease-free survival is attainable and there is a hint of a plateau in the failure-free survival curve with all of these modalities, not all investigators accept that such patients are truly cured because occasional relapses have been described even after 15 years.

Treatment of Stage III Disease

The published literature on stage III presentations is scarce. Most investigators have treated these patients in the same way as patients with stage IV disease and most of the available literature has combined the results of treating stage III disease with the results of treating stage IV disease, thus making it difficult to analyze the outcome. Three studies, however, have reported on them separately. [200] [202] [203] At Stanford University, 66 patients with stage III disease were treated with either total nodal irradiation or total body irradiation. [202] In addition, 13 patients were given CVP chemotherapy. At 10 years, 50% were alive and 40% were disease free. A study conducted at the University of Wisconsin included 29 patients with stage III disease who were treated by central lymphatic irradiation alone. [200] At 5 years, 61% of patients were free of disease. At the M.D. Anderson Cancer Center, with a combination of CHOP-bleomycin and radiation therapy to involved regions, approximately 55% of patients achieved a disease-free state beyond 5 years, with a plateau in the curve that suggests potential curability. [203] However, follow-up beyond 10 years will be necessary to prove that the patients treated in these studies were cured.

Treatment of Stage IV Disease

The treatment of stage IV indolent NHL is controversial. [204] Patients with stage IV disease represent the majority of patients with follicle center cell lymphomas and almost all patients with small lymphocytic lymphomas. Both disorders have a similar behavior and prognosis, and many studies have included patients with both types of histologies. Among the many treatment options available are watchful waiting, conventional chemotherapy, interferon treatment, intensive chemotherapy, high-dose chemotherapy with autologous or allogeneic transplantation, and a number of newer drugs.

Watchful Waiting

Watchful waiting as a treatment option is based on the disappointing results of several chemotherapy studies that used alkylating agents or combination chemotherapy with anthracyclines. Although respectable response rates and even complete remissions were observed, few if any responses were durable, and in comparison with historical control patients who were untreated, no improvement in survival was thought to have resulted. [204] [205] Many experienced physicians believe, therefore, that asymptomatic patients with low-grade lymphomas should not be treated at diagnosis, but rather that treatment should be withheld until symptoms develop. [204] [206] [207] Immediate treatment according to this paradigm may even be contraindicated as it may result in the selection of more resistant clones and disease transformation.

The data implying a lack of survival benefit from chemotherapy are based on retrospective analyses and comparison with historical control patients and should therefore be interpreted with caution. Two studies have prospectively compared watchful waiting and immediate intervention. Young et al. compared watchful waiting followed by ProMACE-MOPP chemotherapy when necessary at the time of progression with immediate treatment with ProMACE-MOPP at diagnosis. [208] In a preliminary analysis, median survival was similar in both treatment groups, but more patients remained free of disease in the arm treated aggressively (51% vs. 12%). These results have not yet been updated. Brice et al. [209] reported a French multicenter study in patients with low-tumor-burden follicular lymphoma. Patients were randomized between no initial treatment, prednimustine, or interferon-. With a median follow-up of 45 months, no difference in survival could be demonstrated between the three study groups. No combination chemotherapy arm was included in this series.

Other investigators believe that watchful waiting is appropriate

---

only for a selected subgroup of older patients with low tumor burden, and that most younger patients should be offered participation in research protocols to develop more effective treatments and identify prognostic features so that treatment can be directed more effectively toward those with the worst prognosis.

Conventional Chemotherapy

No convincing survival benefit has been shown for patients treated with conventional chemotherapy, and in general, only temporary remissions are anticipated. The most commonly used drugs include either chlorambucil given intermittently by mouth or the combination of cyclophosphamide, vincristine, and prednisone (CVP). In randomized studies, response rates were higher with CVP, but no improvement in survival could be demonstrated, perhaps because of the high salvage rate that can be achieved after relapse from single-agent therapy. [210] [211] [212] [213] The median duration of remission with CVP ranges from 1.53 years, but few remissions are durable. Anthracyclines have also been used but have not been shown to significantly increase complete remission rates, remission duration, or survival. [214] [215] On

the other hand, patients who will receive maintenance treatment with interferon may benefit more if they have received induction treatment with an anthracycline-containing regimen (discussed in the following sections).

Several groups have attempted to devise potentially curative approaches to the treatment of indolent NHL. One approach consists of the rapid cycling of non-cross-resistant chemotherapeutic agents, based on the Goldie-Coldman model. Others have utilized induction chemotherapy with CHOP followed by consolidation with high-dose cyclophosphamide and total body irradiation for patients with poor prognostic features. [216] These approaches do not have sufficient follow-up to allow an assessment of their validity and probably should not be recommended outside an investigational protocol.

Interferon

Interferon is a biologic agent that influences the proliferation of a number of hematologic malignancies and induces remissions in patients with low-grade NHL, especially in those with follicular lymphoma. [217] [218] [219] [220] [221] [222] [223] [224] [225] Interferon has been mainly used in combination with chemotherapy, either during the induction of remission or as maintenance treatment after remission has been achieved with alkylating agents (Table 70-10).

The use of interferon concurrently with chemotherapy in remission induction has been evaluated in four randomized studies. The two studies that used both anthracyclines and alkylating agents as induction treatment indicated an improvement in disease-free survival for the patients receiving interferon. In two studies an advantage in overall survival was also found for patients treated with interferon. [226] [227] [228] [551] In the two studies that used a chemotherapy regimen without anthracyclines, the effects of both induction and maintenance interferon were studied through double randomization. In a preliminary analysis of one study, the combination of induction and maintenance interferon with an alkylating agent for induction showed an advantage in progression-free survival over treatment with an alkylating agent alone. [229] In the second study, which is reported as not showing a benefit, the results have been analyzed only for the two induction arms but not for the maintenance interferon arms. [230] Furthermore, the interferon dose used in that study was lower than the standard doses. [230]

Three studies evaluated the use of interferon only as maintenance treatment for patients who had achieved a remission with chemotherapy. They all indicated an improvement in disease-free survival. [231] [232] [233] Interestingly, in one of these studies, the advantage for interferon maintenance was more pronounced if the remission had been induced with an anthracycline-containing regimen rather than with the CVP regimen. [231] No improvement in survival has been demonstrated in these three studies, in part because of limited follow-up. A recent update of the study by McLaughlin et al. [203] revealed that with longer follow-up, a survival advantage of borderline statistical significance has been achieved. [234]

The majority of the data indicate a significant role for interferon in the treatment of indolent lymphomas. When used concurrently with anthracycline-based chemotherapy, it has a role in remission induction and in maintenance treatment. When used in combination with anthracycline-containing chemotherapy regimens, it has a significant impact on survival. [542] [551] [552]

Nucleoside Analogs

Fludarabine and 2-CDA are nucleoside analogs with considerable activity in indolent lymphoid malignancies. Fludarabine was initially tested in CLL and 2-CDA was tested in hairy cell leukemia. Both agents have also been used in grade I and II follicle center lymphoma and in small lymphocytic lymphoma. [235] [242] A number of studies are summarized in Table 70-11 . Response rates of 4080% have been demonstrated with single-agent 2-CDA or fludarabine. Response rates may be somewhat higher in patients who have not received any prior treatment. Both agents have cumulative hematopoietic toxicity, which may result in mild but prolonged thrombocytopenia. This usually is of limited immediate clinical significance but may be important if consolidation with autologous transplantation is planned, as it may impair the ability to collect stem cells. Both agents are profoundly immunosuppressive and their use can be complicated by opportunistic infections, such as *Pneumocystis carinii* pneumonia, recurrent herpes, or occasionally fungal pneumonias.

Recently the combination of nucleoside analogs with other agents has been evaluated. The combination of fludarabine, mitoxantrone, and decadron was tested in a Phase II trial of 51 patients with recurrent indolent NHL. Twenty-four patients (47%) achieved a complete remission and 24 (47%) achieved a partial remission. [242] The median failure-free survival time for patients with complete remissions was 21 months. Opportunistic infections occurred in some of the initial patients but could be prevented with the prophylactic use of trimethoprim-sulfamethoxazole. Similarly, the combination of 2-CDA and mitoxantrone was tested in 23 patients with recurrent indolent NHL and resulted in complete responses in 22% and partial responses in 48%. [236] The median duration of a complete response was 15 months. 2-CDA has an advantage over fludarabine in that it can potentially be administered as an oral agent. On the other hand, combination chemotherapy with 2-CDA, mitoxantrone, and prednisone resulted in an unacceptable incidence of opportunistic infections. [236]

Monoclonal Antibody Treatments

A number of monoclonal antibodies have been raised against surface epitopes of NHL and have been used for therapy for NHL. [243] Different approaches have been followed, including (1) labeling antibodies with radioactive isotopes, (2) attachment of cell toxins (immunotoxins) to antibodies, and (3) the infusion of unlabeled (naked) antibodies, sometimes raised as anti-idiotypic antibodies against the patients NHL. [244] The dose-limiting toxicity of radiolabeled antibodies is myelosuppression,[245] whereas immunotoxins can cause hepatic toxicity and a vascular leak syndrome.[246] Some of the unconjugated antibodies (Campath-H1) are also myelosuppressive and can cause profound immunosuppression. [247] All monoclonal antibodies derived from mouse cell lines can give rise to the development of human anti-mouse antibodies (HAMA), which may prevent their repeated administration. [243] Many of these agents are still investigational, but promising results have been recently reported with four types of antibodies.

Idec-C2B8 (Rituximab) is a chimeric anti-CD20 therapeutic antibody. The CD20 antigen is expressed in 95% of B-cell lymphomas and thus has been chosen as the target for this molecule, which has an acceptable toxicity profile and induced responses in 50% of 166 patients with recurrent follicle center lymphoma with a median duration of 13 months. [a]One patient with T-cell PLL without prior treatment was included.

study, molecular remissions, i.e., the disappearance of polymerase chain reaction (PCR)-detectable *bcl-2* rearrangement in the bone marrow and blood, were noted in patients treated with Idec-C2B8.[248] This has not been observed after treatment with CHOP. The lack of significant myelosuppression and the short treatment schedule are other attractive features of this new agent. Its major side effects are fever, chills, and occasionally hypotension. These effects are mostly seen during the first dose. Eight cases of anaphylactoid reactions have been reported among more than 12,000 patients treated worldwide. Because the antibody is partially humanized, it does not significantly induce neutralizing antibodies. [252]

Iodine-131 anti-B1 is a nonhumanized mouse antibody that is labeled with radioactive iodine. Its main toxic effect is myelosuppression. It has been used in high doses with autologous stem cell support and also in lower doses that do not induce permanent myelosuppression. [253] In Phase I studies, durable remissions have been obtained in patients with indolent and more aggressive NHL. [253] [254] This drug is currently under investigation in a Phase II study.

Anti-CD52 (Campath-H1) has been mainly tested in Europe for the treatment of CLL and has resulted in a high incidence of responses, some of which are durable. [247] It is a humanized antibody and therefore does not cause the production of neutralizing antibodies. Its main side effect is profound immunosuppression. Reactivation of HSV and several cases of *P. carinii* pneumonia have occurred during treatment with this drug. Anti-idiotypic antibodies are antibodies directed against the idiotypic determinants of the surface immunoglobulin of the patients lymphoma. In most patients such antibodies can be induced by injection of a modified lymphoma immunoglobulin.[244] The generation of such antibodies leads to durable molecular remissions in patients with minimal disease. [553] While currently not applicable in large numbers of patients, these data are of considerable interest.

High-Dose Chemotherapy and Autologous or Allogeneic Transplantation

Patients with recurrent follicular lymphoma have a poor prognosis. The median survival after first recurrence is estimated to be 4.5 years for patients with follicle center cell lymphomas and decreases with successive recurrences. [255] Autologous transplantation has been used as salvage treatment for patients with chemosensitive recurrences of indolent NHL. [256] [257] [258] [259] The initial reports on autologous transplantation indicated a high incidence of durable responses. With increasing follow-up, higher recurrence rates have been documented, [260] as has a considerable risk for secondary myelodysplastic syndromes. [257] [261] [262] [263] Recurrences may in part be due to the reinfusion of occult lymphoma cells, and improved marrow purging techniques may lead to improved results. [264] Recently, allogeneic transplantation has been proposed for the treatment of patients with recurrent low-grade lymphoma. A number of reports indicate the potential for long-term disease-free survival. [145] [265] [266] [267] [268] [269] [270]

Disease Transformation

Disease transformation to a higher-grade malignancy is a common event in follicle center lymphoma. Clinically, transformation occurs in at least 2030% of patients with follicle center lymphoma. It is probably a much more frequent event that is underdiagnosed because biopsies are not always performed at the time of recurrence.[186] [271] [272] [273] [274] [275] [276] [277] [278] Disease transformation should always be suspected at the time of disease progression or recurrence, especially if the serum LDH level is elevated or in the face of rapidly enlarging lymph nodes, constitutional symptoms, or invasion of extranodal sites such as lung, pleura, CNS, or bone. Repeat biopsies should be done to establish the diagnosis and guide further treatment. The use of FNA has facilitated the diagnosis of transformation.

The median survival after disease transformation ranges from 7 to 22 months, but 20% of patients with disease transformation, mainly those with low tumor bulk, low LDH levels, or those who have not been exposed to combination regimens containing alkylating agents and anthracyclines, can achieve prolonged survival. [186] [279] Some patients with transformed disease have successfully undergone high-dose chemotherapy and autologous or allogeneic transplantation. [140] [280]

Marginal Zone Lymphoma

B-cell lymphomas of the mucosa-associated lymphoid tissue (MALT lymphomas), monocytoid B-cell lymphomas, splenic marginal zone lymphomas, and splenic lymphoma with villous lymphocytes are four independently recognized and described entities. However, their morphologic, immunophenotypic, cytogenetic, and molecular characteristics suggest that they are very closely related disorders occurring in different organs, [1] [281] and they have therefore been grouped under the name marginal zone lymphomas. Their normal counterpart is thought to be the marginal zone B cells that are located outside the mantle zone of the lymphoid follicle. This marginal zone is clearly seen in the spleen and in Peyers patches, but not in peripheral lymph nodes. Cells from the marginal zone have the capacity to differentiate into plasma cells and home to specific tissues.

Morphologically marginal zone lymphomas are characterized by a rather heterogeneous infiltrate of cells ranging from centrocytes to monocytoid B cells, small lymphocytes, and plasma cells. When localized in lymphoid tissue, they usually infiltrate the marginal zones. Occasionally there is colonization of the follicles. Extranodal marginal zone lymphomas are characterized by this same pleomorphic infiltrate as well as by the presence of lymphoepithelial lesions, the hallmark of MALT lymphomas. When peripheral blood involvement occurs, monocytoid cells predominate, but villous lymphocytes or cells indistinguishable from CLL can be observed.[282] [283]

Immunophenotypically these disorders are B-cell malignancies. CD5, CD22, CD23, and CD10 expression is absent (in contrast to what is seen in CLL), and 40% of cases express cytoplasmic immunoglobulin. A monoclonal serum IgM or IgD can occur in some cases with nodal and bone marrow involvement but is usually absent in cases of MALT lymphoma. The immunoglobulin genes are consistently rearranged, confirming the clonal nature of the disorder, even when the infiltrate is pleomorphic. No rearrangements of *bcl-1, bcl-2, bcl-6,* or c-*myc* have been consistently demonstrated.[1] Common cytogenetic abnormalities include trisomy 3 in two-thirds of cases, trisomy 18 in 40% of the cases, and structural changes involving 1q21 (in 40% of cases) or 1p34 (in 15% of cases). [281] [284] [285] [286] [287] Although these abnormalities are not pathognomonic for marginal zone lymphomas, they occur at a much higher frequency than in other lymphomas. There are differences in presentation and treatment among the different types of marginal zone lymphomas, as discussed in the following sections.

MALT Lymphomas

The extranodal presentation of marginal zone lymphoma is called MALT lymphoma. [288] [289] [290] [291] MALT lymphomas occur in many organs, including the stomach, small intestine, parotid, bronchial tissue, thyroid, and other nonmucosal organs such as skin, breast, liver, pancreas, and kidney. They are commonly associated with chronic inflammatory conditions such as Sjögren syndrome in the parotid, [292] Hashimoto thyroiditis, or *H. pylori* infection in the stomach.

Patients with MALT lymphomas typically present with indolent and localized, stage I or II disease and without systemic symptoms. In a recent study, the predicted 5- and 10-year survival rates were 87% and 75%, respectively. [289] The few patients with stage III or IV disease appear to have a more aggressive course, with a median survival of 3 years.[153] Also, MALT lymphoma of the thyroid has an unusually aggressive behavior.

Gastric MALT lymphoma is the most common presentation of MALT lymphoma. This entity is similar to what used to be called pseudolymphoma of the stomach. Typically patients are

diagnosed during endoscopy performed for vague abdominal discomfort.[293] The endoscopic findings are those of gastritis or ulcer; a mass is less common. Endoscopic US is very useful in better defining the extent of disease in the stomach and the response to treatment. [294] Although the disease rarely spreads to other organs, dissemination to other parts of the GI system can occur and has been shown to be due to the same tumor clone. [295] Gastric MALT lymphoma usually arises as a consequence of chronic stimulation of MALT by *H. pylori*.[296] [297] The treatment of *H. pylori* with antibiotics results in eradication of the bacteria and in regression of the lymphoma in the majority of patients with indolent MALT lymphoma.[298] [299] [300] The most popular antibiotic regimen is a metronidazole-amoxicillin combination plus omeprazole. A 2-week regimen is considered sufficient treatment to eradicate *H. pylori* and produce an antitumor response in most cases. Clarithromycin has been used mostly as a second-line treatment. Histologic regression of the lesions can take from 3 to 18 months to occur. Those with localized disease in whom antibiotic therapy fails may benefit from radiation therapy, which induces high response rates. [301] Antibiotic therapy has mainly been used in cases with flat mucosal lesions. Large tumor masses also respond well to antibiotics, but less frequently. It is unknown whether patients whose disease has spread to regional lymph nodes respond to antibiotic treatment. Those with more extensive disease can be treated with single-agent chlorambucil or, if this treatment fails, with CHOP or similar regimens. For nongastric MALT lymphomas single-agent chemotherapy or simple combination chemotherapy regimens such as the COP regimen have been used with good success.[291] Radiation therapy has also been used in selected cases. [289] [290] A response to antibiotic therapy has been reported in a case of parotid MALT lymphoma and leads to speculation that such treatment might be effective in some cases of non-GI MALT lymphoma.[302]

Monocytoid B-Cell Lymphoma

Monocytoid B-cell lymphoma is the lymph node form of marginal zone lymphoma. Considerable overlap exists between this disorder and MALT lymphoma, and part of

the difference between the two disorders is semantic. The median age for patients with monocytoid B-cell lymphoma is 60. There is a preponderance of females and an association with autoimmune disorders such as Sjögren syndrome. Patients usually present with stage II disease and involvement of peripheral lymph nodes. In many reported cases there has also been involvement of extranodal organs such as the parotid or stomach; therefore those cases could also be considered stage II MALT lymphoma. Bone marrow or peripheral blood involvement is rare.[283] Monoclonal gammopathies can occur.[303] [304] Patients with monocytoid B-cell lymphoma usually have indolent disease and no systemic symptoms, although disease transformation can occur. No prospective treatment studies have been reported in this disorder. Patients have responded to a variety of chemotherapy regimens. Based on the available information, treatment should be tailored to the individual patient, the disease characteristics, age, and performance status. As in follicular lymphomas, minimal therapy may be indicated for older patients and more aggressive approaches for younger patients

Splenic Marginal Zone Lymphoma and Splenic Lymphoma with Villous Lymphocytes

The third component of marginal zone lymphomas is splenic marginal zone lymphoma, which in most cases represents the same disease as splenic lymphoma with villous lymphocytes.[282] [305] [306] [307] This disorder occurs mainly in the elderly (median age, 70 years) and has a male preponderance. Patients typically present with massive splenomegaly. Bone marrow involvement and involvement of the peripheral blood by abnormal lymphocytes with irregular cytoplasm are almost always present. The white blood cell (WBC) count, however, rarely exceeds 30,000/l. Lymphadenopathy, if present, is not very striking. The majority of symptoms are related to splenomegaly and include abdominal discomfort and cytopenias. A small monoclonal spike is common. It is important to distinguish this disorder from hairy cell leukemia, CLL, prolymphocytic leukemia, Waldenström disease, and mantle cell lymphoma with peripheral blood involvement. The differential diagnosis is based on the clinical picture and on histopathologic studies, including immunophenotyping and cytogenetic assays.

Splenic marginal zone lymphoma is an indolent disorder with, in one series, 78% survival at 5 years, and only one-third of deaths due to lymphoma.[305] For symptomatic patients, splenectomy usually results in rapid improvement. For those unable to tolerate splenectomy, splenic irradiation has been used. Only one-third of the patients responded to single-agent chemotherapy such as chlorambucil. Other drugs such as interferon or nucleoside analogs have not been extensively tested.

PRESENTATION AND MANAGEMENT OF T-CELL AND NK CELL LYMPHOMAS

Lymphoblastic Lymphoma

T-cell NHLs are clonal proliferations corresponding to different stages of maturation of T cells. By definition, peripheral T-cell lymphoma corresponds to post-thymic stages of development. They lack terminal deoxynucleotidyl transferase (TdT), an enzyme important in T-cell receptor gene rearrangement. By contrast, T-lymphoblastic lymphoma corresponds to an intrathymic or prethymic stage of T-cell development and expresses TdT. [308] Young adults and children are the most commonly affected by T-lymphoblastic lymphoma and present with large mediastinal masses, commonly associated with bone marrow and peripheral blood involvement. As in Burkitt disease a rapid diagnosis is important and should, if possible, be based on the examination of bone marrow or peripheral blood, the latter examination to include immunophenotyping. As in other high-grade lymphoid malignancies, a lumbar puncture is essential. The disease is closely related to T-cell ALL and should be treated as such, even in the occasional case with isolated mediastinal involvement. [309] [310] [311] [312] An alternative treatment is the so-called Stanford regimen. This consists of a CHOP-like induction regimen in which the doses of anthracyclines are increased. [313] This induction treatment is followed by cranial irradiation, consolidation with further CHOP chemotherapy, and ALL-type maintenance treatment. A high incidence of CNS recurrence has been reported after treatment with this regimen.[314] (These issues are discussed in Chaps. 58 and 59 .) A recent randomized trial from Europe indicates an improvement in relapse-free survival for patients undergoing autologous transformation in first remission. [554] Follow-up in this trial, however, is very short. B-cell lymphoblastic lymphoma is an extremely rare entity that in many instances may represent either a blastic variant of mantle cell lymphoma or an extramedullary presentation of common ALL. [308] Its treatment is not well defined, but it has a poor prognosis.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATL) is a T-cell malignancy caused by infection with the HTLV-1 virus. HTLV-1 infection is widespread in Japan and in some of the Caribbean islands such as Jamaica, and most affected patients live in these areas or originate from them. The estimated cumulative risk of development of ATL in an individual who has been exposed to HTLV-1 ranges between 0.5% and 7%. Another disorder associated with infection by HTLV-1 is tropical spastic paraparesis, a progressive encephalomyelitis involving the pyramidal tracts.

The usual clinical presentation of ATL is that of an acute disorder, with a leukemic picture characterized by peripheral blood involvement with lymphocytes with convoluted nuclei similar to those of Sézary cells. These cells are usually CD4+ and CD8. Skin involvement and lymph node involvement are common, as is hypercalcemia. The marrow is involved in 60% of cases. In addition to the acute form, three other subtypes are recognized. The smoldering form presents with predominantly skin and lymph node involvement. The peripheral blood usually contains small numbers of abnormal T cells. The chronic leukemia form is associated with increased abnormal lymphocytosis but minimal organ involvement. In the lymph node form, no or minimal blood or marrow involvement is present but the patients present with a lymphoma that is difficult to differentiate from other forms of T-cell lymphoma. [315] Patients with the smoldering type of ATL and some with the chronic leukemia type have a relatively good prognosis even without treatment, although transformation to the acute type can occur. The lymphoma and acute types, on the other hand, have a very poor long term outcome, with a median survival of only 9 months. The disease is very refractory to treatment. In 1995 Gill et al. reported responses in 10 of 19 patients with ATL with a combination of azidothymidine and IFN-. [316] Similar results have been reported from France. [317]

Peripheral T-Cell Lymphomas

Peripheral T-cell lymphomas originate from T cells that have completed thymic maturation and are TdT negative. Many different subtypes of T-cell lymphoma have been recognized, some of which are well characterized and require special treatment. Mycosis fungoides is discussed in Chapter 74 . T-cell CLL or prolymphocytic leukemia is discussed in Chapter 72 . Other well-defined categories include Ki-1-positive anaplastic large cell lymphoma, AILD-like T-cell lymphoma, intestinal T-cell lymphoma, and T-cell lymphoma. Each of these subtypes is briefly discussed below. The majority of patients with T-cell lymphoma cannot currently be categorized in any of these types and are designated in the REAL classification as having peripheral T-cell lymphoma, unspecified. [1] The classification of peripheral T-cell lymphomas is evolving rapidly. Angiocentric lymphomas, which used to be considered T-cell lymphomas, are now known to be of NK cell or of B-cell origin and are discussed in the next section. Lymphomatoid papulomatosis is a benign skin disorder with a propensity to evolve into T-cell lymphoma and is discussed in this section. The diagnosis of T-cell lymphoma depends on immunophenotyping, and the disease may be indistinguishable clinically from B-cell NHL. Nevertheless, a higher incidence of extranodal disease and constitutional symptoms and the fairly frequent occurrence of hemophagocytic syndrome are considered typical of T-cell NHL. Differentiation from HTLV-1related lymphoma can be difficult as well, and HTLV-1 serology should be considered in patients with peripheral T-cell lymphoma.

Peripheral T-Cell Lymphoma of Angioimmunoblastic Lymphoma Type

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is a T-cell malignancy with unique clinical and morphologic features. Patients present with lymphadenopathy, hepatosplenomegaly, skin rashes, profound systemic symptoms, hypergammaglobulinemia, and hemolytic anemia. [318] Many patients have a history of allergic reactions to drugs or prior viral infections. The constitutional symptoms often predominate, and other signs and symptoms such as lymphadenopathy or hemolytic anemia can have an intermittent course. The patients are often initially evaluated because of fever of unknown origin. The diagnosis depends on the demonstration of the typical histologic picture in the lymph nodes. Affected lymph nodes show an effaced architecture caused by a proliferation of small lymphoid cells and endothelial venules intermingled with variable proportions of B immunoblasts, plasma cells, and eosinophils embedded in a network of follicular dendritic cells. [318] Originally AILD was thought to be an autoimmune disorder, but cytogenetic and molecular studies have demonstrated its clonal nature, and currently the designation AILD-related T-cell lymphoma is commonly used.[319] Gene rearrangement studies have established the T-cell origin of the disorder in the majority of cases; occasionally immunoglobulin gene rearrangement, mixed T-cell and B-cell gene rearrangement, or even biclonality as indicated by T-cell receptor gene rearrangement studies has been observed. [320] [321] Some patients with AILD have been reported to ultimately develop B-cell immunoblastic lymphoma. [322] The development of Kaposi sarcoma has also been reported.

Untreated, the disease usually has a rapidly progressive course, but occasionally spontaneous remissions occur. Only one prospective study of the treatment of AILD has been reported.[323] Patients initially received prednisone. Those with life-threatening complications, recurrent disease, or refractory disease received the COPBLAM/IMVP-16 regimen. This is a second-generation anthracycline-containing chemotherapy regimen. Only eight of 28 patients receiving prednisone achieved complete remissions, and only three of these were durable. The complete remission rate in response to COPBLAM/IMVP-16 was 59% (17 of 29 patients treated). The probability of event-free survival at 36 months was 32%. There were no recurrences beyond 1 year after the initiation of treatment, indicating that the disease is curable in a percentage of patients. Because of the low rates of response to steroid therapy and the fact that a substantial number of patients deteriorated while receiving steroids, anthracycline-containing combination chemotherapy is recommended for all patients.

Enteropathy-Associated Intestinal T-Cell Lymphoma

Lymphomas of the small intestine, especially of the jejunum, are commonly of T-cell origin. Such cases represent 7% of all GI lymphomas. T-cell lymphomas often occur in patients with a history of gluten enteropathy or dermatitis herpetiformis, or both, and are therefore called enteropathy-associated T-cell lymphoma (EATCL).[324] Occasionally, patients without a history of prior GI disorders are diagnosed with T-cell lymphoma involving the small intestine, and some patients develop mild or atypical gluten enteropathy after the diagnosis of lymphoma has been made. The term EATCL-like NHL is used to classify such cases. [325] Patients with EATCL present usually in their fifth or sixth decade with worsening symptoms of diarrhea and malabsorption. Many also present with an acute abdominal event such as perforation or obstruction. The entire length of the jejunum may be affected and a mass may be present. A pleomorphic infiltrate of abnormal lymphocytes that have a clonally rearranged T-cell receptor and a variable degree of villous atrophy are present. [1] [325] The lymphoma often involves the abdominal lymph nodes but rarely spreads beyond the abdominal cavity. Systemic symptoms and elevations in LDH levels or other signs of systemic disease are uncommon. The much increased risk of NHL in patients with gluten enteropathy and the occasional observation of monoclonal T cells in the biopsy specimens of patients with otherwise straightforward gluten enteropathy have led to speculation that gluten enteropathy itself represents an indolent form of NHL. [326] [327]

No satisfactory treatment for EATCL exists. There is no response to the institution of a gluten-free diet, and curative surgery is often precluded by the extent of involvement. No prospective studies of chemotherapy are available, but in several retrospective series of intensive combination chemotherapy, the

prognosis was poor. Remissions are usually short, with the median survival <1 year from diagnosis, although occasional long-term survivors have been reported. [325] [328]

Ki-1-Positive Anaplastic Large Cell Lymphoma

In 1982, the presence of a new antigen expressed on Reed Sternberg cells of patients with Hodgkin disease was reported. The antigen was named Ki-1 (CD30 or Ber H2) and was later found to represent a membrane protein that belongs to the family of tumor necrosis factor (TNF) receptor molecules. [329] A number of cases of NHL with anaplastic features were found to display CD30 as well and have been identified as a specific disease entity, termed Ki-1-positive anaplastic large cell lymphoma.[330]

Clinically, three types are recognized, cutaneous Ki-1-positive anaplastic large cell lymphoma, nodal Ki-1-positive anaplastic large cell lymphoma, and HIV-associated Ki-1-positive anaplastic NHL. [331] [332] [333] [334] [335] [336] Some cases of cutaneous involvement are secondary lymphomas occurring after a transformation from mycosis fungoides, lymphomatoid papulomatosis, or Hodgkin disease. The entity of anaplastic Ki-1-positive NHL in association with HIV infection [337] is discussed in the section on HIV-related NHL.

Patients with primary cutaneous disease usually present with localized or solitary nodules or tumors. Lymph node involvement can occur. The disease is fairly indolent, and spontaneous remissions occur in 25% of cases. [4] [331] Cutaneous Ki-1-positive anaplastic large cell lymphoma is only rarely associated with t(2;5) and probably represents a different biologic entity than the nodal form. The management of cases with isolated skin disease should include careful staging and observation to ascertain the behavior of the disease so that lymphomatoid papulosis can be ruled out. In selected cases, local surgery or radiation therapy, or both, may suffice.

The age distribution of nodal anaplastic Ki-1-positive NHL is bimodal, with a first peak in the second and third decades and a second peak after age 60. The majority of patients present with extensive and rapidly progressive disease. Extranodal involvement is fairly common and includes skin involvement (Plate 70-1).[338] Mediastinal masses can occur, but the incidence varies considerably among different studies. Most likely the majority of cases with mediastinal masses represent Hodgkin-related anaplastic large cell lymphoma and not classic anaplastic large cell lymphoma.

Morphologically, anaplastic large cell lymphoma is characterized by a pleomorphic infiltrate with a majority of anaplastic large cells. [1] [330] [332] [339] [340] [341] There is a predilection for involvement of the T-cell areas of the lymph node and of the lymph node sinuses. B-cell areas are commonly spared. Skin involvement is characterized by a nonepidermotropic infiltrate. In most series, the majority of cases have a cytotoxic (CD8) T-cell phenotype, but cases with a null cell phenotype are also common. In such cases distinguishing the entity from carcinoma, melanoma, sarcoma, or Hodgkin disease can be extremely difficult, as the tumor cells may lack expression of all lineage-specific markers. B-cell anaplastic large cell lymphomas with Ki-1 positivity also occur but are not currently recognized by the REAL classification as part of the Ki-1 anaplastic large cell entity. Translocation t(2;5) (p23;q35) is commonly detected in cases of nodal Ki-1 anaplastic large cell lymphoma.[341] This translocation leads to the production of an aberrant tyrosine-kinase resulting from the fusion of the ALK-kinase (anaplastic lymphoma kinase) on chromosome 2 and the *NMP* (nucleophosmin) gene on chromosome 5. The t(2;5) translocation is not found in cases of primary cutaneous anaplastic Ki-1 lymphoma or in Hodgkin disease. [342] [343] [344] [345] [346] [347] [348] [349] Interestingly, expression of the complete, nonrearranged ALK-kinase was reported in a newly recognized subtype of large B-cell lymphoma that does not carry t(2;5) and does not express CD30. [350]

Initial reports indicated a poor prognosis for Ki-1-positive anaplastic large cell lymphoma. Subsequent studies of treatment with intensive anthracycline-based combination chemotherapy have demonstrated that a high proportion of complete remissions can be obtained and that a large percentage of these remissions are durable. [332] [334] [335] [336] [340] In a recent French cooperative group study on the treatment of aggressive lymphoma, the subset of patients with anaplastic large cell lymphoma had a more favorable outcome than other patients.[338]

Lymphomatoid Papulomatosis

Lymphomatoid papulomatosis is a clinically benign, histologically malignant cutaneous lymphoproliferative disorder. [4] [351] In this entity the clinical picture overrides the microscopic appearance of the disorder. Patients typically present with multiple papular or nodular lesions of the skin in different stages of development. The disease has a chronic, recurrent course. Individual skin lesions appear and disappear within 36 weeks. Histologically there is a dermal infiltrate of malignant-appearing anaplastic cells expressing CD30, rendering the diagnostic distinction from anaplastic large cell lymphoma difficult. In other instances there is epidermotropism and infiltration by lymphoid cells with cerebriform nuclei akin to mycosis fungoides. Rearrangement of T-cell receptor genes can be demonstrated in most cases. The clinical criteria for the diagnosis of lymphomatoid papulomatosis are (1) the appearance of multiple small (0.52.0 cm) nodular or papular skin lesions, (2) spontaneous regression followed by recurrence, i.e., waxing and waning, and (3) no systemic or lymph node involvement. Management may consist of observation. If the cosmetic appearance is compromised, either PUVA therapy, topical chemotherapy, or low doses of methotrexate can be used. The initial response rate is high, but response is usually followed by recurrence. There is a very high cumulative risk for development of a secondary large cell lymphoma or Hodgkin disease (up to 80% in one series).[351]

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma is a newly recognized disorder. [352] [353] [354] It has been reported mainly in young males who present with aggressive lymphomas involving the liver and spleen. Rearrangement of the T-cell receptor has been demonstrated in these cases. Isochromosome 7q has been described as a specific cytogenetic finding. The cells in this disorder can be CD56 positive, and therefore hepatosplenic T-cell lymphoma should be considered in the differential diagnosis of NK cell leukemia/lymphoma. The disease has a rapidly progressive course, and no effective treatment is known. Several cases of nonhepatosplenic T-cell lymphoma have also been reported. [355] Affected patients present with involvement of skin or mucosal surfaces.

T-Cell Lymphoma, Unspecified

The majority of patients with T-cell lymphoma cannot be classified in any of the above described categories and are classified as having T-cell lymphoma, unspecified. This is a very heterogeneous group of malignancies, some indolent and others more aggressive. [1] [356] Patients with aggressive histologic types are usually treated in a fashion similar to patients with B-cell lymphoma; they more commonly present with extranodal disease and poor prognostic features, and their prognosis is generally somewhat worse than that of patients with aggressive B-cell lymphomas. [44] [76] [357] [358] [359] [360] [361] [362]

Because of the major differences in disease biology between B- and T-cell lymphomas, it is expected that new drugs will be

identified with specific activity in T-cell lymphomas. A number of drugs specific for mycosis fungoides have already been developed (see Chap. 74). Other drugs under evaluation include 2-CDA, retinoic acids, monoclonal antibodies, and Ara-G. 2-CDA has activity against mycosis fungoides, and in a pilot study was also effective in a small number of patients with other T-cell lymphomas.[363] Retinoic acids are differentiating agents. In a Phase I trial from Taiwan, responses were observed in six of 12 patients with T-cell NHL, versus none of six with B-cell NHL.[364] Campath-H1 (anti-CD52) is a humanized monoclonal antibody. It has activity in B-cell malignancies, but has also been tested in T-cell prolymphocytic leukemia. Major responses were observed in 11 of 15 patients.[365] Finally, compound 506U (Ara-G) is a 6-methoxy derivative of arabinosyl guanine that preferentially accumulates in immature T cells and is converted there to Ara-GTP. In a Phase I trial, responses were observed in 19 of 25 patients with T-cell ALL, in four of six patients with T-cell CLL and in eight of 12 patients with peripheral T-cell lymphomas. The response rate in patients with B-cell disorders was only 25%.[366]

Angiocentric Lymphomas

The term angiocentric immunoproliferative lesions was proposed in 1984 to encompass a spectrum of disorders characterized by angiocentric and angiodestructive lymphoid proliferation.[367] These disorders include lymphomatoid granulomatosis in the lung and sinonasal lymphoma in the facial area. Because of similar morphologic and immunophenotypic characteristics, these disorders were thought to represent closely related entities of T-cell origin. This appears not to be the case. Immunoglobulin gene rearrangements have been demonstrated in lymphomatoid granulomatosis, indicating its B-cell origin.[5] Sinonasal lymphoma, on the other hand, is currently thought to be an NK cell disorder.[368] Both lymphomatoid granulomatosis and sinonasal lymphoma are related to infection with EBV.[6] [369]

Patients with lymphomatoid granulomatosis typically present with diffuse pulmonary lesions.[370] [371] Secondary involvement of the skin or CNS is common. Lymphomatoid granulomatosis was originally described as an atypical reactive lymphoid infiltrate in the lung, associated with extensive necrosis and to be distinguished from Wegener granulomatosis. It rapidly became clear that lymphomatoid granulomatosis represented a form of lymphoma with a spectrum of histologic features. Various histologic grades are currently recognized.[371] Grade I is characterized by a polymorphous cellular infiltrate with an angiocentric and often angiodestructive character. Grade II lesions have the same polymorphic infiltrate but also have considerable cellular atypia, and grade III lesions are characterized by monomorphic vascular infiltrates of both large and small lymphoid cells. The lymphocytic infiltrate consists predominantly of mature T cells with a predominance of CD4+ cells, but the malignant cells are of B-cell origin, and the T cells represent merely an inflammatory infiltrate. In situ hybridization studies show EBV infection in the B cells.[5]

Historically, the disease had a poor prognosis, with a median survival of only 14 months.[370] Treatment with cyclophosphamide and steroids results in a high rate of remission, but also a high recurrence rate in patients with grade I histology.[371] Treatment with CHOP or similar regimens results in durable remissions in at least 50% of patients and is preferred by many investigators.[371] [372] [373] Recently, interferon treatment has been reported to be highly effective in a small number of patients, including some in whom chemotherapy had failed.[5]

Sinonasal lymphoma, previously known as lethal midline granuloma and polymorphic reticulosis, is an uncommon disorder in the West but is common in Asia and in the indigenous populations of Central and South America.[302] [369] [374] [375] [376] Patients present with destructive infiltrates of the nose and facial structures. The disease can spread in later stages to other nodal and extranodal sites. Owing to their proximity, the cranial nerves are commonly involved. Prospective studies of treatment are not available in this disorder. The prognosis for sinonasal lymphoma depends on the stage and extent of disease.[377] The treatment is discussed in the section on head and neck lymphomas.

Lymphomas of Large Granular Lymphocytes and Related Disorders

The syndrome of lymphocytosis with large granular lymphocytes (LGLs) was recognized more than a decade ago. Several closely related disorders of large granular lymphocytes, differing in phenotype and in biologic behavior, have since been recognized. New disease entities continue to be reported frequently, resulting in a confusing and still evolving classification.[6] [378] A list of currently recognized entities is given in Table 70-12 .

Immunophenotyping has played a major role in the recognition of these entities, which are either of T-cell or NK cell origin. Analysis of T-cell receptor gene rearrangement may be necessary to establish the diagnosis and to rule out inflammatory disorders. LGL morphology, although typical in some cases, is not always present and cannot constitute the sole basis for diagnosis in these disorders.[379] T-cell disorders usually express most of the pan-T-cell markers, namely, CD2, CD3, CD5, and CD7. They also often express either CD4 or CD8, or both. The NK cell marker CD56 is usually but not always absent. CD16, on the other hand, is commonly present. In cases with CD56 positivity, T-cell receptor gene rearrangement can establish the T-cell origin of the disorder.

NK cell malignancies by definition lack T-cell receptor gene rearrangement. They usually express the NK cell markers CD16 and CD56. They usually lack CD4 and CD8. They also lack the pan-T-cell markers CD3 and CD5 but express CD2 and CD7. Demonstration of clonality in these disorders can be difficult.

Chronic T-cell LGL leukemia (synonyms: chronic T-cell lymphocytosis with neutropenia, T8 chronic lymphocytic leukemia, granulated T-cell lymphocytosis, T-suppressor cell CLL, T-lymphocytosis, and lymphoproliferative disorder of T lymphocytes) is a disorder of T cells characterized by a moderate lymphocytosis (lymphocyte count is usually between 5×10^9 /L and 10×10^9 /L), often accompanied by profound neutropenia.[378] The median age at presentation is 60, and there is a slight male predominance. An indolent, asymptomatic form of this disorder may be fairly common.[379] Symptomatic patients often present initially with recurrent infections due to neutropenia and are often found to have a moderate lymphocytosis. But some patients with very low lymphocyte counts ($<2 \times 10^9$ L) may have demonstrable clonal T-cell populations and may be symptomatic as a result of neutropenia.[380] Moderate thrombocytopenia and anemia are common. Mild splenomegaly and hepatomegaly may be present. Lymphadenopathy is virtually always absent. There is a strong association with rheumatoid arthritis, and large granular lymphocytic leukemia may explain at least some of the cases that were formerly classified as Felty syndrome as well as some cases of cyclic neutropenia. Serologic abnormalities such as a positive rheumatoid factor assay, positive antineutrophil antibody (ANA) assay, and circulating immune complexes are demonstrated in at least half of patients. Hypergammaglobulinemia is frequent, and hypogammaglobulinemia has been noted in occasional patients. T-cell LGL leukemia should be differentiated from a number of viral infections, including acute infectious mononucleosis, acute CMV infection, and early HIV infection, all of which can be associated with lymphocytosis, and from disorders of NK cells.

The circulating lymphocytes often have abundant cytoplasm that contains azurophilic granules. The bone marrow is focally involved by an interstitial lymphoid infiltrate. Sinusoidal liver

TABLE 70-12 -- Classification and Treatment of NK Cell and NK-Cell-like T-Cell Disorders

Disease	Clinical Manifestations	Course	Cell Type	Phenotype[a]	EBV
Undifferentiated NK cell/myeloid leukemia[544]	Acute leukemia (MO or LBL), and extranodal disease	Aggressive	NK, myeloid precursor	**DR, CD33+, CD56+**, CD16, TCRr, TdT	
ALL of NK cell type[545]	Acute leukemia	Aggressive	NK cell precursor	**CD7+**, CD5, **CD2+, CD56±, TCRr**	?
Precursor NK cell leukemia[546]	Acute leukemia (M3 microgranular)	Aggressive	NK cell precursor	**DR, CD33+, CD56+**, CD16, TCRr+	
Aggressive NK cell leukemia[387] [388]	BM, PB, liver, spleen, skin	Aggressive	NK cell	CD13, CD33, CD7+, CD5, CD2+,**CD56+**, CD16±, **TCRr**	±

Aggressive TLGL leukemia/lymphoma[384]	BM,PB, liver, spleen, GI tract	Aggressive	Cytotoxic T cell	**CD3**+, CD5+, CD8+, **CD56**+, **TCRr**+	
Chronic TLGL leukemia/lymphoma[378]	Leukemia, neutropenia, rheumatoid arthritis	Indolent	Cytotoxic T cell	**CD3**+, CD5+, CD8+, **CD56, TCRr**+	
Nasal and nasal-type NK cell lymphoma[302] [369]	Extranodal tumors, sinonasal, skin and subcutis, GI tract, testis	Aggressive	NK cell	CD13, CD33, **CD7**+**, CD5**, CD2+, CD16±, TCRr	+
Lymphomatoid granulomatosis[5]	Lung, skin, brain, GI tract, kidney	Variable	B cell		+
Hepatosplenic T-cell lymphoma[352] [353] [354]	Liver, spleen, focal bone marrow	Aggressive	T cell	TCR+, CD56+	
Intestinal T-cell lymphoma[325]	GI tract	Aggressive	T cell	CD3+, CD56+	

Abbreviations: NK cell, natural killer cell; TLGL, T-cell large granular lymphocyte; BM, bone marrow; PB, peripheral blood; GI, gastrointestinal; TCR, T-cell receptor; TCRr, T-cell receptor gene rearrangement; TdT, terminal deoxynucleotidyl transferase; EBV, Epstein-Barr virus.

Modified from Jaffe,[6] with permission.

[a]The most relevant phenotypic characteristics are indicated in **bold**.

involvement and involvement of the splenic red pulp with sparing of the follicles and even follicular hyperplasia are typical. Immunophenotyping of the peripheral blood reveals usually a CD3+, CD8+, CD16+, CD56 phenotype, suggesting a cytotoxic/suppressor cell origin. T-cell receptor gene rearrangement is present. Rare cases have rearrangement of the T-cell receptor and are CD4, CD8+/. Occasional cases of TCR+, CD4+, CD8 LGL leukemia have been reported as well. Cytogenetic abnormalities have been demonstrated in some patients, but no specific karyotype has emerged. There may be an association with HTLV-1 or HTLV-2 in some cases.

The mechanism for the neutropenia associated with T-cell LGL leukemia is unclear. The marrow typically shows a maturation arrest of the myeloid series. Specific suppression of myelopoiesis by the LGLs, however, has not been demonstrated. Although ANAs are often present, their specificity is somewhat unclear. [378] The thrombocytopenia can be caused by the formation of autoantibodies. Pure red cell aplasia and Coombs-positive hemolytic anemia have also been reported.

T-cell LGL leukemia usually has an indolent but not altogether benign course. In one series, 20% of patients had died after 4 years of follow-up. [381] In other series, survival was better.[379] [382] Differences in prognosis may in part be attributed to inclusion of earlier and asymptomatic cases. The major causes of death are infections related to neutropenia and in some cases progressive lymphoproliferation. Hence, recurrent infections and progressive lymphoproliferation are the two major indications for treatment.

A variety of treatment approaches have been attempted for neutropenia.[378] Splenectomy has been used with variable success. Some patients have responded to granulocyte colony-stimulating factor (G-CSF). In patients with cyclic neutropenia, pulsed steroids have been useful. Low-dose oral methotrexate (520 mg/m ^{2} PO every week) was studied in ten patients. A complete response was achieved in five patients and a partial response in one. [383]

A rare, more aggressive variant of T-cell LGL leukemia has also been described. Patients presented with fever, marked hepatosplenomegaly, and mild lymphadenopathy. Lymphocytosis or bone marrow involvement was present in the majority of patients. The course was rapidly progressive, and five of six patients died within 26 months despite aggressive chemotherapy. Immunophenotyping in these cases revealed a T-cell phenotype with T-cell receptor gene rearrangement and expression of the T-cell receptor and of CD3. There was also aberrant expression of CD56, an NK cell marker, which according to the authors of this report indicated a more aggressive disorder.[384] Subsequently investigators from Japan have reported cases with a similar phenotype but an indolent clinical course. [385]

A disorder called chronic NK cell lymphocytosis shares many clinical features with T-cell LGL leukemia. [378] [386] It is less commonly associated with autoimmune disorders and has an indolent course. Patients typically present with lymphocytosis, usually with morphologic features of large granular lymphocytes. Immunophenotypically the cells are CD3, CD16+ and do not show T-cell receptor gene rearrangement. Clonality is often difficult to demonstrate in NK cell disorders as there is no NK cell receptor and no demonstrable gene rearrangement. Cytogenetic studies however, have demonstrated clonality in a minority of these patients. In others, the NK cell proliferation may be more inflammatory in nature.[378]

CD3, CD56+ LGL leukemias are clinically aggressive disorders of NK cell origin that occur in younger patients. [6] [387] [388] The median age in one series was 39 years. Patients present with fever, massive hepatosplenomegaly, and commonly jaundice. GI tract involvement and CNS involvement are also common. Blood, bone marrow, and other organs are involved by lymphomatous cells. The usual phenotype of these cells is CD3,

CD5, CD7+, CD16+, CD56+, CD8, CD4, suggesting an NK cell progenitor origin. The T-cell receptor is not rearranged. Clonality has been shown in several cases by the demonstration of karyotypic abnormalities. EBV infection of the malignant cells has been demonstrated in several Asian patients. This disorder has a rapidly progressive course, and most patients have died within a short period despite intensive treatment.

Composite, Discordant, and Hodgkin-Related Anaplastic Large Cell Lymphoma

The term *composite lymphoma* is used when two different but related lymphoma entities involve the same lymph node or organ. In many cases, one of the lymphomas represents a transformation of an indolent lymphoma to an aggressive type (such as follicular grade 1 small cleaved to B-cell large cell). However, a small number of cases of true composite lymphoma have been reported. In such cases, two presumably unrelated histologic types are detected in one single node (such as Hodgkin disease and large cell lymphoma).[389] [390] The treatment of such cases is usually dictated by the treatment of the most aggressive component.

More commonly one encounters cases of *discordant* (*divergent*) *lymphoma*, in which different subtypes of lymphoma involve different lymph nodes or extranodal sites. It is common to find involvement of the bone marrow with low-grade malignancy simultaneously with large cell lymphoma in the lymph nodes.[29] There is also an association between the occurrence of mycosis fungoides in the skin and Hodgkin disease in the lymph nodes in which both are derived from the same clone. [391] Other associations are those of B-cell NHL or, rarely, T-cell NHL after Hodgkin disease, [392] [393] of paraproteinemia in Sézary syndrome,[394] and of B-cell immunoblastic lymphoma after AILD. Possible pathogenetic mechanisms for such associations include (1) chronic immunostimulation by cytokines secreted by the original malignancy; this is thought to play a role in secondary lymphomas in AILD; (2) a common clonal origin for the different lymphoid disorders, as has been demonstrated in cases of Hodgkin disease associated with mycosis fungoides;[391] (3) chronic viral infection, which induces sequential neoplasms; [395] or (4) chemoradiotherapy-induced secondary malignancy.

Finally, a newly recognized entity, *Hodgkin-related anaplastic large cell lymphoma*, is an aggressive disease seen in young adults, who often present with large mediastinal masses. The tumor is composed of confluent sheets of lymphoma cells similar to anaplastic large cell lymphoma; but the architectural features, such as the presence of collagen bonds, resemble nodular sclerosing Hodgkin disease. In the newly proposed WHO classification, this entity would be called anaplastic large cell lymphoma-like Hodgkin disease in recognition of the fact that it most likely represents a histologic variant of Hodgkin disease. This disorder appears to have a poor prognosis when treated with regimens designed for Hodgkin disease. [396] [397]

CASTLEMAN DISEASE AND OTHER LYMPHOMA-LIKE DISORDERS

Occasionally, patients present with lymphadenopathy, skin lesions, or systemic symptoms suggestive of lymphoma but the biopsy is not conclusive. Such cases pose major diagnostic and therapeutic dilemmas. In a retrospective review of 172 such cases with prolonged follow-up, some form of malignancy, including lymphoma, myeloma, thymoma, and Castleman disease, developed in 43%. Other diagnoses included infections (EBV, toxoplasmosis, HIV) in 10% of cases, rheumatologic disorders (Sjögren syndrome, systemic lupus erythematosus) in 4%, and sarcoidosis in 6%. [398]

A number of disorders that are closely related to lymphoma may also pose differential diagnostic problems. They include Castleman disease, [399] [400] [401] true histiocytic lymphoma,[402] [403] and rare polyclonal or reactive disorders associated with lymphadenopathy. [404] [405] [406] [407] An awareness of these disorders is necessary in order to diagnose unusual cases and because some of these entities require specific management. In addition, the study of some cases that are related to mutations in the *fas* gene has provided important information on lymphocyte biology. [405]

Castleman disease consists of a massive growth of lymphoid tissue presenting either as localized or as multicentric disease. Histologic findings include follicular hyperplasia and marked capillary proliferation; in the plasma cell variant, there is a massive accumulation of polyclonal plasma cells in the interfollicular space. The localized form of the disease is usually asymptomatic and is found incidentally on chest radiographs as a mediastinal mass. Cases of abdominal localization have also been reported. Localized Castleman disease is a self-limited process; surgical resection is usually curative. [399]

The multicentric form of Castleman disease is much more aggressive. Patients present with widespread adenopathy or constitutional symptoms, or both. [408] Hepatic or splenic enlargement is present in the majority of cases. Infections, transformation to non-Hodgkin lymphoma, and the development of Kaposi sarcoma are common causes of death. Only limited information is available on the treatment of this disorder. Treatment with prolonged courses of high-dose steroids (e.g., prednisone, 12 mg/kg/day for several months) has been reported to result in durable remission. Other treatment strategies have consisted of the administration of combination chemotherapy regimens, which has resulted in favorable responses in many cases, [409] or of radiation to areas of bulky disease. Responses to interferon treatment have also been reported. Recently, Castleman disease has been shown to be related to infection with human herpesvirus 8 (HHV-8), the virus responsible for Kaposi sarcoma.[410] [411]

DIAGNOSIS AND MANAGEMENT OF LYMPHOMA INVOLVING EXTRANODAL SITES

Approximately 40% of all NHLs present in extranodal sites. The most common sites of extranodal involvement are the gut and the skin, but almost every organ can be affected by NHL. Some sites are associated with unique subtypes of NHL and require specific management. In other sites, various disease histologies can be found, and appropriate management requires an awareness and diagnosis of the exact disease subtype.

Differential Diagnosis and Management of GI Lymphomas

The GI tract is the most frequently involved extranodal localization in NHL. In order of frequency the following sites may be involved: stomach, ileum, jejunum, and, rarely, the colon. Factors predisposing to GI lymphoma are infection with *H. pylori* in MALT lymphoma of the stomach,[293] [296] and celiac disease in EATCL.[324] [325] [326] Both indolent lymphomas and aggressive lymphomas are encountered. A classification and a staging scheme have recently been proposed and are summarized in Tables 70-13 and 70-14 , which list most types of NHL that can occur in the GI tract.[412]

Lymphoma Involving the Small Intestine

In developed countries the differential diagnosis for small intestinal NHL includes MALT NHL, extranodal presentation of mantle cell lymphoma, EATCL, Burkitt disease, or extranodal manifestations of large cell lymphoma. Small intestinal MALT may require surgery for diagnosis and is usually treated by resection. Adjuvant chemotherapy is often administered.[289] The

TABLE 70-13 -- Histologic Classification of Gastrointestinal Non-Hodgkin Lymphomas

B-cell lymphomas
Lymphomas of mucosa-associated lymphoid tissue (MALT)
Low-grade B-cell lymphoma of MALT
High-grade B-cell lymphoma of MALT, with or without evidence of a low-grade component
Mediterranean lymphoma (immunoproliferative small intestinal disease), low grade, mixed, or high grade
Malignant lymphoma centrocytic (mantle cell or lymphomatous polyposis)
Burkitt-like lymphoma
Other types of low- or high-grade lymphoma corresponding to peripheral lymph node equivalents
T-cell lymphomas
Enteropathy-associated T-cell lymphoma
Other types not associated with enteropathy

management of mantle cell lymphoma is by aggressive combination chemotherapy and was discussed earlier. EATCL NHL is usually treated with aggressive chemotherapy but has a poor prognosis. Burkitt disease can currently be successfully treated with chemotherapy in many cases.

In developing countries, and especially in the Middle East, involvement of the small intestine by a special form of B-cell immunoproliferative disease, immunoproliferative small intestinal disease (IPSID), is common and may be related to chronic GI infection.[413] [414] [415] This disorder is virtually nonexistent in the West and is not included in the REAL classification. Usually persons in the second and third decades of life are affected. There is an association with low socioeconomic status. The disease is preceded by a reversible premalignant phase that is characterized by malabsorption and weight loss. In the blood or GI fluids, or both, a monoclonal protein can usually be detected that represents an aberrant heavy chain. The small intestine shows a lymphoplasmocytic infiltrate, usually with preserved villous architecture (in contrast to EATCL, where the villous architecture has often disappeared). Lymph nodes as well may have a plasmocytic infiltrate, but the lymph node architecture is usually preserved. At this stage the disease often responds to treatment with antibiotics (usually tetracycline). Commonly there is chronic GI infection, suggesting a possible infectious etiology for this disorder. In contrast to MALT lymphoma, a specific infectious etiology has not been demonstrated.

As the disease progresses, it invades the submucosa and may invade the entire intestinal wall and the mesenteric lymph nodes. Although the advanced stages might not respond as well, there have been occasional reports of response to antibiotic therapy. No prospective studies of chemotherapy have been performed in this disease, but patients are usually treated with

TABLE 70-14 -- Staging System for Gastrointestinal Non-Hodgkin Lymphomas

Stage	Description
I	Tumor confined to gastrointestinal tract without serosal penetration (one or multiple primary sites)
II1	Local (gastric, mesenteric) lymph node involvement
II2	Distant (para-aortic, caval) lymph node involvement
IIE	Penetration of serosa to involve adjacent organs or perforation/peritonitis
IV	Disseminated extranodal involvement or a gastrointestinal tract lesion with supradiaphragmatic nodal involvement

Reproduced from Rohatiner,[412] with permission from S. Karger AG, Basel.

combination chemotherapy (CHOP or similar regimens) and tetracyclines. Prolonged antibiotic therapy is continued after a remission has been achieved. Durable remissions can be obtained in a substantial fraction.

Gastric Lymphoma

In the stomach, the most common form of lymphoma is indolent MALT lymphoma, but aggressive lymphoma either due to transformation of MALT or as an extranodal manifestation of Burkitt disease or diffuse large cell lymphoma can also be encountered. The treatment of gastric lymphoma has evolved considerably recently. Low-grade MALT is now usually treated with antibiotic therapy, especially if the disease is localized. [293] The most popular regimens are a combination of clarithromycin, amoxicillin, and omeprazole or amoxicillin, metronidazole, and omeprazole. Currently, a 2-week regimen is considered sufficient treatment to eradicate *H. pylori* and produce an antitumor response in most cases. Improvement can be expected to occur soon after initiation of antibiotics but can continue for 612 months after the antibiotics are discontinued.

The treatment of localized gastric large cell lymphoma is more controversial. The treatment of choice used to be surgery, which served both diagnostic and therapeutic purposes. It was thought that surgery could prevent chemotherapy-induced complications such as fatal GI tract bleeding. Recent studies indicate that the combination of chemotherapy (CHOP or similar regimens) with or without radiation therapy, or in some instances radiation therapy alone, is equally efficient and less debilitating, and that the risk of perforation with chemotherapy is minimal. [416] [417] [418] [419] [420] Surgery is currently considered unnecessary in the majority of cases.

B-Cell Lymphomas of the Skin

The majority of primary skin lymphomas are of T-cell origin and include mycosis fungoides, Sézary syndrome, and large cell lymphoma (Ki-1 positive or negative). [4] These disorders are discussed in Chapter 74 . Several types of primary skin lymphoma of B-cell phenotype have also been recognized. In their presentation, biology, treatment, and outcome they are somewhat different from other B-cell lymphomas. The classification of primary skin lymphomas of B-cell type as proposed by the EORTC study group is shown in Table 70-15 .[4] The EORTC defined primary cutaneous lymphoma as any lymphoma that is limited to the skin and remains limited to the skin for at least 6 months after initial diagnosis. NHLs with any degree of extracutaneous involvement were excluded from consideration in this classification with the exception of mycosis fungoides and Sézary syndrome. This restrictive definition of primary skin lymphoma may have led to exclusion of a number of cases with a more aggressive clinical behavior.

Three major types of primary cutaneous B-cell lymphoma are recognized by the EORTC: (1) primary cutaneous follicle center cell lymphoma (PCFCCL), (2) marginal zone lymphoma of the skin, and (3) large B-cell lymphoma of the leg. Rarer subtypes include intravascular large B-cell lymphoma (also called malignant angioendotheliomatosis) and plasmocytoma of the leg.

TABLE 70-15 -- EORTC Classification of Primary Cutaneous B-Cell Lymphomas

Follicle center cell lymphoma
Immunocytoma (marginal zone B-cell lymphoma)
Large B-cell lymphoma of the leg
Intravascular large B-cell lymphoma
Plasmocytoma
Reprinted from Willemze et al.,[4] with permission.

Patients with PCFCCL present with localized plaques, papules, and tumors, often limited to the head and neck area or to the trunk. [4] [421] Untreated, the lesions enlarge, but dissemination to extracutaneous sites is uncommon. Histologically, a nodular or diffuse dermal infiltrate consisting of centrocytes and centroblasts is present. In contrast to mycosis fungoides, the epidermis is usually spared. Unlike nodal follicular center cell lymphomas, these NHLs do not have t(14;18) or rearrangements of *bcl-2.* Radiation therapy is the preferred mode of treatment. Only in rare cases with generalized skin lesions should chemotherapy be considered, but in those cases, CHOP chemotherapy is highly efficient. [421]

Marginal zone B-cell lymphomas (primary cutaneous immunocytomas) are considered extranodal marginal zone lymphomas or MALT lymphomas. Patients present with solitary or multiple, localized subcutaneous tumors that preferentially involve the extremities. Histologically a somewhat pleomorphic infiltrate is found that contains small lymphocytes, lymphoplasmocytoid cells, and plasma cells. In the central areas of the infiltrates variable numbers of T cells are intermixed. The lesions show clonal rearrangements of immunoglobulin genes, confirming their B-cell nature. Treatment usually consists of radiation therapy. The prognosis is excellent. [422] In one series the 5-year survival of 12 patients was 100%. [4] *Borrelia burgdorfferi*, the causative agent of Lyme disease, may play a role in the pathogenesis of some cases of PCFCCL and of primary cutaneous marginal zone lymphoma.[4] [422] In contrast to primary cutaneous immunocytomas, secondary cutaneous immunocytomas present with more widespread skin disease and paraproteins, and autoimmune disorders commonly coexist. Their prognosis is not as favorable as for primary cutaneous immunocytoma.

Large B-cell lymphoma of the leg typically affects older patients. Patients present with nodules or tumors on one or both legs. [423] Histologically there is a dermal infiltrate predominantly composed of large B-cells. Localized cases should be treated with CHOP chemotherapy followed by involved-field radiation therapy. [424] This is a more aggressive disorder than PCFCCL and marginal zone lymphoma. The estimated 5-year survival rate is 58%.

Although not included in the EORTC proposal, aggressive B-cell lymphoma can also be encountered in other skin areas (Plate 70-2). In a recent review of 54 patients with primary cutaneous lymphoma (excluding mycosis fungoides and Sézary syndrome), an aggressive histology was found in 50 patients. [424] Thirteen of 27 patients tested had a B-cell phenotype. The outcome of patients treated with anthracycline-based combination chemotherapy was significantly better than that of patients treated with radiation alone (10-year failure-free survival rate of 70% vs. 11%, $P < 0.0001$). On the other hand, the addition of radiation therapy to chemotherapy had no discernible impact on failure-free survival rates.

CNS Lymphoma

Three different entities of CNS lymphoma are recognized. The most common presentation is that of CNS lymphoma associated with AIDS (see Chap. 75). In the non-HIV setting, CNS disease can arise as a complication of systemic lymphoma (secondary CNS lymphoma) or as primary CNS lymphoma. CNS lymphoma should not be confused with extradural lymphoma, which, by compression, can cause CNS symptoms. The latter disorder has a good prognosis when treated with combined radiation therapy and chemotherapy. [425]

Secondary CNS lymphoma is commonly associated with high-grade NHL of Burkitt and lymphoblastic type, and intrathecal and systemic CNS prophylaxis is now usually part of the treatment for these disorders. In contrast, CNS involvement is extremely uncommon in follicular lymphomas or other indolent lymphomas. In aggressive lymphomas, CNS involvement occurs in approximately 5% of patients (Plate 70-3). [426] [427] Factors predictive of this complication include adverse prognostic features such as involvement of multiple extranodal sites and increased LDH levels. [426] Certain subtypes of lymphoma such as testicular lymphoma,[428] sinonasal lymphoma, [429] or aggressive variants of mantle cell lymphoma [171] may have a higher incidence of CNS recurrence than others. Routine CNS prophylaxis has been recommended in high-risk patients, but data on the efficacy of CNS prophylaxis are lacking. The few prospective studies on CNS prophylaxis have failed to demonstrate any survival benefit for patients so treated. [430] [431] The optimal approach to the prevention of CNS relapse of aggressive lymphoma remains difficult and may require a combination of intensive CNS-directed systemic chemotherapy and intrathecal prophylaxis. Secondary CNS lymphoma often occurs in association with, or is rapidly followed by, systemic recurrence and is usually rapidly fatal. In one study, only two of 23 patients with CNS recurrence survived beyond 1 year. [426] A small fraction of patients who respond to either radiation therapy or intrathecal treatment can successfully undergo consolidation treatment with high-dose chemotherapy. [432] [433] [434]

Primary CNS lymphoma is a diffuse infiltrative tumor that spreads along white matter neuronal tracks and through the CSF. [435] It typically affects patients between the ages of 40 and 60, who commonly present with symptoms related to intracranial hypertension, seizures, or generalized or focal neurologic deficits. A significant percentage of patients with primary CNS lymphoma have episodes of uveitis preceding the diagnosis of lymphoma for months to years. The diagnosis of primary CNS lymphoma should therefore be considered in any patient with steroid-resistant uveitis. Another commonly encountered presentation is that of a multiple sclerosis-like

illness, with exacerbations and (corticosteroid-induced) remissions. The radiologic appearance is that of a solitary tumor or multifocal lesions (Fig. 70-2). MRI indicates that many tumors are multifocal at diagnosis. There is a rapid and often complete disappearance of the tumor on CT after treatment with corticosteroids (ghost tumor). CSF abnormalities are common, although lymphoma cells can be demonstrated in the CNS in only one-fifth of cases. Like other brain tumors, the disease rarely spreads beyond the CNS. The classic management scheme consists of cranial radiation therapy. Typically 40 Gy is administered to the brain and the meninges with an additional 20 Gy boost to the tumor bed. Such treatment results in a median survival of at best a year, and a 2-year survival rate of at best 28%, with continued relapses beyond 2 years. [435] [436] [437] Most of the recurrences occur in the

Figure 70-2 Primary CNS lymphoma in a non-HIV-infected patient. Multifocal involvement is typical and occurs in at least one-third of cases.

tumor bed, indicating the limited efficacy of radiation therapy in this disorder. Based on the rates of response to systemic chemotherapy, [438] recent research has focused on the use of systemic chemotherapy prior to radiation therapy or sandwiched around the radiation treatment. Results from some studies have indicated improvement in disease-free survival, [440] while others have been more disappointing. [441] Prolonged remissions after combined chemoradiotherapy have been associated with a high incidence of debilitating encephalopathy, especially in older patients. [440] [548] Some investigators have, therefore, tested combinations of intravenous and intrathecal chemotherapy using agents with good penetration across the blood-brain barrier. [443] [561] Preliminary results of these treatment approaches without radiation are encouraging. Another interesting approach is that of blood-brain barrier disruption with the use of hyperosmolar solutions prior to chemotherapy. This has resulted in durable remissions and preservation of cognitive functioning, sometimes without radiation therapy. [442]

It is now generally accepted that chemotherapy has a role in the treatment of primary CNS lymphoma. The optimal chemotherapy regimen and schedule however, are far from agreed upon. The regimen should probably include drugs with activity across the blood-brain barrier, such as high-dose methotrexate and Ara-C. Other drugs such as cyclophosphamide, cisplatin, and vincristine have only limited penetration across the blood-brain barrier and may therefore have less of a role (although they have been used in some regimens).[435] [438] Primary CNS lymphoma is a relatively rare disorder that is difficult to treat. Ideally all patients should be enrolled in investigational treatment protocols.

Testicular Lymphoma

Testicular lymphoma is a disease of men in their 60s and 70s. It is the most common testicular tumor in that age group. [444] [445] [446] The majority of patients present with disseminated disease (i.e., stage III or IV disease). Most testicular lymphomas have a diffuse histology and an aggressive behavior. [447] The large majority of cases are of B-cell phenotype. This disorder has a high propensity to disseminate to other extramedullary sites, especially to the CNS.

A few patients are diagnosed with isolated testicular involvement, i.e., stage I disease. Simple orchiectomy is insufficient treatment for these patients. Current treatment recommendations include either contralateral orchiectomy or radiation treatment of the contralateral testis and a short course of doxorubicin-based chemotherapy (i.e., four cycles of CHOP). This results in durable remissions in >70% of such patients. [444] [448] [449] The role of pelvic and para-aortic radiation is unclear in this situation, as is that of CNS prophylaxis.

For stage III and IV disease, intensive chemotherapy and intrathecal CNS prophylaxis is recommended. Despite such treatment, only a small fraction of patients achieve durable long-term survival. [428] [444]

Orbital and Ocular Lymphoma

Orbital lymphoma affects the anterior compartment of the orbital cavitythe eyelids, lacrimal gland, and conjunctiva, or the retrobulbar space. [425] Most orbital lymphomas are of MALT origin and have an indolent behavior. A few are of follicular type. [450] [451] [452] The contralateral eye should always be examined carefully because bilateral diseases are common. The usual treatment consists of moderate doses of radiation (2535 Gy), which carries few risks of ocular complications. [425] [453] [454] The few patients with aggressive histologic types may need systemic chemotherapy. The prognosis is good, with an estimated 10-year survival rate of 6075%. Recurrences, if they occur, are systemic or in the contralateral eye.

Ocular lymphoma is a rare disorder that affects the orbital globe, usually the vitreous, retina, and choroid, and is frequently an expression of primary CNS lymphoma.[425] [455] [456] Spread to other parts of the CNS is common. The diagnosis of ocular lymphoma should be considered in patients with steroid-resistant chronic uveitis. Treatment involves bilateral ocular and whole brain radiation therapy, combined with intensive chemotherapy, usually including high-dose Ara-C. The prognosis is poor. As in primary CNS lymphoma, intensive chemotherapy regimens without radiation are being investigated. [561]

Lymphoma of the Thyroid

Lymphoma of the thyroid is usually of MALT origin.[452] [457] It manifests as a rapidly enlarging mass in older women with a history of Hashimoto thyroiditis. [425] [457] [458] In contrast to other types of MALT lymphoma, the majority of cases are aggressive lymphomas. Radiation therapy alone is insufficient treatment and results in a high rate of systemic recurrence, except in patients with small localized masses and provided that the mediastinum is included in the radiation field. [459] Chemotherapy alone has been complicated by a fairly high incidence of local recurrence. [425] [455] Recently excellent results have been reported with combined modality therapy consisting of CHOP-like chemotherapy and involved-field radiation therapy. [459] [460] Surgery is no longer recommended in the treatment of this disorder. [461]

Primary Lymphoma of the Bone

Primary lymphoma of the bone accounts for 5% of all extranodal NHLs.[425] Most patients have aggressive B-cell lymphomas. Historically, radiation treatment has resulted in durable remissions in 4045%. Currently, combined chemotherapy with CHOP-like regimens and radiation therapy is usually recommended and results in excellent long-term outcomes.[462] [463] Children with primary lymphoma of the bone are often treated with chemotherapy alone because of the adverse impact of radiation on growth and the risk of secondary tumors in the radiation field. [464] [465]

Primary Lymphoma of the Lung

Three types of lymphoma can affect the lung: diffuse large B-cell lymphoma, lymphomatoid granulomatosis, and indolent lymphoma of the BALT type (bronchus-associated lymphoid tissue), which is part of the spectrum of MALT lymphomas.[425] Diffuse large B-cell lymphoma should be treated as any other form of aggressive B-cell NHL with combination chemotherapy. Lymphomatoid granulomatosis should be treated with chemotherapy or with interferon and is discussed elsewhere. Like low-grade MALT lymphomas, BALT-type lymphomas are indolent disorders and are usually treated with single-agent or moderately aggressive combination chemotherapy regimens, or even with local radiation therapy. [289]

Primary Lymphoma of the Liver

Large cell lymphoma of the liver is commonly associated with chronic hepatitis C infection but can also occur outside this setting. [425] [466] It should be treated with combination chemotherapy similarly to other types of aggressive NHL. Its prognosis does not appear to be any worse than that of other large cell lymphomas. If liver function is severely affected, the anthracycline dose may have to be reduced. Patients with underlying hepatitis C do not appear to have a worse prognosis. [466] Primary hepatosplenic lymphoma is a recently described entity with a poor prognosis. [352] [353] [354] It was discussed earlier in the section on T-cell NHL.

Lymphoma of the Head and Neck Area

Lymphomas of the head and neck area present special diagnostic and therapeutic difficulties. [425] One should differentiate between NHL of the tonsils or Waldeyers ring, NHL arising in the parotid, NHL of the oral cavity, NHL of the paranasal sinuses, and NHL of the nose. NHLs of tonsil or Waldeyers ring should be considered nodal lymphomas and their treatment should follow the guidelines discussed for each histologic subtype. One peculiarity of these disorders is their frequent spread to the GI tract. A GI workup should therefore be part of the staging workup of these disorders.

Parotid lymphomas are commonly of the MALT type. These are indolent disorders that are found in 14% of cases of parotidectomy. [467] [468] They often arise from the intraparotid lymph nodes rather than from the parotid itself. Many cases are associated with Sjögren syndrome or hepatitis C. [292] [469] Surprisingly, a high incidence of t(14;18), as in follicle center lymphomas, has been documented in these disorders. [470] Excellent survival has been reported after treatment with chemotherapy or radiation therapy, or both. [292] [471] Some cases of parotid lymphoma are of an aggressive histologic type. They are usually treated with doxorubicin-containing combination chemotherapy, often followed by involved-field radiation therapy. [471] Their outcome is predicted by the same prognostic features that apply in other patients with aggressive lymphomas. Patients with a low IPI score have a favorable outcome. Those with more advanced disease have a worse prognosis.

Lymphomas of the oral cavity are rare. They have a diffuse histology and behave aggressively. Their treatment should include combination chemotherapy and local radiation therapy. [425]

Lymphomas of the paranasal sinuses are usually aggressive. No cases of MALT lymphoma have been reported in this disease site. In the past the prognosis was poor, owing to CNS or systemic recurrence. [425] [472] Two recent series indicate that with combined modality treatmenti.e., combination chemotherapy (CHOP) followed by radiation therapyprolonged disease-free survival can be obtained in >50% of patients, and the risk of CNS recurrence can be minimized. [473] [474] As in other aggressive lymphomas, the IPI score is the most significant prognostic factor for patients treated in this fashion. [474]

Lymphoma of the nose or nasopharynx is much more common in Asian countries (Fig. 70-3). Many cases are so-called angiocentric lymphomas of NK cell origin and are associated with EBV infection. [369] [374] [375] Other cases are T-cell or B-cell lymphomas. In a retrospective study of primary nasal lymphoma in Hong Kong, patients with clinically limited disease were treated with radiation therapy or combined radiation therapy and chemotherapy and had an 50% disease-free survival at 5 years. [377] Those with stage III and IV disease were treated with conventional chemotherapy. Their 5-year disease-free survival rate was only 10%. In another series, reported from Mexico, chemotherapy alone for early-stage disease was associated with a poor outcome; combined modality therapy appeared indicated for all patients. [376]

In a series of 113 patients reported from Hong Kong, 45% had an NK-cell phenotype, 21% had a T-cell phenotype, and 34% had a B-cell immunophenotype. Different clinical behaviors and outcomes were associated with the different phenotypes. [302] Patients with NK cell and T-cell lymphoma were significantly younger (median age 53 and 54 years, vs. 64 years for B-cell lymphoma). Patients with NK cell and T-cell lymphoma more commonly had involvement of the nasal cavity and midfacial destructive disease at presentation, whereas B-cell lymphoma was often limited to the nasopharynx alone. Neck node involvement at presentation was more common in B-cell lymphoma. Patients were fairly uniformly treated with anthracycline-based combination chemotherapy followed by radiation therapy, except for a small percentage of patients with

Figure 70-3 Primary nasopharyngeal lymphoma with obstruction of the nasopharynx by tumor.

stage III disease who received radiation therapy alone. Regardless of stage, patients with NK cell neoplasms had the worst prognosis. In these patients there was a high frequency of local recurrence and of systemic dissemination to extranodal organs such as the skin and liver. Hemophagocytic syndrome occurred in four of 51 patients with NK cell lymphoma (vs. one of 62 with other histologic types). The 2-year failure-free survival rate of patients with NK cell lymphoma was 30%, whereas it was 52% for those with T-cell NHL and 41% for those with B-cell NHL ($P = 0.007$ in multivariate analysis).

LYMPHOMA RELATED TO INFECTION AND IMMUNOSUPPRESSION

AIDS-related lymphomas and lymphoproliferative disorders related to congenital immunodeficiency represent well-documented instances of malignancy related to a deficient immune system. They are discussed in Chapter 75 . A number of other lymphoproliferative disorders related to infection or immunodeficiency are discussed here, because their management or recognition may be of interest to the practicing oncologist.

Post-transplantation Lymphoproliferative Disorders

Post-transplantation lymphoproliferative disorders are well-known complications of solid organ or allogeneic bone marrow transplantation and can occur any time after transplantation. The large majority of cases are B-cell malignancies and are EBV

related.[475] [476] [479] Rare cases of B-cell lymphoma without detectable EBV have also been reported, as have a small number of cases of T-cell post-transplantation lymphoproliferative disorders.[476] [477] [478] The risk for post-transplantation lymphoproliferative disorders is related to the degree of immunosuppression; very high rates have been reported after the use of OKT-3 (an anti-T-cell antibody) in high doses for the prevention or treatment of rejection in solid organ recipients, [480] or after T-cell-depleted allogeneic bone marrow transplantation, especially when ATG is used for further immunosuppression. [481] [482] The incidence of post-transplantation lymphoproliferative disorder is also higher in pediatric transplant recipients than in adults, probably because many children have not been exposed to EBV and therefore have no immunologic memory against the virus.[483] Rarely, EBV-induced lymphoproliferation has been reported in non-transplant patients receiving maintenance chemotherapy for malignant hematologic disorders.[484]

In solid organ recipients, different types of post-transplantation lymphoproliferative disorder are recognized, corresponding to various degrees of EBV-driven lymphoproliferation.[475] The earliest lesions, called plasmocytic hyperplasia, commonly arise in the oropharynx and lymph nodes, are nearly always polyclonal, and usually contain evidence of multiple EBV infections or a minor population of cells infected by a single form of EBV. They lack oncogene alterations. The second type of lesions are called polymorphic B-cell hyperplasia. They are associated with post-transplantation lymphoproliferative disorders occurring within the first 6 months after transplantation and manifest as a polymorphic lymphoproliferation. They usually contain a single form of EBV, and also lack oncogene alterations. This disorder is associated with a poor prognosis. The third type of post-transplantation lymphoproliferative disorder usually occurs >6 months after transplantation, typically in the form of a monomorphic proliferation of diffuse large lymphoma cells or immunoblasts or occasionally as multiple myelomas. This type of lymphoma has alterations of one or more oncogenes in addition to EBV infection and has a better outcome. In most cases the lymphoma originates from recipient cells, but lymphomas of donor cell origin have also been demonstrated.

Clinically, post-transplantation lymphoproliferative disorder manifests in extranodal sites, including sometimes the transplanted organ. The disease presentations range from a slow-growing localized mass that can be surgically resected to rapidly proliferating and widespread disease, sometimes involving the CNS. [476] [477] [480] [483] [485] The treatment options for post-transplantation lymphoproliferative disorder include (1) a reduction in immunosuppression, (2) treatment with antivirals such as ganciclovir and acyclovir, (3) surgery, (4) treatment with monoclonal anti-B-cell antibodies, and (5) chemotherapy.

Reduction of immunosuppression can occasionally result in durable remission. [477] [485] [486] [487] It is most effective in the earliest phase of post-transplantation lymphoproliferative disorder (i.e., plasmocytic hyperplasia) but can also be effective in the other phases. The withdrawal of immunosuppression is associated with a considerable risk of graft rejection. Treatment with antivirals such as high-dose acyclovir or ganciclovir [487] [488] or with IFN- and intravenous immunoglobulins [489] occasionally results in a response in patients with post-transplantation lymphoproliferative disorder. Given the relative safety of antivirals, they are routinely combined with a reduction in immunosuppression as the first step in the treatment of post-transplantation lymphoproliferative disorder.

For patients in whom withdrawal of immunosuppression and provision of antiviral treatments are unsuccessful, surgery, chemotherapy, and monoclonal antibody treatments have been tried. A new treatment approach under investigation is the infusion of genetically modified virus-specific T lymphocytes. [490]

Surgery may result in durable remissions for occasional patients with localized disease. [491] The use of combination chemotherapy and especially the ProMACE-CBOM regimen has been prospectively tested in heart transplant patients with posttransplantation lymphoproliferative disorder. [485] ProMACECBOM was chosen because it contains a lower dose of anthracyclines and a higher and more prolonged dose of steroids than other treatments. It was therefore thought to be minimally cardiotoxic and sufficiently immunosuppressive, thus potentially reducing the risk of congestive heart failure and graft rejection. In three patients with early post-transplantation lymphoproliferative disorder (<6 months after transplantation) no durable responses were observed. Patients died from multi-organ failure or sepsis within days of institution of therapy. By contrast, among eight patients with post-transplantation lymphoproliferative disorder occurring more than 6 months after transplantation, complete remission was obtained in six and no recurrences were observed. The main toxicity of this regimen was moderate neutropenia. Two patients died in remission from infections. Cardiac toxicity was observed in four of seven evaluable patients.

The use of anti-B-cell monoclonal antibodies has been evaluated mainly in Europe. [477] [492] Durable responses were observed in six of eight patients with early post transplantation lymphoproliferative disorder and in two of two with late posttransplantation lymphoproliferative disorder. Toxic effects were minimal. Responses were not observed in two patients who received intrathecal monoclonal antibodies for post-transplantation lymphoproliferative disorder with CNS involvement.

Post-transplantation lymphoproliferative disorder occurring after bone marrow transplantation used to be a uniformly and rapidly fatal complication. [476] [482] Currently, the infusion of small numbers of immunocompetent donor lymphocytes can reverse the lymphoproliferation and rapidly and reliably results in durable remissions. [481]

Lymphoproliferative Disorders Associated with Rheumatoid Arthritis and Sjögren Syndrome

Autoimmune disorders and their treatment are associated with a certain degree of immunosuppression. It is therefore not surprising that some autoimmune disorders have been associated with an increased incidence of NHL. T-cell large granular lymphoma, closely associated with rheumatoid arthritis, was discussed in a previous section. Recently another form of NHL that is possibly EBV related was described in patients with rheumatoid arthritis who were treated with methotrexate. In a literature review, 37 patients were identified who had been treated for rheumatoid disorders with methotrexate and in whom a lymphoproliferative disorder developed.[493] Disease histology was available for 32 patients and was consistent with Hodgkin disease in five patients, diffuse large cell lymphoma in 17, high-grade lymphoma in three, and low-grade lymphoma in seven. Methotrexate withdrawal was evaluated in 16 patients, and responses occurred in nine. Fifteen of the lymphomas were tested for the presence of EBV genome and nine were positive. Responses to methotrexate withdrawal occurred in seven of nine EBV-positive patients but in only one of six EBV-negative patients. It therefore appears that at least in some cases, lymphoproliferative disorders associated with methotrexate-treated rheumatoid arthritis are caused by EBV. The immune systems surveillance for EBV is reduced in rheumatoid arthritis, resulting in a higher than

normal frequency of circulating EBV-positive B cells. [494] Treatment with methotrexate may allow the expansion of EBV-driven clones. Treatment approaches for patients with rheumatoid disorders and lymphoproliferative disorders should include consideration of methotrexate withdrawal in addition to more conventional methods of treatment.

In Sjögren syndrome, the prevalence of NHL may be as high

as 6.4 per 1,000 cases per year (up to 44 times the risk in the general population). [495] The large majority of cases are MALT lymphomas, sometimes presenting with disease transformation.[292] The histologic lesion of Sjögren syndrome is a benign lymphoepithelial lesion composed of a majority of CD4 T cells. A similar CD4 T-cell population may be present in the lacrimal glands, lungs, and kidneys of patients with Sjögren syndrome. It is hypothesized that chronic B-cell stimulation by T cells secreting a variety of cytokines leads to B-cell proliferation and ultimately transformation. Lymphoma related to Sjögren syndrome may be difficult to differentiate from the pathognomonic lymphoid infiltrate of Sjögren syndrome, and the diagnosis may be aided by demonstrating a B-cell immunophenotype. The use of PCR techniques to detect immunoglobulin gene rearrangement has also been tried but remains controversial, because immunoglobulin gene rearrangement can be detected in a large proportion of cases of Sjögren syndrome without evidence of lymphoma and may therefore represent a premalignant event. [496]

In a review of 16 NHLs occurring in patients with Sjögren syndrome, 13 were extranodal lymphomas.[292] Affected sites included the parotid (three cases), stomach (four), skin (three), buccal mucosa (one), and thymus (one). Twelve cases, including the three nodal cases, were classified as low-grade marginal zone lymphomas. Diffuse large cell lymphomas were seen in four cases but represented transformation from MALT in at least two cases. A viral etiology could not be demonstrated. Most patients were treated with chemotherapy. Those with marginal zone histologies responded well, and most had durable remissions. Disease transformation occurred in one patient and an unrelated aggressive T-cell lymphoma occurred in another.

Lymphoma Associated with Hepatitis C Virus Infection

Hepatitis C virus (HCV) is a single-stranded RNA virus that is responsible for most cases of transfusion-associated hepatitis. Shortly after its discovery it was found to be the causative agent of type II essential mixed cryoglobulinemia, a disorder considered to be lymphoproliferative in nature. [497] A high risk for NHL in HCV-positive patients has been demonstrated in a series of studies from Italy. [498] [499] [500] [501] More recently, similar associations have been reported in the United States. [466] [502] The large majority of HCV-associated cases are an indolent form of lymphoma, lymphoplasmacytoid lymphoma or immunocytoma. Some are aggressive lymphomas that transformed from immunocytoma. In all cases a cryoprecipitable IgM is present, and a majority of the patients also have essential mixed cryoglobulinemia. Many have evidence of liver disease or membranous glomerulonephritis (or both). In a series of 31 patients with essential mixed cryoglobulinemia and HCV infection, 38% sooner or later developed NHL, usually of an indolent type and commonly with bone marrow involvement. [499] An increased incidence of B-cell NHL has also been found in patients with HCV infection without evidence of essential mixed cryoglobulinemia. [466] [501] [502] Both large cell and indolent (usually marginal zone) lymphomas are found in such patients. There is a high incidence of primary extranodal lymphomas, and specifically a high incidence of lymphoma of the liver and salivary glands, two target organs for HCV infection.[466] [501]

It is unclear whether the pathogenetic role of HCV is limited to certain subtypes of HCV or whether all subtypes can be associated with NHL. The mechanism by which HCV may cause NHL is not completely defined either. The bulk of the evidence points, however, toward an indirect mechanism of chronic stimulation of B cells by nonlymphoid target cells infected by HCV. The presence of HCV proteins has been demonstrated in the residual parotid epithelium of a patient with parotid lymphoma and in a number of patients with hyperplastic reactive lymphadenopathy or low-grade lymphoma. [469] [503] In no case could the virus be demonstrated in the lymphoma cells.

Lymphoproliferative Disorders Associated with Other Infections

The virus most commonly associated with lymphoma is EBV. This virus was originally discovered because of its association with Burkitt lymphoma. [54] It is also associated with primary immunodeficiency-related lymphomas, Hodgkin disease, post-transplantation lymphoproliferative disorders, rheumatoid arthritis-related lymphomas, some cases of AIDS-related lymphoma, angiocentric lymphomas, lymphomatoid granulomatosis, aggressive NK cell lymphomas, AILD, and many other cases of T-cell lymphoma.[504] In all these cases it is thought that expression of the EBV genome leads to lymphoproliferation. EBV is much more commonly associated with endemic Burkitt lymphoma or intestinal NHL in developing countries than in the West, [505] perhaps as a result of exposure to EBV at a younger age in developing countries or of the immunosuppressive effects of chronic infections or malnourishment. In sporadic nonlymphoblastic T-cell lymphoma, the demonstration of an EBV genome in the malignant cells has been associated with an extremely poor prognosis. [506]

Other viruses are also implicated in the pathogenesis of lymphoproliferative disorders, among them HIV, HTLV-1, HTLV-2, the Kaposi sarcoma virus or HHV-8, and HHV-6. HIV is not directly implicated in lymphomagenesis but, by causing immunosuppression, it allows the proliferation of lymphomas, some of which are driven by EBV or HHV-8. HTLV-1 is the causative agent of adult T-cell leukemia/lymphoma, an aggressive disorder that is discussed elsewhere. In a study from China, HTLV-1 antibodies were found much more frequently in patients with T-cell lymphomas than in the control population. [507] Some cases of T-cell LGL lymphoma have also been associated with HTLV-1 or the related HTLV-2. [378] This indicates that the pathogenetic role of HTLV-1 in NHL may well extend beyond adult T-cell leukemia/lymphoma.

HHV-6 is a ubiquitous herpesvirus that is the cause of exanthema subitum in childhood. [508] Its reactivation causes pancytopenia and CNS infections in bone marrow transplant patients.[509] It has also been associated with some cases of Burkitt-like lymphoma.[510] Kaposi sarcoma virus, or HHV-8, is the causative agent of Kaposi sarcoma. It has recently been associated with a distinct type of lymphoma, primary effusion lymphoma.[511] These lymphomas present as effusions in the peritoneum or pleura without a distinguishable mass. The cells have a distinctive morphology bridging large cell and anaplastic large cell lymphoma. They express CD45, lack B-cell-associated antigen, and lack alterations of *bcl-2, bcl-6, ras*, or *p53*, but show immunoglobulin gene rearrangements. Usually this disorder is associated with HIV infection, but it has also been reported in HIV-negative patients. [512] In the majority of cases both EBV and the HHV-8 genome can be detected in the lymphoma cells. The prognosis of HHV-8-associated primary effusion lymphoma is poor. Most patients are in advanced stages of HIV infection and die within a year. HHV-8 is also the causative agent of some cases of Castleman disease,[410] [411] and it has been implicated in the pathogenesis of multiple myeloma.[513]

Bacteria have also been associated with the pathogenesis of NHL. *Helicobacter pylori* is thought to lead to MALT lymphoma of the stomach, and treatment with antibiotics can reverse the disease.[293] [297] *Borrelia burgdorfferi*, a spirochetal agent and the causative agent of Lyme disease, has been associated with some cases of primary cutaneous B-cell NHL.[423] An as yet unidentified pathogen may be causing immunoproliferative disease of the small intestine, a common disorder in developing countries that often responds to treatment with antibiotics.

Chapter 71 - Malignant Lymphomas in Childhood

John T. Sandlund Jr.

INTRODUCTION

Malignant lymphomas are the third most common malignancy among children and adolescents.[1] [2] [3] [4] [5] Among children <15 years of age, non-Hodgkin Lymphoma (NHL) is more frequent; however, in patients up to 18 years of age, Hodgkin disease is predominant. [6] NHLs in children are usually extranodal diffuse high-grade tumors, whereas low- and intermediate-grade nodal lymphomas predominate in adults. [7] These differences are speculated to reflect maturational changes in the function and composition of the immune system.[2] The different histologies explain in part the differing clinical features, disease course, and treatment strategies used in adults and children.

The differences in treatment approach and disease subtypes are less striking in adults and children with Hodgkin disease. [8] However, there are significant challenges in the management of children with Hodgkin disease. These primarily comprise the sequelae of therapy, such as radiation-induced bone growth abnormalities, endocrine dysfunction, and chemotherapy-related sterility. Of greater concern are the radiation- and chemotherapy-related second malignancies and late cardiac deaths. Current trials are examining ways to reduce the toxicity of therapy without compromising the excellent outcome generally achieved. These issues, as well as differences between children and adults, in the proportion of histologic subtypes are covered in Chapter 68 , which deals with the management of Hodgkin disease in adults.

EPIDEMIOLOGY

The incidence of NHL increases steadily throughout life, in contrast to Hodgkin disease, which has a bimodal age distribution with peaks in early and late adulthood. [2] From 1973 to 1991, the average annual incidence of NHL in the United States increased by almost 30%, [6] for reasons that remain unclear. NHL occurs two to three times more often in boys than in girls and is almost twice as common in whites as in African Americans. [2] [9] Specific populations at risk include those with acquired immunodeficiency syndrome (AIDS), those with congenital immunodeficiency syndromes (ataxia-telangiectasia, Wiskott-Aldrich syndrome, or X-linked lymphoproliferative syndrome), and those who have received immunosuppressive therapy (e.g., recipients of bone marrow or organ transplants). [2] [10] [11] [12] Deficient T-cell function probably contributes in part to this increased risk.

There are differences in both the incidence and proportion of histologic subtypes in different parts of the world. [1] [2] For example, the NHLs are very rare in Japan, whereas they account for approximately half of all childhood malignancies in equatorial Africa. Burkitt lymphoma is the predominant histologic subtype in equatorial Africa and northeast Brazil, [13] but comprises approximately one-third of cases in the United States and western Europe. In equatorial Africa, the region of high incidence of Burkitt lymphoma overlaps with the malaria belt. This observation prompted investigators to search for an infectious cause for this disease, leading to discovery of the association

Figure 71-1 Distribution of histologic subtypes of NHL in children and adults. *(From Sandlund et al., [6] with permission.)*

between Epstein-Barr virus (EBV) and this tumor. [2] Although no direct pathogenic role has been demonstrated for this virus, it has been speculated that as a B-cell mitogen, EBV increases the target pool of cells for transformation. An EBV nuclear antigen 1 (EBNA-1) variant has been found associated with the majority of EBV positive Burkitt lymphoma cases, suggesting that this mutation may provide a growth advantage to lymphoma cells by modifying EBNA-1 function in some way. [14] EBV is associated with 90% of African (endemic) Burkitt lymphoma cases, but with only 15% of cases in the United States (sporadic). [2] Disrupted and aberrant expression of the EBV genome has recently been identified in the host genome of sporadic Burkitt lymphoma cells that appeared to be EBV negative by conventional EBNA testing. [15] This finding, together with the 50% EBV-positive rate among Burkitt lymphoma cases in other parts of the world (including South America and Moscow, Russia) suggests that EBV has a widespread role in the pathogenesis of this malignancy. [13] [16] [17]

CLASSIFICATION

After Thomas Hodgkin described the disease bearing his name in 1832, various schemes emerged to classify the tumors now collectively referred to as the NHLs. In an attempt to reduce the confusion of multiple classification schemes, the National Cancer Institute (NCI) sponsored a workshop to design a single classification scheme for clinical usage. This scheme, now referred to as the NCI Working Formulation, divides the tumors into three grades (low, intermediate, and high) based on their clinical aggressiveness. [7] In contrast to the NHLs in adults, which are primarily low and intermediate grade, the NHLs in children are predominantly diffuse high-grade tumors (Fig. 71-1). The high-grade lymphomas comprise the small noncleaved cell (SNCC), lymphoblastic, and large cell subtypes (Plate 71-1 , panels AC). The clinical and biologic characteristics of NHL in children are summarized in Table 71-1 .

TABLE 71-1 -- Clinical and Biologic Characteristics of NHL in Children

Subtype[a]	Proportion of Cases (%)[b]	Phenotype	Primary Site	Translocation	Affected Genes[c]
Small noncleaved cell (Burkitt)	39	B cell	Abdomen or head and neck	t(8;14)(q24;q32) t(2;8)(p12;q24) t(8;22)(q24;q11)	IgHc-*MYC* Ig c-*MYC* Ig c-*MYC*
Lymphoblastic	28	T cell[d]	Mediastinum or head and neck	t(1;14)(p32;q11) t(11;14)(p13;q11) t(11;14)(p15;q11) t(10;14)(q24;q11) t(7;19)(q35;p13) t(8;14)(q24;q11) t(1;7)(p34;q34)	TCR *TAL1* TCR *RHOMB2* TCR *RHOMB1* TCR *HOX11* TCR *LYL1* TCR *MYC* TCR *LCK*
Large cell	26	B cell, T cell, indeterminate	Mediastinum, abdomen, head and neck, or skin	t(2;5)(p23;q35)	*NPM-ALK*

From Sandlund et al.,[66] with permission.

[a]The subtypes are classified according to the National Cancer Institutes working formulation.
[b]Proportion at St. Jude Childrens Research Hospital; other histotypes account for approximately 7%.
[c]Ig denotes immunoglobulin and TCR (T-cell receptor).
[d]B-cell progenitor variants have also been described.

Small Noncleaved Cell

The SNCC lymphomas have been subdivided into the Burkitt and non-Burkitt subtypes based on the respective absence or presence of heterogeneity in nuclear size. The clinical and biologic irrelevance of this morphologic distinction has led to widespread intechangeable use of the terms Burkitt lymphoma and SNCC lymphoma. [18] Heterogeneity in nuclear size may also blur the morphologic distinctions between the non-Burkitt and large cell subtypes. Burkitt lymphoma is a diffuse B-cell lymphoma expressing surface immunoglobulin (usually IgM, although IgA and IgG have been described), as well as other B-cell-associated antigens, including CD19 and CD20.[2] These lymphomas contain sheets of monomorphic lymphoid cells with basophilic cytoplasm and one or more prominent nucleoi. The starry sky appearance frequently associated with this tumor is caused by tingible body macrophages in the field.

Cytogenetically, Burkitt lymphomas are characterized by the presence of one of three reciprocal chromosomal translocations. [2] [19] [20] [21] The unifying feature in these translocations is the juxtaposition of the c-*myc* proto-oncogene on chromosome 8 with one of the three immunoglobulin genes, resulting in deregulation of the c-*myc* gene. The classical translocation, t(8;14)(q24;q32), which involves the heavy chain immunoglobulin locus, is identified in approximately 85% of cases. Each of two variant translocations, t(2;8)(p12;q24) and t(8;22)(q24;q11), involves one of the two light chain immunoglobulin loci; these account for the remaining 15% of cases.

Expression of the c-*myc* gene is associated with cell proliferation. For example, in normal B cells, mitogenic stimulation results in increased rates of c-*myc* transcription. The c-myc protein induces cell cycle progression from G_1 to S phase through the activation of various target genes. [22] This DNA-binding protein forms heterodimers with related proteins (e.g., MAX, MAD) that subsequently influence cell cycling. [23] [24] [25] [26] In Burkitt lymphoma, it has been speculated that the deregulated expression of c-*myc* results in an increased proportion of MYC-MAX complexes, leading to tumor cell proliferation. [27]

There are various theories about the pathogenic mechanism of c-*myc* deregulation in Burkitt lymphoma.[28] [29] [30] The invariable presence of mutations (truncations or point mutations) in the translocated c-*myc* gene has led to speculation that these mutations result in deregulated expression. The mutations may occur in either the regulatory or coding regions of the gene. For example, mutations in the myc-inhibitory factor binding sites in the first intron regulatory region negate the repressive effect of myc-inhibitory factor binding on transcription. [31] Gu et al.[29] have demonstrated that in cases that contain a coding region mutation in the amino terminal transactivation domain where p107 would normally bind and block transactivation, tumor cells are no longer responsive to p107-mediated functional suppression. Other hypotheses focus on the juxtaposition of c-*myc* to the immunoglobulin loci. It has been suggested that the immunoglobulin gene usurps control over the translocated c-*myc* gene, perhaps through long-range enhancer sequences. [28] [30] It is likely that multiple mechanisms deregulate c-*myc* in Burkitt lymphoma.

The apparent abrogation of the c-*myc* induction of apoptosis suggests that other factors besides deregulation of c-*myc* are involved in the pathogenesis of Burkitt lymphoma.[32] Data supporting this position have emerged from a transgenic mouse model in which insertion of a deregulated c-*myc* gene mimicking the abnormality in SNCC NHL results in the development of B-cell malignancies. [33] [34] The fact that these tumors are monoclonal and take 69 months to develop suggests that additional factors or molecular events are necessary for malignant transformation. The identity and potential role in pathogenesis of other oncogenes or tumor suppressor genes is currently under investigation. [32] [35]

Abnormalities in the p53 gene have been identified in cases of SNCC NHL and B-cell acute lymphoblastic leukemia (ALL). [36] [37] [38] The mutations in these tumors differ from those seen in solid tumors such as lung, breast, and colorectal carcinomas. Beyond the mere association of p53 with these tumors, observed regulatory interactions between c-*myc* and p53 have supported hypotheses regarding the role of p53 in pathogenesis. The frequency of mutations in primary tumor biopsies is

much lower than that reported in cell lines, which are usually established from cells obtained at relapse (33% vs. 70%, respectively). This suggests that p53 mutations in Burkitt lymphomas may be involved in disease progression, reminiscent of its hypothesized role in the progression of adenomas to adenocarcinomas. [37]

Lymphoblastic Lymphoma

The morphology of these tumor cells is similar to that of ALL. The lymphoblasts are small with round or convoluted nuclei, distinct nuclear membranes, inconspicuous nuclei, and a scant rim of basophilic cytoplasm. The vast majority (>95%) are of T-cell immunophenotype. A small percentage have a B-cell progenitor immunophenotype and are associated with cutaneous involvement. [39] [40] [41] [42]

Because of the similarities in cellular origin, immunophenotype, morphology, and clinical features, it is generally assumed that lymphoblastic lymphoma and T-cell leukemia are different presentations of the same disease process; however, this has yet to be proved. [43] Most theories regarding the pathogenesis of lymphoblastic lymphoma are based on studies of T-cell ALL. The reciprocal chromosomal translocations identified in T-cell leukemia and lymphoblastic lymphoma typically involve one of the T-cell receptor genes and result in deregulation of the reciprocal partner gene. [44] [45] [46] [47] [48] [49] [50] [51] [52] The reciprocal partner gene is often a transcription factor gene such as *TAL1,* which is not usually operative in T cells. [45] [46] [51] [52] In T-cell leukemia, a submicroscopic deletion of *TAL1* can be identified in up to 25% of cases, suggesting that this deletion may also be the most common molecular abnormality in lymphoblastic lymphoma. [51] Examples of other genes involved in translocations that have been described in these T-cell malignancies include the *HOX11* transcription factor gene and the *RHOMB* genes whose products are members of a family of proteins that contain a cysteine-rich (LIM) protein-protein interaction domain. [47] [49] [50]

Large Cell Lymphoma

The large cell lymphomas are a heterogeneous group of malignancies that vary in immunophenotype and histology. [53] [54] [55] Immunophenotypically, these lymphomas may be T cell, B cell, or non-B, non-T cell. When classified according to the NCI Working Formulation, the majority are high-grade large cell, immunoblastic, with a smaller percentage being intermediate-grade diffuse large cell. These two groups receive the same therapy with no significant difference in outcome. In the Kiel system, however, up to 50% of cases can be classified as having anaplastic features (abundant cytoplasm, atypical lobulated nuclei, and prominent nucleoli in sheets of adherent cells with sinusoidal involvment). [54] [55] [56] [57] These anaplastic large cell lymphomas appear to represent a unique clinicopathologic entity and are associated with CD30 expression (an activation antigen first identified on Reed-Sternberg cells), [58] the presence of the t(2;5)(p23;q35) translocation, [55] [57] [59] [60] a T-cell or non-T, non-B-cell immunophenotype, and extranodal disease sites (e.g., skin, bone, and soft tissue). Some studies have suggested better overall survival in this group of patients; however, it remains controversial. [61]

The t(2;5) chromosomal abnormality is present in approximately 50% of cases of pediatric large cell NHL. [60] In contrast to Burkitt and lymphoblastic lymphoma, in which the translocation results in deregulated expression of a transcription factor gene by its reciprocal partner gene, the t(2;5) results in fusion of the involved genes (the amino-terminal portion of the nucleophosmin gene, *NPM,* on chromosome 5 with the catalytic domain of the anaplastic lymphoma kinase gene, *ALK,* on chromosome 2) on the der(5) chromosome. [62] This results in a novel chimeric NPM-ALK protein product with properties unlike those of either component. [63] The cytoplasmic localization of this product may inappropriately phosphorylate subtrates involved in normal cell growth and differentiation. The molecular characterization of the t(2;5) has led to the development of a reverse transcriptase-polymerase chain reaction assay that enables the detection of NPM-ALK transcripts, even in patients with no detectable t(2;5) by standard cytogenetics. [64] This technology not only facilitates diagnosis and classification, but theoretically provides a tool for following minimal residual disease.

CLINICAL FEATURES

The clinical features at presentation vary with both primary site (Table 71-2) and extent of disease spread.[2] [9] [39] [65] [66] There is a striking difference in primary site between the SNCC and lymphoblastic histologic subtypes.[9] The primary site of SNCC NHL may be either abdomen or head and neck, but rarely the mediastinum. In contrast, lymphoblastic NHL may primarily involve the mediastinum or head and neck, but rarely the abdomen. Children with large cell NHL, on the other hand, may present with primary involvement of head and neck, abdomen, or mediastinum.[2] [9] The bone marrow may be involved at diagnosis in any of the histologic subtypes.[67] The central nervous system (CNS) may be involved at diagnosis in both the SNCC and lymphoblastic histotypes, but almost never in large cell NHL.[9] [53] [68]

Children who have a mediastinal mass may present with a spectrum of symptoms ranging from cough to severe respiratory distress caused by direct airway compressionthis condition may be worsened by an associated pleural effusion (Plate 71-1E). Mediastinal disease may also compress the superior vena cava, resulting in swelling of the neck and shoulder (superior vena cava syndrome).[2]

Primary involvement of the abdomen may be associated with nausea, vomiting, and abdominal pain. Abdominal lymphoma often arises from the distal ileum and may result in intestinal obstruction secondary to either intussusception or compression by an expanding mass encasing the bowel lumen (Plate 71-1D). These tumors may invade adjacent structures and be associated with ascites and other intra-abdominal sites of disease, including kidney, liver, and lymph nodes.[2]

TABLE 71-2 -- Distribution of Primary Sites of Tumor in Children and Adolescents with NHL

	St. Jude Childrens Research Hospital	The Hospital for Sick Children
No. of cases	338	102
Intra-abdominal	31%	40%
Mediastinal	26%	23%
Head and neck	29%[a]	11%[b]
Nodal	7%[c]	21%
Other[d]	7%	6%

From Murphy, [8] *with permission.*

[a] Includes Waldeyers ring and/or cervical lymph nodes.
[b] Includes only Waldeyers ring.
[c] Includes cases with primary nodal disease arising outside the head/neck region.
[d] Includes a variety of less common locations, including bone, skin, epidural space, thyroid.

Involvement of the bone marrow may result in pancytopenia with associated pallor and bruising. Involvement of the CNS may be associated with cranial nerve palsies or symptoms of increased intracranial pressure such as headache and vision changes. Cutaneous involvement may also occur and is usually associated with CD30+ anaplastic large cell lymphoma;[55] [61] however, lymphoblastic lymphoma (often non-T-cell immunophenotype) may also involve skin.[40] [41] [42] Bone involvement may be associated with pain or limping (Plate 71-1F).

LABORATORY EVALUATION

Initial laboratory evaluation should include a complete blood count with differentialthese may identify abnormalities in children with bone marrow involvement. A chemistry profile, which should include electrolytes, blood urea nitrogen, creatinine, lactic dehydrogenase (LDH), calcium, phosphorus, and uric acid is also important, particularly for children with bulky Burkitt lymphoma, who often present with metabolic abnormalities such as hyperuricemia. A screen for human immunodeficiency virus should be performed on all patients with newly diagnosed lymphoma. These individuals may be at increased risk for therapy-related toxicity, specifically, life-threatening infections. Serologic studies for EBV infection may be helpful in children in whom lymphoproliferative disease is highly suspected in the differential diagnosis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of NHL includes both benign and malignant conditions. If the blood counts are normal and there is no mediastinal mass, a single 1014-day trial of antibiotics for painless enlarged peripheral adenopathy is permissible to treat presumed bacterial adenitis. Other infectious causes for adenopathy simulating lymphoma include histoplasmosis, tuberculosis, and EBV infection, for which serologic and skin testing may be helpful. If the diagnosis of NHL is suspected, consultation with a pediatric oncologist is indicated.

The diagnosis of NHL is usually established by examination of tissue obtained by open biopsy of the involved site. A comprehensive characterization of the biologic features of the tissue will help to distinguish NHL from the small round blue cell tumors, including Ewing sarcoma, neuroblastoma, and rhabdomyosarcoma. Sufficient tissue should be obtained not only for histology, but also for immunophenotypic, cytogenetic, and molecular studies. In some cases, a patient is too unstable to undergo anesthesia for open biopsy, as in children with large anterior mediastinal masses and associated airway compression. In such cases, the diagnosis may be established by parasternal fine-needle aspiration or biopsy with local anesthesia. If there is an associated pleural effusion, thoracentesis with cytologic examination of pleural fluid is usually diagnostic. In cases of large abdominal Burkitt tumors, direct percutaneous aspiration of the mass for cytology and cytogenetics is often diagnostic, as is cytologic examination of associated ascitic fluid obtained by paracentesis. In children with suspected NHL, a bone marrow and cerebrospinal fluid examination may be diagnostic, averting the need for more invasive procedures and possible increased morbidity.

STAGING

It is imperative that a meticulous staging work-up be performed because therapy is determined in part by location and degree of disease spread. Additionally, because NHL in children grows very rapidly, there should be no unnecessary delay in the staging work-up or in starting appropriate therapy. The staging work-up should include a complete history and physical, including the documentation of the presence or absence of B

TABLE 71-3 -- Stages of NHL[a]

Stage I
A single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exclusion of the mediastinum and abdomen
Stage II
A single tumor (extranodal) with regional node involvement
Two or more nodal areas on the same side of the diaphragm
Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm
A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable
Stage III
Two single tumors (extranodal) on opposite sides of the diaphragm
Two or more nodal areas above and below the diaphragm
Any primary intrathoracic tumor (mediastinal, pleural, or thymic)
Extensive primary intra-abdominal disease
Any paraspinal or epidural tumor, whether or not other sites are involved
Stage IV
Any of the above findings with initial involvement of the CNS, bone marrow, or both

From Murphy,[70] with permission.

[a]Based on the classification proposed by Murphy.

symptoms (e.g., weight loss and fever) by history. Diagnostic imaging studies should include computed tomography scanning of the chest, abdomen, and pelvis, and bone scanning. Gallium scanning may also be helpful in selected cases, particularly in following residual masses that were gallium positive at diagnosis. The cerebrospinal fluid and bone marrow must be examined in all patients. Bilateral posterior iliac crest aspiration and biopsy increases the chance of identifying marrow involvement, thus reducing the possibility of underestimating the disease stage. [69]

On completion of the above work-up, the stage of disease is usually determined according to the St. Jude Staging System described by Murphy (Table 71-3),[70] which was developed to accommodate the noncontiguous nature of disease spread, predominant extranodal involvement, and involvement of the bone marrow and CNS. Stages I and II are considered limited stage disease, whereas stages III and IV represent advanced stage disease.

THERAPY

General Principles

The dramatic improvement in treatment outcome achieved over the past 25 years is in large part due to the refinement in multiagent chemotherapeutic strategies through sequential clinical trials. [2] [9] [53] [71] [72] [73] [74] [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] [91] [92] [93] [94] [95] [96] [97] [98] [99] [100] [101] [102] [103] [104] [105] [106] [107] [108] The experience at St. Jude Childrens Research Hospital (SJCRH) is shown in Figure 71-2 . The most recent era features both a stage- and histology-directed treatment strategy (see box). A randomized trial performed by the Childrens Cancer Group (CCG) that compared two of the earliest effective treatment regimens for childhood NHL (COMP [cyclophosphamide, Oncovin, methotrexate, prednisone] and LSA_2L_2) provided data supporting this approach. [80] In this trial, children with limited stage disease had an excellent outcome regardless of histology or treatment regimen used. In contrast, among children with advanced stage disease, outcome varied with histology and therapy. Children with SNCC NHL had a better outcome with the cyclophosphamide-based COMP regimen, whereas children with lymphoblastic NHL had a better outcome with LSA2L2, a regimen designed for children with ALL. Among children with large cell NHL, outcome did not vary with treatment protocol. In the United States, subsequent trials built on this histology- and stage-directed approach. In Europe, and more recently in some US trials, an immunophenotype-directed approach is being used. Data suggest that immunophenotype-directed therapy is particularly important for children with advanced large cell NHL, who have varied treatment outcomes with respect to immunophenotype. [54]

There is a minimal role for radiation therapy and surgery in the management of childhood NHL. [2] [9] Prospective randomized trials in children with either limited or advanced stage disease have shown there is no improvement in treatment result when involved-field radiation is included; in fact, this modality may only add to treatment-related morbidity. The use of radiation therapy in certain emergency situations, at relapse, and in the management of CNS disease at diagnosis for certain histotypes will be discussed later. Apart from the initial diagnostic biopsy or the complete resection of an isolated peripheral node, tonsil, or ileocecal primary tumor associated with mesenteric nodes only (see discussion on staging), there is no other clear indication for the surgical management of this disease. Of note, aggressive debulking procedures are not indicated.

To prevent the spread of disease to the CNS, prophylactic intrathecal and high-dose systemic chemotherapy are used in most children. Prophylactic intrathecal therapy may not be necessary in children with limited stage disease, sparing the head and neck region, and in children with advanced stage large cell disease not involving the head and neck bone marrow. Some groups have included cranial radiation for CNS prophylaxis in pediatric lymphoblastic lymphoma; however, this approach is controversial. [101] Among children who present with overt CNS disease, intensification of both intrathecal and systemic chemotherapy is often needed, and, with the exception of Burkitt lymphoma, the addition of cranial irradiation.

Limited Stage Disease

The excellent prognosis for children with limited stage disease has prompted investigators to develop treatment strategies that reduce treatment-related morbidity while maintaining an excellent treatment result (Table 71-4). [71] [73] [74] [96] These studies have examined various ways to reduce treatment intensity. For

Figure 71-2 Event-free survival of patients with NHL treated from 1962 to 1993 at St. Jude Childrens Research Hospital. From 19621974, various chemotherapeutic approaches were used, including radiation therapy in some cases. From 19751978, patients were treated with a single combined-modality protocol. From 19791993, treatment was based on both the stage and histologic subtype of lymphoma. The numbers in parentheses are the total numbers of patients. Because some patients were not in complete remission at year 0 the curves do not begin at 100%. *(From Sandlund et al.,* [66] *with permission.)*

TABLE 71-4 -- Treatment Outcome for Limited Stage NHL

Regimen	Strategy	No. of Patients	Outcome
SJCRH[73]	Decrease intensity	28	86% 2 yr DFS

example, in the first of two sequential trials performed by the Pediatric Oncology Group (POG), [74] it was demonstrated that involved-field radiation therapy could be safely deleted from a 33-week chemotherapy regimen that comprised three courses of CHOP (cyclophosphamide, Adriamycin, vincristine, and prednisone) given over a 9-week period, followed by a 24-week maintenance phase consisting of weekly 6-mercaptopurine and methotrexate. In the subsequent trial, they demonstrated that the 24-week maintenance phase could be deleted without compromising the treatment result for those with either large cell or SNCC NHL. The optimal approach for children with limited stage lymphoblastic NHL remains controversial. In the POG trial, one-third of these children treated with the 33-week regimen experienced treatment failure but were successfully salvaged

ALGORITHM FOR MANAGEMENT OF PEDIATRIC NHL

in most cases. French investigators have taken a different approach, treating children with limited stage lymphoblastic NHL with the same regimen used for those with advanced stage disease.[95] Although this approach may reduce the need for retreatment, it also increases the risk of treatment-related morbidity.

Advanced Stage Disease

In the United States, efforts to improve the treatment outcome for children with advanced stage disease have primarily examined strategies to increase treatment intensity in the framework of a histology-directed approach,[53] [54] [72] [75] [76] [80] [81] [82] [83] [84] [85] [87] [88] [89] [90] [91] [92] [93] [98] whereas in Europe, an immunophenotype-directed strategy is generally used.[71] [77] [78] [79] [86] [94] [95] [97] [101] [102] [103] [106] [107] [108]

Advances in the treatment outcome of patients with SNCC NHL represent one of the true success stories in pediatric oncology (Table 71-5). Following the CCG trial that demonstrated the efficacy of the cyclophosphamide-based COMP regimen for advanced stage SNCC NHL, improved treatment results were achieved by including high-dose methotrexate and cytarabine[72] [75] [76] [77] [79] [83] even in regimens given over as short a period as 24 months.[77] [84] In the past decade, further improvement has been achieved by dose intensification of therapy and by the inclusion of additional active agents such as etoposide or ifosfamide.[71] [78] [79] [82] [101] [104]

Most of the regimens used successfully to treat lymphoblastic NHL are similar to or derived from those designed for children

with high-risk T-cell ALL (Table 71-6).[80] [85] [87] [88] [89] [95] [99] [100] A St. Jude study demonstrated the benefit of adding teniposide and cytarabine to an otherwise conventional antimetabolite-based regimen.[87] The French cooperative group (SFOP) demonstrated that an excellent response could be achieved by incorporating courses of high-dose methotrexate into an $LSA_2 L_2$ backbone.[95]

The German Berlin-Frankfurt-Munster (BFM) group has incorporated a reinduction phase into their treatment strategy and in their most recent trial have featured high-dose methotrexate pulses (5 g/m^2) as an early consolidation with very encouraging preliminary results90% event-free survival at 3 years. [101] [106] Although the French and German studies suggest an important role for high-dose methotrexate in the management of advanced stage lymphoblastic lymphoma, the multiagent nature of the regimens studied to date makes the relative value of individual components uncertain.

The optimal approach to the treatment of advanced stage large cell NHL has been a challenge to identify, both because of the biologic heterogeneity of these tumors and the markedly varied treatment strategies reported. In the United States, children with large cell NHL are treated on histology-directed protocols (Table 71-7). [53] [54] [80] [81] [90] [91] [92] Most of these histology-directed strategies are CHOP based, with current trials examining the benefit of adding agents such as carboplatin, high-dose cytarabine, etoposide, ifosfamide, and high-dose methotrexate. Some trials have examined the feasibility of eliminating individual agents with significant late effects, such as Adriamycin or cyclophosphamide.[54] [81] In a POG trial, children with large cell lymphomas of B-cell immunophentotype had a superior treatment result compared with those with a non-B-cell immunophenotype, suggesting that an immunophentotype-directed approach should be explored in future trials. [54] In this regard, European trials[71] [101] for children with large cell NHL have generally been designed according to immunophenotype; children with B-cell tumors are treated like those with SNCC NHL,[107] [108] those with T-cell tumors are treated like those with lymphoblastic lymphoma or T-ALL; and those with CD30+ anaplastic lymphomas are treated with various approaches, including therapy designed for Burkitt lymphoma. [94]

Emergency Situations

Various emergency situations may arise in the management of the child with newly diagnosed malignant lymphoma.[2] Those with a large anterior mediastinal mass may present with severe respiratory distress secondary to direct tracheal compression, a situation that may be worsened by an associated pleural effusion. If the diagnosis has been confirmed, appropriate chemotherapy should be started as soon as possible. If the diagnosis has not been established, efforts should be made to establish it expeditiously (see section on diagnosis). If the degree of respiratory compromise requires emergency management, involved-field irradiation of the tumor mass should be considered, with sparing of peripheral portions of the tumor so that a biopsy can be obtained when the patient is stable. Steroids may also be considered; however, this approach risks altering the tumor histology making it difficult to establish the correct diagnosis.

Children with a large tumor burden, particularly those with Burkitt lymphoma are at increased risk of significant metabolic abnormalities. Specifically, they may present with hyperuricemia, hyperkalemia, hyperphosphatemia, and associated renal dysfunction. This situation may only worsen with the massive tumor cell lysis that follows administration of chemotherapy ("tumor lysis syndrome").[2] Some of these children develop renal failure requiring dialysis. To help prevent this complication, children at risk should be vigorously hydrated (34 L/m^2 /day with D5 1/4 NaCl and 40 mEq/L $NaHCO_3$; there should be no added potassium) and started on allopurinol, a xanthine oxidase inhibitor. The urine pH should be maintained at about 7.0; at a more alkaline pH, phosphorus is less soluble, and at a more acidic pH, uric acid is less soluble. In some cases, mannitol followed by Lasix (furosemide) is required to maintain urine output. Uricolytic agents, such as uricozyme, which has been used for many years in Europe, directly cleaves the uric acid molecule, resulting in a precipitous drop in serum uric acid levels within a few hours. [109] A recombinant form (SR29142) is currently being studied. These agents have significantly reduced the frequency of renal failure and subsequent need for dialysis. They have recently become available in the United States as investigational agents.

Children with NHL may present with epidural masses and associated neurologic deficits caused by spinal cord compression. If the diagnosis is known, chemotherapy should be started as soon as possible. If the diagnosis is not known, or if there is a sluggish response to chemotherapy, low-dose radiation therapy may be considered.[2]

SALVAGE

Children who fail initial therapy are generally considered to have a poor prognosis, particularly if they have received intensive therapy up front. Current approaches to the management of these patients incorporate intensive multiagent therapy, which may be followed by hematopoietic stem cell or bone marrow transplantation (BMT). Various multiagent regimens have been studied. For example, VIPA[110] (etoposide, ifosfamide, and cytarabine) has been shown to be active in relapsed Burkitt lymphoma, and DHAP (dexamethasone, cytarabine, and cisplatin) has been shown to be active in relapsed large cell NHL. [92] Other regimens, including ICE[111] (ifosfamide, carboplatin, and etoposide) and MIED (methotrexate, ifosfamide, etoposide, and dexamethasone) are under investigation. Children who have chemosensitive recurrent disease are considered candidates for an intensification phase with autologous hematopoietic stem cell support (stem cells obtained by peripheral blood pheresis or bone marrow harvesting) or allogeneic BMT.

Autologous hematopoietic stem cell transplantation has been used successfully in children with relapsed large cell lymphoma [112] and in certain cases of relapsed Burkitt lymphoma.[113] [114] It has recently been reported by the European Lymphoma Bone Marrow Transplantation Registry that among children with poor-risk Burkitt lymphoma, in their experience, two groups of patients responded well to high-dose chemotherapy followed by autologous BMT: those with a partial response to induction therapy and those with chemosensitive relapse. They point out, however, that with intensive modern frontline protocols, postrelapse salvage with high-dose chemotherapy and autologous BMT may be less successful and they suggest that novel approaches including antibody-targeted therapy or the graft-versus-lymphoma effect following an allogeneic BMT approach be explored. [115] There are limited published data on the comparative effectiveness of autologous and allogeneic BMT for children with relapsed NHL; however, most investigators would consider allogeneic BMT strategies in cases of relapsed lymphoblastic or SNCC lymphoma if there is a matched related donor, particularly in cases in which the bone marrow is involved at the time of relapse.

SUPPORTIVE CARE

Optimal supportive care is critical for the successful management of children with NHL. The increased intensity of many current regimens requires the availability of the appropriate expertise and resources to manage the complications encountered during periods of profound pancytopenia. The management of life-threatening infections requires the availability of appropriate broad-spectrum antibiotics and antifungals and an intensive care facility. The use of prophylactic trimethoprim-sulfamethoxazole is recommended in all patients to reduce the chance of *Pneumocystis carinii* pneumonitis; for patients on aggressive B-cell protocols, treatment should be continued for approximately 6 months after chemotherapy is completed. Access to a blood bank that can quickly provide irradiated leukocyte-depleted packed red blood cells and platelets is also important. The role of colony-stimulating factors (CSF) such as granulocyte-CSF or granulocyte/macrophage-CSF has yet to be fully elucidated; however, they provide the potential benefit of reducing the duration of neutropenia and thus reducing infectious morbidity. The placement of a permanent venous access device, such as a Hickman catheter or subcutaneous port, greatly facilitates the delivery of hydration fluids, chemotherapy, antibiotics, and blood products. Consultation with a nutritionist or nutritional support team regarding need for enteral or total parenteral nutritional support is often necessary, particularly for children on intensive advanced stage B-cell NHL protocols, which are associated with significant gastrointestinal tract toxicity.

PROGNOSTIC FACTORS

Factors that are associated with treatment outcome include treatment era and tumor burden as reflected by both stage and serum LDH. [2] [9] [116] Those with limited stage (I and II) disease generally have a better prognosis than those with advanced stage (III and IV) disease; however, more intensive therapies for children with advanced stage disease have resulted in approximately equal outcomes in the two groups. Involvement of the CNS and bone marrow, both features of stage IV disease, has historically been associated with a poorer prognosis. However, for certain histologic subtypes, such as Burkitt lymphoma, modern intensive therapy has resulted in a good prognosis for those with marrow involvement, and in some studies, CNS disease has been eliminated as an adverse prognostic factor. [117] Elevated serum LDH (>500 IU/L) and interleukin-2 receptor are associated with outcome. [118] [119] Within specific histologic subtypes, certain biologic features have prognostic value. For example, among those with large cell NHL, those with a B-cell immunophenotype have better treatment results than do those with a non-B-cell immunophenotype (i.e., T cell or non-B, non-T cell). [54] Because prognostic factors are reflective of the specific treatment used, they will continue to change as therapy improves.

FUTURE DIRECTIONS

Although there have been dramatic improvements in treatment outcome for children with NHL over the past 25 years, approximately 30% of children with these tumors either relapse or do not respond to initial therapy. [6] Additionally, late effects such as anthracycline-related cardiomyopathy, secondary malignancies such as epipodophylotoxin-related acute myeloid leukemia, and endocrine abnormalities such as cyclophosphamide-related azospermia remain a concern. [120] [121] Thus, a major goal for the future is to develop treatment strategies that will provide a cure for the remaining 30% while reducing treatment-related morbidity. There are several areas to target if this goal is to be achieved.

The identification at diagnosis of both clinical and biologic features that predict treatment failure will enable investigators to determine which patients need aggressive or novel therapy. More intensive therapy may require autologous hematopoietic stem cell support provided by either peripheral blood or bone marrow harvesting. The administration of CSFs may be necessary in some cases, although their role in therapy is currently under investigation. Novel approaches may include immunotherapeutic strategies such as tumor vaccines, phenotype-specific immunotoxins, [122] or the use of surface protein-specific cytotoxic T lymphocytesan approach that has been successful in both the prevention and treatment of EBV-related post-transplant lymphoproliferative disease. [123]

The continued investigation of lymphoma-related cytogenetic and molecular abnormalities as well as the pathogenetic mechanisms of malignant transformation are critical. These studies may help to further refine disease classification and provide a means of detecting minimal residual disease during clinical remission. Additionally, these studies may provide clues to novel and more successful treatment strategies, including those directed toward tumor-specific molecular lesions.

Chapter 72 - Chronic Lymphocytic Leukemia

Kanti R. Rai
Dilip V. Patel

Chronic lymphocytic leukemia (CLL) as a distinct clinical entity was first identified in 1903 by Turk, [1] who gave us not only the criteria for its diagnosis but the features that distinguish it from the lymphomas. In 1924, Minot and Isaacs [2] presented a detailed clinical description of CLL. Although several physicians studied this disease in the ensuing decades, it was not until 19661967 that the pathophysiology of CLL was fully explained. Galton [3] and Dameshek [4] independently but virtually simultaneously suggested that the main characteristic of CLL is a progressive accumulation of functionally incompetent, long-lived lymphocytes.

EPIDEMIOLOGY

Chronic lymphocytic leukemia is the most common form of leukemia in the Western Hemisphere, accounting for about 2530% of all leukemias. Approximately 10,000 new cases are diagnosed every year in the United States. [5] Characteristically, CLL is a disease of advancing age, the incidence being >20 per 100,000 people >70 years of age. [6] However, the disease is being diagnosed in increasing frequency among younger age groups and is no longer considered unusual even in patients 35 years of age. The median age at diagnosis is 55 years. The incidence of CLL is higher among men, with the male/female ratio being nearly 1.7:1. CLL is rarely seen in Japan, China, and other Asian countries. The reason for this wide disparity in incidence of CLL in different parts of the world remains unknown. More than 95% of patients have a B-cell phenotype; T-cell CLL is a rare disease, accounting for only 25% of all cases. Unless otherwise specified, most descriptions of CLL pertain to B-cell disease.

GENETIC ASPECTS

Chronic lymphocytic leukemia is an acquired disorder. There is one report in the literature of CLL occurring in twin sisters who were monozygous, but not identical. Immunoglobulin gene rearrangements in the CLL cells of these twins were found to differ from each other. [7] Relatives of patients with CLL have an increased frequency of CLL, other B-cell malignancies, and autoimmune disorders. [8] [9] [10] [11] The risk for development of CLL among first-degree relatives of patients with CLL is higher than expected. Consanguinity and chromosomal abnormalities have been proposed as possible explanations. No human leukocyte antigen (HLA) haplotype has been found to be consistently associated with CLL. [12]

ETIOLOGY AND ONCOGENESIS

The etiology of B-CLL remains unknown. No causal relationship has been found with exposure to radiation, chemicals, and alkylating agents. Human T-cell leukemia/lymphoma virus 1 (HTLV-1) is known to cause adult T-cell leukemia. Although retroviruses and DNA viruses such as HTLV-1 and Epstein-Barr virus are not considered to be etiologic agents for CLL, Mann et al. [13] observed two patients with B-CLL who were HTLV-1 seropositive, but the virus was not present in the cellular genome.

In CLL, there is a progressive accumulation of the leukemic lymphocytes, with no increase in their rate of proliferation. Lymphocytes in CLL are known to be long-lived. The early observations of Galton [3] and Dameshek[4] suggested that CLL lymphocytes are long-lived because they are functionally incompetent. Recent work has demonstrated that CLL represents a classic example of a human cancer resulting from defects in the pathways for programmed cell death or apoptosis. The Bcl-2 family of proteins is known to serve as a key regulator of apoptosis. Bcl-2, the prototype of this family, is a blocker of apoptosis. [14] [15] Leukemia cells from approximately 90% of patients with CLL have high levels of Bcl-2. [15] [16] Thus, nearly 30 years after Galtons and Damesheks observations, we now have an explanation for the longevity of CLL cells and, therefore, the first clues in understanding the pathogenesis of this disease.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

GROWTH AND DIFFERENTIATION

Leukemic cells in CLL are known to be arrested in the G_0 phase of the cell cycle with a relatively rare cell in the peripheral blood showing evidence of being in the active proliferative cycle.[17] [18] CLL cells, arrested in the late stages of B-cell differentiation, reveal certain characteristics in vitro that may explain at least some aspects of the pathophysiology of this disease. When cultured [19] without cytokines and mitogens, in vitro, CLL cells die rapidly by apoptosis. It has been demonstrated that CLL cells lose bcl-2 protein during culture. [20] Addition of interleukin (IL)-4 [21] or interferon (IFN)- [22] to the cultures inhibits the cell death by apoptosis, an observation correlated with a simultaneous increased expression of bcl-2 protein in IL-4treated B-CLL cells. [21] When CLL cells are cultured in the presence of B-cell mitogens or the phorbol ester TPA (12-0-tetradecanoylphorbol-13-acetate), they are capable of plasmacytoid differentiation, suggesting that these cells are not frozen at an intermediate stage in the B-cell differentiation pathway. The process of stimulation of differentiation of CLL cells, however, is complex and requires all the co-stimulatory factors necessary for normal B cells undergoing differentiation in vitro, including various cytokine-producing, non-neoplastic T cells. [23]

CHROMOSOMAL ABNORMALITIES

Chronic lymphocytic leukemia lymphocytes are resting cells in G_0 that have no spontaneous mitoses in vitro. Until the recent introduction of B-cell mitogens, cytogenetic studies were not possible in CLL because metaphases were only rarely inducible. In the past decade, however, several laboratories have been successful in performing cytogenetic studies in CLL following the availability of a battery of B-cell mitogens, including lipopolysaccharide, TPA, cytochalasin B, pokeweed mitogen, and Epstein-Barr virus supernate, which induce readable metaphases in a large proportion of cases. Juliusson and Gahrton, [24] in an update on the cytogenetic data pooled by the International Working Party on Chromosomes in CLL and drawing on additional data from the published literature, have provided a detailed status report on this subject. In this collected series [24] of

---

G-banded metaphase analysis of 1,244 cases of CLL, clonal chromosomal abnormalities were seen in 43% (533 cases), and trisomy 12 was the most frequently observed abnormality, occurring in approximately 15% of all patients studied and approximately one third of all cases with clonal abnormalities. Structural abnormalities involving the long arm of chromosome 13 accounted for 20% of cases with clonal abnormalities, and other, less frequently occurring structural abnormalities involved the long arms of chromosomes 6 and 14.[24]

The study of chromosomal abnormalities in CLL has benefited from recent molecular biology techniques such as fluorescence in situ hybridization (FISH), constructing a high-resolution physical map of yeast artificial chromosome, and comparative genomic hybridization. These studies have identified abnormalities of chromosome 12, chromosome 13q14 and 13q12, and chromosome 11. Fluorescence in situ hybridization has proven to be the most reliable method to detect trisomy 12 abnormality. A study by Garcia Marco et al.[25] revealed 20% of 600 CLL patients with trisomy 12. These investigators found that patients with 12+ had an increased proportion of prolymphocytes and an overall poorer prognosis.

Abnormalities of the long arm of chromosome 13 have been the subject of intense investigations by several workers. These studies reveal a loss of chromosome material on 13q, initially suggesting the involvement of retinoblastoma susceptibility gene (*RB1*) because of frequency of allelic loss in its locus, 13q14. However, it has since been demonstrated that the actual region of deletion is telomeric to *RB1,* close to the marker D13S25.[26] A genomic region of consensus of approximately 300 kilobases has been identified, and it is expected that a candidate tumor suppressor gene for CLL may soon be discovered in this area of minimal deletion at 13q14.[27]

Döhner et al.[28] reported that in a study of 338 patients with B-CLL by FISH, the frequency of chromosomal abnormalities (in decreasing order) was as follows: 13q (54% single and complex and 36% single), 11q (17%), +12q (15%), 17p (8%), and 6q (7%). In an attempt to correlate prognosis with chromosomal abnormalities, Döhner et al.[28] observed that 17p and 11q deleting were associated with rapid disease progression and inferior survival, while in the better prognosis group there was no significant survival difference among patients with normal karyotype, 13q (single abnormality) and trisomy 12.

In a study of more than 200 CLL cases, 20% were found to have deletions of 11q23, a structural abnormality second only in frequency after deletions of 13q1214. [29] Patients with 11q deletions are reported to have progressive disease, tend to be young, may be associated with extensive adenopathy, and have short treatment-free survival.[30]

IMMUNOPHENOTYPIC PROFILE OF LYMPHOCYTES

B Cells

The normal T-cell/B-cell ratio is reversed in CLL. In B-CLL, the B cells usually account for nearly 90% of all lymphocytes. There is a characteristic immunophenotypic profile of B cells, as shown in Table 72-1 .[31] [32] [33] CLL B cells express low surface density of immunoglobulins, usually IgM or IgM with IgD, which are monoclonal, as revealed by expression of only one light chain, either or . These cells form rosettes with mouse erythrocytes. Intracytoplasmic immunoglobulins may be detectable in a few cases. Some B cells have receptors for Fc fragments, for IgG, and for complement (C3d). By using a wide range of monoclonal antibodies, it has been established that B cells of B-CLL stain positively with one pan-T-cell antibody Leu-1 (CD5), [34] [35] [36] while simultaneously also staining with at least one of the B-cell monoclonal antibodies B1 (CD20), B4 (CD19), CD23 (activation marker, low-affinity FcE receptor), and BA1 (CD24). These cells

TABLE 72-1 -- Immunophenotypic Pattern of B-Cell Chronic Lymphocytic Leukemia Cells

Surface immunoglobulin (slg):
Usually IgM or IgM and IgD of low intensity (infrequently, the amount of slg may be so low that the cell is read as slg negative)
Mouse-erythrocytes rosetting
One or more of the following B-cell markers
CD19 (B4), CD20 (B1), CD24 (BA1), CD21 (C3dR), CD23 (activation marker)
Ia
CD5 (pan-T, Leu-1)
Heterogeneous with respect to
CD11c ($_2$ integrin)
Surface adhesion molecules CD54, CD58, L-selectin, and CD25 (interleukin-2 receptor)

express HLA-DR, the major histocompatibility class II antigen. There is a considerable degree of heterogeneity in the expression of CD25 (IL-2 receptor) and CD11c ($_2$ integrin) and surface adhesion molecules CD54, CD58, and L-selectin. [31] [32] [37] The overall interpretation of this phenotypic expression is that CLL cells are relatively mature cells that are arrested at an intermediate stage in the pathway of B-cell differentiation.

The CD5 positivity of B cells in CLL has become a subject of active investigation. A very small subset of normal B lymphocytes is known to be CD5+. [34] It is not clear whether this normal CD5+ B-cell subpopulation is the one that proliferates and accumulates in CLL. [38] Normal CD5+ B cells express activation markers, and >10% of these cells may be in active proliferative cycle, whereas only <1% of CD5+ B cells in CLL are in active cycle [38] (Table 72-1). Investigations in this area, however, do not provide clear evidence that CD5+ B cells constitute a separate B-cell lineage. [39]

T Cells and Natural Killer Cells

The absolute number of T cells in B-CLL may be normal, decreased, or increased according to the total lymphocyte count and percentage of T cells. The interplay of cytokines produced by cell-cell interaction among malignant B cells, macrophages, and T cells may provide an explanation for the heterogeneity of B-CLL. [40] T cells in B-CLL may influence the expansion of the malignant clone by the increased numbers of CD4 and helper T cells in the bone marrow and lymph nodes. In addition, although T cells may otherwise be normal, they have alterations in the T-cell receptor repertoire, as revealed by the observations that within both CD4+ and CD8+ populations in B-CLL there is an increase in oligoclonality. These oligoclonal T cells coexpress CD57 marker, and their expansion is a function of disease duration. [41] T cells also produce several cytokines under the control of accessory cells, which happen to be the malignant B-CLL cells. [42]

The population of large granular lymphocytes (natural killer [NK] cells) is usually decreased. [43] [44] The functional status of T cells and NK cells in CLL remains unresolved and unclear.[45]

Autoimmune Complications

Autoimmune complications are known to occur frequently in CLL and are due to antibodies restricted to blood cell self-antigens. [42] [46] [47] CLL patients also have a significant degree of hypogammaglobulinemia. Autoimmunity and immunodeficiency have been related to B-CLL biologic properties and cellular origin. [42] It has been suggested that CD5+ B cells may play an important role in the production of IgM autoantibodies. An

TABLE 72-2 -- Factors Contributing to Immunodeficiency in Chronic Lymphocytic Leukemia

Reduced serum immunoglobulin
Reduced percentage of CD4+ cells, increased percentage of CD8+ cells (worsening with disease prognosis)
Reduced response to antigens and mitogens

Modified from Foa R: Pathogenesis of the immunodeficiency in B-cell chronic lymphocytic leukemia. In Cheson BD (ed): Chronic Lymphocytic Leukemia: Scientific Advances and Clinical Developments. Marcel Dekker, New York, 1993, p. 147, with permission.

increase in the number of CD5+ B cells has been reported in rheumatoid arthritis and other autoimmune diseases. [48] Autoimmune phenomena in CLL are often directed against hematopoietic cells. A positive direct antiglobulin test has been noted in 35% of CLL cases. Autoimmune hemolytic anemia occurs in 1025% of cases at some time during the course of the disease.[39] In most cases, the autoantibodies against erythrocytes are warm reactive and polyclonal, [48] with or without red-cell-associated C_3 b or C_3 d. Immune thrombocytopenia occurs in a few CLL cases. Pure red cell aplasia and autoantibodies against neutrophils are observed less frequently.

Hypogammaglobulinemia is a not unusual feature of CLL. The levels of serum IgG, IgA, and IgM may all be markedly decreased, or just one or two of the immunoglobulin classes may be involved. The pathogenesis of this complication is poorly understood, but regulatory abnormalities of helper T, suppressor T, NK, and antibody-dependent cellular cytotoxicity cells may play a role. [49] NK cells from patients with CLL with hypogammaglobulinemia were found to cause a decrease in immunoglobulin secretion by normal B cells.[50] It is also possible that a decrease in or inhibition of normal B cells (CD5) results in hypogammaglobulinemia. [39] A monoclonal serum immunoglobulin spike (usually IgM) has been observed in 5% of cases with CLL. Patients with CLL tend to have defective specific antibody responses to infection and to immunization.[51] Infections with encapsulated organisms as well as with gram-negative bacteria are recognized as the most frequent cause of morbidity and mortality in CLL. [51] [52]

A summary of the currently recognized factors that may play a role in the heterogeneous immunologic abnormalities in CLL is shown in Table 72-2 . There are additional factors (such as reduced NK, antibody-dependent cellular cytotoxicity, and lymphokine-activated killer cell activity, increased levels of soluble IL-2 receptors, and reduced IL-2 availability), but their role is far from clearly proven. The available data strongly suggest that the abnormalities of the T- and cytotoxic cell compartments represent a secondary event occurring during the course of CLL. [45]

CLINICAL MANIFESTATIONS

Criteria for Diagnosis of CLL

The National Cancer Institute-sponsored Working Group (NCI-WG) on CLL was charged with the task of developing guidelines for protocol studies in this disease, and in that context it recommended the following three diagnostic requirements: [53] [54]

1. An absolute lymphocytosis in the blood, with a count of 5×10^9 /L, and cells morphologically mature in appearance, sustained over at least a 4-week period.
2. At least 30% lymphocytes in a normocellular or hypercellular bone marrow.
3. A monoclonal B-cell phenotype expressed by the preponderant population of blood lymphocytes with low levels of surface immunoglobulins and simultaneously showing CD5 positivity (a pan-T-cell marker).

The requirement that the lymphocytosis should be sustained over a period of time is included in these diagnostic criteria to exclude those conditions (e.g., infectious mononucleosis, pertussis, toxoplasmosis, and cytomegalovirus infection) in which lymphocytosis is transient. In our view, if a bone marrow lymphocytosis also is required for the diagnosis of CLL, it is not necessary to prove that blood lymphocytosis is of a sustained nature because none of the conditions with transient lymphocytosis is associated with bone marrow involvement.

The International Workshop on CLL (IWCLL) [55] proposed somewhat similar diagnostic criteria, but it requires 10×10^9 /L lymphocytes in the blood for the diagnosis to be made if facilities to obtain phenotyping are not available. IWCLL recommended that a diagnosis of CLL can be made in a patient with $<10 \times 10^9$ /L lymphocytes in the peripheral blood, provided phenotyping is performed and reveals the pattern characteristic of CLL, as described previously.

The FAB Cooperative Group [56] states that when >10% of cells in the blood are large (or prolymphocytic) in appearance, the diagnosis of mixed-cell-type CLL should be considered. In our experience, clearly identifiable forms of prolymphocytic leukemia are a consistent clinical identity. The importance of occasional prolymphocytic-appearing cells in the peripheral blood in CLL is controversial.

Symptoms

The usual complaints of patients with CLL are weakness, easy fatigue, night sweats, fever without infections, weight loss, frequent bacterial and viral infections, increased bleeding tendencies, and exaggerated responses to mosquito or other insect bites. These are symptoms often associated with malignancy and immunodeficiency. Symptoms may be entirely absent, or only some or all may be present in varying severity.

Findings on Physical Examination

The most frequently noted abnormal finding on physical examination is lymphadenopathy. Only a single node-bearing area may be involved, or lymph nodes may be palpably enlarged in the cervical, axillary, and inguinofemoral areas. These nodes may be small (e.g., about 1 cm in diameter) or massively enlarged. The enlarged lymph nodes in CLL are almost always nontender, nonpainful, discrete, firm, and easily movable on palpation. Enlargement of spleen and liver when present may range from barely palpable to 15 or 20 cm below the respective costal margin. In addition, infiltration by CLL cells may be manifested in virtually all other parts of the body, including the meninges and skin.

Laboratory Evaluation

Absolute lymphocytosis in blood, with mature-appearing cells, is one of the two major presenting features of CLL (Plate 72-1). The blood lymphocyte count may range from 5 to 500 $\times 10^9$ L, but in most cases it is $>20 \times 10^9$ /L. Similarly, the differential count of bone marrow aspirate smear may reveal lymphocytes accounting for as little as 30% of all nucleated cells or as much as 99%; in the latter, the marrow is totally replaced by monotonously similar-appearing lymphocytes. The overall cellularity of bone marrow is normal or increased; a hypocellular marrow is not a typical finding in CLL unless it is the result of cytotoxic therapy. Depending on the extent of lymphocytic infiltration, myeloid and erythroid precursors and megakaryocytes may be decreased or normal. Pure red cell aplasia, [57] [58] however, may also occur in CLL. Bone marrow biopsy examination has become virtually routine whenever an aspiration procedure is performed in CLL. Biopsy specimens are characteristically infiltrated with lymphocytes, but the patterns of such infiltration

may be diffuse, nodular, or interstitial [59] [60] [61] [62] [63] [64] (Plates 72-2 , 72-3 , 72-4).

Lymphocytes in the blood and the marrow appear morphologically mature. However, it is now well recognized that functionally they are not mature inasmuch as they are arrested at an intermediate level of differentiation. [65] Lymphocytes in CLL are usually small, with the nucleus filling almost the entire cell, and the nuclear chromatin is dense and clumped and without any discernible nucleolus (Plate 72-1). Occasionally the CLL lymphocyte may be a large cell with a round or somewhat notched nucleus, there may be an indistinct nucleolus, and the cytoplasm may be abundant and slightly basophilic or orthochromatic. Several morphologic variants of CLL have been described in the literature (e.g., prolymphocytic leukemia and Sézary cell leukemia). [56] Preparation of blood films may cause severe morphologic deformities of CLL lymphocytes, recognized as smudge cells (Plate 72-5).

Although CLL is characterized by leukocytosis, the proportion of neutrophils is always reduced, but to a varying degreefrom as low as 1% to as high as 40%. Thus, the absolute neutrophil count may be normal, extremely low, or extremely high, depending on total leukocyte count and percentage of neutrophils.

Approximately 30% of all patients with CLL may have somewhat decreased hemoglobin values or platelet counts, but these values are significantly decreased in only 15% of cases (hemoglobin <110 g/L, platelets $<100 \times 10^9$ /L) at the time of initial diagnosis. Autoimmune complications, including Coombs-positive hemolytic anemia, immune thrombocytopenia, and hypogammaglobulinemia, were discussed previously.

There is no characteristic abnormality of the blood chemistry profile in CLL, but hypercalcemia and abnormal liver and kidney function test results may be encountered.

Differential Diagnosis

The differential diagnosis of CLL includes the entire spectrum of chronic lymphoproliferative disorders. Malignant lymphoma in the leukemic phase may sometimes be indistinguishable from CLL, and the most helpful findings in such situations are phenotypic profiles of lymphocytes. Whereas the fluorescence intensity of surface immunoglobulins on B lymphocytes is bright in lymphomas, it is very faint in CLL; only CLL B lymphocytes form rosettes with mouse erythrocytes. On flow cytometry, B lymphocytes show dual positivity with CD19 and CD5 or CD20 and CD5 both in CLL and in the leukemic phase of mantle cell lymphoma, but CLL cells are CD23+, whereas mantle cell lymphoma cells are CD23.

T-cell CLL and morphologic variants of CLL (e.g., prolymphocytic leukemia, Sézary syndrome, hairy cell leukemia) are distinguished by their respective characteristic phenotypic and microscopic appearances.[56] The phenotypic characteristics useful in differentiating these various disorders are summarized in Table 72-3 .

Prognosis

Just as the initial extent of disease is variable in CLL, the prognosis and clinical course also are extremely variable. Some patients have a rapid downhill course and die within 23 years after diagnosis, whereas others have a very benign, indolent course and live for 10 or 20 years without major problems from CLL. Approximately one half of patients with CLL have a disease course somewhere in between the two extremes. Boggs et al.[66] studied several prognostic factors and concluded that the extent of disease at initial diagnosis correlates inversely with survival.

Clinical Staging System of Rai

Building on the work of Dameshek,[4] Boggs et al.,[66] and of Hansen,[67] my colleagues and I (KRR)[68] were able to devise a clinical staging system in which patients with minimum evidence of disease (those merely satisfying the minimum diagnostic criteria) were considered to be in the earliest stage of disease, whereas those demonstrating significant compromise of bone marrow function (as an index of high leukemic cell burden) were considered to be in advanced stages. This staging system is detailed in Table 72-4 .

The definition of lymphocytosis in our original description consisted of a 15 × 10^9 /L or higher absolute lymphocyte count in blood and 40% of lymphocytes in the marrow differential count of all nucleated cells. However, following the recommendations of the NCI-WG [53] [54] and the IWCLL[55] detailed previously, we suggest that these thresholds be modified to 5 × 10^9 /L and >30% in blood and marrow, respectively. The presence of palpably enlarged lymph nodes was found to be of prognostic value (stage I), but it did not seem to make much difference

TABLE 72-3 -- Markers Useful in Distinguishing Chronic Lymphocytic Leukemias (CLL)

Marker	CLL	Prolymphocytic Leukemia	Hairy Cell Leukemia	Leukemic Phase of Follicular Non-Hodgkin Lymphoma	Mantle Cell Lymphoma	T-CLL	Sézary Syndrome
Surface immunoglobulin	Weak	Strong	Strong	Strong	+	Negative	Negative
Mouse red cell rosetting	++		±	±			
Sheep red cell rosetting						++	++
CD2						++	++
CD3						++	++
CD4						+	++
CD5	++	±			++	++	++
CD7						++	
CD8						+

TABLE 72-4 -- Rai Clinical Staging Systems

Level of Risk	Stage	Description
Low[a]	0	Lymphocytosis only (in blood and marrow)
Intermediate[a]	I	Lymphocytosis plus enlarged nodes
	II	Lymphocytosis plus enlarged spleen or liver with or without enlargement of nodes
High[a]	III	Lymphocytosis plus anemia (hemoglobin <110 g/L) with or without enlarged nodes, spleen, liver
	IV	Lymphocytosis plus thrombocytopenia (platelets <100 × 10^9 /L) with or without anemia or enlarged nodes, spleen, liver

[a]Modified Rai system.

whether adenopathy was bulky or minimal, or whether it involved a single node-bearing region or was generalized. Median survival correlated inversely with the clinical stage: stage 0, 12+ years; stage I, 8.5 years; stage II, 6 years; stage III, 1.5 years; and stage IV, 1.5 years. [68]

Modified Rai System

Although several investigators confirmed the validity of the staging system of Rai et al. as a reliable predictor of survival time in CLL, many workers found that having as many as five stages in the system made it difficult to plan prospective therapeutic trials. We had, however, acknowledged in our original proposal [68] in 1975 that in the actuarial survival curves, there were indeed only three, not five, distinct patterns: (1) stage 0, (2) stages I and II combined, and (3) stages III and IV combined. [68] Therefore, a formal modification[69] of the staging system was published in 1987, which assigns stage 0 to the low-risk group, stages I and II combined to the intermediate-risk group, and stages III and IV combined to the high-risk group (Table 72-4). The survival curves according to the modified Rai system in a large series of patients with CLL followed in the Hematology Clinic of the University of Barcelona in Spain [70] are shown in Figure 72-1 . These curves are statistically

significantly different from each other and demonstrate that the patients in the low-risk group have the best outlook for survival. The NCI-WG recommends

Figure 72-1 Survival according to the modified Rai staging criteria in 443 patients with chronic lymphocytic leukemia at the Postgraduate School of Hematology, Barcelona, Spain. *(From Montserrat E, Rozman C: Chronic lymphocytic leukaemia: prognostic factors and natural history. Baillieres Clin Haematol 6:849, 1993, with permission.)*

[53] [54] using the modified Rai staging system for prospective therapeutic trials.

Staging System of Binet and Colleagues

The only other staging system that has found wide acceptance in clinical practice is the one devised by Binet et al. [71] This system is similar to the Rai system in concept. Stage C consists of all patients who have anemia (hemoglobin <100 g/L) or thrombocytopenia (platelets <100 × 10^9 /L). All other (non-C) patients are divided into A or B stages depending on the number of lymphoid-bearing areas palpably enlargedtwo or less for A and more than three for B (there are five of these areas: the cervical, axillary, and inguinofemoral nodes; spleen; and liver). This three-stage system is an excellent predictor of survival and is useful in planning therapeutic trials. Binet et al. have observed that the survival times of stage A patients do not differ from those of age- and sex-matched normal members of the French population. Inasmuch as stage A patients include those who have splenomegaly with one area of lymphadenopathy (or two areas of adenopathy without splenomegaly), it is somewhat surprising that the life expectancy of such patients is equal to that of the nonleukemic normal French population. Conceptually, in our opinion, the stage 0 subgroup of Binets A should have a better prognosis than all other (non-stage-0) patients in stage A. In actual practice, both the Rai and the Binet systems are used in clinical management and in therapeutic protocols.

Other Staging Systems

The IWCLL recommends the use of an integrated Binet and Rai system in which each Binet stage (A, B, or C) is subclassified according to the corresponding Rai stage.[55] However, clinicians use either of the two systems without the recommended integration.

Jaksic and Vitales[72] total tumor mass estimation yields a score indicating the size of the spleen and the largest palpable lymph node, while also including a factor related to the blood lymphocyte count. Other systems proposed include those of Mandelli et al., [73] Lee et al.,[74] Baccarini et al.,[75] Skinnider et al.,[76] and Paolino et al.[77] Each of these systems has certain advantages and helps a physician in individual cases, but none has found wide usage, perhaps because the Rai and Binet methods are simple to apply and succeed in segregating large populations of patients with CLL into distinct groups of survival outlook.

Additional Prognostic Features

Numerous clinical, hematologic, and laboratory abnormalities, as well as immunophenotypic and cytogenetic characteristics have been reported to be indicative of adverse prognosis in CLL. Some of these are listed in Table 72-5 . Perhaps only a few of these features have a consistent impact on prognosis, and are described in the following sections.

Lymphocyte Doubling Time

Although, as an indicator of prognosis, the lymphocyte count acts as a continuous variable, we have not found a threshold (such as a cut-off level of 4050 × 10^9 /L) count consistently reliable. However, the rate of increase of the absolute lymphocyte count in the blood of patients with CLL not receiving cytotoxic therapy has proven to be a reliable indicator of disease activity. A serial plotting of blood lymphocyte counts provides a measure of this activity and, either by extrapolation or by actual observation, it can be determined whether the blood lymphocyte count doubles slowly (12 months) or rapidly (<12 months); the latter is associated with a worse prognosis.[78] [79] [80]

TABLE 72-5 -- Factors Associated with a Poor Prognosis

Clinical
Lymphadenopathy
Splenomegaly
Hepatomegaly
"Bulky" disease
Poor performance status
Hematologic
Anemia
Thrombocytopenia
Large and atypical lymphocytes in blood
Diffuse bone marrow lymphocytic infiltration
Laboratory abnormalities
Increased serum lactate dehydrogenase level
Hypoalbuminemia
Increased serum calcium level
Cytogenetic abnormalities
Complex and multiple cytogenetic abnormalities and 17p, 11q
Immunologic
Hypogammaglobulinemia
Immunophenotype (different abnormalities related to poor prognosis (e.g., Smlg+++, CD5, CD23)
Increased serum-soluble CD25 receptors
Increased serum-soluble CD23 receptors
Kinetic parameters
Rapid doubling time
Others
Poor response to therapy

Bone Marrow Histopathology

The pattern of lymphocytic infiltration in the bone marrow biopsy specimens (Plates 72-2 , 72-3 , 72-4) can be classified as either diffuse or nondiffuse. The nondiffuse pattern may be nodular, interstitial, or mixed nodular and interstitial. Patients with diffuse infiltration have a worse prognosis than those with nondiffuse. The diffuse pattern is seen most frequently in CLL of advanced clinical stage, whereas a nondiffuse infiltration is the more likely pattern in early stages of CLL. [59] [62] [63] [81]

Immunophenotypic Features

A large, prospective study of flow-cytometric immunophenotyping in Denmark provides the most systematic analysis of the prognostic value of these findings. [82] There were 503 CD5+ and 37 CD5 cases. The survival of CD5 patients was on the borderline of being significantly shorter than that of CD5+ patients. Most CD5 patients had malignant lymphocytes with strong sIgM fluorescence, and were FMC7+ and CD23, indicating that CD5 cases represent an atypical variant of CLL. [82] Among the CD5+ cases, by Cox multiple regression analysis, a few features emerged with independent prognostic importance: higher age, low CD23 expression and high sIgM fluorescence intensity, and advanced clinical stage were all associated with worse prognosis. CD20, CD21, and CD22 expression did not have prognostic importance.[82]

Cytogenetics

A clonal chromosomal abnormality indicates a poorer prognosis compared with a normal karyotype. [24] As noted in an earlier section, recent studies suggest that patients with normal karyotype, single abnormality of 13q and trisomy 12 have better prognoses than those with 17p and 11q. [28]

TABLE 72-6 -- Definition of Smoldering Chronic Lymphocytic Leukemia

Prediction of Clinical Course in Patients with Early Stages

Neither the Rai nor the Binet system of clinical staging can reliably predict the clinical course of patients in the nonadvanced stages (0, I, and II for the Rai and A and B for the Binet) of CLL. It is widely recognized that there is a group of patients in these stages whose disease course remains indolent for prolonged periods (several years) and another group with a relatively progressive and active course. Several prognostic factors have been tested by numerous investigators since the 1970s. These include a blood lymphocyte count above or below a certain threshold; [75] [83] [84] lymphocyte morphology and size;[79] [85] serum levels of several enzymes (e.g., lactate dehydrogenase[86] and deoxythymidine kinase[87]); serum -microglobulin levels;[88] phenotype of blood lymphocytes;[82] [89] and chromosomal abnormalities.[24] [28] The value of these criteria for predicting the clinical course of CLL has not been universally accepted.

Patients with early stages of CLL whose blood lymphocyte doubling time is long (>12 months) and whose bone marrow biopsy shows a nondiffuse pattern of lymphocytic infiltration tend to have an indolent course of the disease. The Spanish group [90] retrospectively tested certain criteria associated with nonprogressive (or stable) CLL among patients in Binets A stage, which they call smoldering CLL. They noted that (in addition to the two criteria mentioned previously) a relatively low (30 × 10^9 /L) absolute lymphocyte count and a relatively high (13 g/dL) hemoglobin (Table 72-6) characterize the category of smoldering CLL. The patients with smoldering CLL were found to have life expectancies no different than those of an age- and sex-matched control population and a significantly lower risk of disease progression compared with the Binets stage A patients not meeting the criteria of smoldering CLL (and were deemed to have active CLL; [70] Table 72-7).

CLL in the Younger Age Group

Chronic lymphocytic leukemia is a disease of the elderly, with a median age at diagnosis of 55 years. However, with the easy

TABLE 72-7 -- Disease Activity in Smoldering versus Active Chronic Lymphocytic Leukemia (CLL)

	Smoldering CLL[a] (%)	"Active" CLL (Nonsmoldering)[b] (%)

[b] 161 patients.

availability of routine blood counts in todays society, CLL is being diagnosed in increasing frequency both at earlier stages of the disease as well as in younger age groups. Approximately 12% of patients are <50 years of age at diagnosis. Although nearly two thirds of younger patients with CLL are >40 years of age, a Mayo Clinic report shows 18 years as the lower end of the age range.[80] With the advent of newer and more aggressive therapies in CLL, several studies have been conducted to determine whether younger patients with CLL have different outcomes from those in the more typical, older age groups. These studies show that there are no differences in the presenting features, treatment response rates, and median durations of response between the younger and the older age groups. [91] [92] [93] [94] [95] [96] The Mayo Clinic study was confined to the prognostic features of nonadvanced stages of CLL in the younger patients, and it showed that the survival curves for stages 0 and I were virtually superimposable, with a median duration of 140 months, which was significantly longer than the median duration of 60 months for stage II patients. On multivariate analysis of several factors, only clinical stage (0 and I vs. II) and lymphocyte doubling time (>12 vs. 12 months) emerged as prognostically useful among younger CLL patients in the nonadvanced stages.[80] These observations are helpful in planning long-term therapeutic options for these patients, who do not find it particularly reassuring to be informed when they are 40 years of age that their median life expectancy is 10 or 12 years. The same prognosis may not have such a grim impact on a 70-year-old person. Therefore, although it is helpful to know that there are no unique prognostic factors for the younger patients with CLL, the ability of the physician as well as the patient to weigh the risks and benefits of various treatment options is greatly influenced by the patients age.

THERAPY

Period of Observation Without Cytotoxic Therapy

It is prudent to withhold cytotoxic therapy after the initial diagnosis of CLL has been established. [97] Even after a period of observation, it may be the best operational decision in most patients to continue the policy of no treatment with reassessment of this decision at regular intervals of 36 months. Because the clinical course is highly variable in this disease, the physician can use the therapy-free period to observe whether the disease is stable or progressive in an individual patient. The following criteria are most helpful in these periodic reassessments:

1. Chart the blood lymphocyte counts and determine the rate of increase in their numbers, to estimate whether the doubling time (actual or projected) is long (>12 months) or short (12 months).
2. Continue to reassess clinical stage.
3. Note the pattern of lymphocytic infiltration in bone marrow biopsy specimen.
4. Note the presence or absence of constitutional symptoms. The therapy-free period may be extended indefinitely for those patients whose disease appears to be indolent. A minority of patients have an aggressive course of CLL and require institution of some therapy within 24 weeks from the time of initial diagnosis.

Indications for Therapeutic Intervention

A decision to start antileukemic therapy is made in the presence of any of the following indications: [97]

1. Disease-related progressive symptoms (e.g., weight loss without trying, fever without overt infection, night sweats, weakness, or easy fatigability).
2. Progressively worsening anemia or thrombocytopenia.
3. Autoimmune (Coombs-positive) hemolytic anemia or autoimmune thrombocytopenia.
4. "Bulky" lymphadenopathy that is getting progressively worse, and poses risk to the patient from pressure on underlying tissues, or causes significant cosmetic problems.
5. Massive splenomegaly that is worsening progressively or results in hypersplenism.
6. Progressive hyperlymphocytosis. It is not possible to set a rigid upper threshold for the blood lymphocyte count that must be met before starting therapy, but it is our current practice not to allow this count to be >150 × 10^9 /L. Hyperviscosity syndrome associated with hyperlymphocytosis in CLL can be catastrophic. [98] [99] As noted earlier, the rate of increase of blood lymphocyte count is of importance; thus, a short doubling time (12 months, actual or by extrapolation) is an indication for therapeutic intervention.
7. Increased susceptibility to bacterial infections. [50] [51] This may result from marked hypogammaglobulinemia, in which case intravenous high-dose -globulin therapy has a proven protective effect.[100] Severe neutropenia or agranulocytosis may occur in CLL, and may play a major role in the development of bacterial sepsis.[51]

Choices of Therapeutic Modalities

Alkylating Agents

Chlorambucil and cyclophosphamide are the most frequently used initial drugs of choice. Chlorambucil is administered orally and is readily absorbed from the gastrointestinal tract. There are two methods of treatment with this drug: small-dose continuous therapy (0.07 mg/kg/day with adjustments as needed by monitoring blood counts at weekly or biweekly intervals) or large-dose bolus intermittent therapy (0.7 mg/kg at intervals of 3 or 4 weeks). [101] Both methods are approximately equally effective, markedly reducing the size of previously enlarged lymph nodes or spleen, but patient compliance is perhaps better with intermittent therapy. The premise[102] [103] that the intermittent method may enable recovery of normal hematopoietic elements in the marrow before regrowth of leukemic cells between two successive doses and thus be superior to daily continuous administration of chlorambucil was not conclusively proven to be the case in a randomized trial sponsored by the Cancer and Leukemia Group B (CALGB).[101] Our preference is for intermittent chlorambucil, but both methods are commonly used by physicians caring for patients with CLL. The dose-limiting toxicity is bone marrow suppression, which is reversible if it is recognized promptly by frequent blood counts. Nausea, vomiting, mucositis, and so forth, are not major problems with chlorambucil.

The second most frequently used alkylating agent in CLL is cyclophosphamide, which may be given orally or intravenously. This drug, like chlorambucil, is also given either on a daily basis (50150 mg/day PO) or intermittently (1,0001,200 mg every 24 weeks PO). The intravenous dose is the same as the intermittent oral dose. Cyclophosphamide is equal to chlorambucil in its effectiveness in control of CLL, but some patients who are starting to show refractoriness to the latter respond to the former. Besides bone marrow suppression, chemical cystitis is a major side effect of cyclophosphamide, but is avoidable in most cases by ensuring adequate hydration and advising the patients to urinate frequently after each intermittently administered dose. The incidence of nausea is somewhat greater than with chlorambucil. Both drugs are effective as first-line single-agent therapy in CLL. Other alkylating agents (e.g., melphalan or nitrogen mustard) may also be effective, but they are associated with considerable toxicities and are rarely used in CLL.

Fludarabine monophosphate is a fluorinated analogue of adenine that is resistant to deamination by the enzyme adenosine

deaminase. This drug has proved an effective therapy for patients with CLL who are resistant to alkylating agents. [104] Fludarabine is given intravenously at a dose of 25 mg/m^2 /day for 5 consecutive days every month. Usually four to six treatments at monthly intervals are required to achieve the maximally achievable benefits from this drug. Although fludarabine does not cause nausea, vomiting, and hair loss, prolonged use may result in cumulative myelotoxicity and infectious complications. Precautions against tumor lysis syndrome during the initial phase of therapy with fludarabine are advised. Addition of prednisone does not increase response rates of fludarabine, but may increase the risk of opportunistic infections. [105] [106]

Other Chemotherapeutic Drugs

Alkylating agents and fludarabine are the only cytotoxic drugs used as single agents in CLL, but vincristine, doxorubicin, nitrosoureas, mitoxantrone, and others are administered as part of several combination chemotherapy protocols. Even though vincristine has been administered frequently in CLL (being a part of several treatment schedules tested in the lymphomas and used when a patient with CLL is refractory to single-agent therapy), there is no clear evidence that this drug is

indeed useful in the treatment of CLL. Considering the potential for significant peripheral neuropathy associated with vincristine therapy in patients with CLL, who usually are elderly, we recommend either reduced dosage or avoidance of this drug when using a combination chemotherapy schedule in patients with CLL, who usually are elderly.

Glucocorticosteroids

Glucocorticosteroids (e.g., prednisone) are frequently used in CLL either as single agents in the management of autoimmune hemolytic anemia and thrombocytopenia or as part of combination chemotherapy protocols in other cases. Prednisone has significant lymphocytolytic effect; it causes marked reduction in previously enlarged nodes and spleen, and after an initial phase of causing a further increase in blood lymphocytosis, eventually results in a significant decrease when therapy is continued for several days or a few weeks. Side effects of prednisone use (especially in elderly patients with CLL) that should be kept in mind are increased blood sugar levels, worsening of pre-existing osteoporosis, psychiatric reactions ranging from euphoria to severe depression, and increased susceptibility to infections, particularly reactivation of old healed tuberculous lesions. Prednisone is given orally on an intermittent schedule of 4080 mg/day for 57 days every month. In some patients with persistent chronic hemolysis, a lower-dosage maintenance schedule (e.g., 515 mg/day or twice a week) may be necessary.

Androgens or Anabolic Steroids

Androgens or anabolic steroids[107] have been used in patients with CLL with marked anemia (considered to be due to leukemic infiltration of bone marrow or erythroid hypoplasia) to stimulate erythropoiesis. These agents are not uniformly effective, but in some patients have been very beneficial; therefore, in selected situations, their use is justifiable. Side effects include hepatic toxicity, hirsutism, and prostatism. There have been reports of diethylstilbestrol causing significant reduction in blood lymphocyte counts when used in those patients with prostate cancer who happened also to have CLL,[108] but these results have not been confirmed in any controlled trials in CLL.

Radiation Therapy

The most frequently used form of radiation therapy is splenic irradiation,[109] [110] which in selected patients results in prompt reduction in the size of an enlarged spleen, accompanied by evidence of partial control of overall disease. This treatment is particularly beneficial in patients with marked splenomegaly who are not responsive to chemotherapy. Irradiation of large, bulky lymphoid masses localized in one region, nonresponsive to chemotherapy, is also an effective method of treatment. Experimental therapies, including extracorporeal irradiation of blood,[111] mediastinal irradiation,[112] [113] [114] total-body irradiation,[109] [115] [116] and administration of radioactive isotopes,[117] have proved to be either too toxic or ineffective. A consultation with a radiation oncologist experienced in treating CLL and other hematologic malignancies is recommended in deciding whether radiation therapy is advisable.

Splenectomy

Splenectomy [118] [119] [120] [121] [122] [123] is an effective treatment for CLL in specific clinical situations. Patients with extensive splenomegaly unresponsive to chemotherapy and with significant anemia or thrombocytopenia attributed to hypersplenism (some of these patients are not considered for splenic irradiation because of fear of worsening anemia or thrombocytopenia, and some of them may have failed radiation therapy), and patients whose response to steroid therapy is inadequate in the presence of autoimmune anemia are among those considered to be candidates for splenectomy. Beneficial response to splenectomy may last from a few months to several years. Pneumococcal vaccine should be administered before surgery.

Leukapheresis

Leukapheresis [124] [125] has a very limited role in the long-term management of CLL. When the blood leukocyte count is >500 × 10^9 /L either at diagnosis or during the course of the disease, catastrophic complications of hyperviscosity and thromboembolic phenomena may be avoided by resorting to intensive leukapheresis (using one of the automatic cell-separating machines) while simultaneously providing adequate hydration and initiating cytotoxic chemotherapy. Leukapheresis as the sole therapeutic measure is of no benefit because the reduction in blood lymphocyte count so achieved is very transient.

Criteria for Evaluating Response

The NCI-WG[53] [54] and the IWCLL[55] have separately proposed a series of criteria to assess objectively complete or partial remission in CLL. To qualify for complete remission, a patient must have no adenopathy, no hepatosplenomegaly, no constitutional symptoms, normal hemogram (hemoglobin >110 g/L, platelets >100 × 10^9 /L, absolute lymphocytes <4 × 10^9 /L, and absolute neutrophils >1.5 × 10^9 /L), and the bone marrow must contain <30% lymphocytes. To qualify for partial remission, IWCLL criteria require an improvement in clinical stage (e.g., from Binets C to B or A or from Binets B to A). The NCI-WG recommends a similar approach (i.e., improvement in clinical stage), but in addition defines partial remission by a >50% reduction in the previously enlarged nodes, spleen, or liver, together with a >50% improvement of peripheral blood values over baseline (when they do not approach the levels described for complete remission).

Therapy Based on Clinical Stage

Low-risk (stage 0) patients should not be started on cytotoxic therapy unless significant constitutional symptoms develop or there is evidence of an active clinical course, as described previously.

Intermediate-risk (stage I and II) patients should also be observed without antileukemic therapy until there is evidence of

an active clinical course, as described previously, or of any of the indications for therapeutic intervention, also as enumerated previously. In randomized studies, CALGB[126] and the French Cooperative Group[127] assigned early-stage patients to chlorambucil therapy or observation alone. Both these studies showed that early treatment with chlorambucil did not improve survival, although it did correlate with a somewhat slower progression to the more advanced stages. If treatment is indicated, chlorambucil as a single agent is the appropriate first-line therapy. The therapeutic end point is unclear; we do not know whether pushing treatment to try to achieve a complete remission is necessarily beneficial for the patient. The current practice, however, is to at least try to eliminate whatever indication required initiation of therapy in the first instance, and, if possible, to maximize the best achievable level of response without subjecting the patient to undue toxicity.

High-risk (stages III and IV) patients have a uniformly poor prognosis and should be started on cytotoxic therapy. A large trial by CALGB [101] revealed that if at least a partial (complete if possible) remission is achieved after chlorambucil and prednisone therapy, there is a significant improvement in survival compared with survival in those patients who failed to achieve such a response. This was the first study that defined the therapeutic end point in advanced CLL (i.e., a partial or complete remission). The French Cooperative Group[128] demonstrated a significantly better survival of advanced-stage patients after treatment with COP (cyclophosphamide, vincristine [Oncovin], prednisone) together with low-dose doxorubicin (CHOP), compared with patients who received COP without doxorubicin. [128] The results of this study, however, have not been confirmed by subsequent trials, nor has there been any evidence that a somewhat higher response rate with CHOP provides a survival advantage over COP, or chlorambucil and prednisone therapy. [129] [130] [131]

Fludarabine as Initial Therapy

Among the three nucleoside analogues fludarbine, pentostatin, and 2-chlorodeoxyadenosine that have been used in CLL, only fludarabine has been tested in prospectively controlled clinical trials in previously untreated patients with active disease. These results demonstrate clear superiority of fludarabine in inducing a higher incidence of remissions (both complete and overall) compared with patients treated with chlorambucil or combination chemotherapy. [132] [133] Although use of fludarabine as a front-line agent in CLL has so far not been shown to increase the overall duration of survival, encouraged by the higher response rates, some clinicians are using this drug as the initial therapy. We recommend including fludarabine alongside chlorambucil and cyclophosphamide among the list of drugs worthy of consideration of use in front-line treatment of CLL and making the choice between it and an alkylator on the individual patients clinical status, such as age, co-morbid conditions, and overall goals of therapy (whether it is palliative or likely to be followed by high-dose chemotherapy and stem cell transplantation). Fludarabine, like chlorambucil and cyclophosphamide, is useful in all stages of CLL when therapeutic intervention with drugs is indicated. It is advisable to avoid the

use of glucocorticosteroids with fludarabine because of an increased risk of opportunistic infections.

Second-Line Therapy

Fludarabine

Fludarabine has proven to be an extremely effective drug for patients with CLL who have failed prior therapy with an alkylating agent. [104] [105] [106] A large proportion of such patients obtain objective responses, and responding patients have an improved survival rate.

Combination Chemotherapy

Other multiagent combination chemotherapies (e.g., POACH [COP plus cytosine arabinoside and doxorubicin], [134] devised at the M.D. Anderson Hospital in Houston, TX) or the M-2 protocol[135] (COP plus melphalan and carmustine, developed for treatment of multiple myeloma at the Memorial Sloan-Kettering Cancer Center in New York) also have some promise in the management of advanced stages of CLL, but the results are not uniformly consistent.

Special Therapeutic Issues

High-Dose Intravenous Immunoglobulin

As mentioned earlier, significant hypogammaglobulinemia is frequently observed in CLL, rendering these patients highly vulnerable to bacterial infections. With the availability of purified immunoglobulins for intravenous administration, it is now possible to treat those patients with CLL who are at increased risk of infections. In a multi-institutional, placebo-controlled, randomized trial, [100] it was observed that replacement therapy with intravenous -globulin provides a significant protection from major bacterial infections in patients with CLL who would otherwise be at risk. The -globulin dosage in this study was 400 mg/kg body weight every 3 weeks for 1 year. Although such therapy appears rather expensive, when the potential costs of treating bacterial pneumonia in a hospital inpatient setting are considered, the cost of such preventive measures becomes justifiable in certain selected patients who are at high risk for infections. We have been using a lower dosage (200 mg/kg body weight) of intravenous immunoglobulin, which appears to provide protection from infections at significantly reduced costs. A multicenter trial comparing a high dosage (500 mg/kg/mo) with a lower dosage (250 mg/kg/mo) has been conducted, and the preliminary results show that both dosages are equally effective in preventing bacterial infections in the at-risk patients with CLL. [136] Thus, if the patients are selected for their previous history of major bacterial infections or severe hypogammaglobulinemia and the dosage of intravenous immunoglobulin is lowered, the overall cost of such a preventive measure would not remain as big an issue as was previously considered.[137] This therapy is well tolerated and can be given at the patients home or in outpatient clinics.

Interferon-

Although initial results[138] with IFN- in advanced stages of CLL were very disappointing, subsequently performed studies suggest that this agent may benefit patients in early stages of the disease, or when the tumor burden is relatively low. [139] [140] [141] [142] The clinical benefits from a combination of IFN- and chlorambucil and prednisone have been reported, but need confirmation by additional studies. [143] The mechanism of action of IFN- in CLL is not understood. In vitro, it causes differentiation of CLL cells,[144] and there are also data to suggest that it inhibits apoptosis of CLL cells. However, there is no evidence of direct cytotoxicity from IFN-; it may interfere with cellular interactions necessary for the survival and growth of CLL cells or, alternatively, it may inhibit the proliferation of the small fraction of clonogenic CLL progenitors.[145] Until more data from some of the recently completed trials become available, IFN- should be considered an experimental agent in the treatment of CLL.

Pure Red Cell Aplasia

Pure red cell aplasia is a relatively rare cause of anemia in CLL. Some studies suggest that suppressor cytotoxic T cells exert inhibitory effects on erythroid progenitor cells in the bone marrow.[57] [58] Therefore, an immunosuppressive agent such as

cyclosporine has been proposed for therapy of pure red cell aplasia with the objective of attacking the erythropoiesis-inhibiting effect of suppressor T cells. Since the first report of Chikkappa et al.[146] of successful treatment of pure red cell aplasia in CLL with cyclosporine, others [147] [148] have confirmed these results in a small number of patients. This therapy is well tolerated, the only reported side effect being mild and reversible renal toxicity. A reticulocyte response is noted within 2 weeks of therapy and is soon followed by an increase in hemoglobin levels. We have observed [147] that not only hemoglobin but platelet counts increased in a patient with CLL who had significant, refractory anemia and thrombocytopenia before cyclosporine therapy.

Late Complications and Terminal Events

The quality of life and performance status of patients with CLL gradually deteriorate with progression of the disease, and a refractoriness to all cytotoxic therapies becomes increasingly evident. A marked degree of persistent anemia is not unusual in the last phases of this disease, and the patients require frequent and regular transfusions of packed red cells. Recombinant human erythropoietin may be effective in some patients with anemia. Although platelet transfusions are not routinely recommended in patients with profound degrees of thrombocytopenia who have no evidence of any bleeding, such transfusions are necessary in the presence of bleeding.

Infections

Infections from bacterial, viral, and fungal agents are the most important cause of morbidity and mortality in CLL. [50] [51] There are several factors that contribute to the increased incidence of infections in CLL, but advanced stages or long duration of the disease, hypogammaglobulinemia, and neutropenia (from CLL or from myelosuppressive effects of chemotherapy) are the most significant. The new nucleoside analogues, which have found increasing use in the therapy of CLL, are known to cause marked lymphopenia, especially of the T-helper cell populations. [104] [105] [106] This in turn renders the patients vulnerable to infections with opportunistic organisms. Therapy is directed at identification of the causative organisms and use of the appropriate antibiotics after consultation with an infectious diseases specialist. Judicious use of granulocyte-stimulating factor is helpful in septic patients with chemotherapy-induced neutropenia. Prophylactic use of high-dose intravenous immunoglobulin has been discussed previously. Prophylactic use of antibiotics in neutropenic or hypogammaglobulinemic patients is not recommended.

Richter Syndrome

A large cell lymphoma develops in approximately 110% of patients with CLL. It is known as Richter syndrome because it was Richter who first described this association.[149] In a retrospective review of 1,374 patients with CLL seen at the M.D. Anderson Cancer Center during a 20-year period between 1972 and 1992, Richter transformation was reported to have developed in 2.8%. [150] Richter syndrome is often characterized by sudden clinical deterioration, development of systemic symptoms, and usually a rapid increase in the size of a lymphoid mass at one site. Less frequently, a monoclonal gammopathy or lytic bone lesions are observed. The histologic type of lymphoma is either diffuse large cell or its immunoblastic variant. [150] One of our patients had a lymphoma of Burkitt-type pathology. Immunoglobulin gene rearrangements and light chain isotype analyses in the study at the M.D. Anderson Cancer Center suggest that CLL and Richter syndrome had a common origin, indicating that a bona fide transformation occurred in the CLL cells. [150] The published literature, however, supports both theories: [151] [152] some studies show that lymphoma cells and CLL cells have identical features, whereas others show that lymphoma cells arise de novo with characteristics distinct from those of CLL cells. There have been separate reports of two cases extensively studied with molecular markers, one conclusively proving a common origin and another equally conclusively revealing that CLL cells and lymphoma cells were clonally distinct. [151] [152] These reports prove that diffuse large cell lymphoma may occur both ways: by a transformation of the original clone of CLL cells as well as through development of a new or second malignancy. It is customary to treat patients with Richter transformation with chemotherapeutic agents known to be effective in treating de novo diffuse large cell lymphoma. Therapy has so far proven to be uniformly unsuccessful, and the overall duration of survival of patients is approximately 6 months after Richter transformation.

Prolymphocytoid Transformation

In addition to Richter transformation, prolymphocytoid transformation may occur terminally in approximately 10% of patients with CLL. The morphology of blood lymphocytes changes into that of a large cell with convoluted nucleus, immature-appearing nuclear chromatin, and one or two large nucleoli. Therapy of this complication also is unsatisfactory. Besides the drugs commonly used in therapy of CLL, antilymphoma agents have also been tried, but the success rate has been low. Acute leukemia and multiple myeloma are extremely rare late events in CLL.

Patients with CLL are known to have a higher incidence of development of a second malignancy (e.g., cancer of the gastrointestinal tract, lung, or any other organ) than the general population. Patients with CLL also have a high risk of development of skin cancers.

Paraneoplastic Pemphigus: An Autoimmune Complication

Anhalt et al.[153] have suggested that the term paraneoplastic pemphigus, which is clinically distinct from pemphigus vulgaris and pemphigus foliaceus, be applied to the painful, persistent, and treatment-resistant erosions of the oral mucosa, vermilion borders of the lips, and conjunctiva that appear in patients with various types of cancers, including CLL. These acantholytic mucocutaneous lesions are characterized by autoantibodies that are pathogenic after passive transfer.

FUTURE DIRECTIONS

Although chlorambucil and cyclophosphamide have been the mainstays of chemotherapy in CLL over the last 2030 years and both drugs induce a high rate of partial remissions, it is also recognized that no treatment available to date has resulted in improvement of the natural history of this disease. The overall median survival time has remained at approximately 6 years. Besides the two nucleoside analogues discussed in the following sections, the future directions in the treatment of CLL are likely to lead us into the areas of bone marrow and stem cell transplantation and monoclonal antibodies.

2-Chlorodeoxyadenosine

2-Chlorodeoxyadenosine (2-CdA) is also a purine analogue like fludarabine, and is resistant to the action of adenosine deaminase. This drug has proven to be extremely effective in inducing lasting remissions in hairy cell leukemia. 2-CdA has been used in a relatively small number of patients with CLL, mostly previously treated and refractory to alkylating agents.[154] The preliminary results are very encouraging, and controlled clinical trials in previously untreated patients with CLL are being planned; the results of such studies will have an impact on the future

therapies of this disease. 2-CdA is given by a 2-hour intravenous infusion at a dose of 0.120.14 mg/kg/day for 5 days every month. Most patients obtain maximally attainable response after 46 months of therapy. Myelosuppression and immunosuppression are the major toxicities of 2-CdA.

Pentostatin

Pentostatin (deoxycoformycin) has a chemical structure somewhat similar to that of 2-Cda and is a potent inhibitor of adenosine deaminase. This drug also seems to offer benefit[155] [156] to previously treated patients with CLL, but it is used less often in CLL than fludarabine or 2-CdA.

Bone Marrow Transplantation as Therapy

With the recognition that CLL is being diagnosed today in increasing numbers in patients in the 35- to 50-year age group, even a relatively long survival outlook of 610 years is not satisfactory for people this young. Simultaneously, we are developing an increasing level of expertise in performing bone marrow transplantation and in managing the various complications of this therapy in several other types of human malignancies. In the United States [157] [158] and in Europe,[159] results of small trials have been reported that show that bone marrow transplantation is a feasible approach in properly selected groups of patients with CLL. An allogeneic bone marrow transplantation is preferred if a sibling is available as an HLA-compatible donor. In the absence of a compatible donor, autologously harvested marrow (after intensive chemotherapy-induced maximal reduction of leukemic cell mass in the patients bone marrow) is reinfused after myeloablation with massive doses of chemotherapy. The preliminary results are encouraging, and in the next few years we expect to learn more about this interesting and promising therapy. [158] [159]

Monoclonal Antibodies

IDEC-C2B8, a chimeric antibody[160] directed against CD20 that is expressed to some extent in most leukemic B cells in patients with CLL, has received approval by the U.S. Food and Drug Administration for treatment of low-grade lymphoma. CALGB has initiated a trial to study the efficacy of this new monoclonal antibody used either simultaneously or sequentially with fludarabine in previously untreated patients with CLL who have active disease.

CAMPATH-1H monoclonal antibody was developed by humanization of rodent variable immunoglobulin regions with human immunoglobulin gene sequences that present fewer xenogenic peptide sequences and are thus less immunogenic.[161] Our own limited experience with CAMPATH-1H has been extremely promising,[162] and we are continuing these studies on a larger number of patients. Osterberg et al. have reported excellent responses with CAMPATH-1H in both previously treated as well as untreated patients with CLL.[163] [164]

T-CELL CLL

The T-cell variant of CLL, a rare form accounting for only 25% of all CLL cases, is briefly reviewed here. The diagnosis is suspected when confirmation of a lymphocytosis in blood and bone marrow is accompanied by phenotype analysis of blood lymphocytes revealing a preponderance of T cells. [165] Within this rare group of diseases there is considerable heterogeneity with respect to clinical features, clinical course, and phenotypic markers. [165] The most benign end of the spectrum consists of large granular lymphocytic leukemia associated with neutropenia, a T8+, T4, T3+ phenotype (suppressor T lymphocytes), multiple autoantibodies (rheumatoid factor, antinuclear antibodies), splenomegaly, and absence of lymphadenopathy. Cytogenetic, immunologic, and functional studies indicate that this disease results from a clonal proliferation of immature NK cells. [166] The clinical course is variable, but in most cases is rather indolent. Treatment is generally based on corticosteroids, with the addition of alkylating agents if there is evidence of disease progression. The T4 CLL variant [167] [168] usually affects patients <40 years of age and is associated with hyperlymphocytosis and marked generalized lymphadenopathy, frequently involving the skin and central nervous system. The lymphocyte morphology reveals small, mature-appearing cells with a notched nucleus that lacks a nucleolus and without cytoplasmic granules. The phenotype is T3+, T4+l, and T8. The clinical course is aggressive, the response to the usual cytotoxic therapy is inadequate, and overall survival is <2 years. Sézary syndrome is the leukemic manifestation of cutaneous T-cell lymphoma. The lymphocyte phenotype is CD4+, CD2+, CD3+, and CD5+. Treatment is directed to the underlying lymphoma. Adult T-cell leukemia, which is seen in certain areas of Japan, the Caribbean, and in the southeastern United States, is an HTLV-1-associated disease and bears little relation to CLL.

Chapter 73 - Hairy Cell Leukemia

Martin S. Tallman
David Hakiman
LoAnn C. Peterson

Hairy cell leukemia (HCL) is an uncommon chronic lymphoproliferative disorder initially described by Bouroncle and colleagues in 1958. [1] Although the etiology remains unknown, the morphologic features and clinical manifestations have been well defined over the past 40 years. HCL is characterized by splenomegaly, pancytopenia, and infiltration of the bone marrow with lymphocytes that have irregular cytoplasmic projections when identified in the peripheral blood [2] [3] (Fig. 73-1). The disease is now recognized as a clonal B-cell malignancy, as identified by immunoglobulin gene rearrangements. [4] [5] [6] The expression of B-cellassociated surface antigens reflects differentiation between the immature B cell of chronic lymphocytic leukemia and the plasma cell of multiple myeloma. [7] [8] Although many patients have a paucity of symptoms, others have life-threatening pancytopenia, painful splenomegaly, or constitutional symptoms requiring treatment. [9] [10]

Splenectomy, the treatment of choice for many years, led to normalization of the peripheral blood counts in approximately one half of all cases. [11] [12] [13] [14] Interferon- was first introduced for patients with HCL in 1984, [15] and although a high overall response rate was achieved, most responses were partial. [14] [15] [16] [17] [18] [19] [20] [21] [22] Furthermore, patients invariably relapsed when the drug was discontinued. The most remarkable progress has occurred with the introduction of the two purine analogs, 2-deoxycoformycin (2-DCF) [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] and 2-chlorodeoxyadenosine (2-CdA). [35] [36] [37] [38] [39] [40] Most patients with both previously treated and untreated HCL achieve

Figure 73-1 A hairy cell in the peripheral blood smear from a patient who presented with anemia, thrombocytopenia, and splenomegaly. The nucleus of the hairy cell is eccentrically located and exhibits a reticular or netlike chromatin. The cytoplasmic borders are irregular, with fine, hairlike projections. (Wright-Giemsa stain; orig. mag. × 1,000.)

durable complete remission (CR) with either of these agents. The purine analogs appear to have changed the natural history of this disease.

EPIDEMIOLOGY

In the United States, HCL represents 2% of adult leukemias; approximately 600800 new patients are diagnosed each year. [41] [42] Although there have been several reports of familial HCL, there is no known genetic predisposition. [43] [44] [45] [46] [47] [48] [49] The median age of diagnosis is 52 years, and the disease occurs in men more often than in women by a ratio of approximately 4 to 1. [50] Although the incidence is similar in the United States and Great Britain, [41] [42] classic HCL is rare in Japan, where a distinct variant form occurs. [51] [52] [53]

ETIOLOGY AND PATHOGENESIS

The etiology of HCL has not been determined. Although some investigators have suggested that exposure to benzene, [54] [55] organophosphorus insecticides, [56] or other solvents[57] may be associated with disease development, this has not been confirmed by other reports. [58] Exposure to radiation, [59] agricultural chemicals,[55] wood dust,[42] and a previous history of infectious mononucleosis[57] have also been suggested as etiologic associations; however, a causal relationship has not been firmly established.

CLINICAL PRESENTATION

When a middle-aged man presents with splenomegaly, pancytopenia, and circulating hairy cells, the diagnosis is usually clear (Table 73-1). The initial evaluation of a patient with HCL should include a history and physical examination, a complete blood count with differential count, review of the peripheral blood smear, routine serum electrolytes, blood urea nitrogen and creatinine, hepatic transaminases, a bone marrow aspirate and trephine biopsy, tartrate-resistant acid phosphatase (TRAP) stain, and immunophenotyping of peripheral blood or bone marrow aspirate by flow cytometry (Table 73-2).

At the time of diagnosis, most patients present with symptoms related to anemia, neutropenia, thrombocytopenia, or splenomegaly. Approximately 25% of patients present with fatigue or weakness, 25% with infection, and 25% because of the incidental discovery of splenomegaly or an abnormal peripheral blood count. [50]

Patients usually appear well at the time of diagnosis. Invariably, the most common and often sole physical finding is splenomegaly, occurring in approximately 80% of patients.[3] [50] The spleen is palpable 5 cm below the left costal margin in approximately 60% of patients. Hepatomegaly occurs in approximately 20% of patients. Unlike many other lymphoproliferative disorders, peripheral adenopathy is uncommon, with less than 10% of patients presenting with peripheral nodes larger than 2 cm. Although adenopathy is not common at diagnosis, internal adenopathy may develop after a prolonged disease course, [60] [61] and is present in 75% of patients at autopsy.[62]

Patients with HCL are susceptible to both gram-positive and

gram-negative bacterial infections,[63] but are also susceptible to atypical mycobacterial infections, [64] particularly *Mycobacterium kansasii*, as well as invasive fungal infections.[65] Acute bacterial infections result from neutropenia, whereas opportunistic infections occur because of cellular immune defects, including monocytopenia. Other opportunistic infections that have been reported include Legionnaires disease, [65] toxoplasmosis, [66] and *Listeria monocytogenes* infection.[67]

Patients with HCL may have associated systemic immunologic disorders[68] including scleroderma and polymyositis,[69] and polyarteritis nodosa.[70] HCL has been associated with other cutaneous lesions such as erythematous maculopapules [71] and pyoderma gangrenosun.[72] [73] An associated coagulopathy manifested by factor VIII antibodies has been reported.[74] Osseous involvement has also been described, primarily lytic lesions in the axial skeleton, usually the proximal femur. [75] [76] Rarely, osteolytic lesions may be associated with paraproteinemia. [77] A rare case of HCL occurring with systemic mast cell disease has been reported.[78]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

LABORATORY EVALUATION

Pancytopenia is present in approximately 50% of patients with HCL at diagnosis, whereas most other patients present with suppression of only one or two cell lines. [3] [50] Most patients with HCL present with leukopenia, although 1020% of patients exhibit a leukemic phase with a white blood cell count >1020 × 10^9 per liter. Monocytopenia is a frequent, but often overlooked finding. [1] [3] [50] [79]

Other laboratory findings include abnormal hepatic transaminases (19%), azotemia (27%), and hypergammaglobulinemia (18%), which is rarely monoclonal. [3] [77] [79] Hypogammaglobulinemia is uncommon.

Hairy cells can be identified in Wrights-stained peripheral blood smears from most patients with HCL. The number of circulating hairy cells is variable, but is usually low. In some patients, hairy cells can be found only after a prolonged search. Bone marrows are often inaspirable, resulting in a dry tap. However, when bone marrow aspiration is successful, hairy cells similar to those in the blood are found.

The morphologic features of hairy cells are characteristic (Fig. 73-1). The neoplastic cells are approximately one to two times the size of a small lymphocyte. The nuclei are usually round, oval, indented, or monocytoid; rarely, they appear convoluted. [80] The nuclei are located in a central or eccentric position. The chromatin pattern is reticular or netlike in appearance; nucleoli are indistinct or absent. The cytoplasm is variable in amount and pale blue-gray in color. The cytoplasmic borders are irregular with fine, hairlike projections or ruffled borders. Occasionally, cytoplasmic granules are present. Rarely, the cytoplasm exhibits rod-shaped inclusions that correspond to ribosomal lamellar complexes, observed ultrastructurally in approximately 40% of cases. [81]

Examination of the bone marrow trephine biopsy plays a critical role in the diagnosis of HCL because of the characteristic histopathologic appearance [82] [83] [84] [85] (Fig. 73-2). The bone marrow is hypercellular in most patients. Hairy cell infiltration may be diffuse

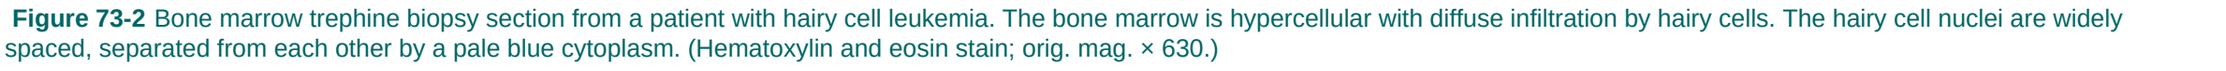

Figure 73-2 Bone marrow trephine biopsy section from a patient with hairy cell leukemia. The bone marrow is hypercellular with diffuse infiltration by hairy cells. The hairy cell nuclei are widely spaced, separated from each other by a pale blue cytoplasm. (Hematoxylin and eosin stain; orig. mag. × 630.)

or focal. In patients with diffuse involvement, large areas of the bone marrow are replaced by hairy cells, with complete effacement of the bone marrow in some patients. When the marrow is focally involved, the infiltrates are randomly situated and may include paratrabecular locations. Residual hematopoietic cells are usually decreased in HCL. The granulocytes are typically more severely reduced than erythroid precursors and megakaryocytes. The hairy cell nuclei are widely separated from each other by abundant, clear or lightly eosinophilic cytoplasm. Mast cells are often numerous. Extravasated red cells are frequently seen and blood lakes, similar to those observed in the spleen, may also be present. The hairy cell nuclei typically merge with the surrounding normal hematopoietic tissue. The complete extent of involvement of the bone marrow by HCL may be difficult to appreciate in routinely stained sections, and is usually accentuated when examined with antibodies to B lymphocytes. Approximately 1020% of patients exhibit a hypocellular bone marrow (Fig. 73-3). The hypocellularity may be severe, with small numbers of hairy cells infiltrating around

Figure 73-3 A markedly hypocellular bone marrow from a patient with hairy cell leukemia who presented with pancytopenia and splenomegaly. A markedly hypocellular bone marrow in hairy cell leukemia may closely resemble aplastic anemia. (Hematoxylin and eosin stain; orig. mag. × 312.)

Figure 73-4 The hairy cells in the hypocellular bone marrow biopsy shown in Figure 73-3 are accentuated by immunostaining for the B-cell antigen CD20. (Orig. mag. × 400.)

fat cells [81] [82] [83] [84] [85] [86] (Fig. 73-4). The morphology of these latter cases strongly resembles aplastic anemia.

Reticulin stains of the bone marrow trephine biopsy almost always show a moderate to marked increase in reticulin fibers. In some cases, the reticulin fibers appear to surround individual hairy cells, with the fibrosis extending into the adjacent, more normal-appearing bone marrow tissue.

Cytochemical demonstration of TRAP activity has been traditionally used to confirm the diagnosis of HCL. [87] In HCL, the enzyme activity resides in isoenzyme 5, one of seven acid phosphatase isoenzymes in human leukocytes. TRAP-positive cells are found in almost all cases of HCL at diagnosis, although the percentage of positive cells varies greatly among patients. A positive TRAP stain in conjunction with a characteristic bone marrow biopsy is essentially diagnostic of HCL. However, a wide variety of other hematopoietic neoplasms, including prolymphocytic leukemia, Sézary syndrome, and adult T-cell leukemia/lymphoma, may rarely show positive reactions. The TRAP reaction is usually performed on peripheral blood cells, marrow aspirates, or touch preparations of bone marrow; a monoclonal antibody against TRAP that is reactive in paraffin-imbedded material has also been described. [88] The introduction of immunophenotyping for the diagnosis of chronic lymphoproliferative disorders has made reliance on the TRAP stain less important.

Hairy cell leukemia is a B-cell neoplasm, as demonstrated by both immunologic and molecular studies. [6] [89] Hairy cells exhibit a mature B-cell phenotype and typically express one or more heavy chains and monotypic light chains. Hairy cells strongly express panB-cell antigens, including CD19, CD20, and CD22, and hairy cells usually lack CD5 expression.[90] The mucosal lymphocyte antigen, CD103, has been shown to be a highly sensitive marker for HCL. [91] CD103 is a member of the integrin family and is also present on intraepithelial T cells and some activated lymphocytes. The presence of CD103, when coexpressed with other panB-cell markers, is strongly suggestive of HCL. Hairy cells also strongly express CD11c, a marker associated with myelomonocytic cells and CD25, the interleukin-2 receptor.[90] [91]

CD20 (L26) and DBA.44, B-cellassociated antibodies, react with hairy cells in fixed, routinely processed tissue sections (Fig. 73-4). Neither is specific for HCL, but these antibodies are useful in highlighting the extent of bone marrow infiltration at the time of diagnosis and following therapy. [92] [93] [94] [95]

Clonal cytogenetic abnormalities are present in approximately two thirds of patients with HCL. The most frequently

involved chromosomes include chromosomes 1, 2, 5, 6, 11, 19, and 20. In particular, chromosome 5 is altered in 40% of patients, most commonly as trisomy 5, pericentric inversions, and interstitial deletions involving band 5q13. [96] [97]

Splenic involvement in HCL is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy or replacement of the white pulp. Blood-filled sinuses, lined by hairy cells, are often a prominent but not pathognomonic finding in the spleen; they have been referred to as pseudosinuses. [98]

The liver shows both sinusoidal and portal infiltration by hairy cells. Involved lymph nodes commonly exhibit partial effacement, with hairy cells infiltrating the paracortex and medulla in a leukemic pattern. The leukemic cells often surround residual lymphoid follicles and extend through the capsule.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of HCL includes other small B-cell lymphoproliferative disorders associated with splenomegaly, [99] such as prolymphocytic leukemia,[100] [101] [102] splenic marginal zone lymphoma (splenic lymphoma with villous lymphocytes),[103] [104] [105] [106] and HCL variant[107] [108] [109] (Table 73-3). Patients with prolymphocytic leukemia typically present with splenomegaly, but this disorder can usually be readily distinguished from HCL by the marked elevation of the white blood cell count and the morphology of the prolymphocytes. Splenic marginal zone lymphoma exhibits some clinical and morphologic features similar to HCL but, in contrast, the cells usually do not exhibit TRAP positivity, the bone marrow infiltrates are sharply demarcated, and the immunophenotypic profile differs from HCL, including negativity for CD103.[106] HCL variant exhibits morphologic features intermediate between hairy cells and prolymphocytes, and is associated with leukocytosis, lack of monocytopenia, and expression of the interleukin-2 receptor chain, but not the chain (CD25). [110] Finally, systemic mastocytosis may resemble the variant of HCL in which the hairy cells are spindle shaped in the biopsy sections. Immunohistochemical studies show the mast cells, unlike hairy cells, to be negative for B-cell markers and positive for lysozyme and tryptase.[81]

TREATMENT

Indications

Because HCL usually has an indolent course, treatment may not be required for many months or years after the diagnosis is established. Therapy is indicated when the patient has significant cytopenias; symptomatic organomegaly or adenopathy; infections; or constitutional symptoms such as fever, night sweats, or fatigue. Typical peripheral blood counts that warrant treatment include an absolute neutrophil count of <1,000/l, a hemoglobin <11.0 g/dl, or a platelet count <100,000/l.

Role of Splenectomy

Splenectomy was the first effective therapy for HCL and remained the initial treatment of choice until recently. [11] [12] [13] [14] Although

TABLE 73-3 -- Differential Diagnosis of Hairy Cell Leukemia

Prolymphocytic leukemia
Splenic marginal zone lymphoma

Systemic mastocytosis

MANAGEMENT

For patients with newly diagnosed HCL who require treatment (absolute neutrophil count <1,000/l, hemoglobin <11.0 g/dl, and platelet count <100,000/l or symptomatic organomegaly), we administer 2-chlorodeoxyadenosine (2-CdA) 0.1 mg/kg/day by continuous IV infusion for 7 days as an outpatient procedure by portable pump using a midline percutaneous intravenous central catheter (PICC). If fever of 100.5°F or greater develops while the patient is neutropenic, blood cultures are drawn, urine culture and chest radiography are done, and oral ciprofloxacin 750 mg po bid is administered. If cultures are sterile at 2448 hours, naproxen 250 mg po bid is added for 24 days. 2-CdA is not discontinued. Hematopoietic growth factors are not routinely given. The platelet count is usually the first cell line to recover (within 24 weeks), followed by the white blood cell count, and, finally, the hemoglobin. We repeat the bone marrow at 3 months to assess remission status. We currently do not administer a second cycle of 2-CdA for patients with MRD.

For patients with relapsed HCL who have been previously treated with either splenectomy, interferon, or 2-deoxycoformycin (2-DCF), we administer a repeat cycle of 2-CdA as described previously. For patients who relapse after a single cycle of 2-CdA, we give a second cycle of 2-CdA. For patients with a relapsed HCL previously treated with at least two prior cycles of 2-CdA, we consider either 2-DCF 4 mg/m^2 IV every 2 weeks for 36 months or interferon 2 × 10^6 units/m^2 three times each week for 1218 months.

splenectomy does not produce pathologic remissions in the bone marrow, all three cell lines return to normal in approximately 4070% of patients. [13] [111] This response is maintained for a median of 20 months in approximately two thirds of patients, and the overall 5-year survival rate is approximately 70%. [111] There appears to be no correlation between spleen size and response to splenectomy.

Chemotherapeutic Approaches

A variety of chemotherapy regimens have been used and reported in several small series of patients who have failed splenectomy. [112] Chlorambucil at a dose of 4 mg/day for 6 months produced an improvement in blood counts in some patients; however, neutropenia did not resolve and patients remained at significant risk of infection. Combination chemotherapy with rubidazone, cytosine arabinoside, and cyclophosphamide produced complete pathologic remissions lasting more than 2 years in three of seven patients, but three other patients died of infection during the period of marrow aplasia. [113] More recently, CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy was reported to produce long-lasting normalization of the peripheral blood counts with significantly less morbidity.[114] High-dose chemotherapy with syngeneic (identical twin) bone marrow transplantation has been successfully carried out in one patient who enjoyed a prolonged disease-free survival of more than 5 years. [115] HCL is clearly sensitive to chemotherapy, but toxicity has been significant. Although hematopoietic growth factors may diminish this toxicity, newer therapies such as the purine analogs have made conventional chemotherapy treatment unnecessary.

Interferon

Interferon was first reported to be an effective therapy for patients with HCL in 1984, [15] and since then numerous large studies have confirmed its activity. [15] [16] [17] [18] [19] [20] [21] [22] The precise mechanism of action of interferon is not known, but may be due to a reduction in the production of cytokines such as granulocyte colony-stimulating factor, granulocytemacrophage colony-stimulating factor, interleukin-3, interleukin-6, and tumor necrosis factor, perhaps related to the characteristic monocytopenia associated with interferon treatment. [116] Despite a high overall response rate or 7590%, most patients achieve only partial remission (PR; defined as normalization of all peripheral blood counts). [19] [20] Interferon is commonly administered subcutaneously at a dose of 2 million international units/m ^{2} subcutaneously three times a week for 1218 months. During the first 2 months of treatment, the white blood cell count and hemoglobin are often decreased, occasionally necessitating transfusion. The platelets normalize first in responding patients, followed by the hemoglobin and the white blood cell count. An absolute neutrophil count >1,500/l is achieved after a median of 5 months of therapy. Common toxicities include flulike symptoms, anorexia and fatigue, nausea and vomiting, diarrhea, dry skin, peripheral neuropathies, and central nervous system dysfunction. The latter is usually manifested as depression or memory loss. Elevated hepatic transaminases are the most common laboratory abnormality, other than myelosuppression. The median failure-free survival after discontinuing interferon ranges from 6 to 25 months in different series. [19] [20] [21] [117] Patients with >30% hairy cells in the marrow or a platelet count of <160,000/l at the end treatment have a higher risk of early relapse. [19] [20] [21] In addition, patients who express the CD5 antigen appear to respond poorly to interferon. [118] A recent report suggests that patients can be maintained on long-term interferon at a dose of 3 million units subcutaneously given three times a week with minimal toxicity. Sixty percent of patients have sustained their initial response for a median of 5 years, 9% discontinued therapy early because of unexpected neurologic toxicity, and only 13% stopped therapy because of progressive disease. [119] In summary, treatment of HCL with interferon is effective, resulting in normalization of the peripheral blood counts in most patients. However, CRs are uncommon, and failure-free survival is usually short after discontinuation of treatment.

Purine Analog Therapy

Twenty-five years ago, Giblett and colleagues observed that 30% of children with severe combined immunodeficiency syndrome lacked the enzyme adenosine deaminase (ADA). [120] It appeared that the accumulation of the triphosphorylated form of deoxyadenosine was responsible for lymphocyte destruction. [121] Therefore, the deliberate inhibition of ADA emerged as a potentially useful antileukemic strategy. The methods to accomplish this included the development of agents to bind irreversibly to ADA or to resist the action of the enzyme.

2-Deoxycoformycin

2-Deoxycoformycin was the first agent found to induce a significant number of CRs in HCL. [23] [24] This drug is an irreversible inhibitor of ADA, [122] an enzyme found in all lymphoid cells that is important in purine metabolism. Deoxyadenosine triphosphate metabolites accumulate and are thought to be responsible for the cytotoxicity in HCL. [123] [124]

Several studies using various dosing schedules of this drug have been published (Table 73-4). [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] In an Eastern Cooperative Oncology Group study, 50 patients with HCL were treated with 2-DCF at a dose of 5 mg/m ^{2} /day intravenously (IV) for 2 consecutive days every 2 weeks until maximum response. [27] This therapy resulted in a CR rate of 64% and an overall response of 84%, with most patients achieving maximal response within 6 months. Toxicities were moderate and included nausea, vomiting, skin rash, and conjunctivitis, as well as significant neurologic toxicities in four patients. Neutropenia was life threatening in 70% of patients; however, this was limited to the first two to three cycles of therapy. Mortality as a result of therapy was attributable to infection in 6% of patients. Other investigators have administered a lower dose of 2-DCF and have produced similar results. [25] [26] In one study, patients were treated with 2-DCF at dose of 4 mg/m^2 IV every other week, and CR was attained in 20 of 23 patients (87%). [25] In this study, infections were infrequent and there were no deaths. CD4+ T cells were found to be significantly decreased after treatment. However, this laboratory finding was reversible, and no opportunistic infections or secondary malignancies were noted after 2 years of follow-up. In an additional study, patients were treated with 2-DCF at a dose of 4 mg/m ^{2} IV weekly for 3 consecutive weeks with therapy repeated every 8 weeks. [26] CR was achieved in 25 of 28 patients (89%) after completing two cycles of therapy. Transient neutropenia occurred during the first cycle only, and 12 patients had fever or infection, but no deaths occurred.

A large, prospective, randomized study showed that the CR rate and relapse-free survival rate are significantly better with 2-DCF than interferon. [34] However, the overall survival rate was not different between these two treatments.

2-Chlorodeoxyadenosine

2-Chlorodeoxyadenosine is a purine analog that does not inhibit ADA, but is resistant to the enzyme. This agent accumulates in the lymphoid cells presumably because they are rich in the enzyme deoxycytidine kinase. [121] This enzyme phosphorylates 2-CdA, creating a deoxynucleotide that cannot readily exit the cell. These deoxynucleotides are thought to be responsible for the lack of lymphocyte development in ADA-deficient

children.[120] 2-CdA was first reported to be effective for HCL by Piro and colleagues in 1990. [35] Twelve patients were treated with a single cycle of 2-CdA at a dose of 0.1 mg/kg/day by continuous infusion for 7 days, and a complete pathologic remission was obtained in 11 of the 12 patients within 8 weeks of treatment. None of the patients had relapsed at a median of 15.5 months of follow-up. Toxicity was minimal. In fact, no patients experienced the usual toxicities of cytotoxic chemotherapy, including nausea, emesis, alopecia, or other constitutional symptoms. Fever was common toward the end of therapy and coincided with a rapid decline in the number of circulating hairy cells. Remarkably, no infections were documented, and it was believed that the fever may be the result of cytokine release from hairy cells. In a recently updated report by the same investigators, 144 patients were treated and 85% achieved a CR [125] (Table 73-5). Even those patients with residual disease evident by routine light microscopic evaluation had complete normalization of their peripheral blood counts. At Northwestern University, 40 (80%) of 50 assessable patients achieved CR and 9 (18%) achieved PR, with minimal toxicity.[126] Hoffman and colleagues reported that 37 (76%) of 49 patients achieved CR. [39] No viral, fungal, or other opportunistic infections were observed other than a single case of dermatomal herpes zoster 16 months after treatment. It is now clear that most patients remain disease free for a prolonged period of time. [126] [127] [128] [129] Alternative routes and schedules of administration to the standard 7-day continuous intravenous infusion have included a 5-day, 2-hour bolus infusion, [129] subcutaneous administration,[130] and oral administration.[129] [131]

Fludarabine monophosphate is a third purine analog that is resistant to ADA. Two brief case reports suggest that fludarabine can produce normalization of the peripheral blood counts in previously treated patients with HCL. [132] [133]

The purine analogs are uniquely effective in patients with HCL. Extremely high CR rates are achievable and the incidence of toxicity is low. These agents should be considered the treatment of choice for HCL.

Immunosuppression with Purine Analogs

Both 2-DCF and 2-CdA are associated with prolonged immunosuppression. [37] [134] [135] [136] With 2-DCF, a decrease in the total lymphocyte count occurs, with a greater reduction in T cells than B cells or natural killer cells. [135] The levels of CD4+ and CD8+ cells decrease to <200 cells/l for at least 6 months after 2-DCF treatment is discontinued. In a series of 15 patients treated with 2-DCF with long follow-up, the median time to recovery of CD4+ lymphocyte counts to normal was 54 months. [136] Treatment with 2-CdA induces similar suppression of CD4+ lymphocyte counts.[127] The median time to recovery of CD4+ lymphocyte counts to normal after 2-CdA was 40 months. Despite such immunosuppression, opportunistic infections, other than an occasional case of herpes zoster, are distinctly uncommon, unless purine analog treatment is associated with corticosteroid exposure. [37]

Prognosis

Several studies have addressed the relapse rate, progression-free survival, and overall survival for patients with HCL treated with 2-DCF and 2-CdA. [126] [127] [128] [137] [138] These studies have indicated that most patients with either previously treated or untreated HCL achieve durable remissions with either multiple cycles of 2-DCF or a single cycle of 2-CdA, and the relapse rates appear low. In the report from Northwestern University, 7 of 52 patients (14%) had relapsed at a median duration of 24 months (range, 1244 months).[126] The progression-free survival rate is 72% at 4 years and 83% for those patients achieving CRs (Fig. 73-5). The overall survival rate is 86% at 4 years. Seymour and

Figure 73-5 Kaplan-Meier curves showing the progression-free survival **(A)** and overall survival **(B)** for 50 patients with hairy cell leukemia treated with a single cycle of 2-CdA.

colleagues from the M. D. Anderson Cancer Center reported that 8 of 40 patients (20%) relapsed at a median of 30 months. [127] The largest number of patients treated with 2-CdA has been reported by Saven and colleagues.[138] Of 349 patients with either previously treated or untreated disease, 91% achieved a CR and 7% achieved a PR. The relapse rate for 341 patients responding to 2-CdA was 19% at 48 months. The overall survival rate was 96% at 48 months.

Several investigators have reported similarly favorable long-term outcomes after treatment with 2-DCF. Kraut and colleagues reported that 11 of 24 patients (45%) had relapsed from CR after treatment with 2-DCF at a median of 30 months.[33] Grever and colleagues reported a relapse-free survival rate of 91% at 7 years among 117 patients achieving CR on the 2-DCF arm of a prospective, randomized study comparing 2-DCF with interferon [34] (Fig. 73-6). A recent update of the long-term outcome of these patients indicated that 76 ± 4% of patients remain alive and disease-free at 8 years, and the overall survival rate was 87 ± 2%. [137] A similar excellent outcome was reported by Catovsky and associates.[31] These investigators observed a 5-year survival rate of 88% among 110 patients treated with 2-DCF. Because of the indolent natural history of this disease, very long follow-up of patients treated with either purine analog will be required to determine if one of the agents offers a

FOOD AND DRUG ADMINISTRATION-APPROVED TREATMENTS FOR HAIRY CELL LEUKEMIA

Interferon- 2 × 10^6 international units/m^2 subcutaneously three times a week (for 1218 months)
2-Deoxycoformycin (2-DCF; Pentostatin) 45 mg/m^2 IV q 2 weeks until remission (usually 36 months)
2-Chlorodeoxyadenosine (2-CdA; cladribine, Leustatin), a single cycle, 0.1 mg/kg/day continuous infusion for 7 days

substantially longer remission duration or overall survival. However, it seems unlikely that such a prospective, randomized comparison between 2-CdA and 2-DCF will ever be conducted because the CR rates with each agent are so high, and many years and resources would be required to detect even large differences.

Evaluation of Minimal Residual Disease

The remarkable activity of the purine analogs has led to the examination of post-treatment bone marrow biopsies to detect minimal residual disease (MRD) in patients otherwise in CR. Immunohistochemistry using anti-CD20 antibodies in paraffin-embedded biopsy specimens is a useful technique. [92] [93] [94] [95] [139] [140] [141] Depending on the criteria used, 1351% of patients in apparent CR have evidence of MRD. [92] [93] [94] [95] The presence of MRD may predict relapse.[94] However, molecular studies have suggested that the malignant clone of cells may remain even in patients in apparent remission. [142]

Risk of Second Malignancies

Kampmeier and colleagues reported a significantly increased incidence of second malignancies in HCL patients treated with interferon. [143] Among 69 patients treated with interferon-2b followed for a median of 91 months, a second malignancy developed in 13 (19%), half of which were of hematologic origin. However, this association has not been uniformly observed.[144] Given the fact that the purine analogs are immunosuppressive, it will be important to determine if patients treated with either 2-DCF or 2-CdA are at risk for second malignancies. Kurzrock and colleagues reported no excess of second malignancies among 350 patients treated with either interferon, 2-CdA, or 2-DCF. [145]

FUTURE DIRECTIONS

Remarkable progress has been made in the treatment of HCL. Several very effective approaches are now available. The purine analogs have supplanted splenectomy and interferon as the treatment of choice. The long-term outcomes appear equivalent with either 2-DCF or 2-CdA, but very long-term follow-up will be important to determine if one or the other agent offers a significant survival advantage. Future directions will include clinical testing of an oral formulation of 2-CdA [146] and exploring approaches for patients with MRD. Patients who relapse after 2-DCF usually respond well to 2-CdA, [147] but whether the reverse is true will require further study. Finally, although patients who fail purine analogs may respond to interferon, [148] it is not likely to be curative. Novel strategies are needed for this subset of patients, and might include the anti-CD20 monoclonal antibody recently shown to be very effective in patients with other indolent B-cell lymphoproliferative disorders.[149]

Chapter 74 - Cutaneous T-Cell Lymphomas

Timothy M. Kuzel
Joan Guitart
Steven T. Rosen

INTRODUCTION

The T-cell non-Hodgkin lymphomas have been recognized to include a wide variety of clinical disorders with differing prognoses. The revised European-American classification of lymphomas (REAL)[1] suggests that more than 10 discrete clinicopathologic entities can be considered part of this family. This chapter focuses on the disorders that would be encompassed by the diagnosis cutaneous T-cell lymphoma (CTCL) (Table 74-1). The most common subtypes of cutaneous T-cell lymphoma are the epidermotropic variants mycosis fungoides (MF)

TABLE 74-1 -- Cutaneous T-Cell Lymphomas (CTCL)

Primary
Indolent
Mycosis fungoides
Mycosis fungoides + follicular mucinosis
Pagetoid reticulosis (Woringer-Kolopp disease)
Large Cell CTCL, $CD30^+$
Anaplastic
Immunoblastic
Pleomorphic
Lymphomatoid papulosis
Aggressive
Sézary syndrome
Large cell CTCL, CD30
Immunoblastic
Pleomorphic
Provisional
Granulomatous slack skin
CTCL, pleomorphic small/medium size
Subcutaneous panniculitis-like T-cell lymphoma
Systemic T-Cell Disorders with Skin Manifestations
Angioimmunoblastic lymphodenopathy
Lymphomatoid granulomatosis
Adult T-cell leukemia and lymphoma
Modified from the EORTC Classification. Blood, July 1997, p. 355.

and the Sezary syndrome (SS). The bulk of this chapter focuses on the approach to these more common disorders, although features that allow the clinician to exclude the distinct variants will also be described.

Epidemiology

MF and SS are the most frequent primary lymphomas involving the skin.[2] [3] Data collected from the Surveillance, Epidemiology, and End Results (SEER) program showed a rapidly increasing incidence from 0.2 cases per 100,000 population in 1973 to 0.4 cases per 100,000 population in 1984. This corresponds to approximately 1,000 new cases each year in the United States. Whether this represents a true increase in incidence or is attributable to a better awareness and therefore more frequent recognition of this disease is not resolved.

The incidence of MF/SS increases with advancing age, as does the incidence of non-Hodgkin lymphomas in general. The average age at presentation is approximately 50 years. Although very young patients have been reported, most patients are at least 30 years of age. [4] [5] MF/SS is seen in all racial groups. There is a 2:1 ratio of black people to white people and a 2.2:1 ratio of men to women with this disorder.

Clusters of cases of MF/SS within families have been reported.[6] Furthermore, an association with histocompatibility antigens AW31, AW32, B8, BW35, and DR5 has been described.[7] However, a solid genetic predisposition or inherited genetic defect has not been demonstrated.

BIOLOGY AND MOLECULAR ASPECTS

The T lymphocyte is central to the body's ability to mount an immune response and is the precursor of neoplastic cells in MF/SS. These cells spontaneously form rosettes with sheep red blood cells. Sezary cells will respond to phytohemagglutinin and perform T-cell immunoregulatory functions similar to normal lymphocytes. [8] [9] Clonal rearrangements of the T-cell receptor

---

(TCR) can be demonstrated by Southern blotting or polymerase chain reaction (PCR) techniques.

The development of monoclonal antibodies directed against a specific cluster of differentiation (CD) antigens has allowed for more precise identification of surface markers on the malignant cell.[10] In most instances, the cells express the pan T-cell antigens CD3 and CD5. The sheep erythrocyte receptor, another pan T-cell marker, has been designated CD2. Early T cells may also express CD7 on their cell surface. This marker is frequently deleted in MF/SS, but may also be deleted in benign dermatoses and inflammatory skin lesions. The majority of cases of MF and SS are of the T-helper memory/effector subset with a $CD4^+$, $CD45RO^+$ phenotype. Occasional cases expressing the suppressor $CD8^+$ phenotype have been described. Low expression of the interleukin-2 receptor (CD25) is detected in less than half the patients with heterogenous expression on the malignant cells.

Cytogenetic analyses have demonstrated both numerical and structural chromosomal abnormalities in MF/SS. [11] Hyperdiploidy and complex karyotypes are common. Nonrandom deletions of chromosomes 1, 6, 8, 10, and 17 have been reported. Regions of the genome that include genes encoding the T-cell receptor do not appear to be involved, suggesting that the genetic basis for malignant transformation in MF/SS appears to be different from that involved in other T-cell malignant disorders.

Modest data exists on the aberrant expression of oncogenes and/or suppressor genes in MF/SS. Mutant forms of the P53 tumor suppressor gene, noted in high grade lymphomas, are rarely seen in MF/SS.[12] LYT-10, a member of the NF-KB family of transcription factors associated with translocations in lymphoid malignancies, is rearranged in a small proportion of cases.[13] However, BCL-2, a gene whose rearrangement is characteristic of follicular B-cell lymphomas and which slows programmed cell death, is overexpressed in MF.[14] In addition, constitutive expression of STAT 3 (a member of the transcription factor family that contributes to the diversity of cytokine responses) has been reported. [15] Altered expression or release of select cytokines or their receptors including IL-1, IL-2R, IL-4, IL-5, IL-6, IL-7, IL-8, IL-12, and TGF-B receptor II has been noted. [16]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ETIOLOGY AND PATHOGENESIS

The etiology of MF/SS remains unknown. It is considered to be a sporadic disease without compelling evidence of transmissibility. Several viruses have been implicated in the pathogenesis of MF/SS including Human T-cell lymphotropic virus-I/II, Herpes simplex virus, Herpes virus-6, and the Espstein-Barr virus. [13] However, a viral cause of MF/SS has not been proven.

Investigators have suggested that prolonged exposure to contact allergens may lead to enhanced immune responses leading directly or indirectly to the development of MF/SS. Sezary cells respond in vitro to superantigenic exotoxins, and colonization by *Staphylococcus aureus* may influence disease activity.[17] In addition, several reports suggested that exposure to metals or their salts, pesticides or herbicides, and organic solvents (halogenated or aromatic hydrocarbons) could be related to the development of MF/SS.[18] However, two well-designed case-control studies have failed to support these observations. [19] [20]

Various theories have been advanced to explain the epidermotropism of malignant T cells in MF/SS. Organ-specific affinity to skin and other organs has been recognized in subsets of normal T cells. Homing of CTCL cells to the skin is probably mediated by more than one adhesion receptor mechanism. CTCL cells express cutaneous lymphocyte antigen (CLA), a skin homing receptor that interacts with e-selectin on cutaneous endothelium. [21] It has been noted that peripheral blood mononuclear cells bind to cultured keratinocytes exposed to interferon gamma. The MHC II proteins, along with intercellular adhesion molecule 1 (ICAM-1), present on keratinocytes, will attract lymphocytes. Class II MHC proteins recognize the CD4 antigen and ICAM-1 binds to the lymphocyte function-associated molecule 1 (LFA-1). [22]

An additional feature of MF/SS cells is the production of a cytokine profile consistent with T-helper-2 type cells (T_{H2}).[23] The T_{H2} cells produce IL-4, IL-5, and IL-6 and they are inhibited by interferon gamma. The T_{H2} cells are critical for stimulating antibody and eosinophil-mediated responses. Hypergammaglobulinemia and eosinophilia are often seen in advanced cases of MF/SS and are consistent with a T_{H2} profile. Stimulation of T_{H2} cells inhibits the T_{H1} subpopulation of lymphocytes involved in cell-mediated immunity. A cause as well as a consequence of the progression of MF/SS is immune suppression as a result of depletion of this T cell subset. The T_{H2} cytokine profile also explains the decrease in tumor infiltrating lymphocytes during tumor progression.

CLINICAL PRESENTATION

Alibert reported the first case of MF in 1806.[24] His patient developed a skin eruption that progressed into mushroom-like tumors, prompting the term mycosis fungoides. Later in the nineteenth century, Bazin defined the three classic cutaneous phases (patch, plaque, and tumor stage) of the disease.[25] The recognition of the clinical triad of intensely pruritic erythroderma, lymphadenopathy, and abnormal hyperconvoluted monstrous cells in the peripheral blood led to the description of SS.[26]

More than 50% of CTCL patients have MF. The initial course of patients with MF is usually indolent. Most patients will give a history of antecedent skin lesions, usually nonspecific erythematous patches that can mimic eczema or psoriasis. In many cases, there is an orderly progression from limited patches to more generalized patches, plaques, tumors, and finally nodal or visceral involvement. The characteristic patch lesion is typically poorly demarcated, lightly erythematous, and usually on the trunk or the extremities (Fig. 74-1). Plaque lesions are more erythematous, have well-demarcated margins, and some scaling (Fig. 74-2). They frequently resemble psoriasis. Plaques can arise from patch lesions or previously uninvolved areas of skin. Tumor lesions tend to be later lesions, frequently associated with previous patches or plaques. They can be located on any part of the body. Ulceration of these lesions is common and secondary infection is a major cause of morbidity (Fig. 74-3). Tumors may be the initial presentation in a small percentage of patients (D'emblée presentation).

SS patients present with generalized erythroderma, pruritus, and circulating malignant cells. Peripheral blood usually shows more than 15% hyperconvoluted atypical lymphocytes (Fig. 74-4). Approximately 5% of all newly reported cases of CTCL are SS. In its most advanced form, patients with SS suffer from leonine facies, hyperkeratosis and fissuring of the palms and soles, and severe pruritus and cutaneous pain. Many other entities can clinically mimic this disease including drug eruptions, atopic dermatitis, contact dermatitis, and erythrodermic psoriasis.

A number of variant presentations of CTCL have been described. The following sections discuss the premalignant variants of CTCL.

Poilikoderma Vasculare Atrophicans

Poilikoderma vasculare atrophicans is characterized by reticulate hyperpigmentation and hypopigmentation, telangiectasia, and skin atrophy.[27] The classic presentation includes multiple skin lesions of variable size, affecting covered areas such as the breasts, buttocks, and flexures in a symmetric distribution.

Figure 74-1 Erythematous and scaly patch lesion of MF.

Lesions typically improve with sun exposure. Peak incidence occurs between 40 and 60 years of age. A small percentage of patients will evolve into MF.

Large Plaque Parapsoriasis

Large plaque parapsoriasis is the classic premalignant lesion of MF. It most commonly consists of a few scattered, erythematous to brown, plaques that are usually greater than 6 cm is size.[28] There is a predilection for the buttocks and intertriginous areas. Histologic examination shows a superficial lymphocytic infiltrate with minimal nuclear atypia. Epidermotropism is scant or absent and dermal fibrosis correlates with the chronicity of the process. Plaques can persist for decades before a frank evolution to MF occurs. Approximately 1030% of patients ultimately develop an overt malignant transformation.

Alopecia Mucinosa

Alopecia mucinosa presents with grouped erythematous follicular papules or boggy or indurated nodular plaques, notably devoid of hair (Fig. 74-5).[29] There is a predilection for the head and neck area, especially the forehead, which has the highest density pilosebaceous units. Histopathologic evaluation reveals follicular mucinosis and mucinous degeneration of epithelial cells in sebaceous glands and hair follicles, associated with lymphocytic infiltration. Most patients have a benign course, but lymphoma associated with follicular mucinosis has been

Figure 74-2 Plaque lesion of CTCL.

Figure 74-3 Ulcerated tumors arising from MF plaques.

Figure 74-4 Sezary cells: the nuclei are cerebriform and hyperconvoluted with fine chromatin and scant cytoplasm.

reported in the literature to range from 967%.[30] In general, patients over the age of 40 years with a more generalized cutaneous involvement and a chronic course are more likely to develop associated MF. No cases of MF have been reported in children with alopecia mucinosa, although few reports of Hodgkin disease have been reported in children with follicular mucinosis.[31]

Lymphomatoid Papulosis

Lymphomatoid papulosis is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules

Figure 74-5 Follicular mucinosis showing a patch of alopecia with follicular prominence.

and nodules (Fig. 74-6).[32] This entity represents 510% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical $CD4^+$ lymphocytic infiltrate with a variable mixed inflammatory infiltrate (Fig. 74-7). These may be primarily small cerebriform cells similar to those seen in MF (type B) or primarily larger $CD30^+$ cells of the Reed-Sternberg type (type A). A third variety of lymphomatoid papulosis (type C) with sheets of anaplastic large cells has also been reported.[33] T-cell receptor gene rearrangement studies demonstrate a clonal origin. Though the typical course is usually indolent, spanning decades, approximately 30% of patients develop MF, Hodgkin, or non-Hodgkin lymphoma during their lifetime. However, the cumulative risk of developing a lymphoma approaches 80% at 15 years, with negligible risk of transformation during the first five years. [34] A direct link between lymphomatoid papulosis, CTCL, and Hodgkin disease was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone as shown by TCR gene studies. [35]

The malignant variant presentations of CTCL are discussed in the following sections.

Pagetoid Reticulosis (Woringer-Kolopp Disease)

This rare condition affecting young adults presents with hyperkeratotic, often verrucous plaques on the lower limb. [36] Biopsies show atypical cerebriform lymphocytes with a perinuclear halo almost exclusively localized within the intraepidermal compartment. [37] This is a localized form of CTCL. Pagetoid reticulosis typically affects a distal limb and extracutaneous dissemination is exceedingly rare. A predominantly CD8 immunophenotype has been reported in pagetoid reticulosis. Although most cases have an indolent protracted course, generalized and sometimes aggressive variants have been reported. [38]

Granulomatous Slack Skin

In granulomatous slack-skin syndrome, clonal $CD4^+$ T cells elicit a reactive granulomatous response that destroys the elastic fibers, rendering skin slack, fibrotic, and inelastic (Fig. 74-8).[39]

Figure 74-6 Lesions of lymphomatoid papulosis appear in crops and consist of ulcerated papules and scars.

Changes characteristic of MF are often found within the epidermis and papillary dermis, while the reticular dermis contains numerous tuberculoid granulomas with multinucleated giant cells. Some patients with granulomatous MF do not have destruction of the elastic fibers with slack-skin changes. The differential diagnosis for such cases includes sarcoidosis and tuberculoid leprosy.

LABORATORY EVALUATION

The diagnosis of MF/SS is based on light microscopic evidence of a band-like infiltrate involving the papillary dermis containing small, medium-sized, and occasionally large mononuclear cells with hyperchromatic, hyperconvoluted (cerebriform) nuclei and variable numbers of admixed inflammatory cells. [13] [40] Epidermal exocytosis of single or small clusters of neoplastic cells is a characteristic finding (Fig. 74-9). The presence of Pautrier microabscesses is classic, but seen only in a minority of cases. Tumor stage lesions demonstrate a more diffuse superficial and deep, dermal infiltrate with fewer reactive cells, and an absence of epidermotropism (Fig 74-10). The malignant T-cell clone often evolves into large cell morphology during

Figure 74-7 Skin biopsy of lymphomatoid papulosis with a mixture of large atypical lymphocytes with inflammatory cells.

tumor progression, although rare cases show large cell morphology from the early patch lesions. [41] The histologic features in SS may be similar to those of MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may be absent.

Lymph node involvement initially involves the paracortical regions. Progression is associated with small to large clusters of atypical cells with preserved nodal architecture, followed by partial or total effacement of the node by neoplastic cells. Visceral involvement is a late clinical feature. Peripheral blood involvement can be demonstrated in all stages of skin disease, though most prevalent in patients with tumor or erythrodermic presentations. Patients with SS may have circulating neoplastic cells, but be lymphopenic. Bone marrow involvement can often be demonstrated in patients with SS or advanced tumor- or plaque-stage MF, but rarely influences management outside an investigational setting.

The malignant cells are typically $CD3^+$, $CD4^+$, $CD45RO^+$, CD8 , and CD30 by immunohistochemistry. CD7 is often deleted from the early stages. More aggressive variants and advanced CTCL may have multiple pan-T-cell antigen deletions, especially CD2, CD5, and even CD4. T-cell receptor genes are clonally rearranged, and can be demonstrated in most cases by Southern blotting or polymerase chain reaction (PCR) assays when a sufficient malignant infiltrate exists.

Analysis of peripheral blood may reveal an elevated LDH (lactate dehydrogenase) in a small percentage of patients with advanced disease or an aggressive tempo. Eosinophilia and hypergammaglobulinemia is not uncommon is SS patients. A limited number of patients will have an associated monoclonal gammopathy. Elevated serum B_2 microglobulin and IL-2 receptor levels have also been noted in advanced cases.

Imaging studies for classic MF/SS are generally of modest utility. CT scans of the chest, abdomen, or pelvis should be reserved for patients with SS, nodal involvement, or CTCL variants. In an investigational setting electron microscopy, cytogenetics, and molecular analyses have shown that a higher percentage of patients will have occult involvement of internal organs.

DIFFERENTIAL DIAGNOSIS

Primary CTCL represents a heterogenous group of disorders with considerable variability in histology, phenotype, and prognosis.

Figure 74-8 Lesions of granulomatous slack skin with destruction of the dermal elasticity.

The Kiel Classification, Working Formulation, and the Revised European-American Lymphoma (REAL) classification system were developed for non-Hodgkin lymphomas and are not designed to provide an adequate characterization of the spectrum of CTCL. To address the deficiencies of the previously proposed systems a more clinically useful classification has been developed by the European Organization for Research and Treatment of Cancer (EORTC). [2] A number of other disorders in which malignant T cells infiltrate the skin should be distinguished from MF/SS. These disorders are discussed in the following sections.

CD30-Positive Cutaneous Large T-Cell Lymphoma

Primary cutaneous $CD30^+$ large cell lymphoma ($CD30^+$ LCL) typically occurs in adults presenting with solitary or localized

Figure 74-9 Skin biopsy of mycosis fungoides showing a dermal infiltrate of cerebriform lymphocytes with epidermotropism.

(ulcerating) nodules or tumors (Fig. 74-11). [42] Regional lymph node involvement is seen in 25% of patients at presentation. These primary cutaneous $CD30^+$ LCL are probably closely related to lymphomatoid papulosis, regressing atypical histocytosis, and primary cutaneous Hodgkin disease. The tumor

Figure 74-10 Tumor stage mycosis fungoides with a deep and dense mononuclear cell infiltrate without significant epidermotropism.

Figure 74-11 Lesions of $CD30^+$ large cell lymphoma with ulceration.

has a favorable prognosis and often complete or partial spontaneous regression occurs. This is in contrast to primary noncutaneous $CD30^+$ LCL, which can be seen in children or adults and which carries a poor prognosis. [43] Histopathology consists of diffuse nonepidermotropic infiltrates with cohesive sheets of large CD30-positive tumor cells (Fig 74-12). In most instances the tumor cells have an anaplastic morphology, showing round, oval, or irregularly shaped nuclei, prominent (eosinophilic) nucleoli, and abundant cytoplasm. Less commonly, the neoplastic cells have a pleomorphic or immunoblastic appearance. Reactive lymphocytes are often present. The immunophenotype of this disorder is characteristically $CD4^+$ with the majority (>75%) of neoplastic cells expressing CD30. In contrast to the poor outcome of MF that has transformed to a $CD30^+$ large cell variant, primary CD30-positive cutaneous large T-cell lymphomas are associated with an excellent prognosis. Radiotherapy is the preferred treatment for solitary or localized disease, with combination chemotherapy reserved for patients with generalized skin lesions or extracutaneous dissemination.

CD30-Negative Cutaneous Large T-Cell Lymphoma

These lymphomas tend to have an aggressive clinical course. Patients present with localized or generalized plaques, nodules, or tumors. [44] Histopathology demonstrates that infiltrates are nonepidermotropic with variable numbers of medium-sized to large pleomorphic T cells with or without cerebriform nuclei, and immunoblasts. The tumor cells are $CD4^+$ with CD30 staining negative or restricted to few scattered tumor cells. Multiagent chemotherapy is used in most instances, with radiation therapy reserved for patients with localized disease. The five-year survival rate is less than 20%.

Pleomorphic Small/Medium-Sized CTCL

This is an uncommon entity. Patients typically present with red-purplish nodules or tumors. Histopathology shows a dense, diffuse, or nodular infiltrate with small/medium pleomorphic neoplastic cells within the dermis, often with extension into the subcutis. [34] [45] The neoplastic cells are of the helper phenotype and do not express CD30. Localized disease is typically treated with radiation therapy. Patients with more generalized disease have been treated with regimens used for indolent non-Hodgkin lymphomas.

Figure 74-12 $CD30^+$ large cell lymphoma with sheets of large atypical lymphocytes.

Subcutaneous Panniculitis-like T-Cell Lymphoma

This is an extremely rare entity. Patients present with subcutaneous nodules and plaques. [46] [47] Systemic symptoms are common including fevers, fatigue, and

anorexia. Histopathology reveals a subcutaneous infiltrate with pleomorphic T cells of variable size, mixed with benign macrophages. Tumor cell necrosis, karyorrhexis, and erythrophagocytosis are common findings. Differential diagnosis includes the frequently fatal but non-neoplastic cytophagic histocytic panniculitis. Neoplastic infiltration of deep blood vessels can be noted in some cases. [48] Immunophenotyping reveals post-thymic T-cell markers with both $CD4^+$ and $CD8^+$ subtypes. The prognosis is in general poor despite aggressive chemotherapy.

Angioimmunoblastic Lymphadenopathy

Angioimmunoblastic lymphadenopathy is a rare lymphoproliferative disorder frequently accompanied by hepatosplenomegaly, fever, skin rash, and generalized malaise.[49] Approximately 50% of patients have skin involvement at presentation. Common laboratory features include anemia (often Coombs-positive hemolytic), thrombocytopenia, leukocytosis with lymphopenia, and polyclonal hypergammaglobulinemia. Histologic features of lymph node biopsies include complete architectural effacement with replacement by a diffuse polymorphous cellular infiltrate composed of lymphocytes, immunoblasts, and plasma cells, with or without histiocytes and eosinophils. Prominent arborization of postcapillary venules and atrophic germinal centers are seen.

Skin biopsy findings are nonspecific, revealing a perivascular lymphocytic infiltrate in the dermis with a cytologic composition similar to that of the lymph node. Histologic progression to an appearance of a high grade lymphoma is common. Molecular and immunologic studies usually demonstrate an activated mature clonal T-cell phenotype. The median survival is approximately 1.5 years, and only 30% of patients survive 2 years. Treatment with corticosteroids and/or chemotherapy rarely provides durable control. An association with Kaposi sarcoma has been noted.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare multiorgan disease of the lungs, nasopharynx, joints, peripheral and central nervous system. [50] Cutaneous involvement occurs in 2550% of patients. Though nodules are most common, some patients have nonspecific macules, papules, or ulceration. Histologic evaluation reveals an angiocentric, polymorphous infiltrate of both atypical lymphocytes and histiocytes surrounding and invading blood vessels within the dermis. Molecular and immunologic studies suggest a mature clonal helper T-cell process. However recent reports have suggested a massive reactive T-cell infiltrate driven by a small number of clonal B cells.[51]

Epstein-Barr virus DNA sequences are frequently present, and their role in the pathogenesis of this disorder is being explored. Though the clinical course is variable, the prognosis for patients with diffuse pulmonary involvement or the appearance of high-grade lymphoma is poor, with a median survival of less than 2 years. Treatment that depends on histologic findings and extent and location of disease, may include corticosteroids, radiotherapy, and/or chemotherapy. Recently interferon has been demonstrated to have significant activity against this disease. [52]

Adult T-Cell Leukemia and Lymphoma (ATLL)

ATLL is in most instances a rapidly progressive T-cell neoplasm expressing a helper phenotype. [53] [54] It is endemic in southern Japan

Figure 74-13 Skin lesions in adult T-cell lymphoma/leukemia syndrome.

and the Caribbean islands and is associated with the retrovirus HTLV-1. However, most HTLV-l infected patients remain asymptomatic and only 24% develop ATLL. The clinical presentation is polymorphous and can resemble MF or SS. Cutaneous lesions are variable, ranging from a rash simulating a viral exanthem to large tumors and plaques similar to MF (Fig. 74-13). Advanced stages of the disease, which affects a younger population than seen with MF, are characterized by visceral involvement, immunodeficiency, elevated LDH, and hypercalcemia. Malignant lymphocytes often have convoluted or multilobed nuclei and can be detected in the peripheral blood in 75% of patients. The neoplastic T cells express high levels of the IL-2 receptor (CD25). For purposes of treatment and prognosis it is wise to view ATLL as a spectrum with two subgroups, acute and all others, with treatment, though inadequate, reserved for those with acute ATLL. Therapeutic options include multiagent chemotherapy and antibody or recombinant toxins directed against the IL-2 receptor. Patients with acute ATLL have poor survival rates, with median duration of 46 months.

PROGNOSIS

The goals of treatment in MF are the relief of symptoms and improvement in cosmetics. Despite some uncontrolled clinical trial results that have been reported to suggest cures in this

disease, the general perception remains that this disease is not curable with standard therapies available today. The disease behaves similarly to other low-grade lymphomas, with periods of remission gradually becoming shorter with subsequent therapeutic interventions. Unlike B-cell low grade lymphomas, however, advanced stage MF is associated with a relatively short median life expectancy. Patients with either significant nodal involvement (LN3 or LN4) or extensive skin involvement (T4) have median life expectancies of 3055 months.[55] [56] Thus, a driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor prognosis patients. No clinical trial has yet determined that aggressive early therapy is better than sequential palliative approaches or investigational approaches,[57] and thus new treatments continue to be developed and tested for these patients.

Techniques such as flow cytometry, cytogenetic analysis, and determination of nuclear contour indices are specialized methods, which may also improve diagnostic and prognostic specificity. Flow cytometry and cytogenetic analysis are complementary techniques. Flow cytometry allows the detection of cell populations with the normal (diploid) number of chromosomes versus abnormal (aneuploid) numbers, while cytogenetic analysis precisely identifies the individual chromosomal structure and number. Bunn et al.[58] demonstrated that this can be important prognostically in MF/SS, as the presence of aneuploidy during the clinical course was associated with more aggressive behavior of the disease. Hyperdiploid cell clones were demonstrated in patients with large-cell histology, aggressive disease, and shortened survival time.

The nuclear contour index has been used by several groups in an effort to separate benign cutaneous lymphocytic disorders, such as lymphomatoid papulosis and pityriasis lichenoides, from MF/SS.[59] [60] Electron microscopy allows the calculation of a value based on the degree of nuclear folding: this nuclear contour index is significantly greater in patients with MF than in other benign conditions.

Most recently, the density of epidermal Langerhans' cells in biopsy samples, as determined by immunoperoxidase stains, has been identified as a prognostic feature.[61] Epidermal Langerhans' cells are necessary for antigen recognition and processing in the normal immune response. Patients with Langerhans' cell densities greater than 90 cells per square millimeter had a significantly reduced risk of death from MF/SS compared with those with lower densities. Furthermore, there was no prognostic significance identified for the presence or absence of CD30 positive (Ki-1) cells.

Occasionally patients may develop a more clinically aggressive lymphoma concurrent with a change in the histologic appearance of the neoplastic cells. This progression from typical small, convoluted lymphocytes to larger lymphocytes, such as those associated with large-cell lymphoma, has been documented.[62] [63] Whether this conversion is secondary to prior therapeutic modalities used remains uncertain.

The gold standard for the diagnosis of mycosis fungoides is still routine histopathology with adequate clinical correlation. Early lesions of MF are frequently accompanied by heavy infiltrates of benign reactive T cells, hampering the detection of abnormal T-cell clones by any laboratory method. Hence most adjuvant laboratory methods are not helpful at the precise time when they are most needed.

In 1979, the staging committee at an international workshop on MF proposed a staging system based on the international tumor-node-metastasis (TNM) system (Table 74-2).[64] This classification was based on the evaluation of 347 patients and a multivariate analysis of potential prognostic factors. This group identified several independent prognostic factors: extent of skin disease at diagnosis (T), type of lymph node (N) involvement, presence or absence of peripheral blood (PB) involvement, and presence or absence of visceral (M) involvement. The group also

TABLE 74-2 -- TNM Classification of Cutaneous T-Cell Lymphomas

Classification	Description
T skin	
T_0	Clinically or histopathologically suspicious lesions
T_1	Limited plaques, papules, or eczematous patches covering 10% of the skin surface
T_2	Generalized plaques, papules, or erythematous patches covering 10% of the skin surface
T_3	Tumors (one or more)
T_4	Generalized erythroderma
	Pathology of T_{14} is diagnostic of a cutaneous T-cell lymphoma. When more than one T stage exists, both are recorded and highest is used for staging. Record other features if appropriate (ulcers, poikiloderma, scale, etc.)
N lymph nodes	
N_0	No clinically abnormal peripheral lymph nodes
N_1	Clinically abnormal peripheral lymph nodes (record number of sites)
NP_0	Biopsy performed, not CTCL
NP_1	Biopsy performed, CTCL
PB peripheral blood	
PB_0	Atypical circulating cells not present (5%)
PB_1	Atypical circulating cells not present (>5%), record total WBC, total lymphocyte count, and % of abnormal cells
M visceral organs	

M_0	No visceral organ involvement
M_1	Visceral involvement (must have pathologic confirmation), record organ involved

Note: Staging classification: Stage Ia: T_1 , N_0 NP_0 , M_0 ; Stage Ib: T_2 , N_0 NP_0 , M_0 ; Stage IIa: T_{12} , N_1 NP_0 , M_0 ; Stage IIb: T_3 , N_0 NP_0 , M_0 ; Stage III: T_4 , N_0 NP_0 , M_0 ; Stage IVa: T_{1-4} , $N_{0,1}$ NP_1 , M_0 ; Stage IVb: T_{1-4} , $N_{0,1}$ $NP_{0,1}$, M_1 .

translated this staging into a recommended clinical staging system (see note in Table 74-2).

More recently, investigators at the National Cancer Institute retrospectively analyzed 152 patients who underwent uniform pathologic staging. [65] They were able to identify three distinct prognostic groups. Good-risk patients had plaque-only skin disease without lymph node, blood, or visceral involvement, and a median survival of more than 12 years. Intermediate-risk patients had skin tumors, erythroderma, or plaque disease with lymph node or blood involvement (but no visceral disease), and a median survival of 5 years. Poor-risk patients had visceral disease or complete effacement of lymph nodes by lymphoma, and a median survival of 2.5 years.

THERAPY

Therapy can be conveniently divided into two approaches: (1) topical (skin-directed), such as psoralens with ultraviolet light A (PUVA), topical chemotherapy application (nitrogen mustard or carmustine), and total skin electron beam radiotherapy, and (2) systemic (skin- and viscera-directed), such as interferons, oral or parenteral chemotherapy, photopheresis, retinoids, and investigational new compounds (Table 74-3). No studies have demonstrated that one topical therapy is more effective than another, and patient and investigator preference remain the most important discriminating factor governing choice. However,

TABLE 74-3 -- Therapeutic Options for Mycosis Fungoides

Combination chemotherapy
Oral retinoids
Investigational agents

as the biology of the neoplastic cell has become better understood, [66] it has become clear that some therapies may actually have topical and systemic effects through alterations in the body's cytokine milieu and ability to mount a host response against the neoplastic cell. [67] Finally, investigational approaches combining therapies remain active research strategies. The following sections will detail the individual treatment options, discussing mechanisms of action, rationale for use, and outcomes.

PUVA

8-Methoxypsoralen (8-MOP) is a member of a family of photoactivated compounds (furocoumarin derivatives), which may inhibit both DNA and RNA synthesis through formation of mono- or bifunctional thymine adducts, gene mutations, or sister chromatid exchanges. [68] [69] These drugs are only active if the tissue containing the psoralen compound is exposed to ultraviolet A rays (UVA). It has become apparent recently that the mechanism of cell cytotoxicity for many therapies of cancer involves the induction of apoptosis. Yoo et al. have demonstrated that peripheral blood mononuclear cells from Sezary syndrome patients and controls exposed in vitro to PUVA undergo apoptosis.[70] This finding was confirmed with light microscopy, flow cytometry, and electron microscopy, and by gel electrophoresis. Unfortunately, normal and neoplastic lymphocytes were equally sensitive to the apoptosis induction with PUVA (as opposed to with psoralen alone). However, macrophages appeared to be resistant to apoptosis induction, and phagocytized apoptotic lymphocytes (but not non-apoptotic lymphocytes). Thus, apoptosis induction may be the ultimate endpoint yielding benefit, but an immunologic effect due to monocyte phagocytosis and antigen presentation to secondary effector cells may also be present.

Photochemotherapy units with UVA lamps emit a continuous spectrum of long UVA in the range of 320400 nm with peak emission between 350 and 380 nm. Initial exposure times of patients to high output UVA are based on the degree of pigmentation before therapy, history of ability to tan, and the output of the photochemotherapy units. Exposure times are increased with each treatment depending upon the patient's response, and evidence of erythema. The initial UVA dose is between 1.0 to 2.0 J/cm^2 , and can be increased by approximately 0.5 J/cm^2 per treatment as tolerated. UV light-blocking glasses should be worn for 24 hours after administration of 8-MOP. Therapy is typically given three times weekly until complete clearing occurs. The frequency of treatments can then be reduced, but some maintenance therapy (once every two to four weeks) may prolong the duration of remission. As new data emerges regarding the long-term risks of second skin malignancies after PUVA, this maintenance therapy recommendation may change.

Initial trials using PUVA noted benefit in psoriasis patients. [71] Several clinical trials with PUVA for patients with MF soon followed. [72] These studies all demonstrated high rates of remission induction in early stage (patch/plaque stage of disease). The Scandinavian study group reported a 58% complete remission rate for these patients within 412 months of initiation of therapy. [73] Maintenance therapy allowed remission duration of up to 53 months. In these early studies, the same group also reported a surprisingly high rate of objective remission induction in tumor stage patients of 83%. [74] We have recently reported our large modern era results of PUVA therapy for patients with MF.[75] Eighty-two patients were followed for a median of 43 months. An objective response rate was observed in 95% of patients, with a 65% complete clearance rate. The majority (90%) of these patients had early stage disease (stage IAIIA). A single patient with tumor stage disease attained a short remission with PUVA alone. Two of six patients with generalized erythroderma cleared completely (no evidence of circulating neoplastic lymphocytes). Given the difficulty in treating advanced stage patients with PUVA alone, we usually restrict PUVA therapy to patients with stage IAIIB disease (note Table 74-2), monitoring patients with tumor disease closely for progression.

Side effects with PUVA are quite tolerable. Occasional nausea or vomiting due to the psoralen ingestion is observed, and erythema, pruritus, and chronic dry skin is an effect of the UVA light damage to the skin. Long-term PUVA exposure has been associated with a number of late effects. These include dry skin, lichenification, keratosis, and rarely amyloid deposition in the skin. [76] Most important is the late development of iatrogenic (both basal and squamous) carcinomas, [55] [77] secondary malignant melanomas of the skin, [78] and rarely cataract formation. Because the cumulative dose of PUVA is correlated with the risks of second skin neoplasms, routine use of maintenance therapy may be less desirable, especially for patients with an excellent prognosis (stage IA). Despite these problems, the long remissions

induced, the ease of administration, and the lack of interactions with other therapeutic modalities make PUVA an attractive early intervention.

Radiation Therapy

The non-Hodgkin lymphomas in general, and the CTCL in particular, have been shown to be radiosensitive. [79] External-beam radiation has been shown to adequately control local areas of otherwise resistant MF, or provide palliation in cases of bulky tumor lesions. [80] [81] Unfortunately, the cumulative dosage that can be given to patients over time is limited due to normal organ toxicity. In addition, side effects consisting of leukopenia, thrombocytopenia, and radiation dermatitis may prevent long-term therapy with other agents. Newer techniques involving total nodal irradiation, fractionated total body irradiation, or hemibody irradiation may have a role to play in the development of multimodality approaches to this disease.

The limitations of external-beam radiation led to increasing use of electron-beam radiotherapy for cases of MF confined to the skin. Linear accelerator-generated electron beams are scattered by a penetrable plate placed at the collimator site. The energy of the electrons is reduced to 47 MeV and allows adequate field distribution. Because of this low energy level, the beam only penetrates the surface several millimeters to 1 cm (into the dermis). Patients may be treated using six-field or rotational treatments. [82] [83] Thus, the total skin surface can be treated without significant internal organ toxicity. [61] Most patients are able to tolerate total doses of approximately 3,0003,600 cGy over an 810 week period. [62]

An excellent review has recently compared results of external beam therapy at Stanford University with those achieved in Hamilton, Ontario. [84] The results cited in this paper reflect the extensive expertise of both centers in the delivery of this therapy, and may not be applicable to centers with much less

ALGORITHM FOR CARE OF PATIENTS WITH MF/SS

frequent use of the technique. For patients with stage IAIIA (see Table 74-2 , note), nearly 6595% of patients achieved a complete remission. Treatment delivered without adjuvant therapies is associated with a relatively high rate of relapse in patients of all stages except stage IA. Ten-year relapse-free survival rates at the two centers range from 3352% for this good-prognosis group. However, for stage IB and worse disease, 10-year unmaintained remission rates are only 16% or less. Still the benefits of therapy may extend beyond crude estimates of relapse rates or survival. Patients with tumor lesions, generalized erythroderma, peripheral blood or nodal involvement, and even visceral spread can be successfully palliated with electron beam radiation therapy, as well. Side effects, however, can be occasionally extreme, including scaling, dryness of skin, erythema, extremity edema, telangiectasia formation, skin ulceration, and hair or sweat gland loss (frequently permanent). Careful radiation dosimetric techniques are required to ensure adequate skin treatment without excessive normal organ toxicity. [64] We do not use electron beam radiotherapy early in the disease now that other topical therapies have been developed that yield similar response rates with less potential toxicity. Furthermore, the long duration of remissions observed in patients with stage IA disease does not equate with cure, as their life expectancy is essentially the same as age-matched controls, and these patients may simply have indolent biology. One group has reported their experience with multiple courses of therapy. [85]

They re-treated 15 patients with relapsed MF a mean of 41 months after the initial course of electron-beam therapy. All patients had received intervening therapies for disease control. Eleven of the 15 had a complete remission with their first cycle of radiation. The second course achieved 6 complete remissions and 9 partial remissions. The median duration of initial complete remission was 11 months. The median duration of complete remission to the second course of therapy was only 3 months, suggesting radioresistance had developed between the first and second cycles in many patients. In general, toxicity was thought to be tolerable.

Topical Chemotherapy

The earliest therapies for MF focused on treatment of the skin disease. Novel approaches by dermatologists to apply chemotherapy topically to avoid systemic therapy complications were therefore devised. Mechlorethamine hydrochloride was the first topical agent evaluated to demonstrate efficacy in MF. [86] The solution used for topical application contains 1020 mg of mechlorethamine dissolved in 50100 ml of tap water (no vesicant activity at this low concentration). Although several methods may be used for administration, self-administration at home to the entire skin surface is preferred. The concentration may need to be varied depending on patient tolerance and sensitivity. [87] The time to initial response is usually short, approximately 12 weeks, but long-term application is usually required to obtain the maximum response.

Several large studies have been completed demonstrating the benefit of mechlorethamine, especially in early stage disease. [88] [89] One by Vonderheid et al. [68] reported their experience with topical mechlorethamine and found that it compared favorably with electron beam treatment results. Complete remissions were seen in 80%, 68%, and 61% of patients with limited plaque, extensive plaque, and tumor lesions, respectively. The corresponding median duration of remissions were in excess of 15, 5, and 12 months, respectively. It is difficult to draw definite conclusions from these data, as many patients included in the analysis also received intravenous mechlorethamine or methotrexate, and some may have received radiation therapy. In addition, several patients have relapsed as long as 8 years after the completion of therapy, suggesting that follow-up times must be long to compare various topical therapies for early stage disease. Hoppe et al. [69] confirmed these findings using an ointment-based (aquaphor or polyethylene glycol) topical mechlorethamine, which may be associated with a lower incidence of cutaneous sensitivity.

For early-stage disease, therefore, topical mechlorethamine offers an efficient, convenient (outpatient treatment), and relatively inexpensive treatment option. Side effects consist of delayed hypersensitivity in approximately 35% of patients, although ointment-based solutions appeared to offer a reduced risk of allergic contact dermatitis. Once hypersensitivity develops, patients can be desensitized by injecting minute daily doses of mechlorethamine over a period of several weeks. [90] This should only be done in a medical setting with appropriate anaphylaxis precautions observed. Other investigators had difficulty replicating the results using this risky procedure, and now topical desensitization has become much more common. Constantine et al. propose that therapy should be transiently discontinued until clearance of the allergic dermatitis is achieved (using topical steroids if necessary). [91] Then 0.01 to 0.1 mg per 100 ml of the drug should be applied daily for 1 week. If this dilution was tolerated, the dosage was doubled weekly until the dose achieved was often identical to the initial concentration that induced the hypersensitivity.

Some clinicians, however, believe that a mild hypersensitivity reaction may have beneficial antitumor effects. Ratner et al. previously demonstrated that plaque lesions of MF cleared when exposed to topical doses of 2,4 dinitrochlorobenzene, a known universal inducer of delayed hypersensitivity responses. [92] Anergic individuals failed to improve. Other known sensitizing agents yielded similar but less dramatic responses. Thus, some hypersensitivity may be beneficial; the generalized erythroderma and pruritus are usually poorly tolerated when severe, however, and some alteration in therapy is required.

There has been an increased risk of secondary skin cancers in patients receiving long-term mechlorethamine. Of recent concern is the safety of family members or health care workers secondarily exposed to the topical solutions. However, we are unaware of any documented adverse outcomes, and believe this to be a theoretical concern more than a practical one.

Several other topical agents have been tested and shown to be of benefit in the treatment of MF, including corticosteroids, cytarabine, dianhydrogalactitol, dacarbazine, quanazole, teniposide, hydroxyurea, thiotepa, and methotrexate. [93] However, topical carmustine is the only agent that has demonstrated clinical use. [94] A stock solution is created with 300 mg carmustine in 150 ml of 95% ethanol (sufficient for 30 days of treatment). The patient then adds 5 ml of the 0.2% stock solution to 60 ml of room temperature tap water. This solution can then be applied to the general body surface, with the exception of the head, genitals, palms, soles, and intertriginous zones, unless involved by disease. Applications are daily for 26 months if necessary. Brief exposures to double-dose solution can be tried for resistant

disease.

Results in 188 patients with patch/plaque disease demonstrate efficacy similar to that of topical mechlorethamine. [74] For limited patch disease, there was a failure-free rate of 90% at three years. For more extensive patch stage disease the freedom from treatment failure rate at three years was 62%. Some patients have been managed as long as 10 years with the topical carmustine. Side effects of contact dermatitis are less frequent with this agent, but systemic side effects, mainly leukopenia, are more common. This drug may be helpful for the treatment of patients who do not tolerate topical mechlorethamine as there is no cross-sensitivity.

Hamminga et al. have performed one of the few prospective trials comparing total-skin electron beam radiation to topical mechlorethamine. [95] A total of 42 patients with MF localized to the skin (no documented nodal or visceral involvement) were treated. Patients were not randomized to their treatment; rather, the physician based the decision on patient health, availability of the linear accelerator, and the distance the patient lived from the clinic. In patients with minimal skin disease, no difference was noted. In more advanced skin disease, a trend toward superior initial response was seen with electron beam, but there was a high relapse rate in those patients, necessitating subsequent therapy.

Systemic Chemotherapy

Systemic chemotherapy should be reserved for those patients with relapsed or refractory disease after topical interventions, or for those patients with advanced nodal or visceral disease at presentation. Single-agent chemotherapy with alkylating agents, cisplatin, etoposide, bleomycin, doxorubicin, vincristine, and vinblastine have been used for the treatment of MF or the Sezary syndrome.[96] [97] [98] [99]

McDonald and Bertino have reported particularly good results with methotrexate administered intravenously followed by oral leucovorin factor. [100] Patients received 15 mg/kg of intravenous methotrexate every 5 days. If a patient tolerated the lowest dose, each subsequent dose was escalated. After 5 intravenous doses, patients were switched to oral methotrexate (2550 mg) with oral citrovorum as weekly maintenance. All eleven patients achieved good or better clearing (>60%) for a median duration of 24 months. Mucositis and skin ulceration were

the most significant toxicity witnessed. Myelosuppression was mild in general.

Subsequently this group has explored the benefits of adding 5-fluorouracil to the regimen exploiting the synergy between these agents. [101] The methotrexate was administered as a 24-hour continuous infusion at 60 mg/m^2 . Immediately following this infusion, 5-fluorouracil (20mg/kg each 24 hours) was continuously infused for 3648 hours. Oral leucovorin factor (10mg/m^2) was administered intravenously 6 hours after cessation of the methotrexate infusion, and then orally for five additional doses. The methotrexate dose was escalated to a maximum of 120 mg/m^2 , as allowed by toxicity, and response. Ten patients were treated for an average duration of 33 months (range 378 months). The number of cycles administered ranged from 545. All patients achieved a partial remission. Initial cycles were given every 58 days. Once a good response was achieved, cycles were administered every 3 months as maintenance.

Other groups have anecdotally reported success with low doses of oral methotrexate. In general, these regimens appear to be fairly well tolerated.

A new family of compounds, the purine anti-metabolites, has been developed and shown to be active in the treatment of MF. These compounds do not have a single mechanism of action, but all ultimately interfere with intracellular regulation of deoxyribonucleotide pools and this imbalance partially explains their cytotoxicity. This family of drugs includes 2-deoxycoformycin (DCF), fludarabine phosphate, and 2-chlorodeoxyadenosine (2-CdA). [102]

DCF is a transition state inhibitor of adenosine deaminase. Inhibition of this enzyme, necessary for the conversion of adenosine to inosine, results in accumulation of 2-deoxy-ATP and subsequent inhibition of the enzyme ribonucleotide diphosphate reductase necessary for DNA synthesis in dividing cells. DCF is also effective against cells in the resting state, where ribonucleotide diphosphate reductase levels are barely detectable. It has now been shown that deoxy-ATP accumulation in resting lymphocytes results in increased DNA strand breaks over time; this results in the activation of Ca^{++} /Mg^{++} dependent endonuclease that produces double-stranded DNA strand breaks at internucleosomal regions, and also activation of a poly-ADP-ribose polymerase that consumes both NAD and adenosine triphosphate. These perturbations lead to apoptotic cell death.

Fludarabine phosphate represents the fluorinated derivative of ara-A. This compound was known to retain cytotoxic action against leukemias, and was resistant to degradation by adenosine deaminase. Solubility was poor, however, unless the 5'-monophosphate derivative was used; hence fludarabine monophosphate is the 5'-monophosphate form of F-ara-A. Similar to the mechanism of action of cytarabine or ara-A, fludarabine phosphate requires phosphorylation by deoxycytidine kinase to the active triphosphate metabolite F-ara-ATP. Again, this triphosphate derivative inhibits ribonucleotide reductase, resulting in nucleotide pool imbalances, which prevent DNA repair and ultimately cause apoptosis.

2-CdA represents another chemical modification of deoxyadenosine rendering the drug resistant to adenosine deaminase. After activation via deoxycytidine kinase, the triphosphate derivative similarly inhibits ribonucleotide reductase, and accumulates intracellularly perturbing the deoxyribonucleotide pool balance, resulting in DNA damage and cell death.

Enzymes such as cytoplasmic 5'-nucelotidase catalyze the degradation of the active triphosphate derivatives noted previously. Cells with relatively greater levels of the activation enzymes versus degradation enzymes were identified as likely clinical targets. Lymphocytic disorders make good targets for these agents due to their high levels of deoxycytidine kinase, low levels of 5'-nucleotidase, and their dependence upon polymerase alpha for DNA repair. It was known that T-lymphoblastoid cell lines were most sensitive to these drugs, and thus it was thought that T-lymphocyte disorders would be sensitive in vivo to these agents.

A number of studies of small numbers of patients with MF have been performed to date with these drugs. Table 74-4 shows the results of these studies. Three studies used DCF as a single-agent at doses ranging from 410 mg/m^2 daily for three doses every 28 days.[103] [104] [105] Twenty-five patients with MF or Sezary syndrome were included in these studies; overall 3 complete responses (12%) and 12 partial responses (48%) were documented.

The use of fludarabine for the treatment of MF has been more thoroughly tested by von Hoff et al. [106] They treated 33 patients good risk (no prior systemic therapy) or poor risk (prior systemic therapy) with fludarabine alone at doses of 25 or 18 mg/m^2 for the two groups respectively. One complete response and five partial responses were observed for an overall response rate of 18%.

Finally, 2-CdA has been evaluated as a single agent for the treatment of MF or the Sezary syndrome. At Northwestern University we have treated 21 patients who had failed at least one prior therapy. [107] There were three complete responses and three partial responses (overall response rate = 28%). The median duration of response in this heavily pretreated group, however, was only 4 months. Three other groups have also reported results in small numbers of patients for the treatment of MF.[108] [109] [110] A total of 21 patients were reported when the results from these studies were combined. Seven patients achieved responses, giving an overall objective response rate of 33%, remarkably similar to our large single institution result.

The similarity in mechanism of action of these compounds would suggest that toxicity associated with the various compounds would be similar. This has definitely not been the case, however. There are distinct differences in the spectrum of both acute and chronic toxicities with these agents. DCF and fludarabine are associated with higher rates of nausea/vomiting and alopecia then commonly associated with 2-CdA. The most significant toxicity with DCF and fludarabine, however, are neurotoxicity and immunosuppression. Approximately 15% of patients developed sepsis, and 10% developed an opportunistic infection, such as disseminated toxoplasmosis or cytomegaloviral infection, *Pneumocystis carinii* pneumonia infection, atypical mycobacterial infection, and fungemia also have occurred in patients in studies with these drugs. Another 15% developed severe neurotoxicity in the form of confusion, motor weakness, parasthesias, and central nervous system demyelination. 2-CdA therapy is extremely well-tolerated acutely, but may result in somewhat greater myelosuppression than the other agents. This myelosuppression may even be more significant when the agent is used to treat T-lymphocyte disorders compared to B-cell diseases. In the study by Betticher et al., significant decrements in neutrophils and lymphocyte populations occurred in 46% and 41%, respectively. In our study of 2-CdA, we reduced the days

TABLE 74-4 -- Response Rates of Treatment with Purine Anti-metabolites for MF

Author/Drug	Response Rate
ECOG/DCF	66%
Grever/DCF	100%
Dearden/DCF	54%
von Hoff/Fludara	18%
Kuzel/2-CdA	28%
Saven/2-CdA	38%
O'Brien/2-CdA	18%
Betticher/2-CdA	100%

Abbreviations: DCF, 2-deoxycoformycin; Fludara, fludarabine; 2-CdA, 2-chlorodeoxyadenosine; ECOG, Eastern Cooperative Oncology Group.

of therapy delivered by continuous infusion to 5 days, from the usual 7, because of a perception that the toxicity, primarily prolonged thrombocytopenia, was unacceptable. These results suggest that patients treated with these agents should be carefully evaluated for infectious complications, especially opportunistic infections, and that prophylactic antibiotic, antifungal, and/or antiviral therapy should be considered during and following therapy if significant immunosuppression is documented. Additionally, one should carefully consider the value of continuing to administer cycles of therapy if there is not evidence of further improvement in clinical response, because of the risk of patients suddenly developing prolonged cytopenias that may limit further therapeutic approaches.

Combination chemotherapy has often been employed for patients with advanced disease, either at presentation or with progression. Usually alkylating agents are used, in combination with doxorubicin, or vinca alkaloids. [111] [112] Response rates of 80100% have been achieved, with longer duration of remission than those seen with single agent therapy. However, no trial has demonstrated survival benefits in patients treated with more aggressive regimens versus milder palliative therapies alone. Thus, single agent and combination chemotherapy regimens should generally be reserved for use after less toxic interventions have been attempted.

The natural evolution of combination chemotherapy has been to use dose-intensified approaches with hematopoietic reconstitution with autologous [113] or allogeneic bone marrow.[114] There are few reports in the literature of such treatment programs. Of a total of 9 patients (of whom we are aware) who received high-dose chemotherapy with or without total body irradiation and autologous bone marrow transplants, only two had reasonable disease-free intervals (greater than 12 months). Given the propensity for Sezary cells to be detectable despite a lack of clinical symptoms even in early stage disease if sophisticate molecular techniques are used, it is likely that reinfusion of neoplastic cells may occur with autologous bone marrow. The questionable benefit in low-grade B-cell lymphomas of autologous bone marrow transplant similarly suggests that this approach will not benefit patients. Allogeneic bone marrow transplantation, on the other hand, has been presumably curative in small percentages of patients with low-grade B-cell lymphomas. Therefore, this approach should be investigated in the small subset of young patients with HLA identical siblings, who have poor-prognosis disease and demonstrated relapse or resistance to interferon and topical therapies. A single patient treated with cyclophosphamide and total body irradiation was reported to achieve a complete remission to therapy. This patient, however, relapsed by day 70, necessitating additional therapy. The patient remained clear of lesions and alive at least 6 years after the transplant. These reports provide little reliable information regarding the efficacy of such approaches, but do suggest that the procedure can be performed safely without excessive toxicity. Further information is needed.

Photopheresis

An adaptation of the use of psoralens with UVA light called photopheresis has been described by Edelson et al. [115] Patients ingest 0.6 mg/kg of oral 8-methoxypsoralen before a treatment. The treatment consists of routine leukapheresis with isolation of the mononuclear cell fraction. The cells are then exposed to UVA light ex vivo within a special chamber within the pheresis device. In the initial report, Edelson et al. documented an 88.5% loss of lymphocyte viability compared to control patients treated with drug alone. Overall 64% of patients responded to therapy, with the best results in those with generalized erythroderma, and, presumably, higher circulating Sezary cell levels. The mechanism is not thought to be directly cytotoxic, but rather to induce a host immune response to the reinfused altered Sezary cells. This theory would explain the findings of some investigators that patients without leukemic involvement do poorly with this therapy. This treatment modality has given best results in SS patients with erythroderma of short duration and with adequate CD8+ blood counts.

Several other groups have reported their experiences with photopheresis. [116] [117] When the data are analyzed on an intent-to-treat basis, overall response rates of 3652% are observed. Only 1218% achieve complete remissions using this therapy. These investigators attempted to wean patients from therapy as clearing of lesions was documented. Ultimately, most responders developed recurrent disease.

Toxicity is mild and includes occasional nausea, erythematous flares, and temperature elevations. Patients may develop hypotension during leukapheresis, which usually responds to saline infusions.

Interferons

It is now recognized that the most active agent for the treatment of MF is interferon alpha. [118] [119] [120] [121] [122] Dosages and routes of administration have differed among studies. Initially, high dose interferon was used with maximum doses of 3650 million IU. Bunn et al. and Olsen et al. independently demonstrated complete response rates of 1027% in heavily pretreated patients. The duration of response was only 5.5 months. More recent trials of untreated patients with doses of 318 million IU subcutaneously daily have demonstrated response rates of 8092%. From all these studies it appears that a reasonable and tolerable single agent dose is 12 million IU per square meter administered subcutaneously daily. We recommend starting at 3 million IU and gradually increasing as treatment is tolerated by the patient.

Side effects are dose-dependent. Most common adverse effects are constitutional symptoms consisting of fever, chills, myalgias, malaise, and anorexia. Rarely, cytopenias, elevations of liver function tests, renal dysfunction, cardiac dysfunction, or changes in mental status can be seen. Patients need to be monitored closely while on interferon.

Investigational Approaches

Because of the chronic relapsing nature of MF, new therapies with different mechanisms of action are needed to circumvent tumor resistance. A variety of such approaches are under investigation. These include the use of existing or newly developed retinoid compounds [123] or combinations of retinoids with interferons. [124] Other combination modalities under study include retinoids, interferons, and chemotherapy or radiation therapy, [125] and total skin electron beam radiotherapy followed by photophereis or chemotherapy.[126] Given the lack of benefits of combination chemotherapy and radiotherapy previously, the role of such approaches should remain investigational. Another less toxic combination approach has been the simultaneous administration of interferon and phototherapy. [127] Kuzel et al. demonstrated an overall response rate of 92% with this combination in all stages of patients, many of whom had been previously treated with other therapies. The combination of interferon and topical therapy is now being tested against topical therapy alone in a national cooperative group trial.

Another approach to the therapy of this disease has involved new drugs to exploit the biology of these neoplastic cells. Targeted therapies against unique tumor antigens continue to be tested,[128] such as monoclonal antibodies and ligand-toxin fusion proteins. Knowledge of the unique cytokine milieu associated with these neoplastic T-cells has led to trials testing cytokines that may inhibit the growth of these cells, such as IL-12 [129] or IL-2.[103] Finally, vaccine approaches may be practical.[130]

It is clear that a significant amount of basic and practical research has been performed in an attempt to control this disease.

It is certainly hoped that one of the strategies under development or study will lead to treatments that will control the disease and symptomatic effects, or even cure this neoplasm.

Chapter 75 - AIDS-Related Lymphomas

David T. Scadden

INTRODUCTION

Non-Hodgkin lymphoma is the most lethal complication of HIV disease. This disorder was noted to be associated with HIV infection early in the epidemic and was added to the list of complications defining the acquired immunodeficiency syndrome (AIDS) in 1987. [2] [3] [4] [5] [6] [7] [8] [9] [10] The clinical landscape of HIV infection has changed over the last several years and with these changes have come modifications in both the understanding and treatment of AIDS-related lymphomas. This chapter covers current background information, evolving concepts in pathophysiology, treatment guidelines, and prospects for future development in AIDS-related lymphoma (ARL).

Lymphoid proliferation is common among many different types of immunodeficiencies. Congenital abnormalities of lymphocyte function such as Wiskott-Aldrich, or immunosuppressive therapy employed in the setting of organ transplantation have long been identified as predisposing patients to developing often-fatal lymphoproliferative disease. The incidence of non-Hodgkin lymphoma following organ transplant is related to the severity of immunosuppressive regimen used and is more common in multi-organ transplants for that reason. While the depth of immunosuppression enhances the likelihood of developing lymphoma, immune stimulation may also participate in the lymphomagenic process. This is supported by the association of lymphoma with autoimmune diseases considered reflective of excessive immune activation such as rheumatoid arthritis or sicca syndrome (Table 75-1).[11] [12] [13] [14] [15] [16] [17] [18] [19] [20]

Despite a common association of immunodeficiency with lymphoma, HIV-1 induced immunosuppression and resultant lymphoma do have distinctive features. For example, the relatively high incidence of a polyclonal, prodromal phase in post-transplant patients appears to be relatively infrequent in ARL, although the issue remains controversial.[21] Epstein-Barr virus is virtually uniformly present in the post-transplant lymphomas, whereas it is present only in approximately half of AIDS-related lymphomas. Translocations of *c-myc* are generally not seen in the post-transplant setting, but are common in ARL. The small

TABLE 75-1 -- Magnitude of Relative Risk of Lymphoma[a]

High (RR > 15)	Intermediate (RR > 2)	Low (RR 2)
Multiple transplants	Sibling transplant	Splenecotomy
Cadaver transplant	Mild sicca syndrome	Sarcoidosis
Severe sicca syndrome	Nontropical spruce Crohn disease	Hyperimmunization Asthma
Wiskott-Aldrich syndrome	Short-term HIV infection	Hansen disease
Ataxia-telangiectasia	Rheumatoid arthritis	
Long-term HIV infection		Systemic lupus erythematosus

Abbreviation: RR, relative risk.

[a] Risk of lymphoma in patients with the condition relative to a risk of 1.0 to comparable individuals without the condition.

non-cleaved cell- or Burkitt-like lymphoma seen in ARL is not an entity among the other immunodeficiency lymphomas. It is extremely rare in the post-transplant patient, strongly suggestive of unique pathophysiologic characteristics in the setting of AIDS.

The heterogeneity of lymphomas within the HIV-infected population emphasizes the complexity of tumor development. A range of different mechanisms have been evoked, including abnormal B-cell activation, excessive cytokine stimulation, altered microenvironment preferentially supporting lymphomatous cells, the predisposition to the persistence of specific chromosomal abnormalities, and perhaps most important, the inadequate immunologic control of persistent viral infections with transforming potential. Understanding how these factors may result in the manifestation of malignancy offers the potential for unraveling how immunologic function interfaces with immunologic malignancy with implications extending beyond that of the AIDS epidemic.

EPIDEMIOLOGY

An increased incidence of non-Hodgkin lymphoma (NHL) was first noted among middle-aged unmarried men in the San Francisco area in 1984 and became a criterion for defining an AIDS illness with the first redefinition of the syndrome by the Centers for Disease Control. This association has been reaffirmed in other epidemiological series and includes individuals from virtually every risk group for HIV infection. Unlike the other major neoplastic complication of AIDS, Kaposi sarcoma (KS), NHL is fairly uniform across the spectrum of HIV-infected individuals. [22] [23] There is a slight increase in incidence noted among hemophiliacs [22] [23] [24] that has provided an intriguing link and potential window on other contributing cofactors, but this remains simply a statistical observation at this time. Lower incidences of lymphoma among IV drug abusers in some series probably reflects the early death of such patients from other opportunistic diseases as well as issues related to their overall care, rather than a true biologic difference.

The incidence of NHL in HIV-infected individuals has been variably estimated between 1.6 and 6% per year. [25] [26] [27] The discrepancy in estimates may be related to inclusion of postmortem diagnoses in the series with high estimates. The incidence of lymphoma does increase with worsening immunosuppression and most often is seen in patients with longstanding HIV infection. However, lymphoma may be the presenting symptom of HIV and consideration should be given to this possibility in patients with aggressive lymphomas. Concerns have been voiced that antiretroviral therapy may predispose to the development of lymphoma because of the potential effect of nucleoside analogs on cellular DNA synthesis. However, subsequent studies have failed to note any association and discount the notion that retroviral therapy should be withheld out of concern about induction of lymphoma. [28]

Projected increases in the incidence of NHL in AIDS have not materialized, as other opportunistic disease has been better controlled. [29] How the recent advent of highly active antiretroviral

therapy will affect the incidence of lymphomas remains unclear. Since the introduction of protease inhibitor therapy and combined antiretroviral therapy in 1996, there has been a dramatic change in the overall prognosis for patients with AIDS. The reduction in death rates in the United States has been profound and has been paralleled by markedly reduced frequencies of many opportunistic complications. For example, the rate of cytomegalovirus disease, which had been increasing before the advent of protease inhibitor therapy, has now fallen precipitously and admissions for this disorder are a relative rarity in most US centers. Within the context of AIDS-related malignancies, spontaneous regression of Kaposi sarcoma has been documented and decreased incidence and marked reductions in the number of patients requiring systemic therapy for Kaposi sarcoma have been observed. Firm epidemiologic data regarding the impact of these therapies on lymphoma are yet to evolve. However, clinical impressions suggest that there is a marked reduction in those patients who present with primary CNS lymphoma, generally a manifestation of end-stage immunosuppression. Systemic lymphomas continue to occur and alterations in their frequency appear to be far more subtle than that of primary CNS lymphoma.

PATHOPHYSIOLOGY

The epidemiology of non-Hodgkin lymphoma is generally changing within the United States, with an increased incidence noted particularly among men. The bases for this change are poorly understood, but a contributing factor is the HIV epidemic and AIDS-related lymphoma. The epidemiology of ARL is influenced by HIV treatment and coincident associated viruses such as EBV and the recently described Kaposi sarcoma herpesvirus (KSHV) also known as human herpesvirus-8 (HHV-8). [30] There are likely other, yet undetected cofactors that account for some of the other subsets of this disease. In particular, the small non-cleaved or Burkitt-like lymphomas represent a subset for study for identification of new, potentially infectious, cofactors contributing to ARL.

HIV-1 itself rarely participates directly in the malignant process, but rather provides the background of immunodeficiency within which lymphomas may arise. A small minority of lymphomas seen in AIDS are of T-cell origin. Molecular analysis of some of these cases has indicated that HIV was either integrated in the T cells or highly expressed in tumor-associated macrophages. The site of HIV integration into the host genome was evaluated and found to be in a common site upstream of the proto-oncogene, *c-fes.* [31] Apart from these relatively uncommon tumors, the transformed cells do not contain HIV-1 DNA. Rather, other mechanisms of lymphomagenesis likely predominate.

Potential contributing underlying abnormalities include most prominently:

1. Inadequate immunologic control of persistent viruses with transforming capability
2. Alteration in regulatory environment for lymphoid growth control
3. Accumulation of genetic abnormalities in target cells

The issue of participating secondary infectious processes in ARL is supported by the spectrum of AIDS malignancies generally (Table 75-2). Tumors with definite or probable increased frequency in HIV disease are notable for the relatively small number of tumor types seen. Unlike tumors outside the setting of HIV disease, where a broad spectrum of epithelial neoplasms occur, the spectrum of malignancy is narrow. Unifying each of these diseases is an association with underlying infectious agents. The herpes virus, KSHV, is associated with both KS and a subset of NHL. It may also participate in the development of

TABLE 75-2 -- AIDS-Associated Tumors

Hodgkin disease
Leiomyosarcoma
Plasmacytoma

plasma cell dyscrasias [32] and it has been implicated in the development of Castleman disease. [33] The squamous cell neoplasia of the uterine cervix in HIV-infected women, of the anus of homosexual men, and of the conjunctiva in individuals in Africa is associated with the human papillomavirus. [34] [35] [36] [37] [38] [39] [40] Epstein-Barr virus is a well known participant in a subset of lymphomas as well as the leiomyosarcoma seen in children [41] and in the Hodgkin disease seen in the setting of HIV. [42] Thus viral pathogens are strongly related to the development of neoplastic complications. The specific mechanisms participating in transforming events are in the process of further evaluation. These offer the potential for novel types of therapeutic intervention and the viral antigens associated with them offer possible immunotherapeutic targets.

The Epstein-Barr virus genome has been reported to be present in 3367% of AIDS-related lymphomas as opposed to 5% of high grade lymphomas outside the setting of HIV. [43] The frequency varies depending on the cell type involved. Immunoblastic tumors of the CNS virtually uniformly have the EBV genome present, whereas only 2034% of the Burkitt-like tumors contain EBV. [44] [45] Recently described oral cavity ARLs with T-cell markers [46] and plasmablastic lymphomas in the oral cavity [47] all appear to have EBV present. Leiomyosarcomas occurring in children with HIV disease, but not in adults, also uniformly contain EBV within the tumor cells. [41]

EBV is thought to infect cells and induce their altered proliferation by expression of virus genes that are part of the virus latent (as opposed to lytic) phase. The pattern of EBV gene expression varies with the clinical and pathologic setting. In patients with primary CNS lymphoma, the EBV latent gene expression pattern is identical to that of post-transplant lymphoproliferative disease, including Epstein-Barr nuclear antigens (EBNA)-2 through EBNA-5 and latent membrane protein (LMP)-1 and -2. [48] [49] In Burkitt lymphoma, only EBNA-1 is usually detectable. [48] [49] [50] [51] For some systemic ARL, a unique combination of EBNA-1 and LMP-1 expression has been reported. [52] Molecular analysis of EBV latent genes has indicated that EBNA-1 is important for transformation due to its effects on transcription and maintenance of the EBV episome. LMP-1 is essential for primary B cell transformation and for transforming effects on non-lymphoid cells. [53] [54] [55] LMP-1 interacts with the signaling pathway used by the tumor necrosis factor receptor family of genes through very specific molecular interactions at its c-terminus. [53] [54] [55] [56] A number of mutations have been noted within the LMP-1 portion of the EBV genome and some data have supported the possibility that these variants are associated with ARL or HIV-related Hodgkin disease. [57] [58] [59] [60] However, controversy on this continues as some studies have indicated that LMP-1 mutations occur with similar frequency in patients with lymphoproliferative disease and in unaffected individuals. [58] The relationship of EBV to transformation is clear, but why certain individuals are more predisposed to develop lymphoma is still unknown. Molecular evolution of the virus within the host remains a tenable, but unproven hypothesis.

An alternative possibility is that some individuals will selectively lose their immunologic reactivity to EBV or other transforming

viruses. A number of immunologically recognized antigens within the Epstein-Barr genome have been characterized as being targets for cytotoxic T lymphocytes. [61] These may be masked by effects of EBV EBNA-1 on antigen presentation through altered processing pathways [41] [62] [63] or through deletion of reactive cytotoxic T lymphocyte (CTL) clones during the course of progressive immunodeficiency. Alteration of the T-cell receptor repertoire is a well documented phenomenon in AIDS and may result in non-homogeneous losses of reactivity to specific foreign or tumor antigens. [64] This phenomenon suggests the potential for clonal repletion as a strategy for intervention and indeed such an approach has been successfully demonstrated in post-transplant patients with EBV lymphoproliferation. [65] [66] [67] Adoptive

transfer of T cells has induced tumor regression in other immunodeficiency-related lymphomas.

The vigor of immunologic response may also be affected by virus gene products. In particular an EBV gene (BCRF-1) has homology with human interleukin 10 (IL-10) and mimics IL-10 function.[68] [69] [70] IL-10 has been noted to inhibit interferon gamma and IL-2 elaboration by helper T-cells (TH-1), cells important in immunologic function.[69] Cell lines and primary tumors isolated from patients with AIDS lymphoma produce a high level of interleukin-10 and elevated circulating levels of interleukin-10 in mouse models of AIDS-lymphoma have been well documented.[68] [70] [71] [72] [73] Other cytokine-related effects include the production of CD40 (a B cell proliferation signal) by HIV-infected bone marrow endothelial cells [74] and IL-6 production by HIV-infected macrophages or by KSHV-infected cells.[75] [76] Indeed increased IL-6 levels have been noted to correlate with malignancy and increased serum CD23 (a marker of activation) to precede it. [77] [78] Dysregulation of cytokines further induces alterations in B-cell biology contributing to a hyperproliferative state.

Another viral pathogen that contributes to ARL is the recently described member of the gamma-herpesvirus family, KSHV. This virus was originally identified by comparative analysis of the DNA content from Kaposi sarcoma (KS) tissue versus uninvolved tissue.[79] This genetic approach to pathogen identification revealed a virus that has now been shown convincingly to be associated with KS, but also with a subset of ARL, Castleman disease, and perhaps plasma cell dyscrasias. [30] [32] [33] [80] The lymphomas are generally restricted to body cavities without tumor masses and are termed primary effusion lymphomas (PEL). Features of this clinicopathologic entity will be further discussed in a separate section, but features of this virus are extremely interesting from the pathophysiologic perspective.

KSHV is known to be capable of infecting primary B cells[81] and is uniformly found in the transformed B cells of PEL. Mechanisms by which this virus participates in the malignant process remain speculative since in vitro infection with KSHV does not result in B cell transformation. However, a number of components of the KSHV genome suggest the potential for this virus to alter B cell physiology. These include a constitutively active chemokine receptor which causes cell lines to have enhanced malignant potential when transfected, a physiologically active cyclin D homologue, a viral interleukin-6 with potent function, a BCL-2 homologue, and CC chemokine homologues.[76] [80] [82] [83] [84] [85] [86] [87] This constellation of different immunoregulatory proteins is highly suggestive of direct mechanisms by which the virus may perturb cell functions, but the details have not yet been clarified. The immunologic response to KSHV at this time is also poorly understood. However, the association of KSHV-related tumors with immunodeficiency of multiple types strongly supports the role of immune function in tumor control.

A large fraction of ARLs do not have evidence for either EBV or KSHV infection. While it has been hypothesized that these may represent cells transformed by still-unknown infectious agents, a number of potential etiologies remain. These include the proliferative drive provided by EBV or HIV-induced cytokine alterations as noted previously. In addition, a gross dysregulation of B-cell biology is evident early on in HIV disease regardless of the subsequent development of lymphoma. [88] This includes the presence of hypergammaglobulinemia, which is perhaps the most common serologic abnormality among HIV-infected individuals.[89] [90] As patients progress in HIV disease, lymphadenopathy with follicular hyperplasia is common and is similarly reflective of disordered regulation of the B-cell lineage. [91] [92] It has been postulated that a portion of the HIV envelope may be capable of inducing T-cell-mediated B-cell activation. [93] [94] This may result in particular outgrowth of HIV-specific B cells. With chronic stimulation transformation may occur and sporadic multiple myeloma with HIV specificity has been reported. [95] [96] [97] Characterization of the variable chain repertoire of immunoglobulins produced by B cells in patients with HIV disease has indicated that preferential use of the VH subsets occurs early in HIV infection[98] and in ARL tumors.[99] These findings suggest that there may be an antigen-driven expansion of selected B-cell clones that may provide the mitogenetic background for mutogenesis to result in malignancy.

A number of specific genetic mutations have been observed in ARL and are associated with specific tumor-types. [100] [101] [102] That is, tumors of small-cell or Burkitt-like histology uniformly exhibit *c-myc* gene rearrangements, may have p53 gene mutations, and do not exhibit BCL-6 rearrangements.[103] [104] [105] [106] This is in contrast to large cell lymphomas, among which approximately one-third will demonstrate BCL-6 rearrangement, 40% *c-myc,* and 25% p53 mutations.[107] The *c-myc* rearrangement that is found most often juxtaposes *c-myc* with the immunoglobulin heavy chain switch region.[105] [108] [109] [110] [111] The involvement of this region suggests that the transforming event has occurred in a B cell that is undergoing transition between heavy chain isotopes: phenomena occurring at a relatively late stage in B-cell ontogeny.[23] [103] [104] [106] [112] [113] [114] The malignant cell therefore appears to be a relatively mature B lymphocyte. In ARL, *c-myc* rearrangement and EBV infection are not necessarily present in association with one another. [103] [104] [105] [106] Similarly, BCL-6 rearrangements are variably associated with the presence of EBV. It is of interest that no coincident *c-myc* and BCL-6 rearrangements have been detected.[107] Molecular abnormalities associated with low-grade lymphomas (such as the 11:14 rearrangement) are generally not seen in ARL.

CLINICAL MANIFESTATIONS

AIDS-related lymphomas are generally extremely aggressive, high-grade lymphomas of B-cell origin. However, the spectrum of lymphoproliferative disease is broad and is continuing to expand. T-cell malignancies have been reported, including large granular lymphocyte disease, large cell or anaplastic T-cell lymphoma, Sezary syndrome, and angiocentric T-cell proliferation. [97] [115] [116] [117] [118] [119] [120] [121] [122] Virus infection with human T-cell leukemia/lymphoma virus (HTLV-1) has been noted in some cases of T-cell malignancy with coincident HIV infection. [123] In addition, HIV itself has been noted to be integrated in some of these lymphomas, [31] [122] as previously discussed. Oropharyngeal T-cell lymphoma has been described in AIDS patients and is associated with the presence of EBV in the tumor cells. [46]

Castleman disease or angiofollicular lymph node hyperplasia has been reported in patients with advanced HIV disease. [33] This is typically a multicentric variant of Castleman disease that is associated with fever, peripheral adenopathy, weight loss, hepatosplenomegaly, pulmonary symptoms, and anemia or pancytopenia. Both the hyalin-vascular and plasma cell subtypes of Castleman disease have been reported in AIDS patients. There is a very high association of this process with the presence of KSHV in the involved nodes and a high prevalence of coincident or subsequent Kaposi sarcoma. [33] [80] [124] [125] This lymphoproliferative process is often aggressive with poor outcome, although responses to chemotherapy have been reported. [33]

TABLE 75-3 -- Primary Effusion Lymphoma (Body Cavity Lymphoma)

Positive fluid cytology without mass
Distinct phenotype: null cell immunophenotype with rearranged immunoglobulin genes)
HHV8-positive

Plasma cell disorders appear to be increased in the setting of HIV infection. Plasmablastic lymphomas of the oral cavity have recently been described [47] as a relatively uncommon neoplasm, notable for the frequent absence of typical lymphoid markers such as CD45 (leukocyte common antigen) or CD20. Extramedullary plasmacytomas have been reported, as well as overt multiple myeloma. [126] [127] The clinical course of these disorders is highly variable and the clinical approach should be based on standard guidelines for these diseases outside the context of HIV infection.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

HODGKIN DISEASE

Controversy remains regarding the incidence of Hodgkin disease in patients with HIV infection, but data are accumulating to support the notion that the frequency of the disease is increased in infected individuals. [128] [129] The clinical presentation in the setting of HIV infection is often distinct in that the clinical stage is more advanced and the mixed cellularity subtype more common. [6] [117] [129] [130] [131] [132] [133] [134] [135] [136] Stage 34 disease at presentation has been noted in over 80% of HIV-seropositive patients. [131] Extranodal disease is also more common in HIV-seropositive patients with one series reporting a frequency of 63% compared to 29% in seronegative patients. [135] In addition, histopathologic features of Hodgkin disease in AIDS are different both in the frequency of mixed cellularity and the presence of EBV. Virtually all tumors have detectable EBV and express LMP-1. [137] A high frequency of LMP-1 molecular abnormalities has also been noted in patients with AIDS compared to patients with Hodgkin disease who do not have AIDS. [137]

The clinical approach to patients with Hodgkin disease in the setting of HIV infection is similar to that in other contexts with standard staging methods. Treatment strategies should be applied as appropriate for stage, similar to guidelines outside the setting of HIV infection. However, the underlying level of immunosuppression and overall performance status of the patient must be considered. A higher incidence of treatment complications may be expected if the patient has very advanced AIDS, and appropriate prophylaxis for *Pneumocystis carinii* should be undertaken. However, cure of Hodgkin disease has been well demonstrated in the setting of HIV infection and dose attenuation should be contemplated only in those patients with advanced AIDS or those who have demonstrated intolerance to the standard dose regimens.

NON-HODGKIN LYMPHOMA

The vast majority of lymphomas that occur in the context of HIV are of B-cell origin and are typically aggressive, high-grade malignancies. The lymphomas can basically be broken down into two major subcategories: primary CNS lymphoma and systemic lymphoma that may or may not include CNS involvement. In the systemic disease category, a subset of patients have the primary effusion lymphoma (PEL) mentioned previously (Table 75-3).

These PEL or body cavity lymphomas are generally present in body fluids without associated tumor masses. [30] [138] They have a common immunophenotype in that markers of B or T cells are generally absent from the cell surface, but evidence for immunoglobulin gene rearrangement by analysis of tumor DNA indicates that they are of B-cell origin. These tumors are uniformly associated with the presence of the KSHV genome in the tumor cells. Although many also contain Epstein-Barr virus (EBV), this finding is less uniform. [100] [101] Sero-epidemiologic data regarding this virus remain quite controversial. However, emerging information suggest that this is a virus that can be transmitted sexually and is present in subsets of the North American population with estimates ranging from 520%. [139] [140] Other areas associated with the higher frequency of Kaposi sarcoma, such as the Mediterranean basin and Central Africa, have been noted to have far higher frequencies of seropositivity for KSHV. [139] Patients with PEL often have advanced immunosuppression and present with rapidly evolving pleural or pericardial effusions or ascites. The bowel may be involved [141] and some patients will show dissemination to bone marrow and blood. This tumor generally behaves very aggressively and the outlook with current approaches is unfavorable.

The most common histologic types of NHL in AIDS are small non-cleaved cell types (Burkitt or Burkitt-like) representing approximately one-third of cases, with the rest approximately equally divided among the diffuse large cell and immunoblastic subtypes (Table 75-4). The latter two subcategories would be lumped together under the Revised European-American

PREFERRED APPROACH

Patients who present with non-Hodgkin lymphoma in the setting of AIDS should be assessed with a standard complete blood cell count and chemistry panel to which should be added a lymphocyte subset analysis and plasma HIV RNA. Patients who have B symptoms and a CD4 count <200 cells/cm^3 should also have blood cultures and blood isolator tubes sent. A CMV serum titer, toxoplasmosis titer, and cryptococcal antigen are also indicated along with sputum analysis for *Pneumocystis carinii* pneumonia. Imaging studies for evaluation of the extent of lymphoma should be completed in the manner employed outside the setting of HIV disease. However, we also recommend imaging of the central nervous system and sampling of the cerebrospinal fluid. Bone marrow aspiration biopsy should be obtained and special stains and cultures performed to exclude opportunistic infections.

For those patients who have a small, non-cleaved or Burkitt-like histology, paranasal involvement, bone marrow involvement, or testicular involvement, we prefer the administration of intrathecal ara-C at 50 mg weekly times 4. This should be started at the initiation of chemotherapy. Chemotherapy, in patients for whom a protocol is not available or practical, is generally standard CHOP unless patients have advanced AIDS or poor bone marrow reserve. In such cases, a modified or half-dose regimen can be justified and is often quite effective.

If patients have active involvement of the meninges, twice weekly ara-C is used until clearing of the CSF of lymphoma cells is achieved and then ara-C is administered monthly for three months. Whole brain radiation is also added.

With relapse there are no standard regimens available. We commonly use a combination of ifosfamide 2 grams/m^2 by continuous infusion and etoposide 150 mg/m^2 /d IV over 1 hour for 2 days each with MESNA support, but encourage consideration of investigational protocols for such patients.

Patients who present with primary CNS lymphoma should receive Decadron 4 mg, 4 times daily until improvement of symptoms and then the dose should be gradually reduced during a course of CNS radiation therapy. Steroids should be tapered as rapidly as tolerated to avoid the complications of prolonged immunosuppression.

In general, all patients undergoing treatment for non-Hodgkin lymphoma should have prophylaxis for PCP. We prefer trimethoprim sulfamethoxazole when tolerated. Our policy regarding antiretroviral therapy awaits the results of ongoing clinical trials; however, we generally prefer the nucleoside analogs, D4T and 3tC with indinavir or nelfinavir protease inhibitors. Alterations in drug metabolism are more likely to be encountered with the use of ritonavir or the non-nucleoside reverse transcriptase inhibitors delaverdine or nevirapine and these should therefore be used with caution. Growth factor support is often required due to poor marrow reserve in patients with AIDS.

Lymphoma (REAL) classification. Low-grade B-cell malignancies are a distinct minority among HIV-infected patients. Such tumors may occur, but with a frequency approximately comparable to the background for the population.

Like high-grade malignancies outside the setting of HIV disease, ARL often involves sites outside the confines of the lymphatic system (Table 75-4). Extranodal disease has been estimated to occur in up to 95% of patients with ARL, with extranodal tissue frequently the source of diagnosis. [4] [6] [8] [104] [134] [142] [143] [144] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154] Disease that is exclusively outside the lymphatic system has been reported in up to 56% of patients. [154]

The frequency of extranodal disease emphasizes the necessity of exercising particular vigilance in evaluating these patients. Unusual symptoms must be assessed with attention to possible direct tumor involvement as the cause. AIDS-lymphoma can also mask or be confused with other opportunistic disease. In particular, the constitutional or B symptoms which are generally seen in lymphoma will suggest possible opportunistic infection. In addition, lymphadenopathy occurs frequently in the course of HIV infection and is often simply evidence of hyperproliferation without transformation. A high index of suspicion must be maintained, particularly for those patients who have coincident B symptoms or who have rapidly progressive asymmetric lymphadenopathy.

Sites of extratumor involvement are favored by particular histologic subtypes. For example, the small non-cleaved cell histology often favors bone marrow or meninges. In contrast, immunoblastic histology often favors the GI tract and brain parenchyma. The most common extranodal sites of involvement are the bone marrow in approximately 25% of patients, central nervous system (CNS) in 23%, gastrointestinal tract in 15%, and liver in 13%. [5] [6] [8] [9] [104] [105] [106] [134] [142] [143] [144] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154]

Although approximately 1525% of patients will present with stage 1 or 2 disease (Table 75-4), the sites of involvement are often extranodal. If local therapies are undertaken, it is highly likely that patients will relapse at remote sites and therefore systemic therapy is generally favored regardless of the stage at presentation.

DIAGNOSIS AND PROGNOSIS

Staging of patients with systemic AIDS-related lymphoma includes tests performed in other lymphoma populations, such as CT scans of the chest, abdomen and pelvis, bone marrow biopsy and, if bulky mediastinal or abdominal disease is present, gallium-67 scanning. In addition, the frequency of involvement of the CNS supports the use of both radiographic imaging and CSF sampling at the time of initial staging. [143]

Patients who present with constitutional or B symptoms should have a thorough microbiologic workup to address the possibility of coincident opportunistic infections. This should include isolator cultures of the blood for mycobacteria, serologic assays for cryptococcal antigen, cytomegalovirus (CMV) antigen and toxoplasmosis antibody, induced sputum for *Pneumocystis carinii,* and routine blood culture.

The prognostic indicator that has been most predictive in patients with ARL is the stage of immunodeficiency as reflected by the CD4 count at the time of diagnosis. CD4 cells of <100/cm^3 are associated with a shorter survival in several series. In addition, prior AIDS-defining diagnoses, the Karnofsky performance score, and the presence of extranodal disease have been regarded as indicators of outcome. [135] [148] [155] [156] [157] A study involving 192 patients recently completed by the AIDS Clinical Trials Group (ACTG) demonstrated that poor overall survival on multivariant analysis was associated with age >35 years, IV drug use, stages III/IV, and CD4 cells <100. The median overall survival for patients with no or one adverse factor was 46 weeks and 30% were alive at 144 weeks. Patients with three or four factors had a median overall survival of 18 weeks with no survivors at 144 weeks. [158] Although the International Prognostic Index established for other patient populations with lymphomas has not been specifically evaluated within ARL, the results of the ACTG study and other studies suggest that these parameters will likely be useful in assessing AIDS patients as well. [159]

Other features that have been associated with outcome include polyclonality, which in one study was associated with a

more positive outcome. [155] This feature was particularly favorable if tumors were EBV negative and the CD4 counts >200 ccm^3 .

The presence of PEL has generally been associated with a very poor outcome; however, the compiled number of cases with this syndrome remains relatively limited. [138]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TREATMENT

Treatment of patients with ARL should include several components that distinguish this patient population from others. These include the use of prophylaxis for *Pneumocystis carinii* pneumonia regardless of the CD4 count at initiation of chemotherapy. This practice is generally applied because of the high potential risk during treatment-induced exacerbation of immunosuppression. The high incidence of CNS involvement in a series reported early in the epidemic [145] has led to a controversy as to whether or not CNS prophylaxis should be provided for all patients. There are no definitive data on this point, but with use of CNS prophylaxis the previously observed frequency of CSF relapse has been diminished.[156] No clinical standard can be said to have been defined, although many centers including our own administer either ara-C or methotrexate weekly for 4 weeks by intrathecal injection to at least those patients with Burkitt-like histology, bone marrow involvement, testis involvement, or perinasal sinus disease.

A concern regarding myelotoxicity has led many investigators to use growth factors prophylatically. Bone marrow dysfunction is a common feature of advanced HIV disease and those patients who present with cytopenias at diagnosis are reasonable candidates for prophylactic growth factor use. A small randomized, prospective trial in patients receiving a cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) regimen indicated that patients who received GM-CSF had statistically significantly reduced instances of fever and neutropenia and fewer days of hospitalization than patients who received chemotherapy without growth factor support.[150]

The use of antiretroviral therapy in conjunction with chemotherapy remains controversial. Earlier in the epidemic when zidovudine (AZT) was essentially the only retroviral agent available, the myelotoxic effects of this medication generally precluded its use. Most reports of treatment in patients with ARL are patients who have not received concurrent antiretroviral therapy. A study by Levine and colleagues assessed whether or not antiretroviral DDC could be given concurrently with modified m-BACOD chemotherapy[157] [160] and did not note any enhanced toxicity. In particular, neurotoxicity was not worsened and a favorable effect on HIV p24 antigen levels was noted. Ongoing studies are intended to assess whether or not highly active antiretroviral regimens including protease inhibitors can safely be given in conjunction with chemotherapy. Pharmacokinetic interactions of these medications have not yet been defined. A variable effect on the p450 pathway of drug metabolism has been documented with the use of protease inhibitors or non-nucleoside reverse transcriptase inhibitors and must be considered when they are used with chemotherapy. Although the aggressive treatment of the underlying HIV infection during treatment for lymphoma has theoretic appeal, it should be noted that HIV levels have generally remained stable during the administration of chemotherapy regimens even in the absence of specific antiretroviral drugs. In addition, the threat of HIV viremia is generally one of chronicity as opposed to the acute need for lymphoma treatment. Therefore, antitumor chemotherapy should not be compromised to accommodate antiretroviral therapy. If antiretrovirals are to be given, they should be used at doses that maximally suppress the virus since submaximal suppression may permit the emergence of resistant strains of the virus.

Selecting treatment for lymphoma is largely dictated by the patients overall clinical status. Until recently, a fair amount of skepticism has existed as to whether a curative approach should be undertaken in ARL patients since they all had what was considered a uniformly fatal underlying disease, AIDS. However, with the optimism surrounding the recent developments in anti-HIV therapy, it is now clear that a curative approach should be strongly considered. For those patients, however, who have far-advanced AIDS, are refractory to antiretroviral therapy and have poor performance status, a palliative approach may be appropriate. No specific guidelines in this situation can be provided except that careful consideration should be given to patients history of antiretroviral therapy, their history of HIV-related complications, their current CD4 count, their HIV RNA levels, and most important, their wishes regarding the level of aggressiveness of care.

For those patients in whom a curative strategy is planned, there remains ongoing controversy on how to proceed. Early in the epidemic, the high level of toxicity reported following the use of chemotherapy regimens led to exploration of the minimum necessary dose of chemotherapy needed to achieve a good clinical outcome. A regimen was originally tested that used essentially half-dose mBACOD. Encouraging results of this study [143] led to a randomized Phase III trial by the ACTG. Results of this study indicated comparable tumor outcomes for patients who were treated with a low-dose (modified m-BACOD) compared to those treated with full-dose mBACOD.[156] The rate of complete remission (50% vs. 46%), relapse after complete remission (19% vs. 23%), time to progression (22 weeks vs. 28 weeks), overall median survival (31 weeks vs. 34 weeks), death from AIDS (20 patients vs. 12 patients) and death from lymphoma (24 patients vs. 36 patients) indicated that the standard-dose and low-dose mBACOD groups were equivalent. The major difference between the two arms of the trial was that grade 4 neutropenia occurred with greater frequency in patients receiving the standard dose regimen despite the fact that all such patients received GM-CSF as a part of their treatment program. While the size of this study was relatively large (198 patients), it should be noted that it was conducted before the protease inhibitor era. The overall entry CD4 count was approximately 100 and the overall prognosis for patients was quite poor. The number of patients enrolled was not sufficient to allow subset analysis in those with more preserved immune function, but there is concern that reduced dosing may result in compromised clinical outcomes that should not be risked in such patients, since they do tolerate full-dose regimens quite well. A reasonable approach would be to use standard dose regimens such as CHOP, except for those patients in whom advanced immunosuppression raises concerns about tolerability, and with whom a modified dose intensity may be employed.

In contrast with the effort in the United States, European investigators have evaluated more chemotherapy-intensive regimens for patients with AIDS lymphoma. In a 140-patient study conducted by a French-Italian Cooperative Group using the LNH84 regimen, 65% of patients achieved a complete remission with a relatively low relapse rate of 24%.[161] In a follow-up study patients who had CD4 counts of >100 cells/mm^3 , no prior AIDS-defining illnesses and good performance status were enrolled. The patients were randomized to receive either CHOP chemotherapy or ACVB (doxorubicin 75 mg/m^2 day 1, cyclophosphamide 1.2 grams/m^2 day 1, vindesine 2 mg/m^2 day 1, bleomycin 10 mg days 15, prednisolone 60 mg days 15) with granulocyte-colony stimulating factor (G-CSF) support. More severe toxicity in the ACVB arm, but a higher response rate has been reported.[162] Further analysis of this data is required before firm conclusions can be drawn. However, the potential for dose-intensive regimens for patients in this population with good prognostic factors is suggested and needs to be further explored.

Other trials have used continuous infusion regimens for patients

as first line therapy. The CDE regimen (cyclophosphamide 800 mg/m^2 , doxorubicin 50 mg/m^2 , etoposide 240 mg/m^2 , all over four days) to which ddI was added, resulted in a complete response rate of 58% with a median response duration exceeding 18 months. [163] A follow-up study using this approach is ongoing at present.

Although controversy remains regarding the optimal strategy for treating patients who present with AIDS-related lymphoma, each of the trials indicates the potential for durable response. These data emphasize the need to approach patients with otherwise good prognostic features in a manner focused to maximize cure. However, the fraction of patients failing to respond continues to remain high and the frequency of relapse significant. Development of salvage regimens in AIDS-related lymphoma has been impeded by the generally poor ability of patients to tolerate subsequent rounds of chemotherapy. A small number of studies has indicated that regimens used in other contexts for relapsed high-grade lymphoma may have some impact on relapsed ARL. However, durability of response has been very poor.

Efforts are currently underway to explore other approaches to relapsed lymphoma that again span the spectrum in terms of treatment intensity. A Phase II trial using

the polyamine synthesis inhibitor, mitoguazone, demonstrated a response rate of 23%. [164] This medication has advantages in that it is minimally myelosuppressive and has excellent CNS penetration. However, the agent remains investigational at this time. Other efforts using dose-intensive regimens and studies with antiviral regimens are ongoing.[165] The European experience with more dose-intensive regimens when used with good supportive care has provided rationale for investigating the potential for autologous transplantation and such protocols are underway in ARL patients. This type of approach should be reserved only for clinical trial.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PRIMARY CNS LYMPHOMA

Patients with HIV presenting with a mass lesion of the brain raise a number of diagnostic possibilities. Abscesses (toxoplasma, mycobacterial, or bacterial) or progressive multifocal leukoencephalopathy (PML) must all be considered in addition to primary CNS lymphoma. [166] [167] [168] Criteria for distinguishing between these entities remains imperfect without tissue sampling. However, for those patients in whom biopsy is either impossible or refused, certain parameters can raise or lower the likelihood of a lymphoma diagnosis. Perhaps the most important among these is the patients toxoplasmosis serologic status and whether the patient has been using trimethoprim-sulfamethoxazole as PCP prophylaxis. The latter is highly effective for toxoplasma and this coupled with a negative toxoplasma titer are strong evidence against toxoplasmosis. More commonly, patients have had prior toxoplasma exposure and have an IgG titer to this agent; differentiating an IgG versus IgM response can weigh the relative likelihood of an acute process. In addition, cultures for mycobacterium, fungus, and serum assay for cryptococcal antigen can be helpful in defining the nature of the CNS process. Some radiographic criteria have been described as being more suggestive of AIDS-lymphoma than toxoplasma brain abscess. These include large size (>2 cm), central location, and lack of multifocality. [144] [169] Lymphoma may cross the midline, but this is extremely rare in the case of infectious causes. Some recent studies have addressed whether high sensitivity assays for Epstein-Barr virus in cells within the CSF may be useful. Data in toxoplasma seronegative patients suggest that the presence of EBV detected by polymerase chain reaction (PCR) strongly correlates with the presence of EBV-related disease (lymphoma) in the CNS.[170] [171] In some centers it has now become acceptable to use positive DNA PCR with radiographic imaging (often including thallium or positron emission tomography (PET) scanning) to begin empiric therapy for lymphoma. In those patients in whom ambiguity remains, but biopsy is not possible, it is reasonable to begin an empiric trial of antibiotic therapy (sulfadiazine or clindamycin and pyrimethamine) directed against toxoplasmosis. Those patients who worsen after day five or fail to improve after 14 days have a higher likelihood of the disease not being due to toxoplasmosis. [172]

The clinical presentation of patients with primary CNS lymphoma can be extremely variable and quite subtle. This is a disease most common in late stage AIDS and in that patient population a high level of vigilance must be maintained for patients who present with neurologic or psychologic symptoms. Treatment of primary CNS ARL has generally been restricted to radiation therapy and steroids. The response rate to radiotherapy is high (6079%), but durable remissions are relatively uncommon.[144] [173] [174] [175] Patients prognoses have often been limited by other opportunistic disease. It may be possible now with improved supportive care to better define the utility of other regimens in this patient population. A recent clinical trial evaluating the combination of systemic chemotherapy with radiation therapy failed to demonstrate any benefit to offset the toxicity of the chemotherapy. However, small studies with high-dose methotrexate have been encouraging. [176] Studies of newer approaches that attempt to exploit the high frequency of Epstein-Barr virus infection with primary CNS lymphoma are ongoing. These trials represent pathophysiologically based methods that include rendering EBV-positive cells sensitive to antiherpes virus agents through chemical or genetic manipulation [177] [178] and represent an evolving trend in the care of patients with ARL. It is important that these approaches be critically evaluated and enrollment of patients in clinical trials is strongly encouraged. If no trial is available the approach must be clearly tailored to the overall status of the patient. Frank discussion of the generally poor prognosis (historically 25 months) in patients with end-stage AIDS should be a part of establishing a treatment plan. In patients with advanced AIDS, palliative measures such as steroids or pain medications alone may be appropriate.

CONTROVERSY AND FUTURE DIRECTIONS

A number of areas within the context of ARL remain to be fully defined. The need for better understanding of the basis for lymphomagenesis is particularly acute in AIDS because of the potential for novel underlying infectious cofactors that may serve as therapeutic targets. Recent identification of KSHV and its clear relationship with a small subset of these tumors has provided a compelling example of this and represents considerable opportunity for new therapeutic interventions. The presence of multiple viruses now identified in ARL raises the question of what role there might be for specific antiviral medications or immunization. Why some patients develop malignancy while others with EBV or KSHV remain tumor-free is a puzzle rich with possibility. Unraveling such issues will potentially point to mechanisms of screening and subsequent intervention. The molecular biologic basis of cell transformation by infectious cofactors is also a highly appealing area for investigation with potential targets for the small molecule or structurally designed pharmacologic agents currently under vigorous study by the pharmaceutical industry.

More extensive clinical investigation into the immunologic, cytokine, and viral profiles of select patient populations or in animal models with EBV-like disease [179] will likely provide significant insights into the pathology of ARL. Looking for potential interactions of virus and host by intensive laboratory study may identify patients with high risk for ARL development and provide surrogate markers for early intervention.

Issues specifically related to therapy of ARL include: which patients need CNS prophylaxis and what the role is for intensive retroviral therapy during ARL chemotherapy. Therapeutic

trials are currently testing whether non-cytotoxic agents such as monoclonal antibodies directed against lymphoma cells may be combined with standard chemotherapy to enhance the overall outcome for patients.[180] Such strategies will likely enter more widespread clinical practice as monoclonal therapeutics become available for the treatment of lymphomas. Augmentation of immunologic reactivity is compelling in a disease arising from an immunologic incompetent background; however, the specific nature of the intervention is yet to be defined. Some investigators are adding interferon alpha to chemotherapy to augment the immunologic reactivity[181] and interleukin-2 at low doses is also currently being evaluated in clinical trials. [182] The use of specific cell-based approaches to therapy in this setting are based on the striking success of adoptively transferred lymphocytes in patients with EBV lymphoproliferative disease in the transplant setting. [65] [66] [67] Attempts employing similar approaches in patients with ARL are ongoing and may offer an alternative approach to those patients refractory to standard cytotoxic agents. The potential of either supplementing or replacing chemotherapy with biologically directed therapies is a focus of clinical investigation in ARL and, if fruitful, may provide benefit not just for patients with ARL, but for non-HIV-infected lymphoma patients as well. The interplay between immune function and lymphomagenesis is an issue best demonstrated by ARL. Unraveling the details of this relationship will provide principles applicable well outside the scope of the AIDS epidemic.

Chapter 76 - Multiple Myeloma and Other Plasma Cell Disorders

Guido Tricot

MULTIPLE MYELOMA

Introduction

Multiple myeloma (MM) is the prototype of a clonal B-cell tumor of differentiated and usually slowly proliferating plasma cells, mainly contained within the bone marrow.[1] This disorder is frequently accompanied by monoclonal (M) protein production [2] [3] and either diffuse osteoporosis or lytic bone lesions. [4]

Myeloma has always been associated with destructive osteolytic bone lesions and bone pain. The bone lesions occur in several patterns. Occasionally, patients develop a single osteolytic lesion; some patients have diffuse osteopenia, which mimics the appearance of osteoporosis and is due to myeloma cells being spread diffusely throughout the axial skeleton. In most patients, there are multiple discrete lytic lesions occurring at the site of deposits of nests of myeloma cells [4] (Fig. 76-1).

Multiple myeloma accounts for approximately 1% of all malignant diseases and 10% of hematologic malignancies. In 1996, an estimated 13,000 new cases of myeloma were diagnosed. The annual incidence of myeloma is 34/100,000. The median age of patients with MM is 65 years and only 3% of patients are <40 years of age. Although myeloma can occur at a young age,[5] the diagnosis of myeloma in patients <30 years old should only be made after careful evaluation of all data. The incidence in African Americans is twice that in whites and myeloma affects males slightly more frequently than females. The incidence of myeloma is lowest in Asian populations. MM mortality rates are increasing in the elderly; for example, in the United States, mortality rates among men and women age 85 and older with MM have increased to 143% and 144%, respectively, from 1968 to 1989. These increases may be related to differences in the gene pool of successive elderly cohorts, as adversity to human survival (mainly mortality due to infections) has declined drastically. [6]

Etiology

The cause of MM is unknown. Both genetic and environmental factors have been implicated. A genetic predisposition is suggested by a significantly higher incidence of MM among African Americans. There are also well-documented reports of familial clusters of two or more first-degree relatives with MM. [2] Additional

Figure 76-1 Radiograph of the skull shows multiple osteolytic lesions.

indirect support is provided by murine myeloma models in which only specific mouse strains display markedly increased susceptibility to MM. Repeated antigenic stimulation has also been implicated in the development of MM. However, in a case control study, myeloma patients had fewer chronic inflammatory conditions than did normal controls.[7] Exposure to radiation may increase the risk of MM as evidenced by a higher than expected rate in atomic bomb survivors, radiation workers in England, and patients who received a single course of radiotherapy for ankylosing spondylitis. Although multiple chemicals and occupations have been linked to myeloma,[8] in a case control study, sheet metal work for 10 years or more was the only occupation associated with a significantly increased risk for MM. [9] These sheet metal workers were exposed to numerous potential toxins, including iron compounds, metallic dust, metal oxide fumes, chlorine dioxides, welding fumes, abrasive dust, aluminum compounds, steel dust, and aromatic hydrocarbons. Of all the common medications, only mineral oils used as laxatives or for dermatitis have been associated with an increased risk of MM, but only in women. [10]

Pathogenesis

Normal B-Cell Development

B-cell development occurs initially in the bone marrow, and subsequently in lymphoid tissues, while terminal B-cell differentiation takes place in the bone marrow. In the bone marrow, hematopoietic progenitor cells differentiate into the earliest identifiable cell type committed to the B lineage, the *pro-B cell.* This cell undergoes rearrangement of its immunoglobulin heavy chain genes and is called a *pre-B cell*; it is characterized by the presence of cytoplasmic chains. Subsequent rearrangement of the light chain enables the cell to express surface IgM and the cell becomes an *immature B lymphocyte*. These cells leave the bone marrow and, on entering the peripheral blood, start to express surface IgD and are called *virgin B cells*. They are arrested in G_0 phase of the cell cycle. These virgin B cells enter the lymphoid tissue, where they are exposed to antigen-presenting cells, become activated, and differentiate into *short-lived plasma* cells or *memory B cells*. These memory cells travel from the extrafollicular area of the lymph node to the primary follicles, where they are confronted with antigens, presented by follicular dendritic cells, resulting in the development of a secondary response. At this stage, primary follicles change into secondary follicles containing germinal centers. Through activation by an antigen, the memory B cells differentiate into *centroblasts*, resulting in Ig isotype switching and somatic mutations in the variable region of the immunoglobulin with the generation of higher affinity antibodies. Centroblasts then progress to the *centrocyte* stage and re-express surface Ig. The centrocytes with high affinity antibodies differentiate into either memory B cells or *plasmablasts,* which subsequently move to the bone marrow and terminally differentiate to *plasma cells*. These bone marrow plasma cells produce the vast majority of serum immunoglobulins and have a life span of about 1 month. [11]

Three distinct gene segments, the variable (V_H), diversity (D), and joining region (J_H) genes, encode the variable region of the heavy chain, whereas two segments, variable (V or V) and joining (J or J) region genes, encode the variable fraction of the light chain. The Ig heavy chain (IgH) locus on chromosome 14q32 contains an estimated 100 to 150 V_H genes, 30 D, and 6 J_H gene segments. Because some of the V_H genes are nearly identical, it is likely that 6070 V_H genes are available for rearrangement. These 6070 genes belong to seven families (V_H 17) whose members have >80% sequence homology. Of the 75 known V sequences, only 36 are potentially functional and of the 36 known V sequences, only 24 are functional. Rearrangement of V gene segments is dependent on the protein products of the recombinase-activating genes RAG-1 and RAG-2. Recombination of V genes starts in lymphoid progenitors within the IgH locus of either the maternal or paternal chromosome 14. If the initial V_H -D- J_H rearrangement yields a sequence that cannot be translated, then rearrangement of the IgH locus proceeds on the other allele.

The presence on the B-cell surface of a fully assembled heavy chain rearrangement begins when one of the V genes rearranges to one of the J genes. If light chain rearrangement is unsuccessful on both alleles, light chains will subsequently rearrange. [12]

The Ig heavy and light chains each contain three hypervariable (complementarity determining regions or CDR) segments, which are in direct contact with the antigen. The CDR 3 is the most variable portion of the Ig molecule, because it not only contains the somatic mutations induced by contact with the antigen as for CDR 1 and CDR 2, but it also encompasses the 3 end of V_H , all of D, and the 5 end of J_H . It is therefore an ideal marker to detect a very small population of the malignant clone within a larger population of normal cells.

The Myeloma Stem Cell

The origin of malignant plasma cells remains a mystery. Bone marrow myeloma cells have only limited self-renewal and proliferative capacity in vivo. Although the predominant cell in MM is the plasma cell, data have accumulated showing that other lymphoid cell types are involved in the malignant process. A significant number of peripheral blood lymphocytes bear the unique paraprotein idiotype found in plasma cells [13] [14] [15] [16] and have clonal immunoglobulin gene rearrangements identical to those seen in the bone marrow plasma cells.[17] [18] These data strongly suggest the existence of a precursor compartment. Cloning and sequencing of V_H genes in myeloma shows somatic mutations characteristic of an antigen-driven process with no intraclonal diversity, [19] [20] strongly implying that the malignant clone in MM evolves from a late cell in B-cell development, probably at the level of the memory B cell or plasmablast in the germinal centers of the lymph nodes. [11] [20] Additionally, bone marrow and peripheral blood of myeloma patients contain B-cell populations at different stages of differentiation that are clonally related to the malignant plasma cells, but have a preswitch isotype, consistent with the existence of a myeloma precursor compartment.[21] [22] However, other investigators have found mutations scattered throughout the variable region with no indication of antigen selection, suggesting that MM may derive from B cells that have rearranged during fetal development rather than during adult life.[23] [24]

Role of Adhesion Molecules in Myeloma

Intercellular adhesion molecules (ICAM) mediate cell-cell interactions that result in homing and activation of cells. Many of the differences in localization and growth of cancer cells versus their normal counterparts have been associated with differences in expression of specific adhesion molecules. [25] Neoplastic cells lacking adhesion molecules may proliferate autonomously, without the requirement for cellular interaction for their growth and survival. MM cells adhere to bone marrow stromal cells, although this binding cannot be totally accounted for by the known adhesion molecules. Adhesion molecules are also important for homotypic aggregation, that is, neoplastic cells adhering to each other and creating tumor masses. In myeloma, such homotypic aggregation occurs through CD56: CD56, syndecan-1:collagen and ICAM-1: leukocyte function-associated antigen 1 (LFA-1) interactions. Adhesion molecules can also regulate cytokine secretion; binding of MM cells to bone marrow stromal cells via very late antigen (VLA)-4 and vascular cellular adhesion molecule (VCAM)-1 induces interleukin-6 (IL-6) transcription and secretion. CD40 ligand regulates autocrine

---

IL-6 secretion in myeloma cells. Myeloma cells localize to the bone marrow via binding of VLA-4 (CD49d) to VCAM-1 or fibronectin and LFA-1 to ICAM-1 (CD54). VLA-5 (CD49e) has also been associated with adherence of MM cells to the bone marrow. Acquisition of CD11b and LFA-1 combined with loss of CD56, VLA-5, and syndecan-1 expression is associated with egress of tumor cells from the bone marrow and the development of plasma cell leukemia. Myeloma cells, seeding extramedullary, re-express syndecan-1 and may acquire at the metastatic sites previously expressed adhesion molecules such as CD56 and VLA-5.

Cytokines and Myeloma

Interleukin-6 is involved in the proliferation of normal plasmablastic cells and terminal differentiation of these plasmablasts to nondividing plasma cells. Terminally differentiated plasma cells produce large amounts of immunoglobulins (>600 pg/cell/24 hours). In MM, IL-6 is a proliferation factor for immature myeloma cells, but in contrast to normal plasma cells, IL-6 is not a differentiation factor for immature myeloma cells. Myeloma cells lack terminal differentiation. They produce much lower quantities of immunoglobulins (<10 pg/cell/24 hours) and are still able to divide, but at a low rate. [26] Although IL-6 is produced by myeloma cells and an autocrine IL-6 loop is functioning in myeloma,[27] almost all of the IL-6 is produced by the bone marrow environment[26] after adhesion of myeloma cells to stroma and bone cells. Moreover, bone marrow stromal cells from MM patients produce higher amounts of IL-6 than do stromal cells from healthy individuals after triggering with myeloma cells.[28] IL-6 promotes MM cell growth via phosphorylation of the retinoblastoma protein (pRB). [29] Dephosphorylated (activated) pRB blocks transition from G1 to S phase of the cell cycle, whereas phosphorylated (inactivated) pRB releases this growth arrest. Dexamethasone treatment induces apoptosis of myeloma cells, resulting in a decrease of the myeloma protein of >50% in half the patients. This dexamethasone-induced apoptosis is prevented by IL-6. [30] Finally, high levels of IL-6 may contribute to the development of renal insufficiency in MM.[31] In addition to IL-6, oncostatin M, leukemia inhibitory factor, but not IL-11, all using the common signal transducer gp130,[32] as well as IL-10[33] and insulin-like growth factor 1[34] stimulate growth of myeloma cells.

Recently, the excessive production of IL-6 by marrow stromal cells has been attributed to an infection by the Kaposis sarcoma-associated virus (KSHV) of a subset of macrophages, namely dendritic cells in the marrow of patients with multiple myeloma.[35] A homolog to human IL-6 has been identified in the KSHV genome. The viral IL-6 is able to support the growth of plasma cells.[35] Apparently the malignant plasma cells in MM are not infected with KSHV. Rettig et al. have concluded that the viral IL-6 may contribute to the mechanism by which the stromal cells infected with KSHV promote myeloma cell growth.[35] This study provides a unique model of malignancy in which a virus can potentially support the growth of a neoplasm by infecting a nonmalignant cell without directly infecting the malignant clone.

Oncogenes/Suppressor Genes in Myeloma

Dysregulation of oncogenes and suppressor genes, controlling cellular proliferation, growth arrest, and apoptosis contribute to the pathogenesis of most malignancies, including MM. The evolution of MM is a multistep process with alterations in the IL-6/Ras pathway, dysregulation of bcl-2 and myc proteins, and loss of tumor suppressor gene product function such as pRB and p53.[36]

RB Protein

In myeloma cells, pRB seems to be constitutively phosphorylated and IL-6 further shifts pRB from its dephosphorylated to its plosphorylated form. [29] Growth stimulatory signals, such as growth factors, induce the accumulation of cyclins, active in the G1 phase, which in turn regulate the catalytic activity of the cyclin-dependent kinases (CDK). Two classes of CDK inhibitors, the inks (p15,16) and cips/kips (p21, p27, p57) block CDK function. Both p15 and p16 are encoded by genes on chromosome 9p. Deletions of p15/p16 are highly specific for lymphoid malignancies, more specifically of B-cell origin, except for MM. However, hypermethylation causing inactivation of genes is observed for p16 in 75% and for p15 in 67% of MM patients. [37] This high frequency makes it one of the most common genetic abnormalities in MM. Concomitant hypermethylation of both genes occurred in two-thirds of the patients and may be associated with plasmablastic transformation or extramedullary plasmacytomas.[37] Although frequent deletions of the RB gene (50%) have been identified in MM, the majority of these deletions are hemizygous and are not associated with lack of pRB protein expression. [38] [39]

p53

Although the p53 tumor suppressor gene is the most commonly mutated gene in human malignancies, its mutations are uncommon in MM (10%) and are mainly associated with the terminal stage of the disease. In contrast, p53 mutations are very common in myeloma cell lines (80%). The p53 gene participates actively in DNA replication and repair and is considered the guardian of the genome. Because cytogenetics in MM are almost always very complex, it is perplexing that the incidence of p53 mutations is so low in MM. However, p53 function may be altered by other mechanisms, such as high expression of mdm-2 as seen in myeloma cell lines and cells of patients with plasma cell leukemia (K. Anderson, personal communication), or through PAX-mediated transcriptional repression of p53. [40] The PAX-5 gene, encoding for the B-cell specific activating protein (BSAP), necessary for CD19 expression, which is lost on MM cells, is altered in myeloma and results in loss of CD19 expression on MM cells.[41]

P21/Ras

The p21/Ras signaling transduction pathway integrates a variety of growth signals that are critical for cellular proliferation and differentiation. The p21 is a

GTP-binding protein that is activated when GTP is bound and inactivated when GDP is bound. IL-6 is a potent growth and survival factor for myeloma cells that uses gp130 as a signaling transducer molecule. Activation of gp130 not only leads to activation of the Janus kinases, but also to activation of the Ras pathway. Point mutations in Ras, most commonly at codons 12, 13, and 61, result in constitutive activation of Ras, thereby making myeloma cells independent of exogenous IL-6. It has been shown that transduction of an IL-6-dependent cell line (ANBL-6) with mutant Ras makes this cell line IL-6 independent. [42] Ras mutations are very common even at diagnosis of the disease, occurring in 40% of patients, and N-Ras is the most frequently mutated. [43]

Bcl-2 Family

The bcl-2 proto-oncogene was initially identified through the t(14;18) present in 85% of low-grade follicular non-Hodgkins lymphomas. Bcl-2 prevents apoptosis induced by a variety of conditions, such as treatment with glucocorticosteroids, alkylating agents, and radiotherapy as well as by cytokine deprivation, without obviously affecting the rate of cellular proliferation. The bcl-2 family contains not only anti-apoptotic members such as bcl-2 and bcl-x_L but also pro-apoptotic members such as bax,

bcl-x_S and bad. The ratio between anti-apoptotic and pro-apoptotic members determines the ultimate fate of a cell. In myeloma the frequency of t(14;18) involving the bcl-2 gene is quite low (2%), yet almost all myeloma cell lines and fresh myeloma cells have elevated levels of bcl-2, possibly due to hypomethylation of the bcl-2 gene. Bcl-2 is probably a critical survival factor for myeloma cells in the early stage of the disease when the myeloma cells are hypoproliferative, whereas it probably loses its importance in the aggressive proliferative phase of the disease. Bcl-2 levels have been correlated with response to interferon-, but in general, no correlation has yet been established between bcl-2 levels and survival or response to chemotherapy. [44]

C-myc

C-myc is expressed in proliferating cells and is tightly associated with cell cycle progression. However, in the absence of growth stimuli, c-myc expression may lead to cell death. Although rare, c-myc rearrangements have been found in some myeloma patients. However, c-myc deregulation is nevertheless observed in the majority of myeloma patients. Both transcriptional and translational regulatory mechanisms account for this deregulated c-myc expression in myeloma. Approximately 70% of myeloma patients transcribe c-myc mRNA from an unusual promotor, P_0 , instead of the common promoters P_1 and P_2 . Translational up-regulation of c-myc expression is probably the most common mechanism responsible for elevated levels of c-myc in myeloma. This translational up-regulation might be due to a specific mutation in the first exon. [45]

Bone Disease in Myeloma

Skeletal-related abnormalities are the most common cause of morbidity in patients with MM. Approximately 80% develop substantial skeletal dysfunction during the course of their disease. [2] Problems related to skeletal dysfunction include diffuse osteopenia, focal lytic bone lesions, pathologic fractures, incapacitating bone pain, hypercalcemia, loss of height, and restrictive pulmonary disease. Quantitative studies of bone histology have shown that MM is characterized by excessive resorption of bone that occurs only in the vicinity of myeloma cells. At the same time, bone formation is inhibited. [46] Myeloma cells stimulate all phases of bone resorption, specifically, the recruitment, differentiation, and bone resorbing activity of osteoclasts. This excessive resorption of bone can be detected histologically months or even years before bone lesions appear radiographically. [46] IL-1, tumor necrosis factor (TNF-) and IL-6 are produced in large quantities by the microenvironment as a direct consequence of myeloma cells adhering to stromal cells. IL-6, an essential growth factor for myeloma cells, is produced by bone cells. Thus, once myeloma cells invade the bone marrow space a vicious circle starts, whereby myeloma cells trigger the release of osteoclast activating factors, mainly IL-1, that stimulate the osteoclasts. These activated osteoclasts resorb bone and this results in the release of IL-6, which in turn stimulates immature myeloma cells and serves as a survival factor for the more mature myeloma cells. This results in more myeloma cells and more osteoclastic activity (Fig. 76-2).

Clinical Manifestations

The clinical manifestations of MM (Table 76-1) are the direct consequence of marrow infiltration by plasma cells, the production of monoclonal protein in blood or urine, and immune deficiency (Fig. 76-3).

Bone Pain

Bone pain, typically in the back or chest and less often in the extremities, is present at diagnosis in more than two-thirds of patients. The pain is usually aggravated by movement. The patients height may be reduced by several inches because of collapse of one or more vertebral bodies. [2] Sudden onset of back pain in an individual over the age of 40, especially if the complaint is new for the patient, is sufficient to suspect the diagnosis of myeloma and should lead to proper work-up for this disease.

Renal Insufficiency

The two major causes of renal insufficiency in MM are myeloma kidney and hypercalcemia. Myeloma kidney is characterized by

Figure 76-2 Myeloma cells invading the bone marrow adhere to stromal cells and induce the release of osteoclast activity factors. This will result in bone reabsorption and release from the bone matrix of multiple cytokines that will directly or indirectly stimulate the growth of myeloma cells. The net result is more myeloma cells and more bone destruction. FGF, fibroblast growth factor; IGF, insulin-like growth factor; TGF-, transforming growth factor-beta.

TABLE 76-1 -- Clinical Features and Therapy of Multiple Myeloma

Anemia	Due to high levels of IL-6, bone marrow replacement and partially dilutional, if M protein is high Therapy: can often be corrected with erythropoietin
Bone lesions	Mainly due to IL-1, also IL-6 and TNF- Therapy: preventable with bisphosphonates
Hypercalcemia	Due to bone destruction, often causes renal insufficiency Therapy: urgenthydration, bisphosphonates, calcitonin
Infection	T-cell deficiency: Fas ligand on plasma cells (?) B-cell deficiency: TGF- Therapy: prophylactic antibiotics with initial cytotoxic treatment
Renal failure	Dehydration due to hypercalcemia Myeloma kidney: precipitation of light chains in tubules (light chains) Light chain deposition disease (light chain) IL-6 Amyloidosis
Hyperviscosity	Mainly in IgA myeloma and IgG_3 Therapy: plasmapheresis

Amyloidosis	Insoluble M protein: cardiac, renal, and neurologic problems Therapy: eradication of malignant clone
Hypoalbuminemia	IL-6 secretion, dilutional
Neurologic symptoms	Central Compression of tumor on cord Compression of bone fragment on cord Peripheral Amyloidosis

the presence of large, waxy, laminated casts in the distal and collecting tubules. These casts are composed mainly of precipitated monoclonal light chains and are surrounded by multinucleated syncytial epithelial cells (giant cells). The casts result in dilation and atrophy of the renal tubules and eventually the entire nephron becomes nonfunctional and interstitial fibrosis may occur. [47] The extent of cast formation correlates directly with the amount of free urinary light chains, but the actual mechanism of nephrotoxicity from Bence Jones proteinuria is unknown, although dehydration, associated with hypercalcemia, and radiographic contrast medium studies may precipitate myeloma kidney. Myeloma kidney is more often encountered with light chains.

The second most common course of renal insufficiency is hypercalcemia, resulting in hypercalciuria and osmotic diuresis, leading to volume depletion and prerenal kidney failure. In addition, hypercalcemia may cause calcium deposits, leading to interstitial nephritis. Hyperuricemia, as well as nonsteroidal anti-inflammatory agents, reducing the blood flow to the glomeruli may also promote the development of renal failure. Patients with myeloma are very sensitive to nephrotoxic medications such as aminoglycosides, cisplatin, amphotericin B, and cyclosporine A. Immunocyte-derived (AL) amyloidosis in myeloma patients is associated with light chain proteinuria and usually presents as nephrotic syndrome, but can lead over time to renal failure (Chap. 77). Probably underestimated as a cause of renal failure is the immunoglobulin light chain deposition disease, commonly associated with light chain myeloma proteins, in which monoclonal light chains are deposited in renal glomeruli. The histopathologic picture resembles nodular glomerulosclerosis, but electron microscopy reveals granular, electron-dense deposits representing light chains. Myeloma involvement of the kidneys is uncommon, but should be suspected in patients who have renal enlargement not due to amyloidosis. Finally, IL-6 may also contribute to renal failure. [31]

Hypercalcemia

Some myeloma patients have paraproteins that avidly bind calcium, resulting in spurious hypercalcemia. The best solution to deal with these problems is to measure an ionized serum calcium

Figure 76-3 Major clinical and laboratory features of multiple myeloma.

level. Hypercalcemia occurs in 3040% of patients with MM and is usually associated with a large disease burden. Hypercalcemia is the presenting finding in 1530% of patients, who may develop lethargy, polyuria, polydipsia, constipation, nausea, and vomiting. [48] Levels of total serum calcium should be adjusted for serum protein concentrations, especially albumin. Pronounced hypoalbuminemia, caused by an increased level of Il-6, poor food intake, or urinary loss in case of concomitant amyloidosis, can mask frank hypercalcemia.

Neurologic Symptoms

Neurologic symptoms are usually the result of a compression by masses of myeloma cells or bone fragments on the spinal cord or on a nerve. The pain is usually in the thoracic or lumbosacral area. Compression of the spinal cord needs to be considered an oncologic emergency, requiring prompt intervention. It is best diagnosed by magnetic resonance imaging (MRI). In addition to back pain with radicular features, weakness or paralysis of the lower extremities and bowel or bladder incontinence may occur. Peripheral neuropathy is uncommon in MM and is almost always associated with amyloidosis. It is also seen in osteosclerotic myeloma and is sometimes part of the POEMS syndromes (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes). Intracranial plasmacytomas usually represent extensions of myelomatous lesions of the skull and may lead to cranial nerve deficits or more infrequently leptomeningeal infiltration (usually only seen in the terminal phases of the disease).

Hyperviscosity

In contrast to Waldenström macroglobulinemia, hyperviscosity is rare in MM, occurring in <10% of patients. Because of a greater tendency for IgA to form polymers, patients with IgA myeloma more often have features of hyperviscosity, resulting in circulatory problems and leading to cerebral, pulmonary, and renal manifestations. Hyperviscosity is often associated with bleeding. Among patients with IgG myeloma, those with IgG 3 subclass are most likely to develop hyperviscosity. The diagnosis can be made by measuring serum viscosity and by fundoscopic examination showing a slow blood flow in often distorted blood vessels. Hyperviscosity can give the clinical and radiologic picture of pulmonary edema, but will only worsen if treated with diuretics. Plasmapheresis is the appropriate treatment for this condition.

Amyloidosis

Amyloidosis is the clinical syndrome that results from the extramedullary deposition of insoluble fibrillar protein. A diagnosis of MM can be made in 20% of cases with AL amyloidosis[49] and about 3% of patients with newly diagnosed MM have overt amyloidosis, [50] but the frequency of asymptomatic amyloidosis in myeloma, as diagnosed with subcutaneous fat aspiration and rectal and bone marrow biopsies is much higher (35%). The most common clinical manifestations are carpal tunnel syndrome or edema due to nephrotic syndrome; less common manifestations are cardiomyopathy, macroglossia, or extensive bruising around the eyelids. The presence of amyloidosis in patients with MM adds to their morbidity and has an adverse effect on survival. [50] When treated with conventional chemotherapy the median survival of patients with both myeloma and amyloid is 12 months.[50]

Infections

Patients with MM have an increased susceptibility to develop infections, because of the associated hypogammaglobulinemia. Myeloma patients are not able to mount a vigorous primary immune response and also have an impaired secondary antibody response to antigens. T-cell, NK-cell, and monocyte defects may accelerate and contribute to the humoral deficiency. The additional immunosuppressive effect of chemotherapy, especially with corticosteroids, further increases infection risk. The average MM patient will suffer from 0.5 to 1.5 infections per year, with the highest frequency during the first 2 months of treatment. Polysaccharide-encapsulated organisms, especially *Streptococcus pneumoniae* and *Hemophilus influenzae*, were initially identified as the major causes of infection. However, it is now clear that enteric gram-negative bacilli are the most common isolates, accounting for about 60%, whereas encapsulated organisms represent <25% of isolates. Oral thrush is the only fungal infection of significance. Other organisms, such as anaerobes, *Mycobacterium tuberculosis*, herpes simplex, and varicella zoster, are uncommon. Early diagnosis and prompt initiation of broad-spectrum antibiotic therapy are critical in patients with MM. Third-generation cephalosporins or extended-spectrum penicillins are used most frequently. Infection prophylaxis with trimethoprim-sulfamethoxazole is effective in decreasing the incidence of infectious complications during the first few months of initial standard-dose chemotherapy. [51] Vaccination against influenza in patients with MM is safe and may have significant benefits. [52]

Extramedullary Disease

Extramedullary plasmacytomas have been found in lymph nodes, skin, liver, spleen, and occasionally kidneys and meninges. This is usually associated with high serum lactic dehydrogenase (LDH) levels and plasmablastic morphology. These patients usually have a poor outcome even with more aggressive treatment approaches.

Bleeding and Anemia

Bleeding problems occur in 15% of IgG and 30% of IgA myelomas and may be due to platelet dysfunction or acquired coagulopathy. Thrombocytopenia, even with extensive bone marrow involvement, is rare in the early phases of the disease. The preserved platelet count might be related to increased IL-6 levels, which are capable of promoting megakaryocyte maturation. Anemia is the consequence of increased IL-6 production by the microenvironment and may be spuriously aggravated by expansion of plasma volume due to large amounts of circulating immunoglobulins. Serum erythroprotein levels are low relative to the degree of anemia, a finding that is probably due to the abundant production of cytokines such as IL-1 and TNF-.

Laboratory Evaluation

The *bone marrow* is involved with an excess of plasma cells (>5%) in approximately 90% of cases (Fig. 76-4); the mean percentage of plasma cells at diagnosis is 30&%.[1] A nodular infiltration is found in <5% of cases.

A *monoclonal protein* (M protein) is evidenced on serum protein electrophoresis as a spike or localized band in the or globulin region in 80% of patients; approximately 10% have hypogammaglobulinemia and 10% have a normal-appearing pattern. The more sensitive immunoelectrophoresis and immunofixation will reveal an M protein in >90% of patients in the serum and 80% in the urine. With these sensitive techniques, an M protein in serum or urine is found in 99% of cases. [2] About 55% of patients have an IgG isotype, 25% have IgA, 1% have IgD, 1% have IgM, and about 20% have only light chain secretion with a / ratio of 2:1. [3] In heavy chain disease, a localized band is often not seen and either immunoelectrophoresis or immunofixation is required for identification of an M protein.

Figure 76-4 The bone marrow is invaded by plasma cells, which are more immature than normal plasma cells as evidenced by a more delicate chromatin structure and the presence of a nucleolus in some of the cells.

Other laboratory manifestations of MM include anemia, present in about two-thirds of patients, increased erythrocyte sedimentation rate in patients with a significant M protein in the serum, elevated creatinine in approximately one-half of cases, and decreased albumin levels, which are associated with increased IL-6 activity.

Diagnosis

Minimal criteria for the diagnosis of overt myeloma include the presence of at least 10% abnormal plasma cells in the bone marrow or histologic proof of a plasmacytoma, the usual clinical features of MM, as outlined above, and at least one of the following abnormalities: serum M protein (usually >3 g/dl), M protein in the urine (usually >1 g/dl), or osteolytic lesions [53] (Table 76-2).

If the diagnosis of MM is suspected, the physician should obtain, in addition to a complete history and physical examination, the following tests: complete blood count with differential, electrolytes, blood urea nitrogen, creatine, calcium, phosphorus, uric acid, LDH, alkaline phosphatase, serum protein electrophoresis, quantitative immunoglobulins, serum immunoelectrophoresis, $_2$ -microglobulin ($_2$ M), C-reactive protein

TABLE 76-2 -- Criteria for the Diagnosis of Multiple Myeloma[a]

Major Criteria
Plasmacytoma on tissue biopsy
Marrow plasmacytosis 30%
Monoclonal protein
IgG > 3.5 g/dl
IgA > 2 g/dl
Bence Jones 1 g/24 hr
Minor Criteria
Marrow plasmacytosis 1029%
Monoclonal protein present but less than the levels defined above
Lytic bone lesions
Decrease in uninvolved immunoglobulins
IgM < 50 mg/dl
IgA < 100 mg/dl
IgG < 600 mg/dl

[a]The diagnosis is confirmed with at least one major and one minor criterium or at least three minor criteria.

(CRP), radiographic survey of the bones, and bone marrow aspirate and biopsy, preferentially with plasma cell labeling index and cytogenetics. In case of a solitary plasmacytoma or severe back pain, an MRI of the head, spine, and pelvis is indicated to evaluate the extent of the disease and the presence of spinal cord compression.

Differential Diagnosis

In patients with monoclonal gammopathies associated with borderline bone marrow plasmacytosis, connective tissue diseases, chronic infections, carcinoma, and lymphoma should be excluded. In most patients, however, the diagnosis of MM is readily established. It is important to distinguish myeloma from monoclonal gammopathy of undermined significance (MGUS), solitary plasmacytoma of the bone, and amyloidosis.

MGUS

Monoclonal gammopathy of undetermined significance is characterized by the presence of a serum M protein of <3 g/dl, fewer than 10% plasma cells in the bone marrow, no or only small amounts of Bence Jones protein in the urine, absence of lytic lesions, anemia, hypercalcemia and renal insufficiency, and most importantly stability of the M protein.[54] MGUS is found in approximately 3% of individuals over the age of 70. Of all patients with monoclonal gammopathies, 62% have MGUS. [54] The majority of patients with MGUS die of unrelated causes (52%), whereas 22% have either no substantial increase in M protein or an increase in M protein without any symptoms; 11% progress to MM.[54] The median interval from recognition of the M protein to the diagnosis of MM is 10 years (range, 229). Currently, no single test can distinguish MGUS from MM. In MGUS the plasma cell labeling index (PCLI) is low, $_2$ M and CRP levels are normal, and CD56 may not be expressed on the plasma cells.[55] It is important to know that 50% of patients with MGUS have an abnormal DNA content either by flow cytometric analysis [55] or fluorescence in situ hybridization.[56] The clinical and laboratory features of patients with MGUS with chromosomal abnormalities are indistinguishable from those without.

Solitary Plasmacytoma of the Bone

Solitary plasmacytoma of bone is uncommon and represents 35% of patients with plasma cell dyscrasias. The most common symptom at diagnosis is pain and the median age of these patients is a decade younger than that in MM. [54]

The diagnosis is based on histologic evidence of a tumor consisting of monoclonal plasma cells with no other lesions on skeletal survey or MRI, a normal bone marrow and absence of an M protein in blood and urine; or, if present, therapy for the solitary lesion should result in disappearance of the M protein. The uninvolved immunoglobulins are usually normal and there is no evidence of anemia or hypercalcemia. Overt MM develops in approximately 50% of these patients with evidence of progressive disease within 3 years in two-thirds of the patients. The 5- and 10-year survival rates are 74% and 45%, respectively. [54] Tumoricidal radiotherapy with 4,0005,000 cGy has been considered the treatment of choice. However, if such a dose is given to the spine, total body irradiation as part of a more intensive treatment approach in case of relapse will not be possible anymore.

Amyloidosis

Immunocyte-derived amyloidosis can occur in the context of MM, but also without myeloma. Primary amyloidosis and amyloidosis associated with myeloma have the same underlying pathologic process, whereby excessive amounts of the Ig produced

by a single clone of B cells are deposited in tissues in a manner and quality sufficient to compromise organ function. In primary amyloidosis, there is a minimal or no clinically detectable increase in plasma cells and no other manifestations of myeloma such as anemia, hypercalcemia, and bone lesions. The diagnosis of amyloidosis is made by staining tissue with Congo red with its classical apple-green birefringence when viewed under polarized light. [47]

Prognostic Factors

Survival of patients with MM is highly variable and ranges from a few months to many years. Without therapeutic intervention the median survival is approximately 7 months.[57] The median survival is 2.53 years with conventional chemotherapy. Only 3.5% of patients survive more than 10 years. [58]

Durie-Salmon Clinical Staging

This staging system[59] (Table 76-3) is based on a combination of factors that correlate with myeloma mass and renal function, whereby patients with a low tumor load and creatinine <2 mg/dl have a median survival of approximately 5 years, whereas patients with a high tumor load and renal sufficiency have a median survival of 15 months. This system has permitted better interpretation of therapeutic trials, based on the composition of the patient population, but it has significant shortcomings, especially in categorizing bone lesions. Moreover, it does not consider important variables such as the proliferative rate of the disease and the quality of response to therapy.

$_2$ M

The $_2$ M level is one of the most significant prognostic factors in myeloma. It reflects both tumor load and renal function and is therefore highly correlated with the Durie-Salmon staging system.[60] However $_2$ M alone predicts survival, regardless of renal function and stage, [61] suggesting that $_2$ M is a reflection of more than these two parameters. It also reflects to some degree disease activity and drug sensitivity. The best cutoff level before any treatment for $_2$ M is 6 mg/L.[60] [61] It is important to remember that $_2$ M levels increase on interferon- therapy.

CRP

Serum CRP[62] concentrations reflect IL-6 activity, a major growth and survival factor for myeloma cells. CRP and IL-6 levels show a linear association and their predictive value largely overlaps. [63]

TABLE 76-3 -- Durie-Salmon Staging System

Stage I	Low tumor mass (<0.6 × 10^{12} /m^2) All of the following Hemoglobin > 10 g/dl IgG < 5 g/dl; IgA < 3 g/dl; Bence Jones < 4 g/24 hr Normal calcium level No or only one lytic bone lesion
Stage II	Intermediate tumor mass (0.61.2 × 10^{12} /m^2) Not fitting stage I or III
Stage III	High tumor mass (>1.2 × 10^{12} /m^2)
	Any of the following Hemoglobin < 8.5 g/dl IgG > 7 g/dl; IgA > 5 g/dl; Bence Jones > 12 g/24 hr Calcium level > 12 mg/dl (adjusted for albumin) Multiple lytic lesions
	A. BUN 3 mg/dl, creatinine 2 mg/dl
	B. BUN 3 mg/dl, creatinine 2 mg/dl

The predictive value of CRP is independent of $_2$ M. Therefore, a combination of these two parameters allows stratification into three groups. A low-risk group with both CRP and $_2$ M < 6 mg/L, an intermediate-risk group with CRP or $_2$ M < 6 mg/L, and a high-risk group with CRP and $_2$ M 6 mg/L. With conventional chemotherapy the median survival in these three groups is 54, 27, and 6 months, respectively. [62] Other acute phase proteins, such as $_1$ -antitrypsin, carry a similar prognostic value as CRP.[64] CRP levels can obviously be a reflection of other ongoing problems than myeloma activity. Almost any infection or inflammation will significantly elevate CRP levels. The prognostic value of CRP is only relevant when no other causes of CRP increase are present. Increased soluble IL-6 receptor levels have been correlated with decreased survival.[65]

PCLI

The PCLI reflects the proliferative activity of plasma cells. Early in the disease most myeloma patients have a hypoproliferative disease, but during disease progression the labeling index may increase substantially. [66] For patients treated with conventional chemotherapy, the PCLI is probably the most important prognostic factor.[67] [68] When PCLI is taken into consideration, CRP values do not provide additional prognostic information. [65] [67] The median survival of patients with low PCLI and $_2$ M was 71 months, compared with only 17 months when both of these parameters were elevated.[65] The median survival of MM patients with a PCLI < 3% was 56 months, compared with 19 months for those with a PCLI 3&%.[68]

Cytogenetics

Cytogenetics have major prognostic importance in acute leukemias. Unfortunately, cytogenetic information is limited in MM because it is a malignancy composed

mainly of well-differentiated B cells with low proliferative activity. Abnormal karyotypes are observed in only 3050% of cases. Typically, previously treated and relapsing patients have a higher frequency of chromosomal abnormalities (3563%) than newly diagnosed patients (2030%) because of the higher growth fraction in advanced disease.[66] It is therefore not surprising that in cytogenetic studies combining newly diagnosed and previously treated patients, abnormal karyotypes have been associated with an inferior outcome.

In contrast to cytogenetics, flow cytometry-derived aneuploidy data and analysis using fluorescence in situ hybridization have found cytogenetic abnormalities in 8090% of patients, irrespective of their disease status. Therefore, the majority of the normal karyotypes in MM are derived from the normal hematopoietic cells and not from the myeloma clone. Karyotypic abnormalities are very complex involving more than three chromosomes in 80% of patients.[49] The most common abnormalities are translocation (51%), followed by multiple trisomies (45%). In patients receiving autotransplants, a particularly poor outcome is observed in those with translocations or abnormalities involving 11q or partial or complete deletion of chromosome 13 (unfavorable karyotype) (Fig. 76-5). On multivariate analysis, the absence of an unfavorable karyotype was the single most important favorable variable for both event-free and overall survival. [49] In contrast, patients with abnormal cytogenetics, excluding the unfavorable karyotypes, had event-free and overall survivals comparable to those with normal chromosomes. It is unclear whether the above-mentioned unfavorable karyotypes would also confer a significantly inferior outcome for patients treated with conventional chemotherapy. Hypodiploidy has been associated with drug resistance[69] and newly diagnosed patients with abnormal cytogenetics have an inferior outcome with standard therapy. [70]

Figure 76-5 Impact of unfavorable karyotypes on outcome. Patients with unfavorable karyotypes have a poor outcome after transplantation when compared with other patients. CR, complete response.

LDH

About 10% of untreated myeloma patients have elevated LDH levels. It is more frequent in patients with a high tumor mass, extramedullary disease, and hypodiploidy. A high LDH level is associated with a short median survival of only 9 months and a low response rate (20%) to standard chemotherapy. [71]

Plasmablastic Myeloma

This MM subtype has 2% plasmablastic myeloma cells in the bone marrow and occurs in approximately 8% of patients with newly diagnosed disease. It is associated with a significantly shorter event-free (1.1 vs. 2.7 years) and overall survival (23.3 vs. 44.6 months). [72] Multivariate analysis has shown that the plasmablastic subtype is a prognostic factor for survival independent of PCLI, CRP, $_2$ M, and creatinine.

Peripheral Blood Monoclonal Plasma Cells

Eighty percent of newly diagnosed MM patients have monoclonal plasma cells in the peripheral blood; 57% of those patients had 4% plasma cells in the peripheral blood. Patients with 4% plasma cells in the peripheral blood have a median survival of 2.4 years versus 4.4 years for those with < 4&%. [73] Patients with a high percentage of plasma cells in the peripheral blood are less likely to have lytic bone disease.

Variant Forms of MM

Smoldering Myeloma

Patients with smoldering myeloma[2] have a serum myeloma protein level >3 g/dl but <4.5 g/dl and >10% atypical plasma cells in the bone marrow, but do not have anemia, renal insufficiency, hypercalcemia, or multiple skeletal lesions. They may have small amounts of M protein in the urine, and the levels of the uninvolved immunoglobulins in the serum are decreased. The PCLI is low.[74] Because these patients are asymptomatic, they should not be treated until there is clear evidence of disease progression or symptomatic disease. The median time to progression in patients with smoldering myeloma is 26 months. Patients with either a lytic lesion of the bone or both serum monoclonal protein >3g/dl and Bence Jones proteinuria have the shortest time to progression (median 10 months) compared to 61 months for those without any of these poor prognostic factors.[73] Despite the markedly different times to disease progression, the response rates and survival after standard chemotherapy are similar.[75]

Plasma Cell Leukemia

Patients with plasma cell leukemia have an absolute plasma cell count in the peripheral blood of 2.0 × 10 ^{9} /L. A distinction needs to be made between *primary,* when diagnosed in the leukemic phase, and *secondary* plasma cell leukemia, when there is leukemic transformation of previously recognized multiple myeloma. Approximately 5% of newly diagnosed MM patients present with plasma cell leukemia.[76] These patients almost always have a high tumor mass and more frequently have thrombocytopenia, hypodiploid plasma cells, high LDH levels, and extramedullary involvement. [76] Primary plasma cell leukemia requires prompt and intensive chemotherapy. Patients with secondary plasma cell leukemia more frequently have IgA myeloma and more lytic bone lesions. These patients are usually refractory to chemotherapy and have a median survival of <2 months.[77]

Osteosclerotic Myeloma

The major clinical feature in osteosclerotic myeloma (POEMS syndrome) is a chronic inflammatory demyelinating polyneuropathy causing predominantly motor disability. It is assumed that the plasma cells secrete a monoclonal immunoglobulin that is toxic to the peripheral nerves and is responsible for the endocrine abnormalities. The bone marrow of these patients usually contains <5% plasma, and hypercalcemia and renal insufficiency are rare. The diagnosis is confirmed by identification of monoclonal plasma cells in the biopsy of an osteosclerotic lesion. When compared to myeloma patients, patients with POEMS have higher serum levels of IL-1, TNF-, and IL-6, but lower levels of TGF-, insufficient to counteract the noxious effects of the proinflammatory cytokines. [78] Other clinical manifestations of this disease are enlargement of lymph nodes, liver, and spleen; low concentration of the monoclonal component; hypertrichosis; and hyperpigmentation. [79] Most M components have light chains. Pathologic findings in the enlarged lymph

nodes and spleen are compatible with Castlemans disease. Solitary bone lesions must be aggressively treated with surgery or radiotherapy. [79] Polychemotherapy should not include neurotoxic agents.

Extramedullary Plasmacytoma

Extramedullary plasmacytomas[2] occur most frequently in the upper respiratory tract, including the nasal cavity and sinuses, nasopharynx, and larynx. They also occur in the gastrointestinal tract and various other organs. The diagnosis is based on the finding of a plasma cell tumor at an extramedullary site and the absence of MM at bone marrow examination, radiography, and appropriate studies of blood and urine. Treatment consists of tumoricidal radiation. Prognosis is favorable and evolution to MM is rare. In stage I disease, therapy may be curative.

Therapy

The approach to therapy for patients with MM is outlined in the accompanying box.

Cytotoxic Therapy

Patients with asymptomatic myeloma usually have low tumor burden and slow disease progression. Their marrows usually contain <30% myeloma cells, serum M protein <5 g/dl, or Bence-Jones proteinuria <1 g/24 hours. They have no or very few bone lesions and no anemia, hypercalcemia, renal insufficiency, or recurrent infections. The PCLI and $_2$M and CRP levels are usually low. These patients should be monitored closely and be treated only in case of clear disease progression. Symptomatic patients or those with anemia, recurrent infections, hypercalcemia, or renal insufficiency require treatment.

Standard-Dose Therapy

Oral melphalan and prednisone introduced approximately 30 years ago have remained the standard therapy for symptomatic myeloma (Table 76-4). They provide control of symptoms and tumor reduction by 50% in approximately half the patients. The usual dose is 9 mg/m^2 of melphalan and 100 mg prednisone given for 4 days every 46 weeks for at least 12 months. Failure to respond to this therapy was thought to be due to poor melphalan absorption, and dose escalation of melphalan with one third has been suggested in patients whose absolute neutrophil count does not fall to <1.5 and 100 × 10^9/L, respectively, 2 weeks after the start of chemotherapy. However, a recent study has reported similar hematologic toxicities in both responders and nonresponders, making it more likely that differences in response are related to drug sensitivity rather than to differences in absorption. [80] Moreover, the quality of response to low-dose melphalan is similar whether melphalan is given orally or intravenously. [81] It is unclear whether the addition of 100 mg prednisone to melphalan is beneficial. The Medical Research Council trials did not find a survival benefit, once the uneven distribution of patients was corrected for $_2$M levels.[82] Patients with IgA myeloma have a significantly inferior outcome with melphalan plus prednisone. [83] The observation of Alberts et al. [84] that the combination of Adriamycin and bis-chloroethyl-nitrosurea was active in patients who had become refractory to melphalan has led to combination chemotherapy regimens. In these combination regimens, vincristine is frequently added to alkylating agents, Adriamycin and prednisone, although the addition of vincristine to melphalan and prednisone has not shown any survival advantage. [82] Most trials have been unable to confirm a clear advantage of combination chemotherapy over melphalan plus prednisone. [83] [85] [86] [87] This

APPROACH TO THERAPY FOR MULTIPLE MYELOMA

Patients who are asymptomatic should not be treated until there is clear evidence of disease progression (hypercalcemia, increase in M protein or anemia, new lytic lesions) or the patient becomes symptomatic. If the physician is not sure whether a patient should be treated, it is rausually better to delay therapy and re-evaluate after 68 weeks. For patients requiring treatment, sufficient evidence is available from randomized studies and pair-mate analysis that high-dose chemotherapy is superior to standard-dose treatment in terms of complete response rate and event-free and overall survival, provided that the patient has adequate cardiopulmonary function, does not have major liver function abnormalities, and has a good performance status, unless the decline in performance status is due to bone pain. Peripheral blood stem cell transplants can be performed safely up to the age of 70 years and also in patients with renal failure, if high-dose melphalan is used as preparative regimen. Usually patients will receive one to three cycles of chemotherapy prior to stem cell mobilization to improve the general condition and to attain a significant tumor reduction. This is best achieved with the VAD regimen or with high-dose dexamethasone pulsing because of the rapidity of response and its stem cell sparing capacity. Before any treatment is given, patients should have a bone marrow aspirate and biopsy performed as well as a skeletal survey. In addition, the following laboratory tests should be obtained: complete blood count, blood urea nitrogen, creatinine, LDH, uric acid, calcium (ionized), CRP, and $_2$M. If possible, cytogenetics and PCLI should be performed on the bone marrow.

Studies are underway to determine whether double transplants are better than a single transplant and whether patients should undergo transplantation initially or after failing first-line treatment. However, peripheral stem cells should always be collected early in the disease before too much alkylating therapy has been given. Patients who are not candidates for high-dose chemotherapy should be treated for at least 12 months or until a plateau phase has been obtained. The duration of the plateau phase can be prolonged by the administration of interferon- maintenance therapy, although it does not result in a longer overall survival. Anemia can be corrected in many patients by the administration of erythropoietin. Hypercalcemia treatment is an oncologic emergency and should consist of fluids and bisphosphonate or gallium nitrate administration. In severe cases, calcitonin may be required for 23 days. To prevent further bone damage, monthly administration of an intravenous bisphosphonate is recommended. During the early stages of chemotherapy, prophylactic antibiotics will decrease the incidence of infections. Because of the high treatment-related mortality, allogeneic bone marrow transplantation should probably only be performed in patients with one or more poor prognostic markers, such as unfavorable cytogenetics elevated $_2$M or CRP levels after two to three cycles of high-dose dexamethasone-containing regimens; >12 months of conventional chemotherapy; or disease refractory to standard chemotherapy, i.e., <50% reduction in M protein.

TABLE 76-4 -- Results of Treatment in Myeloma

	N	Complete Response (%)	>50% Reduction in M Protein (%)	Median Survival (months)	5-Year Survival (%)
Standard Therapy					
Melphalan/Prednisone (SWOG/ECOG)	335	N/A	40	26	18
VMCP/VBAP (SWOG)	115	N/A	53	36	30
VBMCP (ECOG)	220	N/A	72	30	26

[a] 75% reduction in M protein.

indicates that minor increases in dose intensity are insufficient to change the outcome in myeloma.

Patients responding to standard chemotherapy have a much better survival than nonresponders (43 months vs. 19 months) with no survival advantage for complete responders over partial responders. [88] [89] Most responders attain a plateau phase, that is, a state of tumor quiescence in which the malignant plasma cells appear to be dormant. Therefore, a sine qua non of a plateau phase is a low labeling index. [90] The duration of this plateau phase is variable: a plateau phase of at least 3 months is achieved in 80%, at least 6 months in 75%, at least 12 months in 60%, and at least 24 months in 33% of the responders. [89] The median survival of patients with a plateau phase of 311 months, 1223 months, and 24 months or longer is 21, 46, and 81 months, respectively. [89] Escape from the plateau phase can be slow with no clinical symptoms but a progressive rise in serum or urine M protein or it can be clinically fulminant, sometimes associated with the presence of light chains electrophoretically unassociated with the original heavy chain (light chains escape). [90]

In patients with MM refractory to standard alkylating agents, the VAD regimen, combining continuous infusions of vincristine, Adriamycin, and 4-day pulses of high-dose dexamethasone at 40 mg daily, produces marked cytoreduction of 75% in >50% of patients, with an especially high response rate in relapsing patients (i.e., patients with prior response). [91] High-dose dexamethasone alone in refractory myeloma is equally effective as VAD in terms of survival. [92] Responders to VAD and dexamethasone not only have significant reduction to myeloma protein, but also have a drastic reduction in bone marrow plasmacytosis. VAD-based regimens in previously untreated myeloma patients result in a 55% response rate. [93] Response is usually rapid with near-maximum response occurring after two cycles of treatment. [93] [94] Despite these rapid responses, median survival times were similar for VAD and the previously described combination chemotherapy regimes. [93] [95] When compared to VAD the response rate with pulses of dexamethasone alone was 15% less, but the survival times were similar for the two regimens, indicating that dexamethasone was clearly the most active agent in the VAD regimen. [96] Myelosuppression is uncommon with VAD and the toxicity encountered with this regimen is almost exclusively due to the dexamethasone. The failure of the VAD regimen to have a significant impact on survival is probably due to the lack of effect on the myeloma precursors compartment that has receptors for IL-6 and therefore can be rescued from dexamethasone-induced apoptosis by this cytokine; actually an increase in clonogenic myeloma cells has been observed after treatment with VAD. [97] By adding cyclophosphamide to VAD (CVAD), 40% of VAD-resistant myeloma patients show an objective response with the best results obtained in patients with low LDH, low $_2$M, and primary resistant disease. [98]

Autologous Stem Cell Transplantation

Because minor dose increases in alkylating agents, as used in the combination chemotherapies, had not resulted in improvement of overall survival, it appeared logical to try a more pronounced escalation. This was first piloted by McElwain et al. using a dose of 100140 mg/m^2 of melphalan in nine patients, five previously untreated and four refractory to standard therapy. [99] Three of the five previously untreated patients achieved a biochemical and bone marrow complete remission, compared to a 3% complete response rate with standard therapy. High-dose melphalan therapy induced complete remission in one-third of patients previously untreated [100] and partial responses in approximately 40% of refractory myeloma cases. [101] However, the procedure-related mortality was high at 1520%, mainly due to long duration of aplasia. [100] [102] To correct this problem, high-dose melphalan therapy was supported initially with a bone marrow transplant that could contain up to 30% myeloma cells, [103] based on the concept that myeloma is a hypoproliferative disease and that these myeloma cells could not hamper hematologic reconstitution, while significantly shortening the duration of aplasia. However, the median time to granulocyte and platelet recovery with bone marrow transplantation was still approximately 3 weeks, [104] but bone marrow support allowed further intensification of therapy; the dose of melphalan could be escalated to 200 mg/m^2 or total body irradiation could be added to melphalan 140 mg/m^2.

Further progress was made by supporting high-dose chemotherapy with mobilized peripheral blood stem cells, reducing the median time to both granulocytes >0.5 × 10^9 /L and platelets >50 × 10^9 /L to 14 days. [105] With peripheral blood stem cell support, the transplant-related mortality is <5% and tandem transplants are feasible, with >75% of intended patients completing their double transplants. [105] When considering all patients, 30% achieve a stringently defined complete response (immunofixation of serum and urine are negative) with median duration of event-free and overall survival of 26 and 41 months, respectively. [105] Better results are obtained with tandem transplants in previously untreated myeloma patients with a 40% complete response rate and median event-free and overall survivals of 49 and 62+ months [106] (Table 76-4). Double transplants

appear to be superior to single transplants; with single transplants the complete response rate in unselected patients is only 25% [107] with median event-free survival of only 27 months. [107] However, both the French randomized [107] and a pair-mate comparison [106] have demonstrated that high-dose chemotherapy is superior to standard-dose therapy and therefore should be considered the standard of therapy for patients, at least up to the age of 65, who are in generally good condition, and in patients in whom their poor performance status is due to myeloma bone pain. High-dose chemotherapy with melphalan and stem cell rescue can be given safely to patients with renal failure. Pharmacokinetic studies have shown that the melphalan clearance is not delayed in renal failure. [108]

The most important prognostic variables for event-free and overall survival after autotransplant are cytogenetics, duration of standard-dose therapy, and the $_2$M level prior to the first transplant. [49] A model using these three variables accurately separates patients who will do well and who will do poorly with autotransplants. [49] The median time to clear the paraprotein after autotransplantation is 1.5 months with, very rarely, further reduction in paraprotein seen after 6 months. [109] Although IgA myelomas have a significantly more rapid clearing of their paraprotein and are associated with a higher complete response rate, the event-free and overall survival in these patients is significantly inferior. [105] Although peripheral stem cells should always be collected early in the disease, a current Intergroup trial in the United States is addressing the issue of optimal timing of autotransplantation, that is, upfront versus at the time of failure of standard therapy.

Other issues addressed in ongoing multicenter randomized trials are the benefit of CD34 selection as a means to deplete tumor cells and the benefit of one versus two autotransplants. Although it is still unclear whether MM patients can be cured with autotransplants, based on the lack of a plateau in the survival curves, it seems likely that in the low-risk group of patients (i.e., those with favorable cytogenetics, <12 months of preceding standard therapy, and low $_2$M levels prior to transplantation) a plateau is starting to form. Approximately 2030% of these patients (810% of all patients) may be cured. [49] Selected patients may benefit from further autotransplants after relapse post-transplantation, specifically, patients with low $_2$M at relapse and those with late relapse. [110]

Allogeneic Transplantation

The advantages of allotransplantation in myeloma are the lack of tumor contamination of the graft and the potential of a graft-versus-myeloma effect that has clearly been demonstrated in a few cases recently. [111] [112] However, patients with MM are in general older than those with leukemia, are more immunodeficient by nature of their disease and due to the administration of multiple courses of chemotherapy containing corticosteriods, and are in a more compromised condition because of their bone lesions. This results is a high first-year mortality rate after allotransplantation of approximately 4050&%. [113] [114] The complete remission rate in mainly refractory myeloma patients is 3545% and a progression-free survival of 2035% is seen at 5 years. [114] [115] Favorable prognostic factors for outcome are short duration of standard therapy, low $_2$M level before transplantation, and low tumor load at time of transplant. [113] [115] When a case-matched analysis was performed comparing patients treated with allogeneic versus autologous transplantation, the overall survival was significantly better in the autotransplant group. Again, the main reason for the poorer survival in the allotransplant group was the higher transplant-related mortality that was not compensated for by a higher response rate; however, in patients alive at 1 year post-transplantation, the progression-free survival was significantly better in the autotransplant group. [114] Because of the high treatment-related mortality, allogenic transplantation should probably only be considered in patients with more than one poor prognostic marker, that is, unfavorable cytogenetics, high $_2$M, high CRP, high LDH, high PCLI before transplantation, and disease refractory to standard-dose chemotherapy.

Interferon-

Encouraging results have been reported with interferon- therapy as maintenance therapy after 12 cycles of standard treatment with prolongation of response and survival in MM patients responding to conventional chemotherapy. [116] Although subsequent studies have shown a longer plateau phase with maintenance interferon therapy, in patients responding to standard therapy, they failed to show a survival advantage. [117] Similarly, there are no convincing studies showing any benefit from interferon- therapy post-transplantation. Besides a flulike syndrome, interferon can cause general weakness, autoimmune disorders, impotence, and depression. Prolonged interferon- also makes collection of adequate amounts of peripheral stem almost impossible.

Clarithromycin (Biaxin)

An unexpected and surprising activity of this agent in newly diagnosed and previously treated myeloma patients was reported recently by Durie et al. [118] The trial with clarithromycin was based on good responses seen in mucosa-associated lymphoid tissue lymphomas with t(11;14) associated *Helicobacter pylori* infection, as a result of the detection of a circulating nucleotide sequence, which contains the same Bcl-1/J $_H$ break point as observed in some myeloma patients. Patients received a dose of 500 mg clarithromycin twice daily. Thirty patients were enrolled with the longest follow-up being 1 year. Six patients had a 75% and seven had a 50% reduction in M protein. Responses were associated with improvement in clinical status, hemoglobin, $_2$ M, bone marrow plasmacytosis, and lesions detected by MRI. Responses were also observed in patients failing standard or high-dose chemotherapy. The best responders have been patients with IgA or IgG myeloma. A rebound in disease activity was seen if clarithromycin was discontinued before a maximal response was achieved. Although these results appear promising and this therapy is well tolerated, these data need to be confirmed in a larger study and if patients are started on this treatment, they should be monitored very closely for disease progression and switched to proven treatment modalities if progression occurs.

Management of Complications

Anemia

In patients with hemoglobin levels <10 g/dl with stable disease on standard therapy, erythropoietin therapy induces a response, defined as an increase in hemoglobin levels of 2 g/dl, in approximately 70% of patients with the best results in those with limited prior alkylating agent therapy and low endogenous erythropoietin levels. [119] [120]

Pain

Myeloma bone pain is usually severe and requires morphine derivatives. The pain usually improves remarkably with chemotherapy, especially regimens containing high-dose dexamethasone. Use of local radiotherapy for pain should be discouraged because it may interfere with future treatment plans and the collection of adequate numbers of peripheral blood stem cells. Patients should be encouraged to be as active as possible as soon as the pain is controlled to avoid further decalcification of the bone.

Hypercalcemia

Hospitalization is recommended for patients with calcium levels >12 mg/dl and for those with any other symptoms than mild fatigue and constipation. Hospitalization is certainly required in patients with moderate to severe anorexia, nausea, vomiting, and confusion. Treatment of hypercalcemia is urgent because renal insufficiency develops quickly. Intravenous administration of isotonic saline is the first step in the management of severe hypercalcemia; expansion of intravascular volume will also increase renal calcium clearance. The rate of administration of isotonic saline should be based on the severity of the hypercalcemia, the extent of dehydration, and the tolerance of the cardiovascular system. Usually approximately 3 liters of fluid is given daily and diuretics are used if symptoms of fluid overload occur. In addition to hydration, specific agents to lower calcium levels are required. The most commonly used agent is pamidronate, 90 mg as a 2- to 4-hour infusion. An alternative is gallium nitrate at a dose of 200 mg/m^2 /day by continuous intravenous infusion for 25 days; the infusion can be terminated if normocalcemia has been achieved. In patients with mild and moderate hypercalcemia, normal saline infusions and pamidronate should be sufficient therapy. However, in patients with severe and life-threatening hypercalcemia, calcitonin therapy will also be required to lower the calcium levels rapidly. Calcitonin has the most rapid onset of action (24 hours). It should only be given for 23 days until the pamidronate has had time to start working. The dose of calcitonin is 68 IU/kg every 812 hours. However, calcitonin rarely reduces serum calcium levels to normal and should therefore not be relied on as a single agent. Once hypercalcemia is controlled, standard chemotherapy, preferably with a high-dose dexamethasone regimen, should be started.

Prevention of Further Bone Disease

Bisphosphonates do not only have a role in the treatment of hypercalcemia, but they also contribute to the long-term control of bone disease. The administration of monthly pamidronate at 90 mg as an intravenous infusion over 24 hours in 500 ml normal saline significantly reduces the incidence of skeletal events and alleviates bone pain and improves the quality of life in patients undergoing standard-dose chemotherapy. [121] The most significant differences with a placebo control group were seen in patients who had already received more than one treatment regimen, who had experienced prior skeletal events, and who did not respond to standard therapy. Whether bisphosphonates are useful after a marked tumor reduction, as attained with transplantation, remains to be determined. However, until the studies have been completed, it is probably wise to give monthly pamidronate to all patients with myeloma.

Future Directions

Major progress has been made in the biology and treatment of MM. The role of cytokines and of oncogenes/suppressor genes has become more evident. Aggressive treatment approaches are resulting in higher complete remission rates and extended survival. However, relapses still occur. Further progress in the treatment of myeloma will come from one of the following areas:

1. Application of post-transplant chemotherapy in patients who have received minimal standard therapy and immediately proceed to high-dose therapy while still having chemosensitive disease. The post-transplant chemotherapy needs to consist of agents with a different mechanism of action than the alkylators used in the preparative regimens for the autotransplant. Tubulin-active agents, known to be active in cancers with altered p53 function and known to phosphorylate bcl-2, as well as agents interfering with DNA repair should be used in this setting.
2. Immunotherapeutic interventions to eradicate minimal residual disease post-transplantation. Dendritic cell-based protocols are being designed using either the myeloma protein or MUC-1 present on plasma cells, as tumor-specific or tumor-associated antigens.
3. Intervention into the cell cycle. Myeloma cells differ from normal plasma cells by their lack of terminal differentiation and by their capacity to proliferate. Agents that can either induce terminal differentiation or can prevent cell cycle progression, such as flavoperidol, may be important in the treatment of this disease.

WALDENSTRÖMS MACROGLOBULINEMIA

The original description of this disease was provided by Waldenström in 1944 when he reported on two male patients with fatigue, a tendency to bleed from the gums and the nasal mucosa, lymphadenopathy, normochromic anemia, and an increased serum viscosity due to high levels of circulating macroglobulin (IgM). These patients lacked the typical signs of myeloma, including lytic bone lesions even on autopsy.

The main characteristics of the disease are the bone marrow infiltration with lymphoplasmacytoid cells and high levels of IgM in the blood. Patients with IgM paraprotein with lytic bone lesions or hypercalcemia and infiltration of the bone marrow with more typical plasma cells should be considered as having IgM myeloma. The median age of patients with Waldenströms disease is 63 with 60% of patients being male. Lymphadenopathy or splenomegaly is present in 40% of patients if computed tomography or MRI of the abdomen is performed. Tumor cells may infiltrate the lungs, the gastrointestinal tract, and the skin. MRI shows bone marrow involvement in >90% of patients. Anemia, monoclonal lymphocytosis in the peripheral blood, and Bence Jones proteinuria occur in the majority of patients. However, Bence Jones proteinuria very seldom exceeds 1 g/24 hours. One-third of the patients have elevated $_2$ M levels and CRP values are increased in the majority (±66%).[122] Abnormal and complex karyotypes are common. The malignant lymphoplasmacytoid cells express surface and cytoplasmic IgM. By flow cytometric analysis these cells express panlymphocyte surface antigens CD19, CD20, and CD22, but are often also positive for CD5 and CD10. CD38 expression is less intense than that on myeloma cells. Normal immunoglobulins are less frequently and less markedly depressed than in myeloma. Cellular immunity including CD4+ counts are usually preserved unless immunosuppressive therapy is given.

Disease in most patients is diagnosed during assessment for complications caused by the macroglobulin such as hyperviscosity syndrome, cryoglobulinemia, cold hemolytic anemia, peripheral neuropathy, amyloidosis, renal disease, and bleeding problems (Fig. 76-6). The serum viscosity is elevated in most patients, but only 1520% have symptoms related to hyperviscosity. Patients with a blood viscosity greater than four times that of water are at risk of developing clinical problems. Because of the expanded plasma volume, intracranial pressure increases, which causes headaches. Other symptoms related to hyperviscosity are dizziness, blurred vision, easy bleeding, and mental status changes. Because of the anemia, the expanded plasma volume, and the increased viscosity, these patients may develop symptoms of congestive heart failure. Fundoscopic evaluation may show distended, sausage-shaped veins, hemorrhage, and papilledema. In contrast to myeloma, where hyperviscosity is almost never seen until the monoclonal paraprotein exceeds 5 g/dl, patients with Waldenströms disease develop hyperviscosity syndrome with an IgM level >3 g/dl. Cryoglobulinemia may cause Raynauds syndrome, arthralgias, purpura, peripheral neuropathy, liver function abnormalities, and renal

Figure 76-6 Major clinical and laboratory features of Waldenströms macroglobulinemia.

failure. For proper diagnosis, blood should be collected, transported, and separated at 37°C before analysis. In approximately 10% of patients, the IgM paraprotein causes cold agglutinin hemolytic anemia, usually associated with a markedly elevated cold agglutinin titer (>1:1,000). The most common target is the I antigen on red blood cells. Bleeding problems may be caused by platelet dysfunction or clotting abnormalities. Hyperviscosity may contribute to the bleeding severity.

About 10% of patients with macroglobulinemia develop chronic, predominately demyelinating sensorimotor peripheral neuropathy. In approximately half of these patients, the IgM antibody is directed against carbohydrate epitopes of myelin-associated glycoprotein (MAG). The presence of anti-MAG antibodies can be detected by enzyme-linked immunosorbent assay. Patients with anti-MAG antibodies usually have a sensory or ataxic polyneuropathy, whereas the other patients with peripheral neuropathy often have a mixed sensorimotor neuropathy. Renal insufficiency is less frequent in Waldenströms disease than in myeloma. IgM may precipitate on the glomerular basement membrane forming deposits that occlude the capillaries. Some patients develop an immunologically mediated glomerulonephritis associated with a nephrotic syndrome. Amyloidosis is rare (<5%), but may result in cardiac, renal, hepatic, and pulmonary complications.

One-third of patients with macroglobulinemia die of causes unrelated to their disease and one-third succumb to infectious complications; other causes of death are bleeding, transformation to high-grade lymphoma, renal failure, or the development of acute myeloid leukemia or a solid tumor. [123] The best prognostic factors are age, hemoglobin, weight loss, and cryoglobulinemia. [123] [124] Asymptomatic patients should be monitored without treatment until complications occur due to either circulating IgM or tumor bulk. Complications such as hyperviscosity, cryoglobulinemia, cold agglutinin hemolytic anemia, or peripheral neuropathy should be treated with plasmapheresis. Because 80% of IgM is intravascular, the level of IgM will be reduced rapidly. However, most patients will require effective chemotherapy to decrease IgM production by the tumor cells. This treatment has most commonly consisted of an alkylating agent and a glucocorticoid. Almost 75% of newly diagnosed patients will show a 50% reduction in M protein. [120] Treatment is usually continued until maximum reduction of IgM is obtained. Approximately 10% of patients attain a complete remission and have a median survival of 11 years. The median survival for all patients is 5 years. [123] [124] Nucleoside analogs such as fludarabine and 2-chloro-deoxyadenosine (2-CDA) have been studied in previously untreated patients. Fludarabine at a dose of 25 mg/m ^{2} intravenously for 5 days every 4 weeks and 2-CDA at a dose of 0.1 mg/kg for 7 days by continuous infusion through a central venous catheter have revealed an 80% response rate with 10% achieving a complete remission.[122] [125] This treatment is well tolerated but results in a marked and sustained reduction of CD4+ lymphocytes, but without a marked increase in life-threatening opportunistic infections. [125] Based on the successes with myeloablative therapy and autologous stem cell support in myeloma, a formal Intergroup trial evaluating the role of autotransplantation in Waldenströms macroglobulinemia will be started.

HEAVY CHAIN DISEASES

The heavy chain diseases are rare lymphoproliferative disorders of B-cell origin that secrete abnormal immunoglobulins lacking light chains. [2] [126] The major types described are , , and heavy chain disease. The first reported was the heavy chain disease, also called Franklins disease; the most common type is the heavy chain disease, sometimes also referred to as Seligmann disease, of which there are several hundred cases reported in contrast to the types, of which there are approximately 100 cases, and the type, of which there are fewer than 30 documented cases. Infection may play a role in the etiology of some types of heavy chain disease, especially in heavy chain disease. The disease occurs in two forms: the enteric and respiratory forms. The enteric form is prevalent in areas where intestinal infections with parasites, bacteria, and viruses are common, and an occasional patient attains a complete remission after antibiotic therapy. About one-fourth of patients with heavy chain disease have an associated autoimmune disease, such as rheumatoid arthritis, autoimmune hemolytic anemia, Sjögrens syndrome, lupus erythematosus, vasculitis, idiopathic thrombocytopenia purpura, and myasthenia gravis. They usually precede the development of heavy chain disease by many years. Most heavy chain disease proteins have an internal deletion of much of the variable region domain and of the first constant region domain (C_H1 domain). In the absence of light chain expression, the heavy chain is retained within the endoplasmic reticulum or Golgi apparatus. Toxicity can ensue from accumulation of heavy chains within these intracellular compartments ultimately resulting in cell death. Neoplastic B cells producing such abnormal heavy chains may continue to secrete light chains as free monomers or lose expression of light chains altogether.

Heavy Chain Disorder

The median age at onset is 60 years, but occurs before the age of 20 years in about 10% of patients. They usually present with a lymphoma-like illness, but the findings are diverse, ranging from asymptomatic disease to an aggressive lymphoproliferative process. Weakness, fatigue, and fever are common; hepatosplenomegaly and lymphadenopathy occur in about 60% of patients. Anemia is present in 80&%. Other manifestations may be parotid gland swelling, severe soreness of the tongue, skin infiltration, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, enlargement of the thyroid gland, and neutropenia due to hypersplenism. Serum protein electrophoresis may show a broad band, suggestive of polyclonal gammopathy. The M protein is usually in the -area. Most of the proteins are IgG, but the monoclonal band may vary from a trace to 9 g/dl. Immunoelectrophoresis is necessary for detection of the monoclonal heavy chain. The bone marrow and lymph nodes contain an increased number of plasma cells, lymphocytes, or lymphoplasmacytoid cells. Osteolytic lesions are rare. The clinical course of heavy chain disease varies from a rapidly progressive downhill course to a prolonged stable disease. The median survival is approximately 12 months. Therapy is initiated only for symptomatic patients; a CHOP-like (cyclophosphamide, hydroxydaunomycin, Oncovin, prednisone) regimen is preferred. Treatment results are usually disappointing.

Heavy Chain Disease

Most patients are from the Mediterranean region and develop the disorder in the second or third decade of life. The gastrointestinal tract is most commonly involved, resulting in malabsorption, weight loss, and diarrhea. Plasma cell infiltration is seen in jejunal mucosa and mesenteric and para-aortic lymph nodes. The stomach may also be involved. The bone marrow is usually normal as is serum protein electrophoresis in 50% of cases; in the other patients a small broad band may be present in the $_2$ or regions. Usually this disease is progressive and fatal. Patients with diarrhea secondary to the enteric form of heavy chain disease may require intravenous infusions of fluids, electrolytes, calcium and magnesium, albumin, and antibiotic therapy (e.g., tetracyclines) or metronidazole. The preferred therapy for the more advanced stages of the disease is CHOP.

Heavy Chain Disease

The age of these patients varies between 15 and 80 years. Hepatosplenomegaly is found in most patients. The bone marrow shows increased numbers of lymphocytes and plasma cells. Lytic bone lesions are present in 20% of patients. Serum protein electrophoresis may be normal, except for hypogammaglobulinemia, or show an abnormal band; Bence Jones proteinuria is found in two-thirds of patients. The course is variable and survival may vary from a few months to many years. Treatment with alkylating agents and corticosteroids may be of benefit.

CRYOGLOBULINEMIA

Cryoglobulins are immunoglobulins that precipitate at temperatures below 37°C (Fig. 76-7), producing high-molecular-weight aggregates. These aggregates dissolve again when heated to temperatures above 37°C.[127] Leukocytoclastic necrotizing vasculitis involving small and medium-sized arteries occurs in patients with cryoglobulinemia leading to a disorder involving multiple body systems. [128]

Cryoglobulins are best detected by drawing venous blood into a preheated syringe (37°C) and separating the serum in a centrifuge that maintains a temperature between 37°C and 39°C. The serum is removed and placed in capillary tubes and incubated at 4°C for 814 days. Samples with cryoprecipitates are examined daily after being centrifuged for 15 minutes. A cryocrit of 0.4% is considered indicative of a positive test because symptoms attributable to cryoglobulinemia are rare at lower values. Normal serum has been reported to contain up

Figure 76-7 Cryoglobulinemia. **(Left)** Precipitate formed at 1°C. **(Right)** Disappearance of precipitate on heating to 37°C. *(From Kyle and Greipp, [153] with permission.)*

to 80 g/ml of cryoglobulins, whereas levels of 500 to 5,000 g/ml of cryoglobulins are frequently associated with symptoms. [129]

Brouet et al. first classified cryoglobulins into three types. [130] Type I cryoglobulins are composed of one class of monoclonal immunoglobulins, most frequently IgM. Type II cryoglobulins are mixed cryoglobulins, which are composed of a mixture of monoclonal and polyclonal immunoglobulins (monoclonal anti-IgG being the most common). These complexes may also include other proteins such as hepatitis C-related proteins, the third component of complement or lipoproteins. [129] Type III cryoglobulins are composed of polyclonal immunoglobins, most commonly polyclonal IgM anti-polyclonal IgG. In type II and type III, the IgMs are antiglobulins acting as anti-IgG rheumatoid factors.[127] [130] To determine the type of cryoglobulin, the serum cold precipitate can be redissolved by reheating to 37°C. The presence of monoclonal or polyclonal immunoglobulins and complexes is then determined by standard electrophoretic analyses described in Chapter 160 .

Type I cryoglobulins are usually associated with underlying lymphoproliferative disorders including low-grade lymphomas, Hodgkins disease, Waldenströms macroglobulinemia, MGUS, angioimmunoblastic lymphadenopathy, and chronic lymphocytic leukemia.[128] Both type II and type III cryoglobulins are associated with lymphoproliferative disorders (indolent lymphoma, Waldenströms macroglobulinemia), autoimmune disorders (systemic lupus erythematosus, Sjögrens syndrome, scleroderma, rheumatoid arthritis), or a variety of infectious disorders (Table 76-5).[127] [128] [129] Patients in whom an underlying etiology cannot be identified are classified as having essential mixed cryoglobulinemia (Table 76-6 (Table Not Available)). Of the 103 cases of cryoglobulinemia reported by Wooten and Jasin, 28% had type I cryoglobulins, 58% had type II cryoglobulins, and 14% had type III cryoglobulins. [128] In addition, 14% of patients with cryoglobulinemia have been reported to have Waldenströms macroglobulemia. Although 15% of patients with Waldenstroms macroglobulinemia have type I cryoglobulins, only 5% are symptomatic. [128] The patients with type II mixed cryoglobulinemia characteristically have serum hypergammaglobulinemia and decreased complement levels due to activation by immune complexes.[127] [129] Wooten and Jasin analyzed seven large series of patients with symptomatic cryoglobulinemia reported in the literature and determined that 6% (138%) eventually developed a lymphocytic lymphoma.[128] Such data have led a number of investigators to suggest that type II cryoglobulinemia is a forme fruste of low-grade lymphoma.

A growing number of studies have consistently implicated hepatitis C virus (HCV) as the major etiologic agent that leads to type II mixed cryoglobulinemia. [131] [132] [133] Approximately 80% of patients with essential mixed cryoglobulinemia have mixed cryoglobulinemia secondary to an HCV infection. [131] [132] Cryoprecipitates in these patients can be dissociated to hepatitic C virons, IgG, and monoclonal IgM rheumatoid factor. In addition, HCV virons or related proteins have been detected in peripheral blood mononuclear cells, cutaneous tissues, and the residual ductal or acinar parotid structures of patients with non-Hodgkins lymphoma of the parotid gland and in glomerular and tubulointerstitial vascular structures of patients with cryoglobulinemia and membranoproliferative glomerulonephritis. [129] [134] [135] [136] [137] Lymphoid aggregates have been demonstrated in the liver and marrow of such patients and are composed of monoclonal B cells, which likely play a role in the immune-mediated liver damage and the development of lymphoma.[134] [135] [136] [137] The phenotype of the B cells within these lymphoid aggregates is consistent with an indolent lymphoma.[134] In patients with hepatitis, cryoglobulinemia is not a rare event, having been documented in 54% of patients with hepatitis C, 15% of patients with hepatitis B, and 4% of normal controls.[133] Recognition that cryoglobulinemia is an HCV-related disorder lends support to the use of antiviral agents such as interferon- in its treatment.

It is recommended that all patients with mixed cryoglobulinemia be tested for HCV and that all patients with HCV be questioned for symptoms associated with essential mixed cryoglobulinemia. Many of the extrahepatic symptoms of HCV are thought to be due to chronic immune complex disease and can frequently be attributed to a mixed cryoglobulinemia syndrome[138] (Fig. 76-8).

Cryoglobulinemia is a rare disorder characterized by symptoms due to systemic vasculitis. Clinical manifestations range from the triad of palpable purpura, arthralgias, and weakness to life-threatening disease involving vital organs such as the kidneys. [127] [129] [131] Symptoms in many patients are first related to

TABLE 76-6 -- Summary of Clinical Manifestations in 1,033 Patients with Essential Mixed Cryoglobulinemia

(Not Available)

Figure 76-8 Relationship of symptoms of hepatitis C infection and mixed cryoglobulinemia. *(From Wener et al.,[138] with permission.)*

skin manifestations, which are a consequence of cutaneous vasculitis. These patients present with purpura, leg ulcers, Raynauds phenomenon, edema, and urticaria. The purpura is nonpruritic and appears intermittently on exposed parts of the body. [129] The purpura occurs most frequently following cold exposure, lasts for 12 weeks and leaves a hardened, diffusely hyperpigmented area. [129] Chronic leg ulcers in the supramalleolar regions can be associated with purpura.

Intermittent, symmetrical, nonmigratory arthralgias accompanied by profound weakness are common.[129] Liver involvement occurs in almost 50% of patients and can range in severity from minimal changes to sporadic hepatic necrosis within lobules, to a picture consistent with chronic active hepatitis. Sensory and motor peripheral neuropathy mostly involving the lower extremities may occur. Severe abdominal pain occurs in 20% of patients and is a consequence of intestinal vasculitis. [129] Central nervous system dysfunction including transient hemiplegia, dysarthria, mental confusion, or even coma has been reported. [127] [129] Membranoproliferative glomerulonephritis with subendothelial deposits occurs frequently in patients with mixed cryoglobulinemia. These patients present initially with isolated proteinuria, microscopic hematura, and signs of moderate renal insufficiency or nephrotic syndrome. [137] In 2025% of cases, patients present with acute oliguric renal failure due to massive precipitation of cryoglobulins in glomerular capillary loops with subsequent infiltration with monocytes. [137] Progression to end-stage renal failure occurs in 10% of cases usually several years after the onset of symptoms.[129] [137] The most common causes of death in patients with cryoglobulemenia are systemic vasculitis, infections, and severe hypertension leading to cardiovascular and cerebrovascular accidents. [129]

Frequently mixed cryoglobulinemia will evolve into a lymphoid malignancy. In one series of 31 patients with mixed cryoglobulinemia and HCV infection, 39% of patients had marrow biopsy findings consistent with the presence of a low-grade lymphoma. [139] Early in the course of the disease, this lymphoproliferative disorder is limited but often can evolve to a full-blown non-Hodgkins lymphoma. The overt B-cell lymphomas frequently present as diffuse large cell lymphomas originating in extranodal sites such as the liver, spleen, and salivary glands. [140] [141]

Treatment of the systemic vasculitis that accompanies cryoglobulinemia remains problematic. Avoidance of the cold is a mainstay of therapy. Following the identification of HCV in 80% of the cases of mixed cryoglobulinemia interferon- has

been used extensively alone or in combination with other drugs. [129] [142] [143] [144] Cytotoxic drugs such as cyclophosphamide should be avoided in these virally induced vasculitides; their use should be limited to short pulses in patients with severe forms of the disease. Interferon- is usually administered at a dose of 3 million units daily for 36 months, resulting in a 77% response rate. [142] [144] An alternative regimen of interferon- in which a dose of 3 million units is administered three times a week has resulted in sustained response in 35% of patients. [143] In a randomized study the addition of prednisone to interferon- resulted in little therapeutic benefit. [142] Prednisone therapy alone results in 40% of patients in elevations of serum HCV RNA levels, therefore leading to little justification for long-term prednisone therapy. [142] Significant improvement with interferon- therapy can be achieved in patients with cutaneous vasculitis. The therapeutic efficacy of interferon has been demonstrated to be clearly related to inhibition of HCV replication, and clinical responses have been associated with reduction of levels of HCV RNA to a point where the virus can no longer be detected.[144] The absence of HCV RNA in cryoprecipitates of responsive patients suggests that alterations in the composition of cryoprecipitates occur following treatment.[129]

Although responses to interferon are frequently sustained, 80% of patients relapse within 6 months of cessation of treatment. [142] [143] [144] These data suggest that continuous maintenance therapy is indicated in patients with persistently active disease. In some patients with chronic renal disease reduction of the degree of proteinuria and serum creatinine levels has been achieved with interferon therapy. Most clinicians, however, prefer to initially treat patients with acute renal failure with a combination of steroids, cyclophosphamide, and plasmapheresis therapy. [145] [146] Once these patients have been stabilized, interferon therapy should be instituted.

Plasmapheresis in combination with interferon- therapy has been shown to be particularly effective for treatment of arterial leg ulcers, peripheral neuropathy, or situations where digital ulcers or strokes can be attributed to hyperviscosity or cerebral vasculitis. [129] Case reports of successful treatment of cryoglobulinemia and low-grade lymphoma with fludarabine and 2-chlorodeoxyadenosine have appeared in the literature, yet optimal treatment of overt diffuse large cell lymphoma following HCV and mixed cryoglobulinemia requires further investigation. [147] [148]

PYROGLOBULINEMIA

Pyroglobulins are immunoglobulins that precipitate when the serum is heated to 5660°C. The precipitation is irreversible. [149] This thermolabile property distinguishes these proteins from Bence Jones proteins, which will redissolve if heating is continued above 56°C. The presence of pyroglobulins is not associated with any symptoms.[149] [150] [151] [152] The presence of pyroglobulinemia is associated most commonly with MM and Waldenströms macroglobulinemia. [149] [150] [151] [152]

Pyroglobulins are found in 23% of patients with monoclonal paraproteins and are not found in normal individuals. [149] These proteins can be detected serendipitously in individuals in whom fibrinogen levels are detected by heat precipitation. This irreversible denaturation of immunoglobulins with heating is likely the result of conformational changes triggered by light chains with increased molecular hydrophobicity. [151] [152]

Combined cryopyroglobulins are unusual immunoglobulins that form a reversible cryoprecipitate at low temperatures and an irreversible gel when heated to 5660°C.[151] This abnormality has been observed in patients with IgG, IgM, IgA, and K or light chain producing myelomas. [151] Symptoms in these patients have been attributed to the cryoglobulin, not the pyroglobulin, although the occasional combination of cyroprecipitation and pyrogel formation suggests the presence of both defects in the same molecule.[151]

Chapter 77 - Amyloidosis

Madhav V. Dhodapkar
Vittorio Bellotti
Giampaolo Merlini

The term *amyloidosis* is used to describe a heterogeneous group of extracellular protein deposition diseases in which homogeneous protein molecules aggregate in an ordered structure to make linear, nonbranching fibrils 7.510 nm wide and of indeterminate length. The fibrils are arranged in a characteristic -sheet structure, which gives apple-green birefringence under polarized light when stained with Congo red. [1] Amyloid deposits were first recognized by Virchow in 1854, and were so named because of the apparent affinity of the material for iodine, which suggested a resemblance to starch. For historic reasons, the name has been retained, although it is now clear that all types of amyloid deposits are proteinaceous and not carbohydrate

TABLE 77-1 -- Nomenclature and Classification of Amyloid and Amyloidoses

Amyloid Type	Protein Precursor	Protein Type or Variant	Associated Clinical Syndromes
AL	,	A, A	Primary amyloidosis
			Myeloma and Waldenström macroglobulinemia-associated amyloidosis
AH	IgG 1 (1)	A1	Heavy chain disease associated
AA	ApoSAA	AA	Reactive/secondary amyloidosis
			Familial Mediterranean fever
			Muckle-Wells syndrome
ATTR	Transthyretin		Hereditary amyloidoses:
		e.g., Met30[a]	Familial amyloidotic polyneuropathies
		e.g., Met111[a]	Familial amyloidotic cardiomyopathy
		TTR or Ile122[a]	Senile systemic amyloidosis
AApoAI	Apolipoprotein AI	e.g., Arg26[a]	Familial amyloidotic polyneuropathy
		e.g., Arg60[a]	Familial non-neuropathic (Ostertag type)
AGel	Gelsolin	Asn187[a]	Familial amyloidosis (Finnish)
A_2 -m	$_2$ -microglobulin		Dialysis associated
A	-protein precursor A4	A4 protein	Alzheimer disease
			Down syndrome
		e.g., Gln 695[a]	Hereditary cerebral hemorrhage with amyloid (Dutch type)
ACys	Cystatin-C	e.g., Leu 68[a]	Hereditary cerebral hemorrhage with amyloid (Icelandic type)
AScr	PrP^C (cellular protein precursor)	Prp^{SC} , PrP^{CJD}	Spongiform encephalopathies
		e.g., Leu 102[a]	Gerstmann-Sträussler-Scheinker syndrome
ACal	(Pro)calcitonin	(Pro)calcitonin	Medullary carcinoma of thyroid
AANF	Atrial natriuretic factor	Atrial natriuretic factor	Isolated atrial amyloidosis
AIAPP	Islet-associated peptide	Islet-associated peptide	Amyloid of the islets
			Diabetes mellitus type II
A Lys	Lysozmye	e.g., Thr56	Hereditary non-neuropathic systemic amyloidosis
A Fib	Fibrinogen chain	e.g., Leu554[a]	Hereditary renal amyloidosis

Abbreviations not explained in table: AA, amyloid A protein; L, immunoglobulin light chain; H, immunoglobulin heavy chain; SAA, serum amyloid A precursor; apo, apolipoprotein; TTR, transthyretin.

Data from WHO-IUIS Nomenclature Subcommittee: Nomenclature of amyloid and amyloidoses. Bull World Health Organ 71:105, 1993.

[a]Variant amino acid with corresponding position in the mature protein.

in nature. [2] The fibrillary nature of the amyloid protein was first recognized by electron microscopy in 1959 by Cohen and Calkins. [3] The definition of the cross--pleated sheet supersecondary structure was obtained by x-ray diffraction analysis of isolated amyloid fibrils in 1968. [4] Historically, the amyloidoses were classified as either primary or secondary. The primary amyloidoses were thought to occur in people with no underlying illness, whereas amyloid deposition in the setting of chronic infectious or inflammatory conditions was termed secondary. In 1971, Glenner et al demonstrated the sequence homology of a major protein subunit from the primary amyloid fibril to the variable segment of the immunoglobulin (Ig) light chain. [5] Since then, several other proteins have been identified as major

constituents of amyloid fibrils, and the chemical nature of the amyloidogenic protein is the key by which the current classification of amyloidosis is organized [6] (Table 771). The most life-threatening forms are systemic, with multiorgan involvement, but in a number of subtypes the deposition may be localized to a single organ. These disorders are of special interest to hematologists because one of the most common systemic forms (primary or AL amyloidosis) is a plasma cell dyscrasia causing the tissue deposition of monoclonal immunoglobulin fragments.

PATHOGENESIS

The diverse human proteins that can form amyloid fibrils in vivo each have a normal, unrelated protein precursor (Table 771), but they can all polymerize into insoluble fibrils with similar ultrastructural appearances and identical tinctorial properties. The structure of the fibrils, which comprise the protein core of amyloid deposits, consists of a -sheet structure with the strands perpendicular to the long axis of the fiber. The elucidation of the conformational modifications that drive the conversion of different proteins into an identical pathologic fold is important for understanding the molecular basis of the disease and may enable development of rational approaches to the treatment of amyloidosis.

Amyloid Proteins

Immunoglobulin Light Chains

Primary Structure

Determination of the primary structure of amyloidogenic Bence Jones proteins has been one of the most important accomplishments in the elucidation of the structural basis of AL amyloidosis in the last 20 years. An extensive survey and analysis of the published sequences of amyloidogenic proteins in comparison with a few nonamyloidogenic ones has emphasized the role of critical amino acid positions in conferring this pathologic property. [7] All light chain classes can cause AL amyloidosis, but light chains are involved in amyloid deposition two to three times as often as chains. One of the most intriguing findings is that $_{VI}$ light chains are strictly associated with AL amyloidosis. Comparison of the normal and pathologic light chain counterparts suggests that the amino acid replacements affect the light chain scaffold,[8] because they are located in the well preserved positions in the framework regions of the light chain variable regions. The amino acid replacements identified in amyloidogenic light chains and most strictly related to the disease are also frequently located in the framework regions. [9]

Post-translational Modifications

The two post-translational modifications most frequently correlated with the amyloidogenicity of light chains are proteolytic rearrangement and glycosylation.

Proteolysis.

Extraction of fibrillar light chains from amyloid deposits, even when conducted with mixtures of protease inhibitors, demonstrates the presence of light chain fragments associated with different percentages of complete light chains. It has been demonstrated that light chain fragments circulate in small amounts in the serum of these patients,[10] and that the bone marrow plasma cells from patients with AL amyloidosis secrete light chain fragments of heterogeneous molecular weight. [11] The pathogenic role of proteolytic rearrangement of amyloidogenic light chains is still under discussion, [12] and it cannot be excluded that in some cases this represents a postfibrillogenic event. However, two aspects of the problem must be emphasized: the first is that in vitro, fibrillogenesis of these immunoglobulins is accelerated by proteolytic digestion of the constant domain, [13] and the second is that even though postfibrillogenetic, proteolysis of the constant domain stabilizes the fibrillar structure.

Glycosylation.

A pathogenic effect for glycosylation has been hypothesized on the basis of the high frequency of glycosylated amyloidogenic light chains: >50% of them seem to be sugar linked, compared with 15% of nonamyloidogenic Bence Jones proteins. [14] The possibility that these carbohydrates may have a stabilizing effect on the growing fibril in vivo has been postulated. [15]

Three-Dimensional Structure and Folding Abnormalities

Determination of the tertiary structure of amyloidogenic light chains has been achieved at high resolution in a few cases only. One of the most recently resolved three-dimensional structures is that of light chain Bre. [16] The native structure of BRE is not markedly different from that of the nonpathologic light chain $_{I}$ REI. The only significant modifications are located in the regions that participate in the monomer-monomer contacts (loops 4044 in framework 2) and control dimer formation and stability. New light has been shed on the relationship between structure and the tendency to create amyloid fibrils from analysis of the thermodynamic parameters of the unfolding pathway of amyloidogenic and non-amyloidogenic light chains. Several recombinant V_L domains of amyloidogenic light chains were evaluated, and it was determined that these variants are less stable than the wild-type Rei V_L light chain. [17] This finding was confirmed by a natural amyloidogenic light chain isolated as a dimer and presenting the arginine 61-threonine replacement. [18] Conversion of circulating immunoglobulin light chains to the fibrillar state proceeds through at least one conformational intermediate that is accessible to some, but not all light chains. Structural characterization of this unstable intermediate is required to explain the unresolved mystery of this pathologic phenomenon: why do these light chains self-aggregate into a well ordered fibrillar structure instead of remaining an amorphous aggregate?[19]

Heavy Chain Amyloidosis

After the first demonstration by Eulitz et al [20] that an internally deleted IgG1 heavy chain can create amyloid in vivo, a few other cases of heavy chain disease and amyloidosis have been described.

Light/Heavy Chain Deposition Disease

As in AL amyloidosis, there is a relationship in light/heavy chain deposition disease (L/HCDD) between the structure of these immunoglobulins and the molecular basis of disease in which the light chains accumulate, with very selective tissue tropism, in the basement membrane and produce an amorphous, nonfibrillar protein deposit. Unlike in amyloidosis, light chains are more often responsible for the disease than light chains. Structural data obtained from the few pathogenic light chains in which the V_L region has been completely sequenced indicate frequent amino acid replacements that result in the creation of hydrophobic patches in regions normally exposed to the solvent.[21] It is worth pointing out that the deposits in L/HCDD are positive for carbohydrate stains like periodic acid-Schiff (PAS), and that the light chains responsible for L/HCDD are frequently glycosylated. However, the PAS-positive material found in the basement membrane is not associated with light chain glycosylation, but rather is related to glycoproteins and proteoglycans synthesized locally in the basement membrane and in the mesangial cells. Recently, two monoclonal light chains responsible for L/HCDD were studied for folding stability and self-aggregation tendency. [18] [22] Although the two light chains show significantly different stability under denaturing conditions, both have a high tendency to self-aggregate and create an amorphous precipitate. In one case, in a mouse model, a remarkable tropism for the kidney basement membrane was demonstrated.[18] A multistep process can be hypothesized in which the light chain first binds some as yet unknown components of the basement membrane, where it reaches a high concentration; later, protein aging and local conditions could cause unfolding and self-aggregation, which enhance the deposition of insoluble light chain precipitate.

Protein

The fibrils extracted from the intracerebral and cerebrovascular amyloid deposits of patients affected by Alzheimer disease, Down syndrome, and amyloid angiopathy of the Dutch type are constituted by a 39- to 42-residue peptide known as protein. The amyloid protein precursor (APP) is the source of the peptide found in the Alzheimer brain. It constitutes a family of transmembrane glycoproteins encoded on the long arm of chromosome 21. The secretory form of APP is produced along two pathways: a nonamyloidogenic pathway involving proteolytic cleavage within the A region and an amyloidogenic one, leading to the release of A subunits. The first

step in the genesis of A amyloid is the release of the A fragment from the parent APP molecule. This implies the existence of two distinct proteolytic events to generate the N- and C-terminals of A. Any protease that releases APP and the protein from the membrane is known as a *secretase*. Most secreted APP is released by a putative secretase, which cleaves within the A domain and precludes the release of the intact amyloidogenic peptide. A portion of secreted APP is released by a secretase, which cleaves near the N-terminus of A and produces C-terminal fragments containing the whole A domain. The release of the 39- to 42-residue amyloidogenic polypeptide requires the action of a third enzyme, secretase, which can generate the C-terminus of A after release of the transmembrane domain from the lipid bilayer. The identity of the three secretases is unknown, but may provide a novel therapeutic target. To date, six different mutations in exons 16 and 17 of the APP gene have been correlated with early onset of Alzheimer disease. The mechanism by which mutations leading to amino acid substitution cause -protein amyloidosis is unknown. It has been reported that cultured cells expressing APP cDNA encoding the substitutions Asn595-Lys and Leu596-Met, responsible for hereditary Alzheimer disease in a Swedish family, produce six to eight times more protein than cells expressing wild-type APP. [23] The identification of the effect of these mutations on the rate of -protein production has allowed the preparation of a transgenic mouse that reproduces the histopathologic pattern of the disease and provides an irreplaceable model for biomedical and pharmaceutical investigations. [24]

Prion Protein

In prion-related neurodegenerative diseases like scrapie, Creutzfeldt-Jakob disease, and bovine spongiform encephalopathy, the amyloid protein consists of a prion-related protein of 2730 kd (PrP_{2730}). PrP^{SC} or PrP^{CJD} represents the pathogenic protein,

whereas PrP^{C} is the normal cellular isoform. Mutations in the PrP gene have been linked to familial forms of the disease like the Gerstmann-Sträussler-Scheinker syndrome, the familial Creutzfeldt-Jakob disease, and the fatal familial insomnia. The nuclear magnetic resonance structure of mouse prion reveals an -helical structure and a -sheet strand. [25] The conversion of the helical structure into a -sheet secondary structure represents one of the key events of prion disease, but in this case, at variance with other forms of amyloidosis, the interaction of PrP^{SC} with PrP^{C} induces the transition of nonpathologic PrP^{C} into PrP^{SC}, thereby providing a mechanism of transmission of the disease. [26]

Transthyretin

In certain hereditary systemic amyloidoses (previously termed *familial amyloid polyneuropathy* [FAP]) and senile systemic amyloidosis, the amyloid deposits contain transthyretin (TTR). [27] TTR is a plasma protein that carries thyroxine (T_4) directly and retinol indirectly by binding to the retinol-binding protein. The normal wild type forms fibrils in senile systemic amyloidosis, but most of the variants are associated with an earlier onset and aggressive form of the disease. TTR forms amyloid fibrils in vitro on partial acid denaturation and during pH-mediated reconstitution from a partially unfolded state. [28] Extensive biophysical studies on both the wild type and a few FAP variants delineate a fibrillogenic pathway characterized by a rearrangement of the tetrameric structure and dissociation into a monomeric amyloidogenic intermediate with a native secondary but an altered tertiary structure. [29] A model of the TTR fibril structure has been proposed by Blakes group in Oxford on the basis of x-ray diffraction of the natural homozygous Met30 TTR fibrils. [30] This study defined a novel structure for the amyloid fibril composed of helical sheets that can be continuously hydrogen bonded over long distances along the fibril axis. When the functional activity of amyloidogenic TTR variants was investigated, it was demonstrated that some of them show reduced T_4 affinity, [31] and one TTR variant was not able to bind the retinol-binding protein. [32] Recent data seem to demonstrate that the binding of TTR to T_4 can inhibit in vitro fibrillogenesis of both wild-type and amyloidogenic variants through stabilization of the quaternary structure. [33]

Amyloid A Protein

Amyloid fibrils in secondary amyloidosis and familial Mediterranean fever consist of a protein known as amyloid A (AA) protein. AA protein is a single polypeptide chain of approximately 8 kd that contains 76 residues corresponding to the N-terminal portion of serum AA protein (SAA). SAA in plasma is produced by hepatocytes under the transcriptional regulation of interleukin (IL)-1, IL-6, tumor necrosis factor, and other signal transducers. Serum concentrations can rise from a normal level of 1 gml up to 1,000 times higher within 2448 hours after an inflammatory stimulus. Circulating SAA is the precursor of amyloid fibril AA protein, from which it is derived through proteolytic digestion. It is not known whether the process of fibrillogenesis necessarily requires protein cleavage or if this proteolytic rearrangement occurs after fibrillar aggregation. A persistently high level of circulating SAA is a necessary condition for the deposition of AA amyloid, but it is not known why at similar levels of SAA amyloidosis develops in some people and not in others. It is possible to induce an experimental form of amyloidosis in mice by inflammatory stimulation with silver nitrate associated with a complex of molecules called amyloid enhancing factors, whose composition is not completely clarified, but which certainly contain ex vivo AA amyloid fibrils. This has been the most extensively used in vivo amyloid model for testing drugs and verifying various pathogenic hypotheses. [34]

Lysozyme

Lysozyme is a bacteriolytic glycosidase discovered by Fleming in 1922. In 1993, the Pepys group described in two English families a form of hereditary, systemic, non-neuropathic amyloidosis in which the fibrillar protein was constituted by lysozyme variants presenting the Asp67-His mutation in one family and Ile56-Thr in the second. [35] The structure, function, and folding properties of the two amyloidogenic lysozyme variants have been described. Both have a less stable native fold than the wild type. They aggregate to form amyloid fibrils with transformation of the mainly helical native fold, observed in the crystalline structure, to the amyloid fibril cross- fold. Biophysical studies suggest that a partly folded intermediate is involved in fibrillogenesis; this form presents a different structure from the native and unfolded states and has the characteristics of the molten globule state. [36]

Cystatin C

In patients with Icelandic-type hereditary cerebral amyloid angiopathy, the fibrillar protein is constituted by a variant of cystatin C with Leu68-Gln mutation. This protein, known as trace, is an inhibitor of the cysteine proteinases and consists of a single nonglycosylated polypeptide chain of 120 residues. Dimerization of the variant is temperature dependent, and increasing the incubation temperature from 37°C to 40°C results in a 150% increase in the dimerization rate. These biochemical data demonstrate reduced folding stability in this amyloidogenic protein as well, and have direct clinical relevance because therapy to abort febrile periods in carriers of the disease trait may reduce the in vivo formation of cystatin C aggregates. [37]

Gelsolin

Gelsolin is an ubiquitous cytoplasmic protein that binds actin monomers, nucleates actin filament growth, and severs actin filaments. The variants of gelsolin carrying the Asp187-Asn or the Asp187-Tyr mutation are responsible for hereditary systemic amyloidosis, in which the amyloid deposits are mainly located in blood vessels and basement membranes. The major protein component of the fibrils is a 71-amino-acid fragment containing the actin-binding domain (173243) of secreted plasma gelsolin.

$_2$ -Microglobulin

$_2$ -Microglobulin ($_2$ -m) is a nonpolymorphic, single-chain protein of 99 residues with a single intrachain disulfide bridge. Its level increases dramatically in hemodialyzed patients, and after a few years at a persistent serum level of 4070 mg/l, it precipitates as a fibrillar aggregate. Self-aggregation of unmodified $_2$ -m into a fibrillar structure can occur at physiologic pH and low ionic strength, but the fibril yield is scanty in the method of Connors et al, [38] and most of the protein precipitates in an unstructured aggregate. Other, as yet undetermined factors are involved in making the in vivo transition from the native protein to amyloid fibrils more productive and more efficient. A contributing effect of peripheral blood mononuclear cells has been suggested in experiments on $_2$ -m fibrillogenesis in cell culture. [39] Structural modifications like limited proteolysis [40] and glycation [41] are associated with the pathologic turnover of $_2$ -m in hemodialyzed patients, [42] but their relevance to an increased propensity of this protein to make fibrils is uncertain.

Apolipoprotein AI

Apolipoprotein AI (ApoAI) is the most abundant of the high-density lipoprotein particles. Variants of ApoAI are extremely rare, and some of them have been associated

with amyloidosis.

Interestingly, all mutations introduce an extra positive charge in the amino acid sequence. [43] Recently, two separate families affected with ApoAI amyloidosis have been described in which a deletion mutation of the ApoAI gene was responsible for the expression of amyloidogenic ApoAI. [43] The main protein component in the fibrils is constituted by a (182/92) N-terminal fragment associated with a minor component of the complete molecule that is made up of 243 residues. It is unknown whether the mutations principally cause a perturbation of folding stability or an increased susceptibility to proteolytic cleavage.

Fibrinogen

Non-neuropathic renal amyloidosis can be caused by variants of the fibrinogen chain. The mutations reported thus far affect residue 526, where Glu is replaced by Val, and residue 534, where Arg is replaced by Leu, whereas the deletion of a single residue at the third base of codon 524 results in a frame shift and premature termination of the protein at codon 548. [44] Three families have been described with A chain mutations (Val 526 and Leu 554), without any evidence of a clotting disorder, whereas in a subject with a frame-shift mutation, the level of fibrinogen was lower than in noncarrier mutations, and thrombin time and reptilase clotting time were also prolonged.

Endocrine Amyloid

Polypeptide hormones such as atrial natriuretic factor, insulin, and amylin have fibril-permissive sequences and can easily assume the -pleated sheet conformation. [34] Polypeptide hormones are highly concentrated in secretory granules at the site of their release, and high concentrations may favor protein fibrillogenesis.

Common Constituents

Human Serum Amyloid P Component

Human serum amyloid P component (SAP) binds to all forms of amyloid fibrils and constitutes the most common nonfibrillar protein of amyloid deposits. SAP is a member of the pentraxin family, which includes C-reactive protein, and belongs more generally to the category of animal lectins. [45] The quaternary structure of SAP is formed by 10 identical, noncovalently associated subunits of æ25 kd each, arranged in two pentameric, disklike rings interacting face to face. SAP is a calcium-dependent, ligand-binding protein that binds specific carbohydrates like the 4,6-cyclic pyruvate acetal of -galactose as well as DNA, glycosaminoglycans, and all known types of amyloid fibrils. The physiologic function of SAP is not completely known; however, no deficiency has been described, and it is stably preserved in evolution. SAP is synthesized by hepatocytes and its plasma concentration varies in normal subjects between 8 and 55 mg/l. SAP level remains unchanged in patients affected with amyloidosis of any type. The protein is extremely resistant to proteolytic attack, and even though it probably is not a proteinase inhibitor, it can protect amyloid fibrils from degradation. A functional role in amyloidogenesis has been reported by the Pepys group in experimental murine amyloidosis. [46]

Glycosaminoglycans

That carbohydrates are a part of amyloid deposits has been known for more than a century, and this characteristic is still responsible for the term *amyloid*, which means starchlike. Fibrils isolated by the water extraction procedure and separated from other unrelated tissue components contain 12% by weight glycosaminoglycans. Immunohistochemical studies demonstrate the presence of proteoglycans in the core of amyloid deposits, but in isolated ex vivo fibrils, the glycosaminoglycans are constituted by free polysaccharide chains only. The role played by proteoglycans or glycosaminoglycans in amyloidogenesis is uncertain, but levels of perlecan (a heparan sulfate proteoglycan) increase in the spleen during the induction of AA amyloid in mice, [47] and studies with gold-labeled antibodies to protein core have shown that intact proteoglycan is part of the amyloid fibril itself and that glycosaminoglycans are deposited in a periodic fashion along the fibril. [48] The composition of glycosaminoglycans in amyloid deposits is restricted to heparan sulfate and dermatan sulfate, and their tissue content is strictly correlated with the amount of the amyloid deposits. A direct effect of glycosaminoglycans in the conversion of proteins with different structures to a common anti-parallel -sheet secondary superstructure has been hypothesized and demonstrated, at least in in vitro experiments. [49]

Other Common Constituents

Apolipoprotein E4, $_2$ -macroglobulin, $_1$ -antichymotrypsin, extracellular matrix proteins, and protease inhibitors like inter--trypsin inhibitor have been found to be associated with amyloid deposits. Their role in amyloidogenesis is under investigation. Particular interest has been raised by ApoE. In fact, it has been established that subjects carrying the allele E4 have an increased risk for development of Alzheimer disease in an allele dose-dependent manner. The ApoE4 genotype is correlated with younger age at onset of the disease, and there is a correlation between the ApoE4 genotype and increased deposition of A in blood vessels and plaques. The biochemical mechanisms by which ApoE modulates the onset and progression of the disease are unknown. [50]

CLINICAL CHARACTERISTICS

The clinical manifestations in this group of diseases are extremely polymorphic, and depend on the specific organ involved and the extent of resultant organ dysfunction. Amyloidosis (both AL and AA) and L/HCDD should be suspected in patients with unexplained renal disease, especially those with nephrotic syndrome and hepatosplenomegaly, in the setting of underlying plasma cell dyscrasia or chronic inflammatory disease, including rheumatic diseases. L/HCDD and AL amyloidosis should also be considered in patients with known monoclonal protein in the serum or urine, and congestive heart failure, unexplained peripheral neuropathy, weight loss, orthostatic hypotension or malabsorption. Other useful clinical clues in patients with AL amyloid are the presence of macroglossia (Fig. 771), cutaneous purpura (particularly periorbital; Fig. 772), and a history of carpal tunnel syndrome. AA amyloidosis

Figure 77-1 Macroglossia. Note the indentations on the margins of the tongue and dental erosions.

Figure 77-2 Characteristic facial appearance showing periorbital and facial purpura in a patient with AL amyloidosis.

is associated with chronic inflammatory or infectious diseases. Candidates for hereditary or familial amyloidosis are those with a family history of neuropathy with early sensorimotor dissociative neuropathy, carpal tunnel syndrome, vitreous opacities, and unexplained renal or cardiac disease. Finally, patients on chronic hemodialysis for over 5 years in whom carpal tunnel syndrome and bone lesions develop are suspect for $_2$ -m amyloidosis (A_2 m).

Primary Amyloidosis

Epidemiology

Primary (AL) amyloidosis represents the most common form of systemic amyloid deposition in the Western world, accounting for up to two thirds of cases in large series, depending on the referral pattern. [51] In Olmsted County, Minnesota, the overall age- and sex-matched annual rate of AL per million person-years was 8.9. [52] The median age at diagnosis in AL amyloidosis is about 60 years, with a 2:1 male predominance. The incidence of AL amyloid in the setting of myeloma is also variable, and at our institution, 38% of patients with myeloma entered on a prospective clinical trial had a positive screening fat aspirate for amyloid. [53]

Presenting Manifestations

The most common presenting features are weakness or fatigue and often marked weight loss in over half the cases. [51] Peripheral edema may be due to congestive heart failure or hypoalbuminemia as a result of nephrotic syndrome or protein-losing enteropathy. Paresthesias, orthostatic dizziness, and syncope are often noted in patients with peripheral or autonomic neuropathy. In some instances, hoarseness or a change in voice (frequently becoming weaker later in the day) may suggest amyloidosis. Purpura or other skin manifestations may be observed in 510 % of cases. In a recent series of 474 patients with AL amyloidosis, the clinical presentation could be classified as one of the following: nephrotic/renal failure (28%), congestive heart failure (17%), carpal tunnel syndrome (21%), peripheral neuropathy (17%), orthostatic hypotension (11%), macroglossia (9%), and hepatomegaly (24%). [51]

Organ Involvement

Cardiac

Symptomatic cardiac involvement occurs in 2550% of patients with AL amyloidosis. [51] Intractable congestive heart failure may be an initial presentation and is a major cause of disease-related mortality. Cardiac manifestations reflect predominantly myocardial amyloid deposition, and patients usually present as restrictive cardiomyopathy with diastolic dysfunction, or, less commonly, as dilated cardiomyopathy with systolic dysfunction. Rarely, endocardium, pericardium, or valves may be involved, leading in some cases to cardiac tamponade, valvular dysfunction, or rupture of myocardium. Patients may also present with ischemic heart disease due to amyloid deposition in intramyocardial arteries. [54] Electrocardiographic abnormalities include low-voltage QRS complexes in the limb leads or a pseudoinfarction pattern. Both conduction defects and atrial or ventricular tachyarrhythmias are common and may contribute to the increased incidence of sudden cardiac death in these patients. Echocardiography is the most valuable diagnostic tool in the evaluation of cardiac amyloid. [55] [56] Increased myocardial echogenicity with a granular sparkling appearance is almost pathognomonic, but is rarely seen. The major echocardiographic features are increased ventricular wall thickness, left atrial enlargement, and diastolic dysfunction. Early cardiac amyloidosis is characterized by abnormal relaxation, whereas in more advanced cases, restrictive hemodynamics with a shortened deceleration time (<150 msec) is noted. [56] In patients with cardiac amyloid and no serum or urine M component, it is critical to distinguish between AL and ATTR because the latter is associated with a much better prognosis. [57] Vascular involvement in AL may be manifest as arm, calf, or in some instances as jaw claudication due to involvement of the temporal artery.

Renal

Renal involvement with consequent nephrosis or renal failure is a major clinical problem in systemic AL. More than half the patients with AL amyloidosis have significant proteinuria exceeding 1 g/day. [58] Nephrotic range proteinuria (>3 g/day) with consequent hypoalbuminemia and dyslipidemia is present in approximately one third of patients at diagnosis. [51] Frank renal insufficiency (serum creatinine >2 mg/dl) was present in 16% of patients at onset in our series. Hypertension is rare, as is gross hematuria. Renal vein thrombosis, nephrogenic diabetes insipidus, renal tubular acidosis, abnormalities in renal vessels, and priapism have been described. The kidneys are usually enlarged, but a great variation in size has been reported. Bence Jones protein of the type are associated with greater renal impairment and degrees of proteinuria than light chains. [59] Most renal amyloid affects glomeruli and vascular structures, although blood vessels or the interstitial area are involved in a small number. Prognosis correlates more with serum creatinine than the level of proteinuria. [59] Adrenal insufficiency due to amyloid deposition may coexist in a significant proportion of patients with renal failure requiring dialysis.

Neurologic

Sensorimotor peripheral neuropathy may be a presenting manifestation in approximately 15% of patients with AL amyloidosis

and may eventually be manifest in up to a third. It is usually a distal, symmetric, progressive, predominantly sensory neuropathy that generally involves the lower extremities.[51] [60] Autonomic dysfunction is often associated with peripheral neuropathy and may present as gastrointestinal motility disturbances, orthostatic hypotension, bladder dysfunction, impotence, abnormalities of sweating, or a chronic Guillain-Barré-type syndrome. [61] Cranial neuropathy is rare, but may be the presenting manifestation.[62] Axonal degeneration with predominant involvement of small myelinated and unmyelinated fibers is seen histologically. Carpal tunnel syndrome may be the presenting feature in 20% of cases with AL, and the possibility of AL must be considered in any patient with M protein and carpal tunnel syndrome.

Gastrointestinal and Hepatosplenic

Liver involvement, clinically manifest as hepatomegaly, is a common occurrence in AL amyloidosis, present in up to two thirds of patients in autopsy studies. Hepatomegaly may be striking and is often disproportionate to the extent of liver enzyme abnormalities. Serum alkaline phosphatase and transaminases are elevated in a third of patients; however, hyperbilirubinemia is infrequent and, when present, represents an ominous prognosis. [51] [63] Portal hypertension may develop because of sinusoidal involvement. Most patients also have extrahepatic involvement. Splenic involvement may lead to functional hyposplenism and spontaneous splenic rupture.[64] Histologic involvement of the gastrointestinal tract is common, but is usually asymptomatic. Symptoms are present in a third of patients and may result from direct amyloid infiltration or autonomic neuropathy. Clinical manifestations of gut involvement include obstruction, ulceration, hemorrhage, malabsorption, protein loss, and diarrhea.[61] Malabsorption, mostly caused by autonomic neuropathy, is responsible for a reduction of the serum carotene level (<48 g/dl) in 6% of patients and, less frequently, a decrease in the vitamin B_{12} level and steatorrhea. Infiltration of the tongue may lead to macroglossia, which may be striking (Fig. 771) and cause dysphagia, dysarthria, or obstructive sleep apnea.

Pulmonary

Although involvement of the respiratory tract is common, pulmonary dysfunction is usually not a dominant clinical problem. Amyloidosis of the respiratory tract usually occurs in one of three forms: tracheobronchial, nodular parenchymal, or alveolar septal. [65] Tracheobronchial, either nodular (pseudotumoral) or diffuse (multifocal submucosal plaques), and nodular parenchymal types are usually localized forms that rarely become systemic. Alveolar septal amyloid is clinically the most significant and is commonly associated with cardiac involvement.[66] Other pulmonary manifestations include pleural effusion, diaphragmatic weakness due to myopathy, and pulmonary hypertension due to vascular involvement.

Hematologic

The serum M protein concentration is small (median concentration 0.8 g/dl in our series). Using high-resolution serum and urine electrophoresis and immunofixation, it is possible to detect a monoclonal protein in 9095% of patients with AL. [51] [67] Immunofluorescence study of bone marrow using anti- and anti- antisera reveals a monoclonal plasma cell population, even in those rare patients with AL or L/HCDD in whom a monoclonal component is not detectable. [21] [67] [68] However, the plasma cell bone marrow infiltration is usually modest, with a median of 7% in our series, and only 4% of patients had >20% plasma cells. Anemia requiring transfusion is infrequent and, when present, is usually due to renal failure. Functional hyposplenism may lead to thrombocytosis and the appearance of Howell-Jolly bodies in the blood smear.[64] Coagulation abnormalities include prolonged thrombin time in 4050%, [69] factor X deficiency (10%), abnormalities in fibrin formation, and increased fibrinolysis due to defects in antiproteases. Most cases of acquired factor X deficiency have occurred in patients with AL amyloidosis. The deficiency is associated with binding of factor X to amyloid.[70] Splenectomy in such patients can cause a dramatic improvement in the factor X level, presumably by removal of the amyloid-laden tissue that binds factor X.[71]

Miscellaneous

Extensive deposition of amyloid in skeletal muscles may lead to pseudohypertrophy or a frank myopathy. [72] AL amyloidosis can also involve the periarticular structures. The most striking appearance is the well known shoulder pad sign from symmetric swelling of the shoulder joints. [73] Large amyloid deposits in the bone may produce osteolytic lesions and cause pathologic fractures. Amyloid is identifiable in the skin in over half of patients with AL or AA amyloidosis, regardless of whether clinically apparent lesions are present. [74] The lesions vary widely from waxy papules to nodules, tumors, and scleroderma-type changes and may be associated with purpura. Hemorrhagic bullous lesions, ear lesions, lichenoid lesions, dystrophic nail changes, alopecia, and breast lesions have also been reported.

Secondary Amyloidosis

Secondary (AA) amyloidosis (secondary systemic amyloidosis, reactive amyloidosis) is associated mainly with long-standing infectious or noninfectious inflammation and less frequently with cancer, mainly renal cell carcinoma and Hodgkin disease. [75] In many countries, where the incidence of chronic infections such as tuberculosis and leprosy has declined, AA amyloidosis is mostly caused by chronic rheumatic diseases. AA amyloidosis occurs in 410% of patients with rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and occasionally Reiter disease and psoriatic arthropathy, but is rare in diseases such as lupus erythematosus and systemic sclerosis, which are associated with a much lower serum concentration of SAA. [76] Other conditions associated with the development of AA amyloidosis include chronic infections such as tuberculosis, leprosy, osteomyelitis, and bronchiectasis; cystic fibrosis, heroin abuse, and Castleman disease. Amyloidosis usually develops as a late complication in long-standing, often poorly controlled rheumatoid arthritis. The most common clinical manifestation is nephropathic, manifest as proteinuria or renal insufficiency. Indeed, the development of proteinuria in patients with rheumatoid arthritis should always raise the suspicion of AA amyloidosis. Involvement of the gastrointestinal system and liver or spleen is common, but clinically significant cardiac involvement is rare. AA amyloidosis may occur in familial Mediterranean fever, an autosomal recessive disease affecting people of Mediterranean extraction, characterized by painful febrile attacks of serositis and gradual development of amyloidosis.[77] [78] It has also been identified in Muckle-Wells syndrome, a familial amyloid nephropathy with urticaria and deafness. [79]

Treatment of AA amyloidosis depends on the underlying disease.[75] Immunosuppressive therapy with low doses of alkylating agents and prednisone may lead to improvement in nephrotic syndrome and prolong survival. Colchicine may also be useful, and is particularly effective in the treatment of acute attacks and prevention of amyloidosis in patients with familial Mediterranean fever. [77] The efficacy of colchicine in this setting appears to be limited to higher doses (>1.5 g/day) and the absence of renal insufficiency (serum creatinine <1.5 mg/dl). [80]

Hereditary Amyloidosis

Hereditary amyloidoses represent diseases in which a genetically inherited variant form of a normal protein constitutes the

amyloid fibril. Systemic forms of hereditary amyloidosis may be associated with variant forms of TTR (ATTR), apolipoprotein A-I (A ApoAI), gelsolin (A Gel), fibrinogen A 1 (A Fib), or lysozyme (A Lys). Hereditary amyloidosis is a late-onset disease with clinical symptoms beginning in most kindreds in the third to seventh decades of life. The clinical disease usually progresses over 515 years, leading to progressive neuropathy, renal failure, or cardiac disease.

Transthyretin Amyloidosis

Most of the autosomal amyloidoses characterized thus far are associated with (over 50) variants of plasma TTR. [27] Clinical presentations of these pathogenic variants can be classified as predominantly neuropathic, cardiopathic, mixed neuropathic and cardiopathic, and carpal tunnel syndrome. [81] However, ATTR may be associated with normal TTR (as in some cases of senile systemic amyloidosis), and not all TTR variants are associated with amyloidosis.

Neuropathic Syndromes

These disorders (previously termed FAP, type I) are characterized by a progressive sensory peripheral neuropathy, mostly involving the lower extremities, with loss of thermal and pain sensations. Autonomic and gastrointestinal disturbances are prominent, and varying degrees of cardiac and renal involvement are noted. Vitreous deposits of amyloid have been reported, as has been the scalloped pupil abnormality due to involvement of the ciliary nerves. [82] The prototype and most common TTR variant involved is methionine 30 (Met30), characterized by substitution of methionine for valine at position 30. [83] Although the largest numbers of kindreds have been described from Portugal and Japan, the Met30 gene has the highest frequency in northern Sweden, where as many as 3% of the population may be heterozygous for this variant.[84]

Mixed Neuropathic and Cardiopathic

In these variants, both neuropathy (predominantly autonomic) and cardiomyopathy are dominant features. Incapacitation is related to bowel disease, which is due to autonomic neuropathy, and death is due to cardiac involvement. The prototype variant, TTR-alanine, [60] was originally described in a large kindred of Irish descent from West Virginia,[85] and is quite common in Northern Ireland, affecting 1% of the population.

Carpal Tunnel Syndrome

In some variants (originally termed FAP type II), carpal tunnel syndrome is a prominent feature.[86] Vitreous opacities are common and cardiomyopathy is the usual cause of death. The variant seen in the original Indiana/Swiss kindred is isoleucine-to-serine mutation at position 84 (Ser84). [87] Since then, other mutations have been described, with some differences in clinical presentations (e.g., lack of vitreous opacities in the histidine 58 variant).

Cardiopathic

A particular group of TTR mutations is characterized by familial cardiomyopathies in which neuropathy is absent. One of these, the isoleucine 122 (Ile122) TTR mutation is present in nearly 4% of the black population in the United States, and may be a cause of increased prevalence of heart failure among older blacks. [88] Another notable variant is the methionine 111 variant described in a Danish kindred with familial amyloid cardiomyopathy. [89]

Senile Systemic Amyloidosis

Small deposits of amyloid in the brain, heart, aorta, and pancreas of elderly patients (>70 years of age) are common. [90] Amyloid deposition in the heart may occur as isolated atrial amyloid consisting of atrial natriuretic peptide, [91] or as senile systemic amyloid, involving normal or variant TTR (ATTR), of which the Ile122 variant is the most notable.[92] Senile cardiac amyloid has been noted in 25% of patients 80 years of age. Extracardiac involvement is seen, but is clinically insignificant. Antemortem recognition in the setting of congestive heart failure is important because the prognosis with ATTR (median survival, 5 years) is much superior to that in AL amyloid (median survival, 6 months).[57]

Miscellaneous Hereditary Forms

Apolipoprotein AI amyloidosis (A ApoAI) has been described in a kindred with lower extremity neuropathy, prominent renal disease, and striking incidence of peptic ulcer disease.[93] Gelsolin amyloidosis (A Gel) has been reported largely from Finland, and is characterized by progressive cranial neuropathy, lattice corneal dystrophy, and skin changes.[94] Mutations in the fibrinogen A and human lysozyme genes have been identified in people with familial autosomal dominant amyloidoses (A Fib A and A Lys, respectively) characterized by dominant renal involvement and absence of neuropathy. [35] [95]

2-Microglobulin Amyloidosis

In 1980 it was reported that carpal tunnel syndrome in patients on long-term hemodialysis was associated with amyloid deposition in the soft tissues of the wrist. [96] These patients experience diffuse arthralgias, and plain radiographs reveal areas of cystic radiolucency in the juxta-articular bones. Although initially described in patients on prolonged (>10 years) hemodialysis, the syndrome has also been noted in patients on peritoneal dialysis and undialyzed patients with chronic azotemia. The fibril subunit protein was characterized as $_2$ -m.[97] Clinical manifestations of $_2$ -m amyloidosis are mostly articular and skeletal, and although systemic deposition does occur, it is usually of little clinical consequence. In established forms, therapy is mostly supportive. Renal transplantation often leads to dramatic improvement in joint symptoms and, when performed early, represents the most effective preventive measure.[98]

Alzheimer Disease and Prion Disorders

Both of these neurodegenerative disorders are characterized by localized amyloid deposits in the brain leading to progressive dementia. Alzheimer disease, the most common form of senile dementia, is characterized by neurofibrillary tangles, senile plaques, and cerebral amyloid angiopathy consisting of amyloid protein (-A4). [99] Clinically, Alzheimer disease is manifest as gradual loss of memory, followed by progressive deterioration of higher cognitive functions and behavior. The major risk factors for Alzheimer disease are age and genetic loci on chromosome 21 and 14, linked to the presence of early-onset disease.

The human prion disorders/spongiform encephalopathies, including kuru, (occurring in Fore tribesmen of New Guinea), Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Scheinker syndrome, and familial fatal insomnia, can occur at any age and display a remarkable spectrum of clinical abnormalities that include cognitive impairments, myoclonus, motor dysfunction, and ataxia.[99] These symptoms reflect spongiform changes, neuronal loss, and gliosis, particularly in the hippocampus, neocortex, subcortical nuclei, cerebellum, and brain stem. A large body of work by Prusiner and others has shown that these illnesses are transmitted by an abnormal cellular protein, termed the scrapie prion protein (PrP^{SC}).[26]

Other Localized Forms

Type II diabetes is associated with amyloid deposition in the pancreatic islets consisting of islet amyloid polypeptide. [100] In Iceland, the amyloid associated with congophilic angiopathy leading to premature strokes and intracranial hemorrhage in the third or fourth decade has been shown to consist of variant cystatin C. [101] A similar disorder in Dutch cohorts is due to variant protein, analogous to the fibril subunit found in Alzheimer disease. [102] In medullary thyroid carcinoma, the amyloid (A Cal) is composed of peptides derived from precalcitonin, and is limited to the thyroid and tumor metastases. Nonfamilial forms of localized amyloidosis commonly involve the lungs, larynx, urinary tract, and skin. Although the amyloid fibrils consist of or light chains, no M protein is seen and the disease almost never becomes manifest systemically.[103] Therapy is thus directed at local symptoms.

DIAGNOSIS

Histologic

Diagnosis relies on tissue biopsy and microscopic demonstration of typical deposits. The most common diagnostic strategy is to take the biopsy from an easily available tissue known to contain amyloid deposits in most patients with systemic amyloidosis. Small amyloid deposits occur in subcutaneous tissue in most people with AA and AL amyloidosis,[104] and for this reason the preferred initial diagnostic procedure is to obtain an abdominal fine-needle fat aspirate, which was positive in 80% of patients with AL in the Mayo Clinic series [51] and in 93% of our series. This procedure is innocuous, fast, and inexpensive, but requires experience in the staining technique and interpretation before it can be used routinely. This simple procedure has proven useful in AA, AL, and familial ATTR, but not in $_2$-m amyloidosis. [105] Because bone marrow biopsy is usually performed to determine the number and clonality of plasma cells, it should be stained for amyloid because positive findings have been reported in 56% of patients. [51] If both abdominal fat and bone marrow biopsy results are negative, a rectal biopsy, including the submucosal vessels, should be done because the gastrointestinal tract is involved in most cases. This biopsy is positive in 75% of patients with AL. If these three sites are negative, tissue should be obtained from an organ suspected of being affected such as the kidney, liver, or heart, which give a positive result in 94%, 97%, and 100% of cases, respectively.[51] [106] Before doing so, it is advisable to undertake a coagulation screen to exclude an acquired deficiency of clotting factors or other coagulation abnormalities and to consider that patients with systemic amyloidosis are at increased risk of bleeding because of amyloid infiltration of small blood vessel walls. In patients with neuropathy, sural nerve biopsy should be performed only if other, less invasive approaches are negative and the neuropathy is severe, because this procedure results in permanent local sensory loss.

Amyloid is currently defined as fibrils that stain with Congo red and show apple-green birefringence in polarized light. The alkaline-alcoholic Congo red method [107] gives specific and consistent results and remains the reference histochemical test for amyloidosis. It is more reliable than metachromatic stains such as methyl violet and crystal violet, or fluorescent stains such as thioflavin T or S. Congo red staining can be affected by several variables: thickness of the section (optimal is 510 m), the fixative used (more intense in alcohol or Carnoy solution than in formalin), and the freshness of the Congo red solution (which should be prepared every 2 months),[108] and it is therefore recommended that positive and negative controls be included in every stain run. Characterization of the amyloid deposit is necessary for selecting the appropriate treatment and for assessing the prognosis. Chemical (potassium permanganate or alkaline guanidine) treatment of Congo red-stained sections was proposed to subclassify amyloidosis,[108] but these techniques were unreliable and have been replaced by immunochemical methods that use specific antisera against the known amyloidogenic proteins. Antisera to most fibrillar precursor proteins are commercially available and those against AA and $_2$-m give reliable positive results. Antibodies may fail to identify the amyloid protein because the antigenic determinants have been masked or altered during the process of fibril formation or during the tissue fixation and processing phases. Antigenicity is preserved much better in frozen sections than in formalin-fixed, paraffin-embedded tissues. However, structural details are better defined with the latter procedure. In our experience, optimal tissue immunostaining depends in part on the fixation and processing phases, for which short intervals are likely to provide better antigen preservation. [109] Even in optimally processed tissue samples, antigenic epitopes may still be masked, **and** in these cases microwave pretreatment may enhance immunostaining.[109] Immunohistochemical staining of TTR, -protein, and prion protein amyloids may require pretreatment of tissue sections with formic acid or alkaline guanidine or deglycosylation to enhance immunoreactivity. Antiserum to amyloid P component reacts with all amyloid types and may be used to exclude other immunoglobulin deposition diseases.

Electron microscopy allows detection of typical fibrils, which are rigid, nonbranching, and 7.510 nm wide; however, as stated previously, the final diagnosis requires Congo red staining with apple-green birefringence. Ultrastructural immunolabeling may provide definite and reliable results even in cases not otherwise characterized,[110] and it can also be successfully applied to abdominal fat aspirate. [109] In our experience, it has also proven useful in the rare instances of mixed deposits constituted by two amyloidogenic proteins (e.g., AA and light chains). Electron microscopy is useful in distinguishing typical amyloid fibrils from nonamyloid Congo red-negative fibrillar immunoglobulin deposits that occur mainly in the kidney, determining so-called immunotactoid glomerulopathy, [111] or, rarely, systemically. L/HCDD presents several clinical features common to amyloidosis and should be considered in the differential diagnosis. This condition is usually diagnosed on kidney biopsy because of its predominant renal involvement. Light microscopy frequently shows nodular glomerulosclerosis with thickening and wrinkling of the tubular basement membranes.[21] [112] [113] However, morphologic findings at light microscopy are often noncharacteristic, and the use of both electron microscopy and immunohistochemistry has been proposed for a reliable diagnosis of L/HCDD. [110] [113] Immunohistochemical studies using antisera to and light chains and immunoglobulin heavy chain reveal characteristic linear deposits along the tubular and glomerular basement membranes, in the mesangium, and along the basement membrane of Bowman capsule. Electron microscopy demonstrates finely or coarsely granular electron-dense deposits delineating the inner aspect of the glomerular and the outer aspect of the tubular basement membrane. Combinations of amyloid and L/HCDD have been reported. Amyloid typing can also be performed through extraction of fibrils from diagnostic biopsy tissues (even after formalin fixation) and subsequent chemical and immunologic characterization. Several methods suitable for the extraction and characterization of microgram amounts of amyloid deposits have been reported. [114] [115]

Nonhistologic

Radiolabeled human SAP component has been shown to localize rapidly and specifically in amyloid deposits, allowing their visualization and quantification by scintigraphic imaging and metabolic analyses. [116] Scans determine the organ distribution and quantity of amyloid, and turnover studies provide an estimate of the whole-body amyloid burden.[117] [118] However, major limitations are limited availability and poor sensitivity for detection

DIAGNOSTIC WORK-UP OF A PATIENT WITH SUSPECTED AMYLOIDOSIS

The presence or development of nephrotic syndrome, restrictive cardiomyopathy, peripheral and autonomic neuropathy, muscle weakness, carpal tunnel syndrome, giant hepatomegaly, malabsorption, rapid and important weight loss, cutaneous purpura, especially periorbital purpura, and macroglossia in a patient with serum or urinary M protein, should alert the clinician to the possibility of AL amyloidosis. Other forms of amyloidosis have slightly different clinical presentations. For example, in reactive AA amyloidosis, the finding of nephrotic syndrome, occasionally associated with hepatosplenomegaly in a patient with a chronic inflammatory disorder, is the most indicative clinical sign. Peripheral or autonomic neuropathy in combination with any of the following conditionsproteinuria, renal failure, restrictive cardiomyopathy, carpal tunnel syndrome, or vitreous opacitieswarrants consideration of hereditary amyloidosis. Taking an accurate family history is most important. However, a negative history should not rule out hereditary amyloidosis, given the incomplete penetrance of most transthyretin variants and the possible late onset of the disease.

Clinical suspicion must be confirmed by biopsy documentation of amyloid deposits. The site of biopsy should be chosen according to the accessibility and presence of amyloid deposits. For AL amyloidosis, the recommended strategy is as follows: abdominal fat and bone marrow should be sampled first. If the results are negative, a rectal biopsy, including the submucosa, should be performed; if this is negative, a biopsy of a suspected involved organ should be made after checking the coagulation screen. Congo red staining is the reference histochemical method for documenting amyloid.

Typing of amyloid deposits is of utmost importance for treatment and prognosis assessment. In AL, it is necessary to document the presence of an M protein in the serum or urine, or a monoclonal bone marrow plasma cell population, or the presence of light chains as the major constituents of amyloid deposits by immunohistochemical methods. Light and electron microscopic immunohistochemical studies allow amyloid protein characterization in most tissue samples. Micromethods for the extraction and characterization of amyloid protein from diagnostic biopsy specimens are also available. In patients with hereditary amyloidosis, the pathogenic mutation(s) should be identified through DNA testing to optimize treatment and allow genetic counseling.

Once the diagnosis and type of amyloid have been established, it is necessary to determine the extent of systemic damage caused by amyloid deposition. In AL amyloidosis, evaluation of renal function (serum creatinine, creatinine clearance, and 24-hour urinary protein) and cardiac involvement (echocardiogram, with measurement of interventricular septal thickness and ventricular deceleration time, and a baseline 24-hour Holter recording) should be undertaken even in absence of specific symptoms. In patients with peripheral neuropathy, an electromyogram is indicated. In patients with liver involvement, a computed tomography scan or ultrasound of the liver and spleen is obtained to quantitate hepatomegaly. Patients with diarrhea or malabsorption should have a determination of fecal fat and serum carotene. Patients with suspected autonomic neuropathy should be evaluated with orthostatic blood pressure, sudomotor axon reflex test, and gut motility studies, depending on symptoms. If available, radiolabeled SAP can be used for locating and monitoring the extent of systemic amyloidosis.

of cardiac involvement. More recently, it has been reported that radiolabeled aprotinin (an inhibitor of serine proteases) [119] specifically targets amyloid deposits in vivo and shows particular sensitivity for detecting heart involvement. Echocardiography is a valuable technique for the detection and monitoring of amyloid heart deposits.[55] [120] [121] If combined with electrocardiography, which shows low-voltage complexes, it can provide reliable diagnostic hints. [122] High-resolution echography and magnetic resonance imaging are useful in evaluating amyloid involvement in soft tissues, in organs (heart, gastrointestinal tract, liver, lung, thyroid), [123] and especially in bones (with magnetic resonance imaging). [124] In patients and families with hereditary amyloidosis, analysis of leukocyte DNA using restriction fragment length polymorphism analysis, polymerase chain reaction-based methodology, or direct sequencing is valuable for genetic counseling and identification of carriers. [27]

THERAPY

Principles

Recent advances in our understanding of the pathogenic mechanisms of amyloid formation have provided the basis for a more rational and, it is hoped, more effective treatment strategy for systemic amyloidoses. From the pathogenic cascade outlined in Table 772 , it is possible to identify several potential targets and possibilities for intervention. The obvious primary goal of therapy should be the inhibition or suppression of the synthesis of the amyloidogenic precursor protein or, if protein synthesis is constitutive, enhancement of its clearance. This approach has proven feasible and effective in several types of amyloidosis. In reactive AA amyloidosis, aggressive treatment of the underlying chronic inflammatory disorder can dramatically reduce the level of the SAA precursor and results in amyloid regression and restoration of damaged organ function.[125] Timely surgical excision of localized Castleman disease producing IL-6stimulated SAA synthesis results in complete recovery of severe nephrotic syndrome.[126] In hereditary TTR amyloidosis, liver transplantation, even partial liver transplantation from living donors, [127] eliminates the production of the variant pathogenic protein, improves the polyneuropathy, and offers the hope of arresting the progression of the disease. [128] [129] [130] In AL amyloidosis, more aggressive therapies against the amyloidogenic plasma cell clone with high-dose chemotherapy or dexamethasone have resulted in dramatic clinical improvement in a few patients (reviewed in Dhodapkar et al [131]). In constitutively synthesized protein such as $_2$ -m in chronic hemodialysis patients, the aim should be to reduce its plasma concentration by increasing its clearance. In fact, successful kidney transplantation lowers the plasma concentration of $_2$ -m to normal levels and is associated with rapid improvement of osteoarticular symptoms. [132]

In some types of amyloidosis, natural proteolytic modification of the precursor is required to render it amyloidogenic. This process appears particularly relevant in Alzheimer disease because of the putative activity of - and -secretases. Inhibitors of the activity of these proteases are being intensively pursued. [133] Another potential target is represented by structural modifications of the amyloidogenic precursor and its interactions with tissue components during the process of amyloid fibril formation and tissue deposition. Drugs that can stabilize the structure of the precursor, thereby reducing its tendency to abnormal aggregation, and ones that interfere with fibril growth are being

TABLE 77-2 -- Therapeutic Strategies for Amyloidosis: The Potential Targets and Possibilities for Intervention Are Derived from the Pathogenic Cascade

Pathogenic Event	Possible Target (Compounds Tested)	Available Intervention
Synthesis of precursor	Inhibit or suppress synthesis	In AL: chemotherapy (including high-dose therapy) dexamethasone
		In ATTR: liver transplantation
		In AA: suppress the chronic inflammation
Clearance of precursor	Promote the clearance of the precursor	In A_2 -m: kidney transplant
Processing of amyloid precursor	Inhibit the enzymes involved (putative inhibitors of - and -secretases in A)	
Abnormal self-aggregation	Interfere with self-aggregation (cyclodextrin, rifampicin, specific peptides, and other compounds in A)	
Interaction with common components and other enhancers of amyloid formation and deposition (AEF)	Inhibit amyloid precursor/common component interactions	
	(Congo red in prion diseases, IAPP, and A)	
	(Aliphatic sulphonates and sulphates in A and AA)	
	(I-DOX in AL and prion diseases)	
	Inhibit generation of AEF	Colchicine in AA caused by familial Mediterranean fever
Persistence of amyloid deposits	Promote mobilization of amyloid deposits (I-DOX in AL and prion diseases?) (Putative compounds displacing serum amyloid P component or proteoglycans from amyloid fibrils)	Dimethylsulfoxide (topical application)
Organ structural and functional damage	Preserve organ function	Supportive therapy
	Replace organ function	Dialysis
		Kidney and heart transplantation

AA, amyloid A protein; A, amyloid A4 protein; A_2 -m, amyloid $_2$ -microglobulin; AEF, amyloid-enhancing factors; AL, primary (immunoglobulin light chain) amyloidosis; IAPP, islet amyloid polypeptide; I-DOX, 4-iodo-4-deoxydoxorubicin; TTR, transthyretin.

actively sought (reviewed in Kisilevsky [133]). Studies on putative inhibitors of amyloid fibril formation have shown that different compounds (e.g., cyclodextrins, [134] Congo red,[135] and rifampicin[136]) may have these properties. It has also been reported that a peptide that binds specifically to amyloid protein precursors (amyloid -peptides) inhibits their polymerization into amyloid fibrils. [137] Drugs that can inhibit the interaction of amyloid precursor with basement membrane components and with other common components, and thus inhibit the process of amyloid formation and deposition, have been designed and tested successfully in vitro and in animal models.[133] [138]

Contrary to commonly held belief, amyloid is not an inert deposit. Both experimental and clinical data have shown that deposits can be reabsorbed once the supply of precursor is stopped.[117] [126] [139] [140] Thus, agents capable of promoting amyloid resorption may have an important role in the combined treatment of amyloidosis. Displacement of some protective components, such as SAP or proteoglycans, from amyloid fibrils may render them more susceptible to proteolytic degradation. [43] [141] Amyloid deposition causes severe organ damage and dysfunction, ultimately leading to death; for this reason, supportive and replacement therapy for damaged organs represents the mainstay of management of amyloidosis because it has an important impact on quality of life and survival.

Supportive Therapy

Supportive therapy is of crucial importance in the management of patients with amyloidosis because it preserves or palliates vital organ function, improves the quality and duration of life, and buys time while specific therapy is acting. Nephrotic syndrome should be managed with salt restriction and careful administration of diuretic agents. Furosemide is the first-choice diuretic; and may need to be combined with spironolactone or metolazone. [142] Albumin can be combined with diuretics to improve diuresis in patients with pleural and pericardial effusions. Great care should be taken to avoid too rapid or excessive volume depletion, which can aggravate postural hypotension and renal function. Symptomatic azotemia requires dialysis. Hemodialysis and peritoneal dialysis are equally effective and can be interchanged if needed.[143] [144] Patients with slow disease progression and those without multisystem involvementof the heart in particularobtain long-term benefit from dialytic treatment.[58] [143] Patients with these characteristics also represent the best candidates for kidney transplantation. [142] This procedure has been performed mostly in patients with AA type (familial Mediterranean fever or reactive), whereas a limited number of patients with AL have received transplants. Although amyloid recurrence in the grafted organ is well documented, in general it has modest clinical impact, [145] making renal transplantation a viable option in the treatment of young patients with amyloid end-stage renal disease without cardiac and gastrointestinal involvement.

Amyloid congestive heart failure should be managed with salt restriction and very careful administration of diuretics, such as furosemide, to avoid excessive volume contraction, which results in syncope and worsening of renal function. Afterload reduction with low-dose angiotensin-converting enzyme inhibitors is useful, if orthostatic hypotension is not present. Digitalis should be used with caution only in the rare patients with atrial fibrillation and rapid ventricular response, because patients with amyloidosis are unusually sensitive to the drug, which may cause arrhythmias or heart block. Calcium channel blockers may worsen congestive heart failure. In patients with atrial systolic failure due to amyloid infiltration, atrial standstill may predispose to systemic arterial embolization, and prophylactic anticoagulation should be carefully considered. [146] Ambulatory electrocardiographic monitoring is useful because pacemaker installation for severe conduction abnormalities and antiarrhythmic agents for ventricular arrhythmias may be life-saving

PREFERRED APPROACH TO THERAPY IN AL AMYLOIDOSIS

The aim of treatment is the elimination of the cause of the disease, the amyloidogenic bone marrow plasma cell population, and all efforts should be made to reach this goal. However, any reduction in the concentration of the amyloid precursor can be beneficial because this leads to less amyloid deposition and may shift the balance between amyloid deposition and resorption in favor of the latter. Early diagnosis and rapidly effective therapy are the two most important factors. These patients have a narrow window of therapeutic opportunity in view of limited survival, and all efforts must be made to extend this window through supportive therapy and to exploit fully the limited time through rapidly effective therapies.

We treat patients in acceptable general medical condition initially with pulsed high-dose dexamethasone or dexamethasone-based combination therapy for three cycles, with salt restriction, H_2 blocker, and antibiotic prophylaxis. Subsequently, patients (usually <65 years of age) with acceptable performance status (02) undergo stem cell collection for possible high-dose chemotherapy and autologous stem cell transplantation. Patients responding to the dexamethasone induction (particularly those with hepatomegaly and nephrotic syndrome) are switched to maintenance interferon- and dexamethasone. Patients who fail to respond to this regimen and who are candidates for high-dose therapy receive high-dose melphalan with autologous peripheral blood stem cell support. Selected patients without severe multiorgan involvement may be considered for allogeneic bone marrow transplantation. All other patients should be treated with melphalan and prednisone. Patients who fail initial anti-plasma cell approaches are considered for other experimental therapy, such as I-DOX. Supportive therapy is of crucial importance in the comprehensive treatment of patients with AL amyloidosis. Dialysis support is necessary in patients with end-stage renal failure. Kidney and heart transplantation should be offered to eligible patients (see the Supportive Therapy section). All other available means, from pacemakers to total parenteral nutrition, should be used as indicated.

(reviewed by Merlini [142]). Cardiac transplantation should be considered in patients younger than 60 years of age with severe heart involvement, preserved renal function, and no evidence of other symptomatic organ involvement or multiple myeloma.[147] [148] Although survival after heart transplantation in amyloidosis in one report was inferior to that in patients transplanted for other indications, [149] transplantation may significantly prolong life in properly selected patients and allow initiation of specific therapy.

Orthostatic hypotension may be helped by simple measures such as rising slowly and sitting for a few minutes before standing up, and wearing elastic stockings. Orthostatic hypotension in FAP benefits from a norepinephrine precursor (e.g., L-threo-DOPS). [150] [151] No trial results have been reported in patients with AL. Fludrocortisone may improve hypotension but often induces fluid retention.

Peripheral neuropathy may be relieved somewhat by amitriptyline and codeine. [142] Median nerve entrapment at the carpal tunnel may be relieved by surgery. Pain from periarticular deposition of amyloid in the shoulders and knees is usually refractory to local steroid injections, but dramatic improvement has been reported after radiosynovectomy.[152] Nodular cutaneous amyloidosis can be treated with satisfactory cosmetic results by dermabrasion. [153] Macroglossia may produce airway obstruction requiring tracheostomy. Obstructive sleep apnea may be improved by applying nasal continuous positive airway pressure. [154] Macroglossia can hamper chewing and swallowing, and necessitate a liquid diet. Gastroparesis can be effectively treated with metoclopramide or domperidone. Diarrhea may be controlled with a long-acting somatostatin analog, octreotide. [142] Severe pseudo-obstruction caused by amyloid autonomic neuropathy may require total parenteral nutrition support. In general, surgery should be avoided in patients with amyloidosis because it may have catastrophic effects by exacerbating organ failure and bleeding. Bleeding in amyloidosis is multifactorial, and its treatment should be individualized. Parenteral administration of vitamin K may be beneficial in patients with malabsorption. Splenectomy may resolve bleeding due to factor X deficiency and multiple hemostatic defects. [71] Patients with bleeding due to increased fibrinolysis can be treated with epsilon-aminocaproic acid or tranexamic acid. [142]

Specific Therapy for AL Amyloidosis and L/HCDD

Current therapeutic approaches for AL amyloid and L/HCDD are largely targeted to the underlying plasma cell clone. Conventional alkylating agent-based chemotherapy has been shown to effect a response, although the proportion of patients who benefit is still unsatisfactory. Results of the first randomized, double-blinded trial of melphalan and prednisone (MP) versus placebo involving 55 patients suggested that chemotherapy was of some clinical benefit, although survival rates did not differ significantly between the two groups. [155] A subsequent study performed by the same group on 153 patients with AL treated with MP reported a response rate (defined as evidence of regression of organ dysfunction caused by amyloidosis) of 18%. [156] Responses were attained in a median time of 1 year. Responders experienced a survival benefit, with a median survival of 89 months, versus 14 months in nonresponders. Patients with nephrotic syndrome benefited most (39%), and 15% of patients with amyloid cardiomyopathy, usually associated with a very poor prognosis, also responded. [156] Prolonged treatment with alkylating agents can induce cytogenetic abnormalities. In 10 of these 153 patients (6.5%), myelodysplastic syndrome or acute myeloid leukemia developed, and 8

died as a direct result of pancytopenia. The actuarial risk for development of myelodysplastic syndrome in patients surviving 3.5 years was estimated to be 21%. [157]

Small series of patients with L/HCDD treated with MP-based chemotherapy have indicated that this therapy is effective in a small proportion of cases. A retrospective study on 19 patients with L/HCDD showed stabilization or improvement of renal function after chemotherapy in 5 of 8 patients whose serum creatinine concentration was <4 mg/dl, whereas in patients with more advanced renal failure, treatment did not prevent the progression to end-stage renal disease. [158] In a subsequent retrospective study, only 5 of 18 patients treated (10 of whom had multiple myeloma) showed improvement in renal function. [159] The results of this latter study are worse than those reported in other small groups of patients, [112] [160] [161] [162] and may be due to patient selection. This indicates that MP may be most helpful early in the course of disease, when only moderate histologic damage is present. [162] Colchicine has been shown to prevent reactive AA in laboratory mice, to prevent or abort the painfully disabling febrile attacks, and to prevent secondary amyloidosis in patients with familial Mediterranean fever. [80] In view of these data, its use was advocated in patients with AL as well. However, the results of three large studies comparing the effectiveness of MP versus colchicine in patients with AL have consistently shown better outcomes in patients treated with MP. [163] [164] [165] In all three studies, the patients were stratified

according to their dominant clinical manifestation (i.e., renal disease, cardiac involvement, peripheral neuropathy, and other manifestations). In a prospective cross-over study involving 101 patients that compared MP with colchicine, there was no significant difference in median survival between the two groups (MP, 25 months; colchicine, 18 months). [165] However, significant differences in favor of MP were found when the survival of patients who received only one of the treatments was analyzed, or when survival was calculated from the time of entry into the study to the time either of death or disease progression. A subsequent report on a randomized trial involving 100 patients with primary amyloidosis that compared MP combined with colchicine versus colchicine alone indicated longer survival with the regimen containing melphalan (12 vs. 7 months). [164] In this study, better survival, regardless of treatment, was noted in patients receiving satisfactory supportive treatment such as transplantation or dialysis for their organ failure. A significant therapeutic advantage in terms of objective responses and prolonged survival for MP versus colchicine was also shown in a randomized trial comparing MP, MP plus colchicine, and colchicine alone in 220 patients with primary amyloidosis. [163] In this study, patients who showed serum or urinary M-protein responses (disappearance or a reduction >50%) by the end of 12 months of treatment survived significantly longer than the ones who did not respond (median 50 months vs. 36 months, $P = 0.03$). Overall, the results of these controlled trials indicate that colchicine provides no additional beneficial effect over MP.

Dimethylsulfoxide can be effective when used topically on primary cutaneous amyloidosis and when given by local instillation in urologic amyloid lesions (reviewed by Merlini [142]). The efficacy of vitamin C and E supplementation has not been proven in patients with AL amyloidosis.

Newer Approaches to AL Amyloidosis

Current treatment with traditional alkylating agent-based chemotherapy produces significant reductions of light chain amyloidogenic precursors and consequent clinical benefits in an unsatisfactory proportion of patients with AL. Furthermore, MP-based therapy requires a long time to achieve a response (median of approximately 1 year, with 21% of patients requiring an additional year of therapy to show a response), [156] and, unfortunately, the survival of many patients with amyloidosis is less than 1 year. In L/HCDD as well, alkylating agent-based chemotherapy benefits only a minority of patients. [158] [159] This stresses the importance of earlier diagnosis, and the development of more rapid and effective therapies. It appears rational to investigate all available therapeutic tools to maximize inhibition of the synthesis of the offending protein, with the aim of eradicating the amyloidogenic clone. Preliminary results with such approaches (e.g., with high-dose therapy) in AL amyloidosis and L/HCDD indicate that this is both feasible and effective.

High-Dose Dexamethasone and Combination Therapy

Taking the lead from myeloma therapy, we recently reported on nine patients with biopsy-proven AL amyloidosis treated with an induction regimen of pulsed high-dose dexamethasone followed by maintenance therapy with interferon-. [166] Improvement in organ function was noted in six of seven patients with nephrotic syndrome and two of two patients with hepatomegaly. The response to therapy was rapid, with a median time to response of 34 months in patients with nephrotic syndrome. Improvement in organ function following dexamethasone (DEX)-interferon or DEX-based combination therapies such as vincristine, Adriamycin, and DEX has been confirmed. [167] However, others have noted only modest benefit with DEX as single agent. [168] Results from a recent study also failed to demonstrate superiority of M_2 regimen over MP. [169]

Dose Intensive Therapy

High-dose therapy, particularly with high-dose melphalan, has been used in a number of patients with myeloma over the last decade and effected a high proportion of complete responses in this disease. However, until recently, this approach had not been attempted in patients with AL amyloidosis/L/HCDD, primarily because of the common occurrence of renal and cardiac dysfunction in these patients. With recent advances in supportive care and the availability of growth factors and mobilized stem cells, the morbidity and mortality rates with these treatments have been substantially diminished, and the feasibility and safety of high-dose melphalan in patients with renal dysfunction has been documented. This has prompted a number of investigators to attempt high-dose therapy in these patients. [170] [171] [172] [173] In two recent studies with >20 patients, clinical improvement in organ function was noted in up to two thirds of patients with <3 organs involved. [170] [171] In one study the 4 year estimated overall survival in patients with <3 clinical manifestations was 91%, as compared to 11% in those with 2 clinical manifestations. However, early mortality, even in these studies with highly selected patients, has been 1540%. The results in patients with limited organ involvement are quite promising and suggest that dose intensive therapy may be preferable, if these patients meet the functional criteria. Other approaches that hold promise include Total Therapy approach combining DEX and dose intensive therapy [173] and anti-angiogenesis agents.

Iododeoxydoxorubicin
