For long-term outpatient therapy (e.g., for solid tumor-associated chronic DIC), it is also possible to achieve therapeutic heparin levels through subcutaneous injection, with its associated anticoagulant effect occurring 1 hour later and peak levels after 3 hours. Typically, 35,000 U are given daily, divided into two doses 12 hours apart, with a PTT drawn 6 hours after a dose and subsequent dosage adjustments made based on the result. Serial heparin or anti-factor Xa levels may be preferable for monitoring if the baseline PTT is prolonged. If an initial rapid effect is desired, a 5,000-U IV heparin bolus can be given before the initial subcutaneous dose. Efficacy of heparin treatment can be monitored by changes in D-dimer, fibrinogen, and platelet levels.

Early evidence suggests a potential role for lowmolecular-weight heparin in the prevention and management of DIC in association with acute promyelocytic leukemia and Trousseau syndrome.[245] [246] In this case, enoxaparin may be administered subcutaneously prophylactically at 30 mg every 12 hours, or therapeutically at 1 mg/kg every 12 hours, whereas dalteparin doses are 2,500 U daily or 100 U/kg every 12 hours, respectively.

these are carried out, and controlled trials have not been done in acute DIC associated with septic abortion.

The role of heparin in management of aortic aneurysms depends on whether the patient is a surgical candidate. Thus, although a nonsurgical patient with only laboratory evidence of DIC does not need heparin, it is prudent to obtain a DIC screen on any patient with an aortic aneurysm in whom surgery is contemplated to avoid serious intraoperative and postoperative bleeding. Preoperative correction of any hemostatic defects with replacement therapy and continuous heparin infusion is in order.[243] These maneuvers should also be considered in patients with bleeding aortic aneurysms. Those with evidence of an aneurysmal leak associated with factor consumption require transfusion of platelets and cryoprecipitate and emergency surgery, however, and should not receive heparin.

The use of lowmolecular-weight heparins in prophylaxis and treatment of DIC has recently been described in several case reports. [244] [245] [246] Although no control trials have yet been reported, these early reports suggest that lowmolecular-weight heparins may be as efficacious as adjusted-dose heparin, providing reproducible anticoagulation with less frequent dosing. In one study, six patients with acute promyelocytic leukemia received enoxaparin from the day of admission until presenting skin and mucous membrane bleeding resolved and the coagulation values returned to normal (1123 days). Three had laboratory evidence of DIC on presentation, and

significant bleeding complications developed in two patients while on lowmolecular-weight heparin, and in a third 3 days after its discontinuation. [246]

Antithrombin-III and Protein C Concentrates

Antithrombin-III concentrate has been used in the management of subsets of patients with DIC on the premise that systemic consumptive coagulopathies often lead to a relative plasma deficiency of natural inhibitors like antithrombin-III that in turn contributes to a procoagulant state. Antithrombin-III deficiency would also be expected to decrease the effect of any therapeutic heparin used to treat DIC, and so antithrombin-III concentrates warrant consideration in any heparinized patient with DIC, particularly if heparin resistance is encountered.

Exogenous antithrombin-III neutralizes thrombin generated in DIC and potentially ameliorates thrombosis, particularly if the process is associated with hepatic insufficiency with its associated decrease in antithrombin-III synthesis. In this respect, antithrombin-III shortens the duration of DIC in some patients with fatty liver of pregnancy, and should be considered in this setting. [241] Except for hepatic insufficiency, other studies have shown improved hemostatic function in most patients with DIC given antithrombin-III, but no effect on mortality. [247] [248] [249] Thus, more experience is needed with this agent in these other settings.

Activated protein C has been given to animals in concert with infusion of *Escherichia coli* with the subsequent prevention of DIC and gram-negative septicemia. [250] Conversely, when these infusions were supplemented with anti-protein C antibody, inhibition of protein C led to enhanced *E. coli*-associated lethality. Additional studies suggest activated protein C concentrates ameliorate DIC in a rabbit model, with less bleeding than was associated with heparin. [251] [252] Human studies of protein C concentrate replacement in infants with purpura fulminans due to severe protein C deficiency and in infants, children, and adults with meningococcemia appear promising. [253] [254] [255] [256] Further studies are needed to determine if protein C and activated protein C concentrates have any role in treatment of human DIC. A case series of pediatric patients with meningococcemia and DIC managed with either plasma or whole-blood exchange led to survival of seven of eight patients, with no associated bleeding or cardiovascular complications during the procedure. [257]

Fibrinolysis Inhibitors

Under most circumstances, patients with DIC should not be treated with fibrinolytic inhibitors. These agents act by blocking the secondary fibrino(geno)lysis that accompanies DIC to varying extents, and may prevent tissue perfusion. [258] [259]

The DIC setting in which fibrinolytic inhibitors may warrant consideration includes (1) when intense primary fibrino(geno)lysis can be demonstrated in association with disease states, such as acute promyelocytic leukemia, [101] Kasabach-Merritt syndrome, [260] [261] and prostate cancer; and (2) when the patient is bleeding profusely and is not responding to replacement therapy. In the latter case, FDPs may be contributing to bleeding, and the use of fibrinolytic agents should be considered only after the continuously bleeding patient has received both replacement

---

therapy for depleted hemostatic factors and intravenous heparin infusions. [262] [263] epsilon-Aminocaproic acid or tranexamic acid may be useful in these cases in concert with heparin for the co-existing DIC. [264]

An approach to treatment of Kasabach-Merritt syndrome entails administering a fibrinolytic inhibitor either alone or in combination with cryoprecipitate. [101] [261] The result has been tumor shrinkage and correction of hemostatic defects through induction of thrombosis within the tumor.

Chapter 118 - Hemostatic Defects Associated with Dysproteinemias

Howard A. Liebman

INTRODUCTION

Acquired coagulation abnormalities are frequent manifestations of dysproteinemias. [1] [2] Most of these patients do not manifest bleeding, and the hemostatic abnormalities are usually detected only on laboratory evaluation. However, 10% of patients have clinical evidence of bleeding. [3] [4] In most cases bleeding is mild, consisting of purpura, epistaxis, or hematuria. However, occasionally severe bleeding and even fatal gastrointestinal hemorrhages have been observed. The reported hemostatic abnormalities are varied and involve both coagulation and platelet dysfunction.

The pathophysiologic mechanism responsible for these coagulation defects is an abnormal interaction between a hemostatic component and a plasma paraprotein (Fig. 118-1). Paraproteins are monoclonal immunoglobulins produced by plasma cell dyscrasias and lymphoid neoplasms, such as multiple myeloma, plasma cell leukemia, Waldenström's macroglobulinemia, lymphoma, and primary (AL) amyloidosis. The circulating paraprotein may consist of the complete immunoglobulin, the immunoglobulin light chain, or other immunoglobulin fragments. The abnormal immunoglobulin does not have to be present in high concentrations in the circulation but can be expressed on the surface of the malignant lymphocyte or be deposited in the extracellular matrix. The serendipitous synthesis of an immunoglobulin by a malignant lymphocyte that possesses a structure that binds with a component of the platelet surface or coagulation proteins can result in inhibition of function or accelerated clearance of the platelet or coagulation protein.

The hemostatic defects associated with dysproteinemias include (1) coagulation abnormalities that result from plasma paraproteins that bind hemostatic components and inhibit their function; (2) abnormalities secondary to the increased clearance of coagulation proteins by forming complexes with circulating paraproteins, binding to cell-surface immunoglobulins or binding to immunoglobulin fragments deposited in the extracellular matrix; and (3) hemostatic abnormalities observed in association with dysproteinemias for which no clear pathophysiologic mechanism linking the abnormal paraprotein and the hemostatic defect can be found.

INHIBITORS OF HEMOSTASIS

A prolonged bleeding time with a normal or a moderately decreased platelet count is a common hemostatic defect in dysproteinemias. [5] [6] [7] [8] [9] In a prospective study of coagulation abnormalities associated with dysproteinemias, 45% of patients had an abnormal bleeding time. [2] In patients who hemorrhaged, a prolonged bleeding time was observed in 67%. An abnormal bleeding time was also observed in one-third of patients who do not exhibit bleeding.

The prolonged bleeding time in these patients is associated with abnormalities of in vitro platelet function. Abnormalities include decreased platelet adhesiveness, [2] [10] [11] impaired platelet aggregation, [7] [9] [10] and reduced platelet factor 3 availability. [9] [10] [11] Abnormal platelet function studies are usually more frequent with higher concentrations of the paraprotein and with increased plasma viscosity. A paraprotein concentration above 5 g/dl is frequently associated with defective platelet function.

Several investigators have studied the effect of purified paraproteins on platelet function. [9] [11] Depressed platelet function was observed after the addition of the paraprotein to normal platelet-rich plasma. The resulting defects have been attributed to the nonspecific adsorption of the paraprotein to the platelet surface, resulting in defective platelet surface function.

A severe hemorrhagic disorder due to the development of a thrombasthenic-like platelet defect has also been reported. [12] In the patient described, there was high-affinity binding of the monoclonal paraprotein to glycoprotein IIIa on the platelet surface. The immunoglobulin completely inhibited platelet aggregation by preventing fibrinogen binding to the platelet surface.

Since markedly elevated plasma concentrations of paraproteins are more commonly associated with defective platelet function, plasmapheresis has been used in the treatment of hemorrhage.[2] [7] [9] [10] [13] There are no clinical signs or laboratory assays that predict response to plasmapheresis. However, resolution of bleeding has been reported in some patients.

Most patients have other coagulation assay abnormalities in addition to an abnormal bleeding time. [2] Approximately 50% of patients with multiple myeloma and macroglobulinemia have a prolonged thrombin time (TT). [2] This is associated with the appearance of an abnormal fibrin clot. [5] [10] [14] [15] [16] [17] [18] [19] [20] Fibrin clots formed in the presence of the paraprotein are transparent and gelatin-like and display poor retraction. Electron microscopic studies of fibrin clots from these patients show a structure that is poorly branched with narrowed fibrin strands. [10] [20]

The effect of paraproteins on fibrinogen cleavage and fibrin clot formation has been studied extensively. Early investigators suggested that the prolonged TT resulted from paraprotein inhibition of thrombin cleavage of fibrinogen. [14] [15] [16] [17] These paraproteins were termed antithrombin V. [15] [16] However, subsequent studies have failed to demonstrate antithrombin activity. [10] [18] [20]

Inhibition of fibrin polymerization by the paraprotein accounts for the prolonged TT and abnormal clot formation. [18] [19] [20] [21] [22] [23] Studies using purified monoclonal immunoglobulins have shown that these proteins inhibit polymerization of fibrin monomer. Paraproteins of all immunoglobulin subtypes can inhibit polymerization. [21] Using immunoglobulin fragments, the inhibitory activity is found to reside on the $F(ab)_2$ or Fab portions of the molecule. [19] [21] [23] This finding suggests that the antigen-binding domain of the monoclonal immunoglobulin may be responsible for fibrin/fibrinogen binding. However, direct binding of the inhibitory immunoglobulins to fibrin or fibrinogen has not been demonstrated under the conditions employed. [10] [22] [23] Therefore, the interactions between the inhibitory immunoglobulins and fibrin may be of low affinity and not a typical antigen-antibody interaction.

Despite the abnormal TT, bleeding is rarely observed in patients with inhibitors of fibrin polymerization. In patients who hemorrhage, other associated hemostatic defects are usually observed. Abnormalities of platelet function are frequently present. Large-volume plasmapheresis with or without plasma infusions has been effective in controlling hemorrhage in selected

Figure 118-1 Schematic representation of the pathophysiologic mechanisms responsible for hemostatic abnormalities in patients with dysproteinemias. **(A)** Paraproteins bind to platelets or to fibrinogen/fibrin and inhibit their function. **(B)** Circulating paraproteins bind to von Willebrand protein (vWF), resulting in increased clearance by the reticulendothelial system (RES). Factor X is rapidly cleared from plasma by binding to paraproteins deposited in the subendothelium as amyloid.

patients. [6] [9] [10] [13] Fibrinogen given as fresh frozen plasma or cryoprecipitate is not helpful. In fact, most patients have elevated plasma concentrations of fibrinogen. [24]

Circulating paraproteins that inhibit the function of von Willebrand factor (vWF) [25] [26] and factor VIII [27] [28] [29] [30] [31] [32] have been described. Unlike the inhibitors that interfere with fibrin polymerization, these inhibitors are associated with clinical bleeding syndromes. Two patients with IgG multiple myeloma have been described with circulating paraproteins that inhibited ristocetin-induced platelet agglutination and decreased platelet adhesiveness. [25] [26] These paraproteins bound vWF when studied by crossed immunoelectropheresis. Unlike patients with acquired von Willebrand disease, both patients had increased plasma von Willebrand antigen and normal factor VIII activity. A patient with acquired von Willebrand disease and an inhibitor of vWF adherence to collagen has been described. [33] The patient had a low-grade lymphoma and an IgG paraprotein. However, immunoprecipitation studies demonstrated that the inhibitor was an IgM antibody and not the IgG paraprotein.

Six patients with paraproteins that inhibit factor VIII coagulant activity have been described. The patients had IgA multiple myeloma, [27] light chain myeloma, [28] [29] Waldenström's macroglobulinemia, [30] chronic lymphocytic leukemia with an IgM paraprotein, [31] and amyloidosis with an IgA paraprotein. [32] The inhibitory immunoglobulins were characterized by their ability to inhibit factor VIII activity in normal plasma. The paraproteins resemble the type II antibody inhibitors in hemophiliacs. [34] The inhibitory paraproteins were slow-reacting antibodies of low affinity for factor VIII. There was significant residual factor VIII activity (710%) in plasma of three of these patients despite high plasma concentrations of the paraproteins, [27] [30] [32] a characteristic of type II antibodies. One patient with kappa light chain myeloma had less than 1% factor VIII activity and 5 Bethesda units of inhibitory activity in his plasma. The kappa light chains

were isolated from the patient's urine and shown to have factor VIII inhibitory activity. [29]

Large-volume plasmapheresis, combined with the infusion of cryoprecipitate or factor VIII concentrates, is only transiently effective in the treatment of hemorrhage in patients with factor VIII inhibitors. One patient with multiple myeloma experienced a clinical remission with improvement in his bleeding symptoms after treatment with alkylating agents. [26] A patient with light chain myeloma with factor VIII inhibitory activity responded rapidly to treatment with the VAD regimen, and response was closely associated with the disappearance of free light chains in the patient's urine. [29] High-dose intravenous -globulin has been reported effective in combination with infusions of factor VIII concentrate in patients with spontaneous inhibitors to factor VIII, but its clinical value in this condition is unknown. [35] Porcine factor VIII appears to be highly effective in the treatment of acquired factor VIII inhibitors [36] and may be the treatment of choice in this disorder, if the inhibitory paraprotein does not cross-react with the porcine factor VIII. Recombinant factor VIIa has also been shown to be effective in patients with acquired factor VIII inhibitors and may provide an effective alternative to porcine factor VIII. [37]

Paraproteins with a specificity for phospholipids and the characteristics of a lupus anticoagulant have been reported. [38] [39] The in vitro inhibition of coagulation protein binding to phospholipid by the patients' paraproteins was not associated with bleeding or thrombosis.

ACCELERATED CLEARANCE OF COAGULATION PROTEINS

Decreased plasma concentrations of a number of coagulation proteins, including factor V, factor VII, factor VIII, factor X, prothrombin, protein C, and fibrinogen, have been reported with dysproteinemias.[2] [24] [40] [41] [42] Perkins et al.[2] reported severe deficiencies of coagulation proteins in eight (12%) of 62 patients. However, bleeding was observed in only two of the eight patients. Low levels of coagulant activity in these patients are not due to inhibition by the paraprotein. The deficiencies are usually corrected by transfusion of the missing plasma protein. Therefore, a circulating anticoagulant is not present. The proposed mechanism for these deficiencies is an accelerated clearance of coagulation protein and paraprotein complexes, [40] [41] [42] although many investigators have failed to find evidence of these complexes in plasma.[2] [11]

Acquired von Willebrand disease is often reported in association with dysproteinemias and lymphoproliferative disorders. [43] [44] [45] [46] [47] [48] [49] This disorder is characterized by a prolonged bleeding time, decreased platelet adhesiveness, reduced ristocetin-induced agglutination, decreased factor VIII coagulant activity, and plasma vWF. Mixing studies usually fail to detect inhibition of vWF function. The multimer pattern of vWF is normal, although the concentration of all multimers is decreased.[44]

Patients treated with infusions of cryoprecipitate have an appropriate rise in plasma von Willebrand antigen and factor VIII activity. [44] [45] [47] There is no secondary postinfusion rise in factor VIII activity, as seen in congenital von Willebrand disease. [44] [47] A rapid clearance of the von Willebrand protein, necessary for stabilization of plasma factor VIII, accounts for this loss of the secondary rise in factor VIII coagulant activity. Patients treated with DDAVP have an appropriate rise in vWF antigen and activity, followed by an accelerated disappearance of the protein from plasma. [48] [49]

Brody et al. [46] reported on a patient with macroglobulinemia and acquired von Willebrand disease who had a remission in his bleeding disorder after splenectomy. Immunofluorescence of the patient's malignant lymphocytes demonstrated surface-bound vWF. Brody and co-workers proposed that vWF preferentially

EVALUATION AND TREATMENT OF BLEEDING IN DYSPROTEINEMIAS

Clinically significant bleeding occurs in 10% of patients with dysproteinemias. A systematic approach to the evaluation and treatment of bleeding in these patients must be based on an understanding of underlying pathophysiologic mechanisms. The most common hemostatic abnormalities are due to paraprotein inhibitors of platelet function and fibrin polymerization. Patients who are bleeding and have both a prolonged bleeding time and a long TT should be treated with large-volume plasmapheresis. Plasmapheresis is particularly helpful in patients with Waldenström's macroglobulinemia. Cytotoxic chemotherapy or radiation therapy may be employed to reduce the tumor burden and decrease the production of the inhibitory paraprotein, although such therapy is rarely successful.

Patients with dysproteinemias who have inhibitors of factor VIII or vWF or patients with amyloid who have accelerated fibrinolysis or factor X deficiency are at a high risk of bleeding. Inhibitors of factor VIII are resistant to most therapies. Porcine factor VIII or recombinant factor VIIa, either therapy given alone or combined with large-volume plasmapharesis, can be employed during acute bleeding. When possible, cytotoxic chemotherapy to reduce the production of the inhibitory immunoglobulin should be employed. Treatment of acquired von Willebrand disease should be directed toward treatment of the underlying lymphoproliferative disorder. Acute bleeding episodes can be treated with DDAVP, infusions of cyroprecipitate, or factor VIII concentrates enriched in vWF.

Patients with systemic amyloidosis and factor X deficiency may have spontaneous bleeding, which is only transiently controlled by infusions of intermediate purity factor IX concentrates. Large-volume plasma exchange has proved effective in one patient. Stable patients may benefit from splenectomy. Tests for fibrinolysis should also be performed in patients who are bleeding. Patients with increased fibrinolysis should be treated with aminocaproic acid.

bound the monomeric IgM on the surface of the malignant cell.

More than 40 patients with systemic amyloidosis have been described who had an acquired deficiency in factor X. [50] [51] [52] [53] [54] [55] [56] This disorder is characterized by variable deficiencies in plasma factor X (250%) and no evidence of a factor X inhibitor in plasma. Spontaneous bleeding can occur in patients with severe factor X deficiency (<10%), and occasionally precedes the diagnosis of amyloidosis. The clinical course and survival of these patients are variable. Although death usually results from progressive amyloidosis, fatal hemorrhages do occur.

Infusion of large volumes of plasma or partial purity factor IX concentrates results in only transient elevations in factor X. Howell [51] proposed that the factor X deficiency results from factor X binding to amyloid deposits. Furie et al. [56] showed that infused ^{131}I-labeled factor X was rapidly cleared from the circulation of a patient with this disorder. The disappearance half-time was less than 30 seconds (by comparison, the half-time is 1.53 hours in healthy subjects). Total body scans of the patient showed diffuse uptake of radioactivity, but the highest concentrations were seen over the involved liver and spleen. In fact, remissions in factor X deficiency were observed in two patients after splenectomy.[57] [58] Extensive amyloid involvement of the spleen is observed in only 9% of patients with primary amyloidosis

but is reported in 40% of patients with acquired factor X deficiency. [54] Therefore, an enlarged spleen infiltrated with amyloid may be a major site of factor X clearance.[57] [58] [59] Although chemotherapy is only marginally effective in the treatment of systemic amyloidosis, [60] a remission of acquired factor X deficiency was reported in one patient after treatment with melphalan and prednisone. [61] In one patient requiring emergency surgical intervention, large-volume plasma exchange was effective in raising the factor X levels and stopping postoperative bleeding. [62]

With the use of a method of quantitative affinity chromatography, it has been shown that factor X binds to amyloid fibrils. [63] There was no difference in factor X binding to fibrils taken from patients with or without factor X deficiency. Factor IX and prothrombin bound the fibrils to a lesser extent. Combined deficiencies in other vitamin K-dependent proteins along with factor X have been reported with amyloidosis. [59] [60] [64] Also, patients may have decreased functional activity of the residual plasma factor X.[61] [65] The cause of the decreased function is unclear.

HEMOSTATIC DEFECTS UNRELATED TO PARAPROTEINEMIA

Patients with multiple myeloma and plasma cell dyscrasias have been described with a bleeding disorder secondary to a heparin-like anticoagulant. [66] [67] [68] [69] These patients have a markedly prolonged TT that can be corrected with the addition of protamine sulfate or platelet factor 4. The anticoagulant is an effective cofactor for the inhibition of thrombin in assays using purified antithrombin III and is destroyed by treatment with heparinase. In one patient, continuous infusion of protamine sulfate successfully controlled bleeding. [69]

A prolonged TT is the most frequent hemostatic assay abnormality observed in patients with AL-type amyloidosis. [70] The presence of a plasma inhibitor of both TT and reptilase assays has been described in a number of patients with AL amyloid. [71] However, the presence of this inhibitor does not appear to be associated with an increased risk of bleeding. [70] [71]

A syndrome of pathologic and excessive fibrinolysis has been reported in 11 patients with systemic amyloidosis. [72] [73] [74] [75] [76] [77] [78] All patients had a bleeding diathesis characterized by increased fibrinolytic activity, as determined by a shortened time on the euglobulin clot lysis test, whole blood lysis time, or positive fibrin plate assay. Fibrinogen levels were moderately reduced, levels of fibrin/fibrinogen degradation products were elevated, and no evidence of intravascular coagulation was found. The pathophysiology of this disorder remains unclear. Patients have decreased plasma concentration of $_2$ -antiplasmin inhibitor,[75] but this is secondary to complex formation with plasmin.[76] Abnormalities have been reported with increased tissue plasminogen activator activity [76] and decreased plasminogen activator inhibitor activity. Elevated plasma urokinase-type activity has been reported in two patients with this disorder. [77] [78] The increased fibrinolytic activity in one patient was associated with elevated plasma levels of single-chain urokinase plasminogen activator. [78] Treatment with -aminocaproic acid effectively controlled bleeding in 10 patients.

Chapter 119 - Disorders of Coagulation and Platelets in the Neonate

Marilyn J. Manco-Johnson

INTRODUCTION

The hemostatic system of the fetus and neonate is unique. During fetal and early neonatal development, coagulation proteins vary in synthetic rate, post-translational processing, and metabolism, processes that are all undergoing continuous developmental change. Consequently, activities of various coagulation proteins differ not only from adult normal values, but also in proportionate relationship to other neonatal coagulation factors. [1] [2] [3] [4] [5] [6] [7] [8] Tables 1191 , 1192 , and 1193 display the means and lower limits for procoagulant, anticoagulant, and fibrinolytic activities in normal infants at various gestational ages. Many of the proteins, such as the vitamin K-dependent proteins, those of the contact factor system, antithrombin III (AT III), plasminogen, and factor XIII, show a distinct gestational dependency and often do not approximate normal adult levels until several months after birth. Other plasma proteins are only slightly lower (fibrinogen, factor V, $_2$ -antiplasmin) or normal to even increased (factor VIII, von Willebrand factor [vWF]). Most of these changes are quantitative, and in only a few instances is there convincing evidence of a distinct fetal protein with altered function. Such examples include fetal fibrinogen, [9] altered vWF, [10] plasminogen, [11] [12] and possibly protein C. [13] Vitamin K-dependent carboxylation of proteins may be incomplete. [14] Over the last several years, new data have been obtained regarding components of coagulation regulation and fibrinolysis in the newborn infant. [2] [3] [4] [5] [6] [7] [8] [11] Still missing are data regarding critical

TABLE 119-1 -- Procoagulant Coagulation Factor Concentrations for the Fetus and Newborn Infant [a]

Subjects	Fibrinogen mg/dl	Prothrombin	Factor V	Factor VII	Factor VIII	vWF (antigen)	Factor IX	Factor X	Factor XI	Factor XII	PK	HMWK	Factor XIII

endothelial cell functions in coagulation protein synthesis, release, and function.

The plasma-clotting activities resulting from the fetal hemostatic system produce notable changes in the screening tests used in clinical situations. Mostly due to the low contact factors, the partial thromboplastin time (PTT) is prolonged by 2 to 3 seconds in the term infant and may be greater than twice the adult value in the small preterm infant; prolongation of the prothrombin time (PT) may be only a second in the term and up to 3 seconds in the preterm infant; a prolonged thrombin time (if performed without calcium) reflects fetal fibrinogen. These values, found in healthy infants [5] [15] and varying slightly according to technique, instruments, and reagents, are not associated with any bleeding tendency.

Because of the unique interrelationships within the fetal and neonatal coagulation system, investigations of individual components may yield misleading results. Thus, although plasma from healthy neonates shows decreased thrombin generation similar to that of warfarinized adults, [16] [17] neonates who are not vitamin K deficient almost never develop ecchymoses or gastrointestinal or intracranial hemorrhages (ICH) typical of low thrombin-generation states. Likewise, although plasminogen and tissue plasminogen activator (t-PA) are decreased in neonatal plasma, and histidine-rich glycoprotein and $_2$ -antiplasmin are relatively increased, the euglobulin clot lysis time is short and spontaneous thromboses are rare. [18] [19]

Platelet number and function, with the exception of decreased aggregation to epinephrine, low concentrations of adenosine diphosphate (ADP), and collagen, is unchanged from the adult normal values. Platelet adrenergic receptors are decreased. [20] [21] Well term and preterm infants have normal platelet counts and bleeding times.[22]

Characteristics of neonatal red blood cells including increased size and red cell mass relative to adult red cells contribute to accelerated whole blood coagulation activation at birth. Enhanced release of adenosine diphosphate, greater externalization of membrane phosphatidylserine, and increased susceptibility to lipid peroxidation may all contribute procoagulant effects to newborn blood. [23] [24]

HEREDITARY COAGULATION DISORDERS

The hereditary coagulation disorders may present during the neonatal period. These include hemophilia A and B, severe deficiencies of prothrombin or factor V, factor VII, factor X, afibrinogenemia, factor XIII, or $_2$ -antiplasmin deficiencies.[1] Affected infants present most typically with ecchymoses, cephalohematomas, umbilical stump oozing, gastrointestinal bleeding, ICH, and persistent oozing after circumcision or heel stick punctures for routine blood screening. Persistent umbilical cord stump oozing is particularly characteristic of homozygous factor XIII deficiency. ICH in a term infant should always raise suspicion of a familial bleeding diathesis including hemophilia, another hereditary coagulation deficiency, hereditary thrombocytopenia, Glanzmans thrombesthenia, or a connective tissue disorder such as Erhlers-Danlos.[25] [26] Only 50% of infants with severe hemophilia exhibit protracted oozing following circumcision. Failure to bleed excessively following circumcision does not exclude a diagnosis of hemophilia.

When hemophilia is suspected before delivery, efforts

TABLE 119-3 -- Coagulation Regulation in the Neonate

Component	Neonatal Functions	Effect on Coagulation
Reticuloendothelial system	Functionally hyposplenic	Delayed clearance of activated coagulation products leading to further activation
Native coagulation inhibitors	AT III Protein C	Diminished capacity to inhibit activated coagulation proteins
	Protein S	May promote thrombus formation

	t-PA, normal plasminogen activator inhibitor, slower plasmin generation rates	Diminished native fibronolysis in sick infants
Endothelial cells	Largely unknown	Unknown
Production of platelets and synthesis of coagulation proteins	Capacity for compensatory increase in production rate during consumption	Early depletion of platelets and coagulation proteins leading to bleeding complications

should be made to ascertain the diagnosis in the infant as soon as is practical. Prenatal diagnosis may be made by intrauterine chorionic villus sampling, amniocentesis, or periumbilical blood sampling. There is controversy regarding the optimal mode of delivery for babies with severe hemophilia. Occasional case reports and small series describe severe perinatal ICH.[25] There are no prospective data, but this complication probably does not exceed 10% of births involving affected infants. Current recommendations include a delivery as atraumatic to the infant as possible with avoidance of use of vacuum extractors or forceps. [27] Recombinant factor VIII or factor IX should be available in the event of hemorrhage. It should be noted that even though maternal levels of factor VIII and vWF increase during pregnancy, they may fall within hours of delivery and carrier mothers are at increased risk for postpartum hemorrhage. [28]

Plans should be made to obtain an umbilical cord blood sample carefully collected to avoid contamination with maternal blood or amniotic fluid for confirmation of diagnosis at the time of delivery. Laboratory investigations should include specific factor assay. Screening tests including the PTT and the PT are not adequate to confirm or exclude a diagnosis of congenital bleeding disorder in a neonate. Less severe congenital factor deficiencies including type 1 or 2 von Willebrands disease or mild deficiencies of factor IX or factor XI may not be accurately diagnosed at the time of delivery because of the overlap with normal infant values; studies at a later date (3 months of age) will usually allow diagnosis.

Detailed treatment guidelines for the hemophilias are discussed elsewhere (Chap. 109). It is important to use the safest transfusion products available. Recombinant proteins are preferred. Single donor plasma that has been appropriately screened for human immunodeficiency virus, hepatitis B, and hepatitis C and highly purified, viral inactivated plasma-derived products are acceptable if safer products are not available. All affected infants should be immunized for hepatitis A and B.

VITAMIN K DEFICIENCY BLEEDING (VKDB)

The neonatal bleeding syndromes due to vitamin K deficiency generally affect otherwise well infants and constitute the most important preventable cause of bleeding morbidity and mortality in infants worldwide. Cord blood of normal neonates born to well-nourished healthy mothers demonstrates a marginal vitamin K status at the time of birth.[29] [30] Mean plasma concentrations of vitamin K_1 have been reported at 0.009 ± 0.02 nmol/L at birth compared with a normal adult reference range of 0.32.6 nmol/L.[31] Trace amounts of des--carboxy protein C and prothrombin, decreased vitamin K_1 , and increased vitamin K_1 epoxide were found in 27% of these infants; the data suggested decreased vitamin K stores and inefficient hepatic reductase cycling. The marked maternal/fetal gradient in vitamin K level suggests a potential population advantage of relative vitamin K deficiency in the fetus and neonate. Evidence suggests that high concentrations of vitamin K are mutagenic. [32]

After birth with the institution of oral feedings, vitamin K levels rise quickly. Formulas based on cows milk contain approximately 10 times the concentration of vitamin K as human breast milk. However, breast milk has a higher bioavailability provided the infant is fed exclusively breast milk. The incidence of vitamin K deficiency has been estimated at 0.011.5% worldwide and varies widely relating to nutritional and other factors.

The International Society for Thrombosis and Haemostasis has recently published criteria for the diagnosis, prevention, and treatment of this syndrome. [33] Those recommendations form the basis of this summary. It is proposed that the historical name, hemorrhagic disease of the newborn, be abandoned in favor of the more descriptive term, "vitamin K deficiency bleeding" (VKDB).

Vitamin K deficiency bleeding can be classified based on etiology or time of onset. The etiology may be idiopathic, which is generally found in exclusively breast-fed infants or secondary to decreased intake or absorption of vitamin K or vitamin K antagonism by drugs. Time of onset is used to divide cases into onset within the first 24 hours of life (early VKDB), from 24 hours through 7 days (classic VKDB) or up to 8 and rarely 12 weeks (late VKDB). The early form is due almost exclusively to placental transfer of maternal drugs that inhibit vitamin K activity in the baby including anticonvulsants (carbamazepine, phenytoin, and barbituates but not valproic acid),[34] antibiotics (cephalosporins, rifampicin, isoniazid), [35] and oral anticoagulants.[36] ICH or intractable oozing from skin punctures are common in this form. The incidence of bleeding in infants of mothers taking these drugs without supplementation is 612%. [33] The classic form of VKDB occurs in infants with poor oral intake or exclusive breast-feeding. Classic VKDB presents with bleeding from multiple sites, with oozing from skin punctures, the umbilical stump, the gastrointestinal tract, surgical sites, and occasionally ICH. Late VKDB usually manifests with ICH. Most cases are idiopathic but occasionally malabsorption, liver disease, or cholestasis is found. Affected infants should be evaluated for biliary cirrhosis, $_1$ -antitrypsin deficiency, cystic fibrosis, and Wilsons disease.

The diagnosis of VKDB is suggested by a clearly prolonged PT in the presence of a normal fibrinogen and platelet concentration. The PTT is usually prolonged. Severe genetic factor VII deficiency causes an isolated prolongation of the PT and should be confirmed by factor VII assay in infants in whom the PTT is normal. In VKDB, vitamin K-dependent proteins, prothrombin, factor VII, factor IX, factor X; protein C, and protein S are all reduced. Des--carboxy forms of these proteins can be detected circulating in plasma. Des--carboxy prothrombin has been used to diagnose vitamin K deficiency retrospectively. [30]

Therapeutic response to 1 mg intravenous vitamin K with correction of the PT and cessation of bleeding is prompt, thus confirming the diagnosis. Infants with life-threatening hemorrhage may benefit from immediate infusion of fresh frozen plasma in addition.

Vitamin K deficiency bleeding can be prevented with vitamin K prophylaxis. [33] Early VKDB is prevented by giving vitamin K prophylaxis to the mother during pregnancy.[37] [38] Classic vitamin K deficiency can be prevented by 1 mg vitamin K, given either intramuscularly or orally. Intramuscular vitamin K provides stores for 46 weeks, which is adequate in most cases to cover healthy infants until adequate dietary intake is established. Oral vitamin K_1 given as three doses of 1 mg has not completely eliminated VKDB. The arguments against the single intramuscular prophylaxis were potential muscle damage inflicted by the needle and potential increases in childhood cancer risk conferred by temporary unphysiologically high plasma levels of vitamin K after intramuscular injection; the latter has not been substantiated.[39] [40] The arguments against repeated oral prophylaxis chiefly involve difficulties in ensuring compliance and the devastating consequences of ICH that have occurred in treatment failures.

LIVER DISEASE

The coagulopathy of severe liver disease is complex and includes consumption of clotting factors and platelets (due to tissue necrosis, endothelial damage, disseminated intravascular coagulation [DIC], increased fibrinolysis, hypersplenism), as well as failure to synthesize procoagulant and anticoagulant proteins (Chap. 117). Clinical examples of severe neonatal hepatic disease are viral hepatitis, fetal hydrops due to erythroblastosis fetalis, cirrhosis due to $_1$-antiplasmin deficiency,

cholestatic jaundice, hepatopathy of shock (shock liver), and hereditary metabolic defects such as fructose intolerance, tyrosinemia, galactosemia, and neonatal hemachromatosis. The bleeding may be severe, especially if the infant has had surgery. Laboratory tests assessing the severity of the process and the mechanisms that are involved include platelet count, fibrinogen, PT, thrombin time, fibrin degradation (split) products, and D dimer. Specific factor assays that may guide therapy include factor V (a good marker of steady state hepatic synthetic capacity), factor VII (a marker of current liver synthesis, especially after plasma transfusion owing to its short half-life), and AT III (replacement with concentrate may control consumptive coagulopathy).

Treatment consists of replacement therapy with fresh frozen plasma, platelet concentrates, cryoprecipitates, and AT III concentrate, if necessary. In severe cases, all these agents may be needed to obtain minimal hemostatic levels. Alternatively, exchange transfusion followed by platelet transfusion can be used to obtain hemostasis. Advances in liver transplantation for the small infant have provided definitive therapy for many previously fatal infantile hepatopathies; successful interim support of coagulation is an integral part of this therapy.

THROMBOCYTOPENIA

Thrombocytopenia, defined by a platelet count of <150,000/l, is the most common hemostatic disorder diagnosed in the neonatal period. [41] Severe thrombocytopenia (<50,000/l) has been reported in 1% of all term neonates [42] and thrombocytopenia has been determined in 22% of all neonates admitted to an intensive care unit. [43] Although many etiologies have been determined for neonatal thrombocytopenia (Table 1194), the vast majority of infants have thrombocytopenia due to conditions associated with increased destruction of circulating platelets. It is clinically useful to first categorize infants as well or with other medical conditions. In sick infants, thrombocytopenia is most frequently caused by infection, DIC and other intravascular consumptive coagulopathies such as necrotizing enterocolitis, placental chorangioma, and large vessel thrombosis (see later), and vascular disorders such as hemangiomas, heart lesions with abnormal flow mechanics or polycythemia, and pulmonary syndromes (respiratory distress syndrome, aspiration, and pulmonary hypertension). These disorders are relatively easily recognized; often many contributing conditions coexist and treatment is related to management of the underlying disease. The platelet count should be maintained >50,000 using platelet transfusion as necessary for infants who are undergoing mechanical ventilation, extracorporeal membrane oxygenation, surgery, have indwelling arterial lines or drainage tubes, or are acutely ill. Stable infants with none of these risk factors can usually tolerate a platelet count of 20,000 without spontaneous bleeding.

Thrombocytopenia that occurs in an otherwise well infant is frequently immune mediated. Since the classic paper of Pearson et al., [44] neonatal alloimmune thrombocytopenia (NAIT) has been recognized with increasing frequency and clinical concern. NAIT is caused by fetomaternal incompatibility for platelet antigens of paternal origin. The platelet-specific antigen implicated most frequently in Caucasians is PI^{Al} (present in 98% of the population) and next Br^{a} . Pen/Yuk polymorphism is the most common cause of NAIT in Asians. Studies suggest the incidence to be 1/1,0002,000 newborn babies; [45] the first pregnancy is affected in about 50% of cases. NAIT is a serious disorder. Because of the early onset and often severe thrombocytopenia, the risk of ICH is 1030% with half of the cases occurring intrauterine.

The diagnosis of NAIT begins with clinical suspicion, which should be high in any well infant, term or preterm, with unexplained thrombocytopenia, or any ill infant with the severity

TABLE 119-4 -- Causes of Neonatal Thrombocytopenia

Infection
Bacterial: sepsis, congenital syphilis
Viral: cytomegalovirus, herpes simplex, rubella, enterovirus, human immunodeficiency virus (HIV), parvo-B19
Other: toxoplasmosis
Immune Disorders
Alloimmunization
Maternal antibody induced: idiopathic thrombocytopenic purpura, systemic lupus erythematosus
Bone marrow abnormality
Congenital magakaryocytic hypoplasia
Absent radii (TAR) syndrome
Phocomelia syndrome
Fanconis pancytopenia
Aplastic anemia
Trisomy syndromes
Osteopetrosis
Congenital leukemia
Maternal drugs
Tolbutamide, hydralazine, hydantoin, azothiaprine
Infant drugs
Intralipid, tolazoline
Intravascular coagulation syndromes
Disseminated intravascular coagulation
Major vessel thrombosis: renal vein, aorta
Necrotizing enterocolitis
Placental chorangioma
Chorionic vessel thrombosis
Excessive peripheral utilization
Giant hemangioma
Hyperviscosity syndrome
Erythroblastosis fetalis
Congenital heart disease
Hereditary thrombocytopenia
Sex-linked: Wiskott-Aldrich syndrome and variants

Autosomal recessive: associated with renal diseases and deafness
Autosomal dominant: May Hegglin anomaly, Bernard Soulier
Other causes
Postexchange transfusion
Maternal hyperthyroidism
Maternal hypertension (?)
Metabolic disorders: hyperglycinemia, cirrhosis, mucolipidosis
Thrombotic thrombocytopenia purpura
Postmature and small for gestational age infants
Neonatal neuroblastoma
Neonatal cold injury
Perinatal pulmonary syndromes

of thrombocytopenia out of proportion to the clinical setting. Maternal platelet count should be normal; mild maternal thrombocytopenia may be secondary to unrelated causes such as benign gestational thrombocytopenia. Diagnosis includes determination of parental platelet antigen incompatibility by platelet typing, which can be performed using DNA or serologic techniques. Confirmation by demonstration of maternal antibodies directed against paternal antigens is helpful when present, but a negative result does not exclude the diagnosis. Treatment of neonates with intravenous gammaglobulin, 1 g/kg/day for 23 days or intravenous methylprednisolone 1 mg/kg every 8 hours for three doses is usually successful.[41] [46] The disorder generally resolves within 2 weeks. Treatment of sick infants, infants with severe thrombocytopenia, or infants with active bleeding is by transfusion of either washed maternal or typed maternal-compatible cytomegalovirus-negative platelets. Random donor platelets should be given to an infant with life-threatening

hemorrhage, especially ICH, while specific therapy is being prepared. Although survival of untyped platelets is likely to be short, there may be a transient hemostatic effect.

When alloimmune thrombocytopenia is suspected prenatally based on a previous pregnancy or positive family history, platelet typing and antibody studies should be performed immediately. Fetal blood sampling can be performed beginning at 20 weeks to assess the infants clinical involvement. Maternal treatment with intravenous immunoglobulin/g/kg/week or steroids is generally effective.[47] Because of the increased risk of fetal hemorrhage, washed, concentrated maternal platelets should be infused into the fetus at the end of the intrauterine blood sampling procedure. Alternatively, the fetus may be treated with repeated compatible platelet transfusion commencing at 2630 weeks gestation.[48] [49] Delivery should be as atraumatic as possible and documentation of an adequate fetal platelet count before delivery is recommended.

Thrombocytopenia secondary to maternal autoantibodies generally causes less severe disease in the infant. Passively transferred antibodies from mothers with immune thrombocytopenia purpura or systemic lupus erythematosus result in varying degrees of neonatal thrombocytopenia. Mildly affected infants typically need no specific therapy. Infants with platelet counts of <50,000/l, petechiae, or oozing from skin punctures may respond to a 12-week course of prednisone, 2 mg/kg/day. Infants with severe thrombocytopenia (<10,000/l) or significant bleeding usually respond promptly to intravenous immunoglobulin. Platelet transfusions are rarely helpful unless antibody is removed by exchange transfusion.

NEONATAL DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation is the second most frequent coagulopathy in the neonate after thrombocytopenia (Chap. 117). Uncontrolled intravascular thrombin generation results when coagulation activation triggered by acidosis, poor perfusion, or endotoxin overwhelms the native regulatory mechanisms. [1] Several components of the neonates developmentally immature hemostatic system may contribute to the neonates susceptibility to DIC and have been recently reviewed. [49] Neonatal DIC is associated with a wide variety of conditions (Table 1195).

Clinically, an infant with DIC manifests poor perfusion, oozing from puncture sites, ICH, pulmonary and gastrointestinal hemorrhage, and occasionally, large vessel thrombosis. Characteristic laboratory findings include decreased platelet count; diminished levels of fibrinogen, factor V, factor VIII, protein C, and AT III; increased fibrin degradation products; decreased levels of the vitamin K-dependent factors; and a microangiopathic hemolytic anemia. A simple but helpful screening panel includes the platelet count, fibrinogen level, D-dimer assay of cross-linked fibrin, PTT, and PT. With a slightly larger sample volume, AT III and plasminogen can also be assayed. These tests can all be performed on capillary blood specimens and give an estimate both of ongoing activation as well as bleeding potential. AT III and plasminogen are often decreased to a critical level (<20% of normal adult values) and convey a poor prognosis. [50] [51] [52] [53] Other specific factor assays provide confirmatory information but neither increase diagnostic sensitivity nor aid in clinical management.

Therapy for neonatal DIC is primarily directed at reversing the etiologic trigger. Appropriate management with ventilation, intravascular volume support, and antibiotics generally results in normalization of coagulation within 2448 hours.

Infants with DIC who are actively bleeding should be supported with transfusions to maintain a platelet count of >50,000/l and a fibrinogen level of 100 mg/dl (Table 1196). In infants suffering life-threatening hemorrhage, hemostasis

may be achieved more emergently with a two-volume exchange transfusion. AT III concentrate in doses of 100200 U/kg may be given every 2448 hours to infants with depleted regulatory capacity. Plasminogen and protein C may be replaced using fresh frozen plasma in doses of 1020 ml/kg. Occasionally an infant with DIC manifests large vessel thrombosis or circulatory impairment caused by diffuse microthrombi, for which low-dose heparin therapy is appropriate.

Transfusion therapy in babies without bleeding signs may be reserved for a platelet count of <20,000 and a fibrinogen level of <50 mg/dl.

Intracranial hemorrhage is one of the most devastating bleeding complications in neonates. This lesion is associated with prematurity and assisted ventilation. The onset of neonatal ICH is primarily in the first 72 hours with the largest number of cases diagnosed within the first 24 hours. [54] The hemorrhages begin in the germinal matrix of the lateral ventricles (grade I ICH or germinal matrix hemorrhage). More advanced hemorrhages extend into the ventricular cavities (intraventricular hemorrhage: grade II with absence or grade III with presence of ventricular dilatation) or into the parencyma of the brain (grade IV ICH). Neurologic outcome is related to the extent of

TABLE 119-6 -- Treatment of Acquired Hemostatic Defects in the Newborn

Indication	Product	Dosage Guideline
Thrombocytopenia	Platelet concentrate	10 mg/kg will raise platelet count to 75100 × 10^3 /l
Coagulopathy (DIC, liver disease)	Fresh frozen plasma	1015 ml/kg will raise factor level by 0.2 U/ml
Severe fibrinogen depletion	Cryoprecipitate	1 U/3 kg will raise fibrinogen level to >100 mg/dl

hemorrhage with residual motor and cognitive deficits in the majority of infants with grade III or grade IV ICH. Prospective investigations of preterm infants with respiratory distress syndrome determined coagulopathies with thrombocytopenia, hypofibrinogenemia, and low plasma concentration of AT III and protein C to precede the onset of ICH. Autopsy studies demonstrate fibrin deposition in germinal matrix venules suggesting that the clinical syndrome may result from post-thrombotic hemorrhage from these poorly supported vessels. A randomized, controlled study of platelet transfusion in premature infants failed to show a decreased incidence in ICH in infants who were prophylactically supported with platelet transfusion. [55] This study would suggest that the thrombocytopenia is a marker for a process (e.g., germinal matrix infarction), which resulted in ICH rather than being causative. Therapy is supportive although there is evidence that the ICH is more likely to progress in babies with thrombocytopenia and hypofibrinogenemia. [51] Concomitant with improved neonatal intensive support, the incidence and severity of neonatal ICH has decreased.

NEONATAL HYPERCOAGULABILITY AND THROMBOSIS

Thrombosis in the neonate is characterized by an increased incidence during the perinatal period, a predilection for major vessels, and frequent involvement of the arterial circulation. Most neonatal thromboses occur on indwelling arterial and venous catheters where the pathophysiology includes endothelial damage, mechanical obstruction to flow, the composition and design of the catheter itself, an immature regulatory system, and triggers of coagulation activation. Predisposing medical conditions in these sick infants include asphyxia, poor perfusion, infection, respiratory distress syndrome, congenital heart disease, maternal diabetes, polycythemia, and intrauterine growth retardation.

Spontaneous thromboses do occur and most frequently involve the inferior vena cava and renal veins; the aorta, renal and femoral arteries; as well as the middle cerebral arteries. Neonatal hypercoagulability has become a topic of active research and clinical interest over the past few years. Investigations of neonates with thromboses have found genetic deficiencies in the concentration or function of one or more coagulation proteins including AT III, [56] [57] [58] [59] protein C,[60] [61] [62] protein S,[63] and the factor V Leiden mutation.[64] [65] [66] [67] [68] These thromboses most frequently involve the renal veins, inferior vena cava, and central nervous system (CNS) sinuses, although the aorta may also be involved. Most infants did not have a history of antecedent trigger beyond the stress of labor and delivery. Because AT III, protein C, and protein S are easily consumed during thrombosis in an infant without a genetic deficiency, definitive diagnosis requires documentation of the same defect in a parent or persistence of the deficiency for at least 6 months after the acute event. Affected infants have responded to conventional anticoagulant and fibrinolytic therapy, although some were treated with specific protein replacement. The risk of recurrence during infancy appears to be low in all infants except those with the most severe deficiencies. All term infants with idiopathic thrombosis should be evaluated for genetic thrombophilia between 6 and 12 months of age. Preterm and sick term infants with thrombosis should be considered for a thrombophilia evaluation if the thrombus trigger was trivial or the thrombosis was unusually extensive or progressive.

Thrombophilic families with infants who manifest neonatal thromboses are at risk for recurrence in subsequent pregnancies, especially when the genetic deficiencies are severe or involve multiple gene defects. In these cases intrauterine diagnosis has been performed to plan perinatal management or provide information regarding decisions to terminate the pregnancy. In the case of an isolated factor V Leiden mutation, which affects approximately 5% of Caucasian infants, [68] [69] it is possible that reported cases of neonatal thrombosis or purpura fulminans may have involved other unidentified cofactors. [70] Because most affected individuals suffer no neonatal morbidity, caution should be exercised in advising parents on aggressive diagnostic or interventive fetal procedures based on parental carriage of the factor V Leiden gene alone.

Hypercoagulability is a common acquired condition in sick infants. Although the coagulation system of the well term and preterm infant shows low levels of many procoagulant, anticoagulant, and fibrinolytic proteins, hemostasis is functionally balanced and thromboses and hemorrhages are equally rare. The sick infant, on the other hand, is susceptible to severe acquired deficiencies of multiple anticoagulant and fibrinolytic proteins. Thromboses are common in sick neonates, especially in infants with indwelling arterial and venous catheters. Many neonatal conditions have been associated with acquired hypercoagulability and an increased risk of thrombosis including respiratory distress syndrome, [51] [71] [72] asphyxia, [73] congenital heart disease, [53] polycythemia, sepsis,[73] pulmonary hypertension, and maternal cocaine use.[74] It was first noted over 20 years ago that infants with severe respiratory distress syndrome manifest severe decreases in plasminogen and AT III and that the severity of these acquired deficiencies was correlated with a poor prognosis for survival. [71] This disorder presents along a spectrum with DIC and bleeding in a subset of infants with diffuse coagulation consumption at one end and hypercoagulability and thrombosis in infants with more limited consumption.

Acquired coagulopathies caused by transplacental transfer of the lupus anticoagulant have been reported rarely. [75] [76] [77] [78] [79] The resulting thrombotic disorder has mimicked severe genetic deficiencies of the protein affected by the maternal antibody.

The diagnosis of neonatal thrombosis is made by demonstration of the clot with an imaging technique. High-resolution real-time ultrasound produces excellent visualization of thrombi in the aorta, iliac arteries, and inferior vena cava. Color flow Doppler has extended noninvasive imaging to the intrarenal arteries and veins as well as the portal, splenic, hepatic, and cerebral arteries and veins of the neonate. Magnetic resonance imaging produces elegant intravascular images, especially of the intracranial vessels of infants who are sufficiently stable for transport to the radiology department. Contrast angiography is now rarely used in infants because of risks of increased osmotic load and fluid shifts, even using nonionic contrast; contrast studies are contraindicated in infants with renal failure or gut ischemia.

When vascular perfusion is significantly impaired by an indwelling catheter, diagnostic studies should be performed expeditiously. The catheter should be promptly removed after determining whether it can be used for local instillation of fibrinolytic therapy. Nonspecific measures, including warming of the involved or contralateral limb are sometimes helpful. Surgical thrombectomy must be guided by accessibility and local expertise. When evidence indicates recent or progressive thrombosis or organ dysfunction, either anticoagulant or thrombolytic therapy should be carefully considered.

Unfractionated heparin was the initial standard therapy for neonatal thrombosis. [80] [81] [82] [83] Heparin clearance is accelerated in the newborn partly due to neonatal differences in plasma volume and liver metabolism and partly due to the lower level of AT III in the neonate. [80] [84] Unfractionated heparin should be given to achieve and maintain a plasma anti-factor Xa activity of 0.40.7 U/mL. Typical doses required for this effect are shown in the box on Heparin Infusion Dosage. AT III concentrate can be given to overcome heparin resistance in the neonate and should be considered especially when doses of heparin in excess of 40 U/kg/hr are being infused. Confirmation of the subtherapeutic heparin level during aggressive heparin infusion therapy is more useful in gauging the potential value for AT III replacement

HEPARIN INFUSION DOSAGE

Age	Bolus (U/kg)	Maintenance (U/kg/hr)
Preterm (28 weeks)	25	15
Preterm (2836 weeks)	50	20
Full term	100	2540

than plasma concentration of AT III per se. The PTT should not be used to monitor heparin effect in preterm infants because low levels of contact factors will lead to an overestimation of heparin effect.

Low-molecular-weight (LMW) heparins are used successfully to treat neonatal thromboses. [85] [86] Because the effect of LMW heparin is limited to its action on factor Xa, the therapeutic range is somewhat higher than that for unfractionated heparin (0.51.0 U/ml). [86] LMW heparin has the advantage of being given subcutaneously and does not require frequent monitoring. In adults, LMW heparin therapy has been associated with less heparin resistance and a more predictable dose response as compared with unfractionated heparin. Although there are no prospective studies at this time, early clinical reports indicate that results of LMW heparin therapy in neonates may be similar to that in adults.

Many small series and individual case reports document the use of thrombolytic therapy in newborn infants. [81] [87] [88] In vitro and clinical experience suggests that the neonatal fibrinolytic system is less susceptible to activation resulting in requirements of up to 10 times the adult dosage for urokinase of 4,400 U/kg/hr or t-PA of 0.05 mg/kg/hr. A review of the published literature estimates the incidence of ICH in neonates receiving thrombolytic therapy at 1.2% for term infants, 13% of all preterm infants, and 25% of preterm infants treated during the first week of life. [89]

Investigations of neonatal renal vein thrombosis have reported uniform loss of renal parenchymal tissue, reduced renal function or hypertension following standard therapy with either supportive care or heparin anticoagulation. [82] Normal renal outcome has been reported in a few cases using combined therapy with heparin and thrombolytic agents. [90] [91] [92] [93] Infants with renal vein thrombosis are often near term and otherwise stable. Babies with renal vein thrombosis should be carefully evaluated for contraindications to thrombolytic therapy and should be considered for more aggressive treatment.

With both anticoagulant and fibrinolytic therapy, the bleeding risk is greater in infants with thrombocytopenia or hypofibrinogenemia. In these cases, transfusion support during therapy to maintain platelets >50,000/l and fibrinogen >100 mg/dl is appropriate. Thrombolytic therapy is contraindicated in babies with active bleeding, recent surgery (within 10 days), chest tubes, or other invasive procedures. Areas of recent infarct, especially CNS infarcts are prone to hemorrhage during thrombolytic therapy. All infants in whom thrombolytic therapy is being considered must be evaluated for risk of recent CNS ischemia or infarction. A cranial ultrasound should be taken at the initiation and conclusion of therapy to exclude ICH.

PURPURA FULMINANS

A unique clinical syndrome of neonatal DIC and purpura fulminans has been recognized and is related to the absence of protein C or protein S in the plasma. [94] [95] [96] [97] [98] [99] [100] [101] [102] [103] [104] Babies born with homozygous or double heterozygous deficiencies of either protein C or protein S present within a few hours to days of birth with rapidly progressive skin lesions and diffuse oozing from skin puncture sites. The skin lesions often begin at the site of heel or venous puncture for routine blood sampling. These lesions, which are initially red and flat, quickly become indurated and necrotic, form an eschar, and result in gangrene. Venous thromboses of the CNS, kidneys, and primary vitrea of the eyes, often with onset in utero, are common. Coagulation screening tests, which may be normal initially, will subsequently reveal typical evidence of DIC. Family studies document heterozygous deficiencies of protein C or protein S in both parents while the infant has undetectable protein. DIC and purpura fulminans associated with homozygous deficiency of protein C respond quickly and dramatically to fresh frozen plasma, 10 mL/kg infused every 812 hours. There are now several reports of successful treatment using a viral inactivated human plasma-derived protein C concentrate. [105] [106] [107] The plasma half-disappearance time of protein C given either as fresh frozen plasma or the concentrate is approximately 8 hours. [106] [108] If administered before the development of tissue necrosis, the lesions will begin to regress within a few hours. After establishment of the diagnosis and resolution of purpuric lesions, infants are maintained on oral anticoagulation with warfarin or long-term replacement therapy with protein C concentrate. Chapter 120 - Hypercoagulable States

Kenneth A. Bauer

INTRODUCTION

Major advances have been made in our understanding of the natural anticoagulant and fibrinolytic systems that regulate the activity of the hemostatic mechanism. However, it has been only during the last few years that this information has translated into being able to diagnose clinically relevant risk factors in substantial numbers of patients presenting with thrombosis. The impact of these clinical diagnostic advances has been most dramatic in younger patients with idiopathic venous thrombosis, in >50% of whom hereditary defects can be identified. Important strides have also been made in delineating the contribution of thrombotic risk factors to arterial thrombosis, but identification of the common risk factors for atherogenesis (e.g., smoking, hyperlipidemia, diabetes mellitus) retains primacy in the evaluation of such patients.

CLINICAL APPROACH

Differential Diagnosis

When approaching patients suspected of having an active thrombotic process or a thrombotic diathesis, it is useful to place them in one of two major categories. The first group has characteristics that suggest the presence of an inherited thrombotic disorder or a primary hypercoagulable state (Table 1201). These disorders result from mutations in single genes encoding a plasma protein component of one of the major natural anticoagulant mechanisms. The anticoagulant systems most frequently involved in the inherited hypercoagulable states include antithrombin III (AT III) in the heparan sulfate-AT III mechanism and protein C, protein S, and factor V (substitution of the amino acid Gln for Arg at amino acid 506, [1] termed factor V Leiden) in the protein C anticoagulant pathway (Fig. 1201). Elevations in plasma prothrombin levels in association with a G to A transversion at position 20210 in the 3-untranslated region of the prothrombin gene is a newly identified genetic risk

TABLE 120-1 -- Differential Diagnosis of the Patient Presenting with Thrombosis or a Thrombotic Diathesis

Inherited (Primary) Hypercoagulable States
Activated protein C resistance due to factor V Leiden mutation
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Prothrombin gene mutation (G to A transversion at position 20210 in the 3-untranslated region)
Dysfibrinogenemia (rare)
Acquired (Secondary) Hypercoagulable States
In association with physiologic or thrombogenic stimuli
Pregnancy (especially the postpartum period)
Immobilization
Trauma
Postoperative state
Advancing age
Estrogen use
Antiphospholipid syndrome or lupus anticoagulant
In association with other clinical disorders (Table 1202)
Hyperhomocysteinemia

Figure 120-1 A schematic diagram of the pathways that generate factor Xa and thrombin, and the natural anticoagulant mechanisms that regulate the activity of these enzymes.
Factor X can be activated by factor VIIa-tissue factor (TF) complex or the factor IXa-VIIIa-activated cell surface complex. Factor Xa binds to the factor Va on activated platelets and mediates the conversion of prothrombin to thrombin under physiologic conditions. During this pro-cess, the inactive F_{1+2} fragment is released from the amino terminus of prothrombin. Thrombin is then able to act on fibrinogen to form a fibrin clot; the initial step in this conversion results in the liberation of fibrinopeptide A.
Thrombin and factor Xa are inactivated by AT III bound to heparan sulfate molecules associated with the vascular endothelium, resulting in the formation of factor Xa/AT III and thrombin/AT III complexes. Protein C is activated by thrombin bound to the endothelial cell receptor thrombomodulin. Once activated, protein C functions as a potent anticoagulant by inactivating factors VIIIa and Va. Protein S enhances the binding of activated protein C to phospholipid-containing membranes and is able to accelerate the inactivation of factors VIIIa and Va by this enzyme. The complement component, C4b-binding protein (C4b-BP), forms complexes with protein S, which neutralizes its ability to serve as a cofactor for activated protein C in inactivating factors VIIIa and Va.

factor for venous thrombosis.[2] The second category, the acquired or secondary hypercoagulable states, consists of a heterogeneous group of disorders in which there appears to be an increased risk for developing thrombotic complications as compared to the general population (Table 1202). The pathophysiologic basis for the hypercoagulable state in most of these situations is complex and multifactorial. Hyperhomocysteinemia is a common laboratory abnormality that results in an increased risk in venous as well as arterial thrombosis. Plasma homocysteine levels are determined by genetic as well as environmental factors, the latter including primarily dietary intake of folic acid and vitamins B_{12} and B_6 . It is listed separately from the inherited thrombotic disorders because it may result from defects in several genes encoding different enzymes involved in the metabolism of the amino acid.

The inherited thrombotic disorders (Table 1201) have been almost exclusively associated with *venous thrombosis*. Although hereditary deficiencies of AT III, protein C, or protein S will be found in <10% of unselected patients presenting with venous thromboembolism (Table 1203), the likelihood of identifying these defects is increased several-fold by screening patients with initial thrombosis occurring prior to age 50, a family history of venous thromboembolism and recurrent venous thrombosis.[3] Resistance to activated protein C (due to factor V Leiden), the prothrombin gene mutation, and hyperhomocysteinemia are more prevalent defects, and therefore can also be found in significant numbers of patients with first episodes of idiopathic venous thrombosis after age 50 in the absence of a positive family history.[4] [5] [6] [7] [8] Testing for the presence of factor V Leiden, the prothrombin gene mutation, and hyperhomocysteinemia should therefore be considered in such patients.

Women with thrombosis in association with oral contraceptive use or pregnancy should also undergo thorough evaluation because a significant percentage will have an inherited disorder, especially the factor V Leiden mutation. [9] [10] [11] [12] [13] Patients with venous thrombosis in uncommon sites such as the portal, hepatic, mesenteric, and cerebral veins should also undergo a complete laboratory evaluation. Interestingly, patients with axillary vein thrombosis appear to have a low prevalence of hereditary defects, even in the absence of triggering risk factors. [14] The presence of indwelling venous catheters is the most common risk factor today

for upper extremity venous thrombosis, and patients with this complication generally do not warrant evaluation for an underlying hypercoagulable state.

Although the aforementioned classification of patients into hereditary or acquired categories is useful in directing the laboratory evaluation for hypercoagulability, it is simplistic in the sense that thrombosis frequently results from an interplay of

genetic and acquired factors. Patients with hereditary defects are at lifelong risk of developing thrombosis, and stimuli such as pregnancy, estrogen use, or surgery trigger thrombotic episodes in perhaps 50% of individuals. Also, defects in more than one coagulation protein are now being found in venous thrombosis patients due to the high background frequency in the general population of abnormalities such as factor V Leiden (6% in US Caucasians) [15] and the prothrombin gene mutation (2% in the

Figure 120-2 Venous thrombosis can be viewed as a multigene disorder in which susceptible patients will have one or more genetic mutations. Clinical events often occur when they are exposed to exogenous prothrombotic stimuli. *(Modified from Schafer,[22] with permission. © 1994 by the Lancet, Ltd.)*

Netherlands).[2] Such individuals have a more severe thrombotic diathesis than those with a single identifiable mutation. [8] [16] [17] [18] [19] [20] [21] Thus, thrombosis can be viewed as a multigene disorder in which susceptible patients will have one or more genetic mutations, with clinical events occurring when they are exposed to exogenous prothrombotic stimuli[22] (Fig. 1202). In many cases, however, the inciting precipitant to thrombosis is not reported by the patient and is therefore subclinical.

History and Physical Examination

A complete history is mandatory in evaluating patients with a recent or remote history of thrombosis. Details should be obtained regarding the age of onset, location of prior thromboses, and results of objective diagnostic studies documenting thrombotic episodes. The latter is critical because the clinical diagnosis of deep vein thrombosis, in particular, is notoriously inaccurate (Chap. 124). The patient should be carefully questioned about circumstances that were present proximate to the time of thrombosis that might have precipitated the event. These include surgical procedures, trauma, pregnancy, immobility, or estrogen administration. Women should be carefully questioned regarding prior use of oral contraceptives or hormone replacement therapy and obstetric history. An increased risk of recurrent fetal loss is associated with the presence of lupus anticoagulants or antiphospholipid antibodies as well as the hereditary thrombotic disorders. [23] [24] [25] [26] A family history is particularly important because a well documented history of venous thrombosis in one or more first-degree relatives strongly suggests the presence of a hereditary defect. The initial manifestation of a malignancy can be a thrombotic event, so inquiry should be made regarding the presence of constitutional symptoms (diminished appetite, weight loss, fatigue), pain, hematochezia, hemoptysis, or hematuria. It should be ascertained whether the patient has an underlying disease, such as cancer, collagen-vascular disease, a myeloproliferative disorder, atherosclerotic disease, or nephrotic syndrome, or takes synthetic or natural estrogens or drugs that can induce lupus anticoagulants such as hydralazine, procainamide, and phenothiazines. Recurrent thrombosis despite therapeutic anticoagulation with oral anticoagulants is common in patients with an occult neoplasm or recurrent cancer.

In the general physical examination, special attention should be directed to the vascular system, extremities, chest, heart, abdominal organs, and skin. Because venous thromboembolism may be the first manifestation of an underlying malignancy, rectal examination and stool testing for occult blood should be done and women should undergo a pelvic examination.

The hereditary thrombotic disorders include deficiencies of AT III, protein C or protein S, resistance to activated protein C due to factor V Leiden, the prothrombin gene mutation, and rare dysfibrinogenemias. The most common sites of thrombosis

in such patients are the deep leg veins, iliac veins, and pulmonary arteries. Thrombosis in mesenteric, portal, and cerebral veins as well as superficial thrombophlebitis has been described in some series of patients with these disorders. Typical precipitating factors for thrombosis in such patients include the postoperative state, immobilization, trauma, pregnancy, oral contraceptive use, and advancing age.

Patients with thrombosis should be questioned regarding their ethnic background. Factor V Leiden is rarely if ever found in aboriginal African, Native American, or Asian populations,[27] and a recent study determined that this mutation arose only 30,000 years ago in Causcasians in Europe.[28] This information should be considered in determining whether patients should be tested for this abnormality.

Laboratory Evaluation

Routine Laboratory Tests

The initial laboratory evaluation for patients with thrombosis should include a complete blood count, review of the peripheral blood smear, and serum chemistries including liver and renal function tests, and urinalysis.

Elevations in hematocrit or platelet count should lead to consideration of polycythemia vera and essential thrombocythemia in the differential diagnosis. These myeloproliferative disorders predispose patients to venous as well as arterial thrombotic events, particularly when the hematocrit or platelet count is not controlled by therapy. In addition, secondary polycythemia or secondary thrombocytosis may provide a clue to an underlying occult neoplasm that may itself be the predisposing factor to thrombosis. Leukopenia and thrombocytopenia are often found in paroxysmal nocturnal hemoglobinuria, a rare hematologic disorder characterized by chronic intravascular hemolysis with episodes of gross hematuria and a unique constellation of thrombotic complications. These occur almost exclusively in the abdominal venous network, including the mesenteric, hepatic, portal, splenic, and renal veins, and the cerebral venous circulation. The development of thrombosis and thrombocytopenia concurrent with heparin administration should always prompt consideration of the diagnosis of heparin-induced thrombocytopenia.

If the blood smear shows evidence of schistocytes, the differential diagnosis includes disseminated intravascular coagulation (DIC) and the thrombotic microangiopathies (thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome). Although bleeding is the most common coagulation problem in DIC, patients with malignancy can have a low-grade consumptive coagulopathy and can develop venous or arterial thrombosis. The latter can result from emboli arising from fibrin vegetations on the mitral or aortic valves (nonbacterial thrombotic endocarditis [NBTE]). A leukoerythroblastic picture with nucleated red blood cells or immature white blood cells on the peripheral smear should suggest the possibility of bone marrow involvement by tumor.

Patients with Budd-Chiari syndrome, which occurs when there is obstruction of the hepatic venous circulation, have ascites and hepatomegaly along with abnormal liver function tests. The nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, and hyperlipidemia. Renal vein thrombosis can complicate the course of up to one-third of such patients, but patients with nephrotic syndrome are prone as well to venous thrombosis in distant, common sites.

Patients with thrombosis should routinely undergo baseline coagulation tests, including prothrombin time and activated partial thromboplastin time (PTT). If the reagent used for the latter test is sensitive to the presence of lupus anticoagulants, this will provide an initial screen for this acquired abnormality. If the PTT is normal, the use of additional specialized clotting assays for the lupus anticoagulant may facilitate making this diagnosis in patients clinically suspected of having a lupus anticoagulant (Chap. 116). Some, but not all, patients with lupus anticoagulants have elevated titers of anticardiolipin antibodies. Patients with abnormal test results should be re-evaluated because lupus anticoagulants or elevated anticardiolipin antibody levels are generally considered to be risk factors for thrombosis only if the abnormalities persist over several months.

Tests for Specific Biologic Risk Factors

Clinical judgment must be exercised with regard to the scope of the evaluation. The decision as to which tests should be ordered is determined partly by the type of thrombotic event (Table 1204). Hereditary deficiencies of AT III, protein C, and protein S and activated protein C (APC) resistance due to the factor V Leiden mutation predispose principally to venous thrombosis. Although anecdotal reports suggest an association between arterial thrombosis and the inherited thrombotic disorders (particularly protein S deficiency), it is generally not recommended to test for these defects in such patients. The presence of a lupus anticoagulant/elevated antiphospholipid antibody titer or hyperhomocysteinemia, however, is a risk factor for venous as well as arterial thrombosis. Therefore, testing for these two defects is warranted in the latter group of patients, particularly when other factors predisposing to arterial thrombosis are absent.

Additional factors will guide the extent of the laboratory evaluation. Clinical features that increase the likelihood of identifying patients with deficiencies of AT III, protein C, and protein S include an initial venous thrombotic event before age 50, recurrent thrombosis, or positive family history. These features also increase the chances of identifying patients with factor V Leiden and the prothrombin gene mutation, although these genetic defects can also frequently be identified in older patients with an initial episode of deep venous thrombosis who do not have acquired risk factors or a positive family history. It is also warranted to screen for all of these defects, hyperhomocysteinemia, and antiphospholipid syndrome/lupus anticoagulant in patients with thrombosis in unusual vascular beds (i.e., portal, hepatic, or mesenteric vein thrombosis, cerebral venous thrombosis).

Some clinical features have been associated with individual hereditary thrombotic disorders. Approximately one-third of patients who sustain the rare complication of warfarin-induced skin necrosis will prove to have underlying protein C deficiency; however, this syndrome has also been reported in patients with protein S deficiency[29] and factor V Leiden.[30] In newborn infants, the development of skin necrosis and visceral thrombosis (neonatal purpura fulminans) indicates a likely diagnosis of severe hereditary protein C deficiency, although there have been cases reported in association with homozygous protein S deficiency as well.[31] [32] Both conditions require emergent therapy if major morbidity or mortality in neonatal purpura fulminans is to be averted. Although resistance to heparins

[a] Coagulation assays are performed on platelet-poor plasma obtained from blood samples drawn into a solution containing 3.8% (wt/vol) sodium citrate. The ratio of anticoagulant to blood is 0.1:0.9 (vol/vol). In the absence of an accompanying clinical history for the patient, the performance of a prothrombin time will help to exclude the ingestion of warfarin, which will affect the measurements of protein C, protein S, and first-generation PTT-based assays for activated protein C resistance. Performance of a thrombin time as well as a PTT will help to exclude the administration of heparin.

anticoagulant effect, as measured by the PTT, often leads to consideration of AT III deficiency, congenital AT III deficiency is infrequently diagnosed in such patients.

Table 1205 gives a list of tests useful in screening patients suspected of having a biologic defect predisposing to thrombosis. Coagulation assays with high sensitivity and specificity for the factor V Leiden mutation are now widely available and are based on the resistance of the mutant factor Va molecule to inactivation by APC. Testing for the factor V Leiden mutation can also be done by analyzing DNA obtained from peripheral blood mononuclear cells. Testing for hyperhomocysteinemia should be done after an overnight fast when the patient is on a normal diet. Measuring increments in total plasma homocysteine 48 hours after an oral methionine load as well as fasting levels facilitates the identification of 10% more hyperhomocysteinemic patients and improved discrimination of affected subjects from controls. The homocysteine measurements are performed using ion-exchange chromatography, gas chromatography-mass spectrometry, or high-performance liquid chromatography with electrochemical or fluorescent detection.

The best screening tests for deficiencies of AT III, protein C, and protein S are functional assays that detect both quantitative and qualitative defects. Immunologic (antigenic) assays detect only quantitative deficiencies of these proteins. For plasma AT III, convenient functional assays are available that measure the heparin cofactor activity of the molecule. Among protein C assays, coagulation assays provide a more complete evaluation of the functional activity of the molecule than amidolytic assays. However, coagulation assays for protein C as well as protein S can give falsely low values if the factor V Leiden mutation is present, and reliable application of these assays therefore must initially assess whether this mutation is present. [33] Because factor V Leiden is much more commonly encountered than deficiencies of protein C or protein S, clinical laboratories often resort to measuring protein C activity by amidolytic assay and only perform immunoassays for total and free protein S. It is important to measure free protein S because some patients with hereditary protein S deficiency have low free levels with normal or borderline total protein S levels. To screen for a dysfibrinogenemia, the thrombin time is recommended along with measurements of plasma fibrinogen by clotting and immunologic assay.

Timing of Laboratory Testing

An important consideration in the laboratory evaluation of patients with a suspected deficiency of AT III, protein C, or protein S is the timing of testing. Erroneous diagnoses can be made due to the influence of acute thrombosis, comorbid illness, or anticoagulant therapy on the levels of these plasma proteins. Table 1206 provides a list of some of the common causes of acquired deficiencies of AT III, protein C, or protein S.

Acute thrombosis by itself can result in transiently reduced levels of AT III and occasionally protein C and protein S. Heparin therapy can be associated with up to a 30% decline in plasma AT III levels over several days, while warfarin produces a marked drop in the functional activity of protein C and protein S and a lesser decline in immunologic levels. Warfarin has also been shown to rarely elevate AT III levels significantly, sometimes into the normal range, in patients with a hereditary deficiency of this inhibitor. For these reasons, it is optimal to test for these deficiency states at least 2 weeks after completing the initial 36-month course of oral anticoagulant therapy following a thrombotic event. If, however, levels of AT III, protein C, or protein S are obtained on acute presentation that are well within the normal range, these will effectively exclude the diagnosis of their deficiency states from consideration. However, the finding of a low level during this period will need to be confirmed by repeat testing after anticoagulation is discontinued. The investigation of first-degree family members is useful to document the hereditary nature of the deficiency. Confirmation of a deficiency state in first-degree family members is particularly helpful diagnostically in patients in whom the risks of recurrent thrombosis are too great to temporarily discontinue anticoagulation. In such patients, a diagnosis of protein C or protein S can be confirmed by carrying out testing after warfarin has been discontinued for 2 weeks under the cover of intravenous or subcutaneous heparin at therapeutic doses.

The original PTT-based activated protein C-resistance tests were sensitive to the choice of reagents, instrument used for clot detection, and preanalytical conditions. Based on the choice of methodology, certain acquired conditions (e.g., elevated factor VIII levels, pregnancy, oral contraceptive use) could result in the phenotype of APC resistance, although it is not known whether this confers an increased risk of thrombosis. The original tests also could not be used to test patients with

lupus anticoagulants or those receiving heparin or oral anticoagulants because of the increased sensitivity of such plasmas to APC. The discovery that the APC-resistance phenotype was frequently due to the factor V Leiden mutation led to modifications in the original PTT-based activated protein resistance tests and prediluted patients plasma in factor V-deficient plasma. Such second-generation clotting assays have high sensitivity and specificity for the factor V Leiden mutation and can be used reliably in patients taking anticoagulants as well as most of the acquired conditions enumerated previously.

Other Coagulation Abnormalities

There has been renewed interest in elevated plasma factor VIII coagulant activity (VIII:C) as an independent marker of increased thrombotic risk. In a population-based case control study performed in the Netherlands, 25% of patients had levels of factor VIII coagulant activity (VIII:C) that were >150% of normal and they had an adjusted odds ratio of 4.8 for a first episode of venous thrombosis event as compared to individuals with levels under 100%. [34] Elevated VIII:C levels were also found in a similar proportion of English patients referred for evaluation of unexplained thrombosis. [35] This laboratory abnormality could not be attributed to overt inflammation because <10% of patients with VIII:C levels >150% had elevations in acute-phase reactants such as C-reactive protein, fibrinogen, and erythrocyte sedimentation rate. The levels of VIII:C were in reasonable concordance with factor VIII antigen concentrations, and it was postulated that the elevations result from a constitutive increase in synthesis or an exaggerated response to minimal inflammation. [35] Additional studies are required to determine the molecular basis underlying increased VIII:C concentrations and the clinical utility of measuring this parameter in patients with thrombosis.

There have been reports of thrombosis in association with abnormalities in other coagulation or fibrinolytic system proteins. These include heparin cofactor II deficiency,[36] [37] plasminogen deficiency (either hypoor dysplasminogenemias), factor XII deficiency, thrombomodulin mutations, and elevations in histidine-rich glycoprotein or plasminogen activator inhibitor-1 (PAI-1). However, causal associations between these abnormalities and an increased risk of thrombosis have not been clearly defined.[38] Thus, it is not currently recommended to test for these components.

Thrombosis in Association with Malignancy

Cancer is one of the most common acquired risk factors for venous or arterial thrombosis (Table 1202). The clinical manifestations that are attributable to the underlying neoplasm include deep venous thrombosis/pulmonary embolism, migratory superficial thrombophlebitis (Trousseaus syndrome), NBTE with arterial emboli, or thrombosis in the presence of chronic DIC. Thrombosis can also be associated with the administration of various chemotherapeutic agents. The occurrence of a clinical picture of a thrombotic microangiopathy can be due to the cancer itself or antineoplastic treatment, especially mitomycin-C.

Although thrombosis is most commonly encountered in the setting of advanced disease, deep venous thrombosis or pulmonary embolism can be the first sign of malignancy. In previously healthy patients presenting with a first episode of venous thrombosis, one should have a high index of suspicion for cancer because 1020% of such individuals will have cancer diagnosed at presentation or within the ensuing 24 months. [39] [40] [41] The most common sites of origin of cancer are the gastrointestinal tract, genitourinary organs, and lung. A complete medical history, physical examination including digital rectal examination and testing for fecal occult blood, pelvic examination in women, routine laboratory testing, and chest radiograph should be performed in all patients presenting with thrombosis. The presence of constitutional symptoms, unusual pain or bleeding, change in cough or hoarseness, or alterations in bowel or bladder habits warrants further diagnostic testing. It is controversial as to whether patients without any of the aforementioned symptoms or signs of neoplasia should undergo more detailed investigation including computed tomography or endoscopic evaluation. Although the literature contains studies indicating that up to 10% of patients with initial venous thrombotic episodes will have early stage cancers that were not detected by routine studies, no current data show that more aggressive diagnostic testing leads to improved survival or is cost effective. The development of recurrent idiopathic thrombosis following an adequate initial course of anticoagulant therapy is even more worrisome for an underlying cancer and warrants a thorough diagnostic evaluation. [40]

Although the treatment of acute thrombosis with heparin is usually effective in cancer patients, some will develop recurrences when they are switched over to oral anticoagulants despite a therapeutic International Normalized Ratio (INR). This scenario is particularly characteristic of cancer patients with metastatic or locally advanced disease that is refractory to antineoplastic therapy. Long-term anticoagulation with subcutaneous heparin at therapeutic doses is recommended to reduce the morbidity and mortality of thrombotic complications in such individuals.

Patients with Recurrent Thrombosis but Normal Laboratory Tests

Despite recent advances, there remains a substantial fraction of patients in whom we cannot uncover hereditary or acquired risk factors predisposing to thrombosis even after detailed laboratory evaluation (Table 1203). It is sometimes helpful for the clinician caring for such individuals to refer the patient to an appropriate specialist for review of the laboratory evaluation and consideration of additional work-up. Additional prothrombotic mutations will certainly be discovered in the future and specialists in the field will be knowledgeable as to the availability and relevance of new diagnostic developments prior to commercialization and wide clinical availability. In addition, assays are available that measure the extent of coagulation enzyme generation in the blood in vivo (e.g., prothrombin activation fragment F_{1+2}, thrombin-AT III complex, Fig. 1201), although these assays do not give information regarding the specific type of hypercoagulable state that is present. [42]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

INHERITED HYPERCOAGULABLE STATES

Patients with a tendency to thrombosis are defined as having thrombophilia, and the term inherited thrombophilia is applied to individuals with predisposing genetic defects.[43] [44] Prior to 1993, the diagnosis of a hereditary disorder could be established in only about 15% of patients under age 50 presenting with venous thromboembolism. The major disorders known at that time were deficiencies of AT III, protein C, or protein S. With the discovery that many patients with unexplained venous thrombosis have APC resistance due to the factor V Leiden mutation and more recently a prothrombin gene mutation, it is currently possible to define genetic risk factors in >50% of younger patients with idiopathic venous thrombosis. Hyperhomocysteinemia, which is determined by genetic as well as dietary factors, is a common risk factor for venous and arterial thrombosis.

AT III Deficiency

In 1965, Egeberg[45] described a Norwegian family in which certain individuals who had a history of thrombosis had plasma concentrations of AT III that were 4050% of normal. Subsequently,

other investigators described additional families with a similar constellation of clinical and laboratory abnormalities. [46] [47] [48] [49] [50] [51] [52] [53] [54]

Antithrombin III deficiency is usually inherited in an autosomal dominant fashion, and thus, affects both sexes equally. Two major types of inherited AT III deficiency have been delineated (Table 1207). The type I deficiency state is a result of reduced synthesis of biologically normal protease inhibitor molecules. [55] In these cases, the antigenic and functional activity of AT III in the blood are reduced in parallel. The molecular basis of this disorder is either a deletion of a major segment of the AT III gene or, more commonly, the occurrence of small deletions/insertions (<22 base pairs), or single base substitutions. These mutations will introduce a frameshift, a direct termination codon, a change in mRNA processing, or unstable translation products. The most recent update of the AT III mutation database includes 80 distinct mutations in patients with a type I deficiency.[56] The second type of AT III deficiency is produced by a discrete molecular defect within the protease inhibitor (type II). The plasma levels of AT III are greatly reduced as judged by functional activity, whereas AT III immunologic activity is essentially normal.

Using only an immunoassay for measuring AT III levels in the blood, initial estimates of the deficiency state in the general population were 1/2,0005,000. [57] However, recent studies using functional assays that measure AT III-heparin cofactor activity have found that the prevalence of AT III deficiency in the general population is 1/250500.[58] [59] The majority of the AT III-deficient patients identified in these studies did not have a personal or familial history of thrombosis and had a type II defect with mutations at the heparin-binding site (Table 1207).[60] On rare occasions, some of these molecular defects came to clinical attention when homozygous children of consanguinous parents who were asymptomatic carriers of such a defect developed severe venous or arterial thrombosis in association with plasma AT III-heparin cofactor levels of <10%.[61] [62]

Reviews of published cases of familial AT III deficiency indicate that 55% of affected patients experience venous thrombotic episodes. [63] [64] The initial clinical manifestations occur apparently spontaneously in about 42% of subjects, but are related to pregnancy, parturition, oral contraceptive ingestion, surgery, or trauma in the remaining 58% of patients.[63] The most common sites of disease are the deep veins of the leg and the mesenteric veins. Approximately 60% of individuals develop recurrent thrombotic episodes, and clinical signs of pulmonary embolism are evident in 40%. [63] Although cases have been reported in which AT III-deficient infants sustain cerebral venous thrombosis[54] [65] [66] affected children rarely develop thrombotic episodes before puberty. At this time, thrombotic events start to occur with some frequency and the risk of thrombosis increases substantially with advancing age. [63] The first family with a functional deficiency of AT III due to the presence of an abnormal protein (type II) was reported by Sas in 1974. [67] Many families with this type of deficiency state have now been reported and they have been further subcategorized on the basis of two different functional assays of AT III

TABLE 120-7 -- Assay Measurements in Heterozygous Antithrombin III (AT III) Deficiency

Types	Antigen	Activity	
		Heparin Cofactor	Progressive AT III
I	Low	Low	Low
II			
Active site defect	Normal	Low	Low
Heparin-binding site defect	Normal	Low	Normal

activity. The first is the AT III-heparin cofactor assay, which measures the ability of heparin to bind to lysyl residues on the inhibitor and catalyze the neutralization of coagulation enzymes such as thrombin and factor Xa. The second test is the progressive AT III activity assay, which quantifies the capacity of this inhibitor to neutralize the enzymatic activity of thrombin in the absence of heparin.

Heparin cofactor II is another protein in human plasma that exhibits heparin cofactor activity. [68] [69] [70] In contrast to AT III, this inhibitor does not inhibit factor Xa or other serine proteases and requires concentrations of heparin of at least 1 U/ml in the reaction mixture to function as an efficient inhibitor of thrombin; it therefore probably plays a minimal role when heparin is used clinically as an anticoagulant. [69] Because many functional AT III assays use heparin concentrations >1 U/ml, an assay based on factor Xa inhibition is likely to be more specific than one based on thrombin inhibition to identify patients with a congenital deficiency of AT III. [71]

The AT III-heparin cofactor and progressive AT III activity assays have identified AT III-deficient patients with reductions in heparin cofactor activity with or without concordant decrements in progressive AT III activity. Several abnormal AT III molecules have been identified with isolated reductions in heparin cofactor activity that have defects at a heparin-binding site (Table 1208). These variants generally have mutations at the amino terminal end of the molecule.[56] Variants with decreased activity in both AT III functional assays generally have mutations near the thrombin-binding site at the carboxy terminal end of the molecule (Table 1208).[56] All AT III variants cannot be neatly characterized by this schema because single amino acid substitutions can affect both functional domains of the molecule. This is perhaps best illustrated by a mutation in which arginine is replaced by histidine at residue 393. This mutation markedly decreases the ability of the protein to inhibit thrombin, but also leads to increased heparin affinity.

Another type of mutation has been described at the carboxy terminal end of the AT III molecule between amino acids 402429 (Table 1208). These type II variants are termed pleiotropic because they exhibit multiple functional defects.[56] In a large Utah family, trace amounts of an electrophoretically and functionally abnormal

inhibitor molecule have been identified. [72] Leucine is substituted for proline at position 407 in the AT III molecules of the affected members of this kindred. [73] [74] Small amounts of an electrophoretically abnormal inhibitor species have also been observed in the plasma of AT III-deficient members of the Oslo kindred first reported by Egeberg.[45] [75] In this case, threonine replaces alanine at position 404 in the abnormal protein. [76] Mutations at positions 402, 405, 406, and 407 apparently also lead to a similar type of defect.[56] The AT III-deficient subjects in the Utah and Oslo pedigrees appear, however, to have a type I deficiency state as determined by routine laboratory testing. The similar characteristics of these mutations suggest that the region of residues 402407 is important for the maintenance of normal plasma levels of AT III antigen.[74] The mutant inhibitor molecules synthesized by the liver of these deficient individuals may be susceptible to increased intracellular degradation, decreased extracellular export, or increased clearance on entry into the circulation. Finally, the mutation in the first reported AT III variant, Budapest, [67] is replacement of a proline by leucine at residue 429, leading to a molecular defect that affects both the heparin and thrombin binding sites. [77]

The prevalence of thrombosis appears to be different in heterozygous patients with type II defects at the heparin-binding site as compared to the thrombin-binding site.[78] Individuals with plasma AT III-heparin cofactor activity measurements of 50% and normal progressive AT III activity (heparin-binding site defects), have infrequent thrombotic episodes. In contrast to these observations, heterozygous type II patients with both diminished progressive AT III activity and AT III-heparin

TABLE 120-8 -- Point Mutations in Antithrombin III Deficiency (Type II)

City or Region of Propositus	Substitution	Effect of Mutation
Rouen 3	Ile 7 Asn	Defective heparin binding, new carbohydrate attachment site
Rouen 4	Arg 24 Cys	Defective heparin binding
Basel, Clichy, Dublin II, Franconville	Pro 41 Leu	Defective heparin binding

Budapest	Pro 429 Leu	

cofactor activity (thrombin-binding site defects) sustain venous thromboembolism as often as type I patients.

The mean concentration of AT III in normal plasma is 140 g/ml. In plasmas from normal individuals, the range of AT III concentrations as determined by immunologic or functional tests is reasonably narrow. Most laboratories report a normal range between 80% and 120% for AT III-heparin cofactor determinations and a somewhat wider range for immunoassay results. The AT III-heparin cofactor assay will detect all the different subtypes of the familial deficiency state currently recognized and is therefore the best single laboratory screening test for the disorder.

Healthy newborns have about half the normal adult concentration of AT III [79] [80] and gradually reach the adult level by 6 months of age. [81] The levels may be considerably lower in infants born after 3036 weeks of gestation [81] and are even further reduced in infants with respiratory distress, necrotizing enterocolitis, sepsis, or DIC.[82] Thromboembolic events are rare in children with hereditary AT III deficiency. In the absence of heparin, AT III contributes 80% of the thrombin-neutralizing capacity of normal adult plasma.[83] [84] The levels of a second thrombin inhibitor, $_2$ -macroglobulin, are higher during the first two decades of life than in adults, and this may lessen the risk of thromboembolic complications in AT III-deficient patients during childhood. [85]

A variety of pathophysiologic conditions can reduce the concentration of AT III in the blood (Table 1206). Acute thrombosis infrequently lowers AT III levels substantially, but DIC usually reduces the level of this inhibitor. Lowered AT III concentrations occur in patients with liver disease due to decreased protein synthesis. Decreased AT III levels are also observed in individuals with the nephrotic syndrome as a consequence of urinary excretion. [86] Furthermore, modest reductions in plasma AT III concentration are found in users of oral contraceptives [87] [88] as well as in individuals receiving estrogen for other purposes. [63] [89] The levels of AT III do

not change substantially during normal pregnancies, [87] [88] but may decrease significantly in women with pregnancy-induced hypertension, preeclampsia, or eclampsia.[90] Infusions of L-asparaginase, a chemotherapeutic agent used in the treatment of acute lymphocytic leukemia, can substantially lower the plasma concentration of this inhibitor. [91] In addition, the administration of heparin decreases plasma AT III levels, [92] presumably on the basis of accelerated in vivo clearance. Evaluation of plasma samples from patients during a period of heparinization can therefore potentially lead to an erroneous diagnosis of AT III deficiency.

Due to the number of clinical disorders that can be associated with reductions in the plasma concentration of AT III, definitive diagnosis of the hereditary deficiency state is often difficult. Although

---

an AT III level in the normal range is usually sufficient to exclude the disorder, low levels should be confirmed by obtaining another sample at a subsequent time. This determination is ideally performed when the patient is no longer receiving an oral anticoagulant because this medication has rarely been reported to raise plasma AT III concentrations into the normal range in individuals with the hereditary deficiency state. [47] Confirmation of the hereditary nature of the disorder requires the investigation of other family members. Diagnosis of other affected family members also allows for appropriate counseling regarding the need for prophylaxis against venous thrombosis.

Anabolic steroids such as stanozolol and danazol raise plasma AT III levels in individuals with normal [93] as well as with reduced levels of this inhibitor. [94] Despite this effect, these drugs have not been shown to prevent thrombosis in patients with hereditary AT III deficiency. [94]

Protein C Deficiency

In 1981, Griffin et al.[95] described the first kindred in which several individuals had plasma levels of protein C antigen of 50% of normal and a history of recurrent thrombotic events. Subsequently, other investigators[96] [97] [98] [99] [100] have reported numerous other families with heterozygous protein C deficiency.

Heterozygous protein C deficiency is inherited in an autosomal dominant fashion; a more severe form of protein C deficiency is an autosomal recessive disorder. The phenotype of patients with heterozygous protein C deficiency is similar to hereditary AT III deficiency. In severely affected families, 75% of protein C-deficient individuals experienced one or more thrombotic events. The initial episode occurs apparently spontaneously in 70%. The remaining 30% have the usual associated risk factors (pregnancy, parturition, contraceptive pill use, surgery, or trauma) at the time they develop acute thrombotic events. However, patients are infrequently symptomatic until their early twenties, with increasing numbers of individuals experiencing thrombotic events as they reach the age of 50. The most common sites of disease are the deep veins of the legs, the iliofemoral veins, and the mesenteric veins. Approximately 63% of affected patients develop recurrent venous thrombosis and 40% exhibit signs of pulmonary embolism.[101] There is a high frequency of superficial thrombophlebitis of the leg veins [97] as well as several cases of cerebral venous thrombosis in protein C-deficient patients. [102] There have also been reports of nonhemorrhagic arterial stroke in young adults with hereditary protein C deficiency.[103] [104] [105]

Miletich et al.[106] determined that the frequency of heterozygous protein C deficiency is 1/200300 in healthy adult blood donors, whereas Tait et al. [107] reported a prevalence of 1/500 in a healthy general population. None of the affected individuals in this population had histories of thrombosis prior to being tested. Although the inclusion criteria used for these studies do not permit estimation of the relative thrombotic risk conferred by protein C deficiency, they demonstrated that protein C deficiency can have markedly different clinical phenotypes depending on how patients are selected. The data also suggested that other factors modulate the phenotypic expression of heterozygous protein C deficiency, [108] which has become clear with the identification of other frequent prothrombotic mutations such as factor V Leiden. Data from the Leiden Thrombophilia Study indicate that individuals from the general population with heterozygous protein C deficiency have about a sevenfold increased risk of an initial episode of deep vein thrombosis as compared to normal subjects. [109]

Two major subtypes of heterozygous protein C deficiency have been delineated using immunologic and functional assays (Table 1209). The type I deficiency state is the most common form and is characterized by a reduction in both the immunologic and biologic activity of plasma protein C to 50% of normal. [101]

TABLE 120-9 -- Assay Measurements in Heterozygous Protein C Deficiency

Types	Antigen	Activity	
		Amidolytic	Coagulant
I	Low	Low	Low
II	Normal	Low	Low
	Normal	Normal	Low

Studies of the genetic defects in patients with protein C deficiency have led to the identification of more than 160 different mutations. [110] In individuals with type I deficiency, missense and nonsense mutations are most common.[110] [111] [112] In several Dutch families, the linkage between a rare polymorphism and a particular mutation with the deficiency state has indicated the presence of a founder effect. [113] Other types of mutations resulting in type I protein C deficiency include promoter mutations, splice site abnormalities, in-frame deletions, frameshift deletions, in-frame insertions, and frameshift insertions. [110] In families with a type II deficiency state, affected individuals have normal protein C levels on immunologic examination, yet possess lowered functional levels of the zymogen. The point mutations that have been identified in patients with type II protein C deficiency are shown in Table 12010 .[110] [114]

Warfarin-induced skin necrosis has been associated with the presence of heterozygous protein C deficiency. [115] [116] [117] This syndrome typically occurs during the first several days of warfarin therapy, often in association with the administration of large loading doses of the medication (Chap. 121). The skin lesions occur on the extremities, breasts, trunk, and the penis and marginate over a period of hours from an initial central erythematous macule. If a product containing protein C is not rapidly administered, the affected cutaneous areas become edematous, develop central purpuric zones, and ultimately become necrotic. Biopsies demonstrate fibrin thrombi within cutaneous vessels with interstitial hemorrhage. The dermal manifestations of warfarin-induced skin necrosis are clinically and pathologically similar to those seen in infants with purpura fulminans due to severe protein C deficiency.

The pathogenesis of warfarin-induced skin necrosis is attributable to the emergence of a transient hypercoagulable state. The initiation of the drug at standard doses leads to a decrease in protein C anticoagulant activity levels to 50% of normal within 1 day. [118] Although factor VII activity measurements follow a pattern similar to that of protein C, the levels of the other vitamin K-dependent factors decline at slower rates, consistent with their longer half-lives (Fig. 1203). Increased thrombin generation has been documented in patients during this early phase of warfarin therapy using a sensitive immunochemical assay for fragment F_{1+2}, an index of the in vivo activation of prothrombin mediated by factor Xa. [119] During this period, it therefore appears that the drugs suppressive effect on protein C has a greater influence on the hemostatic mechanism than its reduction in factor VII. These effects are likely to be augmented when >10 mg warfarin daily is administered to initiate oral anticoagulation or the patient has an underlying hereditary deficiency of protein C. Only approximately one-third of patients with warfarin-induced skin necrosis, however, have an underlying inherited deficiency of protein C, [120] and this complication is only infrequently reported in individuals with the heterozygous deficiency state. Case reports have also described this syndrome in association with an acquired functional deficiency of protein C, [121] heterozygous protein S deficiency, [29] and factor V Leiden. [30]

A clinical disorder exists in which newborns develop a syndrome described as purpura fulminans and laboratory evidence of DIC in association with protein C antigen levels <1% of normal. [122] [123] [124] [125] [126] In some instances, there was a history of consanguinity in the family, making it highly likely that the affected infants were homozygous for the deficiency state. [123] [124] [126] These newborns can also be double heterozygotes, as was demonstrated in a Chinese patient [125] who had a five-nucleotide deletion in one protein C allele and a missense mutation in the other. [127] The heterozygous parents of these infants infrequently had thromboses, in contrast to patients with thrombotic histories and a hereditary partial deficiency of protein C. There have also been a number of reported cases of older patients with homozygous or doubly heterozygous protein C deficiency who do not present with lesions resembling purpura fulminans. These individuals generally had protein C levels <20% of normal in the absence of oral anticoagulant therapy, and their clinical presentation was similar to that of severely affected subjects from thrombophilic kindreds with the heterozygous deficiency state. [128] [129] Genotyping of such homozygous individuals identified several missense mutations in the protein C gene; [130] [131] [132] [133] the variant protein C molecules produced by these individuals are either synthesized at a decreased rate or are rapidly cleared from the circulation. The parents of these subjects and infants with the so-called syndrome of purpura fulminans have a type I deficiency state.

In patients with heterozygous type I protein C deficiency, it has been of interest to determine whether the genetic basis for the disorder is different between symptomatic and asymptomatic individuals. Common mutations have been found among symptomatic and asymptomatic persons, [112] [133] [134] thereby implying that the nature of the protein C gene defect alone does not explain the marked phenotypic variability among type I patients.

A variety of immunologic and functional techniques have been developed to measure protein C levels in plasma samples. The most common procedures for antigen determination are electroimmunoassay, enzyme-linked immunosorbent assay, and radioimmunoassay. Functional assays have used either thrombin [135] or the thrombin/thrombomodulin complex [118] [136] [137] to activate protein C. Enzyme activity is then assessed using either a chromogenic substrate [135] [136] [137] or by measuring its anticoagulant activity in a factor Xa one-stage clotting assay. [118] The development of simpler functional assays has been facilitated by the observation that the venom of the Southern copperhead snake (*Agkistrodon contortrix*) is able to activate protein C in plasma. After activation of protein C by this venom, the enzymes amidolytic activity can be measured using a suitable chromogenic substrate, or its anticoagulant activity can be measured in a clotting assay.

Functional assays using amidolytic and clotting end points may give useful information regarding the nature of the molecular defect in patients with type II protein C deficiency. Several individuals have been described with normal protein C antigen measurements who have substantial reductions in protein C anticoagulant

Figure 120-3 Mean levels of protein C (PC) anticoagulant activity, factor VII activity, factor X activity, protein C amidolytic activity, and protein C antigen following the initiation of warfarin therapy in patients with deep venous thrombosis. Patients were maintained on heparin infusions and 10 mg warfarin was administered for the first 3 days. Dosages were subsequently adjusted based on the prothrombin time. Measurements are expressed as percentages of prewarfarin levels. *(From DAngelo et al., [116] with permission.)*

activity, but normal or near normal amidolytic activity. [116] These defects may potentially reflect a reduced ability of APC to interact with platelet membranes or its substrates such as factor V and factor VIII. The molecular abnormality in one of these families [138] is characterized by two -carboxyglutamic acid (Gla) domain mutations (Glu 20 to Ala and Val 34 to Met). On the other hand, abnormal protein C molecules that are normally activated by the thrombin/thrombomodulin complex, but fail to exhibit proteolytic activity as measured by amidolytic or anticoagulant assays have been reported. [139] [140] This suggests that the mutations reside near the active site of the protein.

Protein C circulates in human plasma at a concentration of 4 g/ml. The logarithms of the values for protein C antigen in healthy adults are normally distributed with 95% of the values ranging from 70140%. [106] There is no significant gender dependence, but mean protein C concentrations increase by 4% per decade. The relatively wide normal range of protein C measurements in the general population occasionally makes it difficult to identify a given individual as having heterozygous protein C deficiency. [141] If medical and pharmacologic causes of low levels are excluded, patients with a protein C value of <55% are very likely to have the genetic abnormality, whereas levels of 5565% are consistent with either a deficiency state or the lower end of the normal distribution. [106] To document the presence of protein C deficiency with confidence, it is therefore useful to obtain repeat laboratory determinations as well as to perform family studies to identify an autosomal dominant inheritance pattern.

Protein C levels in newborns are 2040% of normal adult levels. [142] [143] Preterm infants have even lower levels, [144] and babies with significant perinatal thrombosis can have levels suggestive of the homozygous deficiency state. [145] Acquired protein C deficiency (Table 1206) occurs in liver disease, severe infection and septic shock, DIC, adult respiratory distress syndrome, the postoperative state, breast cancer patients receiving cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) and in association with L-asparaginase therapy. A particularly severe form of acquired protein C deficiency has been reported in association with purpura fulminans and DIC in patients with acute viral or bacterial infections. [146] [147] [148] In contrast to AT III, the antigenic concentrations of vitamin K-dependent plasma proteins, including

protein C, are often elevated in patients with the nephrotic syndrome. Most uremic patients have low levels of protein C anticoagulant activity, but normal levels of protein C amidolytic activity and antigen. [149] This is attributable to a dialyzable moiety in uremic plasma that interferes with most clotting assays for protein C activity.[149]

Warfarin therapy reduces functional [118] [135] [136] and, to a lesser extent, immunologic measurements of protein C, [95] [96] making it difficult to diagnose individuals with heterozygous protein C deficiency in this setting. Several research laboratories have used a reduced ratio of protein C antigen to prothrombin or factor X antigen to identify patients with a type I deficiency state. [95] [96] This approach, however, can only be used in subjects in a stable phase of oral anticoagulation, and the diagnostic criteria for the disorder vary with the intensity of warfarin therapy. [96] Other groups have successfully used protein C activity assays in conjunction with functional measurements of factor VII, a vitamin K-dependent zymogen with a similar plasma half-life. [150] [151] In practice, it is preferable to investigate patients suspected of having the deficiency state after oral anticoagulation has been discontinued for at least a 1-week period and to perform family studies. If it is not possible to discontinue warfarin due to the severity of the thrombotic diathesis, such individuals can be studied while receiving heparin therapy, which does not alter plasma protein C levels.

An acquired inhibitor of protein C has been documented in an Australian patient. [152] This individual had a bleeding diathesis for several years and developed purpura fulminans before his death. An autopsy showed arterial and venous thrombi in many organs. Laboratory evaluation demonstrated the presence of chronic DIC. The IgG fraction of the subjects plasma completely inhibited the functional anticoagulant activity of APC.

The acute management of thromboembolic events in heterozygous protein C-deficient patients is similar to that of subjects without this disorder. It is advisable to keep the subject fully anticoagulated with heparin during the initiation of oral anticoagulation and large loading doses of the warfarin should be avoided. Oral anticoagulants are effective in managing individuals with protein C deficiency, and the recommendations for its use in such patients who have either sustained recurrent venous thrombosis or are asymptomatic are similar to those in patients with other inherited thrombotic disorders.

Stanozolol and danazol raise protein C levels substantially in heterozygous patients with type I protein C deficiency. [153] [154] However, these drugs do not prevent thrombosis in patients with this disorder, [154] and an increase in fragment F_{1+2} levels, a measure of the in vivo activity of factor Xa on prothrombin, has been observed in conjunction with the rise in protein C levels in two protein C-deficient patients who received stanozolol for 4 weeks. [153]

Protein S Deficiency

In 1984, members from several kindreds who exhibited reduced levels of protein S were described who had a striking history of recurrent venous thrombotic disease. [155] [156] Subsequently, many additional families with this disorder have been reported. [157]

Heterozygous protein S deficiency is inherited in an autosomal dominant fashion; a more severe form of protein S deficiency is an autosomal recessive disorder. The clinical presentation of patients with heterozygous protein S deficiency is similar to that outlined for AT III or protein C deficiency. Among 71 protein S-deficient members from 12 Dutch pedigrees, [158] 74%, 72%, and 38% of the individuals sustained deep venous thrombosis, superficial thrombophlebitis, or pulmonary emboli, respectively. The mean age of the first thrombotic event was 28 years with a range between 15 and 68; 56% of the episodes were apparently spontaneous and the remainder were precipitated by an identifiable factor. Thrombosis has also been reported in the axillary, mesenteric, and cerebral veins. Warfarin-induced skin necrosis has been described in a patient with heterozygous protein S deficiency. [29]

Several case reports have described young patients with arterial thrombosis and hereditary protein S deficiency. [159] [160] [161] In a cohort of 37 consecutive young adults presenting with arterial occlusive disease, 3 had hereditary protein S deficiency. [162] However, the occurrence of arterial thromboembolic events was not increased in protein S-deficient relatives of these people as compared to their biochemically unaffected family members.

Under normal conditions, 60% of the total protein S antigen in plasma is complexed to C4b-binding protein. Only the free 40% is functionally active as a cofactor in mediating the anticoagulant effects of activated protein C. [163] This observation has led to the development of methods for measuring total [156] [164] and free protein S antigen. [165] The most reliable measurements of total protein S antigen are by radioimmunoassay [164] and enzyme-linked immunosorbent assay techniques, which involve dilution of plasma samples and thereby favor dissociation of the protein S C4b-binding protein complexes. After removing protein S C4b-binding protein complexes from plasma by polyethylene glycol precipitation, [165] free protein S may be quantified by immunoassay of the supernatant fractions. It is also now possible to measure free protein S specifically using a monoclonal antibody-based immunoenzymatic assay that uses antibodies specific for the free form. [166] Functional assay methods are based

---

on the ability of protein S to serve as a cofactor for the anticoagulant effect of APC. [167] [168] Some of these assays, however, are not specific for protein S and are sensitive to the defect characterized by resistance to activated protein C, and their use can lead to an erroneous diagnosis of functional protein S deficiency. [33]

The classic type of protein S deficiency is associated with 50% of the normal total S antigen level, [156] [157] and more marked reductions in free protein S antigen and protein S functional activity [165] (Table 12011). The molecular genetic analysis of mutations in patients with protein S deficiency was initially complicated by the presence of a protein S pseudogene, [169] [170] but mutations can now be identified in 70% of thrombophilic families with protein S deficiency using mutation screening strategies. [171] Molecular analysis has identified only three cases of large deletions of the protein S gene. [172] [173] [174] Among 69 candidate causal mutations identified in patients with the classic type of protein S deficiency, 51% are missense mutations, 25% are microinsertions or deletions of base pairs, 14% are premature stop codons, and 9% affect a splice site. [171] Mutations in the protein S promoter have yet to be identified.

Another type of hereditary deficiency state has been described in which total protein S antigen measurements are in the normal range, but levels of free protein S and protein S functional activity are disproportionately reduced to <40% of normal (Table 12011). Although the mutations in the classic type of protein S deficiency are distributed throughout the coding sequence, it has only been possible to identify protein S gene mutations in 44% of patients with this phenotype raising the possibility that some cases represent acquired abnormalities. [171] Among French patients with the low free protein S phenotype in which mutations could be identified, 82% had a single mutation, Ser 460 to Pro, in the sex hormone-binding globulin domain of protein S. [175] The low free plasma protein S may result from increased binding of this abnormal protein S molecule to C4b-binding protein. [165] [176] It is not, however, clear that the Ser 460 to Pro mutation (also termed protein S Heerlen) is associated with an increase in thrombotic risk because it has been identified with similar frequency in Dutch patients with thrombosis (0.7%) and the general population (0.5%). [177] The situation is further complicated by a report of 14 Swedish thrombophilic families in whom laboratory evaluation demonstrated the coexistence of the classic deficiency state along with the low free protein S phenotype; this data led the authors to propose that the two types of protein S deficiency are phenotypic variants of the same genotype. [178]

A third type of protein S deficiency is characterized by normal total and free protein S levels, but diminished protein S functional activity (Table 12011). This phenotype has been identified infrequently, which suggests that current functional assays may not screen for all such defects. All five mutations found in such patients are located in the amino terminal end of the protein S molecule, which includes the domains that interact with APC. Two of the mutations are located in the propeptide at positions 2 (Arg to Leu) and 1 (Arg to His). [179] A substitution of Lys 9 by Glu has been identified, which may alter the conformation of protein S or interfere with carboxylation of the molecules -carboxyglutamic acid domain. [180] The other two mutations

TABLE 120-11 -- Assay Measurements in Heterozygous Protein S Deficiency

	Protein S Antigen		Protein S Activity
	Total	**Free**	
Classic	Low	Low	Low
	Normal	Low	Low
	Normal	Normal	Low

result in substitution of Thr 103 by Asn and Lys 155 by Glu in the first and second epidermal growth factor domains of protein S, respectively. [179] [181] [182]

Patients with recurrent venous thromboembolic disease in association with doubly heterozygous or homozygous protein S deficiency have been identified. [163] The parents of these patients were asymptomatic and had laboratory studies consistent with the heterozygous protein S-deficient state. The syndrome of neonatal purpura fulminans has also been described in association with homozygous protein S deficiency. [31] [32]

The average concentration of total protein S antigen in normal adults is 23 g/ml. [183] Levels increase with advancing age and are significantly lower and more variable in women than men.[184] [185] These factors have confounded the reliable estimation of the prevalence of heterozygous protein S deficiency in the normal population. Thus, it is difficult to make the diagnosis of heterozygous protein S deficiency by performing only a single assay. Repeat sampling as well as family studies are therefore usually required to establish the diagnosis firmly.

Acquired protein S deficiency (Table 1206) occurs during pregnancy[186] and in association with the use of oral contraceptives. [184] [187] Reduced protein S levels have also been noted in patients with DIC[188] [189] and acute thromboembolic disease.[189] C4b-binding protein is an acute-phase protein and the decline in protein S activity in the latter two conditions as well as in other inflammatory disorders is attributable to a shift of the protein to the complexed, inactive form. [189] The levels of total and especially free protein S are significantly reduced in men with human immunodeficiency virus infection. [190] Total protein S antigen measurements are generally increased in patients with the nephrotic syndrome, [191] [192] although functional assays give reduced values. This is, in part, due to the loss of free protein S in the urine and elevations in C4b-binding protein levels. Total and free protein S antigen concentration are moderately decreased in liver disease [164] [189] and in association with L-asparaginase chemotherapy. [193] An acquired severe deficiency of protein S has also been reported in association with cutaneous necrosis. [194] In a patient with thromboembolic disease recovering from chickenpox, a transient isolated deficiency of protein S has been reported due to the presence of an autoantibody. [195]

Interpretation of protein S measurements in individuals taking oral anticoagulants is complicated inasmuch as the antigenic and functional levels of the protein drop substantially. A few groups have used reductions in the ratio of protein S antigen to prothrombin antigen to infer a diagnosis of the classic type of protein S deficient state; this is accomplished by using a strategy similar to that described for protein C-deficient subjects. [156] [157]

Total protein S antigen values in healthy newborns at term are 1530% of normal, whereas C4b-binding protein is markedly reduced to <20%. Thus, the free form of the protein predominates in this setting and functional levels are only slightly reduced as compared to those in normal adults. [196]

The recommendations for the treatment of protein S-deficient patients with anticoagulants and thrombolytic agents are similar to those in individuals without this disorder. Heparin therapy is generally effective for the acute treatment of thrombotic episodes and standard warfarin schedules appear to be effective in preventing recurrent venous thromboembolism. Protein S concentrates have not yet been developed for clinical use. Anabolic steroids such as danazol or stanozolol have not been shown to have a role in the treatment of protein S-deficient patients.

APC Resistance

In 1993, Dahlbäck et al.[197] identified a novel mechanism for familial thrombophilia. They identified individuals with unexplained personal and familial histories of venous thromboembolism

---

whose plasmas exhibited a poor response to APC in a PTT assay. Recognized mechanisms for APC resistance were excluded, such as functional protein S deficiency or inhibitors to APC. Other clinically affected relatives of the probands demonstrated APC resistance in the PTT test, suggesting that the abnormality was hereditary. Poor anticoagulant responses to APC were also demonstrable in the probands in factor IXa- and factor Xa-based assays. Based on these observations, Dahlbäck hypothesized that these patients were deficient in an unrecognized plasma cofactor that functions in concert with protein S to support the anticoagulant activity of APC.

The observations of Dahlbäck facilitated the development of a PTT-based assay to screen for APC resistance. Svensson and Dahlbäck [198] screened 104 consecutive Swedish patients referred for evaluation of venous thrombosis and found that the plasmas of 33% of the subjects showed APC resistance (i.e., defined as an anticoagulant response in the PTT-based assay below the fifth percentile of controls). Precipitating factors for thrombosis, such as pregnancy and the use of oral contraceptives, were identified in 60% of their patients. Family studies revealed that relatives with APC resistance had a significantly higher frequency of thrombosis than relatives without the defect. In a US referral population of patients under age 50 with unexplained venous thromboembolic disease, Griffin et al. [199] found that 50% had APC resistance. Other groups in Italy and Austria confirmed that APC resistance was a frequent laboratory abnormality in patients with unexplained venous thrombosis.[33] [200]

A major contribution to our understanding of the molecular basis and clinical relevance of APC resistance was made by Dutch investigators from Leiden. In 1987, they initiated the Leiden Thrombophilia Study, a large case control study to investigate risk factors for first episodes of venous thrombosis in the general population of the Netherlands.[201] This effort grew from an attempt to define the true risk of venous thrombosis associated with protein C deficiency. There was a seeming paradox in that referred patients from families with protein C deficiency had a high frequency of venous thrombosis, but the deficiency state is present in 1/200500 healthy blood donors. The criteria for accruing subjects into these studies were felt to be a major factor underlying this difference.

Following the initial observations of Dahlbäck, the group in Leiden screened 301 unselected consecutive patients for APC resistance who had been entered into the Leiden Thrombophilia Study following the completion of anticoagulant therapy. [4] Entry criteria were a first episode of deep venous thrombosis in outpatients under age 70 with the diagnosis having been confirmed by objective testing. Patients with malignancy were excluded. Each thrombosis patient was matched with a healthy age- and sex-matched control. APC resistance was found in 21% of thrombosis patients and 5% of controls. Patients with APC resistance were calculated to have a sevenfold increased risk of venous thrombosis as compared to controls (Table 12012). The lower frequency of resistance to APC in this study as compared to other studies of referral populations cited earlier is primarily attributable to different selection criteria for the thrombosis cohorts.

A defect in factor V involving the mutation of arginine 506 to glutamine 506 (Arg 506 Gln or factor V Leiden) is most often the cause of APC resistance. [202] This is the site at which APC initially cleaves factor Va, and this sequence alteration makes the mutant factor Va molecule resistant to inactivation by the enzyme. [202] The Arg 506 Gln substitution was found to be the cause of APC resistance in about 90% of Dutch patients with APC resistance in the PTT assay, [202] and the mutation was found in 24% of healthy Dutch controls. Most patients with APC resistance are heterozygous for the factor V Leiden mutation, but a number of homozygous patients with heightened APC resistance in PTT assays have been identified. [202] [203] [204] Homozygotes are at higher thrombotic risk than heterozygotes (Table 12012)[204] [205]

TABLE 120-12 -- The Leiden Thrombophilia Study Data: Relative and Absolute Risks of an Initial Episode of Deep Venous Thrombosis in the General Population Due to Common Risk Factors

	Risk	Incidence/100 Person Years	Reference
Normal		0.008	
Hyperhomocysteinemia	2.5 ×	0.02	[7]
Prothrombin gene mutation	2.8 ×	0.022	[2]
Oral contraceptives	4 ×	0.03	[9]
Factor V Leiden heterozygotes	7 ×	0.057	[4]
Oral contraceptives + factor V Leiden	35 ×	0.285	[9]
Factor V Leiden homozygotes	80 ×	0.51	[205]

as are patients with heterozygous resistance to APC combined with mutations in the genes for protein C, AT III, and probably protein S. [16] [17] [18] [19] [20] The genes for factor V and AT III are both located on the long arm of chromosome 1, thereby allowing for coinheritance of the factor V Leiden mutation and an AT III mutation within all affected members of a family. This situation is expected to lead to an even more severe thrombotic diathesis. [20]

Mutations at the arginine 306 residue in factor V, the second APC site cleavage in the activated cofactor, have recently been reported. A 49-year-old male patient with proximal venous thrombosis and APC resistance in the absence of the factor V Leiden mutation was identified. [206] Sequencing demonstrated an Arg 306 Thr mutation in the patient and his mother, who had not suffered a thrombotic event. Mutations at the Arg 306 residue appear to be quite rare because this was the only mutation at this site among a selected cohort of 17 selected patients from an initial cohort of 602 individuals with venous thromboembolism. Two Chinese patients with prior histories of venous thrombosis have been identified with an Arg 306 Gly mutation in factor V. [207] However, this abnormality was not associated with APC resistance and was identified in 1 of 40 controls, thereby lending uncertainty as to its clinical importance. Thus far, no genetic abnormalities in the factor VIII gene have been identified to cause APC resistance in humans.

Although the factor V Leiden mutation is the dominant mechanism underlying APC resistance, data exist to support the original hypothesis of Dahlbäck that a second plasma cofactor supports the anticoagulant activity of APC. [197] [208] Factor V itself, but not purified factor Va, is able to enhance the inactivation of factor VIIIa by APC. [209] [210] Factor V Leiden is significantly less effective than normal factor V in mediating this effect. [211]

The US Physicians Health Study has also provided valuable data regarding factor V Leiden as a risk factor for venous thrombosis. In a retrospective case control study of 14,916 healthy men over age 40 with a mean follow-up of 8.6 years, heterozygosity for the factor V Leiden mutation was identified in 12% of subjects (14 of 121) with a first episode of deep venous thrombosis or pulmonary embolism and 6% of controls. [15] The relative risk of venous thromboembolism was increased 3.5-fold in those individuals with no other concomitant risk factors, but surprisingly was reduced to 1.7-fold in those with pre-existent cancer or recent surgery. This study also showed that elderly patients with venous thrombosis frequently have the mutation. [5] [15] Among men over age 60 with initial episodes of venous thrombosis and no identifiable triggering factors, 26% (8 of 31) were heterozygotes for factor V Leiden. [15]

Factor V Leiden-associated thrombotic risk appears to be quite dependent on the underlying clinical setting. Although oral contraceptives and pregnancy significantly increase the risk for venous thrombosis in women with the mutation, the

---

Physicians Health Study showed a 1.7-fold increased risk for an initial thrombotic event in men with pre-existent cancer or recent surgery, which was not statistically significant. [15] A retrospective study of 825 patients undergoing hip or knee replacement surgery, which is associated with a 1525% incidence of venous thrombosis despite antithrombotic prophylaxis, was unable to demonstrate an increased risk of venographically documented events postoperatively among patients with the factor V Leiden mutation. [212] Several groups have also noted that the prevalence of the mutation is lower among patients with isolated pulmonary embolism than venous thrombosis of the legs. This seeming paradox may be explained by the fact that patients with pulmonary emboli more frequently have pre-existing medical illness or have undergone recent surgery where the factor V Leiden mutation does not add much to the underlying thrombotic risk.

There has been considerable interest in determining whether a prevalent prothrombotic risk factor such as factor V Leiden leads to an increased risk for arterial events. There are no convincing data that other thrombophilic states such as deficiencies of AT III, protein C, and protein S confer an increased risk of arterial thrombosis, but evaluation of this association is complicated by the relative infrequency of these defects. In a cohort of men over age 40 in which there was a low prevalence of smoking, the Physicians Health Study did not find an association between the factor V Leiden mutation and myocardial infarction or stroke. In a younger cohort of Italian patients with myocardial infarction before age 45, an increased incidence of the factor V Leiden mutation also was not found vis à vis controls. [213] Furthermore, a report of 36 French homozygous patients with the mutation did not identify a tendency for the development of arterial thrombosis. [214]

However, recent data from a case control study suggest that heterozygosity for factor V Leiden is a risk factor for a myocardial infarction in young women (1844 years old) but only in the presence of other cardiac risk factors. [215] The presence of the factor V Leiden mutation was associated with a 2.4-fold increased risk of myocardial infarction after adjustment for age (8 of 79 or 9.5% of patients with myocardial infarction as compared to 4.1% in controls). The risk of myocardial infarction associated with factor V Leiden, however, was observed only among current cigarette smokers in whom the mutation conferred a threefold increased risk. In comparison to women who did not smoke and did not carry factor V Leiden, women who smoked and carried the mutation had a 30-fold increased risk of myocardial infarction. Interestingly, while other cardiac risk factors such as older age, obesity, hypercholesterolemia, hypertension, diabetes, family history of ischemic heart disease, and postmenopausal status (surgically induced) were associated with cardiac events, the use of low-dose oral contraceptives was not. Data from this cohort indicate that the prothrombin gene mutation is also a risk factor for myocardial infarction, but again only in current cigarette smokers. [216]

The prevalence of heterozygosity for the factor V Leiden mutation in Caucasians, including European, Jewish, Israeli Arab, and Indian populations, ranges from 1% to 8.5%. The mutation is apparently not present in African blacks, Chinese, Japanese, or Native American populations. [27] Using dimorphic sites in the factor V gene to do haplotype analysis, Zivelin et al. [28] provided data for the existence of a founder effect as the basis for the mutation in Caucasians of differing ethnic background. It was estimated that the mutation originated approximately 30,000 years ago, which came after the evolutionary divergence of Caucasian, African, and Oriental populations. [28]

There have been reports of patients in whom there is cosegregation of heterozygous APC resistance due to the factor V Leiden mutation and type I factor V deficiency. [217] [218] [219] [220] The plasma of these individuals manifests severe APC resistance in PTT assays similar to homozygous factor V Leiden patients (i.e., they are pseudohomozygous). These patients were seemingly more prone to thrombosis than heterozygous relatives with factor V Leiden alone, suggesting that their clinical phenotype is similar to homozygous factor V Leiden patients.

Several polymorphisms are present in the factor V gene. [221] [222] Two amino acid substitutions, Leu 1257 IIe and His 1299 Arg, and a codon dimorphism for Ser 1240 are present in exon 13, which codes for the proteins B domain and is removed on activation. [221] In an Italian population, the frequency of the allele encoding Arg 1299 (R2) was 30% in patients with partial factor V deficiency and 7.5% in control subjects. [221] An extended factor V gene haplotype (HR2) containing the R2 polymorphism, distinct from that encoding Arg 506 Gln, contributes to a mild APC resistant phenotype; [222] it also contains nucleotide transversions resulting in the amino acid substitutions, Arg 830 Lys and Arg 837 His. Despite its association with mild APC resistance and its increased frequency in factor V Leiden-positive patients with the lowest APC resistance ratios, the HR2 haplotype has not yet been shown to confer an increased risk of venous thrombosis.

The initial observations of Dahlbäck [197] facilitated the development of a PTT-based assay that serves as a screening test for APC resistance. The PTT is performed in the presence or absence of a standardized amount of APC, and the two clotting times are converted to an APC ratio. Results can be interpreted by comparing the ratio to the normal range, or by normalizing it to the APC resistance ratio obtained using normal pooled plasma. Although this first-generation APC resistance assay was conceptually simple and easy to perform in a coagulation laboratory, it required careful standardization and determination of the normal range in at least 50 controls. The level of APC, the PTT reagent, and the instrumentation used for clot detection affected the performance characteristics of the assay. Some assays using this format, therefore, had inadequate sensitivity and specificity for the factor V Leiden mutation. Also, patients receiving anticoagulants or with an abnormal PTT due to other coagulation defects could not be investigated with this assay, and the test was not validated in patients with acute thrombotic events or pregnant women.

The discovery that factor V Leiden apparently underlies nearly all cases of APC resistance facilitated second-generation coagulation tests that with proper standardization can give nearly 100% sensitivity and 100% specificity for the mutation. This was achieved by diluting patient plasma in a sufficient volume of factor V-deficient plasma and then performing either a PTT-based assay or a tissue factor-dependent factor V assay. [223] This modification also permits the evaluation of plasmas of patients receiving anticoagulants or with abnormal PTT results due to coagulation factor deficiencies other than factor V.

The fact that the dominant mutation underlying APC resistance is factor V Leiden also makes it attractive to diagnose this defect by analyzing genomic DNA in peripheral blood mononuclear cells. This can be readily accomplished by amplifying a DNA fragment containing the factor V mutation site by polymerase chain reaction (PCR) and analyzing the cleavage products on ethidium bromide-stained agarose gels after restriction enzyme digestion with MnlI. [202] The substitution of an A for a G at nucleotide 1691 in the factor V cDNA (CGA to CAA) results in the Arg 506 Gln mutation and the loss of a MnlI cleavage site. Other diagnostic approaches include hybridization with allele-specific oligonucleotide probes.

At present, the most cost-effective approach to diagnosing patients with factor V Leiden is to test for APC resistance using a second-generation coagulation assay. Patients with low APC resistance ratios should then be genotyped for the mutation although it can be argued that such confirmatory testing is unnecessary in labs that have perfect concordance between the results of their APC resistance assays and factor V Leiden genotype.

2023

Leiden mutation can be identified. The clinical implications of this type of APC resistance are uncertain. The use of such assays to identify such individuals is therefore best restricted to thrombosis research centers. Two groups, however, have reported individuals with cerebrovascular disease in association with APC resistance that is not due to the factor V Leiden mutation.[224] [225] In one of the studies, the investigators divided patients into five categories of responsiveness to APC as opposed to the usual practice of using a cut-off value for optimal separation of carriers and noncarriers of the mutation. [225] Statistical analysis showed that a low response to APC was associated with an increased risk of cerebrovascular disease independent of the factor V Leiden mutation.

The acute management of thrombosis in patients with APC resistance is no different than other patients. Due to the prevalence of this disorder, data have emerged regarding the recurrence risk following an initial venous thrombotic episode in association with the factor V Leiden mutation. This information, along with its implications with respect to long-term anticoagulation in such individuals, is presented in the following sections.

Prothrombin Gene Mutation

In 1996, investigators from Leiden reported that a G to A substitution at nucleotide 20210 in the 3-untranslated region of the prothrombin gene is associated with elevated plasma prothrombin levels and an increased risk of venous thrombosis.[2] This mutation, which was discovered by directly sequencing the prothrombin gene of selected patients with venous thrombosis, is located at the last position of the 3-untranslated region at or near the cleavage site for polyadenylation of prothrombin mRNA. There is not yet experimental evidence whether this mutation results in increased prothrombin biosynthesis by the liver or whether it is linked to another sequence variation in the prothrombin gene that was not detected by sequence analysis. In any case, it is likely that the increased thrombotic risk is attributable to the elevated plasma prothrombin concentration.

Investigation of a referral population with a personal and family history of venous thrombosis demonstrated that 18% had the mutation in the 3-untranslated region of the prothrombin gene while it was present in only 1 of 100 healthy controls.[2] Among these thrombosis patients, 40% also carried the factor V Leiden mutation, again emphasizing the current view of venous thrombosis as a multigene disorder.

In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the prothrombin gene mutation.[2] This mutation independently confers a 2.8-fold increased risk of venous thrombosis (Table 12012) and the effect is operative in both sexes and all age groups. Among heterozygotes with the prothrombin gene mutation, 87% of thrombosis patients and controls in the study had prothrombin activity levels that were >1.15 U/ml, whereas only 23% of those with a normal prothrombin genotype were elevated to this degree. Additional studies have confirmed that the prothrombin 20210 mutation is a common risk factor for venous thrombosis in unselected outpatients as well as patients with other inherited thrombotic disorders.[226] [227] [228] [229] The allele frequency of 1.2% for the prothrombin gene mutation in the Dutch population is approximately half that of factor V Leiden, making it the second most common genetic risk factor for venous thrombosis.

Dysfibrinogenemias

Qualitative abnormalities of fibrinogen are usually inherited in an autosomal dominant manner. The dysfibrinogenemias are a heterogeneous group of disorders that may present with either no clinical symptoms, a bleeding diathesis, or a history of recurrent venous or arterial thromboembolism.[230] Fewer than 20 cases of variant fibrinogens have been reported to be associated with thrombotic complications. These defects can be detected with thrombin and reptilase times, which are often prolonged. In one instance, the thrombin time has been substantially shortened.[231] [232] Functional fibrinogen measurements are usually substantially lower than antigenic measurements in the plasmas of these individuals. An occasional individual with a dysfibrinogemia may have a prolonged prothrombin time or PTT, and the inability of some abnormal fibrinogens to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests.

The functional and biochemical defects of a number of abnormal fibrinogens associated with thromboembolic disease have been characterized.[230] The conversion of fibrinogen to fibrin by thrombin results in the proteolytic cleavage of fibrinopeptides A and B from the molecule. Defects in the release of these two peptides [233] [234] [235] [236] [237] or abnormalities in fibrin polymerization [238] [239] [240] have been reported. Such functional defects do not, however, offer a ready explanation for the thrombotic diathesis seen in these subjects. Abnormalities in the binding of thrombin to fibrin have also been found in some dysfibrinogenemias. [241] [242] [243] In one of these kindreds, three homozygous siblings with a B chain substitution of Ala by Thr at position 68 had a severe clinical phenotype sustaining both arterial and venous thrombosis at a young age.[243] [244] It has been suggested that decreased binding of thrombin by this mutant fibrinogen may lead to the presence of excessive thrombin in the circulation and the occurrence of thrombosis.[244] Other fibrinogen mutants have been shown to cause abnormal fibrin polymerization.[238] [239] [240] [242] Some of the abnormal fibrinogens have been evaluated for their ability to resist or promote fibrinolysis on incorporation into a fibrin clot. The fibrin formed from fibrinogen Chapel Hill III has been demonstrated to be abnormally resistant to lysis by plasmin.[238] Plasminogen activation is decreased in the presence of the fibrin formed from fibrinogen Dusart, despite normal tissue-type plasminogen activator binding to the substrate.[245] [246] [247] [248] These abnormalities clearly have the potential for decreasing fibrinolytic activity in vivo, which results in a familial thrombotic diathesis in biochemically affected persons.

Inherited Abnormalities of Fibrinolysis

Although investigators have identified a few individuals with inherited abnormalities of the fibrinolytic mechanism and recurrent venous thromboembolism, the clinical association is considerably less striking than that in many kindreds with deficiencies of AT III, protein C, or protein S, or with APC resistance due to the factor V Leiden mutation and the prothrombin gene mutation. Dysplasminogenemia or hypoplasminogenemia has been reported in approximately 20 individuals with thromboembolic disease. The first case of an abnormal plasminogen was identified in Japan by Aoki et al.[249] The propositus had a history of recurrent thrombosis and family studies demonstrated that the biochemical abnormality followed an autosomal dominant inheritance pattern. Despite the hereditary nature of the defect, none of the other biochemically affected members of the kindred had thrombotic events. Other Japanese pedigrees without thrombosis have since been described with the same biochemical defect,[250] [251] and the gene frequency of this abnormality in Japan is 0.018.[252] Population studies in the United States have not uncovered any cases of this dysplasminogenemia. A study of two unrelated Japanese families with reduced functional and antigenic levels of plasminogen was unable to demonstrate a significant correlation between the deficiency state and thrombosis.[253] The non-Japanese cases of dysplasminogenemias and hypoplasminogenemias have also been remarkable for the lack of thrombotic episodes in biochemically affected family members other than the propositi.

A few reports have documented the existence of thrombophilic families with inherited abnormalities of fibrinolysis.[254] [255] [256]

2024

Individuals from these kindreds were initially observed to have reduced fibrinolytic potential after venous occlusion, [254] and subsequently they were noted to have high levels of PAI. Re-evaluation of two of these families [254] [255] [256] has recently demonstrated the presence of hereditary protein S deficiency and no association between PAI-1 activity and a history of thrombosis.[257] [258] These data provide further evidence that the association between defective fibrinolysis and familial thrombosis has not been established.[259] [260]

Immunochemical methods for the measurement of tissue-type plasminogen activator and functional assays for its inhibitors have been applied to the study of patients with documented venous thromboembolism. These studies have suggested that defective synthesis or release of tissue-type plasminogen activator, as well as increased levels of PAI-1 may be important pathogenetic factors in as many as one-third of these individuals.[261] [262] [263] [264] Reduced fibrinolytic activity due to increased plasma levels of a rapid inhibitor of tissue-type plasminogen activator has been found in young survivors of myocardial infarction. [265] [266] The measurements of this inhibitor correlated strongly with serum concentrations of triglycerides.

Factor XII Deficiency

Factor XII is the zymogen of a serine protease that initiates the contact activation reactions and intrinsic blood coagulation in vitro. The first patient with a deficiency of

factor XII, or Hageman factor, was reported by Ratnoff and Colopy in 1955. [267] Subjects with severe factor XII deficiency (factor XII activity <1% of normal) have markedly prolonged PTTs, but do not exhibit a bleeding diathesis. [268] The absence of a hemostatic defect in patients with a severe deficiency of factor XII, prekallikrein, or high-molecular-weight kininogen indicates that these factors are not required for in vivo hemostasis. However, there have been a number of cases of venous thromboembolism or myocardial infarction in factor XII-deficient patients, [269] including the initial patient described with the abnormality. [270] This thrombophilic tendency has been attributed to reduced plasma fibrinolytic activity. [271] A literature review of data on 121 patients with factor XII deficiency found an 8% incidence of thromboembolism, including several myocardial infarctions in relatively young individuals. [269] Interpretation of such data is difficult because such complications are likely to be reported in the literature as compared to the asymptomatic patient with factor XII deficiency. This has led some groups to perform cross-sectional analyses of thromboembolic events in larger numbers of unselected families with factor XII deficiency. [272] [273] In Swiss families with factor XII deficiency, 2 of 18 homozygous or doubly heterozygous patients had sustained deep venous thrombosis, although each occurred at a time that other predisposing thrombotic risk factors were present. [272] Among heterozygotes with factor XII deficiency, only 1 of 45 heterozygotes had a possible history of venous thrombosis. These investigators concluded that heterozygous factor XII deficiency does not constitute a major thrombotic risk factor, whereas a severe deficiency may predispose some affected persons to venous thrombosis. Other groups have found a 1020% incidence of thrombotic episodes in heterozygotes. [273] [274] Thus, it remains uncertain as to whether an increased thrombotic risk is associated with factor XII deficiency.

Thrombomodulin Mutations

The thrombomodulin gene is a potential candidate for prothrombotic mutations. A patient with a single episode of pulmonary embolism and his asymptomatic son were found to have a point mutation in the thrombomodulin gene resulting in Asp 468 Tyr. [275] Other mutations identified in the thrombomodulin gene of individual thrombophilic patients predict for Pro 483 Leu, Gly 61 Ala, and Asp 468 Tyr amino acid substitutions. [276] Additional studies are required to evaluate whether these mutations alter the structure of thrombomodulin in such a way as to either reduce its cell surface expression or functional activity as well as to determine whether thrombomodulin mutations increase the risk of thrombosis.

HYPERHOMOCYSTEINEMIA

Although premature atherosclerosis and arterial thrombosis were known to be associated with severe hyperhomocysteinemia almost 30 years ago, [277] it has only been in the last several years that mild or moderate hyperhomocysteinemia has been established as an independent risk factor for atherosclerosis as well as thrombosis.[278] [279]

Homocysteine is an amino acid that is formed from methionine (Fig. 1204). It is converted back to methionine by one of two remethylation pathways or undergoes transulfuration to cysteine. In remethylation catalyzed by the enzyme methionine synthase, homocysteine acquires a methyl group from 5-methyltetrahydrofolate and vitamin B_{12} (cobalamin) acts as a cofactor. In a secondary pathway, betaine is the methyl donor in a reaction catalyzed by betaine-homocysteine methyltransferase. In transulfuration, homocysteine condenses with serine to form cystathionine in a reaction catalyzed by cystathionine--synthase followed by hydrolysis by the enzyme -cystathionase to cysteine and -ketobutyrate. Vitamin B_6 (pyridoxine) is a cofactor in both of these reactions.

The normal plasma homocysteine concentration is 516 M. As a result of impaired intracellular metabolism of homocysteine, increased amounts of the amino acid accumulate in the blood, leading to hyperhomocysteinemia. Homocystinuria refers to a group of rare inborn errors of metabolism resulting in severe hyperhomocysteinemia (>100 M) and the excretion of high levels of homocysteine in the urine. The most frequent cause is homozygous cystathionine--synthase deficiency, which has a frequency in the general population of approximately 1/250,000. [280] Affected individuals exhibit premature atherosclerosis and venous thromboembolism along with mental retardation, ectopic lenses, and skeletal abnormalities. A small number of cases are due to homozygous defects encoding

Figure 120-4 Intracellular metabolism of homocysteine occurs through remethylation to methionine or transulfuration to cysteine. Numbered circles indicate the enzymes involved: 1, methionine synthase; 2, methylenetetrahydrofolate reductase (MTHFR); 3, betaine-homocysteine methyltransferase; 4, cystathionine beta-synthase. *(From De Stefano et al.,[276] with permission.)*

methylenetetrahydrofolate reductase (MTHFR), and these individuals are similarly afflicted with premature vascular disease and thrombosis along with neurological problems.

Mild (1624 M) or moderate (25100 M) hyperhomocysteinemia results from genetic and acquired abnormalities. Although heterozygous cystathionine--synthase deficiency is found in only 0.3% of the general population, a MTHFR variant with an alanine to valine substitution at amino acid 677 is more common [281] and can be present in 1.415% of the population depending on their origin. [279] This mutation causes thermolability of MTHFR and a 50% reduction in its specific activity. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B_{12} , folate, or vitamin B_6 , which are cofactors in homocysteine metabolism. A strong inverse correlation exists between hyperhomocysteinemia and folate levels and to a lesser extent with vitamin B_{12} and B_6 concentrations.[6] Elderly patients frequently have elevated plasma homocysteine concentrations even in the absence of vitamin deficiencies as do patients with renal failure. Cigarette smoking is also associated with acquired hyperhomocysteinemia.

The mechanisms by which hyperhomocysteinemia acts as an atherogenic and thrombogenic risk factor have only been partially elucidated, but the major effect is on the vessel wall. In vitro, homocysteine is able to promote vascular smooth muscle cell proliferation [282] and inhibit endothelial cell growth. [283] In primates, it was shown that the infusion of homocysteine causes endothelial cell desquamation, smooth muscle cell proliferation, and intimal thickening. [284] Recent data indicate that moderate hyperhomocysteinemia induced by dietary manipulation leads to vascular dysfunction with impaired vasomotor responses as well as decreased thrombomodulin activity in the aorta.[285] The thrombogenic effects of hyperhomocysteinemia that have been demonstrated in vitro include induction of tissue factor expression,[286] inhibition of heparan sulfate expression, [287] inhibition of nitric oxide and prostacyclin release, [288] [289] inhibition of tissue-type plasminogen activator binding,[290] and inhibition of thrombomodulin-dependent protein C activation. [291] [292] However, most of these studies were carried out at homocysteine concentrations that were considerably higher than are encountered in patients with severe hyperhomocysteinemia, thereby raising questions about their relevance to the prothrombotic diathesis associated with this defect.

Hyperhomocysteinemia is usually diagnosed by measuring plasma levels of homocysteine by high-pressure liquid chromatography. Although patients with homozygous homocystinuria due to cystathionine--synthase deficiency have levels >100 M, individuals with heterozygous defects in this gene or inadequate vitamin B_6 levels may have normal or only slightly elevated levels of fasting homocysteine. The discrimination of such patients from normal individuals can be improved by demonstrating an abnormal increase in plasma homocysteine 4 hours after an oral methionine load. Defects in the remethylation pathway due to MTHFR gene defects or inadequate folate or vitamin B_{12} levels tend to cause elevated homocysteine levels under fasting conditions. The prevalence of hyperhomocysteinemia is almost twice as high when based on homocysteine measurements performed after methionine loading as when based on fasting levels. It is also possible to test for the common Ala 677 Val mutation in MTHFR genetically, but this is not recommended in the initial evaluation of patients suspected of having hyperhomocysteinemia.

Mild or moderate hyperhomocysteinemia due to inherited enzyme defects or acquired vitamin deficiencies is an independent risk factor for myocardial infarction, stroke, and carotid arterial disease. [293] [294] [295] Case control studies have found that up to 40% of patients with atherosclerotic coronary or cerebrovascular disease have mild to moderate elevations in plasma homocysteine. Prospective data have shown that elevated plasma homocysteine concentrations predict for coronary events and especially mortality among patients with established coronary artery disease. [296] An association between fasting plasma homocysteine levels and arterial thrombotic events has also been shown prospectively in patients with systemic lupus erythematosus (SLE). [297]

A relationship between hyperhomocysteinemia and venous thrombosis is also now appreciated. Studies of patients with an initial episode of venous thrombosis prior to age 45 demonstrate that 1318% have moderate hyphomocysteinemia based on homocysteine measurements done fasting and following an oral methionine load.[298] [299] Many of these patients had a history of familial thrombosis in association with hyperhomocysteinemia. A Dutch study showed that 25% of patients with recurrent venous thrombosis had homocysteine levels above the 90th percentile of the control distribution, and the presence of this abnormality conferred a twofold increased risk of recurrence. [300]

Case control studies have provided strong evidence that hyperhomocysteinemia is also an independent risk factor for initial episodes of venous thrombosis in the general population. These studies did not perform homocysteine levels after methionine loading and in some instances did not even obtain homocysteine levels in the fasting state, thereby underestimating the disorders prevalence. In the Leiden Thrombophilia Study, an elevated homocysteine level exceeding the 95th percentile of the control group was found in 10% of patients and conferred a 2.5-fold increased risk of thrombosis (Table 12012). [7] However, only women over age 50 showed a statistically significant association, although a trend was present in both sexes and all age groups. In an older male population, the Physicians Health Study

demonstrated a weak association between total plasma homocysteine level and venous thromboembolism but this was confined to those with so-called idiopathic events.[8] The risk of thrombosis was increased 20-fold in patients with idiopathic thrombosis who were both hyperhomocysteinemic and had the factor V Leiden mutation. This markedly increased thrombotic risk is consistent with a report of individuals with hereditary homocystinuria in whom only those who carried factor V Leiden had sustained venous thrombosis.[301]

The fact that lower plasma levels of folate, and to a lesser extent, vitamin B_6 or vitamin B_{12}, are associated with hyperhomocysteinemia makes it attractive to prescribe vitamin supplements to slow atherogenesis as well as to reduce the risk of arterial and venous thrombosis.[6] Indeed appropriate vitamin supplements can normalize plasma homocysteine levels, but the clinical efficacy of this approach has not been demonstrated in controlled clinical trials. However, because vitamins are relatively inexpensive and have almost no side effects, it is at present reasonable to treat symptomatic hyperhomocysteinemic patients with appropriate doses of folate, vitamin B_6, or vitamin B_{12} to lower their levels of homocysteine.

ACQUIRED HYPERCOAGULABLE STATES

See Table 1202 for a list of acquired conditions associated with hypercoagulable states.

Pregnancy and Oral Contraceptives

Pregnancy is associated with about a sixfold increased risk of venous thromboembolism.[302] Although the incidence of deep vein thrombosis and pulmonary embolism has been estimated to be as high as 1%, the true incidence is unknown due to difficulties in performing screening radiologic studies in pregnant women. Although relatively rare, pulmonary embolism causes 12 deaths per million pregnancies and is estimated to account for 12% of fatalities during pregnancy.[303]

The puerperium, defined as the 6-week period following delivery, is associated with a higher rate of thrombosis than pregnancy itself. Risk factors for thrombosis in pregnancy include

---

increasing age, cesarean delivery, prolonged immobilization, obesity, and prior thromboembolism.[302] Coexistent thrombophilia represents a major risk factor, particularly during pregnancy.[304] In Sweden, 4659% of women with venous thromboembolism had APC resistance and 6575% of the thrombotic events occurred during pregnancy.[11] [13] Among a referral population of Italian women with APC resistance managed without anticoagulant prophylaxis, however, 28% sustained venous thrombosis and 62% of the events occurred postpartum.[12]

Thrombosis during pregnancy and the puerperium is attributable to pregnancy-induced alterations in hemostasis as well as venous stasis in the lower extremities caused by the gravid uterus. Trauma to the pelvic veins during vaginal delivery or tissue injury during cesarean section also contribute to the hypercoagulable state. Compression of the left iliac vein by the crossing right iliac artery is a local, mechanical factor that is believed to underlie the threefold higher incidence of deep vein thrombosis in the left leg as compared to the right.[305]

Marked changes in the coagulation mechanism occur during pregnancy.[306] Increased levels of markers of coagulation system activation can be detected in the systemic circulation by the end of the first trimester. The elevations in thrombin generation, however, likely arise from the uteroplacental circulation because the placenta is rich in tissue factor. The vasculature of the placenta is unique from other tissues in that it is lined by chorionic villi that are covered by trophoblast tissue, rather than endothelium, which is in direct contact with maternal blood. The levels of most coagulation proteins increase during pregnancy, with fibrinogen rising markedly from a normal level of 250400 mg/dl to 600 mg/dl in pregnancy. Among the natural anticoagulant proteins, there is a significant decline in the level of free and total protein S in the second trimester.[186] [307] At the same time, fibrinolytic system activity declines progressively during pregnancy, in large part due to the generation of plasminogen activator-2 by the placenta.[308] Platelet activation and increased platelet turnover also probably occur during pregnancy; mild thrombocytopenia, possibly due to increased consumption, occurs in 8.3% of healthy women at term.[309] The net effect of these hemostatic changes is to promote blood coagulation so as to provide adequate hemostasis at the time of placental separation. The altered levels of hemostatic proteins return to normal within 4 weeks after delivery; fibrinolytic activity rapidly returns to normal levels within hours after placental separation.[310]

Oral contraceptive use is associated with an increased risk of venous and arterial thrombosis. The risk of venous thrombosis is related to the estrogen dose[311] and most oral contraceptives prescribed in the United States contain <50 g ethinylestradiol in combination with a progestational agent (combined oral contraceptives). The use of low-dose estrogen preparations containing older progestational agents (levonorgestrel, lynoestrenol, and norethisterone), however, still confers about a fourfold increased risk of venous thromboembolism as compared to nonusers (Table 12012).[312] The risk of myocardial infarction and stroke is less,[313] [314] [315] which is in part related to estrogens effect in lowering low-density lipoprotein cholesterol and raising high-density lipoprotein cholesterol levels. Unexpectedly, the introduction of newer progestagens (desogestrol, gestodene, and norgestimate) with more beneficial effects on lipid profiles carries a higher risk of venous thromboembolism than the previous generation of combined oral contraceptives.[316] [317] [318] [319] This risk is particularly high among carriers of the factor V Leiden mutation[9] [10] and women with a family history of thrombosis. It is not yet known whether oral contraceptives containing the newer progestagens are associated with any increase in risk of myocardial infarction, which is an extremely rare event in young women.[313]

The mechanisms by which oral contraceptives induce a prothrombotic state are incompletely understood. Oral contraceptive use is associated with changes in the levels of many coagulation proteins.[320] It has recently been suggested that oral contraceptives induce a state of acquired APC resistance.[321]

The Postoperative State and Trauma

Deep vein thrombosis and pulmonary embolism occur with increased frequency in postoperative patients; the thrombotic risk, however, depends on the type of surgery performed. Deep vein thrombosis in this population is usually asymptomatic, requiring the use of reliable noninvasive tests or lower limb venography to establish the diagnosis. Based on patient characteristics and the type of surgery, the postoperative thrombotic risk can be estimated and an assessment made of the need for prophylactic anticoagulation.[322] Risk factors associated with higher rates of thrombosis include older age, previous venous thromboembolism, the coexistence of malignancy or medical illness (e.g., cardiac disease), thrombophilia, and longer surgical and immobilization times. In patients over age 40, the incidence of deep vein thrombosis following general or gynecologic surgical procedures is 2025% and clinically significant pulmonary embolism occurs in 12%. For urologic surgery, the incidence of deep vein thrombosis ranges from 10% for transurethral procedures and up to 40% for radical prostatectomies. Orthopedic procedures on the hip and lower extremities are among the most thrombogenic surgical procedures. In the absence of prophylaxis, the risk of deep vein thrombosis following total knee replacement is 4570% and fatal pulmonary embolism has been reported to occur in 13% of patients undergoing hip surgery. It is now recognized that the increased thrombotic risk is not confined to the immediate postoperative period and continues for several weeks.[323]

Deep vein thrombosis and pulmonary embolism are also commonly encountered after major trauma. A study of patients admitted to a Canadian regional trauma unit demonstrated that 58% of patients had lower extremity deep vein thrombosis, which was usually asymptomatic.[324] Risk factors for thrombosis in this setting were older age, the need for surgery or blood transfusions, and the presence of lower extremity fractures or spinal cord injury. Pulmonary embolism occurs in 222% of trauma patients and is the third most common cause of death in those who survive the first 24 hours.[325]

The mechanism of activation of the coagulation system following surgery or trauma has not been elucidated, but the exposure of tissue factor from injured tissue or activated monocytes is the most likely pathway for increased thrombin generation in these settings. In postoperative patients, the occurrence of thrombosis is determined by the balance between coagulation and fibrinolytic system function.[326] In a study of neurosurgical patients undergoing craniotomy, Owen et al.[327] found that individuals developing venous thrombosis exhibit increased levels of fibrinopeptide A, a marker of thrombin-mediated fibrinogen proteolysis, relative to those of B 142, a marker of plasmin action on noncross-linked fibrin, for several days prior to thrombus visualization as compared to controls. Minor alterations in a number of

hemostatic parameters have been reported in postoperative patients including elevated levels of fibrinogen and von Willebrand factor and decreased levels of AT III and protein C. Decreased venous blood flow in the lower extremities also contributes to postoperative hypercoagulability. [328] In hip replacement surgery, the femoral vein in the operated leg may kink, thereby stimulating proximal venous thrombosis in the absence of pre-existent calf vein thrombosis. [329]

Obesity

Although obesity is an independent risk factor for atherosclerosis and cardiovascular disease, the evidence regarding its role in venous thrombosis is equivocal. An early study by Kakkar et al.[330] suggested that overweight patients had an increased incidence

of venous thrombosis. More recent studies have shown that this association disappears when account is taken of other risk factors such as age, history of venous thrombosis, and the type of surgery.[331] Obesity may however be a risk factor for chronic venous insufficiency. [332]

Malignancy

The incidence of clinical thromboembolic disease in the cancer population has been estimated to be as high as 11%. [333] Autopsy series have described even higher rates of thrombosis for certain tumor types. One autopsy study found a 30% incidence of thrombosis in patients who died of pancreatic cancer and >50% with tumors in the body or tail of the pancreas.[334] Other tumor types commonly associated thromboembolic complications are carcinomas of the gastrointestinal tract, ovary, prostate, and lung. By virtue of its prevalence, lung cancer accounts for the largest number of thromboembolic events. [335]

Patients with malignancy also have a higher rate of postoperative venous thrombotic complications than the general population, with an incidence of 40%. [336] Careful attention should therefore be paid to prophylaxis of deep vein thrombosis in such patients undergoing major abdominal or pelvic surgical procedures.

In some instances, thrombosis manifests itself prior to the diagnosis of an underlying malignancy and may predate the diagnosis by several years. In Trousseaus syndrome, which is classically characterized by migratory superficial phlebitis involving the upper or lower extremities (phlegmasia alba dolens), [336] it is not unusual for a premortem diagnostic evaluation for an underlying malignancy to be unsuccessful. For years it was debated whether the presence of a venous thrombotic event identifies patients at significantly increased risk of developing cancer. Several studies demonstrated an excess risk of cancer in patients who present with pulmonary embolism or deep vein thrombosis,[337] [338] but other investigators were unable to document an increased risk of developing cancer after an idiopathic thrombotic episode. These observations, however, were obtained from small or retrospective clinical trials.

A significant and clinically important association between idiopathic venous thrombosis and the subsequent development of clinical cancer was established in 1992. Prandoni et al.[40] investigated 250 consecutive patients with symptomatic deep vein thrombosis that was objectively documented by venogram. Cancer was identified at the time of diagnosis of the thrombotic event in 3.3% (5 of 153) of patients with idiopathic venous thrombosis, but no cases were found in patients with secondary venous thrombosis due to prolonged immobilization, leg trauma, or hereditary thrombotic disorder. During a 2-year follow-up period, cancer was diagnosed in 7.6% (11 of 145) of the patients with idiopathic venous thrombosis and in 1.9% (2 of 105) of patients with secondary venous thrombosis. The incidence of cancer was considerably higher in patients with recurrent idiopathic venous thrombosis. The probability of detecting an occult neoplasm in patients with a documented thrombotic event was also evaluated by Monreal et al., [39] [339] who found a malignant lesion in 7 of 31 (22.6%) patients with idiopathic deep vein thrombosis in contrast to 5 of 82 (6.1%) patients with secondary thrombosis and 9 of 78 (11.5%) patients with pulmonary embolism. The higher incidence of cancer reported by this group is most likely due to a more aggressive diagnostic approach, which included chest radiography, upper gastrointestinal endoscopy, abdominal ultrasound, and computed tomography scan.

In patients who present with idiopathic venous thromboembolism, recommendations have varied as to the extent of evaluation for malignancy that is appropriate. [340] Decisions regarding diagnostic testing should be based on the status of the individual patient; however, a complete physical examination including digital rectal examination and testing for fecal occult blood, pelvic examination in women, and routine laboratory testing should be performed in all patients presenting with thrombosis. Prospective studies are required to assess if an aggressive diagnostic approach will result in improved survival.

Nonbacterial thrombotic endocarditis, sterile vegetations composed of platelets and fibrin on heart valves, is highly associated with malignant disorders. In autopsy series, cancer was found in as many as 75% of cases of NBTE.[341] The majority of cases of NBTE are in patients with adenocarcinomas, and its incidence among lung cancer patients may run as high as 7%.[342] Laboratory evidence for DIC is often present. The aortic and mitral valves are most commonly affected. The diagnosis of NBTE can be difficult to make antemortem because <50% of patients have audible cardiac murmurs, and small lesions may not be identified by echocardiography. The major clinical manifestations are due to systemic emboli from the vegetations on the heart valve(s) rather than from valvular dysfunction itself. Common sites of embolization include the spleen, kidney, and extremities, with the most significant morbidity arising from emboli to the central nervous system and coronary arteries. NBTE is not an uncommon disorder and should be considered in all cancer patients who develop an acute stroke syndrome as well as in others who have cerebral embolism with an unknown etiology.[343]

Disseminated intravascular coagulation is the cardinal coagulopathy associated with malignancy, and results from generalized activation of the coagulation system (Chap. 117). Malignancy is the third most common cause of DIC after infection and trauma, and accounts for 7% of cases. DIC is a common complication in cancer patients and has been reported in as many as 15% of patients with malignancy. DIC occurs in virtually all patients with acute promyelocytic leukemia. The leukemic promyelocytes contain procoagulants that can trigger DIC, as well as fibrinolytic activators. The cell lysis that results from conventional chemotherapy releases these enzymes and can exacerbate the coagulopathy. Other disease entities, particularly sepsis, which may be responsible or may contribute to the development of DIC in cancer patients, should be ruled out.

Various patterns of DIC are seen in association with malignancy. Acute forms of DIC are rare and usually present with minor bleeding from mucosal or cutaneous surfaces or extensive life-threatening hemorrhage involving visceral sites. Laboratory evaluation demonstrates prolongation of the prothrombin time, PTT, thrombin time, and reptilase time; decreased fibrinogen concentration; thrombocytopenia; and elevated levels of fibrin degradation products. More common in cancer patients are chronic forms of DIC. Many such patients are asymptomatic, and laboratory data often show modest reductions in fibrinogen and platelet count, elevated fibrin degradation products, and minimal changes in the prothrombin time or PTT. Others may have more obvious evidence of platelet, fibrinogen, and coagulation factor consumption. These patients often are hypercoagulable and can manifest deep vein thrombosis, Trousseaus syndrome, or NBTE.

Thrombotic microangiopathy is the descriptive term of a syndrome characterized by hemolytic anemia, thrombocytopenia, pathognomonic microvascular thrombotic lesions, and the involvement of various specific organs (Chap. 128). Depending on the differences in organ involvement, thrombotic microangiopathy is commonly described as thrombotic thrombocytopenic purpura or as hemolytic uremic syndrome. Severe thrombotic microangiopathy in association with thrombocytopenia may occur in as many as 5.7% of patients with metastatic carcinomas, most frequently with gastric, breast, or lung primary sites. Despite the classical manifestations of a Coomb-negative hemolytic anemia and severe thrombocytopenia, patients usually present with neurologic abnormalities, including headache, confusion or paresis, and occasionally signs of DIC.

Renal failure is an uncommon feature of carcinoma-associated thrombotic microangiopathy. The mainstay in the treatment of malignancy-related thrombotic microangiopathy is to decrease the tumor burden because other treatment modalities, such as corticosteroids, plasma exchange, or plasma infusion, only result in a moderate and transient improvement of the clinical symptoms.

Likely contributing to the thrombotic tendency in cancer patients are clinical factors such as vascular stasis due to obstruction of blood flow by the tumor or patient immobility, hepatic involvement and dysfunction, sepsis, advanced age, other comorbid conditions, and certain antineoplastic agents. Thus, the exact details of the mechanisms underlying coagulation activation in malignancy remain uncertain and may be a complex interaction of several of the above mechanisms as well as others yet to be identified.

Nephrotic Syndrome

The nephrotic syndrome results from a variety of pathologic processes that cause excessive kidney glomerular leakage of plasma proteins into the urine. It is clinically characterized by edema, proteinuria, hypoalbuminemia, and hyperlipidemia. Thrombosis is a major cause of morbidity in patients with the nephrotic syndrome, with the renal veins being the most commonly affected site. Renal vein thrombosis occurs in approximately 35% of cases, [344] but it varies considerably based on the underlying renal pathology and the severity and duration of the proteinuria. The incidence of thrombosis in other sites is 20% [344] [345] in adults, deep vein thrombosis and pulmonary embolism are the most common thrombotic complications. Arterial thrombosis is seemingly more common in children with nephrotic syndrome, resulting in stroke, mesenteric infarction, or limb ischemia.

Alterations in many blood coagulation parameters have been reported in patients with the nephrotic syndrome, although some abnormalities are inconsistently reported, of relatively minor magnitude, and poorly correlated with thrombotic events. The variability in findings is attributable to the complex nature of the nephrotic syndrome itself and the resultant marked stimulation of hepatic protein biosynthesis.

Among the natural anticoagulant proteins, plasma AT III levels are often decreased due, at least in part, to urinary excretion. [86] [346] The antigenic levels of protein C and protein S are generally increased. [191] [192] [347] Plasma levels of several components of the coagulation cascade, factors XII, XI, and X, are decreased due to urinary excretion, whereas factors XIII, X, VIII, VII, and V are characteristically elevated in these patients. Data indicate that platelet hyperreactivity [348] or increased whole blood viscosity[349] may contribute to the thrombotic diathesis in the nephrotic syndrome.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare acquired clonal disorder of bone marrow stem cells. Patients generally manifest chronic intravascular hemolysis with episodes of gross hemoglobinuria accompanied by leukopenia and thrombocytopenia. Many have a prior history of aplastic anemia. Despite the presence of thrombocytopenia, thrombosis is more commonly encountered than bleeding. Indeed thrombosis can be a presenting feature of PNH as well as an important cause of morbidity and mortality in this disorder. A diagnosis of PNH should be suspected in patients with a negative family history of thrombosis with evidence of pancytopenia, an elevated reticulocyte count, or iron studies consistent with iron deficiency.

A unique feature of PNH is the predilection for thrombosis to occur in the intra-abdominal venous network (mesenteric, hepatic, portal, splenic, and renal veins) and cerebral vessels as opposed to deep vein thrombosis or pulmonary embolism. Arterial events such as myocardial infarction and stroke have rarely been reported. Acute thrombotic episodes should be treated with heparin or low-molecular-weight heparin. Fibrinolytic agents have been used successfully to treat acute intra-abdominal venous thrombosis. Long-term oral anticoagulation should be considered in patients with thrombosis in association with PNH.

The abnormality of PNH erythrocytes that leads to hemolysis is their increased sensitivity to complement-mediated lysis. Deficiencies of a number of membrane proteins have been observed in PNH, including acetylcholinesterase, leukocyte alkaline phosphatase, decay accelerating factor, CD59 (membrane inhibitor of reactive lysis) antigen, homologous restriction factor, CD58, 5-ectonucleotidase, CD16, urokinase-type plasminogen activator, and CD14 antigen. These proteins are all attached to the cells via a glycosylphosphatidylinositol anchor, and PNH appears to be the consequence of somatic mutations in the X-linked phosphatidylinositol glycan class A gene that participates in an early step in glycosylphosphatidylinositol anchor synthesis. [350] Several of the membrane abnormalities involve proteins that modulate complement function and the absence of CD59 antigen on erythrocytes appears to be the most critical defect. [351] Granulocytes and platelets, like red blood cells, show increased sensitivity to complement-mediated lysis. Although it has been suggested that the membrane abnormalities in PNH may lead to increased platelet activation by complement, there is not currently an adequate explanation for the thrombotic tendency in this disease. Indeed, there is no apparent association between hemolytic and thrombotic episodes nor does the onset of thrombosis correlate with the duration or degree of hemolysis.

Hyperviscosity

Thrombosis can be a manifestation of diseases associated with hyperviscosity. Hyperviscosity of the blood may be due to increased plasma viscosity, an increased number of red or white blood cells, or decreased deformability of cells.

Increased plasma viscosity can result from hypergammaglobulinemia or hyperfibrinogenemia. Hypergammaglobulinemia associated with the hyperviscosity syndrome is most commonly encountered in patients with Waldenströms macroglobulinemia or multiple myeloma. Presenting symptoms of the hyperviscosity syndrome include bleeding due to platelet dysfunction, visual disturbances, and neurologic defects. Thrombosis in hypergammaglobulinemic states is attributable to abnormal rheology.

Hyperviscosity plays an important role in the pathogenesis of thrombosis in polycythemia vera, which is a major complication of this disorder. Patients with elevated hematocrits have increased whole blood viscosity, and these have been inversely correlated with cerebral blood flow. Acquired qualitative platelet defects have also been implicated in the pathogenesis of the hemostatic defects in polycythemia vera. Common thrombotic complications in this disorder include cerebrovascular accidents, myocardial infarction, peripheral arterial occlusion, deep venous thrombosis, pulmonary embolism, and portal and hepatic vein thrombosis (Budd-Chiari syndrome).

In the myeloid and monocytic leukemias, the presence of very elevated white blood cell counts (generally >100,000mm [3]) can increase the viscosity in the microcirculation, which can play a role in the pathogenesis of thrombosis. Small vessels in the lungs, brain, and less commonly in other organs may be obstructed by high levels of immature leukocytes.

In sickle cell disease, the increase in blood viscosity secondary to sickled erythrocytes may contribute to the occlusion of small blood vessels. Enhanced adhesion of sickle erythrocytes

---

to vascular endothelium along with increased coagulation and platelet activation promote vascular occlusion. [352]

Drug-Induced Thrombosis

The contribution of cancer chemotherapy to the development of thrombotic events is difficult to evaluate because the neoplasm itself and other risk factors predispose cancer patients to thromboembolic complications.

Thrombotic events have been reported with induction chemotherapy regimens for acute lymphoblastic leukemia (ALL) that include L-asparaginase. Intracranial thrombosis with hemorrhage is observed most frequently, but deep venous thrombosis and pulmonary embolism can also occur. [353] [354] [355] In one large series of children receiving L-asparaginase as part of induction chemotherapy for ALL, the incidence of thrombotic complications was 1.2%. Generalized bleeding episodes have only rarely been observed.

The inhibition of protein synthesis by L-asparaginase causes deficiencies of numerous plasma proteins, including albumin, thyroxine-binding globulin, and various coagulation proteins. Decreased levels of prothrombin; factors V, VII, VIII, IX, X, and XI; fibrinogen; AT III; protein C; protein S; and plasminogen have all been described secondary to L-asparaginase chemotherapy. [91] [356] This results in prolongation of the prothrombin time, PTT, and thrombin time, as well as hypofibrinogenemia with levels often <100 mg/dl. These coagulation abnormalities resolve within 12 weeks after cessation of the drug.

It is difficult to assess the role of the substantial reductions in the levels of natural anticoagulant proteins such as AT III, protein C, and protein S in the pathogenesis of the thrombotic events. Both procoagulant and anticoagulant protein sythesis in the liver are decreased by L-asparaginase, leading to uncertainty as to whether there is an alteration in the balance of the opposing forces of the hemostatic mechanism. In one study of children with ALL receiving L-asparaginase, prednisone, and vincristine, no correlation was found between protein C, protein S, or AT III levels and the presence or absence of thrombosis. [193] Other clinical factors may contribute to the pathogenesis of thrombotic complications that are observed in these patients including immobility or the concurrent presence of sepsis.

Women with breast cancer receiving certain chemotherapy regimens are at increased risk for developing thrombosis. The availability of large numbers of patients receiving standard adjuvant chemotherapy programs as well as appropriate matched, untreated control populations has facilitated studies of this association. A 1981 study found a 5% incidence of symptomatic venous thrombosis among patients with stage II breast cancer treated with chemotherapy regimens that included CMF. [357] All of the thrombotic events occurred while the patients were receiving chemotherapy. In the post-treatment follow-up period, no clinically evident thromboses were observed. Goodnough et al.[358] reported a 17.6% incidence of thrombosis in a series of patients with metastatic breast cancer receiving chemotherapy, the majority of the events being pulmonary embolism or deep vein thrombosis. Levine et al. [359] randomized 205 patients receiving adjuvant chemotherapy for stage II breast cancer to either a 12-or 36-week course of chemotherapy after primary surgical treatment. During the first 12 weeks of chemotherapy there were similar numbers of thrombotic events; however, during the following 24 weeks there were five additional thrombotic events in the 36-week treatment group, while no further thromboses were seen in the 12-week treatment group that had already completed therapy. Thus, 6.8% of the patients had a thromboembolic event while on chemotherapy, but no further thrombotic events were detected during the >2,400 patient-months of follow-up postchemotherapy. No relationships were found in this study between the development of thrombosis and estrogen or progesterone receptor status, age, number of involved lymph nodes, or subsequent tumor recurrence.

The association of arterial thrombosis and cancer therapy was shown in studies by Wall et al. [360] and Saphner et al. [361] The Cancer and Acute Leukemia Group B (CALGB) study[360] found a 1.3% incidence of arterial thrombosis, either peripheral arterial or cerebrovascular, in 1,014 patients during treatment for stage II or III breast cancer on two separate chemotherapy protocols. All except one of the thrombotic events occurred while patients were receiving chemotherapy. In the study by Saphner et al.[361] including 2,352 patients, a significant increase in arterial thrombosis was found in premenopausal women who received combined chemohormonal therapy, whereas no higher risk for arterial thrombosis was seen in postmenopausal women either receiving tamoxifen alone or in combination with chemotherapy. In both studies, arterial thrombotic events tended to occur early in the course of treatment.

The pathophysiologic basis for the thrombogenicity of chemotherapy in patients with breast cancer is not well understood. In a prospective study of patients receiving adjuvant chemotherapy for breast cancer no alterations in antithrombin III levels were detected. Rogers et al. [362] found a statistically significant decrease in protein C and protein S levels during CMF chemotherapy. Some of these patients had decrements in protein C and S levels that fell below the range of values seen in hereditary thrombotic disorders. Decreases in factor VII and fibrinogen levels were also reported. None of the patients in this small study, however, had clinically evident thrombosis. Other investigators have observed significant declines in protein C concentration during CMF chemotherapy, which returned to baseline values after the completion of therapy.[363] Possible explanations for these chemotherapy-induced abnormalities include impairment of vitamin K metabolism, inhibition of DNA/RNA synthesis leading to a decrease in protein synthesis by the liver, and initiation of intravascular coagulation.

Hormonal therapies, such as estrogen therapy for prostate carcinoma, have clearly been linked to an increased incidence of thromboembolic disease. In the Veterans Administration Cooperative Urologic Research Groups studies of estrogen therapy in patients with prostate cancer, higher death rates from cardiovascular events were reported in those taking 5 mg diethylstilbestrol daily as compared to those on a 1-mg daily dose. [364] The antitumor effect of these two dosages was similar.

Lupus Anticoagulants and the Antiphospholipid Syndrome

Lupus anticoagulants are antibodies that prolong phospholipid-dependent clotting assays in vitro (Chap. 116). These immunoglobulins do not directly inhibit the activity of specific plasma coagulation factors.

The term lupus anticoagulant is a misnomer because this laboratory abnormality frequently occurs in patients without SLE. It has been observed in other autoimmune diseases, following exposure to drugs or various infectious agents, in malignancy, and in some individuals without any apparent underlying disease. [365] [366] Furthermore, subjects with lupus anticoagulants do not suffer from a bleeding diathesis unless other hemostatic defects are present. Paradoxically, the presence of lupus anticoagulants increases the apparent risk of both arterial and venous thromboembolism, [367] [368] and there is conflicting evidence as to whether recurrent events occur in the same arterial or venous distribution as the initial episode. [369] [370] Compilation of published reports suggests that about one-third of patients with such inhibitors will have thrombotic events. [366]

In coagulation tests, lupus anticoagulants are generally detected by finding a prolonged PTT. Other coagulation assays that have been used to screen patients for the presence of lupus

anticoagulants are the dilute Russell viper venom time, [371] the kaolin clotting time,[372] and the tissue thromboplastin inhibition test. [373] It is currently popular to confirm abnormal screening tests using a hexagonal phospholipid assay. If a lupus anticoagulant is present, the antibody will be neutralized by the addition of hexagonal phase phospholipid and the clotting time will normalize.

The presence of lupus anticoagulants has also been associated with the presence of biologic false-positive tests for syphilis because the Venereal Disease Research Laboratory assay depends on the presence of cardiolipin. [374] Some of these antibodies react with anionic phospholipids, [375] [376] but the binding of most antiphospholipid antibodies to cardiolipin requires the presence of a plasma cofactor, $_2$ -glycoprotein I (apolipoprotein H). [377] [378] [379] The relationship between the presence of lupus anticoagulants, antiphospholipid antibodies, and a thrombotic predisposition are complex and there are conflicting data as to which test result is associated with increased thrombotic risk. A study by Triplett et al. [380] demonstrated that antiphospholipid antibodies are not present in all patients with lupus anticoagulants and the presence of such immunoglobulins does not necessarily confer an increased thrombotic risk on these individuals. However, in patients with SLE, persistently elevated levels of IgG anticardiolipin antibodies appear to correlate more strongly with thrombosis and fetal loss than do abnormalities in clotting assays for lupus anticoagulants. [381] [382] [383] The opposite was shown in another study with respect to venous or arterial thrombosis. [384] There are conflicting data with respect to the the risk of arterial and venous thrombosis in such patients. Additional evidence that the presence of IgG anticardiolipin antibodies constitutes a thrombotic risk factor comes from a case control study of healthy adult men participating in the US Physicians Health Study. [385] An antibody titer above the 95th percentile was a significant risk factor for venous thromboembolism but not for ischemic stroke. This study, however, did not test for the presence of lupus anticoagulants. A prospective Canadian study showed that the presence of a lupus anticoagulant conferred a 9.4-fold increased risk of venous thrombosis, but the anticardiolipin antibody titer was not a significant risk factor. [386]

The management of acute venous thromboembolism in patients with lupus anticoagulants is similar to that of other individuals without this laboratory abnormality. However, the initial treatment of such subjects is complicated by the fact that the PTT cannot reliably be used to monitor unfractionated heparin dosage unless proper in vitro calibration studies are done by adding known amounts of heparin into plasma samples and measuring the response of the PTT. Thus, it is preferable to monitor anticoagulant therapy in these individuals by performing an activated whole blood clotting time or plasma heparin measurements using either factor Xa or thrombin and a suitable chromogenic substrate of these enzymes. These problems are obviated by the use of low-molecular-weight heparin, which does not require monitoring. The presence of lupus anticoagulants can also interfere with heparin monitoring during cardiac surgery. [387] Warfarin is effective in preventing recurrent thrombosis, but requires that a relatively high INR be maintained. [369] [370]

The clinical heterogeneity of the patient populations that develop lupus anticoagulants makes it difficult to generalize regarding the long-term antithrombotic management of such individuals. Although the relationship between thrombosis and the lupus anticoagulant appears to be strong in patients with SLE, [382] the significance of the association in patients without this disorder is more ambiguous. [388] Indeed, patients who develop transient lupus anticoagulants in association with infections do not usually sustain thromboembolic episodes and it is unclear whether drug-associated lupus anticoagulants are associated with thrombosis. Thus, the presence of a persistent lupus anticoagulant, a high-titer antiphospholipid antibody, or both in an asymptomatic subject with no prior thrombotic history is not an indication for anticoagulant or antiplatelet medications. However, inasmuch as it is not currently possible to determine reliably the risk of thrombosis in an asymptomatic patient with these laboratory abnormalities, all such individuals should receive appropriate prophylaxis in conjunction with major surgical procedures, [389] or prolonged immobilization, unless there is a strong contraindication to such treatment. Corticosteroids can normalize clotting assay times or reduce antiphospholipid antibody titers in patients with lupus anticoagulants. However, these and other immunosuppressive medications may not prevent recurrent thrombosis.

The presence of lupus anticoagulants, anticardiolipin antibodies, or both has also been reported in women with obstetric complications such as habitual abortions, intrauterine death, and fetal growth retardation. [390] [391] [392] [393] [394] In some cases, pathologic examination of the placenta demonstrates infarction due to decidual vessel thrombosis.[397] In a cross-sectional study of unselected women with SLE, Ginsberg et al. [383] could establish a significant association between persistently positive tests for lupus anticoagulants and anticardiolipin antibodies and pregnancy loss. However, in women without SLE, a prospective study did not demonstrate a

relationship between the presence of a lupus anticoagulant and anticardiolipin antibodies and an initial episode of spontaneous abortion or fetal death. [395]

MANAGEMENT

Approach to Management and Treatment of Acute Thrombosis

The acute management of venous thrombosis or pulmonary embolism in patients with biologic risk factors for thrombosis is generally not different from that of other patients. Thrombolytic therapy should be seriously considered in patients with massive acute venous thrombosis or pulmonary embolism. Unfractionated heparin should be initiated with an intravenous bolus of 5,000 U followed by an infusion of 1,400 Uh, [396] or, if a weight-adjusted regimen is used, a bolus of 80 Ukg body weight followed by an infusion of 18 U/kg/h.[397] The PTT should be performed approximately 6 hours after therapy is initiated, and at least daily thereafter to maintain the PTT in the therapeutic range. For many commercial PTT reagents, this corresponds to a PTT that is 1.83.0 times the mean of the normal range, or an antifactor Xa heparin level of 0.30.7 Uml.[398] For less sensitive PTT reagents, the therapeutic PTT ratio is 1.52.0 times normal. [399] Alternatively low-molecular-weight heparin in therapeutic doses can be administered, which obviates the need for monitoring the PTT. Warfarin can be started within the first 24 hours. Heparin or low-molecular-weight heparin is continued for at least 5 days [400] or until the prothrombin time is in the therapeutic range, namely, an INR of 2.03.0. The principles of anticoagulation are described in further detail in Chapters 121 and 122 .

Patients with AT III deficiency can usually be treated successfully with intravenous heparin [401] although in some situations higher than usual doses of the drug are required to achieve adequate anticoagulation. In AT III-deficient patients receiving heparin for the treatment of acute thrombosis, the adjunctive role of AT III concentrate purified from human plasma is not clearly defined because controlled trials have not been performed. [401] [402] This product should probably be administered when difficulty is encountered in achieving adequate heparinization or recurrent thrombosis is observed despite adequate anticoagulation. It is also reasonable to treat AT III-deficient subjects with concentrate before major surgeries or in obstetric situations where the risks of bleeding from anticoagulation are unacceptable.

The infusion of 50 U AT III concentrate per kilogram of body weight (1 U is defined as the amount of AT III in 1 ml of pooled

normal human plasma) will usually raise the plasma AT III level to 120% in a congenitally deficient individual with a baseline level of 50%. [403] [404] [405] [406] [407] Plasma levels should be monitored to ensure that they remain >80% the administration of 60% of the initial dose at 24-hour intervals is recommended to maintain inhibitor levels in the normal range.[407]

The infrequent occurrence of warfarin-induced skin necrosis, the relatively high frequency of asymptomatic hereditary protein C deficiency, and the diagnostic difficulty in making a rapid and definitive laboratory diagnosis of the deficiency state are arguments against the routine measurement of plasma protein C levels in all individuals with thrombosis before the initiation of oral anticoagulants. If, however, one is starting oral anticoagulants in a patient who is already known or likely to be protein C deficient, it is prudent to start the drug under the cover of full heparinization and also to increase the dose of warfarin gradually, starting from a relatively low level (e.g., 2 mg for the first 3 days and then in increasing amounts of 23 mg until therapeutic anticoagulation is achieved). Patients with heterozygous protein C deficiency and a history of warfarin-induced skin necrosis have been successfully retreated with oral anticoagulants. Protein C administration either in the form of fresh frozen plasma or protein C concentrate provides protection against the development of recurrent skin necrosis until a stable level of anticoagulation is achieved.[116] [408]

Long-term Management

After an initial episode of venous thrombosis or pulmonary embolism, patients are usually continued on oral anticoagulants for 36 months at an INR of 2.03.0 because clinical trials have established the efficacy of this regimen for preventing early recurrences. Recent data indicate that the risk of recurrence is greater in patients with permanent as opposed to temporary risk factors for thrombosis.[409] [410] In patients with inherited thrombophilia, it is therefore reasonable to continue warfarin for at least 6 months in individuals without an identifiable exogenous triggering insult (e.g., surgery, pregnancy) for thrombosis.

After 6 months of anticoagulant treatment for an acute thrombotic event, an assessment must be made as to the relative benefit conferred by long-term anticoagulant therapy in preventing future thromboembolic complications versus the potential side effects, cost, and inconvenience for the patient. Unfortunately, there is a paucity of reliable data regarding the true magnitude of the thrombotic risk in unselected patients with deficiencies of AT III, protein C, or protein S because these are relatively uncommon disorders.

Cross-sectional studies of selected kindreds with thrombosis in association with heterozygous deficiencies of AT III, protein C, and protein S have given estimates of the cumulative risk of thrombosis as a function of age. The risk is extremely low until about age 15, and then occurs at a rate of 24% per year. Cross-sectional studies of family members of unselected patients with these defects indicate that the rate of spontaneous and induced venous thrombosis are lower at 0.41% and 0.52% per year, respectively.[411] Many clinicians with experience in managing patients with these disorders feel that patients with congenital AT III deficiency (particularly type I defects) are at higher thrombotic risk than those with other defects.

Due to the relatively high frequency of the factor V Leiden mutation in patients with a first episode of venous thrombosis, data have recently become available regarding their recurrence risk. Two studies have found a significant increase. Among 77 men in the Physicians Health Study with a first episode of idiopathic venous thromboembolism followed for an average of 68 months, the rate of recurrent venous thromboembolism in factor V Leiden heterozygotes was four- to fivefold higher than in genetically unaffected men (29%, incidence rate of 7.5%/year

TABLE 120-13 -- Management of Biologic Defects Predisposing to Thrombosis

Risk Classification	Management
High risk	Indefinite anticoagulation
2 or more spontaneous thromboses	
1 spontaneous life-threatening thrombosis	
1 spontaneous thrombosis at an unusual site (mesenteric or cerebral venous)	
1 spontaneous thrombosis in the presence of more than a single biologic defect	

Moderate risk	Vigorous prophylaxis during high-risk situations
1 thrombosis with a prothrombotic stimulus	
Asymptomatic	

vs. 11%, incidence rate of 1.82%/year, respectively). [412] In a second study of 251 Italian patients with a first episode of deep vein thrombosis proven by venography, the cumulative incidence of recurrent venous thromboembolism after 8 years of follow-up was over twofold higher among 41 heterozygotes with factor V Leiden than in those without the mutation (39.7% vs. 18.3%).[413] Rintelen et al.[414] and Eichinger et al. [415] have not found an increased recurrence risk in heterozygotes with factor V Leiden, but the former study was retrospective and the latter included patients who were followed up for shorter time periods.

Although recurrent venous thromboembolism may occur more frequently in patients with factor V Leiden and an initial idiopathic event, this does not necessarily imply that oral anticoagulant treatment should be prolonged beyond 36 months; its benefits may be counterbalanced by its hemorrhagic risk. Indeed, a recent trial of long-term warfarin therapy (INR 22.85) in patients with a second venous thrombotic episode found that the drug was highly effective in preventing recurrences as compared to 6 months of therapy (2.6% vs. 21% over 4 years), but there were hemorrhagic complications (8.6% vs. 2.3%, respectively). [416]

Prospective data are not currently available regarding the utility of extending oral anticoagulation beyond 36 months in patients with biologic risk factors for thrombosis. Therefore, only general guidelines for managing and treating such patients can be offered (Table 12013).

When a heterozygous patient with one of the hereditary thrombotic disorders is identified, family studies should be conducted because approximately half of the first-degree relatives will be affected. Affected asymptomatic individuals should receive counseling regarding the implications of the diagnosis and advice regarding symptoms that require immediate medical attention. In women of child-bearing age, oral contraceptives are contraindicated in view of the increased thrombotic risk associated with the use of these medications. Recent data indicate that estrogen replacement therapy can increase the risk of venous thrombosis by two- to fourfold in perimenopausal and postmenopausal women,[417] [418] [419] but data are not yet available for women with specific hereditary thrombotic disorders. Thus, in making a decision as to whether to prescribe hormone replacement therapy to women with thrombotic histories, the potential for recurrence must be weighed against the benefits of the medication.

Management of Pregnancy

The management of pregnancies in women with thrombotic histories or hereditary thrombotic disorders poses special

MANAGEMENT DECISIONS IN PATIENTS WITH AN INHERITED THROMBOTIC DISORDER

All individuals with biologic risk factors for thrombosis should be carefully evaluated prior to surgical, medical, or obstetric procedures. They should then receive appropriate prophylactic anticoagulation regimens. If specific concentrates are available for the patients deficiency state, these can also be administered to raise the plasma levels of the protein to the normal range during the perioperative period.

In patients with or without an inherited thrombotic disorder, the occurrence of two or more spontaneously occurring thromboembolic episodes may lead to the continuation of oral anticoagulants for life. Chronic warfarin therapy is generally not recommended until an individual has had at least one documented thrombotic episode.

With regard to the issue of long-term warfarin therapy in other patients with thrombosis, recommendations must be individualized at the present and clinical features that should be considered along with the presence of biologic risk factors include:

1. The severity and site of thrombosis; e.g., a patient who previously sustained a massive pulmonary embolus is more likely to receive long-term warfarin than one who developed deep venous thrombosis in a calf vein unless there are symptoms or signs of a significant postphlebitic syndrome; patients with mesenteric, portal, or cerebral venous thrombosis are frequently anticoagulated indefinitely after diagnosis due to the potential morbidity or mortality of a recurrence at these sites.
2. Whether the thrombotic episodes were spontaneous or whether triggering factors were present; e.g., if a precipitant such as a major abdominal operation was present, it would be reasonable to manage the patient without long-term oral anticoagulation after the acute episode was adequately treated.
3. Resolution of thrombosis; e.g., if ultrasound was used to diagnose deep venous thrombosis, a follow-up study after 36 months of anticoagulant therapy can indicate whether the initial thrombus has completely resolved. The presence of persistent abnormalities suggests incomplete fibrinolysis of the clot and may prompt the physician to consider long-term anticoagulation if the patient is symptomatic from post-phlebitic syndrome. A baseline study after therapy is also useful in case the patient returns with symptoms of phlebitis in the same leg and ultrasound is to be used to document the recurrence.
4. In patients with hereditary defects, a history of thromboembolism in other biochemically affected members of the family; e.g., while marked intra- and interfamilial heterogeneity has been observed in the phenotypic expression of the inherited thrombotic disorders, it is not unreasonable to place asymptomatic, biochemically affected patients from severely affected kindreds on oral anticoagulants starting at puberty.
5. The sex and lifestyle of the individual; e.g., situations where these factors may influence the decision-making process include: women of child-bearing age planning to conceive, occupations that entail prolonged periods of immobilization and thereby might be associated with an increased risk of thromboembolism, jobs with higher than average chance of trauma that might lead to thrombotic or bleeding complications.

problems.[420] The incidence of thrombotic complications during pregnancy and the postpartum period appears to be greater in women with AT III deficiency than in those with deficiencies of protein C or protein S.[421] The factor V Leiden mutation is frequently identified in Caucasian women with venous thromboembolism during pregnancy and the puerperium,[11] [12] [13] but the thrombotic risk in asymptomatic women from the general population has not been defined. Pregnant women with factor V Leiden and a personal or familial history of thrombosis should, therefore, be considered for anticoagulant prophylaxis. Routine screening for the mutation in women of child-bearing age is not recommended because the potential risks of anticoagulation may equal or exceed its benefits. [422] During pregnancy, adjusted-dose unfractionated heparin administered by the subcutaneous route is the anticoagulant of choice because its efficacy and safety for the fetus are established. [423] Low-molecular-weight heparin is an attractive alternative to unfractionated heparin in these patients due to its better bioavailability and longer half-life. Patients with a previous history of thrombotic episodes should definitely receive treatment throughout pregnancy; affected women with AT III deficiency who have not yet experienced such events should probably likewise receive treatment. Treatment of asymptomatic women with other hereditary thrombotic disorders should be considered on an individual basis.

The dose and duration of heparin therapy in pregnancy is uncertain because appropriately designed clinical trials have not yet been performed in these patient populations. Patients considered to be at high risk should receive LMW heparin at thrombosis doses or full-dose unfractionated heparin by subcutaneous injection every 12 hours for the duration of pregnancy. The dose of unfractionated heparin should be adjusted to maintain the 6-hour postinjection PTT at 1.5 times the control value. In women considered to be at intermediate risk, lower doses of heparin can be used (5,00010,000 U subcutaneously every 12 hours) and therapy can be started during the second or third trimester and continued for approximately 6 weeks into the postpartum period. Low-risk patients can be observed closely throughout the pregnancy with duplex ultrasound imaging of the leg veins at regular intervals.

Management of Warfarin-Induced Skin Necrosis and Neonatal Purpura Fulminans

An association has been established between the rare complication of warfarin-induced skin necrosis and hereditary protein C deficiency. [115] [116] [117] [424] [425] About one-third of patients with warfarin-induced skin necrosis will prove to have hereditary protein C deficiency. [120] This complication has also been described in patients with heterozygous protein S deficiency[29] and factor V Leiden. [30]

Because warfarin-induced skin necrosis is a rare complication, therapy has been guided primarily by knowledge regarding its pathogenesis. The diagnosis should be suspected in patients with painful, red skin lesions developing within a few days after the initiation of the drug and immediate intervention is required to prevent rapid progression and to minimize complications. Therapy should consist of immediate discontinuation of warfarin, administration of vitamin K, and infusion of heparin at therapeutic doses. Lesions, however, have been reported to progress despite adequate anticoagulation with heparin. In patients with hereditary protein C deficiency, the administration of a source of protein C should be seriously considered, and it may also be appropriate in other patients with warfarin-induced skin necrosis as they invariably have reduced plasma levels of functional protein C when the skin lesions first appear. Fresh frozen plasma has been used, but improved results can be expected with the administration of a highly purified protein

C concentrate, which facilitates the rapid and complete normalization of plasma protein C levels. [426]

The management of neonatal purpura fulminans in association with homozygous or doubly heterozygous protein C deficiency is more complicated, and heparin threrapy as well as antiplatelet agents have not been shown to be effective. [122] [124] [125] [427] [428] [429] The administration of a soucre of protein C appears to be critical in the initial treatment of these patients. Fresh frozen plasma has been used with success to treat these infants. However, the half-life of protein C in the circulation is only 616 hours,[118] [430] and the administration of plasma on a frequent basis is limited by the development of hyperproteinemia, hypertension, loss of venous access, and the potential for exposure to infectious viral agents. A highly purified concentrate of protein C has been developed and is efficacious in treating neonatal purpura fulminans.[431] Warfarin has been administered to these infants without the redevelopment of skin necrosis during the phased withdrawal of fresh frozen plasma infusions,[122] [125] [126] [432] [433] and this medication has been used chronically to control the thrombotic diathesis. Successful liver transplantation has been undertaken in a child with liver failure and homozygous protein C deficiency, which resulted in normalization of the plasma protein C level and resolution of the thrombotic diathesis.[434]

Chapter 121 - Oral Anticoagulant Therapy

Bruce Furie

STRUCTURE OF ORAL ANTICOAGULANTS

The vitamin K antagonists were discovered as the result of an intensive investigation into the etiology of a hemorrhagic disease of cattle that plagued farmers in the Great Plains during the 1920s. This disorder, characterized by hypoprothrombinemia, was associated with the ingestion of spoiled sweet clover hay contaminated with specific toxins.[1] [2] Campbell and Link[3] purified 3,3-methylene-bis-4-hydroxycoumarin from bacterial contaminants in the spoiled hay and discovered that this compound caused a syndrome similar to vitamin K deficiency. Bishydroxycoumarin, a vitamin K antagonist, was introduced into clinical practice as an anticoagulant during the 1940s[4] and is prescribed as dicumarol. Other structurally related vitamin K antagonists with varying pharmacologic properties were developed (Fig. 1211). The most important vitamin K antagonist used in the United States is warfarin sodium.

Figure 121-1 Structure of the oral anticoagulants and their relationship to vitamin K. Chemical structures include **(A)** warfarin, **(B)** phenprocoumon, **(C)** dicoumarol, and **(D)** vitamin K. Vitamin K and the coumarin anticoagulants share a common ring structure, shown in red.

MECHANISM OF ACTION OF WARFARIN

As a vitamin K antagonist, warfarin inhibits the complete synthesis of the vitamin K-dependent blood-clotting proteins, including prothrombin and factors VII, IX, and X required for normal blood coagulation.[5] In addition, the vitamin K-dependent regulatory proteins, proteins C and S, are also affected due to a decrease in vitamin K-dependent post-translational modifications. The anticoagulant effect of warfarin depends on the reduction in the synthesis of biologically active vitamin K-dependent blood-clotting proteins and the normal clearance from the circulation of fully active vitamin K-dependent blood-clotting proteins synthesized before the introduction of the vitamin K antagonist. Importantly, the administration of warfarin does not lead to instantaneous anticoagulation. Rather, warfarin must be administered for 45 days before the anticoagulant effect is therapeutic, even when the prothrombin time (PT) is in the therapeutic range.

During the synthesis of the vitamin K-dependent proteins, the post-translational modification of glutamic acid to -carboxyglutamic acid is catalyzed by the vitamin K-dependent carboxylase.[6] -Carboxyglutamic acid is required in these proteins to permit calcium-dependent protein/membrane interaction and for the expression of full biologic activity.[7] [8] [9] The carboxylase is an integral membrane protein [10] requiring carbon dioxide, molecular oxygen, and the hydroquinone form of vitamin K to convert glutamic acid to -carboxyglutamic acid.[6] During this reaction, a -hydrogen on glutamic acid residues on the precursor protein is extracted, and carbon dioxide reacted to form the new carboxyl group. The vitamin K hydroquinone is converted to vitamin K epoxide in a reaction that is closely linked to the carboxylase activity. Although some vitamin K antagonists inhibit the carboxylase directly, warfarin does not inhibit the vitamin K-dependent carboxylase, except at very high concentration,[11] and is thus not a direct competitor of the action of vitamin K.

Inhibition of -carboxylation of the vitamin K-dependent proteins by warfarin yields proteins in the plasma that are partially carboxylated. [12] [13] The elimination of even a single -carboxyglutamic acid usually disables the function of these proteins; some -carboxyglutamic acid residues are so critical that their absence abolishes biologic activity of the protein.[14] Therefore, the induction of acarboxy- and des--carboxyprothrombin, for example, in the plasma of patients treated with warfarin, yields primarily functionally inert vitamin K-dependent blood-clotting proteins. The coagulant activity correlates closely with the quantity of fully carboxylated proteins that remain in the plasma of patients treated with warfarin.[15]

The vitamin K cycle represents a metabolic pathway for the utilization and recovery of vitamin K after its participation in vitamin K-dependent carboxylation reactions (Fig. 1212) (Chap. 115). Warfarin inhibits some of the enzymes involved in this cycle, blocking the availability of the proper form of vitamin K for participation as a cofactor in the reaction catalyzed by the carboxylase.[16] [17] [18] Vitamin K is reduced to the vitamin K hydroquinone by a vitamin K reductase. This enzyme is inhibited by warfarin. The vitamin K hydroquinone is the cofactor for the

Figure 121-2 Vitamin K cycle and its inhibition by warfarin. Vitamin K is reduced to the vitamin K hydroquinone by a vitamin K reductase inhibited by warfarin. The vitamin K hydroquinone is a cofactor for the vitamin K-dependent carboxylase. In this reaction, the hydroquinone is oxidized to the vitamin K epoxide and glutamic acid is converted to -carboxyglutamic acid. The carboxylase is not inhibited by warfarin. The vitamin K epoxide is salvaged by a vitamin K epoxide reductase, an enzyme sensitive to warfarin inhibition, and is recycled back to vitamin K.

carboxylase. During carboxylation of glutamic acid residues by the carboxylase, the vitamin K hydroquinone is oxidized to the vitamin K epoxide. Warfarin has no effect on this reaction, except at very high concentration. The vitamin K epoxide is recycled to vitamin K via a pathway that requires the vitamin K epoxide reductase. This reaction is inhibited by warfarin,[16] leading to increased plasma levels of vitamin K_1 epoxide.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PHARMACOLOGY

Warfarin sodium is almost always administered by the oral route, hence its role in a class of compounds known as oral anticoagulants. Warfarin is nearly completely absorbed, although considerable variation remains in the individual absorption patterns. Peak warfarin levels are observed at 0.54 hours after oral administration. [19] Warfarin circulates in the blood bound to albumin. With 97% of warfarin bound to albumin, only small amounts of warfarin circulate free in plasma. [20] However, it is this free warfarin that is biologically active. The mean half-life of warfarin in the blood is 44 hours, but this varies widely in different subjects from 15 to 48 hours. [21] This plasma half-life depends on the rate of warfarin absorption and on the rate of warfarin degradation. The individual variation in the half-life of this drug is dominated by the variability of the degradation rate. Renal clearance of warfarin is low because most of the warfarin is bound to albumin. Warfarin is metabolized in the liver to yield a series of inactive metabolites that are recovered in

Figure 121-3 The reduction of the activities of the vitamin K-dependent blood clotting proteins by warfarin. Warfarin (10 mg) was administered to a normal subject on 4 consecutive days. The activities of factors VII, X, and IX and prothrombin are presented as a function of time after the initiation of the medication. Factor VII activity disappears most rapidly, while prothrombin activity decreases more slowly. Factor IX and factor X activities decrease at an intermediate rate. Because the PT is so sensitive to the factor VII concentration, with the initiation of warfarin therapy the PT can be disproportionately prolonged before the levels of factors IX and X and prothrombin are reduced sufficiently to promote an antithrombotic effect.

the urine. [22] Oxidation of warfarin is associated with the hepatic cytochrome P-450 complex.

The biologic effect of warfarin, the decrease in the plasma activity of the vitamin K-dependent proteins, lags behind the peak plasma warfarin concentration. The coagulant activity of each of these proteins in plasma represents a balance between the synthesis of the protein in a completely active -carboxylated form and its utilization and metabolism. The administration of warfarin impairs the complete synthesis of the vitamin K-dependent proteins by inhibiting -carboxylation but does not affect the plasma half-life of these proteins. Thus, the disappearance of biologically active, fully -carboxylated factors VII, X, and IX and prothrombin coagulant activities from the plasma is related to the half-life of each of these proteins. Factor VII activity disappears most rapidly with a half-life of about 6 hours (Fig. 1213). Factors X and IX have half-lives of about 24 hours; these activities decrease less rapidly from the plasma than that of factor VII. Prothrombin has a half-life of about 72 hours, disappearing at the slowest rate of the vitamin K-dependent blood-clotting proteins.

INDICATIONS FOR THERAPY

Warfarin and related oral anticoagulants (see box on Initiation of Warfarin Therapy) are used for the prevention of thromboembolic disorders in patients at risk. [23] [24] Because of the 56% incidence of systemic embolization associated with atrial fibrillation and valvular heart disease, chronic warfarin therapy is routinely used in this clinical setting. Recently, oral anticoagulants have been advocated in all patients with atrial fibrillation. [25] [26] [27] Patients with prosthetic heart valves, particularly of the mechanical type, require chronic warfarin administration to prevent embolism of formed thrombi (see box on Management of Chronic Warfarin Therapy). Other patients, such as the family members of patients with serious thromboembolic disorders secondary to defects in the proteins that regulate blood coagulation, may be placed on oral anticoagulant therapy if they also demonstrate a deficiency in these activities and are considered

INITIATION OF WARFARIN THERAPY

When warfarin therapy is planned for chronic anticoagulation after pulmonary embolism or deep venous thrombosis, patients are routinely treated with heparin during the acute phase of anticoagulation. Heparin is usually administered by continuous intravenous infusion for a period of 714 days. Because warfarin will not prolong the PT for 1 or 2 days after the initiation of therapy and because the anticoagulant action of warfarin is adequate only after 4 or 5 days of therapy, warfarin and heparin are given simultaneously for 4 or 5 days. A large loading dose of warfarin is unnecessary. Warfarin therapy (5 mg/day) can be instituted at the initiation of heparin therapy. Subsequently, the warfarin dose can be adjusted to optimize the prolongation of the PT. When adequate control has been established, heparin therapy may be discontinued.

Warfarin is also used for the initiation of anticoagulant therapy without prior overlapping heparin therapy. A typical example is a patient with valvular heart disease with atrial fibrillation who requires prophylaxis with antithrombotic agents. Although warfarin-induced necrosis is a rare disorder, the prevalence of heterozygous protein C deficiency has been estimated to be 1/300 in the United States. To lower the risk of warfarin-induced necrosis, consideration may be given to either the measurement of the functional protein C level in the plasma of a patient to be treated for the first time with warfarin or to the coadministration of subcutaneous heparin therapy for the first 4 or 5 days of warfarin therapy.

at risk of thromboembolic disease. Warfarin is effective in decreasing the incidence of venous thrombosis after hip surgery [28] [29] and has also been used at low fixed doses in patients with indwelling catheters. [30]

Warfarin is also used to prevent the recurrence of thromboembolic disease. After the acute treatment of thromboembolic diseases, such as pulmonary embolism and deep venous thrombosis, with heparin or fibrinolytic agents, patients are routinely maintained on warfarin for 36 months. The decision to extend treatment for longer periods depends on an analysis of benefit versus risk. Risk factors for recurrent thromboembolic disease include specific abnormalities of coagulation or regulatory proteins,

MANAGEMENT OF CHRONIC WARFARIN THERAPY IN PATIENTS REQUIRING MINOR SURGERY

In patients requiring chronic anticoagulation for such conditions as heart valve prostheses or protein C deficiency, warfarin therapy may need to be discontinued briefly to permit the safe performance of surgical procedures. Warfarin therapy may be stopped 1 week prior to surgery and anticoagulation begun using subcutaneous heparin. With a normal diet, the PT will return to the normal range within the week. Heparin can be discontinued just before surgery. Either heparin and warfarin, or warfarin alone, can be reinstituted after the successful completion of surgery. The period between surgery and the reinitiation of anticoagulants depends on the balance between the risk of bleeding and the risk of thromboembolic disease.

a history of recurrent thromboembolism, and a family history positive for thromboembolism (Chap. 120). Other uses of warfarin therapy are more controversial. Despite the widespread use of warfarin for more than four decades for the prevention of second myocardial infarction as well as pooled data showing a statistically significant, albeit modest, effect, definitive clinical evidence that warfarin alters the incidence of reinfarction is lacking. [31] [32] This question has been revisited in that high-intensity warfarin therapy caused a reduction of recurrent infarction, stroke, and mortality. [33] Despite these results, warfarin has not found a major application in patients with myocardial infarction. Nevertheless, anticoagulant therapy, including heparin and warfarin, does play a role in preventing the arterial and venous thromboembolic complications that may occur during the immediate postinfarction period. It is currently recommended that patients with an anterior myocardial infarction, a subset at high risk of thromboembolism, be treated with prophylactic anticoagulants. [34] [35] The role of warfarin in the treatment of stroke is unclear.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

CONTRAINDICATIONS

Warfarin is contraindicated in patients who fail to comply with the routine administration of the drug and in patients who are unable to obtain regular measurements of the PT. Furthermore, oral anticoagulants should not be used or should be used with extreme caution in patients with either hereditary or acquired bleeding disorders or in patients with anatomic lesions that predispose them to serious bleeding (e.g., active duodenal ulcer). Warfarin crosses the placenta in pregnant women. Because it is teratogenic and has been associated with a fetal warfarin syndrome, [3€] warfarin use is contraindicated during pregnancy. Other anticoagulants, such as subcutaneous heparin or enoxaparin, are used preferentially instead of warfarin to prevent thromboembolism in pregnant women at risk of thromboembolism.

REGULATION OF THERAPY

The PT is routinely used for monitoring therapy with the oral anticoagulants, including warfarin. The PT is a biologic test in which recalcified, citrated patient plasma is clotted by the addition of a crude preparation of tissue factor and lipid, also known as thromboplastin, or highly purified recombinant tissue factor. Thromboplastin is an extract of either brain or lung tissue, or a mixture of both. Tissue factor initiates the extrinsic pathway of blood coagulation, including factor VII, factor X, factor V, prothrombin, and fibrinogen. Decreases in the activities of three vitamin K-dependent proteins, factors VII and X and prothrombin, prolong the PT. The patients PT is usually reported as the clotting time, in seconds, and is compared with the PT of a normal plasma sample. Warfarin is administered to prolong the PT from the normal level (12 seconds) into the therapeutic range. The use of the International Normalized Ratio (INR) is also reported to correct for the variation in potency of different thromboplastins (see following discussion). The warfarin dose is adjusted to obtain the recommended therapeutic INR for a given indication. Because factor VII is at the beginning of the extrinsic pathway and factor VII has the shortest half-life of the vitamin K-dependent blood coagulation proteins, the PT is very sensitive to the factor VII levels; furthermore, the factor VII level is suppressed more quickly than the other vitamin K-dependent proteins. The optimal therapeutic range varies with the indication for warfarin anticoagulation [37] (Chaps. 124 and 125). Standard-intensity warfarin therapy includes a therapeutic PT prolongation of 1.52.0 times the control PT value using the thromboplastin preparations currently used in the United States. When the anticoagulant effect is aimed at this level, bleeding complications occur in about 1020% of patients, with

INTENSITY OF ANTICOAGULANT THERAPY: RECOMMENDED INR VALUES	
Prevention of	
Deep vein thrombosis	2.03.0
Subclavian vein thrombosis	2.03.0
Pulmonary embolism	2.03.0
Prophylaxis against systemic thromboembolic disease	
Atrial fibrillation	2.03.0
Cardiac valve replacement	
Mechanical valves	2.53.5
Tissue valves	2.03.0

about half of these complications occurring when the PT is within the therapeutic range. Low-intensity therapy, with a PT of 1.31.8 times control, has been associated with a significantly lower incidence of bleeding. [38] [39] For these reasons, lower-intensity therapy, with a PT of 1.31.5 times the control PT, appears reasonable in the clinical setting of deep venous thrombosis. However, whether low-intensity therapy provides adequate prophylaxis of thromboembolic disease comparable to standard-dose warfarin therapy in other clinical situations has not been definitely demonstrated. Clinicians should use the INR value in making therapeutic decisions regarding the appropriate dose of warfarin (see box on Recommended INR Values). Furthermore, the INR has been shown to have utility during the induction phase of warfarin therapy.[40]

International Normalized Ratio

Thromboplastins used for PT measurements are derived from a variety of tissues, including brain and lung, and various species, including rabbit, bovine, and human. To standardize the potency of these different thromboplastin reagents, these reagents were calibrated using the standardized human brain thromboplastin reagent, the Manchester comparative reagent, as an international reference preparation. More recently, recombinant tissue factor has been used. A calibration system, based on the linear relationship of the logarithm of the PT of the patient compared to the logarithm of the PT of control plasma, yields the INR:

where the ratio of the patient PT to the control PT is the observed ratio, and c represents the International Sensitivity Index (ISI). Because each thromboplastin yields a unique c value, PTs obtained using different thromboplastins can be compared, hence the INR. Currently, all commercially available thromboplastins are calibrated with regard to the ISI, and individual laboratories report both the PT and the INR for a given sample. The ISI varies, at 1.01.2 in thromboplastins used in Europe to 1.82.8 for the North American thromboplastins. [41] [42]

An independent method of monitoring warfarin anticoagulation has been undergoing clinical evaluation. [15] [43] This method does not rely on the PT or the use of thromboplastins. By monitoring the level of fully -carboxylated prothrombin, or native prothrombin, by immunoassay, it has been possible to identify a therapeutic range of 1224 g/ml in which bleeding complications are minimized and at which the warfarin dosage is adequate to prevent thromboembolic disease. [44] [45] This method has been further evaluated in patients undergoing hip replacement. [46]

Low-dose or minidose warfarin therapy in fixed-dose regimens has been advocated for general prophylaxis of thromboembolic disease following surgery as well as to prevent thrombosis in central venous catheters. [47] [48] Because of the highly individual rates of absorption, utilization, and degradation of warfarin, fixed warfarin doses have variable potencies in different patients. However, the PT is insensitive to low-intensity warfarin therapy. The native prothrombin assay may offer an alternative method to monitor low-intensity therapy because it is sensitive to small amounts of warfarin, permitting adjusted low-dose therapy.

COMPLIANCE

Because of the low toxic/therapeutic ratio, the risk of bleeding associated with warfarin therapy is highest in patients who are not carefully monitored. Therefore, only patients who are willing to subject themselves to the regular inconvenience of the PT measurement should be treated with warfarin. During the initiation of therapy, PT measurements may be required two or three times a week, then once weekly, until an adequate dosage is determined. Patients treated chronically with warfarin who have had stable PT measurements require a PT every 3 or 4 weeks. Furthermore, only reliable patients who will take their medication regularly should be considered for warfarin therapy.

DIET AND DRUG INTERACTION

Both diet and the coadministration of certain drugs can have a marked effect on the magnitude of warfarin action [49] [50] (Table 1211). Certain drugs diminish the pharmacologic response to warfarin. Barbiturates induce hepatic microsomal enzymes, enhancing the degradation of warfarin. Vitamin K antagonizes the inhibitory effect of warfarin on the synthesis of vitamin

TABLE 121-1 -- Effect of Drugs on Warfarin Response

Medications That Potentiate the Effect of Warfarin	
Acetaminophen	Isoniazid
Acetohexamide	Mefenamic acid
Allopurinol	Methimazole
Androgenic and anabolic steroids	Methotrexate
-Methyldopa	Methylphenidate
Antibiotics that disrupt intestinal flora (tetracyclines, streptomycin, erythromycin, kanamycin, nalidixic acid, neomycine)	Nalidixic acid
	Nortriptyline
	Oxyphenbutazone*p*-Aminosalicyclic acid
	Paromomycin
Cephaloridine	Phenylbutazone
Chloramphenicol	Phenytoin
Chlorpromazine	Phenyramidol
Chlorpropamide	Propylthiouracil
Chloral hydrate	Quinidine
Cimetidine	Salicylate
Clofibrate	Sulfinpyrazone
Diazoxide	Sulfonamides
Disulfiram	Thyroid hormone
Ethacrynic acid	Tolbutamide
Glucagon	
Guanethidine indomethacin	
Medications That Depress the Effect of Warfarin	
Antipyrine	Glutethimide
Barbiturates	Griseofulvin
Carbamazepine	Haloperidol
Chlorthalidone	Oral contraceptives
Cholestyramine	Phenobarbital
Digitalis	Prednisone
Ethanol	All vitamin preparations containing vitamin K
Ethchlorvynol	

K-dependent proteins. Whether vitamin K is administered parenterally or orally, or in excess because of dietary intake, the effect is a blunting of the anticoagulant effect of warfarin. A common mechanism for the enhancement of warfarin action is the displacement of warfarin bound to albumin by other drugs that compete for this albumin-binding site. Albumin-binding drugs displace warfarin, thereby increasing the amount of free warfarin in the plasma. It is the free form of warfarin that is pharmacologically active, enhancing warfarin inhibition of vitamin K action. Because the clearance of warfarin from the blood is also a function of the free warfarin level, enhancement of the biologic action of warfarin is followed several days later by a reduction in warfarin action. Numerous drugs displace warfarin from albumin, but model examples include phenylbutazone and chloral hydrate. Chloramphenicol inhibits liver microsomal enzyme synthesis, reducing the normal rate of degradation of warfarin and leading to the enhancement of the effect of a particular warfarin dose.

It is good practice to stabilize the PT on a given dose of warfarin while avoiding changes in medications or diet, including alcohol consumption. In addition to the drugs listed in Table 1211 , a large number of drugs perturb the PT of patients treated with warfarin. Some drug interactions have not been clearly defined. For these reasons, the introduction of any new medication in a patient on stable warfarin therapy requires careful monitoring of the PT during the transition period so as to permit adjustments of the warfarin dosage to accommodate the effects of the new medication. Other anticoagulants or antiplatelet drugs should be avoided during warfarin administration. For example, aspirin increases bleeding complications during warfarin therapy.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

WARFARIN RESISTANCE

Warfarin resistance is an occasional problem in some patients who have previously taken warfarin but are now refractory to normal doses and in other patients who are refractory to warfarin from the onset of therapy. The consideration of warfarin resistance is usually reserved for patients who require in excess of 1520 mg/day of warfarin to maintain the PT within the therapeutic range.

The molecular basis of warfarin resistance is unknown in most patients. Patients unknowingly supplemented with vitamin K, such as those undergoing parenteral nutrition or feedings with enteral nutrition products, are resistant to the action of vitamin K antagonists administered at customary doses. [51] Patients with unusual dietary intake, including large amounts of cruciferous vegetables (e.g., spinach, cabbage, or broccoli) may also be resistant to warfarin because of the large quantities of vitamin K in these foods.[52] [53] Once excess vitamin K intake has been ruled out, the mechanism of warfarin resistance remains speculative. There are no proven examples of antibodies arising to warfarin. A rare condition, hereditary warfarin resistance, is characterized by the absence of warfarin effect on the synthesis of the vitamin K-dependent blood-clotting proteins despite the achievement of very high plasma warfarin levels. [54] [55] Based on the study of the warfarin-resistant rat, it appears that the vitamin K epoxide reductase from these rats is less sensitive to warfarin than is the normal enzyme. [55] [56] [57]

Patients resistant to the effects of warfarin can still be treated with warfarin, but higher doses are necessary. With appropriate care, the warfarin dose can be gradually increased until the PT prolongs into the therapeutic range. In these patients, the warfarin dosage threshold at which the PT becomes unacceptably long is higher than in normal persons, but these patients are just as brittle. Small increases in the warfarin dose can prolong the PT significantly beyond the therapeutic range. Treatment with large doses of warfarin (e.g., >50 mg/day) may have toxicities not observed at conventional doses, so the treating physician may elect to use alternative therapies, such as subcutaneous heparin.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

COMPLICATIONS

Bleeding complications are observed in 1020% of patients treated with warfarin therapy. [38] [39] [44] [58] [59] [60] [61] [62] About one-half of these complications occur when the therapeutic range of the PT has been exceeded, but one-half occur despite a PT within the therapeutic range. These complications may be mild, such as epistaxis, purpura, or hematuria, or they may be more serious, such as retroperitoneal bleeding, the formation of large hematomas, or significant gastrointestinal bleeding (see box on Therapy for Prolonged PT). Life-threatening bleeding, such as intracranial bleeding, does occur, and patients should be warned of the symptom complex of such an event so that they can seek medical attention immediately. The most common agents or disorders associated with excessive anticoagulation (INR >6.0) were acetaminophen, advanced malignancy, recent diarrheal disease, decreased oral intake, and warfarin use in excess of that prescribed. [63]

Patients with missense mutations in the propeptide of factor IX are extremely sensitive to the action of warfarin. Although these patients have a normal partial thromboplastin time, normal factor IX activity, and no bleeding phenotype, administration of warfarin leads to a marked decrease in factor IX activity and a marked increase in bleeding risk. [64] [65]

Warfarin-induced skin necrosis is a rare complication. During the onset of warfarin therapy, usually between days 2 and 7, the patient develops a bluish purple lesion on the thigh, breast,

THERAPY FOR PROLONGED PROTHROMBIN TIMES AND BLEEDING COMPLICATIONS

Bleeding complications occur frequently in association with warfarin therapy. Severe complications, such as intracranial bleeding or massive gastrointestinal bleeding, must be treated rapidly and effectively. The PT should be normalized as quickly as possible by the infusion of 23 U of fresh frozen plasma to replenish the activities of the vitamin K-dependent proteins. Current preparations of the vitamin K-dependent proteins labeled as factor IX concentrations (e.g., Konyne, Proplex) have no role in the treatment of warfarin overdosage because these agents carry an unacceptable risk of hepatitis transmission. Vitamin K can be administered to reverse the effects of warfarin, but it must be realized that vitamin K will not be effective until 1236 hours later. Patients given vitamin K may be refractory to the action of warfarin for a period of time after anticoagulant therapy is reinstituted.

Moderate complications, such as hematomas, hemarthrosis, or mild gastrointestinal bleeding, may be treated by the discontinuation of warfarin therapy and the administration of vitamin K. Vitamin K_1 (Aquamephyton) can be administered intravenously (with appropriate caution and monitoring of severe allergic reactions) at a dose of 10 mg. The PT will return toward the normal range within 24 hours.

Mild complications, such as purpura, ecchymoses, or epistaxis, can be treated by withholding or reducing warfarin therapy until the PT returns into the therapeutic range. In this situation, fresh frozen plasma carries an unnecessary risk of viral infection and vitamin K administration greatly complicates reinstitution of anticoagulant therapy with warfarin.

buttock, or toes. This lesion is characterized by a clear line of demarcation between the affected area and surrounding tissue. Over several days, this lesion becomes increasingly necrotic, while the surrounding area becomes erythematous and inflamed. The histology of the lesion reveals thrombi in the microvasculature. This syndrome is often due to the exaggeration of protein C deficiency by warfarin in a patient who has hereditary heterozygous protein C deficiency. [66] Protein C, a regulatory plasma protein that serves as a natural anticoagulant, requires vitamin K for its complete synthesis (Chap. 104). Because protein C has a relatively short plasma half-life (Fig. 1213), warfarin induces a relative protein C deficiency before it reduces the activity of the vitamin K-dependent blood-clotting proteins to an anticoagulant level. Because patients with heterozygous protein C deficiency are especially susceptible to this complication, they should only be treated with warfarin when heparin is used simultaneously during the first 4 or 5 days of therapy. Warfarin-induced skin necrosis has also been reported in rare cases of hereditary protein S deficiency.

REVERSAL OF WARFARIN EFFECT

Overdosage of warfarin is a common problem that occasionally leads to serious bleeding manifestations. Although generally observed in patients being treated for thromboembolism, warfarin overdosage may also be seen after accidental or surreptitious ingestion. Proper therapy depends on the level of bleeding complications. In patients with prolongation of the PT without signs of bleeding, warfarin can be withheld until the PT approaches the therapeutic range. Patients with life-threatening bleeding disorders, including intra-abdominal or intracranial hemorrhage, require urgent, immediate correction of the PT. These patients must be treated with fresh frozen plasma (23 U) as a source of the vitamin K-dependent blood coagulation proteins. Because fresh frozen plasma carries the risk of infection, the severity of the bleeding episode must be balanced against the risk of hepatitis. Factor IX concentrates include the vitamin K-dependent blood-clotting proteins in a partially purified form. However, because current products essentially ensure the transmission of hepatitis to patients who lack immunity to hepatitis, they are contraindicated. Improvements in the large-scale preparation of purified vitamin K-dependent proteins may offer new agents that will prove useful. [67] [68] [69] Vitamin K can be administered to reverse the effects of warfarin. However, the response to vitamin K is delayed for 1224 hours due to the requirement for de novo synthesis of the vitamin K-dependent blood-clotting proteins. Furthermore, vitamin K administration usually results in normalization of the PT and will interfere with re-anticoagulation with vitamin K antagonists. Furthermore, patients treated with vitamin K may be resistant to warfarin action once warfarin therapy is reinitiated. For these reasons, vitamin K therapy is best reserved for patients with serious bleeding complications initially treated with fresh frozen plasma and whose anticoagulant management can be approached with alternative methods (e.g., heparin). Because the absorption of oral vitamin K, vitamin K_1 (Aquamephyton), is variable, the treatment of warfarin overdosage best involves administration of intravenous vitamin K_1 .

Chapter 122 - Heparin

Mark A. Crowther
Jeffrey S. Ginsberg
Douglas M. Tollefsen
Morey A. Blinder

INTRODUCTION

In 1923, Howell[1] used the term heparin to describe an aqueous extract of canine liver that inhibited coagulation of blood in vitro. During the next decade, similar extracts were shown to consist of mixtures of sulfated polysaccharides containing uronic acid and glucosamine. [2] In 1939, investigators in Canada and Sweden reported the successful use of heparin as a treatment for recurrent thrombosis and pulmonary embolism. [2] [3] The indications for heparin were soon expanded to include vascular surgical procedures, extracorporeal circulation, and prophylaxis of thromboembolism.

Heparin is a sulfated glycosaminoglycan that, when administered intravenously, binds to antithrombin, leading to rapid inhibition of proteases of the coagulation pathways. This interaction produces a potent anticoagulant effect. Endogenous heparin-like molecules appear to be involved in the inhibition of coagulation within normal blood vessels and may have a variety of other biologic functions. Although heparin is an effective agent for the treatment and prevention of venous thromboembolic disease, it can produce bleeding and can trigger thrombocytopenia, which is associated with both venous and arterial thrombosis.

Low-molecular-weight (LMW) heparins are produced by enzymatic or chemical depolymerization of standard heparin. LMW heparins produce the majority of their anticoagulant effect by catalyzing the interaction between antithrombin and factor Xa. In clinical practice, the LMW heparins offer substantial benefits over standard heparin; their principle advantages are a predictable pharmacokinetic profile (allowing weight-adjusted subcutaneous treatment without monitoring), a reduced risk of heparin-induced thrombocytopenia, and a potential reduction in the risks of bleeding and osteoporosis.

STRUCTURE AND BIOSYNTHESIS

Heparin

Heparin is found in the secretory granules of mast cells. It is synthesized from uridine diphosphate-sugar precursors as a highly sulfated polymer of alternating uronic acid and D-glucosamine.[4] The glycosaminoglycan chains are built on a core structure consisting of one xylose and two galactose residues covalently attached to serine in a polypeptide backbone. About 1015 glycosaminoglycan chains, each containing 200300 monosaccharide

---

units, are attached to a single core protein to yield a proteoglycan with a molecular weight of 750,0001,000,000.

Related Glycosaminoglycans

Two other glycosaminoglycans, heparan sulfate and dermatan sulfate, also have anticoagulant activity. [5] Heparan sulfate is closely related to heparin and is found on the surface of most eukaryotic cells and in the extracellular matrix. Heparan sulfate proteoglycans vary considerably in structure. In general, they are smaller than the heparin proteoglycan and contain fewer glycosaminoglycan chains linked to a larger and more complex core protein. In some cases, the core protein has a hydrophobic domain that anchors the proteoglycan to the cell membrane. Dermatan sulfate is a repeating polymer of L-iduronic acid and *N*-acetyl-D-galactosamine. [6] Like heparan sulfate, dermatan sulfate is a component of proteoglycans on the cell surface and in the extracellular matrix.

ANTICOAGULANT ACTIVITY

Antithrombin

Studies by Brinkhous et al.[7] in 1939 indicated that the anticoagulant effect of heparin is mediated by an endogenous plasma component, termed heparin cofactor. Thirty years later, antithrombin was purified from plasma and shown to have heparin cofactor activity, that is, the ability to inhibit thrombin rapidly only in the presence of heparin.[8] [9] Antithrombin is a M_r 58,000 single-chain glycoprotein that is homologous to members of the $_1$ -antitrypsin family of serine protease inhibitors (serpins).[10] [11] [12] It is synthesized in the liver and circulates in plasma at a concentration of 3 M. [13] Antithrombin inhibits activated coagulation factors of the intrinsic and common pathways, including thrombin, factor Xa, and factor IXa, but has relatively little activity against factor VIIa. [14] Antithrombin acts as a suicide substrate for its target proteases. Inhibition occurs when a protease attacks the reactive site Arg 393-Ser 394 peptide bond in antithrombin and becomes trapped as a stable 1:1 covalent complex.[15] [16]

The concentration of antithrombin in plasma exceeds that of any of the target proteases that are generated during coagulation. Under these conditions, protease inhibition in plasma can be described by pseudo-first-order kinetics. In the absence of heparin, thrombin and factor Xa are inhibited by antithrombin with a half-life of about 0.51.5 minutes, whereas factor IXa is inhibited about 10 times more slowly. [17] These rates of inhibition are too slow to affect coagulation in vitro. Heparin increases the rate of inhibition of thrombin, factor Xa, and factor IXa by antithrombin approximately 1,000-fold. [17] As a result, inhibition of these proteases in heparinized plasma is essentially instantaneous.

Factor Xa bound to platelets in the prothrombinase complex[18] and thrombin bound to fibrin[19] [20] are both protected from inhibition by antithrombin in the presence of heparin. Thus, heparin may promote inhibition of factor Xa and thrombin in solution only after they have diffused away from these binding sites. By contrast, factor VIIa bound to tissue factor is inhibited by antithrombin in the presence of heparin with a half-life of about 2 minutes, whereas the rate of inhibition of free factor VIIa is negligible.[21] [22] Whether the rate of inhibition of factor VIIa/tissue factor by antithrombin is sufficient to affect coagulation in vivo is unknown. The major anticoagulant effect of heparin is apparently to blunt the positive feedback reactions of thrombin on activation of factors V and VIII and thus to decrease the rate of thrombin generation.[23] [24] [25]

When heparin is added to plasma at a therapeutic concentration (0.11.0 U/ml), factors IXa and Xa and thrombin are inhibited almost exclusively by antithrombin. In the presence of higher concentrations of heparin or dermatan sulfate, thrombin is inhibited primarily by heparin cofactor II. [26] [27] Heparin also stimulates inhibition of thrombin by plasminogen activator inhibitor 1,[28] protein C inhibitor,[29] and protease nexin-1 (glia-derived nexin)[30] and inhibition of factor Xa by tissue factor pathway inhibitor (TFPI).[31] [32] The latter four inhibitors are present in plasma at > 1/100 the concentration of antithrombin. Intravenous infusion of heparin increases the level of circulating TFPI severalfold, presumably by causing release of TFPI from binding sites on the endothelium. [33]

Heparin accelerates plasminogen activation by tissue plasminogen activator (t-PA) or urokinase but decreases the stimulatory effect of fibrin on t-PA activity. [34] Inhibition of t-PA or urokinase by plasminogen activator inhibitor 1 is unaffected by heparin. [35] The net effect of an intravenous infusion of heparin may be to enhance fibrinolysis mediated by endogenous t-PA.[36] However, heparin does not appear to enhance the thrombolytic effect of exogenously administered t-PA. [37]

Binding of Heparin to Antithrombin

Binding of heparin to antithrombin is essential to accelerate formation of antithrombin/protease complexes. When heparin is fractionated according to its ability to bind to antithrombin, the high-affinity molecules possess virtually all of the anticoagulant activity of the starting material, whereas the low-affinity molecules are inactive. [38] [39] [40] Heparin binds non-covalently to antithrombin with a dissociation constant (K_d) of 2×10^{-8} M.[41]

The high-affinity binding site for antithrombin within a heparin chain is a specific pentasaccharide structure. [42] [43] [44] This structure contains a 3-O-sulfate group that appears to be unique to the high-affinity binding site for antithrombin. Several of the sulfate groups within the pentasaccharide are essential for binding to antithrombin, whereas others do not appear to be required. In commercial heparin preparations, approximately 30% of the molecules contain this structure and bind to antithrombin with high affinity.[38] [39] [40] An identical structure is thought to arise during the biosynthesis of heparan sulfate chains, although at a much lower frequency. Heparan sulfate chains that contain this structure bind to antithrombin and stimulate protease inhibition. Other glycosaminoglycans that lack the specific pentasaccharide structure (e.g., dermatan sulfate, chondroitin-4-sulfate, or chondroitin-6-sulfate) do not bind to antithrombin with high affinity. [27]

Heparin binding induces a conformational change in antithrombin that appears to lock the glycosaminoglycan into place on the surface of the inhibitor. [41] The heparin/antithrombin complex then reacts rapidly with a target protease. Interaction with a protease reduces the affinity of antithrombin for heparin, allowing the antithrombin/protease complex to dissociate from the glycosaminoglycan chain.[45] Thus, a single heparin molecule can catalyze the formation of many antithrombin/protease complexes.

Catalytic Mechanism

Two models have been proposed to explain the catalysis of antithrombin/protease reactions by heparin. In the first model, heparin binding induces a conformational change in the reactive site of antithrombin that allows a target protease to interact more efficiently with this site. [9] [17] In the second model, the heparin chain functions as a template that binds antithrombin and the target protease simultaneously to form a ternary complex, and catalysis occurs mainly by an approximation effect. [46] Current evidence suggests that both mechanisms are valid but differ in their relative importance depending on the target protease.

The balance between the two mechanisms may explain differences in the rate enhancement for inhibition of thrombin and

factor Xa produced by heparin chains of varying length. For example, the synthetic pentasaccharide that contains only the antithrombin binding site of heparin increases the rate of inhibition of factor Xa about 270-fold but has relatively little effect on the rate of inhibition of thrombin. [47] Because an oligosaccharide of this size is unlikely to function as a template, induction of a conformational change in antithrombin may be sufficient to catalyze inhibition of factor Xa. Longer heparin chains produce an additional twofold increase in the rate of factor Xa inhibition, which may represent the contribution of the template mechanism. Stimulation of the thrombin/antithrombin reaction requires heparin molecules that contain at least 18 sugar residues (molecular weight 5,400), which is the smallest chain able to form a ternary complex with antithrombin and thrombin.[48] The factor IXa/antithrombin reaction has a similar requirement for longer heparin chains. Therefore, inhibition of thrombin and factor IXa may depend primarily on the template mechanism.

Thrombin binds to heparin with a K_d of 610 × 10^6 M under physiologic conditions.[49] Chemical modifications of thrombin that decrease its affinity for heparin greatly reduce the ability of heparin to stimulate the thrombin/antithrombin reaction. [50] Factor Xa also binds to heparin, but with a much lower affinity in comparison with thrombin. Inhibition of factor Xa by antithrombin in the presence or absence of heparin is unaffected by changes in ionic strength or by chemical modification of factor Xa to reduce its affinity for heparin,[47] [51] suggesting that catalysis of the reaction between antithrombin and thrombin, but not factor Xa, requires binding of heparin both to antithrombin and to the protease.

Heparin Cofactor II

Heparin cofactor II (M_r 66,000) is a single-chain glycoprotein that is about 30% identical in amino acid sequence to antithrombin. [52] [53] [54] It is present in plasma at a concentration of 1 M.[52] Heparin cofactor II inhibits only thrombin; it does not inhibit the other proteases generated during coagulation or fibrinolysis. [55] In contrast to antithrombin, heparin cofactor II also inhibits chymotrypsin-like proteases, albeit slowly. [55] [56]

The affinity of heparin cofactor II for heparin is lower than that of antithrombin. Therefore, an approximately 10-fold higher concentration of heparin is necessary to accelerate thrombin inhibition by heparin cofactor II in plasma. [27] By contrast, the activity of heparin cofactor II is stimulated approximately 1,000-fold by dermatan sulfate, which has no effect on the activity of antithrombin. [27] Heparin cofactor II binds to a high-affinity site in dermatan sulfate. [57]

Addition of dermatan sulfate to plasma causes prolongation of the thrombin time and activated partial thromboplastin time (PTT), [5] and intravenous infusion of dermatan sulfate produces an antithrombotic effect in experimental animals[58] [59] [60] [61] [62] and humans.[63] [64] [65] These effects appear to be mediated primarily by heparin cofactor II.[27] [66] [67] Several other natural or synthetic polyanions, including pentosan polysulfate, [68] fucoidan, [69] and chondroitin sulfate E,[70] have been reported to stimulate inhibition of thrombin by heparin cofactor II; these compounds also appear to have some activity with antithrombin.

PHYSIOLOGIC FUNCTIONS

Vascular Heparan Sulfate

Because of the dramatic effect of heparin on the activity of antithrombin in vitro, it has been assumed that an endogenous heparin-like substance must stimulate antithrombin in vivo. Current evidence suggests that heparan sulfate proteoglycans anchored in the vessel wall interact with circulating antithrombin to produce an antithrombotic effect.

Glycosaminoglycans extracted from cloned endothelial cells have anticoagulant activity, and de novo biosynthesis of heparan sulfate proteoglycans has been demonstrated in cultured endothelial cells. [71] [72] Approximately 110% of the labeled heparan sulfate from endothelial cells binds to immobilized antithrombin with high affinity, suggesting that only this proportion contains the antithrombin-binding pentasaccharide of heparin.

Antithrombin binds to cultured bovine aortic endothelial cells (about 60,000 sites per cell) with a K_d of 12×10^{9} M, and binding is diminished by pretreatment of the cells with heparinase. [72] Electron microscopic autoradiography of ^{125}I-labeled antithrombin bound to endothelial cells in culture or after perfusion of segments of rat aorta ex vivo indicates that >90% of the antithrombin is associated with the extracellular matrix located in the subendothelium. [73] Binding of antithrombin to the subendothelial matrix of the aorta is greatly increased after crush injury, which causes detachment of most of the endothelial cells. Interaction of coagulation proteases with antithrombin bound to subendothelial heparan sulfate proteoglycans may inhibit thrombosis. [73] Interleukin-1 and tumor necrosis factor decrease heparan sulfate biosynthesis by cultured endothelial cells and reduce the amount of antithrombin that can be bound per cell by about 50%. [74] This mechanism may contribute to the increased thrombogenicity of the endothelium induced by cytokines.

When a trace amount of thrombin is injected into the circulation, the thrombin appears to become bound initially to thrombomodulin on the endothelial cell surface. [75] In comparison with free thrombin, thrombin bound to thrombomodulin reacts less rapidly with fibrinogen and heparin cofactor II, more rapidly with protein C, and at about the same rate with antithrombin. [76] The net effect of these changes in substrate specificity may be a small increase (about threefold) in the rate of the thrombin/antithrombin reaction because of diminished competition from other substrates. After the thrombomodulin has become saturated with thrombin, the excess thrombin may be inhibited rapidly by antithrombin bound to heparan sulfate proteoglycans. [77] Platelet factor 4, released by the platelet during platelet aggregation, competitively inhibits binding of antithrombin to heparan sulfate and may promote local clot formation at the site of hemostasis. [78]

Mast Cell Heparin

Heparin binds cationic molecules such as histamine and neutral proteases to form crystalline arrays within the secretory granules of mast cells, [79] but its physiologic function is otherwise unknown. Under normal circumstances, heparin is not released from mast cells into the circulation and cannot be detected in plasma. However, a small amount of heparin may appear in the circulation of patients with systemic mastocytosis and produce mild prolongation of the PTT. [80]

Tumor-Derived Heparan Sulfate

Circulating heparan sulfate, apparently released from tumor cells, has been reported to cause marked prolongation of the thrombin time and PTT and to cause bleeding in a few severely ill patients with malignancies. [81] [82] [83] [84] Protamine neutralizes the heparan sulfate anticoagulant in vitro and may be an effective treatment for patients with this type of anticoagulant. [84] [85] A coagulopathy associated with circulating heparan sulfate and dermatan sulfate has also been observed in a few patients who were treated with high-dose suramin for metastatic adrenocortical carcinoma. [86]

Inhibition of Cell Proliferation

Heparin inhibits growth of a variety of cultured cells, including endothelial cells, vascular smooth muscle cells, and renal mesangial

---

cells. In addition, heparin prevents the extraordinary proliferation of vascular smooth muscle cells that follows damage to the endothelium in vivo, as demonstrated in the rat carotid artery. [87] These effects are independent of the anticoagulant activity of heparin. [88] Heparan sulfate proteoglycans synthesized by postconfluent vascular smooth muscle cells and endothelial cells also have antiproliferative activity and can be removed from the cells by a platelet heparinase. [89] This phenomenon suggests that smooth muscle cell proliferation in a damaged blood vessel might be triggered by heparinase in combination with growth factors released from the platelets. The mechanism by which heparin and heparan sulfate suppress cell growth appears to involve inhibition of a protein kinase C-dependent signaling pathway early in the cell cycle. [90]

Angiogenesis

Acidic and basic fibroblast growth factors (FGF) bind to heparin with very high affinity. [91] These growth factors are mitogens for endothelial cells, smooth muscle cells, and other mesenchymal cells, and they induce angiogenesis. Although heparin inhibits growth of capillary endothelial cells in vitro, it potentiates the growth-promoting effect of acidic FGF on these cells. [92] This effect depends on the size and degree of sulfation of the heparin molecule but not on its anticoagulant activity. Heparan sulfate proteoglycans in the extracellular matrix bind and stabilize basic FGF and may serve as a reservoir from which the growth factor can be released by an excess of heparin or digestion with heparitinase. [93] Heparan sulfate provides a low-affinity binding site for basic FGF on the surface of target mesenchymal cells. Furthermore, cell surface heparan sulfate or exogenous heparin promotes the binding of basic FGF to its high-affinity receptor (a transmembrane protein with tyrosine kinase activity) and is required for the biologic activity of basic FGF. [94] [95] Highly sulfated oligosaccharides that bind basic FGF have been isolated from heparin or heparan sulfate. [96] [97]

CLINICAL APPLICATIONS

Pharmacologic Effects

Heparin produces an immediate anticoagulant effect when administered intravenously. At a plasma concentration of 0.11.0 U/ml, heparin causes thrombin and factor Xa to be inhibited very rapidly (half-lives <0.1 second) by antithrombin. Higher concentrations of heparin (>5 U/ml), which may be present transiently after a bolus intravenous infusion, may also stimulate thrombin inhibition by heparin cofactor II. [26] These effects result in prolongation of the PTT and the thrombin time. Although the prothrombin time may also be prolonged, it is affected to a lesser degree by heparin. LMW heparin and dermatan sulfate have substantial antithrombotic activity at doses that do not predictably affect the PTT. [58] [98]

Heparin clears lipemic plasma in vivo by causing the release of lipoprotein lipase from the endothelium into the circulation. Lipoprotein lipase hydrolyzes triglycerides present in chylomicrons and very-low-density lipoproteins to glycerol and free fatty acids. [99] The clearing of lipemic plasma may occur at a dose of heparin below that which produces an anticoagulant effect, and rebound hyperlipemia may occur after heparin is discontinued. The effects of heparin on lipid metabolism are striking but have no obvious clinical importance.

Preparations

Heparin for therapeutic use is commonly extracted from porcine intestinal mucosa or bovine lung. During the isolation of heparin from these sources, the core protein is removed, and the glycosaminoglycan chains become degraded slightly to yield a heterogeneous mixture of fragments with a mean molecular weight of 12,000 (range 5,00030,000). These preparations may also contain small amounts of other glycosaminoglycans. [100] Despite the heterogeneity in source and composition among different commercial heparin preparations, their biologic activities are similar (150 USP U/mg).

The USP unit is defined as the quantity of heparin that will prevent 1.0 ml of citrate-anticoagulated sheep plasma from clotting for 1 hour after the addition of 0.2 ml of 1% calcium chloride. Standard heparin extracted from porcine intestinal mucosa or bovine lung is available as the sodium salt in aqueous solutions of 10,00040,000 USP U/ml. The calcium salt of heparin from porcine intestinal mucosa has been associated with a lower frequency of local hematoma when injected subcutaneously and is used commonly in Europe in a low-dose regimen for prevention of thromboembolism. [101]

The LMW heparins (mean molecular weight 4,0006,500) are isolated from standard heparin by gel filtration chromatography, precipitation with ethanol, partial depolymerization with nitrous acid, or other chemical techniques. [102] LMW heparin preparations accelerate factor Xa inhibition at a dosage similar to that of standard heparin but have greatly reduced thrombin inhibitory activities. The ratio of antithrombin to anti-factor Xa activity of a given preparation depends largely on the percentage of molecules that are of sufficient length to accelerate the thrombin/antithrombin reaction. [103] The LMW heparins are being used with increasing frequency in patients because of their increased convenience, and in some cases efficacy, when compared to standard heparin.

The heparinoid danaparoid sodium is a mixture of several types of nonheparin glycosaminoglycans (84% heparan sulfate, 12% dermatan sulfate, 4% chondroitin sulfate) extracted from porcine intestinal mucosa. Danaparoid sodium is an effective anticoagulant that has been used for the treatment of acute deep vein thrombosis,[104] prevention of deep vein thrombosis in patients at high risk, [105] [106] [107] [108] and the treatment of patients with heparin-associated thrombocytopenia. [109] [110]

Absorption and Pharmacokinetics

Heparin is not absorbed through the gastrointestinal mucosa and, therefore, must be given parenterally. It is usually administered by continuous intravenous infusion or subcutaneous injection. Heparin has an immediate onset of action when given intravenously. The onset of action of subcutaneous heparin generally occurs within 2060 minutes. The pharmacokinetic profiles of standard heparin vary widely between individuals, as a result of protein binding of the heparin within the plasma. [111] [112] [113] [114] The LMW heparins demonstrate much less protein binding. Thus they have a predictable dose-response profile when administered by subcutaneous or intravenous injection. [102] [111]

Following a bolus intravenous injection, elimination of heparin activity from the blood can be described by first-order kinetics. However, the half-life of standard heparin varies with the dose administered. [115] The half-life of the anticoagulant activity in humans is approximately 1, 1.5, and 2.5 hours at doses of 100, 200, and 400 U/kg, respectively. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system. A small amount of undergraded heparin is excreted in the urine. The half-life of heparin may be shortened in patients with pulmonary embolism and prolonged in patients with hepatic cirrhosis or end-stage renal disease. [116]

The LMW heparins have longer biologic half-lives than standard heparin preparations. Although it is thought that LMW heparins are eliminated in large part by renal excretion,[117] the half-life of reviparine (an LMW heparin) was only slightly prolonged in dialysis-dependent patients when compared with healthy controls. In addition, the half-life of reviparine was near normal while the patients were undergoing dialysis. [118] Of note,

each LMW heparin preparation is produced using a unique process; as a result, the products are not interchangeable, having different pharmacokinetic profiles. [119]

Administration and Dosage

Continuous intravenous infusion is the usual method of administration of full-dose heparin because the incidence of bleeding complications is lower in comparison with intermittent infusions. [120] Heparin therapy can be initiated with a bolus injection of 5,000 U followed by 1,0001,300 U/hr delivered by an infusion pump. Adjusted-dose subcutaneous administration can be used for the long-term management of patients in whom warfarin is contraindicated (e.g., during pregnancy). A daily dose of 25,00035,000 U given as divided doses every 12 hours is usually sufficient to achieve a therapeutic effect similar to that of intravenous heparin. If therapeutic doses of subcutaneous heparin are used, a PTT should be performed 6 hours after the injection, and the dose titrated to achieve a PTT in the therapeutic range. Low-dose heparin (5,000 U subcutaneously every 8 or 12 hours) decreases the incidence of venous thromboembolism in certain high-risk patients; however, it is associated with a slight increase in the risk of perioperative hemorrhage. [121]

The LMW heparins are usually administered using a weight-adjusted dose subcutaneously once or twice daily, but they can be administered intravenously. Dosing of LMW heparins varies among products (Table 1221). The LMW heparins may be preferable to standard heparin for long-term subcutaneous administration because

they do not require monitoring, have a lower risk of producing heparin-induced thrombocytopenia, [122] and may be associated with a reduced risk of osteoporosis. [123] [124]

Laboratory Monitoring

Therapy with standard heparin is usually monitored with a global test of coagulation, such as the whole blood clotting time, whole blood recalcification time, or PTT. Because of its convenience and rapid turn-around time, the PTT is the most widely used test. The optimal PTT therapeutic range for standard heparin is that which produces an equivalent anti-Xa heparin level of 0.30.7 U/ml. The PTT value that corresponds to this range can vary widely between PTT reagents and testing equipment. In most centers, the optimal range will be 6590 seconds. Major bleeding complications can occur even though the PTT is within the therapeutic range. [125] [126] [127]

Because of the fear of bleeding from overdosage, intuitive adjustments in the heparin infusion rate often result in subtherapeutic PTT results during the first 2448 hours of treatment.[127] Recent prescription guidelines for continuous intravenous heparin have reduced the incidence of subtherapeutic PTT results to <2% of patients during the first 24 hours. Supratherapeutic PTT occurred in about two-thirds of patients who received warfarin simultaneously, but the risk of bleeding was not increased in these patients.[127] Although laboratory monitoring of low-dose subcutaneous heparin is generally unnecessary, care should be taken in patients with low body mass, who may become therapeutically anticoagulated at a standard prophylactic dose.

The LMW heparins do not produce a predictable prolongation of the PTT at therapeutic doses. Fortunately, the LMW heparins have predictable pharmacokinetics and can be administered using a weight-based algorithm without laboratory monitoring. [128] However, if monitoring is required, an anti-Xa heparin level using an LMW heparin standard should be performed. The target anti-Xa heparin range for the treatment of acute venous thromboembolism is 0.51.5 anti-Xa U/ml; for the prophylaxis of venous thromboembolism, a level of 0.20.5 U/ml is adequate.

As with the LMW heparins, monitoring of danaparoid sodium cannot be performed using the PTT. Rather an anti-Xa heparin level, using a standard curve of known danaparoid sodium concentrations, is used. The optimal anti-Xa range for danaparoid sodium anticoagulation (either therapeutic or prophylactic) has not been established. Therefore, it is clinical practice to target a range similar to that used for the LMW heparins.

TABLE 122-1 -- Indications and Doses of Low-Molecular-Weight Heparins

Indication	Drug	Dose	Frequency
Prophylaxis			
General surgery			
Low risk	Dalteparin	2,500 U	12 hr preoperatively then once daily after surgery
	Enoxaparin	2,000 U	12 hr preoperatively then once daily after surgery
	Nadroparin	3,100 U	2 hr preoperatively then once daily after surgery
High risk	Dalteparin	5,000 U	1012 hr preoperatively then once daily after surgery
	Enoxaparin	4,000 U	1012 hr preoperatively then once daily after surgery
Orthopedic surgery	Ardeparin	50 U/kg	Twice daily after surgery
	Dalteparin	5,000 U	812 hr preoperatively and once daily after surgery
	Enoxaparin	3,000 U	Twice daily after surgery
	Enoxaparin	4,000 U	1012 hr preoperatively then once daily after surgery
	Nadroparin	40 U/kg	2 hr preoperatively then once daily after surgery for 3 days, then increase dose to 60 U/kg
	Tinzaparin	50 U/kg	2 hr preoperatively then once daily after surgery
	Tinzaparin	75 U/kg	Once daily beginning 1224 hr after surgery
Acute spinal injury	Enoxaparin	3,000 U	Twice daily
Multiple trauma	Enoxaparin	3,000 U	Twice daily
Medical conditions	Dalteparin	2,500 U	Once daily
	Enoxaparin	2,000 U	Once daily
Treatment			
Venous thrombosis	Dalteparin	100 U/kg	Twice daily
	Enoxaparin	100 U/kg	Twice daily
	Nadroparin	90 U/kg	Twice daily
	Tinzaparin	175 U/kg	Once daily
Unstable angina	Dalteparin	100 U/kg	Twice daily
	Enoxaparin	100 U/kg	Twice daily

Heparin Resistance

The dose of heparin required to produce a therapeutic PTT varies from patient to patient. The variability is due to differences in the plasma concentrations of heparin-binding proteins such as histidine-rich glycoprotein, vitronectin, and platelet factor 4, which competitively inhibit binding of heparin to antithrombin. [78] [129] [130] In patients with venous thromboembolism, the therapeutic dose is usually <35,000 U/day. Occasionally, the PTT will fail to become prolonged unless a very high dose (>50,000 U/day) of heparin is administered. The level of heparin in these patients may be therapeutic at the usual dose when measured by other tests (e.g., anti-factor Xa activity or protamine sulfate titration). The majority of these "heparin-resistant" patients have high levels of factor VIII as well as heparin-binding proteins (which are acute phase reactants) in their plasma. Patients with inherited antithrombin deficiency ordinarily have 4060% of the normal plasma concentration of this inhibitor, and the PTT responds normally to heparin in most of these patients. [131] [132] However, acquired antithrombin levels of <25% of normal may occur in patients with hepatic cirrhosis,[133] nephrotic syndrome,[134] or disseminated intravascular coagulation (DIC).[135] In these instances, large doses of heparin may not prolong the PTT. Heparin itself can cause a modest (15%) decrease in the circulating antithrombin concentration, but this effect is unlikely to have clinical significance. [136] [137]

Indications for Therapy

Venous Thromboembolism

Standard or LMW heparins are used in the initial treatment of venous thromboembolic disease because of their rapid onset of action. In patients with deep vein thrombosis, initial treatment with a vitamin K antagonist alone is inferior to the combination of heparin plus a vitamin K antagonist in preventing further thromboembolic complications.[138] Under most circumstances, oral vitamin K antagonists are preferred to heparin or LMW heparin for long-term treatment of thromboembolism because of their convenience and lower cost. However, it is likely that long-term treatment with subcutaneous LMW heparin or standard heparin is at least as safe and

effective as treatment with oral anticoagulants.

Patients with acute venous thromboembolism can be treated safely and effectively with subcutaneous LMW heparin administered out of hospital. Three large, well-designed studies have demonstrated that outpatient treatment of acute deep vein thrombosis using unmonitored, weight-adjusted LMW heparin is as safe and effective as inpatient treatment with adjusted dose intravenous standard heparin. [139] [140] [141] In addition, one of these trials and a separate study [142] have demonstrated the safety and efficacy of treatment of acute pulmonary embolism with LMW heparin. Subsequent clinical experience has demonstrated that the majority (>80%) of unselected patients presenting with acute venous thromboembolism can be safely and effectively treated as outpatients. [143]

Oral anticoagulants can be initiated on the day of presentation with acute venous thromboembolism. However, heparin therapy should be continued for a minimum of 4 days, irrespective of the International Normalized Ratio value. The 4-day overlap of heparin and warfarin is required to ensure adequate anticoagulation during the initial days of warfarin, when an acute warfarin-induced fall in the levels of protein C produces a potential hypercoagulable state, during which acute extension of thrombosis could occur.

Occasional patients will suffer recurrent thromboembolism despite therapeutic anticoagulation with warfarin. These patients can be effectively treated with long-term adjusted-dose standard heparin, or long-term weight-adjusted unmonitored LMW heparin.

Acute Coronary Syndromes

When used alone, heparin is effective in the short-term treatment of unstable angina, but a rebound is seen when the drug is stopped. [144] Aspirin appears to prevent the cluster of ischemic events that occurs when heparin is discontinued. Evidence suggests that the addition of heparin to aspirin improves short-term outcome in patients with unstable angina, but it is uncertain whether this effect is sustained.

Several large studies have recently suggested that LMW heparin in combination with aspirin is at least as effective as standard heparin in patients with unstable angina. [145] [146] [147] These studies, two of which used dalteparin and one of which used enoxaparin, compared the use of subcutaneous LMW heparin with intravenous standard heparin. Once again, the major advantage of LMW heparin in this patient population is its predictable pharmacokinetics that allow weight-based dosing without monitoring.

In patients with acute myocardial infarction, heparin has been reported to reduce reinfarction and death. Moderate doses of heparin (12,500 U subcutaneously 12 hourly) reduce the incidence of mural thrombosis detected by two-dimensional echocardiography, which is a particular problem in patients with anterior wall myocardial infarction. [148]

Heparin prevents early reocclusion of the infarct-related artery after successful thrombolysis with t-PA. However, a recent meta-analysis [149] has suggested that routine administration of therapeutic doses of heparin to patients with acute myocardial infarction is not indicated. This analysis demonstrated that heparin therapy reduced mortality by 6% (95% confidence intervals 010%), and the rate of reinfarction by 1.3%; however, heparin was associated with a clinically important increase in the risk of major hemorrhage that outweighed its observed benefit. Patients with acute myocardial infarction should continue to receive prophylactic doses of heparin (5,000 U every 8 or 12 hours) to reduce the risk of venous thromboembolism.

Cerebrovascular Thromboembolism

The appropriate use of heparin or LMW heparin in patients with ischemic stroke remains poorly defined. Nonambulatory patients may benefit from low doses of heparin to prevent venous thromboembolism. Heparin and LMW heparin do not appear to improve the outcome of patients with partial stable or complete stroke. [150] Although an initial study [151] suggested the administration of fraxiparine to patients with acute cerebral ischemic improved long-term outcome, this finding has not been replicated in several subsequent larger studies. The use of heparin to treat patients with acute embolic stroke of cardiac origin, usually in the presence of nonrheumatic atrial fibrillation, remains controversial because the risk of central nervous system bleeding appears to be high in this situation. [152] Heparin therapy in the management of transient ischemic attacks has not been shown to offer improved survival or a reduced incidence of subsequent strokes. [150]

Other Indications

Disseminated Intravascular Coagulation

Acute DIC is frequently treated with low-dose heparin. DIC is characterized by uncontrolled activation of coagulation, which results in microvascular thrombosis and bleeding due to clotting factor depletion. It is felt that heparin, by catalyzing the inactivation of thrombin, will reduce uncontrolled activation of thrombin and thus lessen the rate at which coagulation factors are being depleted. There is no clinical evidence that this treatment strategy is valid. Furthermore, the potential to exacerbate hemorrhage is substantial. As a result, anticoagulant therapy in patients with acute DIC should be reserved for those patients with objectively confirmed thrombosis.

Patients with acute promyelocytic leukemia frequently have bleeding associated with laboratory evidence of DIC. In the past, low-dose heparin by continuous infusion has been recommended for these patients. The DIC associated with acute promyelocytic leukemia frequently resolves within 48 days after the initiation of all-trans retinoic acid, although this therapy might not reduce the risk of thrombosis in these patients. [153] In the absence of acute thromboembolism, treatment with heparin is not recommended in this setting.

Trousseaus syndrome is a complication of malignancy (most often adenocarcinoma) characterized by venous thromboembolism, arterial embolic disease, and nonbacterial endocarditis. Laboratory findings are consistent with chronic DIC, including mild or moderately severe thrombocytopenia. Many patients with Trousseaus syndrome will suffer recurrent thromboembolism despite adequate anticoagulation with warfarin. In such patients long-term treatment with subcutaneous standard heparin or LMW heparin is recommended. [154] [155] The role of heparin in DIC of other etiologies has yet to be established.

Heparin (100 U/kg/day) has been used in the prevention of hepatic veno-occlusive disease after bone marrow transplantation. A prospective, randomized study found this regimen to be highly effective in the prevention of veno-occlusive disease, but other studies have been less successful. [156] [157] Treatment of veno-occlusive disease with heparin after organ dysfunction has developed is generally unsuccessful. [158]

Toxicities

Bleeding

Bleeding is the principal toxicity of heparin. Major bleeding has been reported to occur in 133% of patients receiving various forms of heparin therapy, and fatal bleeding occurred in 3 of 647 patients treated with heparin in one series. [159] Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction. Heparin can interfere with platelet function and prolong the bleeding time, but it is unclear to what extent the antiplatelet effect contributes to the hemorrhagic complications of heparin therapy. [160] There is no evidence that the PTT response achieved during intravenous standard heparin therapy correlates with the risk of hemorrhage. Furthermore, there is only weak evidence of a dose-dependent relationship in this bleeding risk. [161]

Four randomized studies have compared the incidence of bleeding during intermittent and continuous intravenous infusion of heparin. Two of the studies demonstrated a significantly lower incidence of bleeding in the patients receiving continuous intravenous infusions (01% versus 933%), [126] [162] and a third study reported a similar trend. [163] However, the total dose of heparin administered by intermittent infusion was higher than that administered by continuous infusion. When the same doses were used in one study, the incidence of bleeding was identical, implying that bleeding was related to the dosage and not to the method of administration. [164] In a study in which patients considered to be at high risk of bleeding were initially treated with a lower dose of heparin (30,000 U/day) than those at low risk for bleeding (40,000 U/day), the incidence of major bleeding was 11% in the high-risk group compared with 1% in the low-risk group. [165] Taken together, these

studies suggest that the incidence of bleeding depends both on the total daily dose of heparin and on the presence of underlying risk factors.

Several randomized studies have compared a continuous intravenous infusion of standard heparin with a fixed dose of subcutaneous LMW heparin in treatment of venous thrombosis.[166] [167] [168] The incidence of major bleeding appears to be lower during therapy with LMW heparin, although this finding was not confirmed in larger recent studies.[139] [140] [141]

Heparin-Induced Thrombocytopenia (HIT)

Heparin-induced thrombocytopenia (as defined by a fall in the platelet count to <150 × 10^9 /L or a decrease by 50% in patients with pre-existing thrombocytopenia) occurs in 2.7% of patients receiving intravenous standard heparin for the treatment of acute venous thrombosis. It occurs less frequently in patients receiving therapeutic doses of LMW heparin.[122] HIT is due to an autoantibody that is directed against heparin in association with platelet factor 4.[169] This antibody binds to and activates the Fc receptor on the platelet surface, leading to platelet activation. A diagnosis of HIT should be considered in any patients receiving heparin (either intravenously or subcutaneously) who have an unexplained 50% or greater reduction in platelet count that begins 5 or more days after starting heparin, provided that the patient has not previously received heparin. HIT can develop within 48 hours in patients with previous heparin exposure. Heparin should be discontinued immediately in patients with suspected HIT. In patients with evidence of arterial or venous thrombosis, an alternate anticoagulant should be administered. LMW heparin should *NOT* be used in this situation because of a high risk of cross-reactivity of the heparin-dependent antibody with the LMW heparin. In this situation another anticoagulant such as danaparoid sodium or a direct thrombin inhibitor (such as hirudin or argatroban) should be given.[170] Ancrod, a defibrinogenating snake venom, has also been used in this setting but may not be as effective as other agents, because it does not block thrombin generation and subsequent thrombin-mediated platelet activation. Warfarin should not be started until adequate anticoagulation with these agents has been achieved and the platelet count has returned to the normal range, because it can induce skin necrosis or worsen venous or arterial thromboembolism in patients with HIT.[171] Patients with HIT who have not had thrombosis are likely at high risk for the development of thrombosis. Whether such patients should receive anticoagulants is controversial. Such patients can receive prophylactic or therapeutic doses of danaparoid, although the most appropriate treatment for these patients is currently under investigation.

Osteoporosis

Radiographic evidence of osteopenia has been reported in 17% of women treated with heparin throughout pregnancy.[172] In most cases, the osteopenia resolves within 1 year after delivery. Spontaneous osteoporotic vertebral fractures occur in 23% of pregnant women receiving heparin.[172] [173] High-dose heparin and prolonged duration of treatment appear to enhance the risk of osteoporosis. Several pregnant patients with thromboembolism have been treated successfully with LMW heparin, but the relative risk of osteoporosis in comparison with standard heparin is unknown.[102] [174] The risk of osteoporosis in nonpregnant patients receiving long-term heparin has not been established.

Other Toxicities

Abnormalities in liver function tests occur frequently in patients receiving intravenous or subcutaneous heparin. Mild elevations of the aspartate transaminase and alanine transaminase occur without a concomitant increase in serum bilirubin or alkaline phosphatase.[175] Cutaneous allergic reactions to subcutaneous heparin occur rarely. In many cases, these reactions do not occur when LMW heparin is substituted for standard heparin. In addition, if a cutaneous allergic reaction occurs with one form of LMW heparin, clinical experience suggests it may not occur if another form is substituted.

Use in Pregnancy

In contrast to warfarin, heparin does not cross the placenta and has not been associated with fetal malformations. Therefore, despite

the risk of osteoporosis, heparin is the drug of choice for the prophylaxis and treatment of venous thromboembolism during pregnancy.[176] Heparin may also prevent thromboembolic complications associated with mechanical heart valves.[176] Heparin can be administered either by intermittent adjusted-dose subcutaneous injections or by continuous intravenous infusion. Ambulatory management may be facilitated by the use of implantable intravenous ports and indwelling subcutaneous catheters. It has been recommended that pregnant patients with venous thromboembolism be anticoagulated throughout the course of pregnancy and for approximately 68 weeks after delivery.[176]

There are no methodologically adequate clinical studies examining the efficacy of LMW heparin in pregnant patients. LMW heparin does not appear to cross the placenta.[177] [178] Their reduced requirement for monitoring and potentially lower risk of osteoporosis make the LMW heparins attractive anticoagulants in pregnancy.

An elevated PTT may be associated with increased bleeding at the time of delivery. In the nonpregnant patient, a single dose of subcutaneous heparin is usually cleared within 12 hours, but during the third trimester of pregnancy the PTT may remain prolonged as long as 28 hours after a subcutaneous dose of heparin.[179] It has been recommended that heparin be discontinued 24 hours before induction of delivery or immediately at the onset of labor.

Antagonist

The anticoagulant effect of heparin disappears within hours after discontinuation of the drug, and mild bleeding due to heparin can usually be controlled without administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by intravenous infusion of the sulfate salt of protamine, a mixture of basic polypeptides isolated from salmon sperm. Protamine binds tightly to heparin in vitro and thereby neutralizes its anticoagulant effect. The typical dose of protamine sulfate is 1 mg/100 U heparin. Neither the route (intravenous or arterial) nor the rate of administration of protamine has been found to be of clinical importance.[180]

Protamine is used routinely to reverse the anticoagulant effect of heparin following cardiac surgery and other vascular procedures. An antibody-mediated anaphylactic reaction may occur within minutes after receiving the antagonist. This complication occurs in approximately 1% of patients with diabetes mellitus who have received protamine-containing insulin (neutral protein Hagedorn insulin or protamine zinc insulin) but is not limited to this group.[181] This reaction can be fatal.[182] A less common nonimmunologic reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, and systemic hypotension associated with transient neutropenia may also occur after administration of protamine.[183] [184]

The effectiveness of protamine in patients who have received LMW heparin is unknown. However, as there is no other effective antidote, administration of protamine to a bleeding patient who has received a dose of LMW heparin seems appropriate.

Chapter 123 - Thrombolytic Therapy

Victor J. Marder

Thrombolytic therapy represents a conjoint approach to vascular reperfusion, based primarily on the use of fibrinolytic agents delivered systemically or directly into the offending thrombus and complemented by anticoagulation, antiplatelet, and even mechanical strategies. In theory, any major thrombosed vessel that is the cause of clinically significant disease is amenable to this therapeutic approach, and the decision to use thrombolytic therapy requires an informed choice between the potential for clinical benefit and the risk for serious complication. In actuality, thrombolytic therapy represents an acute phase of a prolonged antithrombotic management plan, and the decision regarding the benefit:risk ratio relates to this usually brief but more aggressive approach to vascular occlusion. This review and others [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] describe the properties of thrombolytic agents (the plasminogen activators), the regimens that include adjunctive antithrombotics, the physiopathology of successful thrombolysis and bleeding complications, effects of treatment on coagulation and fibrinolytic parameters, and clinical results in the major venous and arterial thrombotic disorders. The clinical trials that have been systematically pursued for deep vein thrombosis, pulmonary embolism, acute myocardial infarction, peripheral arterial occlusion, and ischemic stroke (cerebrovascular accident [CVA]) are presented.

FIBRINOLYTIC AGENTS

Mode of Action

All of the plasminogen activators share the potential of inducing plasmin action on fibrin contained within a thrombus, with an associated greater or lesser degree of plasma fibrinogenolysis (lytic state). Degradation of fibrin produces the beneficial effect of reducing thrombus size (thrombolysis), but at the same time, the activators may lyse hemostatic plugs or induce matrix degradation at sites of vascular injury or abnormality (Table 1231). Rethrombosis of the vessel may follow initial reperfusion, usually as a result of a persistent local vascular lesion and a permissive or predisposing state of plasma coagulation. The relationships of these biologic actions of thrombolysisloss of vascular integrity, rethrombosis, and the plasma lytic statedetermine

TABLE 123-1 -- Principal Biologic Effects of Thrombolytic Therapy

Clinical Result	Process	Cellular and Biochemical Events
Benefit	Thrombolysis	Degradation of fibrin and disruption of platelets in the thrombus
Side effect	Systemic lytic state	Plasma fibrinogenolysis and derangement of platelet function
Complications	Bleeding	Degradation of fibrin in hemostatic plugs and of matrix in abnormal vessels, plus blood hypocoagulability
	Rethrombosis	Persistent local vascular lesions plus permissive status of blood coagulation

Figure 123-1 (Figure Not Available) Molecular interactions of physiologic and therapeutic thrombolysis. In the top panel, therapeutic administration of plasminogen activator (PAI-1) accelerates thrombolysis. Free plasmin in the blood exceeds the capacity of antiplasmin to neutralize the protease activity, resulting in fibrinogen degradation and the so-called plasma proteolytic state. In the bottom panel, tissue plasminogen activator is released from endothelial cells in response to a variety of stimuli, mimicking therapeutic administration of plasminogen activator. Free plasmin degrades fibrinogen and soluble fibrin, producing both fibrinogen and fibrin degradation products. *(Reproduced with permission from Francis and Marder.[15])*

the effectiveness and safety of thrombolytic treatment.

Figure 1231 (Figure Not Available) illustrates the molecular interactions by which such treatment is locally augmented at sites of thrombi. [15] [16] Plasminogen and plasminogen activators bind to or react in contiguity with fibrin in the thrombus. Fibrin facilitates the conversion of plasminogen to plasmin, because plasminogen activator inhibitor-1 (PAI-1) and $_2$ -plasmin inhibitor are not efficient for inhibiting thrombus-bound plasminogen activator and plasmin. Plasmin in turn degrades fibrin to fibrin degradation products. Under physiologic conditions, systemic fibrinogenolysis does not occur because tissue plasminogen activator (t-PA) and plasmin are efficiently inhibited by PAI-1 and $_2$ -plasmin inhibitor in the blood. However, with administration of therapeutic dosages of plasminogen activator, virtually all of the plasma plasminogen is converted to plasmin, overwhelming the neutralizing capacity of antiplasmin and leading to some degree of fibrinogenolysis. At the same time, the administered plasminogen activator maximally converts thrombus-bound plasminogen to plasmin, resulting in accelerated thrombolysis. The relationship of the lytic state to hemorrhagic complications and to vascular reperfusion and rethrombosis is an ongoing question of study, with significant implications for the application of laboratory results in predicting clinical outcome.

Available Plasminogen Activators

Five plasminogen activators, streptokinase, [17] urokinase,[18] [19] alteplase (t-PA),[20] [21] anistreplase,[22] [23] and reteplase[24] have been approved by the Food and Drug Administration (FDA) for use in the major thrombotic diseases (Table 1232). These and other plasminogen activators have also been applied in virtually all potential clinical indications, not always with proof of efficacy. However, their clear benefit in reducing short- and long-term mortality after acute myocardial infarction has spawned a plethora of new plasminogen activator variants, principally by

TABLE 123-2 -- Comparison of Plasminogen Activators

Agent	FDA Approval	Source	Relative Cost	Antigenic	Half-life (min)	Regimen	Lytic State	Bleeding
Streptokinase	Yes	*Streptococcus*	1	Yes	20	Infusion	4+	4+
Urokinase	Yes	Cell culture	6	No	15	Infusion	4+	4+
Alteplase (t-PA)	Yes	Recombinant	8	No	5	Infusion	2+	4+
Anistreplase	Yes	*Streptococcus* + plasma product	5	No	70	Bolus	4+	4+
Reteplase	Yes	Recombinant		No	15	Double bolus	3+	4+
Saruplase (scu-PA)	No	Recombinant		No	5	Infusion	13+	4+
Staphylokinase	No	Recombinant		Yes		Infusion	1+	4+
TNK-t-PA[a]	No	Recombinant		No	15	Bolus	1+	4+
BAT-PA[b]	No	Recombinant		Minimal		Infusion	1+	Probable

t-PA, tissue plasminogen activator.

[a] TNK-t-PA is the abbreviation for a t-PA mutant that has been altered at six sites: threonine (T) at position 103, asparagine (N) at position 117, and four residues starting with lysine (K) at positions 296299.

[b] BAT-PA is derived from the salivary gland of a bat species by recombinant technology.

recombinant DNA technology, in attempts to attain improved properties, such as greater activity, prolonged half-life, or a lessened lytic state. For example, the newest approved plasminogen activator, reteplase, consists of the second kringle and the protease domain of alteplase, and the prolonged half-life (from 5 to 15 minutes), allows it to be administered as a double-bolus regimen. [25] [26] A second alteplase variant, TNK-PA,[27] is altered at three specific amino acid sites and is effective as a single-bolus injection.[28] Recombinant forms of urokinase, [29] saruplase (pro-urokinase, scu-PA),[30] [31] staphylokinase,[32] and BAT-PA[33] (from the salivary gland of *Desmodus rotundus*) are at various stages of testing, and chimerics of t-PA and pro-urokinase [34] and bifunctional agents composed of anti-fibrin or anti-platelet antibodies complexed to plasminogen activator[35] show encouraging results in animal models.

The major distinctions between the agents relate to their antigenicity, half-life, potential for inducing a lytic state, and hemorrhagic potential (Table 1232). Those plasminogen activators that are derived from a human protein (urokinase, alteplase, reteplase) are essentially nonantigenic, whereas those from a bacterial species, whether purified from streptococci as streptokinase complexed with human plasminogen (anistreplase), or prepared by recombinant technology from staphylococci as staphylokinase,[36] can induce antibody formation and present a potential for allergic response that could preclude prolonged or follow-up administration. The experience with BAT-PA in humans is limited, but data suggest that treatment is tolerated and that antibody induction may not preclude a full course of therapy.

The half-life of each plasminogen activator determines whether it can be administered as a bolus injection or short infusion, or if a continuous infusion is needed. Among the approved agents, the most suitable for bolus injection is anistreplase (half-life of æ40 minutes) [37] and the least suitable is alteplase (half-life of 5 minutes),[38] which requires continuous infusion for therapy. The rate of infusion of streptokinase may be limited by side effects of tachycardia, fever, and muscle aches even though its half-life is 20 minutes. [37] Results in patients suggest that some of the newer agents have less of a plasma lytic state, especially TNK-t-PA. [39] Although it is an attractive hypothesis that minimizing fibrinogen degradation will result in less clinical bleeding, [40] this potential has not been borne out in clinical trial (see later). To date, all of the approved plasminogen activators and those with extensive clinical trial data are associated with a significant bleeding risk, roughly equivalent for all agents, except for the higher rate of intracranial hemorrhage with t-PA. [41] The anticipation of greater safety with a new plasminogen activator, based on biochemical studies, must be treated with caution, and no agent has been shown to be free of hemorrhagic risk.

Adjunctive Antithrombotic Agents

Inadequate response to plasminogen activator therapy occurs if the thrombosed vessel does not manifest full reperfusion, or if reocclusion quickly follows initial success (Table 1233). In

TABLE 123-3 -- Potential Avenues for Improving Patency Results of Thrombolysis Using New Antithrombotics

Agent	Vascular Response	Need for Better Adjunctive Agent	Example
Streptokinase	Slow-progressive reperfusion Low reocclusion	Potent antithrombin to accelerate reperfusion	Hirudin, hirulog small molecule inhibitors
Tissue plasminogen activator	Rapid early reperfusion Later reocclusion (58%)	Improved antiplatelet agent to passify the vessel wall	Abciximab, other antiglycoprotein IIb/IIIa agents

general, t-PA and recombinant derivatives have potent thrombolytic activity and achieve early vascular patency with relatively mild effects on blood coagulation, but are vulnerable to early reocclusion. Agents such as streptokinase elicit a more potent effect on coagulation and reperfuse vessels more gradually, but tend to maintain vascular patency. Variations in plasminogen activator use have attempted to circumvent one or the other limitation, such as by combined therapy with the two types of plasminogen activator. Unfortunately, the combination of t-PA plus streptokinase does not produce a superior clinical result [42] for patients with acute myocardial infarction. Acknowledging that early and persistent patency is a principal objective of treatment, considerable effort has been directed to adjunctive management with antithrombin and antiplatelet agents.

The first definitive demonstration of antiplatelet efficacy in the treatment of an acute thrombotic event was with the use of a simple aspirin regimen of 160 mg/day for 30 days to decrease mortality after acute myocardial infarction (Second International Study of Infarct Survival [ISIS-2]). [43] In patients treated within 6 hours, aspirin reduced the 35-day mortality rate by 23%, equal to the reduction achieved by streptokinase alone, and both agents together had an additive effect amounting to a 39% relative risk reduction compared with patients who received neither thrombolytic nor aspirin. Whether the addition of heparin to a regimen of plasminogen activator plus aspirin would further improve the clinical outcome in patients with acute myocardial infarction is resolved for streptokinase use but still controversial for t-PA. The Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) study [42] definitively illustrated that early intravenous heparin is no more effective than delayed subcutaneous heparin in patient survival at 30 days after acute myocardial infarction. Coronary artery patency studies show that intravenous heparin in addition to streptokinase or anistreplase (plus adequate aspirin) does not increase the incidence of vascular patency, [44] [45] but does increase bleeding complications.[45] Although the use of delayed subcutaneous heparin in addition to aspirin is relatively safe, Collins et al [10] conclude that there is little evidence of any additional clinical advantage with subcutaneous or with intravenous heparin added to plasminogen activator therapy. There still is a difference of opinion as to the value of heparin added to a regimen of t-PA plus aspirin. When the dose of aspirin is 160 mg/day or more, heparin produces either no increase in patency [46] [47] or a marginal improvement.[48] With 80 mg/day or less aspirin, heparin exerts a marked effect on vascular patency. [49] [50] Thus, although there is general agreement that heparin does not contribute significantly to a regimen of streptokinase plus aspirin, [10] [51] the practice of physicians perseveres in using intravenous heparin in concert with t-PA and aspirin.[51] [52]

In patients with nonlife-threatening thrombotic disease, such as deep vein thrombosis or even many cases of peripheral arterial occlusion, where prolonged plasminogen activator therapy increases the at-risk interval for bleeding complications, concomitant anticoagulant therapy with heparin is usually avoided.

Among the multitude of potential improved adjunctive agents, two groups have received the most attention, the hirudin/hirulog [53] [54] or small molecule inhibitors of thrombin [55] and inhibitors of the glycoprotein (GP) IIb/IIIa platelet fibrinogen receptor by small peptides or chemicals or by monoclonal antibody. [56] [57]

Pilot studies in patients with acute myocardial infarction showed encouraging increases in 90-minute patency rates with hirudin rather than heparin. [58] [59] [60] Unfortunately, these initial studies used relatively high dosage schedules of anticoagulant, and unacceptable rates of intracranial hemorrhage resulted. [61] [62] [63] With a scaled-back dosage regimen of anticoagulant in patients receiving t-PA or streptokinase therapy along with aspirin, a large trial of 3,002 patients (Thrombolysis and Thrombin Inhibition

in Myocardial Infarction [TIMI] 9B) showed no significant difference in clinical outcome using heparin or hirudin. [64] Because most of the patients in this study received t-PA, it remained to be determined whether a newer antithrombin might be beneficial in patients receiving streptokinase. Based on promising results of hirulog in patients with unstable angina,[65] a patency study of 412 patients showed significantly greater patency (46% vs. 35%) and less bleeding using hirulog rather than heparin.[66] It is possible that the relatively high 90-minute patency rate attained with t-PA plus aspirin and heparin is close to the maximal response, whereas the relatively low initial patency rate with streptokinase leaves room for improvement with better antithrombin agents.

Effective GP IIb/IIIa inhibition can be achieved by the monoclonal antibody 7E3 (Abciximab) and by small molecule inhibitors, which effectively block fibrinogen binding to platelets and prevent the cascade of biochemical events leading to aggregation. These agents are effective in preventing adverse outcome after unstable angina and angioplasty,[67] [68] and appropriate dosaging of concomitant anticoagulant therapy prevents excessive bleeding associated with these procedures. [69] Considering that small molecule inhibitors of the fibrinogen receptor can accelerate reperfusion of coronary arteries in patients with acute myocardial infarction, [70] it is not unreasonable to anticipate that inhibitors will ultimately find a role as adjunctive therapy to plasminogen activators. The rationale for this approach would be that passivation of the arterial wall by a long-acting or bound GP IIb/IIIa inhibitor could prevent vascular reocclusion, especially that which follows t-PA therapy. [71]

Other Adjunctive Approaches to Thrombolysis

Because fibrinolysis depends on conversion of plasminogen to plasmin, the rate is determined at least in part by the plasminogen concentration incorporated into a

clot,[72] as well as by the presence of soluble plasminogen in the clot interstices. [73] A decrease in plasma plasminogen is part of the lytic state [74] (see later), which is less striking with fibrinogen-sparing agents such alteplase, saruplase, reteplase, and BAT-PA. [14] Thus, enrichment of plasminogen enhances the thrombolytic rate in vitro[75] and in animal models,[76] especially with agents such as streptokinase, urokinase, and anistreplase. Clinical proof of efficacy of plasminogen supplementation is not yet available, although preliminary observations in patients with deep vein thrombosis, peripheral arterial occlusion, acute myocardial infarction, and acute pulmonary embolism have been reported.[77] [78] [79] [80] Most studies have used plasminogen derived from human plasma, but a recombinant form of human plasminogen has been prepared and studied in animals, [81] and is undergoing clinical trials.

Ultrasound has been applied directly into the thrombus by thin wire, [82] and appropriate conditions of frequency and energy can mechanically disrupt and disintegrate clots and atherosclerotic plaque. Percutaneous, transvascular ultrasonic disruption of a femoral artery thrombus has been reported in patients, [83] and a similar application has been used to enhance t-PAmediated fibrinolysis in animal models. [84] The mechanism whereby ultrasound may produce its accentuation of plasminogen activator-mediated lysis is not known, but potentially such therapy could be achieved locally at the same time that systemic hemorrhagic complications may be avoided. More recent experiments with this approach suggest that transcutaneous ultrasound may induce thrombolysis when combined with systemic infusion of microbubbles, even in the absence of plasminogen activator administration. [85] The role of ultrasound as isolated therapy or as adjunct to plasminogen activator administration remains to be established, but the greatest potential would be in patients with thrombosis that may be amenable to the percutaneous approach, such as peripheral arterial occlusion, deep vein thrombosis, or thrombosed shunts and catheters.

Catheter-Directed (Regional) Infusion

A recurrent issue concerns the administration of plasminogen activator directly through a catheter onto or into a thrombus. The rationale for such regional therapy is compelling for arterial occlusions because the offending thrombus is usually localized to a single vessel downstream from the catheter tip, and the catheter also provides angiographic documentation of progress. It is the hope of the practitioner to confine treatment to the thrombus only, thereby maximizing thrombolysis by minimizing distant bleeding. Local therapy of venous thromboembolic disease has a less compelling rationale, but an extensive experience in which patients are treated by catheter delivery is receiving attention.

Regional treatment of arterial thrombi does achieve better thrombolysis than systemic therapy, but activity of the plasminogen activator is not restricted to the region in question. During the period of infusion, the lytic state may be comparable to that following systemic administration, [86] and bleeding, even intracranial hemorrhage, may complicate therapy. Whether a totally fibrin-specific agent could in fact avoid bleeding complications that accompany regional infusions remains to be determined.

The main decision regarding regional treatment is the clinical exigency of the patient. For example, even though regional infusion into the coronary artery may dissolve clot more effectively, systemic administration is more efficient for first-line treatment of the at-risk population with myocardial infarction. Still, with maximization of effort, such as has been applied to early angioplasty for acute myocardial infarction, some centers have demonstrated the feasibility of local revascularization therapy. Local therapy may also be useful as follow-up for failed systemic treatment of acute myocardial infarction. Regional treatment for slower-progressing illnesses such as peripheral arterial occlusion or deep vein thrombosis have the luxury of time required for this approach, and it is most applicable for dissolving thrombus in occluded catheters. To date, local therapy has proven to be least effective in patients with pulmonary embolism. For the treatment of thrombotic stroke, most studies have used systemic treatment to save time, but results of a trial using a local approach are still to be reported.

EFFECTS OF THROMBOLYTIC TREATMENT ON THE BLOOD

Lytic State

The *lytic state* is a general description of the effects of plasmin activity on the circulation [74] (Table 1234). The shortening of the euglobulin lysis time measures free activator in the circulation. Laboratory parameters reflect the biochemical events that culminate in the degradation of plasma fibrinogen and the hypocoagulable state, manifested principally by prolongation of the thrombin time. Because hemostatic plug dissolution and fibrinolytic hemorrhage can occur in the presence of a minimal lytic state, the simplest and perhaps most physiologic definition of the lytic state is a demonstration of a decrease in plasma fibrinogen.

Free plasmin also affects platelet function by decreasing aggregation induced by adenosine diphosphate or other agonists. [87] Plasmin also cleaves the platelet membrane glycoprotein receptor for von Willebrand factor and reduces ristocetin-induced platelet aggregation. [88] However, the effect of plasminogen activators on platelets and blood coagulation factors is not a direct decrease in functional integrity and activity. For example, platelet hyperactivity and hyperaggregability may result from initial exposure of activator to platelets, [89] [90] and exposure of fresh thrombus surface or underlying vascular lesions, as well as the direct effect of activators on fibrinogen, [91] [92] may actually induce increased local coagulation. Thus, a patient may experience sequential hypercoagulability and hypocoagulability or

TABLE 123-4 -- Development of the Plasma Proteolytic (Lytic) State

Biochemical Step	Laboratory Parameter
Circulating plasminogen activator	Short euglobulin lysis time, variable platelet hyperreactivity
Plasminogen converted to plasmin	Decreased plasminogen
Antiplasmin complexes with and inhibits plasmin	Plasmin-antiplasmin complexes, decreased antiplasmin
Free plasmin	
Direct action	Increased plasma fibrin lysis and chromogenic activity
Degradation of fibrinogen	Decreased clottable protein, increased degradation products
Degradation of other plasma proteins	Decreased factors V and VIII
Action on platelets	Glycoprotein cleavage, decreased aggregation
Hypocoagulable state	Prolonged coagulation tests (thrombin time) and bleeding time

even the simultaneous occurrence of these opposite influences, depending on the phase of lytic state. [93]

Predictive Value of Laboratory Changes

Laboratory markers of hematologic events that occur after plasminogen activator administration have potential relevance for reflecting or predicting vascular events of clinical importance (Table 1235). According to the concept that the actions of plasminogen activators in the blood and on the thrombus are parallel but separate events (see Table 1231 , Fig. 1231 (Figure Not Available)), successful dissolution of the pathologic thrombus through fibrin degradation would not necessarily correlate with the extent of fibrinogenolysis

TABLE 123-5 -- Relationship of Vascular and Hematologic Parameters of Thrombolysis and the Potential for Laboratory Markers of Related Events

Vascular	Hematologic	Potential Marker
Reperfusion	Thrombolysis	Hypofibrinogenemia, elevated D-dimer, fibrin degradation products
Bleeding	Hemostatic plug or matrix disruption	Long bleeding time, hypofibrinogenemia
No reperfusion or reocclusion	Hypercoagulable state, thrombus and vessel thrombogenecity	Increased fibronopeptide A, prothrombin 1.2, thrombinantithrombin complexes, soluble fibrin, persistent high fibrinogen level
Late bleeding (with new injury)	Hypocoagulable state	Long bleeding time, persistent lytic state
Lasting patency	Hypocoagulable state, vascular passivation	Hypofibrinogenemia, long bleeding time, abnormal platelet aggregation/adhesion

(lytic state). Likewise, bleeding that would result from hemostatic plug disruption or vascular matrix degradation could occur independently of changes in hemostatic or platelet parameters in the blood. [3] [4] The controversy of this approach could be stated as follows: does the degree of hypocoagulable state contribute to hemorrhagic events over what might be expected by direct activity of the plasminogen activator on a hemostatic plug or the vessel wall? Proponents of this thesis would state that a plasminogen activator with fibrinogen-sparing properties would cause less bleeding because the induced hypocoagulability is minimized. Similar questions have been asked with regard to the effect of blood changes on vascular reperfusion and reocclusion.

The potential markers of bleeding could include any change in the lytic state cascade (Table 1236), including a decrease in plasminogen, hypofibrinogenemia, increased fibrinogen degradation products, prolonged bleeding time, and deranged platelet aggregation. Markers of vascular reperfusion as a surrogate of clinical recovery could potentially use lytic state markers, including changes in platelet function or direct reflections of thrombolytic degradation of fibrin such as increased D-dimer levels. Resistance to vascular reperfusion or late reocclusion (and clinical deterioration) might be predictable by hypercoagulable assays such as fibrinopeptide A, prothrombin intermediate fragment 1.2, thrombinantithrombin complexes, and soluble fibrin. [94] Retrospective studies have assessed laboratory values with the goal of finding correlations that could be of predictive value in individual patients, but the data show either no correlation with clinical events or only general trends that are of limited value for individual patients.

Bleeding Events

Although patients who receive thrombolytic agents are at risk of bleeding, such complications are at best only weakly correlated with laboratory parameters of the lytic state. For example, urokinase or streptokinase treatment of pulmonary embolism or deep vein thrombosis regularly induces the lytic state, but the laboratory values, including fibrinogen concentration, plasminogen concentration, and euglobulin lysis time, are not significantly different in patients with or without a hemorrhagic complication.[95] [96] In patients with acute myocardial infarction, streptokinase produced a similar fibrinogen decrease in patients with or without bleeding complications.[97] The direct comparison of t-PA and streptokinase in the TIMI trial (phase I) showed significantly lower fibrinogen values with streptokinase than with t-PA, but the incidence of major and minor bleeding complications was the same with both treatments.[98] A subsequent analysis of patients treated with t-PA[99] showed a small and nonsignificant trend toward a lower nadir fibrinogen concentration (100 vs. 130 mg/dl) and higher peak fibrin degradation products concentration (300 vs. 280 g/ml) in patients with major bleeding episodes. Furthermore, patients treated with t-PA who had ischemic (thrombotic) or hemorrhagic CVA had the same nadir concentration of fibrinogen.[100] The only predictive blood

TABLE 123-6 -- Absolute Contraindications to Fibrinolytic Therapy

Risk	Condition
Intracranial bleeding	Hemorrhagic cerebrovascular accident, intracranial neoplasm, recent cranial surgery or trauma (10 days), uncontrolled severe hypertension
Massive hemorrhage	Major surgery of thorax or abdomen (10 days), prolonged cardiopulmonary resuscitation, current severe bleeding (e.g., gastrointestinal)

value for hemorrhagic complication is the plasma t-PA antigen concentration (3.4 g/ml in bleeders vs. 2.2 g/ml in nonbleeders).[99] The higher value in those who bled suggests that t-PA has a direct effect on susceptible hemostatic plugs or vascular sites, greater with higher local concentrations, that could cause bleeding independent of the changes in blood coagulation parameters. This effect might also help to explain the higher rate of intracranial hemorrhage with high therapeutic dosages of t-PA.[101] These data support the concept that bleeding occurs independent of the plasminogen activator effect on blood coagulation, and is probably the result of action at sites of vascular injury or malformation (see Table 1231).

The template bleeding time is prolonged during thrombolytic therapy, either as a direct result of the plasminogen activator or of concomitant aspirin therapy. One report correlates the prolonged bleeding time with spontaneous bleeding,[102] but a subsequent analysis of the bleeding time showed no distinction in patients with or without hemorrhagic complication.[103]

The occurrence of intracranial hemorrhage with plasminogen activator treatment is infrequent but of great clinical import in that more than 50% of patients have lethal outcomes or are left with significant neurologic deficit. Although major hemorrhagic complications other than intracranial hemorrhage are induced with approximately equal frequency by all of the plasminogen activators, the more potent agents such as t-PA have a consistently higher risk of inducing intracranial hemorrhage. The reason is not clear; it is not likely to reflect the presence of a fresh hemostatic plug that is dissolved, but may be related to a vascular abnormality associated with amyloid deposition.[104] As with other bleeding complications, the degree of lytic state does not explain the event because the fibrinogen is the same in patients with intracranial hemorrhage or with a thrombotic CVA.[100] Subcutaneous heparin added to aspirin during plasminogen activator infusion increases the risk slightly (0.6% vs. 0.4%),[8] but the use of t-PA is a most important predictor,[105] along with age greater than 65 years, weight less than 70 kg, hypertension on admission, and a prior history of transient ischemic attack (TIA) or CVA.[101] A retrospective comparison of streptokinase (41,000 patients), anistreplase (21,000 patients), and t-PA (41,000 patients) showed the incidence of intracranial hemorrhage to be 0.2%, 0.6%, and 0.6%, respectively.[14] Recent observations of accelerated regimen t-PA versus streptokinase, reteplase, or double-bolus t-PA show an overall risk of approximately 0.8% for accelerated t-PA, with the risk in elderly patients (>75 years of age) being significantly higher (2.1%)[42] [106] [107] (Table 1237).

Vascular Patency and Reocclusion

Laboratory results also do not predict vascular reperfusion or degree of patency. In the Urokinase Pulmonary Embolism Trial (UPET) study, in which a large systemic dose of urokinase was administered, there was no correlation of laboratory results with decrease of embolus size,[95] and deep vein thrombosis trials also showed a lack of correlation of venographic change after plasminogen activator therapy with degrees of alteration in fibrinogen, thrombin time, plasminogen, or fibrin degradation products.[96] [108] Even intracoronary administration of streptokinase for treatment of acute myocardial infarction showed no difference in nadir plasma fibrinogen in patients who did or did not reperfuse,[109] and similar measurements in patients with acute myocardial infarction receiving t-PA also failed to show a correlation with post-treatment coronary artery patency.[99] Although there is not universal agreement, the data do suggest that changes in blood coagulation or fibrinolytic assays after plasminogen activator administration do not directly influence the degree of thrombus dissolution.

A reasonable hypothesis for noninvasive measurement of successful thrombolysis would be to measure plasma levels of cross-linked fibrin degradation products, but the data thus far are not conclusive, with some showing high predictability for successful vascular reperfusion[110] [111] and others failing to document such a correlation.[112] [113] Prediction of coronary artery reocclusion in an individual patient is problematic, but trials using t-PA provide instructive information.[99] Among 55 patients with reocclusion, the decrease in fibrinogen was less (120 vs. 180 mg/dl), as was the increase in fibrin degradation products (200 vs. 310 g/ml) than in patients whose vessels stayed patent. The data suggest that a more profound lytic state protects against reocclusion and may partially explain the lower tendency for reocclusion with streptokinase, urokinase, and anistreplase than with t-PA.[42] [114] [115] [116] Markers of hypercoagulability such as fibrinopeptide A, thrombinantithrombin complexes, and prothrombin fragment 1.2 tend to be higher in patients with increased mortality rates and lower TIMI flow grades, but application for predicting clinical outcomes in individual patients remains to be proven.

Laboratory Monitoring

Unlike treatment regimens with anti-thrombin agents such as heparin, the plasminogen activator dosage regimens are standardized, either on a total dosage or weight-adjusted basis, and only the duration of infusion leaves room for variation. Thus, the major role for monitoring thrombolytic therapy with laboratory studies would be to document that a given dosage of agent has indeed achieved a lytic state. Furthermore, time constraints in patients with acute myocardial infarction allow little chance to react to a laboratory result during the acute phase of the illness. Once a lytic state has been attained, there is no need to regulate the dose of plasminogen activator because alterations based on laboratory markers would neither improve the chance of thrombolysis nor decrease the risk of hemorrhagic complication. On the other hand, in patients who are anticipated to receive more than bolus injections or short infusions, the absence of a lytic state might reasonably be cause for discontinuation

of therapy and initiation of standard anticoagulation. Another recourse is to administer plasminogen in purified form or as whole plasma, but no evidence for converting a nonresponder to a responder exists, except perhaps by regional plasminogen activator delivery.

MANAGEMENT OF BLEEDING COMPLICATIONS

Prevention of Bleeding

The absolute contraindications to plasminogen activator therapy are those that may result in intracranial hemorrhage or massive, life-threatening hemorrhage (see Table 1236). The risks of minor bleeding or even of the need for blood transfusion are not absolute contraindications. The decision regarding plasminogen activator use must weigh the expected severity of the complication with the potential benefit associated with accelerated thrombolysis. Thus, some patients with obvious life-threatening thrombotic diseasefor example, massive pulmonary embolism with profound shock or a large anterior wall acute myocardial infarctionmay warrant potentially life-saving thrombolytic therapy even in the face of serious contraindications. On the other hand, patients with relatively less threatening thrombotic disease, such as deep vein thrombosis, would reasonably not receive plasminogen activator therapy if there is a relevant history that significantly increases the risk of intracranial hemorrhage (e.g., TIA, prior thrombotic stroke, or current hypertension). The risk of major bleeding after recent surgery of the head, thorax, or abdomen is obvious, but the risk of serious bleeding after brief and relatively nontraumatic cardiopulmonary resuscitation is probably less than feared. Some clinical situations are associated with an increased risk of symptomatic but not serious bleeding, including patients with recent superficial wounds, arteriotomy or venotomy, a remote history of gastrointestinal or genitourinary bleeding, active menses, and minor surgical or biopsy procedures.

The elderly have a higher risk of bleeding, especially intracranial hemorrhage, but they also have a higher risk of death from acute myocardial infarction than do younger patients. Therefore, the survival benefit in patients older than age 70 years is relatively more than in patients younger than 60 years of age (80 vs. 25 lives saved per 1,000 treated).[43] [117] It is important not to withhold plasminogen activator therapy from the elderly, but the clinician must take into account age-related risk factors that may preclude therapy.

Management of Acute Bleeding and Post-treatment Surgery

In patients who have life-threatening bleeding or who have sudden emergencies that require surgical intervention, normal hemostasis can quickly be re-established by discontinuing plasminogen activator infusion, replenishing plasma fibrinogen with either whole plasma or cryoprecipitate, and providing fresh platelets to correct a prolonged bleeding time (Table 1238). If the plasminogen activator is not yet cleared from the circulation (see Table 1231), fibrinolytic activity can be neutralized by infusion of fibrinolytic inhibitors such as epsilon-aminocaproic acid or aprotinin.

Reports of post-thrombolytic surgical intervention exist, but controlled studies of management have not been performed. The reported cases of coronary artery bypass graft surgery after streptokinase usage generally indicate that the operation can be performed immediately, [118] [119] but that such therapy may result in bleeding complications and the need for blood transfusion. [120] Such results are relevant for invasive procedures after t-PA treatment as well, even if performed after a delay of 12 and sometimes 24 hours.[121] In the TIMI-IIA study,[99] angioplasty performed immediately after stopping t-PA resulted in a significantly

TABLE 123-8 -- Management of Hypocoagulable State Induced by Plasminogen Activators

	During Treatment	Immediately After Treatment	636 Hours Later
Plasma fibrinogen	Low	Nadir	Progressive recovery
Need for cryoprecipitate	Yes	Yes	Yes
Bleeding time	Long	Variable	Normal[a]
Need for platelets	Yes	Yes	No
Circulating activator	Present	Variable	Absent
Need for antifibrinolytic agent	Yes	Yes	Yes

[a] Unless aspirin also is administered, in which case the bleeding time and potential for bleeding may persist.

MANAGEMENT OF FIBRINOLYTIC BLEEDING

Most bleeding complications can be anticipated by careful clinical evaluation. Recent and unhealed vascular trauma sites are susceptible to bleeding for approximately 10 days. Depending on its location, the bleeding complication can be unimportant (ecchymoses, hematuria), bothersome and requiring transfusion (duodenal ulcer, accessible surgical site), or life threatening (thoracic or cranial surgery, recent or even remote stroke).

Once a patient is to be treated with a plasminogen activator, avoid unnecessary trauma to the patient. Medication should be administered by mouth or intravenously, but not intramuscularly. Phlebotomy sites should be compressed for 510 minutes, unnecessary arteriotomy should be postponed or avoided, and manual manipulation of the patient should be minimized. Treatment of some thrombotic conditions requires concomitant antiplatelet or antithrombotic treatment, especially certain arterial occlusions, but for deep vein thrombosis and pulmonary embolism, such therapies usually increase the risk of bleeding without adding to the clinical result. The use of intravenous heparin or even subcutaneous heparin in addition to aspirin and streptokinase is probably not reasonable, but heparin use with alteplase is still the rule of thumb, even though definitive evidence of its requirement is not available.

Bleeding that occurs during plasminogen activator infusion should be managed appropriately with blood replacement and, if necessary and possible, by discontinuing the plasminogen activator treatment. If bleeding is to be controlled immediately, the plasminogen activator must be neutralized by fibrinolytic inhibitors, such as epsilon-aminocaproic acid or aprotinin, and cryoprecipitate and platelets should be transfused.

If surgical intervention is required for up to 24 hours after plasminogen activator administration, the hemostatic mechanisms of the patient should be evaluated and maximized to avoid operative bleeding. Depending on the half-life of the activator, fibrinolytic inhibitor may or may not be required, but fresh fibrinogen replacement and often platelet transfusion are often required to ensure hemostasis, because plasma fibrinogen concentration does not recover spontaneously until 2436 hours after discontinuing plasminogen activator treatment. This pertains for both the long- and short-acting agents and also for those that induce a potent or a mild fibrinolytic state.

greater need for blood transfusion than if performed at 1848 hours later. The reason for bleeding coincident with interventional procedures after t-PA, which is cleared quickly from the circulation, is that the nadir fibrinogen remains low for 24 hours. [99] Normal fibrinogen concentrations are not achieved until full repletion by hepatic synthesis of fibrinogen, a process that requires 2436 hours regardless of the plasminogen activator that was administered.

In anticipation of invasive surgery immediately after plasminogen activator treatment, it is reasonable to replenish fibrinogen with cryoprecipitate, because essentially no normal fibrinogen is present during streptokinase [122] or t-PA infusion,[123] and to restore platelet function with fresh platelet transfusion for up to 24 hours after plasminogen activator administration. In addition, antifibrinolytic therapy should be administered prophylactically if activator is still circulating [124] (see Tables 1231 and 1236).

Other Side Effects and Complications

Termination of treatment may be necessitated by allergic or pyrogenic side effects. These complications can be managed with corticosteroids, antihistamines, or adrenergic agents for anaphylaxis and antipyretics for fever. Allergic reactions are three to five times more frequent using bacterially derived products than t-PAtype derivatives, but patients who receive t-PA rarely manifest allergic reactions such as bronchospasm or angioneurotic edema. [125] [126] A second side effect is hypotension, especially in patients with acute myocardial infarction, occurring in approximately 12% of patients exposed to streptokinase or anistreplase and 7% of those exposed to t-PA, compared with only 1.5% of patients not exposed to a plasminogen activator. [127] Whether cardiac rupture occurs more frequently in patients with acute myocardial infarction who receive plasminogen activator than in those who do not is in dispute. [128] [129]

Embolic phenomena of clinical importance are distinctly unusual in patients with venous thromboembolic disease who received plasminogen activator treatment. In the UPET study,[95] recurrent pulmonary embolism occurred in 15% of patients who received either urokinase or only heparin. A venous thrombus breaking off to become a fatal pulmonary embolus is distinctly unusual and may have alternative explanations other than lysis of a vulnerable, free-floating thrombus. On the other hand, distal systemic embolization from a cardiac source during plasminogen activator treatment, although unusual, is clinically apparent, and up to 20% of patients with peripheral arterial occlusion experience sudden, new ischemia of the distal extremity. [130] In this circumstance, the best treatment mode is continued local instillation of plasminogen activator, a treatment that usually succeeds in dissolving the new embolus. Rarely, systemic treatment with plasminogen activator results in cholesterol crystal embolization in the setting of extensive pre-existing atherosclerotic disease. [131]

RESULTS OF CLINICAL TRIALS OF MAJOR VASCULAR OCCLUSIONS

Table 1239 summarizes the FDA-approved agents in the major categories of vascular thrombotic disease, namely myocardial infarction, peripheral arterial occlusion, deep vein thrombosis, pulmonary embolism, acute ischemic stroke (CVA), and catheter occlusion. These approvals are based on pivotal clinical trials, but actual practice may not reflect the specifics of dosage schedules or mode of administration. For example, there has been an evolution of dosage change in the management of patients with pulmonary embolism, mostly resulting from comparative trials of t-PA with urokinase. Thus, a new and short (2-hour) protocol for t-PA proves to be superior to the FDA-approved 24-hour infusion of urokinase, and a similar condensation of urokinase dosage over 2 hours showed results equivalent to those obtained with the 2-hour infusion of t-PA. Given prior evidence showing streptokinase to be equivalent to urokinase, it is reasonable to anticipate a similar improved outcome for high-dose streptokinase over 2 hours. An evolution of the

TABLE 123-9 -- Commentary on FDA Approval[a] and Common Usage of Plasminogen Activators

Agent	Clinical Indication	FDA-Approved Regimen	Common Usage
Urokinase (Abbokinase)	PE	12-h infusion	2-h infusion suffices
	Acute MI	Intracoronary only	Infrequent, for reocclusion or with percutaneous transluminal coronary angioplasty
	Intravenous catheter	5,000 U in 1 ml	Popular therapy
	PAO, DVT	Not approved	Widespread use off-label, catheter delivery
Streptokinase (Streptase)	Acute MI	IV or IC	Intravenous use only
	PE	Duration 24 h for PE,	Therapy tailored for each patient
	DVT	72 h for DVT,	
	PAO	2472 h for PAO	
	Arteriovenous cannulae	Local installation	
Reteplase (Retavase)	Acute MI	Two bolus injections, 30 min apart	Just approved
Alteplase (Activase)	Acute MI	3 h or 90 min	Accelerated dosage used
	Acute ischemic stroke	90 mg/1 h, within 3 h of symptoms	Limited usage
	PE	100 mg/2 h	Urokinase over 2 h has equal efficacy
	PAO, catheter	Not approved	Used off-label
Anistreplase (Eminase)	Acute MI	30 U over 25 min	Infrequently used

DVT, deep vein thrombosis; FDA, Food and Drug Administration; MI, myocardial infarction; PAO, peripheral arterial occlusion; PE, pulmonary embolism.

[a] Based on *Physicians Desk Reference,* 1998.

dosage schedule for t-PA in acute myocardial infarction is reflected in FDA recommendations, with the current approved methodology calling for an accelerated regimen over 90 minutes instead of the prior front-loaded regimen over 180 minutes. Agents under development and clinical trial according to research protocols significantly influence clinical practice, such as in the use of regional (catheter-delivered) urokinase for deep vein thrombosis and of urokinase or t-PA for peripheral arterial occlusion, even though these are not yet approved modalities.

Deep Vein Thrombosis

Save for the unusual patient who has a marked proximal extension of thrombus and unfortunate massive embolization despite apparently effective anticoagulant treatment, the typical patient with deep vein thrombosis is not at risk of a lethal outcome and manifests an apparently benign course of recovery. Thus, most reviews of this clinical situation conclude that the use of thrombolytic treatment in such patients is not a straightforward decision, and a report of the American Heart Association[12] concludes that thrombolytic treatment may be indicated only in selected patients with extensive proximal deep vein thrombosis.

The most discouraging and disabling outcome of proximal deep vein thrombosis and a most compelling rationale for plasminogen activator use is to prevent the postphlebitic syndrome, a condition that usually develops over some years in up to 25% of patients. [132] There is no doubt that a venous thrombus can be lysed more rapidly and in more patients using plasminogen activator in addition to heparin: approximately 50% versus only 10% with heparin alone. [96] [133] Furthermore, a small but important subgroup of patients with more acute symptoms treated only with heparin actually have extension of thrombus, [96] apparently the result of inefficient neutralization of thrombus-bound thrombin by antithrombin III. The time of maximal benefit of plasminogen activator infusion is approximately 7 days after onset of clinical symptoms, after which significant lysis is less likely compared with heparin alone.

The evidence supports the conclusion that effective thrombolysis does reduce the incidence of symptomatic cases of postphlebitic syndrome, from approximately 40% to 10%.[134] [135] Presumably, the desired clinical result depends on rapid clot lysis and maintenance of venous valve leaflet function. This is a desirable outcome considering the debilitating nature of chronic edema and the risk of recurrent infected ulcerations that require hospitalization. Although not life threatening, this complication of deep vein thrombosis significantly affects the patients quality of life. Thus, thrombolytic treatment for proximal deep vein thrombosis induces more rapid clot lysis than does heparin, may dissolve coincidental pulmonary emboli that accompany the process, and reduces the occurrence of severe or symptomatic

postphlebitic syndrome.

Why then is plasminogen activator therapy used so infrequently for deep vein thrombosis? The explanation is the reasonable emphasis by the clinician on clinical outcome rather than a radiologic or physiologic result (Table 12310). Although most patients with significant deep vein thrombosis may have venous duplex evidence of obstruction or reflux,[136] severe postphlebitic syndrome develops only in a minority. Furthermore, even though very few patients actually dissolve a significant amount of thrombus with heparin anticoagulation alone, only the rare patient has a clinically important pulmonary embolism despite heparin treatment.

Because a lethal outcome is rare, careful attention must be paid to the risk of hemorrhage, which is greater than that with heparin treatment alone. With systemic (intravenous) administration over an interval of 27 days, the period of hemorrhagic risk is prolonged and the incidence of intracranial hemorrhage approaches 1%. [137] Thus, the relatively benign course of deep vein thrombosis treated with heparin usually convinces the clinician to reserve plasminogen activator only for the patient with proximal thrombus and without risk factors for serious bleeding.

Since the mid-1990s, a more aggressive approach to plasminogen activator delivery has used regional perfusion by catheter directly into the venous thrombus. Impressive recanalization rates have been attained, with up to 90% complete and partial lysis, and in anecdotal cases, substantial benefit has been noted even in relatively old thrombi, in patients with symptoms longer than 4 weeks.[138] [139] [140] [141] It is likely that the clinical impression that old thrombi are resistant to thrombolysis may in fact reflect

TABLE 123-10 -- Natural History and Anticipated Clinical Benefit of Thrombolytic Treatment for Acute Thrombosis

Thrombotic Disorder	Natural History (with Heparin)	Potential Benefit of Thrombolytics	Clinical Decision
Deep vein thrombosis	Slow resolution, subclinical PE frequent, post-phlebitic syndrome in 2550% with proximal thrombi.	Treatment within 7 days, complete lysis in half the cases; decreased incidence of postphlebitic syndrome.	Treat large proximal thrombi, especially with coexistent PE. Catheter delivery (urokinase, tissue plasminogen activator) under study.
PE	Slow (1 wk) reduction of pulmonary hypertension. Overall mortality 7%, up to 30% with massive PE and hypotension.	Earlier treatment (within 48 h) induces rapid thrombolysis and accelerates reversal of pulmonary hypertension. Possible increased survival in patients with clinical shock.	Thrombolytics for massive PA with shock, coexistent cardiopulmonary disease or submassive PE if no contraindications.
Peripheral arterial occlusion	Major surgical intervention in 95%, cardiopulmonary complications in 50%, loss of limb in 20%, 1-y mortality up to 40%.	Striking thrombolysis in 70%, surgery avoided in 35%, no change in limb salvage but potential for decrease in 1-y mortality.	Catheter delivery of PA superior to systemic infusion. Thrombolytic preferred over surgery for initial. Treatment for the ischemic but salvageable limb.
MI	Overall mortality 11.5%, 8% for inferior MI, 17% for anterior MI.	Overall mortality reduced by 2050%, most striking in patients with anterior MI treated within 4 h after symptom onset.	Indicated for most patients within 6 h of symptoms; angioplasty available in some centers.
Cardiovascular accident	Irreversible deficits and risk of death depending on location; hemorrhagic transformation relatively infrequent (3%).	Good results only if treatment initiated within 3 h, reversal of neurologic deficit at a cost of increased parenchymal hematoma.	Clear-cut functional benefit without increased mortality risk if treatment before 3 h, but with increased risk of hemorrhagic transformation.

MI, myocardial infarction; PA, plasminogen activator; PE, pulmonary embolism.

TABLE 123-11 -- Comparison of Outcome Using Different Plasminogen Activators

Thrombotic Disorder	Comparison of Agent
Deep vein thrombosis	No direct comparison, but equivalent results in separate trials.
Pulmonary embolism	SK (12 h) equal to UK (12 h or 24 h), UK (2 h) equal to t-PA (2 h), no comparison of SK with t-PA in equivalent regimens.
Peripheral arterial occlusion	t-PA equal to UK, historically better results for UK and t-PA than SK, but no direct comparisons.
Myocardial infarction	Comparable results with SK, t-PA, and APSAC in two megatrials, marginal survival advantage (0.9%) of t-PA over SK in a third, reteplase equivalent to t-PA and SK. Intracranial hemorrhage less common with SK than t-PA, reteplase, or APSAC.
Cerebrovascular accident	Only t-PA approved, but no comparative trials and other agents had longer delays (>3 h) before treatment.

APSAC, anistreplase; SK, streptokinase; t-PA, tissue plasminogen activator; UK, urokinase.

a problem of inadequate intravenous delivery of plasminogen activator to a fully occluded vessel, a situation that is overcome by direct catheter delivery of plasminogen activator to an actually susceptible thrombus. This approach often combines stent placement, thereby providing a second revascularization approach in the single invasive vascular procedure. Long-term follow-up studies and comparative trials against systemic therapy [96] [142] [143] [144] [145] [146] are needed to determine their relative values for safety against bleeding and for prevention of the postphlebitic syndrome and recurrence of thrombotic disease. It is likely that all of the plasminogen activators can accelerate thrombolysis relative to heparin treatment alone, but direct comparative trials have not been performed to determine if one agent or regimen is superior to another. Whatever agent is chosen (only streptokinase is thus far approved by the FDA), the use of thrombolytic agents continues to be highly individualized (Table 12311).[147]

Pulmonary Embolism

The rationale for the use of plasminogen activator in patients with acute pulmonary embolism is to reduce acute morbidity, reperfuse the pulmonary vascular bed, and prevent late consequences such as persistent perfusion defects, reduced pulmonary capillary blood volume, and chronic pulmonary hypertension. The anticipated clinical course of patients with pulmonary embolism varies according to the size of the embolus and the cardiopulmonary reserve of the patient. [95] [148] [149] With routine heparin anticoagulant therapy, the overall mortality risk is 79%, with the greatest risk being in patients with a massive embolus and concomitant shock secondary to acute cor pulmonale.[95] [150] In this situation, acute changes associated with the embolus induce right ventricular dilatation and right-sided failure with secondary effects of decreased left ventricular filling and decreased cardiac output, followed inexorably by hypotension, decreased coronary blood flow, worsening right ventricular failure, and, ultimately, circulatory arrest. Other than general measures for support of respiration, blood pressure, and cardiac function, therapy is directed at the thrombotic process using antithrombin agents, plasminogen activators, surgical embolectomy, intrapulmonary artery catheter retrieval of thrombus, and placement of inferior vena caval umbrella filters.

Short-term improvement using urokinase, streptokinase, or t-PA[95] [151] [152] plus heparin, compared with heparin alone, is reflected by rapid thrombolysis and reperfusion of the pulmonary artery, more rapid recovery of abnormal perfusion lung scans, a decrease in pulmonary artery pressure, and improved right ventricular wall motion. These benefits in physiologic response are most evident in patients with relatively recent onset of symptoms (within 48 hours), [95] but some acceleration of response can be seen in patients treated for up to 2 weeks after symptom onset.[153] Studies comparing urokinase and streptokinase document equal efficacy with 12- or 24-hour infusions and for both agents.[151] When administered over 2 hours, t-PA is clearly superior to heparin therapy [152] and achieves more rapid thrombolysis than a 24-hour infusion of urokinase.[154] [155] However, large doses of t-PA and urokinase administered in an equivalent manner over 2 hours produce equal angiographic improvement.[156] Whether a similarly modified streptokinase regimen has results equivalent to those of the 2-hour urokinase or t-PA infusion remains to be established, but prior experience suggests that such would be the case. Short courses of t-PA therapy (50100 mg over 10 or 15 minutes) have proved to be no better than the 2-hour regimen.[157]

Most patients with pulmonary embolism recover with heparin therapy alone. In a population of patients with massive, submassive, or small pulmonary embolism, controlled trials of plasminogen activator versus heparin showed no difference in mortality. [95] [151] This result would tend to obscure any potential benefit in subgroups of patients at higher risk, such as those with massive embolization and clinical shock who have the most dramatic thrombolytic responses and early reversal of elevated pulmonary artery pressures. In uncontrolled studies, clinical experience indicates that patients with massive pulmonary embolism and clinical shock have better outcomes with plasminogen activator therapy than with an invasive surgical procedure using thoracotomy and pulmonary embolectomy. [158] Although one analysis[159] suggests an improved 30-day survival in a review of 719 consecutive patients with major pulmonary embolism (5% vs. 11%), results in any individual trial fail to show a survival benefit with plasminogen activator therapy.

Considering that the risk of serious bleeding complication is doubled (4% vs. 9%) and that the risk of intracranial hemorrhage remains at least 1% with all of the plasminogen activators, some clinicians are inclined to use heparin rather than fibrinolytic agents in patients with favorable-prognosis pulmonary embolism. The time window for maximal therapeutic response likewise limits the exercise of more aggressive therapy using plasminogen activators because natural resolution of the thrombus is not very different using heparin or plasminogen activator in patients with a remote history of symptoms (>48 hours). [95]

Selection of the patient who merits thrombolytic therapy therefore depends on a complex of clinical circumstances that emphasizes minimum delay before initiating treatment, selection of the most seriously ill patient for maximal short-term benefit, and avoidance of patients with absolute contraindications, especially those who are predisposed to intracranial hemorrhage. [160] The American Heart Association guidelines suggest plasminogen activator therapy when it has life-saving potential for patients with massive pulmonary embolism, especially in those who have experienced syncope, hypotension, severe hypoxemia or heart failure, or patients with submassive embolism in the presence of underlying cardiac or respiratory disease. [12] In the circumstance of life-threatening pulmonary embolism, the clinician may opt for plasminogen activator use even in the presence of a relative contraindicationfor example, in patients who are postoperative, during pregnancy, after cardiopulmonary resuscitation, and even within 1 week after neurosurgery. [161] [162] [163] [164] Administration of plasminogen activator directly into the pulmonary artery does not provide results superior to those obtained with systemic therapy. [165]

Insertion of inferior vena caval umbrella filters has been a

popular intervention in patients with pulmonary embolism, and filters are often introduced into patients with deep vein thrombosis who have no evidence but only a risk of pulmonary embolism. This approach was originally developed for management of patients with contraindications to anticoagulant or fibrinolytic therapy, but few studies of efficacy in comparison with medical management have been performed. A recent report followed patients with deep vein thrombosis who were randomized to filter placement or anticoagulation alone, and the final conclusion was that an initial benefit of the filter for preventing pulmonary embolism was counterbalanced by an excess of recurrent deep vein thrombosis without any difference in mortality. [166] Problems exist with inferior vena caval filters, including thrombosis of the filter with proximal propagation of thrombus, caval perforation, and the potential for postphlebitic symptoms secondary to a greater deep vein thrombosis recurrence rate, thus arguing against indiscriminate use of filters.

There is considerable disagreement in the application of thrombolytics for patients with pulmonary embolism, and in general the pulmonologist is reluctant to administer thrombolytic agents.[167] Most clinicians agree, however, that thrombolytic therapy can quickly reverse the pathophysiology of cor pulmonale and that survival of the most severely affected patient is more likely using plasminogen activator therapy, although this is not proven.

Peripheral Arterial Occlusion

More than with any of the other major vessel occlusions, peripheral arterial occlusion illustrates the advantages of regional, catheter-delivered plasminogen activator over systemic (intravenous) administration (Fig. 1232). The benefit is primarily due to more effective thrombolysis than to greater safety from hemorrhage, but the data indicate that such a combined radiologic and medical approach is comparable with and in some ways superior to surgery as initial therapy of the acutely threatened, but not irreversibly ischemic limb. The presence of generalized atherosclerosis, hypertension, and other manifestations of arterial disease in many of these patients makes thrombolytic therapy more problematic than in patients with venous thromboembolic disease. For example, partial dissolution of a mural thrombus may result in systemic embolization during treatment of a peripheral arterial embolus, whereas pulmonary embolization from a treated deep vein thrombosis is seldom of clinical importance.

Chronic arterial occlusions are not amenable to systemic plasminogen activator administration, not only for the lack of clinical benefit but for the absence of vascular reperfusion.[168] [169] Acute arterial occlusions proved to be more amenable to systemic plasminogen activator treatment, especially if initiated within hours of onset of symptoms and if such symptoms were

Figure 123-2 (A) Angiogram of the abdominal aorta showing complete occlusion of the right iliac artery (*arrow*). **(B)** Catheter tip is located within the thrombus proper for effective infusion of plasminogen activator (*arrow*).**(C)** Repeat angiography shows reconstitution of blood flow in the right iliac artery (*arrow*). Extensive atheromatous plaque is visible distal to the original thrombus. **(D)**

due to embolic phenomena rather than secondary to in situ atherothrombosis. [170] [171] Occlusions of small, distal arteries that are less amenable to a surgical approach may be managed by plasminogen activator infusion. The first demonstration of therapeutic efficacy for regional (intra-arterial) administration in peripheral arterial occlusion was reported by Dotter et al[172] in 1974, which showed vascular reperfusion. However, this approach did not prevent a lytic state or avoid bleeding complications. Subsequent studies have verified that reperfusion can be attained in 5080% of patients, but that in a significant proportion of patients, an underlying stenotic lesion requires angioplasty or bypass surgery to protect against reocclusion. [173] [174] [175] [176] [177] [178] [179] [180]

Despite an extensive clinical experience, a prospective, randomized comparison of regional therapy versus bypass surgery as initial management of patients with ischemic limbs secondary to arterial occlusion was not reported until 1994. [181] In a 114-patient study, catheter-directed urokinase infusion into the thrombus reperfused the affected vessels in 70% of cases, and allowed simple angioplasty in the other third. Although overall limb salvage and in-hospital mortality were the same for patients receiving intra-arterial urokinase and surgical repair as initial therapy, the 1-year mortality rate was lower in the thrombolytic group (16% vs. 42%), arguably resulting from a lower incidence of cardiopulmonary complications. This result has been confirmed in a similar study of recombinant urokinase, which achieved patency in 70% and reduced the need for major surgical procedures by 40%. [182] In this follow-up study, however, there was no survival benefit, possibly because the sickest patients were not entered into the study, but rather treated off-protocol with regional plasminogen activator infusion. Systemic activation of fibrinolysis (lytic state) occurred in many patients receiving plasminogen activator and serious bleeding occurred in 13% (vs. 6% with surgery), including intracranial hemorrhage in 1.5%.[182] In a similar trial of t-PA and urokinase, there also was no clinical advantage for plasminogen activator administration over surgery. [183]

It is generally agreed that lysis of occluded arterial grafts can be accomplished equally as well as for thrombosed native arteries. [181] [182] [184] [185] Retrospective analyses[185] [186] [187] show that results with t-PA or urokinase are superior to those with streptokinase for both thrombolytic revascularization (80% vs. 64%) and hemorrhagic complications (5% vs. 25%). One study that compared t-PA with urokinase[183] showed no difference in clinical outcome, but as yet there have been no prospective comparisons of streptokinase with either t-PA or urokinase in peripheral arterial occlusion. The total experience does not represent a strong foundation for definitive conclusions on the relative benefit of t-PA, urokinase, or streptokinase. A recent report suggests that recombinant staphylokinase also is effective in recanalization of peripheral arterial occlusion, albeit also with attendant major hemorrhagic complications, including fatal intracranial hemorrhage. [188] Although only one study has shown a 12-month

survival advantage over surgery (84% vs. 58%),[181] the similar efficacy of different plasminogen activators in comparative trials of pulmonary embolism and acute myocardial infarction suggest but do not provide convincing evidence [189] that all of the plasminogen activators will have equivalent advantages relative to surgery in the management of the ischemic but salvageable limb.

Myocardial Infarction

The potential of thrombolytic therapy for acute myocardial infarction [190] was not recognized until coronary angiography documented thrombus as the cause [191] and the ability of plasminogen activators to lyse such thrombi. [192] In retrospect, evidence of benefit existed in the early 1980s, [193] [194] but definitive data awaited the trials that compared streptokinase, alteplase, and anistreplase with placebo. [43] [117] [195] [196] These studies document that prompt treatment of the coronary artery thrombus by systemic administration of plasminogen activator reduces mortality by more than 40% when administered within 12 hours, and by 2025% at 46 hours after symptoms.[8] Tangible benefit can still be effected at up to 12 hours after symptom onset, but thereafter, plasminogen activator treatment is not better than antithrombotics alone. Aspirin administration virtually doubles the benefit. Even without thrombolytic therapy, mortality is significantly reduced when aspirin is administered within 1 hour or 46 hours after symptom onset. [43] The impact of plasminogen activator therapy on the clinical outcome of patients with acute myocardial infarction has been dramatic, and the survival advantage persists for years after therapy. [197] [198] [199] Although advanced age (>75 years) translates to a higher mortality rate after acute myocardial infarction, thrombolytic therapy saves more lives per 1,000 elderly patients who are so treated than in younger patients. [8] [200] Patients with anterior infarcts show relatively greater benefit than those with inferior infarcts, probably because of the inherent higher mortality risk with the former, and treatment is effective regardless of concurrent hypotension or history of diabetes or prior myocardial infarction, and in both men and women. [43] However, patients with ST segment depression or a normal electrocardiogram do not show the benefit in survival shown by those with ST elevation or bundle branch block. [43]

Because of the prevalence of and high mortality rate associated with acute myocardial infarction, this illness has been the most intensively studied thrombotic disorder to determine the relative value of different plasminogen activators or of regimens of plasminogen activators with anticoagulant or antiplatelet agents.

The trials of note (Table 12312) have involved well in excess of 100,000 patients treated expeditiously, most often within 6 hours of symptom onset. [8] The Gruppo Italiano per lo Studio

[a] Number of patients.

della Streptochinasi nellInfarto Miocardica (GISSI)-2 and ISIS-3 studies [38] [201] [202] performed in the early 1990s showed no statistical difference in short-term mortality rates between streptokinase and t-PA and between streptokinase, t-PA, or anistreplase. The studies showed a significantly lower rate of intracranial hemorrhage for streptokinase than for the other agents, approximately 0.7% versus 0.35%. There was no advantage in overall 35-day mortality rates using subcutaneous heparin beginning at 4 hours over no heparin, but the intracranial hemorrhage rate was increased (from 0.4% to 0.6%), suggesting that heparin did not improve results with plasminogen activator plus aspirin.

The issue of adjunctive intravenous heparin as a substantial contributor to results using t-PA, more so than with streptokinase, was based on patency results that in some cases failed adequately to control for the contribution of concomitant aspirin therapy. [49] [50] Nevertheless, the possibility that inadequate heparin masked a potential benefit of t-PA over streptokinase and the possibility that a more intensive regimen of t-PA is needed for maximal clinical results was the foundation for the accelerated t-PA regimen over 90 minutes.[42] Several conclusions are available from this large, prospective, open-label study. First, the overall mortality rate at 30 days was no different with streptokinase plus intravenous heparin than with streptokinase plus subcutaneous heparin, providing the necessary foundation to document that aggressive heparin use with streptokinase is unnecessary. Second, the combination of t-PA plus streptokinase was no better than streptokinase alone, despite prior patency evidence that the combination was advantageous. [203] Third, there was a small but statistically significant mortality advantage in favor of the accelerated t-PA plus intravenous heparin regimen, over the streptokinase-treated patients (6.3% vs. 7.2%), representing a difference of 9 patients per 1,000 treated. Fourth, the incidence of intracranial hemorrhage was significantly higher in the t-PAtreated group (0.7% vs. 0.5%), somewhat militating against a clear-cut advantage for t-PA in the entire population of treated patients. Subgroup analysis of patients in the GUSTO study showed no difference between streptokinase and t-PA in patients treated after 4 hours or with inferior myocardial infarction. Considering that the risk of intracranial hemorrhage is considerably higher in the elderly treated with t-PA than with streptokinase,[43] tailored therapy with one or other regimen has been proposed, rather than a standard regimen. [9] [204]

The small survival advantage of the accelerated t-PA regimen in GUSTO has been explained by the higher 90-minute coronary artery patency rates with t-PA, [205] almost a 2:1 higher TIMI-3 result in favor of t-PA (54% vs. 30%). Coronary artery patency categorically influences outcome, best exemplified by the higher mortality rate after intracoronary administration in patients without reperfusion than in those with reperfusion (14% vs. 8%). [206] [207] Furthermore, full patency (TIMI grade 3) rather than lesser degrees of patency (TIMI grade 2) or persistent occlusion of the coronary artery (TIMI grades 0 or 1) is dramatically associated with improved survival.[208]

However, the patency results do not fully explain the relatively small difference in survival noted in the GUSTO study, because the patency at 180 minutes was the same for t-PA and streptokinase (42% vs. 35%),[205] as predicted on the basis of prior information.[209] Effort has been directed toward improving early patency rates and preventing the clinical deterioration that follows early reocclusion. [210] In one retrospective analysis of 5,475 patients, [211] an estimate was made that accelerated or front-loaded t-PA induced TIMI grade 3 flow at 90 minutes in 63% or 50% of patients, respectively, compared with only 32% after streptokinase, and that reocclusion occurred in 6%, 12%, and 4%, respectively. The potential for improved early patency is greatest for streptokinase, and that for lessened early reocclusion is greatest for t-PA. One novel approach has been the development of new plasminogen activators with more potent

early thrombolytic effect. Thus, reteplase infusion results in a 90-minute TIMI grade 3 patency rate of 6063% versus only 4549% for accelerated t-PA. [212] [213] Despite favorable reviews for the reteplase data, [214] [215] a subsequent mortality trial (GUSTO-III) [107] showed that the 30-day mortality rate with reteplase was not statistically different from that with accelerated t-PA in a trial of 15,000 patients (7.47% vs. 7.24%). Similarly, reteplase showed no statistically significant difference in mortality from streptokinase (9.02% vs. 9.53%) in a trial of 6,000 patients, [216] despite a clear advantage in 90-minute TIMI grade 3 patency results. In further support of the concept that improved patency rates do not uniformly result in higher survival, a double-bolus regimen of t-PA, which had shown a TIMI grade 3 patency rate of 88%,[217] resulted in a slightly higher mortality rate (7.98% vs. 7.53%) and higher intracranial hemorrhage rate than accelerated t-PA. [106] TIMI grade 3 patency rates after staphylokinase administration or a 60-minute t-PA regimen have been reported to be 68% [218] and 81%,[219] and a 63% TIMI grade 3 patency was noted after a single bolus (40 mg) of TNK-tPA,[220] but these striking findings must be tested in mortality trials before acceptance as superior plasminogen activator agents or regimens.

It is possible that improved antiplatelet strategies, such as using antibodies, small peptides, or chemicals directed against the platelet fibrinogen receptor, [56] [57] will decrease late reocclusion after t-PA, and improved antithrombin agents such as hirudin [53] [54] rather than heparin may accelerate early reperfusion with the relatively slow-acting agents such as streptokinase. The potential benefit for improved antiplatelet therapy could be that a lower dosage of t-PA could be used, [71] which could in theory improve the safety profile of t-PA relative to intracranial hemorrhage. On the other hand, a significant increase in TIMI grade 3 patency at 90 minutes with streptokinase might translate into results that are equivalent to those achieved with accelerated t-PA, but proof of survival benefit with this regimen is not available.

A reasonable alternative approach to early coronary artery revascularization is immediate angioplasty, [221] and this approach is feasible for large centers that can expedite therapy without delay. Although there is some disagreement in the interpretation of results, [204] angioplasty would certainly have advantages for patients with relative contraindications to thrombolytic therapy, especially if there were high risk of intracranial hemorrhage. Intracoronary plasminogen activator administration probably still has a role in patients who fail to reperfuse with systemic treatment or who deteriorate secondary to early reocclusion, [222] in which case local infusion of plasminogen activator may be attempted as a prelude to bypass surgery or concomitant with angioplasty. The risk of serious hemorrhage, even intracranial hemorrhage, is tangibly less than the chance of improved survival after plasminogen activator treatment of an anterior myocardial infarction. However, in the setting of pre-existent hypertension or a prior CVA or TIA, the incidence of intracranial hemorrhage is significantly increased to more than 3%, [101] depending on the plasminogen activator that is infused. The risk of intracranial hemorrhage correlates with four risk factors [41] specifically, age >65 years, body weight <70 kg, hypertension on admission, and the administration of alteplase.

Thus, although the benefit for application of plasminogen activator therapy is striking and physicians have applied these agents for routine care, the risk of serious bleeding may significantly influence the decision in some patients. For example, patients with an inferior myocardial infarction who present more than 6 hours after onset of pain may best be managed conservatively with antithrombin or antiplatelet agents only. On the other hand, a massive anterior myocardial infarction may well warrant plasminogen activator therapy even in the face of a significant risk of serious bleeding, because the mortality rate can be reduced by as much as 25% using thrombolytic agents.

Ischemic Stroke

Because intracranial hemorrhage is the most feared complication of plasminogen activator treatment, the rationale of dissolving cerebral artery thrombi that cause ischemic stroke has presented both a therapeutic dilemma and a technical obstacle. The risk of inducing an intracranial hemorrhage or of converting a subclinical, petechial hemorrhagic stroke into a parenchymal hematomawith its attendant 60% mortality rateis high. Until the availability of accurate technology for distinguishing a hemorrhagic from a thrombotic stroke, the chance of a catastrophic outcome has been unacceptably high. The only satisfactory exception to the general aversion to plasminogen activator treatment of stroke was the application of regional agent into the vertebrobasilar arterial system in patients with severe brain stem thrombotic stroke.[223] In this situation of dire prognosis for coma and death, the results were sometimes dramatically beneficial and helped to establish the feasibility and potential usefulness of this approach.

In a spurt of activity in the mid-1990s, five randomized and blinded trials of intravenous plasminogen activator were completed for ischemic stroke, three of which used streptokinase at 1.5 million units over 1 hour [224] [225] [226] and two of which used alteplase at a maximal dose of 90 or 100 mg over 1 hour.[227] [228] Table 12313 summarizes the results, which were different in various

[a] Study terminated because of excess early mortality.
[b] Increased mortality with SK (over placebo) only in patients treated at 3 h or longer after symptom onset.

details of patient characteristics, diagnosis, treatment, and follow-up evaluation. The most important distinction was the delay from symptoms until treatment, with three studies accepting patients at up to 6 hours after symptoms, one until 4 hours, and one cutting off accession at 3 hours maximum. The major end points were usually a combination of mortality plus severe disability (dependence) at 16 months, the rate of intracranial hemorrhage (parenchymal hematoma) complicating treatment, and functional assessment at 36 months. Of the five studies, three were terminated wholly or in part before completion because of an excess in short-term (10 days) mortality, [224] [225] [226] and a fourth study that was completed showed a nearly significant increase in 30-day mortality in the intention-to-treat group of patients.[227] The only study that showed no increase in mortality at 30 days was the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Study Group,[227] which assessed t-PA in patients who were started on treatment before 3 hours. The other trials entered patients at up to 4 hours [225] or 6 hours.[224] [225] [227] The Australian Streptokinase Trial showed an excess mortality for patients entered after 3 hours but not before 3 hours. [226]

Functional tests on survivors at 36 months regularly showed higher scores in the treated group compared with placebo, but this advantage [229] must be tempered by the unacceptable high early mortality rates of most trials. Uniformly, the patients who received any plasminogen activator had an increased rate of intracranial hemorrhage, especially of parenchymal hematoma, evident as early as 1.5 days or as a measured accumulation over several months. This remains an especially severe complication, associated with a mortality rate of approximately 60%, especially in patients who are screened by computed tomography scanning to rule out overt hemorrhage before treatment.

A summary of 12 trials, representing an experience in almost 3,500 patients, has been published by Wardlaw et al, [13] and draws the following conclusions:

- Thrombolytic treatment is associated with a significant increase in early deaths and total deaths, but with a reduction in combined outcome of death or dependence.
- Symptomatic intracranial hemorrhage occurs in some patients, a large percentage of whom had fatal outcome.
- For all patients randomized within 3 hours, there was a nonsignificant, slight increase in deaths and a reduction in death plus dependence.
- There was significant heterogeneity between trials, most pointedly with regard to the severity of stroke, time before treatment, dosage of plasminogen activator, and use of other antithrombotics.
- Because there has been no direct comparison of t-PA with streptokinase or urokinase, the poor outcome noted in streptokinase trials could be explained by

differing characteristics of the trials, most especially with regard to the time before treatment.

They conclude that there is substantial risk and uncertain benefit with the use of plasminogen activator therapy for acute ischemic stroke. Clearly, more testing is needed, but it is difficult to enter patients into a study within 3 hours, even when a research team is trained and on call. These technical problems are certainly at the root of the limited applicability of conditions described in the NINDS trial [228] for general practice. Of potential relevance is an ongoing trial of recombinant saruplase (pro-urokinase) administered by regional perfusion and a study of the antithrombotic, ancrod, which may prove advantageous by avoiding the complication of intracranial hemorrhage.

Other Indications

A variety of thrombotic disorders have been treated by plasminogen activator infusion, some with dramatic results. [14] Local installation of plasminogen activator into thrombosed access catheters or arteriovenous shunts can lyse thrombus and re-establish flow, but reocclusion may follow. Local administration of plasminogen activator through special catheters that contain multiple pulse-spray openings have been applied for the treatment of otherwise inaccessible thrombi, such as in the mesenteric venous or arterial system, thrombosed cerebral or basilar arteries, upper extremity deep vein thrombi (subclavian/axillary system), and for thrombosed superior vena cavae, especially in the presence of external compression by tumor. In many examples of thrombolysis, residual stenotic areas of vein or artery are identified, and vascular radiologists are increasingly inserting stents into such vessels to impede rethrombosis. A number of patients with retinal artery or vein thrombi have been treated with plasminogen activator, but results are either difficult to interpret or unimpressive, especially considering that retinal vein occlusions are often clinically undetected for days or weeks. Cerebral venous sinus thrombi should be especially amenable to plasminogen activator infusions because relief of the venous obstruction would be expected to correct the venous hypertension and cerebral edema behind the obstructive lesion.

Many unusual thrombotic conditions are potentially correctable by plasminogen activator infusion, including heparin-associated thrombocytopenia with thrombosis, mobile right heart thrombus, inferior vena cava filter thrombosis, central line thrombosis in premature infants, hepatic vein occlusion, renal allograft vein thrombosis, portal vein thrombosis after liver transplantation, and paradoxical embolus through a patent foramen ovale. In all such clinical situations, the potential for clinical improvement must be weighed against that for serious hemorrhagic complication when deciding on a course of treatment.

Chapter 124 - Venous Thromboembolism

Jack Hirsh
Mark A. Crowther

INTRODUCTION

Although venous thrombosis can occur in any vein in the body, it most commonly occurs in the lower limbs. Thrombosis of the superficial veins of the legs frequently occurs in varicosities and is usually benign and self-limiting. In contrast to superficial vein thrombosis, involvement of the deep veins of the leg is a more serious condition. Thrombi localized to the deep veins of the calf are less serious than those involving the proximal veins (popliteal, femoral, or iliac veins) because they are often smaller and therefore less commonly associated with long-term disability or clinically important pulmonary embolism (PE). On the other hand, proximal vein thrombosis is frequently complicated

by PE. In addition, extensive damage to the valves in the veins often leads to disability from the postphlebitic syndrome.

Venous thrombosis and its major complication, PE, have long been known to be important causes of morbidity and mortality in hospitalized patients. Recently, it has become apparent that venous thromboembolism also occurs in otherwise well, ambulant outpatients. The diagnosis of acute thromboembolism in outpatients is now being made more frequently because of increased diagnostic suspicion and the availability of reliable, noninvasive diagnostic tests. Other possible reasons for the increase in the reported rate of venous thrombosis in outpatients include the trend toward early hospital discharge of postsurgical patients who may not have received adequate in-hospital prophylaxis or whose in-hospital prophylaxis was terminated at discharge even through the patient remained at risk for venous thrombosis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM AND CLINICAL RISK FACTORS

Venous thrombi are composed predominantly of fibrin and red cells [1] and usually arise in the large venous sinuses in the calf, in valve cusp pockets in the deep veins of the calf, or at sites of vessel damage. Venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural anticoagulant mechanisms and the fibrinolytic system to prevent fibrin formation. [1] Activation of blood coagulation is usually initiated by tissue or vascular trauma or by inflammation, and is augmented by venous stasis. Vascular wall damage is an important factor predisposing to venous thrombosis after major hip or knee surgery. [1] In addition to activating coagulation, tissue damage can also lead to impaired fibrinolysis because inflammatory cytokines induce endothelial cell synthesis of plasminogen activator inhibitor-1 (PAI-1), the major inhibitor of fibrinolysis. [2]

Under normal circumstances, activated coagulation factors are diluted in the flowing blood and are neutralized by inhibitors on the surface of endothelial cells or by circulating antiproteinases. [3] However, activated clotting factors that escape regulation can trigger the coagulation system, thereby leading to fibrin formation. This in turn activates the fibrinolytic system by inducing the release of tissue plasminogen activator (t-PA) from endothelial cells [4] and urokinase from monocytes and leukocytes, which are attracted to the thrombus by released fibrinopeptides and platelet products.

Thrombogenic Factors

Activation of Blood Coagulation

The coagulation proteins circulate as inactive precursors or zymogens. Each zymogen is converted into an active enzyme that then activates the next zymogen in the coagulation pathway (see Chap. 102).[5] Although coagulation can be activated through either the intrinsic or the extrinsic pathway in vitro, coagulation in vivo is initiated via the extrinsic, or tissue factor, pathway. In this pathway, activated factor VII binds to tissue factor on stimulated monocytes at sites of vascular injury. The tissue factor-factor VIIa complex then activates factors IX and X. The direct activation of factor X by the tissue factor-factor VIIa complex represents the extrinsic pathway, whereas activation of factor IX links the extrinsic and intrinsic pathways. [6] The intrinsic pathway is initiated in vitro by the activation of factor XII that occurs when blood is exposed to an activator, such as kaolin or celite. Activated factor XII then activates factor XI, which in turn activates factor IX. Finally, activated factor IX activates factor X in the presence of factor VIII, phospholipid, and calcium. The rate of this reaction is markedly enhanced by the presence of phospholipid and by prior exposure of factor VIII to thrombin or activated factor X.

Activated factor X completes the coagulation cascade by converting prothrombin to thrombin in the presence of activated factor V, phospholipid, and calcium. The rate of this reaction is accelerated by the presence of phospholipid and by thrombin or factor Xa activation of factor V. Thrombin then converts fibrinogen to fibrin, activates platelets, and activates factor XIII, which, in the presence of calcium, cross-links the fibrin, thereby stabilizing the clot.

Blood coagulation is modulated by positive and negative feedback loops. Thrombin and activated factor X activate factors VIII and V, markedly accelerating the coagulation reactions involving these two cofactors. [5] Although activated factor X can feed back to activate factor VII, this reaction is down-regulated by tissue factor pathway inhibitor (TFPI), which first complexes activated factor X, thereby rendering it inactive. The TFPI-Xa complex then binds the factor VIIa-tissue factor complex and prevents further activation of factor X. [7]

A low level of activation of blood coagulation occurs continuously in normal subjects. [8] However, factor VIIa, which is responsible for the initiation of coagulation in vivo, is the only coagulation factor that normally circulates in its enzyme form. In vivo activation is reduced in patients with hemophilia and is increased above normal in some patients with hereditary deficiencies of antithrombin, protein C, and protein S, [8] in patients with activated protein C resistance, [9] and in patients at increased risk of thrombosis after elective orthopedic surgery (Table 1241).[10] Activation of blood coagulation also increases with age in patients over the age of 45.

Coagulation may be activated by contact of factor XII with collagen on exposed subendothelium of damaged vessels or by contact with prosthetic surfaces. Coagulation is further augmented by activated platelets. Coagulation may also be initiated by the exposure of blood to tissue factor made available locally as a result of vascular wall damage, [6] by activation of endothelial cells by cytokines, and by activated monocytes that migrate to areas of vascular injury. [11] Factor X can be activated directly by extracts of malignant cells that contain a cysteine protease, [12] which may be one of the mechanisms by which thrombosis is induced in patients with malignant disease. A factor elaborated by hypoxic endothelial cells can also directly activate factor X [13] and could lead to thrombosis in patients with severe venous stasis, in whom stagnant hypoxia occurs in the valve cusps.

Clinical risk factors that predispose to venous thromboembolism by activating blood coagulation include malignancy, extensive surgery, trauma, burns, myocardial infarction, and possibly local hypoxia produced by venous stasis (Table 1241).[13]

Venous Stasis

Venous return from the legs is enhanced by contraction of the calf muscles, which propels blood upward from the extremities.

TABLE 124-1 -- Thrombogenesis

Stimulation
Activation of coagulation
Vessel damage
Stasis
Inhibition
Circulating inhibitors
(antithrombin III, protein C, protein S)
Endothelial cell components
(heparan sulfate, thrombomodulin)
Fibrinolytic system
(tissue plasminogen activator, plasminogen)

Venous stasis contributes to thrombogenesis by allowing activated coagulation factors to accumulate. In addition, stagnation of the blood could lead to local hypoxia, which stimulates endothelial cell release of an activator of factor X. [13] Venous stasis is produced by immobility, venous obstruction, increased venous pressure, venous dilation, and increased blood viscosity.

Immobility

Venous thrombosis occurs in immobilized individuals because blood pools in the intramuscular sinuses of the calf, which are dilated during recumbency. Many clinical examples highlight the role of stasis in the pathogenesis of venous thrombosis. Thus, the prevalence of venous thrombosis found at autopsy is markedly increased in individuals who were confined to bed for more than a week before death. Further, preoperative immobility is associated with a higher frequency of perioperative venous thrombosis. After surgery, patients remain at risk for venous thromboembolism for as long as they are immobile. Finally, immobility contributes to the high incidence of postoperative venous thrombosis in patients who have undergone hysterectomy, transabdominal prostatectomy, hip surgery, knee surgery, or surgery for fractures of the lower limb. The effect of immobility on thrombosis is well illustrated by comparing the location of thrombosis in paraplegics with that in stroke patients. Whereas thrombosis occurs with equal frequency in both legs in paraplegics, it occurs more frequently in the paralyzed limb in stroke patients.

Venous Obstruction

Venous obstruction contributes to the risk of venous thrombosis in patients with pelvic tumors, and to recurrent venous thrombosis in patients with persistent obstruction due to proximal vein thrombosis. Raised central venous pressure produces venous stasis in the extremities, which may explain the high prevalence of venous thrombosis in patients with heart failure. A similar mechanism may underlie the propensity for thrombosis in the left leg during pregnancy, presumably from obstruction of the left common iliac vein by the right common iliac artery.

Increased Blood Viscosity and Venous Dilation

Venous stasis can be caused by increased blood viscosity or venous dilation. The blood viscosity can be increased by an elevated hematocrit (polycythemia), hypergammaglobulinemia, dysproteinemias, or an increased fibrinogen concentration. Stasis due to venous dilation could contribute to the increased risk of thrombosis in patients with varicose veins and in elderly patients, particularly if they are bedridden. The ability of estrogen to cause venous dilation may explain the increased prevalence of thrombosis during pregnancy, [14] in individuals taking estrogen-containing oral contraceptive pills, [14] and in patients taking postmenopausal estrogen replacement therapy.[15] [16] [17]

Vessel Wall Damage

Although the normal endothelium is nonthrombogenic, damage or injury to the endothelium can trigger the activation of platelets and coagulation. Thus, vascular injury leads to the expression of tissue factor, either directly by endothelial cells or by monocytes that are attracted to the site of damage. In addition, the exposure of blood to subendothelium leads to platelet adhesion and aggregation.

The vascular endothelium can be damaged by direct trauma or it can be perturbed by exposure to endotoxin, inflammatory cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), thrombin, or low oxygen tension. Perturbed endothelial cells synthesize tissue factor and PAI-1 and internalize thrombomodulinchanges that promote thrombogenesis.[18]

Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping and in patients with severe burns or lower limb trauma. Perturbation of vascular endothelium by exposure to thrombin or inflammatory mediators probably contributes to the thrombosis that occurs after tissue damage, such as surgery or trauma, and in patients with acute or chronic inflammatory states (Table 124-1).

Protective Mechanisms

Endothelial Protective Mechanisms

Normal vascular endothelium is nonthrombogenic to flowing blood. Endothelial cell-surface glycosaminoglycans and thrombomodulin are potent inhibitors of coagulation, whereas vessel wall generation of prostacyclin and nitric oxide and synthesis of plasminogen activators limit platelet aggregation and fibrin deposition.

Thrombomodulin and heparan sulfate present on the luminal surface of endothelial cells are important modulators of thrombin activity. Heparan sulfate, a glycosaminoglycan similar to heparin, catalyzes the inhibition of thrombin and factor Xa by antithrombin. [3] Thrombomodulin serves as a surface-bound receptor for thrombin.[18] Once complexed with thrombomodulin, thrombin undergoes a conformational change that markedly alters its substrate specificity such that thrombin is no longer capable of activating platelets, of converting fibrinogen to fibrin, or of activating factors V, VIII, and XIII. [3] Rather, complexed thrombin acquires enhanced ability to activate protein C, which in turn proteolytically inactivates factors Va and VIIIa. This reaction requires protein S as a cofactor. Thus, once bound to thrombomodulin, thrombin not only loses its procoagulant activity but, by activating protein C, triggers a potent anticoagulant pathway.

The importance of the protein C anticoagulant pathway in the regulation of physiologic hemostasis has been highlighted by the syndrome of activated protein C resistance.[19] [20] [21] Activated protein C resistance is the most frequent hereditary condition predisposing to venous thrombosis, being found in 1630% of patients with acute venous thromboembolism. In 90% of cases, patients with activated protein C resistance have an inherited abnormality in their factor V gene, known as factor V Leiden (Arg506 Gln). This mutation inhibits the inactivation of factor Va by activated protein C. As a result, activated factor V persists, resulting in continued and excessive thrombin generation, thereby predisposing to thromboembolism (Table 1242).

Generation of plasminogen activators[22] by vascular wall cells limits fibrin deposition, while platelet aggregation is inhibited by the release of prostacyclin (PGI_2) and endothelium-derived nitric oxide. [23] Endothelial cell affinity for t-PA, plasminogen, and activated protein C and protein S may also contribute to the thromboresistance of the vessel wall.[3] Plasminogen binds to the cell surface, where it can be activated to plasmin by t-PA, thereby promoting local fibrinolytic activity. Bound activated protein C and protein S have a potent anticoagulant function.

Endothelial cells also have properties that are potentially procoagulant. Intact endothelium possesses receptors for activated

TABLE 124-2 -- Odds Ratio for Thromboembolism in Patients with Congenital Hypercoagulable States

Hypercoagulable State	Odds Ratio
Antithrombin deficiency type I	13.7

Protein C deficiency	11.9
Protein S deficiency	10.0
Dysfibrinogenemia	18.0
Activated protein C resistance	2.7[a]

[a]Relative risk derived from large prospective cohort series. [123]

factors IX, X, and V. Perturbed endothelial cells also synthesize endothelins, which cause local vasoconstriction.

Inhibitors of Blood Coagulation

Activated coagulation factors are serine proteases, and their activity is modulated by several naturally occurring plasma inhibitors. The most important inhibitors of the blood coagulation system are antithrombin, protein C, and protein S. [3] An inherited deficiency of one of these three proteins is found in about 15% of patients who present with venous thrombosis before the age of 45.[24] Some congenital dysfibrinogenemias can also predispose to thrombosis, as can congenital deficiency of plasminogen (Table 124-2). A deficiency in heparin cofactor II, a secondary inhibitor of thrombin, has been associated with thrombosis, but a clear causal relationship has yet to be established.

Antithrombin

Antithrombin primarily inhibits thrombin and factor Xa, but it also inactivates factors XIIa, XIa and IXa to a lesser degree. The rate at which antithrombin inhibits these enzymes is markedly accelerated by unfractionated heparin and by naturally occurring heparin sulfate found on the luminal surface of endothelial cells. Antithrombin levels about 50% of normal are associated with venous thrombosis.

Congenital antithrombin deficiency is inherited as an autosomal dominant trait. Affected patients have antithrombin levels 4060% of normal, and 70% of those affected experience thromboembolic events before the age of 50. Although thrombosis usually occurs in the deep veins of the legs or manifests as PE, it may also occur at unusual sites such as the mesenteric, renal, and cerebral veins. Antithrombin is decreased slightly during heparin therapy, but there is no evidence that this modest reduction is clinically important. Levels of antithrombin are also reduced in protein-losing states, which may contribute to the increased risk of thrombosis in the nephrotic syndrome. Marked reductions in antithrombin levels occur in patients with liver disease or disseminated intravascular coagulation.

Protein C

Like other vitamin K-dependent coagulation factors, protein C contains -carboxyglutamic acid residues that are required for the normal function of this inhibitor. Protein C is activated by thrombin,[3] a process greatly enhanced by the interaction of thrombin with thrombomodulin. [3] [18] Activated protein C proteolytically inactivates factors Va and VIIIa[3] on the platelet and endothelial cell surface and also stimulates fibrinolysis. [3] Protein S, another vitamin K-dependent protein, is a necessary cofactor for activated protein C.[3]

Protein C deficiency is inherited in an autosomal dominant manner and is associated with familial venous thrombosis. [24] The level of protein C in affected heterozygotes is 4060% of normal. Although the clinical manifestations are similar to those of antithrombin deficiency, there are three unique features of protein C deficiency. Homozygotes can develop a severe thrombotic tendency in infancy characterized as purpura fulminans, heterozygotes have an increased risk of developing warfarin-induced skin necrosis because of the short half-life of this protein, and heterozygotes who are identified by mass screening may have a benign form of the condition with a low risk of venous thrombosis.

Protein S

This vitamin K-dependent plasma protein serves as a cofactor for activated protein C. [3] Protein S deficiency is also inherited in an autosomal dominant manner and is at least as common as antithrombin and protein C deficiency.[24] The clinical manifestations are similar to those seen with antithrombin and protein C deficiency. Thrombosis occurs in heterozygotes whose levels of functional protein S are in the range of 1550% of normal.

Dysfibrinogenemia

The majority of patients with dysfibrinogenemia are asymptomatic, about one-third have a bleeding tendency, and a much smaller proportion are predisposed to thrombosis.[25] In this last group, however, the risk of thrombosis in affected family members is much higher than in those who are unaffected, suggesting that there is a true relationship between certain dyfibrinogenemias and thrombosis. [24] The possible mechanisms by which a dysfibrinogenemia may lead to thrombosis include defective thrombin binding to fibrin, and the production of fibrin that is resistant to natural fibrinolysis.

Heparin Cofactor II

A secondary inhibitor of thrombin, heparin cofactor II complexes and inactivates the enzyme. The rate of this reaction is accelerated by both unfractionated heparin and dermatan sulfate. Although there have been reports of thrombosis associated with heparin cofactor II deficiency, a causal relationship remains to be established because the risk of thrombosis in family members with heparin cofactor II deficiency is similar to that in unaffected family members. [24]

Fibrinolytic System

The basic reaction of the plasma fibrinolytic system is the conversion of plasminogen to the active enzyme, plasmin, by limited peptide bond cleavage produced by a variety of plasminogen activators (Chap. 103). Two endogenous plasminogen activators, t-PA and urokinase, are synthesized by and released from endothelial cells. Urokinase is also synthesized by monocytes. Plasmin hydrolyzes fibrin and various plasma coagulation proteins, including fibrinogen, and factors V and VIII. As with the coagulation system, the activity of the fibrinolytic system is modulated by inhibitors that regulate both the plasminogen activators and the proteolytic effect of plasmin.[26]

Decreased fibrinolytic activity occurs in the early postoperative period, [2] in individuals taking oral contraceptives, [27] during the last trimester of pregnancy, [27] and in obese subjects.[28] Fibrinolytic activity in the leg veins is less than that in arm veins, which may partly explain the greater tendency for venous thrombosis to occur in the lower extremities. The relative reduction in fibrinolytic activity in the leg veins is more marked in the elderly.

Impaired fibrinolysis predisposes to postoperative venous thrombosis and possibly to coronary artery thrombosis in patients with coronary artery disease. [2] The impaired fibrinolytic activity reported in patients with venous thrombosis is acquired and is caused by increased levels of plasminogen activator inhibitor. [2] However, there are occasional reports of familial abnormalities of the fibrinolytic system in association with venous thrombosis. [29] [30]

Congenital Plasminogen Deficiency

Congenital plasminogen deficiency has been reported in association with venous thromboembolism in a number of families. [31] The pattern of inheritance appears to be autosomal, with heterozygotes having plasminogen levels (both activity and antigen) decreased to about 50% of normal. Functional abnormalities of plasminogen have also been described, some of which have been associated with venous thromboembolism. [32]

Other Clinical Disorders That Predispose to Venous Thromboembolism

Recently, an association between elevated levels of prothrombin (typically >1.50 U/liter) and venous thromboembolism has

---

been proposed and confirmed. In most cases, the elevated levels are due to a mutation in the regulatory sequence of the prothrombin gene. This results in elevated basal prothrombin levels, which predispose to thrombosis by an unknown mechanism.

Other conditions reported to be associated with venous thromboembolism include thrombocytosis, polycythemia vera, and antiphospholipid antibodies. The antiphospholipid antibodies are a group of autoantibodies directed against anionic phospholipids in concert with cell-surface or plasma proteins (see Chap. 116).[33] [34] [35] There are two major groups of antiphospholipid antibodies, anticardiolipin antibodies and the lupus anticoagulant. The mechanism by which these antibodies predispose to thromboembolism is unclear. The absolute risk of thrombosis in patients with the lupus anticoagulant is increased. This finding has led to recommendations that patients with antiphospholipid antibodies and a history of thrombosis receive long-term, high-intensity warfarin therapy to prevent recurrence. [33] [36] This recommendation is based on methodologically inadequate studies and requires verification prior to its widespread application.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

NATURAL HISTORY OF VENOUS THROMBOEMBOLISM

Most thrombi are asymptomatic and confined to the intramuscular veins of the calf. These calf vein thrombi often undergo spontaneous lysis and rarely, if ever, produce long-term sequelae.[37] In contrast, complete lysis of proximal vein thrombosis is uncommon even when heparin treatment is given. [38]

The symptoms and signs of venous thromboembolism are caused by obstruction to venous outflow, inflammation of the vessel wall or perivascular tissues, or embolization of thrombus into the pulmonary circulation. Asymptomatic PE is detected by perfusion lung scanning in about 50% of patients with documented proximal vein thrombosis.[39] Most clinically significant and fatal PE probably arise from thrombi in the proximal veins of the legs. Although PE may also complicate calf vein thrombosis, these emboli tend to be smaller in size and occur less commonly than in patients with proximal vein thrombosis. [39] Asymptomatic venous thrombosis is found in 70% of patients who present with confirmed PE.[40] These thrombi are usually large and involve the proximal veins.

Extensive venous thrombosis causes venous valvular damage, which leads to the postphlebitic syndrome. [41] In addition, a previous history of venous thrombosis is associated with an increased risk of further episodes, particularly when patients are exposed to high-risk situations. [42]

Prognosis of Venous Thrombosis

Untreated or inadequately treated venous thrombosis is associated with a high complication rate, which can be decreased markedly by adequate anticoagulant therapy. About 20% of untreated silent calf vein thrombi and 2030% of untreated symptomatic calf vein thrombi extend into the popliteal vein. When extension occurs, it is associated with a 4050% risk of clinically detectable PE. [37] Patients with proximal vein thrombosis who are inadequately treated[43] have a 47% frequency of recurrent venous thromboembolism over 3 months, and patients with symptomatic calf vein thrombosis who are treated with a 5-day course of intermittent intravenous (IV) unfractionated heparin without continuing oral anticoagulants have a recurrence rate greater than 20% over the next 3 months. [44]

In contrast, clinically detectable recurrence occurs in less than 2% of patients with proximal vein thrombosis during the initial period of unfractionated heparin therapy[39] if an adequate anticoagulant response is achieved, and the recurrence rate during the subsequent 3 months of treatment with oral anticoagulants or moderate doses of subcutaneous unfractionated heparin is 24%. [43] [45] [46] After 3 months of anticoagulant therapy, the recurrence rate is 510% in the subsequent year.[43] [45] [46] Patients whose first episode of venous thrombosis was idiopathic and those who have ongoing risk factors, such as prolonged immobilization or cancer, are at higher risk of recurrence.

The significance of asymptomatic calf deep vein thrombosis discovered incidentally by screening venography after orthopedic surgery is unclear; recent studies suggest that the risk of these thrombi producing clinical sequelae is low. [47] As a result, if adequate perioperative deep vein thrombosis prophylaxis is given, it is likely not necessary to perform screening tests for deep vein thrombosis in asymptomatic patients.

Postphlebitic Syndrome

The postphlebitic syndrome is caused by venous hypertension, which is usually the result of valve destruction but occasionally can be produced by large proximal vein thrombi that block overflow.[48] Valve destruction results in malfunction of the muscular pump mechanism, which leads to increased pressure in the deep calf veins during ambulation. The high pressure ultimately renders the perforating veins of the calf incompetent, so that blood flow is directed from the deep veins into the superficial venous system during muscular contraction. This leads to edema and impaired viability of subcutaneous tissues and, in its most severe form, to venous ulceration. Outflow obstruction may initially be bypassed by the development of collateral veins, but with time, the veins distal to the obstruction become dilated and their valves become incompetent.

In patients whose thrombosis extends into the iliofemoral veins, the swelling may never disappear. In contrast, the swelling may subside after initial treatment but recur months or years later in patients with less extensive proximal vein thrombosis. Other symptoms and signs of the postphlebitic syndrome may be delayed for 510 years after the initial thrombotic event. These symptoms include pain in the calf that is relieved with rest and leg elevation, pigmentation and induration around the ankle and lower third of the calf, and ulceration, which usually occurs in the region of the medial malleolus.

Patients with extensive thrombosis involving the iliofemoral vein frequently have greater disability and may even have venous claudication, which is characterized by incapacitating, bursting pain with exercise. [49] This complication rarely occurs in patients with thrombosis involving the more distal veins.

The risk of postphlebitic syndrome has recently been quantified. Prandoni et al., [50] in a prospective cohort study, demonstrated that 29.1% of patients with acute deep vein thrombosis will develop the syndrome after 8 years of follow-up. The development of ipsilateral recurrent thrombosis was associated with a large increase in risk for the development of postthrombotic syndrome.

Whether therapy for acute venous thrombosis reduces the long-term risk of postphlebitic syndrome is unclear. Practically, therapy that reduces thrombus extension or prevents the development of profound outflow obstruction from the limb is likely to reduce the long-term risk of postphlebitic syndrome. In addition, the use of graduated compression stockings may reduce the risk of postphlebitic syndrome in patients with deep vein thrombosis.

DIAGNOSIS OF VENOUS THROMBOSIS

The approach to the diagnosis of venous thrombosis has changed radically over the past 20 years. It is now accepted that the clinical diagnosis of venous thrombosis is nonspecific[51] and that objective tests are necessary to confirm the diagnosis. This concept has led to three new developments. The first is the widespread use of venography to confirm a clinical suspicion

---

of venous thrombosis, the second is an improvement in the technique and safety of venography, and the third has been the development and careful evaluation of noninvasive tests to replace venography.

In symptomatic patients, venous ultrasonography (US) is sensitive and specific for proximal deep vein thrombosis (thrombosis of the popliteal or more proximal veins); however, US is insensitive to calf vein thrombosis and to deep vein thrombosis occurring after orthopedic surgery. [52] To increase the sensitivity of US for clinically important calf thrombosis and to improve the safety of diagnostic strategies that do not include venography in patients with suspected calf vein thrombosis, US can be repeated 7 days after the initial study. This strategy will detect the 1030% of calf vein thrombi that extend proximally. If the test remains negative after 7 days, the risk of clinically important proximal extension is negligible, and it is safe to withhold treatment. [53] [54] [55] [56]

Clinical Diagnosis

Although clinical diagnosis is nonspecific, careful documentation of clinical symptoms and signs is helpful in ruling out venous thrombosis when an alternative cause is identified (e.g., sciatica, cellulitis, ruptured Bakers cyst, muscle or tendon tear, cutaneous vasculitis, arthritis). In addition, a recent study found that patients could be classified into high-, intermediate-, and low-probability groups based on their clinical manifestations and the presence or absence of risk factors such as recent immobilization, hospitalization within the past 6 months, or malignancy. [57] Patients with the classic symptoms and signs of deep vein thrombosis, such as localized pain, tenderness, swelling, and discoloration, and who had at least one risk factor had an 85% probability of venous thrombosis, while those with atypical symptoms and no risk factors had only a 5% probability of venous thrombosis. These low and high pretest probabilities can be combined with the results of objective noninvasive tests to make clinical decisions. Thus, a low pretest clinical probability and a negative result on noninvasive testing can be used to exclude a diagnosis of venous thrombosis, thereby obviating further testing. In contrast, a high pretest clinical probability and a negative noninvasive test result should prompt further investigation with venography.

About 70% of patients referred for clinically suspected venous thrombosis will not have the diagnosis confirmed by objective tests. [53] [54] Of the 30% who have venous thrombosis, about 85% have proximal vein thrombosis and the remainder have thrombosis confined to the calf. [53] [54] The conditions that most frequently simulate venous thrombosis are a ruptured Bakers cyst, cellulitis, muscle tear, muscle cramp, muscle hematoma, external venous compression, superficial thrombophlebitis, and the postphlebitic syndrome.

Objective Tests for the Diagnosis of Venous Thrombosis

Both invasive and noninvasive tests are useful for the diagnosis of venous thrombosis. Venography is the only invasive test of proven value, whereas the noninvasive studies that are useful are impedance plethysmography and venous US. Because venous US is the most sensitive and specific noninvasive test, it is considered the test of choice. Unlike venography, both of the noninvasive tests lack sensitivity for calf vein thrombosis.

Venography

Venography remains the reference standard for the diagnosis of venous thrombosis. [58] It is technically difficult to perform, and its proper execution and interpretation require considerable experience. With good technique, ascending venography outlines the entire deep venous system of the lower extremities, including the external and common iliac veins. Venography may produce superficial phlebitis and can cause deep vein thrombosis. [58]

Impedance Plethysmography

This noninvasive test uses electrical resistance (impedance) to detect blood volume changes in the calf produced by inflation and deflation of a pneumatic thigh cuff. The changes in blood volume are reduced if the popliteal or more proximal veins are obstructed.

The impedance test does not distinguish between thrombotic and nonthrombotic obstruction to venous outflow. Thus, falsely positive results may be obtained during pregnancy if a patient is positioned incorrectly or inadequately relaxed, if the vein is compressed by an extravascular mass, or if venous outflow is impaired by increased central venous pressure. Reduced arterial inflow to the limb due to severe obstructive arterial disease can also lead to reduced outflow, thereby producing a falsely positive result.

The reported sensitivities and specificities for the diagnosis of symptomatic proximal venous thrombosis range from as low as 65% to as high as 95%. [53] [59] [60] [61] [62] [63] The test may not detect large, nonocclusive proximal vein thrombi and fails to detect most thrombi within the calf veins.

In patients with proximal vein thrombosis, the result of impedance plethysmography returns to normal in about 30% of patients by 3 weeks, in 60% of patients at 6 weeks and 3 months, in 80% of patients at 6 months, and in 90% of patients at 1 year. [61] Information on the status of impedance plethysmographic findings is clinically useful if the patient returns with recurrent symptoms. Thus, in patients whose study returned to normal after an episode of venous thrombosis, a positive test result and appropriate clinical symptoms are highly suggestive of recurrent venous thrombosis.

Venous Ultrasonography

This test is performed using a high-resolution real-time scanner equipped with a 5-MHz electronically focused linear array transducer. The common femoral vein and femoral artery are first located in the groin with the patient in a supine position. The superficial femoral vein is then examined along its course. Once this has been done, the popliteal vein is located and examined down to the level of its trifurcation into the peroneal and tibial veins. At each of these locations, the vein being examined is compressed gently but firmly with the transducer probe and the results are observed on the monitor. Hard copies from freeze frame images of both stages

of the procedure are obtained and serve as a permanent record.

Venous US is very accurate for the detection of proximal vein thrombosis in symptomatic patients but relatively insensitive to calf vein thrombosis. If the field of examination is extended to the distal popliteal vein and the proximal deep calf veins, venous US detects about 50% of calf vein thrombi in symptomatic patients. [64] [65] Potential limitations of venous US include inability to visualize the iliac veins and the segment of the superficial femoral vein within the femoral canal. This is not a serious limitation because isolated thrombi within the femoral canal or the iliac vein are rare. [66] Further, the obstruction produced by iliac vein thrombi often limits the compressibility of the common femoral vein segment and hence will be detected by venous US.

Other Techniques

A number of new techniques are being evaluated for the diagnosis of acute and recurrent deep vein thrombosis. One such technique is the D-dimer assay, which uses mono- or polyspecific antibodies against D-dimer to provide quantitative or

CLINICALLY SUSPECTED VENOUS THROMBOSIS

A practical noninvasive approach for the diagnosis of clinically suspected deep vein thrombosis (DVT) using serial venous ultrasonography. [a]

[a] *If noninvasive testing is unavailable, venography should be performed.*

qualitative data on the concentration of D-dimer in whole blood or plasma. D-dimer is a product of fibrin lysis and as such is increased in patients with acute venous thromboembolism. However, the test is nonspecific, because the level of D-dimer is also increased in a variety of acute illness, including malignancy and infections. Therefore, the D-dimer assay is most useful as a tool to rule out suspected deep vein thrombosis. [67] [68]

Other techniques that may prove useful in the diagnosis of acute venous thromboembolism include contrast agentenhanced co-axial tomography (CT), spiral CT, and magnetic resonance angiography. Techniques such as thermography do not have sufficient accuracy to be useful.

Approach to the Diagnosis of Venous Thrombosis

Venous US is the noninvasive method of choice because it is the most sensitive and specific. Although it is relatively insensitive to calf vein thrombosis, this shortcoming can be overcome by repeating the test after 57 days.

A diagnostic algorithm for the noninvasive diagnosis of clinically suspected venous thrombosis is shown in the box. If venous US is not available or does not reveal evidence of thrombosis in a patient with a high pretest likelihood of deep vein thrombosis, the diagnosis should be confirmed with ascending venography. Alternatively, in patients with a moderate pretest likelihood of thrombosis who have a negative initial US study, serial US examination is a safe and effective alternative to venography.

DIAGNOSIS OF PULMONARY EMBOLISM

The clinical diagnosis of PE is as nonspecific as the diagnosis of venous thrombosis. Therefore, objective tests are necessary. However, PE is more difficult to diagnose than venous thrombosis, and the diagnosis is confirmed in less than half of patients with clinically suspected PE. [40] [69]

The chest radiograph is not specific for PE and usually does not show any diagnostic abnormality. However, it is useful to exclude other causes for the presenting symptoms (e.g., pneumothorax) and is essential for interpreting the lung scan findings. Like the chest x-ray, the electrocardiogram (ECG) is frequently normal or shows nonspecific abnormalities. However, in the appropriate clinical setting, ECG evidence of right ventricular strain is strongly suggestive of PE.

Perfusion lung scanning is useful because a normal scan excludes the diagnosis of PE, whereas a large perfusion defect that is not matched on the ventilation scan is highly suggestive of PE. Other lung scan findings, which are seen in about 70% of patients, cannot be used to rule out or rule in PE. It is in these patients that pulmonary angiography or objective tests for venous thrombosis are needed. Tests for venous thrombosis are useful because 70% of PE are associated with venographically detected deep vein thrombosis of the legs.

Clinical Manifestations of Pulmonary Embolism

Most PE are clinically silent. Dyspnea is the most frequently reported symptom. [69] [70] Chest pain is common and is usually pleuritic in nature but may be substernal and compressing. Hemoptysis is a less frequent feature of PE. [40] [69] [70]

The physical signs of PE are nonspecific. Syncope is usually associated with massive PE and is caused by a reduction in cardiac output. This in turn results in hypotension and transient impairment of cerebral blood flow.

Although 70% of patients with PE have venographic evidence of thrombosis at presentation, less than 20% of these patients have leg symptoms. [40] Massive PE causes tachypnea, tachycardia, cyanosis, and hypotension. In these patients, cardiac examination may reveal a right ventricular heave, a loud pulmonary second sound, and a gallop rhythm. Physical examination of the chest may be normal or nonspecific abnormalities may be detected. Patients with pulmonary infarction or atelectasis may have reduced movement of the affected portion of the chest. There may be signs of pulmonary consolidation or atelectasis, a pleural friction rub, crackles, or a pleural effusion, and a low-grade fever may be present.

Differential Diagnosis

The differential diagnosis of shortness of breath includes atelectasis, pneumothorax, pneumonia, acute bronchitis, acute bronchiolitis, acute bronchial obstruction due to mucous plugging or bronchoconstriction, and acute PE. Entities in the differential diagnosis of pleuritic chest pain include pneumonia, viral pleurisy, chest wall pain from trauma or viral infection, pericarditis, and pleural inflammation caused by an immune disorder.

Diagnostic Tests for Pulmonary Embolism

The diagnostic tests for PE include pulmonary angiography and ventilation-perfusion lung scanning. Recently, spiral CT has been introduced for the diagnosis of acute PE. This test, which involves taking high-resolution, high-speed scans of the lung after a bolus injection of contrast agent, is able to demonstrate intraluminal filling defects in the pulmonary vasculature. However, spiral CT has not been compared, in methodologically rigorous studies, to currently available widely used imaging techniques for diagnosing PE. Therefore, its role in the diagnosis of PE is uncertain.

Pulmonary Angiography

This test is the reference standard for establishing the presence or absence of PE. [71] Selective angiography and magnification views improve resolution and reduce the risk of the procedure. [71] When adequately performed, a negative result on pulmonary

angiography excludes the diagnosis of PE. [71] However, unless the tertiary pulmonary arteries are visualized in a patient with a small perfusion defect, the diagnosis of PE cannot be excluded.

Arrhythmias, cardiac perforation, cardiac arrest, and hypersensitivity reactions to contrast medium occur in up to 34% of patients undergoing pulmonary angiography. [72] Patients with a history of allergy to radiopaque dye should not undergo pulmonary angiography.

Lung Scan

The lung scan consists of both a perfusion and a ventilation component. For the perfusion component, particles of isotopically labeled microaggregates of human albumin are injected IV and become trapped in the pulmonary capillary bed. Their distribution reflects lung blood flow and is recorded with an external photoscanner. A normal perfusion scan excludes PE, but an abnormal perfusion scan is nonspecific. [40] [70] [73]

Ventilation lung scanning is performed using either radioactive gases or aerosols that are inhaled and exhaled by the patient while a gamma camera records the distribution of radioactivity within the alveolar gas exchange units. The purpose of ventilation imaging is to improve the specificity of perfusion scanning for the diagnosis of PE. When ventilation scanning was initially introduced, it was assumed that ventilation would be preserved in areas of reduced perfusion caused by PE (so-called ventilation-perfusion mismatch), whereas ventilation would be abnormal when perfusion defects occurred as a consequence of primary abnormalities of ventilation (ventilation-perfusion match). This assumption has proved to be only partially correct. [40] [70] [73]

Approach to the Diagnosis of Pulmonary Embolism

Patients with large perfusion defects (one or more segments or more extensive defects) and a ventilation mismatch have a 90% probability of PE. However, the frequency of PE is not sufficiently low to rule out PE in patients with a large ventilation-perfusion match and in those with small perfusion defects. [40] [70] [73] As a result, patients with these lung scan findings require further investigation with either pulmonary angiography or objective tests for venous thrombosis. Although a positive

result on venography or compression US can be used to make the diagnosis of venous thromboembolism in a patient with an abnormal perfusion scan, a negative result cannot be used to exclude venous thrombosis because the thrombus may have completely embolized to the lungs. [40] [70]

A diagnostic algorithm for the management of clinically suspected PE is shown in the box. After a history and physical examination, ECG, and chest radiography, all patients should undergo ventilation-perfusion lung scanning. A negative perfusion lung scan rules out clinically significant PE, and anticoagulant therapy is withheld. If the perfusion scan demonstrates one or more segmental (or larger) defects and ventilation to these regions is normal, a diagnosis of PE is made. Although a ventilation-perfusion mismatch supports a diagnosis of PE, a

DIAGNOSTIC APPROACH WHEN PULMONARY EMBOLISM SUSPECTED

ventilation-perfusion match does not exclude PE, and further objective testing is required in these patients. Similarly, the diagnosis of PE cannot be excluded in patients with small perfusion defects (one or more subsegmental defects) or those with indeterminate lung scan findings (in which the perfusion defects correspond to abnormalities on the chest radiograph). In these cases, bilateral venography or venous US should be performed. If deep vein thrombosis is documented, anticoagulant therapy can be started, thereby obviating pulmonary angiography. However, if these tests are negative, pulmonary angiography is required in patients in whom the clinical suspicion of PE is high. For those with a lower pretest likelihood of PE, an alternative strategy is to withhold anticoagulants and to perform serial noninvasive tests to detect ongoing venous thrombosis. In patients with a low or low to moderate pretest likelihood of PE, a D-dimer test may prove useful; if the D-dimer assay is negative, further testing could be avoided, whereas if it is positive (increasing the likelihood of acute thrombosis), further testing is likely warranted. [74] [75]

DIAGNOSIS OF RECURRENT VENOUS THROMBOEMBOLISM AND THE POSTPHLEBITIC SYNDROME

The majority of patients with a history of venous thrombosis who develop new-onset leg pain do not have recurrent deep vein thrombosis when investigated with the appropriate diagnostic tests. Some of these patients have the postphlebitic syndrome, while in others the pain is unrelated to venous thrombosis. [76]

Diagnosis of Acute Recurrent Venous Thrombosis

The diagnosis of acute recurrent venous thrombosis is difficult to make because the clinical manifestations of recurrence are nonspecific. In addition, all of the validated diagnostic tests for acute venous thrombosis have limitations in this setting because the venous occlusion produced by the initial episode of venous thrombosis makes it difficult to identify new abnormalities.

Our approach to the diagnosis of clinically suspected recurrent venous thrombosis is to use a combination of impedance plethysmography, compression US, and venography. Once anticoagulants are discontinued, patients undergo serial impedance plethysmography and compression US at 3- to 6-month intervals until the test results normalize. Although the impedance plethysmogram normalizes more frequently than venous US, both tests are useful because they provide results that can be used for comparison should the patient present with recurrent symptoms.

The diagnostic algorithm for patients with suspected recurrent venous thrombosis is shown in the box. Both the impedance plethysmography and compression US are performed. If either test is positive and the previous result was negative, a diagnosis of recurrence is made. Similarly, if venous US shows more extensive thrombosis than that seen on previous examinations, a diagnosis of recurrent disease can also be established. However, if both impedance plethysmography and venous US are positive and the previous tests also were positive, venography is performed. If this study shows a new intraluminal filling defect or evidence of thrombus extension when compared with the previous venogram, a diagnosis of recurrence is made. If no new defect is found, the diagnosis of recurrent thromboembolism is based on clinical features. Finally, if both impedance plethysmography and venous US are negative at presentation, the patient is followed with compression US repeated once over the next week.

Diagnosis of the Postphlebitic Syndrome

The clinical spectrum of the postphlebitic syndrome varies from a course that may mimic acute venous thrombosis to one of persistent leg pain that is worse at the end of the day and is associated

CLINICALLY SUSPECTED RECURRENT VENOUS THROMBOSIS

with dependent edema, stasis pigmentation, and, in its most severe form, skin ulceration. [77] Rarely, patients may complain of venous claudication on walking. [78] When symptoms are acute or subacute in onset, a diagnosis of postphlebitic syndrome should be considered only after recurrent venous thrombosis has been excluded by objective tests. There is no single definitive diagnostic test for the postphlebitic syndrome, but a past history of objectively documented deep vein thrombosis, appropriate clinical findings, and evidence of venous reflux or outflow obstruction on venous US constitute sufficient evidence to make this diagnosis.

Other causes of recurrent leg pain or swelling include recurrent muscle strain, internal derangement of the knee or hip, recurrent cellulitis, extrinsic compression of the vein, lumbosacral disk disease, sciatic pain, and factitious causes of leg pain and swelling. In some patients there is no explanation for the leg pain, and the possibility of thromboneurosis should be considered. These patients may complain of leg pain and tenderness that is disproportionate to the physical findings, or they may present with highly atypical symptoms. Patients with severe thromboneurosis may be incapacitated by the fear of recurrent venous thrombosis or death. Frequently, there is a history of multiple hospital admissions for treatment of recurrent venous thrombosis, and many of these patients are on long-term anticoagulant therapy, and some have had caval interruption procedures. Thromboneurosis may have an iatrogenic component, as the fear of recurrent thrombosis is reinforced each time the attending physician admits the patient to the hospital and orders treatment on the basis of clinical suspicion alone. To prevent this, it is important that a clinical suspicion of acute venous thrombosis (either the first episode or recurrent episodes) is always confirmed by appropriate objective tests. In some patients, the fear of thrombosis is relieved only after suspected recurrent episodes of venous thrombosis have been excluded by appropriate tests on multiple occasions.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

PE is the most common preventable cause of death in hospital.[79] Hospitalized patients can be classified as at low, moderate, or high risk for developing venous thromboembolism (Table 1243).[79] In the absence of prophylaxis, the frequency of postoperative fatal PE ranges from 0.10.8% in patients undergoing elective general surgery to 0.31.7% in patients undergoing elective hip surgery and 47% in patients undergoing emergency hip surgery.[79] Effective prophylaxis is very cost-effective and is available for most high-risk groups.[80]

Prophylaxis is directed toward either suppressing activation of blood coagulation or preventing venous stasis. These objectives can be achieved by using one of the following proven prophylactic approaches: low-dose subcutaneous unfractionated heparin,[79] [81] [82] intermittent pneumatic compression of the legs,[79] [82] IV dextran,[79] oral anticoagulants,[79] [82] [83] adjusted doses of subcutaneous unfractionated heparin,[84] graduated compression stockings,[82] [85] or low molecular weight heparins.[83] [86] Antiplatelet agents such as aspirin are relatively ineffective for preventing venous thromboembolism.[79] [82] [83]

Low-Dose Unfractionated Heparin

Low doses of unfractionated heparin prevent thrombosis by catalyzing the inhibition of thrombin and factor Xa by antithrombin. Unfractionated heparin is given subcutaneously at a dose of 5,000 U 2 hours prior to surgery and is continued postoperatively at a dose of 5,000 U every 12 hours. Low-dose unfractionated heparin prophylaxis does not require laboratory monitoring and is simple and convenient to administer. It is the method of choice for moderate-risk general surgical and medical patients, and it reduces the risk of venous thromboembolism by 5070%.[79] [81] [82] [83] When used in these doses, unfractionated heparin is safe and free of serious bleeding complications, but because of the potential for minor bleeding, it should not be used in patients undergoing cerebral, eye, or spinal surgery. Although low-dose unfractionated heparin is effective in patients undergoing elective hip surgery and reduces the incidence of venous thrombosis by about 40%, it is less effective than warfarin, adjusted-dose unfractionated heparin,[84] and low molecular weight heparin.[83] [86] Low-dose unfractionated heparin has not been shown to be effective in patients with hip fractures or those undergoing major knee surgery.

Intermittent Pneumatic Compression

Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and increases blood fibrinolytic activity.[79] It is the method of choice for preventing venous thrombosis in patients undergoing neurosurgery,[85] is effective in patients undergoing major knee surgery,[87] and is as effective as low-dose unfractionated heparin in patients undergoing abdominal surgery.[82] Intermittent pneumatic leg compression is virtually free of clinically important side effects and is particularly useful in patients who have a high risk of bleeding.

Graduated Compression Stockings

Graduated compression stockings also reduce venous stasis in the legs and are effective for preventing postoperative venous thrombosis in general surgical patients[82] and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs.[85] In surgical patients, the combination of graduated compression stockings and low-dose unfractionated heparin is significantly more effective than low-dose unfractionated heparin alone.[88] [89] However, graduated compression stockings alone are inadequate prophylaxis in patients undergoing

TABLE 124-3 -- Risk Categories for Venous Thromboembolism

Risk Category	Risk of Venous Thromboembolism (%)		
	Calf Vein Thrombosis	Proximal Vein Thrombosis	Fetal Pulmonary Embolism
High Risk			
1. General surgery in patients >40 years with recent history of DVT or PE	4080	1020	15
2. Extensive pelvic or abdominal surgery for malignant disease			
3. Major orthopedic surgery on lower limbs			
Moderate Risk[a]			
1. General surgery in patients >40 years lasting 30 minutes or more	1040	210	0.10.7
2. Immobilization with major medical illness, including stroke, cardiac disease, chronic respiratory disease, bowel disease, and malignancy			

[a]Risk is increased by advancing age, malignancy, prolonged immobility, varicose veins, and cardiac failure.

surgery associated with a very high risk of thromboembolism.[90] Graduated compression stockings are inexpensive and should be considered in all high-risk surgical patients, even if other forms of prophylaxis are used.

Oral Anticoagulants

When administered in doses that prolong the prothrombin time to an International Normalized Ratio (INR) of 2.0, oral anticoagulants effectively prevent postoperative venous thromboembolism in patients in all risk categories.[79] [83] Oral anticoagulants can be given preoperatively, at the time of operation, or in the early postoperative period. When started at the time of surgery or in the early postoperative period, the anticoagulant effect is not achieved until the third or fourth postoperative day. Nevertheless, when used in this fashion, oral anticoagulants are effective in very high-risk patient groups, including patients with hip fractures.[91] However, prophylaxis with oral anticoagulants is relatively inconvenient because careful laboratory monitoring is necessary.

Dextran

Dextran 40 is usually given IV at a daily dose of 500 ml over 46 hours. Treatment is started at the time of surgery and continued for 25 days postoperatively. [79] [83] Although dextran is an effective form of prophylaxis, it is inconvenient, can cause fluid overload in patients with cardiovascular impairment, and increases the risk of postoperative bleeding. In addition, dextran is less effective than warfarin [92] and low molecular weight heparin. [93] Given these limitations, dextran is rarely used for prophylaxis.

Adjusted-Dose Subcutaneous Unfractionated Heparin

In this regimen, unfractionated heparin is given subcutaneously at a dose of 3,500 U three times daily starting 2 days before surgery. The unfractionated heparin dose is then adjusted to maintain the activated partial thromboplastin time (aPTT) at the upper limit of the normal range. Leyvarz and associates [84] and Green and associates [94] have reported that adjusted-dose unfractionated heparin regimens are more effective than fixed low-dose unfractionated heparin in patients undergoing elective hip surgery and in those with spinal cord injury. When the unfractionated heparin dose was adjusted to prolong the postoperative aPTT into the upper normal range, there was no increase in bleeding. [84] However, an unfractionated heparin dose that prolonged the aPTT to 1.5 times normal did cause excessive bleeding. [94]

Low Molecular Weight Heparins

Low molecular weight heparin is an effective and safe form of prophylaxis in the following high-risk groups [86] : patients undergoing elective hip surgery, [86] those with hip fractures, patients undergoing major general surgery or major knee surgery, those with spinal injury, and those who have sustained a stroke. Low molecular weight heparin is more effective than standard low-dose unfractionated heparin in general surgical patients, [86] patients undergoing elective hip surgery, [86] and patients with stroke [86] or spinal injury. [86] In addition, low molecular weight heparin has also been shown to be more effective than warfarin in patients undergoing hip or major knee surgery, [86] better than adjusted-dose unfractionated heparin in preventing proximal vein thrombosis after elective hip surgery, [86] and superior to dextran or aspirin after hip surgery. [86]

Choice of Prophylaxis in Different Patient Groups

The recommended prophylactic approaches for patients in the various risk categories are summarized in Table 124-4 .

TABLE 124-4 -- Recommended Prophylactic Approaches for the Alternative Risk Categories and Different Surgical Groups

Risk Category	Recommended Approaches[a]
Moderate Risk	
General surgery or major medical illness	Low-dose heparin or intermittent compression
Neurosurgery or genitourinary surgery	Intermittent compression
High Risk[a]	
Elective hip surgery or very high-risk general surgery	Low molecular weight heparin or oral anticoagulants
Fractured hip or major knee surgery	Low molecular weight heparin or oral anticoagulants

[a] In high-risk patients.

General Surgical and Medical Patients

Early ambulation should be encouraged, and graduated compression stockings should be considered for all patients. Moderate-risk patients should be given prophylaxis with low-dose unfractionated heparin. If anticoagulants are contraindicated because of an unusually high risk of bleeding, intermittent pneumatic compression should be used. Patients at very high risk, for example, those with recent venous thrombosis, should receive low molecular weight heparin, oral anticoagulants, or adjusted-dose unfractionated heparin.

Hip Surgery

Low molecular weight heparin, oral anticoagulants, or adjusted-dose unfractionated heparin is effective. In direct comparisons, fixed-dose low molecular weight heparin was more effective than warfarin in preventing thrombosis and was better than adjusted-dose unfractionated heparin in preventing proximal vein thrombosis.

Major Knee Surgery

Although intermittent pneumatic compression is effective in preventing venous thrombosis after major knee surgery, low molecular weight heparin is more convenient and is the treatment of choice.

Genitourinary Surgery, Neurosurgery, Ocular Surgery

Intermittent pneumatic compression, with or without the use of static graduated compression stockings, is effective and does not increase the risk of bleeding.

Stroke and Spinal Injury

Low molecular weight heparin is more effective than low-dose standard unfractionated heparin in these patient groups and is the prophylactic method of choice.

TREATMENT OF VENOUS THROMBOEMBOLISM

The objectives of treating patients with venous thromboembolism are to prevent death from PE, to reduce morbidity from the acute event, to minimize postphlebitic symptoms, and to prevent thromboembolic pulmonary hypertension. All of these goals can be achieved with adequate anticoagulant therapy.

Preventing Death Due to Pulmonary Embolism

Anticoagulants are effective in reducing mortality from PE. [95] Vena caval interruption, usually with an inferior vena caval filter,

---

should be considered when anticoagulant therapy is contraindicated because of the risk of previous or life-threatening hemorrhage. [95] Far less commonly, caval interruption is used when anticoagulant therapy has failed.

Thrombolytic therapy with streptokinase, urokinase, or t-PA is more effective than unfractionated heparin alone in improving the angiographic defects produced by PE,[95] and may be better than unfractionated heparin in preventing death in patients with massive PE associated with shock. [96] [97] Based on these findings, thrombolytic therapy is the treatment of choice for patients with massive PE, or in those with underlying cardiac or pulmonary disease, in whom even a small or moderate embolus may be life-threatening.

Thromboendarterectomy is effective in selected cases of chronic thromboembolic pulmonary hypertension with proximal pulmonary arterial obstruction. [98] Urgent pulmonary embolectomy is usually reserved for patients with a saddle embolism lodged in the main pulmonary artery or for those with massive embolism whose blood pressure cannot be maintained despite thrombolytic therapy and vasopressor agents. [95]

Anticoagulant Therapy to Reduce Morbidity from the Acute Event

Anticoagulants are the mainstay of treatment for most patients with venous thromboembolism. A recent study in patients with proximal vein thrombosis highlights the importance of early unfractionated heparin therapy. [99]

Three large clinical trials have recently been published that demonstrate the effectiveness and safety of outpatient treatment of acute deep vein thrombosis in otherwise well patients.[100] [101] [102] In each of these studies, fixed-dose, weight-adjusted, low molecular weight heparin was compared with adjusted-dose, inpatient treatment with IV unfractionated heparin. When the results of these three studies are combined, outpatient treatment was not associated with either an increase in the risk of recurrent thromboembolism or an increased rate of significant hemorrhage. Based on these findings, outpatient treatment of acute deep vein thrombosis should be considered in all patients who present with acute venous thromboembolism but are otherwise well.

Treatment should consist of weight-adjusted once or twice daily subcutaneous low molecular weight heparin. Monitoring of the anticoagulant effect of the low molecular weight heparin is not required. If anticoagulant-related complications develop, if the patient is very large (>100 kg) or very small (<40 kg), or if the patient has renal insufficiency, then the anticoagulant effect of the low molecular weight heparin can be assessed using anti-factor Xa heparin levels. The target anti-factor Xa heparin level is 0.51.5 U/ml. Low molecular weight heparin does not have a predictable effect on the aPTT; thus this test cannot be used for monitoring low molecular weight heparin. Warfarin should be initiated on the same day as the unfractionated heparin. The low molecular weight heparin should be continued for at least 4 days and until the INR has been between 2.0 and 3.0 on 2 consecutive days.

Patients with co-morbid conditions that preclude outpatient treatment, with symptomatic PE, or who develop thromboembolism during hospitalization should be treated with either unfractionated heparin or low molecular weight heparin in the hospital. [103] Prospective randomized trials have compared the safety and effectiveness of unfractionated heparin given by either continuous IV infusion, intermittent IV injection, or subcutaneous injection. Although continuous IV unfractionated heparin infusion[95] produces less bleeding than intermittent IV injections, unfractionated heparin delivery by intermittent subcutaneous injections appears to be as safe and efficacious as continuous IV unfractionated heparin infusion in the treatment of venous thrombosis. [95] [104] Regardless of whether unfractionated heparin is given by continuous IV infusion or by subcutaneous injection, it is important to give doses sufficient to produce an adequate antithrombotic effect (see section on Practical Recommendations).

Unfractionated heparin has a half-life that varies considerably among individuals. [105] After a single IV injection, there is an initial rapid disappearance owing to a saturable clearance mechanism, followed by a more gradual linear clearance, [106] with a mean heparin half-life of approximately 60 minutes. Whereas IV unfractionated heparin produces an immediate anticoagulant effect, peak heparin levels are not achieved until 3 hours after subcutaneous injection, but the levels will remain therapeutic for up to 12 (or more) hours, depending on the dose.

Unfractionated heparin therapy can be monitored using the activated clotting time and the aPTT, or by heparin assays that measure the ability of heparin to accelerate the inactivation of factor Xa or thrombin. It is important to give adequate initial unfractionated heparin doses, as the risk of recurrent venous thromboembolism is likely increased if insufficient unfractionated heparin is given. Accordingly, the aPTT should be maintained above a level equivalent to a heparin level of 0.3 U/ml as determined by measuring the anti-factor Xa activity. For most currently used aPTT reagents, this is equivalent to an aPTT ratio of 1.8 times the control value. Thus, the recommended therapeutic range is an aPTT ratio of 1.82.5. [107] Higher unfractionated heparin doses may be associated with an increase in the risk of bleeding.[106]

In the past, heparin was administered for a period of 710 days, and oral anticoagulants were started after 35 days and overlapped with heparin for 45 days. The period of overlap is necessary because the antithrombotic effects of oral anticoagulants are delayed. [109] [110] Two studies have demonstrated that 910 days of unfractionated heparin therapy is no better than a 4- to 5-day course of unfractionated heparin with overlapping warfarin. [108] Since neither study included many patients with major PE or extensive iliofemoral vein thrombosis, it would be prudent to use heparin for at least 7 days in these individuals.

After an initial course of heparin therapy, patients with venous thromboembolism require continuing anticoagulant therapy for weeks or months to prevent recurrence.[43] [44] Both therapeutic doses of subcutaneous heparin and oral anticoagulants are effective for this indication. Although adjusted-dose unfractionated heparin produces less bleeding than high-intensity warfarin (target INR of 3.55.0) in this setting, [45] less intense warfarin therapy (target INR of 2.03.0) is just as effective as the higher-intensity regimen but produces significantly less bleeding.

Preventing Morbidity from the Postphlebitic Syndrome

The postphlebitic syndrome is a major cause of morbidity. The risk of postphlebitic syndrome in patients with symptomatic deep vein thrombosis is 22.8% after 2 years, 28.0% after 5 years, and 29.1% after 8 years.[50] Surgical thrombectomy does not prevent the disorder because most thrombi recur after surgical removal.[95] [111] The ability of thrombolytic therapy to prevent the postphlebitic syndrome has been evaluated to a limited extent. Streptokinase treatment produces complete lysis of acute venous thrombi in 3040% of cases and causes partial lysis in an additional 30%.[95] In contrast, complete lysis of venous thrombi occurs in less than 10% of patients treated with unfractionated heparin.[95] It is estimated that thrombolysis occurs 3.7 times more often in patients treated with streptokinase than in those given unfractionated heparin, but major bleeding occurs 2.9 times more frequently with streptokinase.[95] Although five randomized studies have reported that the frequency of the postphlebitic syndrome is significantly higher in patients treated with unfractionated heparin than in those given streptokinase, [95]

---

one trial[112] reported that patients treated with streptokinase and those treated with unfractionated heparin had similar manifestations of the postphlebitic state after 5 years of follow-up. Two recent studies reported that the incidence of the postphlebitic syndrome was reduced by the early use of graduated compression stockings.[95] Accordingly, patients with proximal vein thrombosis should be encouraged to wear these stockings at the first sign of leg swelling.

Prevention of Late Effects of Pulmonary Embolism

Clinically significant pulmonary hypertension is an uncommon complication of PE. In randomized trials comparing unfractionated heparin with either streptokinase or urokinase for the treatment of patients with acute PE, thrombolytic therapy produced greater improvement in lung scandetected perfusion defects than unfractionated heparin during the first week. However, there were no apparent differences in the lung scan findings at 2 weeks, 3 months, and 1 year.[113] Subsequent long-term follow-up in small subgroups of these patients indicated that pulmonary capillary blood volume and both pulmonary vascular resistance and functional status were significantly better in patients treated with fibrinolytic therapy than in those given unfractionated heparin.[95]

Moser and colleagues[98] have reported their experience with surgical pulmonary endarterectomy in carefully selected patients with chronic thromboembolic pulmonary hypertension. Most patients with obstruction of the proximal pulmonary arteries show impressive improvement after endarterectomy. The authors stress the importance of careful patient selection and expert perioperative management.

Side Effects, Cost, and Clinical Utility of Thrombolytic Therapy

Bleeding occurs more frequently with thrombolytic therapy than with unfractionated heparin.[95] [114] The risk of hemorrhage increases with the duration of thrombolytic infusion and usually occurs at a site of previous surgery or trauma. Intracranial hemorrhage occurs in about 1% of patients at risk, about twice as frequently as with unfractionated heparin treatment.

Practical Recommendations

The majority of patients with proximal vein thrombosis or calf vein thrombosis should be treated with outpatient low molecular weight heparin, while those with symptomatic PE should be treated in the hospital with low molecular weight heparin or with high-dose IV unfractionated heparin. High-dose unfractionated heparin can be given either by continuous IV infusion or by twice daily subcutaneous injection. For IV unfractionated heparin therapy, a bolus of 5,000 U should be followed by a continuous IV infusion at a dose of 1,300 U/hour. The initial dose of subcutaneous unfractionated heparin should be 35,000 U/day given in two divided doses. Because of its delayed onset of action after subcutaneous injection, a 5,000 U IV bolus of unfractionated heparin should be given together with the first subcutaneous injection in high-risk patients. Low molecular weight heparin should be weight adjusted and administered once or twice daily, depending on the manufacturers recommendations. Heparin should be administered for a total of 47 days. Warfarin should be started at the same time as the heparin, using an initial dose of 5 mg if the patient weighs less than 80 kg and 7.5 mg if the patient weighs more than 80 kg. The duration of warfarin therapy is variable. Patients with a persistent, major risk factor for recurrence, such as malignancy, should receive warfarin for as long as the risk factor persists. Those with a secondary thrombosis (such as after orthopedic surgery) who have returned to normal mobility may need warfarin for as little as 6 weeks. Patients with idiopathic deep vein thrombosis (i.e., those without a clear precipitant) and patients with a known hereditary predisposition to thrombosis should receive warfarin for an indefinite period of time. Based on currently available literature, this period should be in excess of 1 year, although the optimal duration of warfarin therapy is unknown.

The dose of unfractionated heparin should be adjusted to maintain the aPTT at 1.82.5 times control. To monitor unfractionated heparin given by continuous IV infusion, the aPTT should be measured 6 hours after the bolus dose so that it reflects the anticoagulant effects of the infusion. If twice daily subcutaneous unfractionated heparin is given, a midinterval aPTT should be measured (i.e., 6 hours after the injection).

The INR is used to monitor oral anticoagulant therapy, and the dose of warfarin should be adjusted to achieve an INR of 2.03.0. Heparin can be discontinued when the INR has been therapeutic for 2 successive days.

Thrombolytic therapy is only indicated in patients with major PE (i.e., those with hemodynamic compromise) and in young patients with very extensive proximal vein thrombosis and no contraindications to thrombolytic therapy.

VENOUS THROMBOSIS IN UNUSUAL SITES

Subclavian or Axillary Vein Thrombosis

Although thrombosis of the subclavian or axillary veins most frequently occurs as a complication of a chronic indwelling catheter, it may also occur as a consequence of local malignancy, and is a well-documented complication of mastectomy and radiationtherapy. [115] Subclavian vein thrombosis is particularly common in children with indwelling central venous catheters; this complication develops in up to 20% of children who have catheters placed for cancer chemotherapy or parenteral nutrition. In adults, the cause of subclavian or axillary vein thrombosis is uncertain, and idiopathic subclavian or axillary vein thrombosis often occurs in young patients and may be preceded by repetitive, strenuous activity that involves the affected arm. Occasionally, subclavian or axillary vein thrombosis can occur in patients with activated protein C resistance or congenital deficiency of antithrombin, protein C, or protein S, or in patients with antiphospholipid antibodies. Finally, thrombosis of the axillary or subclavian vein or the superior vena cava is a rare complication of perivenous endocardial pacing using an implantable system. [116] [117] Upper extremity deep vein thrombosis is associated with PE, a complication seen frequently in children with catheter-related thrombosis.

Patients with subclavian or axillary thrombosis experience pain in the axilla and edema and cyanosis of the arm. If thrombosis extends into the superior vena cava, patients can develop edema and cyanosis of the face, neck, and upper extremities. Dilated superficial veins on the chest and arms appear after a number of days. Occasionally, asymptomatic thrombosis of the internal jugular vein accompanies subclavian vein thrombosis. The definitive diagnosis is made with venography, although venous US may also be useful.

Subclavian or axillary vein thrombosis is usually treated with anticoagulants. Thrombolytic therapy also is effective and should be considered because it is estimated that over two-thirds of the patients with subclavian vein thrombosis will have persistent symptoms in the affected arm. However, subclavian vein stenosis that persists after thrombolytic therapy may predispose to recurrence, thereby limiting the benefits of this treatment modality. [118]

Mesenteric Vein Thrombosis

Mesenteric vein thrombosis is uncommon. In an extensive literature review, [119] only 367 patients with mesenteric vein thrombosis

were identified. The disorder occurs most commonly in the sixth and seventh decades of life and affects segments of the small bowel (rarely the colon), leading to hemorrhagic infarction rather than gangrene. Bowel infarction often produces bloody ascites, and adhesions frequently develop between the involved bowel and the omentum.

Many of the affected patients have associated disorders, such as thrombosis at other sites, inflammatory bowel disease, recent abdominal surgery, malignant disease, and portal hypertension. Mesenteric vein thrombosis may also complicate hypercoagulable states (such as antithrombin, protein C, or protein S deficiency), polycythemia vera, or the use of oral conceptives, [120] and it has also been reported in late pregnancy. In about 20% of cases no underlying cause is found.

The clinical manifestations of mesenteric vein thrombosis include intermittent abdominal pain, abdominal distention in the later stages of the disorder, vomiting, diarrhea, and melena. Although the diagnosis is often difficult to make, blood-stained ascites fluid on abdominal paracentesis and hemorrhagic bowel infarcts at peritoneoscopy are characteristic findings.

Management includes supportive care and surgical resection followed by anticoagulant therapy. The mortality is about 20%, and recurrence occurs in up to 20% of cases.

Renal Vein Thrombosis

Renal vein thrombosis can occur as a complication of the nephrotic syndrome, possibly because antithrombin is lost in the urine, and is commonly seen in association with membranous glomerulonephritis. [121] Patients may be asymptomatic, may present with mild symptoms of abdominal or back pain, or may have severe flank pain and tenderness. PE has been described as a relatively common complication of renal vein thrombosis. With anticoagulant therapy there is a gradual improvement in renal function tests, although patients may suffer from long-standing proteinuria. Thrombolytic therapy has been used successfully in a small number of patients with renal vein thrombosis. [122]

Chapter 125 - Arterial Thromboembolism

Jack Hirsh
Mark A. Crowther

INTRODUCTION

Arterial thrombosis usually occurs as a complication of atherosclerosis. Atherosclerosis is the most common underlying cause of coronary heart disease, cerebrovascular disease, and peripheral arterial disease and as such is the single most common cause of mortality and morbidity in the Western population. Arterial narrowing due to atherosclerosis limits blood flow and causes ischemic symptoms when the oxygen requirements are increased by exercise. For example, angina pectoris occurs when the coronary arteries cannot supply sufficient blood flow to meet the demands of the myocardium. Similarly, intermittent claudication reflects ischemia of the leg muscles as a result of an imbalance between arterial blood supply and the demands of the exercising muscles, whereas intestinal angina occurs after a large meal when the blood supply to the gut is insufficient to meet the requirements.

Tissue infarction occurs when the arterial supply is completely occluded for a critical period of time. Arterial occlusion usually is the result of the rupture or fissuring of an atherosclerotic plaque, which exposes thrombogenic material and triggers the formation of a platelet-fibrin thrombus.

PATHOGENESIS OF ATHEROSCLEROSIS

The term atherosclerosis was introduced by Marchand, who recognized the association of fatty degeneration and vessel stiffening. [1] Atherosclerosis affects medium and large-sized arteries and is characterized by patchy intramural thickening of the subintima that encroaches on the arterial lumen and eventually leads to vascular obstruction. The earliest lesion of atherosclerosis is the fatty streak, which is due to an accumulation of lipid-laden foam cells in the intimal layer of the artery. With time, the fatty streak evolves into the fibrous plaque, the hallmark of established atherosclerosis.

Atherosclerotic lesions are composed of three major components. The first is a cellular component with increased numbers of intimal smooth muscle cells and an accumulation of macrophages. The second component is the connective tissue matrix, large amounts of which are produced by the proliferating smooth muscle cells, and extracellular lipid. The third component is lipid that accumulates within the smooth muscle cells and the macrophages, thereby converting them into foam cells. Thus, the development of atherosclerotic lesions involves proliferation of smooth muscle cells, synthesis of connective tissue matrix, and accumulation of macrophages and lipid.

Over the years, two main hypotheses have been proposed to explain the pathogenesis of the atherosclerotic process, the lipid hypothesis [2] [3] and the chronic endothelial injury hypothesis. [4] Experimentally, atherosclerosis can be produced by cholesterol feeding [2] or by chronic endothelial injury. [4]

The Lipid Hypothesis

The lipid hypothesis postulates that with increased levels of low-density lipoproteins (LDL), lipid accumulates in smooth muscle cells and macrophages as the LDL penetrates the arterial wall. LDL is oxidized in the presence of endothelial cells, and in its oxidized form becomes more atherogenic. Thus, oxidized LDL causes endothelial damage[5] and is chemotactic for monocyte-macrophages. The monocytes first adhere to the altered endothelium by interacting with surface adhesion molecules, and then migrate through the endothelium and basement membrane by elaborating hydrolases that degrade connective tissue matrix. As these cells accumulate, they take up lipid and are converted to foam cells. Macrophages bind intra-intimal LDL via a family of novel receptors known as scavenger receptors, which recognize LDL only after it has been oxidized. Oxidation affects both lipid and apoprotein moieties of the LDL molecule; the lecithin component of LDL phospholipid undergoes

conversion to lysolecithin, which is chemotactic for monocytes. [5] In addition, uptake of oxidized LDL renders the macrophages less mobile, thereby promoting the accumulation of these lipid-laden cells in the intima.

An experimental model of atherosclerosis has been carefully studied in monkeys fed a diet rich in cholesterol. [2] Within 2 weeks of induction of hypercholesterolemia, monocytes become attached to the surface of the arterial endothelium, migrate into the subendothelium, and accumulate lipid, which gives them the appearance of foam cells. Proliferating smooth muscle cells then emerge, and they also accumulate lipid. As the fibrous plaque enlarges, the endothelial cells retract, exposing the subendothelium to the blood and triggering the formation of platelet-fibrin thrombi. The release of platelet-derived growth factor leads to further smooth muscle proliferation, as described in the response-to-injury hypothesis. Support for the important role of oxidized LDL in atherogenesis comes from several sources. Thus, administration of antioxidants to hyperlipidemic rabbits inhibits the formation of fatty streaks. Oxidized LDL can be extracted from human lesions, and many humans have circulating antibodies that are specific for epitopes of oxidized LDL. [6]

The Chronic Endothelial Injury Hypothesis

The response-to-injury hypothesis has been reviewed by Ross. [4] It postulates that endothelial injury results in loss of endothelium, adhesion of platelets to subendothelium, aggregation of platelets, release of platelet-derived growth factors and elaboration of chemotactic factors that attract leukocytes, which in turn release other growth factors. The growth factors induce replication and migration of smooth muscle cells into the intima and result in the formation of a fibrous plaque. The smooth muscle cells synthesize and secrete connective tissue matrix containing collagen, proteoglycans, and elastic fibers, which contributes to the mass of the lesion. Plaque fissure or rupture may trigger the formation of a platelet-fibrin plug, which is then incorporated into the lesion. With repeated injury there is further intimal proliferation and progressive narrowing of the lumen.

The lipid hypothesis and the endothelial injury hypothesis are closely linked. Oxidized LDL is cytotoxic to cultured endothelial cells and may cause endothelial injury, attract monocytes, and stimulate smooth muscle growth. Modified LDL is also a potent inhibitor of macrophage mobility. Stimulated macrophages release growth factors that promote the proliferation and migration of smooth muscle cells. The smooth muscle cells in turn elaborate a monocyte chemotactic factor and synthesize connective tissue matrix.

With the development of atherosclerosis, there is impaired regulation of vascular tone. This is due in part to decreased production of endothelial-derived nitric oxide. The impaired release of nitric oxide is associated with increased vascular tone, and may be associated with increased platelet activation and intimal proliferation. [7]

Atherosclerotic lesions can develop in the absence of endothelial denudation and without the involvement of platelet-derived growth factors. [2] Thus, smooth muscle hyperplasia occurs in hypertension without associated endothelial cell loss [8] [9] [10] [11] and persists long after platelet interaction with the vessel wall has ceased. [12] [13] [14] Cells other than platelets produce growth factors, [15] including macrophages, [16] endothelial cells, [17] and arterial smooth muscle cells, [18] and these may contribute to the growth of the atherosclerotic plaque. [4] In this context, local synthesis of platelet-derived growth factor has been demonstrated in human atherosclerotic plaques removed at surgery. [19]

Growth of the Atherosclerotic Plaque

The atherosclerotic plaque grows slowly over a period of years and can produce severe stenosis or even total vascular occlusion. The mature plaque consists of a fibrous cap composed of collagen, a lipid core containing intracellular and extracellular lipid, and areas of calcification. Lipid-rich plaques are prone to spontaneous fissuring or rupture when exposed to high shear stress at sites of stenosis and arterial branching. Two forms of plaque injury are recognized, superficial and deep. Superficial injury produces areas of focal endothelial denudation that can enlarge and lead to the formation of mural or even occlusive thrombi. Plaques that are capped with superficial collagen fibers separated by large number of lipid-filled macrophages tend to predispose to superficial injury. [20] [21]

Deep intimal injury is characterized by a split or tear that extends from the luminal surface of a plaque deep down into the plaque substance. This type of injury, which

tends to occur in plaques that contain a large lipid-rich pool, exposes blood to the highly thrombogenic contents of the plaque and leads to intraluminal and extraluminal thrombosis. Intraluminal thrombi become incorporated into, and increase the size of, the atherosclerotic plaque, while extraluminal thrombi can be partly or completely occlusive.[22]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PATHOGENESIS OF ARTERIAL THROMBOSIS

Arterial thrombi form under conditions of high flow and are composed mainly of platelet aggregates held together by fibrin strands. Thrombosis is initiated by rupture of the atherosclerotic plaque, which exposes thrombogenic material in the subendothelium to the blood. [22] [23] If the thrombus is nonocclusive and blood flow remains rapid, the thrombi may organize and become incorporated into the atherosclerotic plaque. [23] With more marked arterial narrowing, shear rates increase and promote more extensive platelet and fibrin deposition, which can result in the formation of an occlusive thrombosis.

Thrombogenic Factors

Thrombosis occurs when the balance between thrombogenic factors and protective mechanisms is perturbed. The protective mechanisms include the nonthrombogenic properties of intact endothelial cells, fluid-phase antiproteases, and the dissolution of fibrin by the fibrinolytic system. Thrombogenic stimuli include perturbation or loss of endothelial cells and activation of platelets and coagulation.

Nonthrombogenic Properties of Endothelial Cells

The fluidity of blood in vivo is enhanced by the thromboresistant properties of intact vascular endothelium and is threatened by damage to the vessel wall. [24] Endothelial cell-surface glycosaminoglycans and thrombomodulin are potent inhibitors of coagulation, while vessel wall generation of prostacyclin and nitric oxide, and plasminogen activators limit platelet aggregation and fibrin deposition, respectively. [25]

Damage to the Vessel Wall

Thrombogenesis is promoted by loss of endothelium, which may be caused by direct physical damage such as occurs with angioplasty, hemodynamic stress, use of tobacco products, high blood cholesterol levels, or enzymes released from platelets and leukocytes. [15] The shedding of endothelial cells exposes the subendothelium to platelets and blood coagulation factors. Platelets that adhere to the subendothelium undergo a shape change, aggregate, and secrete their granular contents, thereby recruiting more platelets. At physiologic shear rates, platelet adhesion to subendothelial collagen is mediated by von Willebrand factor and possibly other adhesive proteins, which bind to a glycoprotein receptor (GPIb) on the platelet surface [26] as well as to subendothelial components.

Although endothelial cell loss represents the most severe form of vascular damage, more subtle injury may also promote thrombogenesis. Thus, endothelial cells exposed to endotoxin, cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), thrombin, hypoxia, or increased shear stress synthesize tissue factor and internalize thrombomodulin, thereby promoting coagulation. In addition, these perturbed cells also produce PAI-1, which impairs fibrinolysis, and acquire receptors to which leukocytes and platelets adhere. [25] Finally, the altered endothelial cells synthesize factors that regulate local blood flow. These include vasoconstrictors known as endothelins, as well as vasodilators such as prostacyclin and nitric oxide. [7] [25]

Platelet Activation

Platelets adhering to collagen undergo a shape change, secrete their granular contents, and aggregate. In addition to collagen, a variety of other agonists, including thrombin, epinephrine, and thromboxane A_2 (TXA_2), also promote platelet aggregation. [27] Whereas all of these agents stimulate the synthesis of TXA_2, collagen, thrombin, and TXA_2 also induce the release of adenosine diphosphate (ADP) from platelet granules, which amplifies the aggregation process. In addition to these pathways, thrombin-induced platelet aggregation occurs through a third mechanism that may involve the activation of platelet calpain. [28]

Virtually all agonists that induce platelet aggregation act through a common pathway that involves the accumulation of ionized calcium within the platelet cytoplasm either by mobilization of calcium from the dense tubular system [28] or by increased transport across the membrane. This in turn results in the functional expression of the platelet glycoprotein GPIIb/IIIa, which serves as a receptor for fibrinogen and other Arg-Gly-Asp-containing adhesive proteins such as fibronectin, von Willebrand factor, and thrombospondin. [28] Binding of fibrinogen to GPIIb/IIIa is essential for platelet aggregation because the dimeric fibrinogen bridges the platelets together.

An increase in platelet cyclic adenosine monophosphate (AMP) levels reduces the calcium-mobilizing effect of all agonists. Prostacyclin produced by endothelial cells inhibits platelet aggregation by activating platelet adenylate cyclase, thereby elevating cyclic AMP levels. [29]

Activation of Coagulation

Damage to the vessel wall activates the blood coagulation pathway by exposing blood to tissue factor and by activating platelets. Stimulated platelets promote further activation of coagulation by providing a phospholipid surface on which efficient assembly of coagulation factor complexes can occur. Thrombin formed as a result of these processes then serves to convert fibrinogen to fibrin, which stabilizes the platelet aggregates.

EPIDEMIOLOGY AND PREVENTION OF ATHEROSCLEROSIS

The most effective means of preventing arterial thrombosis is to prevent atherosclerosis. The proven risk factors for atherosclerosis are hypercholesterolemia, hypertension, cigarette smoking, obesity, physical inactivity, age, family history, diabetes and male sex. The first five of these risk factors are potentially reversible, and there is evidence that their reversal reduces the complications of atherosclerosis.

Cholesterol and Lipids

The plasma level of cholesterol is determined by genetic factors, by the type and amount of fat in the diet, and by other factors such as obesity, physical activity, and disease states. Based on the results of animal studies, epidemiologic data, and interventional studies, there is good evidence for an association between hypercholesterolemia and atherosclerosis.

Of the three major classes of lipoproteins, very-low-density lipoproteins (VLDL), LDL, and high-density lipoproteins (HDL), LDL contain 6070% of the total serum cholesterol and are the most atherogenic. In contrast, the levels of HDL are inversely correlated with the risk of coronary heart disease.

The association between serum cholesterol levels and the risk of coronary heart disease is continuous. [30] [31] Familial hypercholesterolemia, a disorder caused by an absent or defective LDL receptor, causes premature coronary heart disease. [32] [33] In the heterozygous form of this disorder, which occurs in 1 in 500 people, the total cholesterol concentration is usually in excess of 300 mg/dl. Approximately 5% of all patients who present with acute myocardial infarction (MI) before the age of 60 have heterozygous familial hypercholesterolemia. The homozygous form of familial hypercholesterolemia occurs in 1 in 10^{6} subjects. These individuals have cholesterol levels ranging from 6001,000 mg/dl and usually develop severe coronary heart disease before the age of 20.

Reduced levels of HDL cholesterol are associated with an increased risk of coronary heart disease. The main causes of reduced HDL cholesterol include cigarette smoking, obesity, physical inactivity, androgenic and related steroids (including anabolic steroids), -blocking agents, hypertriglyceridemia, and genetic factors. In contrast, weight reduction and exercise elevate HDL cholesterol levels.

Both the cholesterol level and the prevalence of coronary heart disease are influenced by environmental factors, including diet. Thus, individuals who immigrate from countries where the prevalence of coronary heart disease and the serum cholesterol levels are low to a country with a high prevalence of coronary heart disease will often sustain increases in both serum cholesterol levels and rates of coronary heart disease.

The evidence that decreasing serum cholesterol levels with cholesterol-lowering drugs or dietary modification slows or reverses the progression of coronary atherosclerosis[34] [35] and reduces coronary events[36] comes from over 20 randomized trials that included almost 40,000 subjects. [34] [36] [37] [38] Lowering the serum cholesterol level with diet or drug therapy also slows the progression of angiographically documented coronary atherosclerosis in patients with arterial bypass grafts.[34] Modifying several risk factors, such as by lowering the serum cholesterol level, the blood pressure, and the levels of LDL cholesterol and by cessation of smoking,[36] reduces the risk of ischemic heart disease. [39] [40] Individuals with several risk factors benefit most from these measures. [41]

Aggressive lowering of the serum cholesterol level in patients with recent MI results in a rapid decrease in the risk of subsequent ischemic cardiac complications, the need for surgical revascularization, and death rates. [42] [43] This effect occurs even when the total cholesterol level falls within the upper range of normal (5.55.8 mmol/l, 213310 mg/dl).

Smoking

Cigarette smoking increases the risk of coronary heart disease, peripheral arterial disease, cerebrovascular disease, and graft occlusion after reconstructive arterial surgery. It is particularly hazardous in those with a poor cardiovascular risk profile and in women taking estrogens, and there is a dose relationship between the risk of coronary heart disease and the number of cigarettes smoked daily. [44] Those who stop smoking have only half the risk of those who continue to smoke, regardless of how long they smoked. Smoking cessation also reduces mortality after coronary bypass surgery, reduces morbidity and mortality in patients with peripheral vascular disease, and decreases mortality after MI.

Although the mechanism by which smoking increases the

risk of atherosclerosis is uncertain, there are several possibilities. Cigarette smoking decreases the levels of HDL, increases LDL cholesterol, and, by raising levels of carbon dioxide, leads to hypoxia, thereby perturbing the anticoagulant properties of the endothelium. In addition, smoking increases platelet reactivity and, by elevating the plasma fibrinogen and the hematocrit, also increases blood viscosity.

Hypertension

Hypertension is a risk factor for stroke, MI, and cardiac and renal failure. [45] Treatment of hypertension reduces the incidence of stroke and lowers overall mortality, but there is less convincing evidence that it affects coronary events. [46] Thus, pooled analysis of all studies examining the effects of lowering the blood pressure shows a 10% risk reduction for mortality and a 40% risk reduction for stroke. However, there is only an 8% risk reduction for fatal and nonfatal MI, a difference that is not statistically significant.

Physical Inactivity

Individuals who exercise regularly have a lower incidence of MI and death, [47] but it is uncertain whether the association is causal or whether it merely reflects the fact that healthier individuals are more likely to exercise. In patients who have recovered from an acute MI, [48] exercise produces a 19% reduction in the risk of recurrent infarction or death. Regular exercise may exert these protective effects by increasing the levels of HDL cholesterol and lowering the blood pressure. [49] [50]

Obesity

Although some observational studies[51] have suggested that obesity is an independent risk factor for coronary heart disease, this has not been a universal finding.

Emerging Risk Factors

Evidence is increasing that a variety of additional risk factors for atherosclerotic disease exist. Congenital or acquired hyperhomocysteinemia is associated with an increase in the risk of both arterial and venous thromboembolism. In some cases, homocysteine levels may be reduced with the administration of folic acid or vitamins B_6 or B_{12} . Whether these interventions reduce the risk of atherosclerosis and its complications is unclear.

Impaired fibrinolysis has been linked to atherosclerotic vascular disease in some but not all studies. Antiphospholipid antibodies are clearly associated with premature arterial thromboembolism, and may be associated with accelerated atherosclerosis. Both thoracic radiation therapy and heart transplantation are associated with accelerated atherosclerosis and ischemic cardiac syndromes.

NONSURGICAL TREATMENT OF ARTERIAL THROMBOEMBOLISM

Treatment of atherosclerosis and its thromboembolic complications includes surgical procedures such as endarterectomy, embolectomy, arterial bypass surgery, and angioplasty, as well as medical management. The three forms of medical therapy that are of proven effectiveness in the treatment of arterial thrombosis are antiplatelet drugs, thrombolytic agents, and anticoagulants.

Antiplatelet Agents

Three antiplatelet agents, aspirin, ticlopidine, and clopidogrel, a new thienopyridine derivative similar to ticlopidine, have been shown to be effective in the prevention and treatment of arterial thrombosis.[52] [53] In addition, agents that inhibit the interaction between fibrinogen and its receptors on platelets reduce the risk of acute ischemic cardiac syndromes after coronary angioplasty.

Aspirin

The antithrombotic effects of aspirin reflect its ability to inhibit the synthesis of TXA_2, a potent inducer of platelet aggregation and vasoconstriction, by inactivating platelet cyclooxygenase. Aspirin is rapidly absorbed from the gastrointestinal tract and peak levels are reached 1520 minutes after ingestion. Despite its rapid clearance from the circulation, the inhibitory effects of aspirin persist for the life span of the platelets because the drug irreversibly acetylates cyclooxygenase. To achieve rapid and complete inhibition of TXA_2 production, for example, in a patient with an evolving MI, a 325-mg tablet of non-enteric-coated aspirin should be used. However, lower aspirin doses can be used for maintenance treatment[54] because as little as 80 mg/day is sufficient to maintain the inhibition of TXA_2 synthesis.

Aspirin reduces the incidence of MI and death in the following groups: men and asymptomatic women over the age of 50, and patients with asymptomatic myocardial ischemia, stable angina, unstable angina with or without non-Q-wave infarction, acute MI, or cerebrovascular disease. In addition, aspirin also reduces the risk of stroke in patients with cerebral ischemia and decreases the risk of acute thrombosis after either aortocoronary bypass surgery or coronary angioplasty. Finally, aspirin was shown to lower the incidence of nonfatal MI in healthy U.S. physicians.[52]

The side effects of aspirin are primarily gastrointestinal, and gastrointestinal hemorrhage can occur in some patients. These complications are dose related and are reduced if enteric-coated aspirin is used. Aspirin is contraindicated in patients with active peptic ulcer disease or aspirin-induced asthma, and it should be discontinued if gastrointestinal side effects are severe.

In most randomized studies, patients with a history of active peptic ulcer disease were excluded, and the beneficial effects of aspirin occurred without hemorrhagic complications.[55] However, in the U.S. Physicians Study the use of aspirin was associated with an increased incidence of cerebral hemorrhage, a finding not observed in the thousands of symptomatic patients treated with aspirin to prevent the complications of atherosclerosis.[55] [56] The preoperative use of aspirin in patients undergoing bypass surgery was associated with an increased incidence of operative bleeding, which probably reflects the combined antiplatelet effect of aspirin and the anticoagulant activity of high-dose heparin used during cardiac surgery.[57]

In studies in which aspirin alone was compared with the combination of aspirin and dipyridamole, no additional benefit was observed from the addition of dipyridamole.[55] However, like aspirin, dipyridamole also augments the antithrombotic effect of oral anticoagulants in patients with mechanical prosthetic valves.[58]

Ticlopidine and Clopidogrel

Ticlopidine and clopidogrel are thienopyridine derivatives that inhibit ADP-dependent platelet aggregation. They are metabolized by the liver after consumption, producing active metabolites that inhibit platelet aggregation. Because the production of intermediate active metabolites is required, the inhibitory effects of ticlopidine and clopidogrel on platelet function are delayed for 2448 hours after administration.

Ticlopidine has been shown to be more effective than aspirin in reducing stroke in patients with transient cerebral ischemia or minor stroke. Ticlopidine is also effective in (1) reducing the risk of the combined outcome of stroke, MI, or vascular death in patients with thromboembolic stroke, (2) decreasing vascular death and MI in patients with unstable angina, (3) reducing

TABLE 125-1 -- Thrombotic Disorders for Which Aspirin or Ticlopidine Has Been Shown to Be Effective

Indication	Effective	
	Aspirin (minimum effective dose)	Ticlopidine (250 mg bid)
Asymptomatic males and females >50 years old	Yes (325 mg every 2nd day)	
Silent myocardial infarction	Yes (75 mg)	
Stable angina	Yes (325 mg every 2nd day)	
Unstable angina	Yes (75 mg)	Yes
Acute myocardial infarction	Yes (160 mg)	
Aortocoronary bypass surgery	Yes (100325 mg)	Yes
Acute occlusion following coronary angioplasty	Yes (650 mg)	Yes
Peripheral vascular disease	Yes (325 mg)	Yes
Transient cerebral ischemia and incomplete stroke	Yes (30 mg)	Yes
Complete stroke	No evidence	Yes
Placental insufficiency	Yes (60150 mg)	

Atrial fibrillation	Yes (325 mg)[a]	
Prosthetic heart valves	Yes (100 mg)[b]	

From Hirsh, [88] with permission.

[a]In combination with warfarin.
[b]Not as effective as warfarin.

acute occlusion of coronary bypass grafts, and (4) improving walking distance and decreasing vascular complications in patients with peripheral vascular disease. [52]

The most common side effects of ticlopidine are diarrhea and skin rash; the most serious complication is irreversible neutropenia. Nevertheless, ticlopidine should be considered in place of aspirin in patients who are allergic to or intolerant of aspirin, or who have had a vascular event despite the use of aspirin.

Clopidogrel and ticlopidine are more effective than aspirin for the prevention of ischemic stroke, MI, or vascular death in patients at high risk of these complications. [53] Clopidogrel, unlike ticlopidine, is not associated with the development of neutropenia.

The thromboembolic disorders for which aspirin or ticlopidine are effective are listed in Table 125-1 . Ticlopidine is more effective than aspirin in patients with transient cerebral ischemia and incomplete stroke, but aspirin is safer and less expensive. The role of clopidogrel is not yet clear: although it is safer than ticlopidine and more effective than aspirin, cost constraints are likely to limit its initial use to patients who have arterial thromboembolism while receiving aspirin.

Platelet Glycoprotein IIb/IIIa Blockade

Blockade of the platelet fibrinogen receptor (GPIIB/IIIa) using antibody fragments (abiximab, c7E3 Fab) or peptides reduces the risk of clinically significant ischemic events in patients undergoing coronary angioplasty. Three studies [59] [60] [61] that enrolled a total of 4,774 evaluable patients have demonstrated that c7E3 reduces the risk of death, MI, or urgent coronary artery bypass grafting in the first 30 days after percutaneous coronary angioplasty in patients with acute or chronic coronary artery syndromes. c7E3 produces an immediate and profound inhibition of platelet activity that persists for 612 hours after termination of its infusion. Administration of c7E3 is associated with an increase in the risk of hemorrhage, although this risk can be moderated with the judicious use of heparin and careful patient selection.

Thrombolytic Therapy

Thrombolytic therapy is useful in the treatment of arterial thrombosis because rapid clot lysis and restoration of blood flow prevent permanent tissue damage. More than 80% of patients with acute MI have thrombotic occlusion of the infarct-related coronary artery, [62] and thrombolytic agents produce rapid lysis of these thrombi in 5075% of cases.[62] Tissue plasminogen activator (t-PA) is more effective than streptokinase in achieving early coronary lysis, [63] but both agents improve left ventricular function and reduce mortality. Thus, streptokinase and t-PA decrease mortality by approximately 25% [62] [64] when used without adjunctive aspirin or intravenous heparin, and reduce mortality by 4050% when either agent is combined with aspirin. [62] In the GUSTO study, an accelerated t-PA regimen combined with high-dose intravenous heparin produced a 14% greater reduction in mortality than streptokinase. This difference was most evident in patients treated within 4 hours of onset of symptoms.

Following successful thrombolysis there is a 1020% reocclusion rate, and a 34% reinfarction rate. [62] Aspirin reduces the incidence of reinfarction. [56] Reocclusion is less common with streptokinase than with t-PA because streptokinase causes extensive plasma proteolysis and the resultant fibrinogen degradation products produce a systemic anticoagulant state. There is experimental evidence that direct thrombin inhibitors, such as hirulog and hirudin, are more effective than heparin at preventing reocclusion after coronary thrombolysis. However, large-scale clinical trials have been disappointing because treatment with the direct thrombin inhibitors has been complicated by a high rate of hemorrhage. [65] [66] [67]

Anticoagulants

The role of anticoagulant therapy in the treatment of arterial thrombosis is controversial. [68] [69] When used alone, heparin is effective in the short-term treatment of unstable angina,[68] but a rebound effect is seen when the drug is stopped. Aspirin appears to prevent the cluster of ischemic events that occur when heparin is discontinued. There is suggestive evidence that the addition of heparin to aspirin improves the short-term outcome in patients with unstable angina, but it is uncertain whether this effect is sustained.

In patients with acute MI, heparin has been reported to reduce reinfarction and death. [68] Moderate doses of heparin (12,500 U subcutaneously every 12 hours) also reduce the incidence of mural thrombosis detected by two-dimensional echocardiography, which is a particular problem in patients with anterior infarction.

Heparin prevents early reocclusion of the infarct-related artery after successful thrombolysis with t-PA. However, a recent meta-analysis [70] has suggested that routine administration of heparin to patients with acute MI is not indicated. This analysis demonstrated that heparin therapy reduced mortality by 6% (95% confidence intervals: 0, 10%), and the rate of reinfarction by 1.3%. However, heparin was associated with a clinically important increase in the risk of major hemorrhage that outweighed its observed benefit.

Oral anticoagulants are effective for the treatment of arterial thrombosis. [68] Two studies have shown that oral anticoagulants are effective for long-term treatment of patients with MI.[71] [72] Both studies used high-intensity warfarin regimens (INR 2.74.5 and 2.84.8, respectively), and the risk of bleeding was increased with anticoagulants. The recently reported Coumadin Aspirin Reinfarction Study demonstrated that fixed low-dose warfarin (1 or 3 mg) combined with 80 mg of aspirin per day does not provide benefit beyond that achieved with 160 mg of aspirin/day. [73]

Direct thrombin inhibitors, such as hirudin, are currently under evaluation for the treatment of acute ischemic coronary syndromes. Two large studies have failed to show that the administration of hirudin reduces the risk of death or nonfatal reinfarction at 30 days in patients who present with coronary ischemia. [74] Evidence from three large clinical trials shows that

hirudin in high dose is associated with a clinically important increase in the risk of cerebral hemorrhage. Currently, the value of direct thrombin inhibitors in patients with arterial thromboembolic disease is unclear.

Atrial Fibrillation

Patients with nonvalvular atrial fibrillation are at increased risk of stroke, which occurs at a frequency of 5% per year. [75] [76] [77] [78] [79] The risk of stroke increases with age,[80] [81] and is increased by a number of associated cardiac disorders, including a history of MI, angina, heart failure, or thromboembolic event, and the presence of left atrial dilation, left ventricular dysfunction, mitral calcification, or hypertension. In such patients, warfarin (INR 2.03.0) produces a 6080% reduction in the risk of stroke, with only a modest increase in bleeding complications. [75] [76] [77] [78] [79] Therefore, warfarin (target INR 2.03.0) should be administered to all patients with nonvalvular atrial fibrillation who do not have a contraindication to anticoagulant therapy. This recommendation applies particularly to those patients with nonvalvular atrial fibrillation who have an additional risk factor for stroke, such as hypertension, diabetes, or previous cerebral ischemia, in whom warfarin therapy (target INR 2.03.0) is clearly more effective than either fixed low-dose warfarin or aspirin. [82] Aspirin should be used in patients with nonvalvular atrial fibrillation who are at high risk for stroke when warfarin is contraindicated. The risk of cerebral hemorrhage increases with age; as a result, warfarin therapy should be initiated in the very elderly only after careful evaluation of the bleeding risk and discussion with the

TABLE 125-2 -- Indications for Anticoagulant Therapy and Aspirin in Arterial Thromboembolism

Indication	Anti-coagulants Effective	Aspirin Effective	Drug of Choice

Acute myocardial infarction			
Prevent systemic embolism	Yes[a]	No	Anticoagulants
Prevent reinfarction	Yes[a]	Yes[a]	Either
Prevent death	Yes[a]	Yes[a]	Aspirin
Angina			
Unstable angina	Yes[a]	Yes[a]	Both
Stable angina	No	Yes[a]	Aspirin
Coronary artery bypass graft	?	Yes	Aspirin
Atrial fibrillation			
Prevent systemic embolism	Yes[a]	Yes	Anticoagulants
Treat systemic embolism (including stroke)	Yes[a]	No	Anticoagulants
Valvular heart disease			
Prosthetic	Yes[a]	(Augment effect of anticoagulants)	Anticoagulants
Rheumatic	Yes	No	Anticoagulants
Systemic embolism			
Prevention	Yes	No	Anticoagulants
Treatment	Yes	No	Anticoagulants

Cerebrovascular disease	No	Yes[a]	Aspirin

[a] Evidence from randomized clinical trials.

patient. Low-risk patients (i.e., those with intermittent atrial fibrillation or who are less than 65 years old and without a history of cerebral ischemia, diabetes, or hypertension) should receive aspirin, 325 mg/day.

Mechanical and Bioprosthetic Valves

Patients with prosthetic heart valves are at risk of systemic embolism, which most often manifests as a stroke. The embolic risk is greater with mechanical than with bioprosthetic valves, with prosthetic mitral rather than aortic valves, and when there is associated atrial fibrillation. [83] For patients with tissue prosthetic valves who are in sinus rhythm, the risk of embolism is largely confined to the first 3 months after valve insertion, [83] whereas patients with mechanical prosthetic valves (particularly in the mitral position) have a lifelong risk of systemic embolism. [83]

Randomized trials in patients with mechanical prosthetic valves have shown that warfarin is effective in reducing the risk of systemic embolism, even when given at a lower intensity than that used in the past. [84] [85] For this reason, an INR of 2.53.5 is recommended for these patients. [83] Furthermore, the risk of systemic embolization, valve thrombosis and vascular death is reduced by the addition of aspirin (100 mg/day) to warfarin in these patients. [86]

The risk of thromboembolism is lower with uncomplicated bioprosthetic valves than with mechanical valves. In the absence of complications or atrial fibrillation, warfarin should be given for 3 months. [83] [87]

The relative effectiveness of anticoagulants and aspirin in the treatment of arterial thromboembolism is summarized in Table 125-2 .

Chapter 126 - Immune Throbocytopenic Purpura, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

James Bussel
Douglas Cines

INTRODUCTION

Immune thrombocytopenic purpura (ITP) is one of the most common causes of thrombocytopenia encountered in medical practice. The disorder has been estimated to affect approximately 1 in 10,000 in the general population and to account for 0.18% of hospital admissions (see Berchtold and McMillan [1] for review). ITP is caused by autoreactive antibodies that bind to platelets and shorten their life span. The clinical presentation varies widely, from the acute onset of petechiae and severe thrombocytopenia to the discovery of asymptomatic mild thrombocytopenia during the evaluation of another illness. ITP may accompany other systemic diseases having more than one potential cause of thrombocytopenia. In such cases, recognition and treatment of the autoimmune component may have an important impact on morbidity. Pregnancy in women with ITP may be complicated by neonatal thrombocytopenia.

Over the past few years several of the antigens recognized by the autoantibodies that cause ITP have been identified. This has enabled new tests to be developed that may facilitate the diagnosis of ITP and its differentiation from other causes of thrombocytopenia. Several important new treatment modalities have also been introduced into practice, each of which is effective in some patients. However, each of these also has important potential side effects and some have considerable cost. In addition, a practice guideline was developed by a committee of the American Society of Hematology that provides one approach to diagnosis and management.[2]

This chapter reviews the general clinical features of ITP, with an emphasis on an appraisal of new developments in diagnosis and management. The authors also describe how these newer treatment modalities are best utilized in the most common clinical settings they encounter. Discussion of ITP in adults and children is separated in order to emphasize the separate diagnostic and treatment issues pertinent to each age group.

ITP IN ADULTS

Presentation

Among adults, ITP occurs most commonly in women during the second and third decades of life, [3] [4] but the disorder occurs in both sexes and at any age. Most patients come to medical attention because they develop petechiae, purpura, or ecchymoses over the course of several days. Evidence of cutaneous bleeding may occasionally be widespread and may be accompanied by bleeding from mucosal sites such as epistaxis, gingival bleeding, hematuria, menorrhagia or, less commonly, melena. Rarely, patients present with signs of intracranial hemorrhage or bleeding at other internal sites. It is not uncommon for patients to have a history of easy bruisability for several months or longer prior to an acute exacerbation. Most patients are otherwise in good health, although some complain of easy fatiguability. In contrast to children, few adults have had a systemic viral illness in the weeks preceding the onset of bleeding. A few others have evidence of a preexisting systemic disorder such as systemic lupus, antiphospholipid syndrome, chronic lymphocytic leukemia, common variable immunodeficiency, or HIV infection. The typical patient, however, is entirely well with the exception of bleeding.

Differential Diagnosis

ITP is the most common cause of severe thrombocytopenia in an otherwise healthy young adult, but remains a diagnosis of exclusion. [2] Other disorders that need to be considered can be divided into those that cause isolated thrombocytopenia and those in which there are usually additional hematologic abnormalities. The former include familial thrombocytopenia, hypersplenism, or systemic lupus, drug-induced thrombocytopenias, (see Chap. 129) and HIV infection (see Chap. 155). During pregnancy, the differential diagnosis also includes gestational thrombocytopenia and preeclampsia. Other causes of thrombocytopenia are less common and generally are evident from the initial presentation. Among older adults, the major additional consideration is myelodysplasia, in which thrombocytopenia may precede other manifestations of the disease by months to years. [5]

Initial Evaluation

The physical examination should reveal only signs of bleeding, typically petechiae and purpura. The presence of splenomegaly

or lymphadenopathy suggests another diagnosis or an underlying illness with secondary immune thrombocytopenia. The blood counts are normal except for the platelet count unless there has been significant bleeding. Thrombocytopenia determined by automated analyzer must be confirmed by a thorough examination of the peripheral blood smear to exclude the diagnosis of pseudothrombocytopenia (see the following section) and other common hematologic conditions that generally affect multiple cell lines. The mean platelet size is increased in most, but not all patients, although platelets consistently approaching the size of erythrocytes are more typical of a hereditary thrombocytopenia. Coagulation tests to exclude a diagnosis of disseminated intravascular coagulation are rarely needed other than in an occasional patient who presents during pregnancy. Bone marrow aspiration and biopsy may be performed in older individuals to exclude other causes of thrombocytopenia, [2] but are rarely revealing when the presentation is typical. Erythroid and myeloid development should be normal. Megakaryocytes are generally normal or increased in number and there should be no dysplastic features such as megakaryocyte clumping. No additional studies are required to make a diagnosis of ITP in the typical case. [2]

Pseudothrombocytopenia

The blood count of every patient should be repeated and the blood smear must be inspected visually before making a diagnosis of ITP, both to exclude another cause of thrombocytopenia and to exclude pseudothrombocytopenia. Failure to diagnose pseudothrombocytopenia may lead to serious errors in management. [6] Pseudothrombocytopenia is an in vitro artifact of automated cell counting that occurs with a frequency of between 1 in 1,000 and 1 in 10,000 blood specimens collected in EDTA. [7] [8] The phenomenon occurs when platelets are agglutinated by IgG, and less commonly when they are agglutinated by IgM or IgA autoantibodies or monoclonal proteins, [9] [10] which bind to a divalent cation-dependent conformer of the platelet glycoprotein IIb-IIIa complex [11] [12] or another cryptic antigen [10] induced by a low concentration of ionized calcium attainable only in vitro. The diagnosis should be suspected when platelet clumping is observed on a blood smear made from EDTA-anticoagulated blood. [7] In some patients, the clumping is extensive enough to cause a spurious leukocytosis. [13] The diagnosis is confirmed by demonstrating that the platelet count is substantially higher when measured in citrated or heparinized blood, or in blood obtained without an anticoagulant. The in vitro clumping occurs at body temperature, which distinguishes this phenomenon from clumping caused by cold agglutinins, [7] [14] although the two phenomena may coexist. [9] [11] [15] Less commonly, the peripheral blood smear also shows platelets adherent to [16] or within [17] [18] granulocytes or monocytes, a phenomenon known as platelet satellitism. Occasionally, pseudothrombocytopenia may occur when giant platelets are excluded from automated analysis. [19] Because pseudothrombocytopenia and ITP, or other causes of thrombocytopenia, can coexist, [17] [20] the blood smear of patients with ITP must be analyzed to confirm the automated platelet count before therapy is initiated or changed.

Pathogenesis

Prior to 1950, the pathogenesis of ITP remained a matter of debate. An immunologic cause was suspected based on the prevalence of neonatal thrombocytopenia in affected women, the frequency of coexisting immune hemolysis, and the clinical response to steroids and splenectomy. However, it was not until the studies of Harrington et al., showing that infusion of plasma from ITP patients induced transient but severe thrombocytopenia in normal recipients, that the importance of platelet autoantibodies was generally accepted. [21] This observation was followed by efforts to identify and to isolate the autoantibodies and to identify the platelet antigens recognized. The cumulative efforts of many investigators have provided definitive evidence that ITP is caused by platelet-reactive autoantibodies, but the nature of the derangement that leads to autoantibody production remains unknown.

Platelet life span is reduced in essentially all patients with ITP, [22] [23] primarily as a result of the clearance of antibody-coated platelets by tissue macrophages. [24] [25] The contribution of intravascular destruction, if any, has not been established, but the possibility has been suggested because platelet-derived microparticles [26] and antibodies to cytoplasmic components of platelet glycoproteins [27] are found in the plasma of some patients. However, the rapid response to splenectomy in many patients suggests extravascular clearance is the major cause of thrombocytopenia in most patients.

The extent of compensatory *platelet production* in ITP is a matter of contention. Initial studies were consistent with the notion that platelet production increased as much as fivefold in most patients in response to shortened platelet survival. [23] This conclusion was in keeping with the increased number of megakaryocytes in the bone marrow and the larger, presumably younger, platelets seen on peripheral smear. In addition, bleeding time studies (see discussion later in this chapter) suggested enhanced hemostatic effectiveness of the residual platelets, consistent with their presumed greater mass. Other studies suggest that platelet production is

more heterogeneous than previously understood.[28] [29] Impaired platelet production, presumably resulting from destruction of antibody-coated platelets by intramedullary macrophages[30] or a direct effect of autoantibodies on the later stages of megakaryocyte differentiation [31] may contribute to the thrombocytopenia in some refractory patients. Again, the rapid response to splenectomy remains strong supportive evidence for the importance of extramedullary platelet destruction as the primary cause of the thrombocytopenia in most patients with ITP.

Platelet function also appears to be more variable than was previously understood. Most autoantibodies identified to date are directed at platelet glycoproteins that serve important hemostatic functions. Yet, the extent of bleeding generally correlates with the severity of thrombocytopenia, with spontaneous bleeding rarely becoming a problem until the platelet count falls below 30,000/l. This clinical experience is consistent with the observation that bleeding times remain within the normal range in at least some patients with ITP at somewhat lower platelet counts than among patients with aplastic anemia. [32] However, a subset of patients with a clear history of easy bruising and only moderate thrombocytopenia has been identified, in whom acquired storage pool deficiency and impaired release reaction caused by antiplatelet antibodies have been demonstrated. [33] [34] [35] In extreme cases, platelet autoantibodies cause an acquired thrombasthenia [36] [37] or Bernard-Soulier-like disorder which can be clinically severe. [38] A few patients have been described in whom bruising has persisted despite normalization of the platelet count and who were benefited by measures to inhibit antibody production. [39] [40] Such severe qualitative platelet defects are infrequent, however, and it is sufficient in most ITP patients to monitor the platelet count to predict the risk of hemorrhage (see discussion later in this chapter).

Laboratory Diagnosis

IgG and/or IgM antibodies against platelet glycoprotein (GP) complexes, including GP IIb/IIIa, Ib/IX, Ia/IIa, V, and IV and other specific platelet glycoproteins, [41] [42] [43] [44] have been identified on the platelets or in the plasma of most ITP patients. Detection is based on the principle of antigen capture in which, for example, a monoclonal antibody to a cell-specific glycoprotein is immobilized on a solid support to which a lysate of the patients

platelets or normal platelets sensitized with the patients plasma is added. This step enables the antigen, and any associated human antibody, to be captured onto the solid support where it can then be detected with an appropriately tagged antihuman immunoglobulin by radioimmunoassay or ELISA. These assays have largely replaced antiglobulin tests, which have a high incidence of false-positives presumably as a result of the uptake of plasma immunoglobulin by megakaryocytes followed by secretion and rebinding of plasma IgG when platelets are activated in the circulation. [45] However, antiplatelet antibodies are not detected in at least 20% of typical cases of ITP even using these newly developed techniques. False-negative test results may be caused by competition between the monoclonal and human antibodies for the same epitope on the platelet and antibodies may dissociate from the antigen during test performance either due to low affinity or loss of the epitope during solubilization of the platelet. Or, serum may contain antibodies to cytoplasmic portions of these glycoproteins that are exposed in vitro but not on the surface of circulating platelets in vivo. [27] Little information is available on the incidence of false-positives, that is, specific antiplatelet glycoprotein antibodies in presumably nonimmune thrombocytopenic conditions that may be hard to distinguish from ITP clinically, including myelodysplasia, preeclampsia, chronic liver disease, sepsis, and so forth, in which such tests would provide the most benefit. Additional clues may come from the absence of markedly elevated levels of thrombopoietin that occur in hypomegakaryocytic disorders [46] [47] and elevated plasma levels of glycocalicin, [48] but neither assay is clinically available at this time. Therefore, ITP remains a clinical diagnosis and a diagnosis of exclusion, and it is premature to rely upon available platelet antibody or other tests either to confirm or to exclude this diagnosis.[2]

INITIAL TREATMENT OF ADULTS WITH ITP

The choice of initial management depends in large part on the clinical presentation. Life-threatening hemorrhage rarely occurs at platelet counts >10,000/l, [49] [50] and therapy is generally not required at platelet counts >3050,000/l in the absence of bleeding or predisposing comorbid conditions. [2] However, because it is uncommon for ITP to remit spontaneously in adults, [2] [49] some form of treatment is generally indicated for the typical patient who presents with bruising or bleeding, especially in patients over the age of 60 and those with a previous history of bleeding. [49] [51] In the absence of hemorrhage or another medical emergency, such as concurrent trauma or surgery (see discussion later in this chapter), treatment is generally initiated with prednisone 12 mg/kg/day, although somewhat lower doses (0.250.5 mg/kg/day) may provide comparable benefit.[35] [52] The goal of initial treatment is to identify the lowest total dose of prednisone that will reverse and prevent severe thrombocytopenia for a sufficient period to permit the occasional adult who will have a durable response to be identified. [2] [53]

The response rate to prednisone varies from 6090% depending on the intensity and duration of treatment. [2] [53] [54] It is unlikely that additional benefit is achieved by continuing prednisone beyond 34 weeks, by which time considerable toxicity is generally evident. Therefore, if the patient is not in complete remission by this time, alternative forms of management should be sought, since there is no compelling evidence that prolonging treatment further will alter the natural history of the disease. In the authors experience less than 15% of adults with chronic ITP have a durable remission once prednisone is tapered, although remission rates approaching 25% have been reported by others.[2] [53] [54] Therefore, it is likely that even steroid responders will eventually require alternative forms of treatment.

The mechanism of action of prednisone in ITP remains controversial. Evidence suggests that glucocorticoids impair the clearance of antibody-coated platelets by tissue macrophages,[55] inhibit antibody production, [56] and increase platelet production, possibly by inhibiting phagocytosis of platelets by bone marrow macrophages.[30] In addition, cutaneous bleeding may resolve before an increase in the platelet count is seen, either because prednisone has a direct effect on vascular integrity or because the first platelets to circulate are recruited preferentially to sites of bleeding.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

EMERGENCY TREATMENT

Emergency treatment is indicated for internal or widespread mucocutaneous bleeding. Hospitalization should be considered even for asymptomatic patients presenting with platelet counts of <20,000/l, and certainly for those with counts <10,000/l, until a beneficial effect of treatment can be documented. General measures to reduce the risk of bleeding should be instituted including avoidance of drugs that interfere with platelet function, control of blood pressure and other medical conditions that inhibit coagulation, and measures to minimize the risk of trauma. Platelet transfusions are indicated if there is evidence of life-threatening bleeding and are often surprisingly effective in this setting, [57] [58] especially when given in conjunction with other therapies. [59] Treatment should be initiated with either intravenous immunoglobulin (1 g/kg/day for 2 days) (see discussion later in this chapter) or intravenous methylprednisolone (12 g/day for 13 days). [2] [60] [61] Emergency splenectomy should be reserved for the rare patient who fails to respond and requires additional treatment, for example, prior to emergency craniotomy for intracranial hemorrhage. Plasmapheresis has been used widely with few lasting effects but may play an adjunctive role with IVIG in emergency settings. [62] [63]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

SPLENECTOMY

Although there are no controlled studies showing that the duration of treatment with glucocorticoids alters the clinical course of responding patients, most hematologists taper prednisone over a period of 14 months. Most adults relapse during or after prednisone is discontinued, at which time splenectomy is considered. In general, splenectomy is the treatment of choice in any ITP patient who requires additional medical treatment (platelet count of <3050,000/l) and who is capable of undergoing the procedure.

Some investigators have reported a correlation between response to splenectomy and prior response to steroids, [57] [64] [65] intravenous immunoglobulin (IVIG),[66] or site of platelet clearance,[67] but there are too many exceptions to exclude a splenectomy from consideration based on any combination of clinical or laboratory parameters.[56] [68] [69] [70] Approximately two-thirds of adults will have an initial complete response to splenectomy and another 15% will have a stable partial response. [2] [53] [54] Approximately 15% of responding patients will relapse either soon after splenectomy or, less commonly, many years later. [49] Laparoscopic splenectomy may provide an alternative approach in some patients,[71] although there is some concern that operating time is longer and accessory spleens may be more likely to be overlooked. Using either approach, clinically significant bleeding is rare even when the patient is severely thrombocytopenic, and the practice of prophylactic platelet transfusions is to be discouraged.[2] Splenic irradiation has been used successfully in a few patients in whom splenectomy was judged to be medically hazardous, [72] but the procedure requires further evaluation.

The major risk of splenectomy is that of overwhelming bacterial sepsis, which occurs in less than 1% of otherwise healthy adults with uncomplicated ITP managed appropriately.[73] Patients should be immunized with polyvalent pneumoccocal vaccine at least 2 weeks prior to splenectomy, and in some settings, with *Hemophilus influenzae* type b vaccine and quadrivalent

meningococal polysaccharide vaccines.[2] It is also our practice to have patients seek medical attention and begin antibiotics immediately at the onset of a systemic febrile illness; fever 102°F should be treated in a hospitalized setting with IV antibiotics. Evidence does not suggest any benefit of prophylactic antibiotics in otherwise healthy adults after splenectomy for ITP.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TREATMENT OF SPLENECTOMY FAILURES

Overview

Approximately 30% of adults require additional therapy after splenectomy because of recurrent or persistent thrombocytopenia; [53] [54] the response rate is lower in patients with Evan syndrome or systemic lupus erythematosus (SLE). Spontaneous remissions are uncommon[74] and a mortality rate in excess of 5% has been reported for those in whom severe thrombocytopenia recurs or persists after splenectomy. [1] However, in the authors experience, this rate can be reduced substantially with the proper use of newer forms of treatment.

The initial approach to patients with recurrent bleeding or severe thrombocytopenia after splenectomy is generally the same as for those who present with severe, acute ITP: the diagnosis must be affirmed, measures to limit bleeding must be instituted, and treatment with corticosteroids and/or IVIG must be reinstituted depending on the severity of the presentation, even if these modalities were ineffective prior to splenectomy. Once the platelet count has increased to a safe level, the process of tapering steroids is resumed. An occasional patient will prove to be manageable with alternate-day corticosteroids or sufficiently low daily doses of prednisone (510 mg) to permit long-term use, but most will require one or more of the treatments described later in this chapter. Consideration should be given to modalities to decrease the incidence of osteoporosis if more than 10 mg of prednisone per day is required. [35]

Multiple treatment options are available. [2] [53] [54] However, it is important to be clear that the goals of therapy for splenectomy failures differ from those for patients at initial presentation because the chance of inducing a durable, complete, and unmaintained remission is much lower. Treatment must be therefore individualized with the aim of achieving a platelet count that is sufficient to prevent spontaneous bleeding and, if possible, one that affords protection from injury or other emergencies (generally a platelet count >2050,000/l). This risk also depends on the patients age and bleeding history [51] [75] as well as comorbid conditions. Further, an assessment of the bleeding risk must be balanced against a similar estimate of potential complications that may result from each form of treatment. Therefore, no single treatment paradigm is applicable to all patients.

Search for an Accessory Spleen

The presence of an accessory spleen should be sought in any patient who has relapsed and is likely to require additional treatment, since antibody-coated platelets may be removed even if all Howell-Jolly bodies are not. [76] [77] Most accessory spleens can be detected using ^{99m} technetium sulfur colloid, although more sensitive radionucleotide imaging techniques or CT or MRI scanning may be required in select cases. [77] [78] Neither the size of the accessory spleen nor any other characteristic has been useful in predicting response to surgery. The reported response rates to removal of an accessory spleen vary widely. [76] [77] Less than one-quarter of patients will have a long-term remission after removal of an accessory spleen. Therefore, the decision to recommend removal of an accessory spleen depends upon its location, the severity of the thrombocytopenia, the perceived risk of surgery, and the response to alternative forms of therapy.

Agents That Impair Platelet Clearance

Most patients do not have accessory spleens and require intolerable doses of corticosteroids to maintain adequate platelet counts. The options for treatment in this setting are described. Although each is discussed in the context of being used as the sole modality of therapy, it is often possible and desirable to use these agents in combination at lower doses or at longer intervals with synergistic benefits and reduced toxicity.

Intravenous Immunoglobulin (IVIG)

A major treatment advance was made in 1981 when Imbach and coworkers observed an increase in the platelet count of two children with immunodeficiency who had been treated with IVIG for infection.[79] A single course of therapy will increase the platelet counts to >50,000/l in approximately 85% of adults and to >100,000/l in approximately 65% of adults.[80] [81] IVIG is generally given by intermittent intravenous infusion over 12 days in total doses ranging from 0.52 g/kg/course with comparable response rates.[82] The infusions are generally repeated as needed every 1021 days, consistent with the half-life of IgG in the circulation, although unexpectedly high rates of durable responses have been reported when IVIG was given on a fixed schedule. [83] [84]

IVIG impairs the clearance of IgG-coated platelets presumably by competing for binding to tissue macrophage Fc IIA receptors. [80] [84] The biologically active fraction of IVIG is unknown, that is, it is uncertain whether monomeric IgG competes directly with antibody-coated platelets for binding to macrophages, or whether IgG aggregates in the preparations or cell-associated or soluble immune complexes formed in the recipient are responsible for the drugs effectiveness. Anti-idiotypic antibodies that interfere with binding or formation of antiplatelet autoantibodies may contribute in the occasional patient who develops long-term remissions, [85] but the observation that Fc fragments are as effective and the comparable efficacy of anti-D argues that Fc IIA blockade is of prime importance. [61] There is no evidence that currently available commercial preparations differ in their efficacy or toxicity other than in the rare patient with IgA deficiency, but the possibility of transmission of hepatitis C mandates that at least one effective form of viral inactivation be included (see discussion later in this chapter). Preferable characteristics, in addition to lower cost, include solvent detergent and/or other antiviral treatment, liquid state, and lower incidence of reactions during infusion.

Toxicity is generally mild and self-limited. As many as half the patients complain of headache (most often during the initial infusion), which is responsive to oral analgesics and slowing of the rate of administration. Occasional patients experience a more severe, but generally self-limited, migraine syndrome beginning 12 days after infusion, which may be associated with a pleocytosis in the cerebrospinal fluid. [86] [87] Positive direct antiglobulin tests occur commonly but are typically short-lived,[88] whereas overt hemolytic anemia has occasionally been reported to occur from infusion of high-titer isoagglutinins, [89] as has the formation of red cell isoagglutinins resulting from transfer of blood group A substance. [90] Other rare side effects include thrombosis,[91] pulmonary or renal failure,[92] and anaphylaxis in IgA-deficient patients with IgE anti-IgA antibodies, in whom IgA-depleted preparations should be used. [93] [94] Antiviral antibodies[95] can be passively acquired after administration of IVIG, but there are no documented cases of HIV or hepatitis A or B having been acquired as a result of treatment. A single large outbreak of hepatitis C was reported in 19935 and was attributed to a single preparation affected by a change in donor screening and the absence of viral inactivation, [96] but no cases have been reported after infusion of a solvent-treated product. Lots continue to be recalled if a donor is at risk for Creutzfeld-Jacob

disease, although no cases of IV transmission have been documented.

Major limitations of IVIG treatment have been the need for repeated intravenous infusion and its high cost, which averages almost $3,000 per course in adults. Approximately one-third of patients become refractory after multiple courses of therapy. [81] Whether maintenance treatment alters the natural history of chronic ITP

remains an open question. In the absence of a controlled study the major indications for IVIG are: (1) treatment of medical emergencies; (2) preparation for splenectomy in patients intolerant or resistant to corticosteroids; (3) as a means to defer splenectomy in young children or debilitated adults; (4) during pregnancy when potentially teratogenic drugs must be avoided; (5) in chronic management of the rare patient who is refractory to other measures; and (6) while awaiting a response to slower-acting agents such as azathioprine or danazol.

Anti-D

Salama and Mueller-Eckhardt proposed that induction of a mild hemolytic anemia by infusing anti-D into Rh(D)+ individuals might inhibit macrophage Fc receptor function and clearance of antibody-coated platelets analogous to the infusion of large amounts of nonspecific IgG. [97] Comparable response rates are seen after administration of 1/100 as much IgG given as anti-D compared with the amount given in a typical course of IVIG. [98] Further, anti-D, given at a dose of 75 g/kg, induces a comparable increase in the platelet count within the first 24 hours of treatment (37,000/l). [99] Treatment requires approximately 5 minutes, is less expensive than IVIG, and the systemic side effects of IVIG are avoided. The dose-limiting toxicity of anti-D is hemolytic anemia with a mean decrease in hemoglobin of 1.0 g/dl, occasionally accompanied by chills and nausea.[98] A higher response rate is seen in those in whom the hemoglobin in reduced by 2 g/dl when the dose of anti-D is increased. Other limitations of anti-D treatment include its inapplicability to Rh(D) individuals, lower increments in the platelet count with a mean increase of 45,000/l, and minimal efficacy in splenectomized patients.[98] The indications for anti-D are essentially the same as those for IVIG. Anti-D is especially useful in HIV-positive individuals and others who require chronic treatment in whom it is desirable to avoid both long-term treatment with corticosteroids and splenectomy.

Danazol

The impeded androgen, danazol, given at a dose of 1015 mg/kg/day for 46 months, is effective in the majority of adults, [100] [101] [102] as well as in some children[103] and patients with secondary immune thrombocytopenia.[104] Danazol may impair macrophage-mediated clearance of antibody-coated platelets initially, [105] but inhibition of antibody production [100] [101] [106] may contribute to its effectiveness after prolonged use. Despite these favorable reports, the efficacy of danazol in refractory patients remains controversial.[107] [108] The variation in the observed response rates may in part be due to differences in the duration of treatment. [105] In one series, the mean duration of treatment was 2.7 months, but some individuals required as much as 6 months of treatment until a response was seen. [101] In our experience, the major indications for danazol are to defer splenectomy and as a potential corticosteroid-sparing drug. Although an occasional patient will experience an extended, unmaintained remission after a prolonged course of treatment, remissions usually require continued drug administration, albeit at much lower daily doses, [109] with relapses typically occurring weeks to months later if therapy is stopped. Danazol shares with other androgens the potential for causing hepatic injury including cholestatic hepatitis, peliosis, [110] and neoplasia.[111] Thrombocytopenia was reported as a complication of danazol in a few patients treated for disorders other than ITP.[112]

Vinca Alkaloids

Vinca alkaloids bind avidly to platelets from which they are released slowly into the plasma. [113] This may permit the drug to be delivered by antibody-coated platelets to tissue macrophages, thereby inhibiting their phagocytic capabilities. [105] [113] Vincristine (0.025 mg/kg or 11.5 mg/m^2 , not to exceed 2 mg) and vinblastine (46 mg/m^2 , not to exceed 10 mg) can be administered either by injection or by slow infusion. The latter method is reported to be somewhat more efficacious and potentially more toxic.[114] Reported response rates vary widely. Contrary to initial favorable reports, the results of more recent and larger series indicate that the response rate to either drug is closer to 1020% among patients with chronic refractory ITP, and sustained complete remissions are uncommon. [68] [115] [116] [117] Treatment must be given every 24 weeks for an indefinite period; many patients become refractory or treatment must be stopped because of neurologic or hematologic toxicity.

Immunosuppressants

Although immunosuppressive drugs have generally been reserved only for refractory patients intolerant of the treatments mentioned earlier in this chapter, their proper place in the treatment of refractory patients is being reassessed. Among patients treated with azathioprine, 2040% attain a complete remission and an additional 1020% have a partial response, [74] [117] [118] although lower response rates have been noted by some.[117] [119] Again, the variable outcomes may reflect differences in the intensity or duration of treatment. For example, the median time to response among patients in one study was 4 months, and maximal benefit was not attained in some cases until 78 months of treatment.[118] Responses are generally durable and, at least in some patients, persist after treatment is discontinued. Side effects are rare and predominantly limited to reversible elevations of serum transamidases.

Comparable or only slightly lower response rates have been reported with the use of cyclophosphamide as a single agent. [117] [119] [120] Cyclophosphamide may be given orally at a dose of 12 mg/kg/day titrated based on the neutrophil count, or 12 courses may be given intravenously at a dose of 11.5 g/m^2 every 3 weeks. The use of cyclophosphamide should be restricted, especially among younger patients, because of the risk of infertility and leukemia. The combination of cyclophosphamide and prednisone with one of a number of additional agents has been effective in a small number of refractory patients with acceptable toxicity. [121] [122] A few patients have been treated successfully with cyclosporin.[123] The high response rate reported for pulse dexamethasone has not been confirmed in subsequent studies but remains under study.[124]

Treatments Whose Mechanism of Action Is Unknown

A few patients with chronic ITP have been treated by incubating their plasma with columns coated with staphylococcal protein A. An overall response rate approaching 30%, including many sustained responses, has been reported by the manufacturer of the columns. [125] The mechanism of action is unknown. Approximately one-third of the patients developed an acute hypersensitivity-type reaction; 5% required discontinuation of treatment. [125] [126] Cases of hypotension and fatal anaphylaxis have been reported in patients treated with protein A pheresis for other disorders. [126] Dapsone[127] and colchicine[128] have been reported to be effective in relatively small numbers of patients. Their mechanism of action is not established and the response rates in otherwise refractory patients have not been studied prospectively. Occasional patients have been treated successfully with recombinant -2b interferon [129] although worsening of thrombocytopenia has been noted.[130]

SECONDARY IMMUNE THROMBOCYTOPENIAS

Introduction

Secondary immune thrombocytopenias comprise 4050% of cases in some series.[131] [132] The reason for this increased recognition of secondary ITP is not apparent although it may be related to the recent epidemic of HIV-1 infection (see Chap. 155). The incidence of secondary immune thrombocytopenias should be considered in determining when to treat a patient with a systemic illness for presumed ITP when other causes of thrombocytopenia are more frequent or may coexist. Because ITP remains a diagnosis of exclusion, the accuracy of these decisions depends on the familiarity of the treating physician with the prevalence, implications, and proper management of secondary immune thrombocytopenia in each of its associated conditions.

Systemic Lupus Erythematosus

Presentation

Approximately 1525% of patients with systemic lupus erythematosus (SLE) develop thrombocytopenia during the course of their illness, although the problem is severe enough to require treatment in only 510% of patients. [133] [134] Thrombocytopenia may precede the diagnosis of SLE by months to years,[135] but such progression occurs in <5% of patients with classic ITP. [3] [136] [137] Therefore, serologic evaluation should be restricted to those individuals who show additional evidence of lupus. [2]

The prognostic significance of thrombocytopenia in patients with SLE depends on the clinical context. Four clinical presentations have been described. The clinical course of patients who develop immune thrombocytopenia without a worsening of other disease manifestations is similar to that of patients with ITP. [133] [138] [139] In contrast, severe thrombocytopenia that develops during a systemic exacerbation of vasculitis may have a different pathogenesis (see the following section) and carries a poorer prognosis. [133] [134] [139] [140] Thrombocytopenia also occurs in patients with antiphospholipid antibodies, who may be at a somewhat higher risk for thrombosis and recurrent spontaneous abortions. [141] [142] Amegakaryocytic thrombocytopenia has been detected in a few patients. [143]

Pathogenesis

The pathogenesis of thrombocytopenia in SLE patients may be multifactorial. First, circulating platelet-reactive antibodies with diverse specificities have been identified,[144] [145] [146] but which of these cause thrombocytopenia has not been determined. Second, plasma from most patients contains immune complexes that bind to platelets in vitro [147] and both DNA and anti-DNA antibodies have been identified on patient platelets. [148] However, since such complexes are found in many patients in the absence of thrombocytopenia, their importance in accelerating platelet clearance or altering platelet function remains uncertain. [149] [150] Further, platelet clearance may be influenced not only by the composition of these immune complexes, which are undoubtedly heterogeneous, but also by impaired macrophage IgG Fc receptor-mediated clearance resulting from the underlying disease and its treatment. [151] Finally, when severe thrombocytopenia occurs as part of a systemic relapse, platelet activation and deposition may also occur within vessels involved by vasculitis, such as the kidney. [152] Thrombocytopenia caused by vascular injury may not respond to measures that suffice to manage ITP.

Management

For several reasons, treatment of thrombocytopenic episodes in patients with SLE is more complicated than the management of patients with classic ITP. First, thrombocytopenia caused by platelet-specific antibodies must be distinguished from that caused by systemic vasculitis. In extreme cases, the distinction may be relatively straightforward. At one end of the spectrum, patients with severe thrombocytopenia in whom there is no other evidence of active SLE should be treated as if they had ITP. At the other extreme, it is generally necessary to control the systemic vasculitis before thrombocytopenia will improve. However, in many patients the extent to which vasculitis contributes to the thrombocytopenia is not apparent and may vary. Second, because patients with SLE may experience repeated episodes of thrombocytopenia, treatment should only be used when a risk of bleeding exists in order to avoid excessive use of corticosteroids or other medications in these heavily treated patients. Third, attempts to induce long-term remission with splenectomy should be tempered by the knowledge that many patients continue to require corticosteroids to control the underlying disease. Therefore, treatment decisions should be predicated on the extent to which thrombocytopenia per se is the predominant reason for treatment and the likelihood that systemic vasculitis will necessitate treatment in the future.

When thrombocytopenia occurs in the absence of a systemic flare-up, the short-term response to corticosteroids, danazol, IVIG, and immunosuppression in patients with SLE and classic ITP are comparable.[153] [154] [155] [156] The role of splenectomy remains controversial. Variability in the long-term response rates is undoubtedly influenced by differences in the severity of the underlying disease. [157] [158] [159] It is our opinion that splenectomy is indicated only when thrombocytopenia is severe and persistent, and when systemic manifestations of the SLE are otherwise well-controlled. In such cases, the procedure is as effective as in ITP. Profound thrombocytopenia that occurs during the course of a systemic exacerbation of SLE may require pulses of high-dose corticosteroids [160] or cyclophosphamide,[161] or both.

Lymphoproliferative Disorders

Chronic Lymphocytic Leukemia

Thrombocytopenia caused by marrow and splenic infiltration is a common feature of advanced chronic lymphocytic leukemia (CLL) [162] and has a mean survival time of about 19 months.[163] In contrast, immune thrombocytopenia, which occurs in approximately 2% of patients with CLL, [164] [165] does not confer a poor prognosis[166] [167] [168] and requires distinct treatment. ITP may precede the diagnosis of CLL or develop at any stage. [167] [169] The pathophysiology of autoantibody production in CLL and its relationship to clonal B-cell proliferation has been reviewed. [170]

The diagnosis of an antibody-mediated thrombocytopenia becomes progressively more difficult as the disease progresses. ITP should be suspected in patients with early stage CLL whose bone marrow contains adequate numbers of megakaryocytes or in patients at a more advanced stage in whom the severity of thrombocytopenia is disproportionate to the extent of marrow infiltration or splenomegaly. The concurrent development of autoimmune hemolytic anemia may also suggest the diagnosis.[167] The cause of thrombocytopenia may be difficult to establish in patients who have a significant tumor burden. A short course of therapy, such as IVIG, may be indicated. Although most patients with CLL and immune thrombocytopenia respond to corticosteroids or splenectomy, [166] [167] [168] immunosuppressive therapy that inhibits B-cell proliferation and antibody production may be required. [166] [167] [168] [169] IVIG prophylaxis (400 mg/kg/month) should be considered in patients postsplenectomy and for those who require immunosuppressive therapy.

Hodgkin Disease and Non-Hodgkin Lymphomas

ITP occurs in approximately 1% of patients with Hodgkin disease. The clinical courses of approximately 50 patients have

been reported. [132] [164] [171] In three-quarters of the reported cases, ITP was diagnosed an average of 52 months (1 month22 years) after Hodgkin disease was detected.[172] Hodgkin disease was discovered at the time of splenectomy for ITP in a few patients. [3] In most of the remaining cases, ITP preceded the diagnosis of Hodgkin disease, although in some instances the interval was so long as to place the significance of the association in doubt. [172] [173] [174] One persistent dilemma is whether the development of ITP in a patient with Hodgkin disease signals recurrence of the lymphoma. Although such cases have been reported, [132] [172] approximately two-thirds of the patients did not have any evidence of active Hodgkin disease. [171] [172] [175] [176] Virtually all patients in whom there was no evidence of recurrent Hodgkin disease responded to some combination of corticosteroids, [172] [176] splenectomy,[175] [177] and azathioprine.[176] Treatment of the Hodgkin disease has been required in some patients before the thrombocytopenia resolves. [167] [178] [179]

The association between immune thrombocytopenia and non-Hodgkin lymphoma appears almost coincidental, and few generalizations can be made. [132] [175] [180] [181] [182] The histologic type of lymphoma and extent of the underlying disease has varied widely. In most cases, thrombocytopenia has proved difficult to manage unless the underlying malignancy responded to chemotherapy.

Leukemia of Large Granular Lymphocytes

The term leukemia of large granular lymphocytes (LGL) is applied to two disorders that can be distinguished by the phenotype of the clonally expanded cell population.[183] Thrombocytopenia occurs in both forms of the disease, although the pathogenesis and treatment differ. In >90% of the patients there is a clonal expansion of $CD3^+$, $CD16^+$ T cells (T-LGL), and the natural history is generally one of stability or slow expansion of this cell population. In the remaining patients, the LGL cells express an NK phenotype (CD3 , $CD16^+$, $CD57^+$). NK-LGL is more typically aggressive, and severe thrombocytopenia, caused by marrow replacement and splenic infiltration, may develop over months. [183]

Most patients with T-LGL come to medical attention because of recurrent infections secondary to neutropenia. [184] Thrombocytopenia, which occurs in 520% of these patients, is generally mild and may be secondary to splenic enlargement, [185] but occasional patients present with severe thrombocytopenia and a clinical picture compatible with ITP.[184] [185] The diagnosis of LGL should be suspected in patients with thrombocytopenia accompanied by neutropenia, arthralgia, splenomegaly, and a positive test for rheumatoid factor. On occasion the number of LDL cells is increased only modestly, [183] making the disorder hard to distinguish from severe ITP in which an increase in $CD56^+$ CD53 cells has also been observed. [186] Data is not sufficient to determine whether the response to treatment of immune thrombocytopenia in patients with T-LGL differs from typical ITP.

Miscellaneous Disorders

Mild thrombocytopenia, attributed to hypersplenism, has been noted in patients with autoimmune hyperthyroidism and resolves slowly with return of the euthyroid state.[187] [188] Immune thrombocytopenia probably also occurs more commonly in these patients.[188] [189] [190] Although most of these patients respond to measures effective in ITP, others require control of the hyperthyroid state before the thrombocytopenia abates. [188] [189] In patients with sarcoidosis, immune platelet destruction may be superimposed on thrombocytopenia caused by splenic and marrow infiltration with granulomas. [191] [192] ITP has also been reported in association with myasthenia gravis[193] and in patients with a variety of benign and malignant neoplasms, most of whom responded to conventional treatment for ITP. [182] [194] [195] [196] Thrombocytopenia commonly occurs after allogeneic bone marrow transplantation in the setting of graft-versus-host disease in which platelet autoantibodies, vascular injury, viral infection, and hypersplenism all may contribute to accelerated platelet destruction. [197] [198] Both transient and persistent immune thrombocytopenias have also been reported after organ and bone marrow allografts donated by patients with presumed compensated ITP. [199] [200] ITP also occurs with increased frequency in patients with common variable immunodeficiency (CVI)**.** The average age at diagnosis was 28 years in one large series. [201] CVI should be suspected in patients with recurrent infections and allergies. Splenectomy and immunosuppressive agents should be avoided, to the extent possible. Thrombocytopenia associated with HIV infection is discussed in Chapter 155 .

ITP IN CHILDHOOD

Introduction

Treatment of children with ITP differs substantially from that for adults with respect to the differential diagnosis that must be considered at presentation, the much higher frequency of spontaneous remission, and, therefore, the greater delay before splenectomy is considered. In addition, the potential long-term effects of treatment must be taken into consideration in a population with a >50-year life expectancy. No clear pathophysiologic explanation has emerged that explains the obvious difference in the clinical course of ITP in these two age groups.

Presentation

As in adults, children with acute ITP typically present with the sudden onset of petechiae and purpura and platelet counts <2030,000/l. The relationship between the risk of bleeding and the platelet count appears to be the same as in adults. However, intracranial hemorrhage (ICH) has been reported in approximately 0.51% of children,[202] an incidence that may be higher than that seen in adults. Both sexes are affected with equal frequency. The peak incidence occurs between the ages of 3 and 5 but the disorder may occur at any age.[203] Although many patients have a history of nonspecific viral infection in the weeks prior to developing symptoms, such symptoms are common in children and a relationship of preceding infection to the development of ITP is hard to document. Occasional patients present with ITP during or within 4 weeks after an otherwise typical systemic viral infection caused by Epstein-Barr virus, [204] varicella, [205] cytomegalovirus,[206] rubella,[207] or hepatitis A, B, or C,[208] [209] [210] parvovirus,[211] and others,[212] or after vaccination with attenuated live virus. [213] The parents and pediatrician are usually more concerned than the child who continues to feel and act completely well. As in adults, the physical examination is notable only for signs of bleeding, the absence of hepatomegaly or lymphadenopathy, and two normal radial rays. Minimal splenomegaly is detectable in less than 10% of children. The CBC should be within normal limits for age with the exception of the platelet count. This includes the white blood cell differential, which normally has more lymphocytes than neutrophils in children <45 years of age.[203]

Evaluation

To experienced pediatric hematologists, this constellation of findings (i.e., an otherwise healthy child with isolated thrombocytopenia and a physical examination notable only for bruising or petechiae) is sufficient to make a diagnosis of ITP, which is by far the most common (>95%) cause of isolated, especially severe, thrombocytopenia in childhood. In general, no additional testing, including a bone marrow biopsy, is required if the presentation is typical, irrespective of therapy. [2] [214] The outcome of cooperative childhood cancer study group trials, which

included thousands of children, demonstrated that it is extremely unlikely (<0.1%) for acute leukemia to present with isolated thrombocytopenia, an otherwise normal blood count and smear, and the absence of hepatosplenomegaly or lymphadenopathy. [202] [215] One survey showed that most pediatric hematologists no longer believe that examination of the bone marrow is necessary to make a diagnosis of ITP when the presentation is typical, but that such an examination is required if there are abnormalities in the physical examination or in nonplatelet components of the CBC or if the patient fails to respond to treatment. [214] A response to IVIG in this setting is also essentially diagnostic of ITP. [216] HIV testing should be performed if the child or mother is considered to be at risk, including expremature infants who received transfusions or when significant cervical or axillary adenopathy is detected. [217] [218]

Differential Diagnosis

Once thrombocytopenia is documented in a healthy child with an otherwise normal CBC and no abnormalities other than bleeding manifestations on physical examination, the first diagnostic consideration is to exclude familial, nonimmune thrombocytopenias. These disorders are seen in 210% of children presenting with isolated thrombocytopenia.[219] A bone marrow examination will not help to differentiate ITP from these inherited syndromes. The diagnosis of a familial disorder may not be suspected despite careful questioning, since other affected family members may be asymptomatic. On occasion, an inherited cause of thrombocytopenia may only be suspected after the child has failed to respond to treatment for ITP. Fortunately, most children with inherited thrombocytopenias have mild to moderate thrombocytopenia (40100,000/l) and do not have symptoms or require treatment other than when platelet production is further impaired during periods of infection. The presence of uniformly small platelets should raise a suspicion of Wiskott-Aldrich syndrome, which may present with thrombocytopenia alone. Bernard-Soulier syndrome should be suspected with moderate thrombocytopenia and giant platelets. The causes of inherited thrombocytopenia are considered in detail in Chapter 127 . Amegakaryocytic thrombocytopenia may be indistinguishable from ITP on clinical presentation, and the diagnosis is generally considered only when the child fails treatment. Bone marrow biopsy is the definitive diagnostic test. Too few cases have been reported in children to determine the response to measures effective in adults. However, approximately 50% of the cases progressed to marrow aplasia, some of whom have been treated successfully with bone marrow transplantation. [220]

The second diagnostic consideration is to exclude an underlying disorder associated with ITP. Only HIV, SLE, and humoral immunodeficiency states occur with sufficient frequency in childhood to merit consideration. HIV as a cause of ITP in childhood is being seen with increased frequency. In utero transmission is the most common mode of infection. Usually the diagnosis is made apparent by maternal history or during the initial examination of the child, which typically reveals axillary adenopathy, hepatosplenomegaly and/or an abnormal hemoglobin, total white blood cell count, or white cell differential. However, some affected children have no clinical evidence of HIV even after many years of infection. HIV testing is reliable for diagnosis in children over 12 months of age. SLE may develop in as many as 25% of female adolescents who present with ITP.[221] This concern has led some pediatricians to an inappropriate search for antinuclear antibodies (ANA) in every child with ITP. A positive ANA does not predict the development of SLE, its severity, its responsiveness, or the incidence of spontaneous remission in otherwise healthy children.[222] Therefore, testing for antinuclear antibodies should only be performed if additional specific symptoms or laboratory findings are present that suggest the presence of SLE. Humoral immunodeficiency is found in 12% of children with ITP, most commonly as a result of IgA deficiency. [223] ITP also occurs in 15% of children with CVI and IgG_2 deficiency.[201] This incidence may be sufficiently high to warrant measuring immunoglobulin levels and documenting response to polyvalent pneumococcal vaccine prior to splenectomy.[224] Immunoglobulin measurements may therefore also be indicated in children who are to receive IVIG, because the use of IgA-depleted preparations may prevent formation of anti-IgA antibodies and is effective when such antibodies already exist. [80]

Third, additional diagnosis must be considered if other cytopenias are present. For example, the finding of severe anemia, even when there has been significant epistaxis, should lead to an investigation of alternative diagnoses such as aplastic anemia, myelodysplasia, and disorders associated with accelerated erythrocyte and platelet destruction such as thrombotic thrombocytopenic purpura and Evans syndrome. The diagnosis of the latter may be complicated if the patient has recently been treated either with IVIG, which may contain anti-A or -B isohemagglutinins, or with anti-D, since both therapies may cause a positive direct antiglobulin test. [225]

Management at Presentation

Which children with acute ITP should be treated and which treatment should be used, if any, remains a matter of intense controversy. [2] [226] [227] Treatment is intended primarily to prevent ICH. However, the incidence of ICH is too low [228] to perform a controlled study. The risk of ICH may be higher in children with platelet counts <20,000/l,[229] children presenting with extensive wet purpura or internal bleeding, and those with SLE or coexisting coagulopathies. However, because ICH can occur in the absence of bleeding at other sites, our approach is to treat all children with platelet counts <20,000/l. It should be emphasized, however, that no trial has demonstrated a reduction in ICH and other experienced pediatric hematologists may use more restrictive criteria. A secondary goal of therapy is to prevent the development of chronic disease. However, at least 80% of affected children recover spontaneously, many within the first 2 months. [230] [231] Chronicity is more likely to develop in teenagers, in children with SLE, and in those with Evans syndrome. However, children at any age can develop chronic ITP even with an otherwise typical presentation and there is as yet no firm evidence that the natural history is altered by early treatment. [124]

It is clear through the results of several recent controlled trials that prednisone (24 mg/kg/day), [232] intravenous methylprednisolone (30 mg/kg/day for 3 days), [233] IVIG (1 g/kg/day for 2 days),[234] and anti-D given at a dose of 75 g/kg [235] all shorten the duration of severe thrombocytopenia compared with no treatment. With IVIG, the mean increase in the platelet count was 54,000/l within the first 24 hours. [216] The combination of IVIG and corticosteroids may be synergistic. [236] Platelet transfusions should be reserved for ongoing or imminent major hemorrhage.[56] We recommend that all severely thrombocytopenic children with acute ITP (platelet counts <20,000/l) be treated with a combination of IVIG (1 g/kg/day) and intravenous methylprednisolone (30 mg/kg/day), both for 13 days, until a platelet count >2030,000/l is achieved and there is no evidence of bleeding. The diagnosis of ITP should be reconsidered in the rare situation in which a child fails to demonstrate a partial response to IVIG and/or methylprednisolone.

Management of Acute ITP after the First Week

The goal of treatment is to maintain a platelet count >2030,000/l with a minimum of toxicity. Drugs that impair platelet function, such as aspirin and glycerol guaiacolate, should be

CHRONIC ITP IN CHILDREN: MANAGEMENT AFTER 6 MONTHS

Most pediatric hematologists delay recommending splenectomy for at least 1 year for two reasons. First, children who have platelet counts >2030,000/l and who are asymptomatic can be followed safely with little or no treatment. Virtually all children can be managed with IVIG or anti-D if the platelet count falls below 2030,000/l, with small doses of prednisone (<0.2 mg/kg/qod) added if necessary. Our experience and those of others is that platelet count generally improves over time. However, the platelet count may fall at puberty in previously stable patients with mennorhagia as a complicating feature. Second, the risk of postsplenectomy sepsis may be as high as 2% over 10 years in children and greater in those less than 12 years of age.[73] Indeed, there have been as many reported deaths from postsplenectomy sepsis as from bleeding in this age group. [240] [241] It remains to be determined whether this risk is reduced substantially by the use of pneumococcal and H Flu B vaccines in conjunction with prophylactic antibiotics, which is the current standard of care. How often to revaccinate and the value of prophylactic antibiotics in this setting remain unsettled. We currently recommend that Pneumovax be given every 510 years, but do not administer hepatitis vaccine unless a special risk is identified. We recommend that prophylactic antibiotics be used for the first year after splenectomy and thereafter should be given immediately for any infection; intravenous antibiotics should be initiated urgently for children with a fever >102°C. No other long-term health risks have been identified in children who have been splenectomized for ITP. Therefore, most pediatric hematologists prefer waiting until a child has reached 5 years of age before recommending splenectomy because of the frequency of infection and high fevers in this population, although there is insufficient data on the risk of sepsis after the age of 2 to make firm recommendations. In the youngest children, it may be wise to document protective titers of antibody to the most common serotypes of pneumococcus before proceeding to splenectomy. Durable clinical remission occurs in 7090% of children with typical ITP after splenectomy. [242]

Among the few children refractory to splenectomy, alternate diagnoses should be investigated. Few children have significant bleeding problems even if they remain thrombocytopenic, which must be borne in mind when recommending potentially toxic forms of treatment. The rare, symptomatic, refractory pediatric patient should be approached in the same manner as a comparable adult, although the potential side effects of various drugs may differ depending on the age of the child.

avoided. Guidelines must be set for physical activity. Competitive contact sports, such as football or basketball, lacrosse, soccer, and hockey, should be avoided by children with platelet counts <30,000/l, but other physical activities including track, swimming, bicycling, baseball, and tennis need not be restricted for most children.

Primary reliance is often placed upon prednisone because it is relatively inexpensive, can be given orally, and the toxicity is tolerable when the duration of treatment is limited. One approach is to taper the dose of prednisone over 2 weeks to 3 months, although there is no evidence that any specific duration of treatment increases the probability of sustained complete remission. An attempt should be made to administer prednisone on an alternate day regimen to avoid toxicity, including osteoporosis, which may be the most medically significant, long-term side effect of corticosteroids in children. The utility of high-dose dexamethasone remains to be defined.[124]

The authors recommend the use of IVIG[237] or IV anti-D (Winrho-SD) [235] for children who require more than 0.2 mg/kg/day of prednisone as their initial treatment or when treatment beyond 23 months is required. Both IVIG and anti-D are generally administered on an as needed basis rather than at fixed intervals. The combination of prednisone with IVIG (and probably anti-D) may be synergistic. Treatment should be continued for at least 12 months if a response is seen, since spontaneous remissions may be delayed. With this combination of drugs, few children require splenectomy. Treatment with vinca alkaloids, [238] azathioprine,[239] or danazol[103] may be chosen in a few children in order to defer splenectomy. Because the disease will remit between the first and twelfth month in >80% of children with typical ITP, splenectomy should be deferred, if at all possible, for at least 1 year from the time of diagnosis.

The advantage of IVIG in managing children includes its lack of toxicity, its high rate of efficacy, and the possibility of curative effects. [216] [227] The disadvantages are that it must be given intravenously for hours, optimal use in maintenance depends upon the platelet count (making scheduling difficult), postinfusion headaches are common, and its cost is high.[237] In contrast to adults, less than 10% of pediatric patients become refractory even with prolonged treatment. There is no evidence that any of the commercially available products differ in clinical effectiveness. Anti-D appears to be equally safe and comparably effective to IVIG for Rh+ patients who have not undergone splenectomy.[235] The cost is considerably less and infusion is complete within minutes. Whether early treatment with IVIG or anti-D will alter the

incidence of chronic ITP remains to be determined. Children have been treated with each modality for years without evidence of toxicity.

ITP DURING PREGNANCY

Diagnosis of ITP in Pregnancy

Because ITP commonly occurs in young females, hematologists are often asked to manage this disorder during pregnancy. The incidence in referral institutions is approximately 12 per 1,000 deliveries,[243] but is likely to be lower in the general community. Proper management of ITP in pregnancy requires consideration of two patients: the mother and the fetus. Therefore, management involves not only careful attention to the maternal platelet count and risk of bleeding, but an awareness of the incidence and consequences of neonatal thrombocytopenia caused by transplacental passage of maternal autoantibodies, as well as the risks and benefits to the fetus of maternal therapy, invasive monitoring, and surgical delivery. Several comprehensive reviews offer a more in-depth discussion of the differential diagnosis and management of thrombocytopenia in pregnancy.[244] [245]

It may be difficult to diagnose ITP when a woman presents near term with no prior platelet counts. The most common condition that must be distinguished from ITP is gestational thrombocytopenia, which occurs in approximately 4% of women (see Chap. 129). Gestational thrombocytopenia is quite likely when an otherwise entirely healthy women known to have had a normal platelet count develops mild thrombocytopenia (>100,000/l) toward the end of the third trimester of an uncomplicated pregnancy.[246] The importance of making the intrapartum distinction from ITP is that severe neonatal thrombocytopenia is rare and there is no indication for diagnostic or therapeutic intervention other than following the maternal platelet count. [246] However, gestational thrombocytopenia and ITP are both diagnoses of exclusion. Although the incidence of gestational thrombocytopenia in the typical setting vastly exceeds all other causes of thrombocytopenia combined, on occasion a previously healthy woman will present for the first time at term with mild-to-moderate ITP, early preeclampsia, type IIb

THERAPY OF ITP IN PREGNANCY

Most women with ITP can be managed without great difficulty during pregnancy, although occasional patients experience severe exacerbations. The only contraindication of treatment during pregnancy involves the use of cytotoxic drugs having teratogenic potential during the first trimester. [249] Pregnancy does not alter the indications for maternal treatment, since platelet counts >30,000/l are considered safe for otherwise uncomplicated pregnancy and delivery. [250] Corticosteroids are the mainstay of treatment. Although adverse effects have been noted in some experimental and clinical studies, it is generally accepted that corticosteroids pose little risk to the human fetus even during the first trimester. [250] Refractory patients and those intolerant of prednisone can generally be managed with IVIG. [251] Splenectomy has been performed successfully during pregnancy,[252] but is rarely necessary. Experience with azathioprine during pregnancy for ITP is limited, although it has been used in other settings without clear evidence of teratogenicity. [250] Other drugs, including danazol and dapsone, should be avoided if possible, because far less is known about their potential effects on the fetus.

The major concern comes at the time of delivery. Platelet counts >50,000/l suffice for cesarean section [253] and it is probably wise to use this number as a guidepost for treatment during the third trimester, when emergent obstetrical indications occur more commonly. Some anesthesiologists require higher platelet counts to perform epidural anesthesia, although studies to support this position are lacking.

The other major goal of management is to prevent intracranial hemorrhage from occurring in a severely thrombocytopenic neonate during a difficult vaginal delivery.[254] [255] However, there is no generally accepted noninvasive means to identify neonates at risk, the benefits of cesarean section have not been proven to reduce the occurrence of ICH,[256] and the relative risks of newer interventional diagnostic and therapeutic measures may be even greater in some settings. [257] [258] Therefore, the best approach to managing delivery in women with ITP remains controversial. Initial studies suggesting that women with ITP are at high risk for severe neonatal thrombocytopenia may have been biased by the overinclusion of women first diagnosed after delivery of a clinically affected child. [259] The risk of severe neonatal thrombocytopenia, defined as <50,000/l, is now estimated to be 1015%, but the incidence of platelet count below 20,000/l is probably <5% and the risk of intracranial hemorrhage in the neonate is <1%. [243] [258] [260] Further, antenatal intracranial hemorrhage occurs rarely, [243] [253] [260] arguing against a role for maternal treatment of the fetus as has been proposed for alloimmune thrombocytopenia (see discussion later in this chapter).

Unfortunately, there is no noninvasive means by which the fetal platelet count can be predicted. No significant correlation between fetal and maternal platelet counts either before or after treatment has been found.[243] [248] [253] [256] [261] Severely thrombocytopenic neonates have been born to mothers with normal platelet counts before[262] or after splenectomy, [256] as well as to women who have responded to corticosteroids or IVIG.[248] [263] [264] The risk of severe neonatal thrombocytopenia appears higher if the mother has had a previously affected fetus.[265] It is possible to directly measure the neonatal platelet count before delivery by means of fetal scalp sampling[266] or by percutaneous umbilical blood sampling (PUBS).[248] However, neonatal platelet counts determined by fetal scalp sampling may be complicated by falsely low values resulting from platelet clumping, leading to unnecessary emergency cesarean sections unless the adequacy of the count is affirmed by direct inspection of the blood smear.[267] [268] The risk to the fetus of PUBS may exceed that of ICH even in the hands of a skilled operator [248] [253] [269] [270] and the procedure is now rarely performed for ITP in the United States. [243] [257] [258] There is also no direct evidence that cesarean section prevents ICH, although no affected children born by this route of delivery have been reported and some experts would recommend the procedure when severe neonatal thrombocytopenia has been documented.[2]

The neonatal platelet count commonly falls in the first few days postpartum, possibly related to the maturation of the fetal reticulo-endothelial cell system. [256] The fall is transient but may infrequently require treatment. Therefore, it is mandatory to obtain a radiological investigation to diagnose or to exclude ICH as soon after birth as possible in all severely thrombocytopenic neonates. Management with platelet transfusions, corticosteroids, and/or IVIG [271] should be instituted emergently pending the results of the study if there is any suspicion of bleeding, even in the absence of signs of neurologic impairment and even when the anterior fontanel is flat.

von Willebrand disease, or a previously undiagnosed congenital thrombocytopenic condition. The prevalence of these other disorders is likely to be higher among women with platelet counts <75,000/l and when thrombocytopenia is detected before the third trimester. Conventional antiglobulin tests do not distinguish ITP from gestational thrombocytopenia, although antigen capture assays may prove to be helpful. [247] Rigorous criteria for making the diagnosis have not been identified, especially at earlier time points in gestation, and the rare reported examples of neonatal thrombocytopenia occurring in women with presumed gestational thrombocytopenia may be examples of maternal ITP.[248]

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Clinical Presentation

Neonatal alloimmune thrombocytopenia (NAIT) is the platelet analogue of hemolytic disease of the newborn, although there are important differences in their natural history and management. NAIT occurs in 1 in 15,000 term pregnancies (approximately 8004000 cases per year in the United States), [272] [273] accounting for approximately 1020% of the total number of cases of neonatal thrombocytopenia. [272] [274] [275] The higher estimate is probably more accurate, as additional affected neonates with moderate thrombocytopenia are being identified as a result of greater awareness combined with the use of recently developed serologic techniques. In contrast to hemolytic disease of the newborn, almost half of the cases of NAIT occur during the first term pregnancy, [272] [276] although the incidence of prior miscarriage in these women is unknown.[272] Typically, the diagnosis is suspected when bleeding and severe thrombocytopenia occur in a neonate born after an otherwise uneventful pregnancy. ICH is common (1020%) and is fatal in up to 5% of cases. [272] [277] [278] The affected child may show signs and symptoms of hydrocephalus or porenchephaly as a result of ICH in utero in up to 10% of cases, [272] [278] [279] which may occasionally occur before the 30th week of gestation. [278] [280] [281] Thus, in contrast to neonatal thrombocytopenia caused by maternal ITP, NAIT is often severe and potentially life-threatening. [282] The platelet count may

continue to fall and bleeding may occur during the first several days after delivery, necessitating prompt diagnosis and management. [272] Thrombocytopenia typically persists for several days to 3 weeks.[274]

Pathogenesis

NAIT is caused by the transplacental passage of maternal alloantibodies against platelet antigens shared by the father and the fetus. Shed fetal platelet antigens can pass into the maternal circulation by the 14th week of gestation, [283] at which time the placenta has already developed the capacity to transport maternal antibodies to the fetus. Several biallelic antigen systems have been implicated. Most identified cases in whites occur in homozygous HPA-1b (PI^{A2}/PI^{A2}) mothers.[272] Most cases of NAIT due to anti-HPA-1a have been severe, as have the few cases attributable to alloantibodies against other determinants on platelet GP IIIa, i.e., anti-HPA-1b [284] and anti-HPA-4 (Yuk^a/Pen)[285] and GP IIb, i.e., anti-HPA-3a (Bak^a/Lek).[286] The clinical picture is generally milder in NAIT caused by anti-HPA-5a (Br^a), which accounts for 1520% of the cases of NAIT in Europe,[272] [287] presumably because platelets express far fewer copies of GP Ia/IIa complex on which the HPA-5 alleles are located. This difference may also contribute to the observations that more cases of NAIT caused by anti-HPA-5b (Br^a) occur for the first time in second or subsequent pregnancies than those caused by anti-HPA-1a and that as many as 60% of the neonates are asymptomatic at birth, [287] although two fatal cases have been reported.[272] [288] Too few cases of NAIT due to antibodies to other antigens [289] [290] [291] [292] [293] have been reported to estimate the risk of severe NAIT. The prevalence of ABO and HLA antibodies as a cause of NAIT remains unsettled, [294] although an association between anti-HLA antibodies and neonatal amegakaryocytic thrombocytopenia has been reported in a few patients. [274] [295] Additional novel alloantibody specificities will likely be identified in the future. These advances place additional demands on referral laboratories to acquire and maintain the appropriate roster of typed controls, reference sera, and DNA-based techniques for haplotyping. Serologic diagnosis of NAIT requires demonstrating parental platelet incompatibility and antiplatelet antibody in maternal serum of matching specificity.

Additional genetic factors modify the risk of NAIT in HPA-1b homozygous mothers. Neonatal thrombocytopenia occurs in only 16% of women who are homozygous for the HPA-1b allele and who carry an HPA-1a fetus.[272] [273] Production of anti-HPA-1a antibodies occurs predominantly in women who carry the HLA haplotype B8-DR3[296] [297] [298] and the supertypic determinant DRw52a, [299] [300] [301] in whom the incidence of NAIT exceeds 25%,[273] a relative risk 10- to 100-fold above HPA-1b/1b women with other HLA haplotypes. Genetic restriction in the development of anti-HPA-5a antibodies may exist as well. [302] These genetic linkages may have important implications in the management of relatives of affected women. Because fetal blood sampling may induce sensitization, it is our policy to test all HPA-1b/1b, Dw52a-positive women for anti-HPA-1a antibodies monthly and at 3638 weeks in cases when the childs father is HPA-1a positive. PUBS is then performed immediately if antibodies are detected.

Management of the Affected Child

The index case can be devastating and typically occurs without warning. Because ICH develops in 10% of affected neonates during the peripartum period and may extend in those with antenatal hemorrhage, immediate diagnosis and treatment are mandatory. The maternal platelet count should be documented as normal, although NAIT can occur coincidentally with ITP or other causes of thrombocytopenia. [303] [304] A neonate born with a platelet count <20,000/l should be presumed to have NAIT even if there is evidence of bacterial sepsis, disseminated intravascular coagulation, or congenital viral (herpes, CMV, varicella, rubella) or toxoplasma infections. NAIT should also be considered in any neonate with ICH, if there is a positive family history, or if thrombocytopenia is unexplained.

The urgency of treatment should be governed by the likelihood of ICH. If the ultrasound is normal and there is no clinical evidence of ICH, IVIG should be started, [272] [305] [306] [307] although responses can take 23 days. Corticosteroids provide marginal, if any, benefit and should not be used as the sole modality. [272] [288] [308] If ICH has occurred, then random donor platelets should be given for immediate benefit along with IVIG and corticosteroids while antigen negative, usually maternal, platelets are procured.[309] Although theoretically platelets should be washed to remove circulating alloantibody and resuspended in AB-positive plasma, in actual practice, maternal platelets can be administered safely after centrifugation. However, the platelets should be irradiated to lessen the risk of graft-versus-host disease. [310] A rise in the platelet count should be verified. Random donor platelets have been effective in cases shown subsequently to be due to anti-HPA-5b (Br^a), since approximately 80% of the population lack this antigen. Serologic studies should be performed on the parents to confirm the diagnosis because of the implications for subsequent pregnancies and the need for genetic counseling of other family members. Maternal antibodies that react with paternal platelets are generally demonstrable, although on occasion they may not be detected initially, presumably because of adsorption to fetal platelets. In up to 15% of typical cases, they may not be detectable at all.[272]

Management of Subsequent Pregnancies

The introduction of PUBS has permitted children at risk for severe thrombocytopenia and hemorrhage to be identified. An invasive approach is warranted, especially in cases of HPA-1a incompatibility[311] for several reasons: (1) severe thrombocytopenia occurs in >99% of subsequent pregnancies; (2) the majority of fetuses will be more severely affected than their previously affected sibling, and >50% will have initial platelet counts <20,000/l; (3) severe fetal thrombocytopenia occurs early, with 42% of patients having platelet counts <20,000/l by 24 weeks; (4) neither the presence nor the absence of alloantibody in the mother nor a change in antibody titer clearly predicts the neonatal platelet count; [273] [288] (5) up to one-half of the cases of ICH occur antenatally and, therefore, would not be prevented by elective cesarean section at term; (6) when treatment is withheld, fetal platelet counts commonly fall rapidly or remain very low during gestation; [312] and (7) effective antenatal treatment

is available.[311] [312]

Neonates at risk for NAIT during subsequent pregnancies should be identified. PUBS is probably warranted in all HPA-1a-negative women if the childs father is homozygous HPA-1a positive. Fetal genotypes can now be determined at 1018 weeks gestation using cells obtained by chorionic villus sampling or amniocentesis [313] [314] if the father is unknown, is unavailable for testing, or is heterozygous for the antigen in question. The fetal platelet count should be determined by PUBS as early as 2024 weeks gestation in women with a history of NAIT and an antigen-incompatible fetus. Maternal or antigen-negative platelets can be transfused to lessen the risk of hemorrhage from the procedure itself. The optimal approach for an HPA-1a-negative relative is less clear. Because fetal blood sampling can cause sensitization, it is our policy to obtain monthly antibody testing in women without a previously affected sibling and to restrict PUBS to those women with positive tests.

Two approaches to antenatal management of thrombocytopenic fetuses have been studied. The more aggressive approach, pursued primarily in several European centers, involves weekly transfusion of washed, irradiated, maternal antigen-matched

platelets in utero,[312] [315] starting as early as 2630 weeks gestation. [312] [316] This approach requires matched donors in addition to the mother because of transfusion frequency, although frozen maternal platelets have been used successfully. Each procedure also carries a risk of fetal exsanguination and side effects from transfusion[317] and is labor-intensive and costly. In the United States, it has become the practice to administer IVIG, 1g/kg/week, to the mother once an HPA-1a-positive fetus has been identified and thrombocytopenia has been documented. PUBS is repeated 46 weeks later to document response. [311] [318] In utero transfusion of maternal platelets is given during the procedure to guard against exsanguination of the thrombocytopenic fetus. [270] [312] [319] [320] Prednisone (1 mg/kg) is given in addition if a response is not seen. Therapy is begun at 12 weeks if there has been ICH during a prior pregnancy. IVIG has also been administered directly to the fetus in utero with limited success.[321] [322] In the authors experience, ICH has not been detected in any of the 73 fetuses managed in this way compared with an approximate 20% incidence during the index pregnancies.

POSTTRANSFUSION PURPURA

Introduction

Posttransfusion purpura (PTP) is an uncommon, acquired thrombocytopenia that develops approximately 1 week after blood transfusion. Plasmas from affected individuals contain alloantibodies to antigens expressed on intact platelets or on platelet membranes in the transfused blood. Through a mechanism yet to be defined, alloantibody production is accompanied by destruction of the recipients platelets. The temporal association of thrombocytopenia with blood transfusion was first described by Zucker et al.[323] and by van Loghmen et al. [324] A relationship between the development of platelet-specific isoantibodies and the consumption of host platelets was first suggested by Shulman et al.[325] The clinical course of untreated PTP is typically severe and protracted and may end in fatal hemorrhage. Therapy is rapidly effective in almost all cases, making an early, accurate diagnosis of this disorder imperative.

Clinical Presentation

The prototypic clinical presentation of PTP is now well-defined. The typical patient is a multiparous middle-aged female who presents with the acute onset of bleeding resulting from severe thrombocytopenia 1 week after the administration of a blood product containing platelet material. This may include fresh or stored whole blood, packed or washed red blood cells, or fresh or frozen plasma. In a recent retrospective analysis of 104 affected individuals, 99 were women with a mean age of 58.4 years.[326] Thrombocytopenia was first noted a mean of 68 days (range 114 days) after transfusion and platelet counts were found to be <10,000/l in over 80% of cases at presentation.[326] Approximately one-third of the patients reported having had chills or fever after the transfusion. In the absence of prior pregnancies, almost all of the remaining patients reported have had a history of previous exposure to blood through prior transfusions, [276] [327] suggesting that PTP occurs as part of an anamnestic immune response. PTP is therefore exceptionally rare in males or in nulliparous females who have no history of prior transfusion. [326] [327] [328] In these patients, the onset may be delayed (24 days), consistent with a primary immune response.[329] Subclinical cases have been reported,[330] [331] but the actual incidence of asymptomatic, milder forms of PTP is unknown. PTP after bone marrow transplantation has recently been described.[332]

On rare occasions, thrombocytopenia has developed within hours after transfusion of plasma, whole blood, or packed red blood cells. [333] [334] [335] In these cases, isoantibodies reactive with recipient platelets have been identified in the transfused blood product. In each case, the donor was a multiparous female, homozygous for an allele not found on the recipients platelets.

Pathogenesis

The pathogenesis of PTP remains unclear. The enigma is why the recipients platelets are destroyed by alloantibodies directed at a determinant they seemingly do not express. Any proposed explanation for this disorder must also account for the low incidence in susceptible individuals exposed to blood products known to contain the provoking antigen, the absence to date of the PTP syndrome in women whose pregnancies are complicated by NAIT due to alloantibodies with same apparent specificity, the prolonged duration of the thrombocytopenia, the reported lack of response to transfusion of antigen-negative platelets during the acute phase, [336] and the fact that the syndrome may or may not recur after inadvertent or deliberate re-exposure to antigen-mismatched blood products.[276] [330] [337]

It is known that serum from over 90% of patients with PTP contains antibodies to the platelet antigen Pl^{A1} (HPA-1a), which is expressed on the platelets of 9798% of the Caucasian population. The remaining cases have been associated with antibodies to the Pl^{A2} (HPA-1b) allele[326] [338] and other epitopes on platelet glycoproteins IIb-IIIa,[326] [338] [339] [340] [341] [342] or, less commonly, those found on another platelet surface protein.[343] Although in a few patients only antibodies directed to HLA determinants were detected,[326] [344] it is uncertain whether these were the actual cause of the PTP syndrome.[345] Despite the ease with which these isoantibodies are demonstrated in essentially every patient with PTP, their role in the destruction of autologous platelets is unproven. Indeed, in at least one instance, reinfusion of plasma obtained during the period of severe thrombocytopenia did not reproduce the syndrome.[325] Moreover, although alloantibodies with the same apparent specificity circulate in many women with NAIT, PTP has never developed concomitantly.

Another unanswered question is why PTP is a rare disorder. Based on the frequency of HPA-1b homozygous individuals, anti-HPA-1a antibodies would be expected to develop after 13% of random donor transfusions. One factor that may contribute to the lower than expected frequency is the apparent genetic restriction on the production of anti-HPA-1a antibodies. Development of PTP and NAIT is closely linked to the HLA B8 and DRw52 loci.[273] [296] [300] [346] Yet, only a single instance of sisters with PTP[347] and PTP occurring in a woman with a history of NAIT have been reported.[348] Therefore, additional factors, including the specifics of the anamnestic response (see discussion later in this chapter) may be required to develop severe thrombocytopenia and overt bleeding.

An increased amount of IgG and/or IgM has been detected on platelets of affected individuals during the thrombocytopenic episode. However, the composition and the antigen(s) recognized by the eluted immunoglobulin has not been identified. Three theories have been advanced for which at least some supportive experimental data has been obtained.

The initial hypothesis, proposed by Shulman and coworkers, was that donor platelets are lysed by a complement-dependent interaction between the alloantibody (e.g., anti-HPA-1a) and the transfused platelets, which releases antigen-antibody complexes into the circulation.[325] These complexes may then bind to HPA-1a-negative host platelets, possibly via Fc receptors, thereby perpetuating the destructive process. Such destruction of platelets in an antigen-independent manner by immune complexes might explain why transfusion with HPA-1a-negative platelets may be ineffective in acute cases. This hypothesis derived support initially from the failure to detect platelet autoantibody in plasma obtained when, or soon after, thrombocytopenia developed. More recently, immunoglobulin with anti-HPA-1a reactivity has been found in platelet eluates from affected patients for periods as long as 100 days after the acute

episode.[349] [350] In addition, reactivity of eluted immunoglobulin with autologous and other HPA-1-negative platelets has been noted, [349] [351] as would be expected if complexes were present and played a role in vivo. However, there has been no direct evidence to date that HPA-1a-anti-HPA-1a complexes are present in PTP sera or that these immune complexes can volley for several weeks between rapidly destroyed platelets and their replacements without themselves being cleared from the circulation. Nor has it been shown directly that sera or platelet eluates from affected individuals contain anti-HPA-1a complexed with specific antigen, and alternate explanations for the serologic activity of the eluates have been proposed (see discussion later in this chapter).

A second, interrelated hypothesis is that the HPA-1a antigen, released into plasma from lysed donor platelets, binds specifically and with high avidity to antigen-negative platelets. This interaction may permit HPA-1a containing immune complexes to bind to platelets initially through a site on the antigen itself, and this binding may then be stabilized through secondary interactions with platelet Fc receptors, or the immune complexes may form in situ. Only during an anamnestic

response would sufficient alloantibody and donor platelet antigens be found coincidentally in the host to initiate the syndrome. The interaction of HPA-1a antigen with the platelet membrane may also explain why such complexes are not more rapidly cleared by tissue macrophages. In support of this hypothesis, soluble HPA-1a antigen has been detected in plasma, and antigen negative platelets incubated with this material acquire the capacity to bind anti-HPA-1a antibody. [352] [353] The biochemical basis of this interaction is unknown and it is possible that the HPA-1a antigen circulates and binds to platelets as microparticles. [354] [355] Theoretically, recycling of the antigen and/or antigen-antibody complexes from destroyed to newly synthesized platelets would prolong antigen expression on the host platelets for longer than might otherwise be expected. It has been deduced that binding of <5% of the amount of soluble HPA-1a antigen estimated to be present in a single unit of blood would permit sufficient alloantibody to bind and destroy all of the circulating platelets in vivo. [356] [357] Sufficient circulating antigen-antibody complexes would remain to perpetuate this level of sensitization of the markedly reduced number of residual platelets after the first round of destruction. [356] Although measurable amounts of HPA-1a antigen have been detected in PTP plasma during the acute phase of the syndrome, [356] [357] it remains to be proven that HPA-1a antigen is present on host platelets complexed with anti-HPA-1a antibody in vivo during the period of thrombocytopenia.

An equally compelling case can be made for a third possibility, that a subset of anti-HPA-1a antibodies cross-react with undefined determinants on HPA-1b platelets.[358] Although the HPA-1a and 1b antigens differ at a single amino acid, the epitope recognized by naturally occurring anti-HPA-1a antibodies is not composed of a linear amino acid sequence. Rather, the amino acid substitution induces a conformational change within the glycoprotein IIb-IIIa complex that generates a distinct neoepitope.[359] [360] In some patients, a variable proportion of anti-HPA-1a antibodies formed against this neoantigen may cross-react with the backbone structure of glycoprotein IIIa. The alternative is that autoantibodies directed at entirely different epitopes may be generated coincidentally. There are several pieces of evidence in support of this possibility. First, in certain experimental models, animals immunized with allogeneic or xenogenic platelet or erythrocyte antigens produce autoreactive antibodies, and occasionally develop immune destruction of the sensitized host cells. [361] [362] [363] In the best-studied example, a substantial proportion of marmosets sensitized to platelets from another species developed acute, persistent (30100 days) immune thrombocytopenia several weeks after immunization. Platelet eluates from the affected animals contained both autoreactive as well as anti-donor-specific antibodies. [364] Second, autoreactive anti-erythrocyte antibodies have been detected after transfusion [362] [363] [365] [366] or experimental sensitization to heterologous or alloantigens, [361] in some cases accompanied by overt hemolysis.[363] [365] [366] Such antibodies may persist beyond the expected life span of the transfused red cells. [363] [367] Finally, serum and platelet eluates from some individuals with PTP have been found to contain immunoglobulin reactive with autologous platelets and platelets presumably totally lacking in glycoprotein IIb-IIIa.[368] A similar finding has been reported in HPA-1a-negative women sensitized during pregnancy. [351]

The hypothesis that only a subset of alloantibodies cross-react with autologous platelets is consistent with: (1) the infrequent occurrence of overt PTP in HPA-1-negative patients exposed or re-exposed to blood products containing the antigen; (2) the absence of the PTP syndrome in HPA-1a-negative mothers with NAIT; (3) the prolonged course of thrombocytopenia in the absence of treatment; and (4) the presence of anti-HPA-1a reactivity in eluates from autologous platelets and those congenitally lacking platelet glycoprotein IIIa. However, none of these clinical and serologic observations exclude the role of HPA-1a-antibody complexes. It is also possible that the alloantibodies recognize an epitope that is only generated in vivo. To date, the inability to obtain sufficient $F(ab)_2$ fragments of immunoglobulin from in vivo eluates in the presence of profound thrombocytopenia has precluded definitive analysis of the pathologic antibody.

Diagnosis

PTP should be suspected in any patient who develops severe thrombocytopenia approximately 1 week after transfusion. Suspicion is heightened if the patients plasma is capable of lysing platelets from random normal donors, because few other conditions, other than quinidine purpura or the presence of multiple HLA antibodies, are associated with lytic antibodies. Treatment must be initiated immediately based on clinical criteria, because it generally takes several days until the results of confirmatory tests become available.

The presence of alloantibodies to platelet proteins can be demonstrated by Western blotting or an antigen-capture assay. The diagnosis is generally confirmed by demonstrating that serum from the affected patient contains antibodies to a specific alloantigen, this is, binding of antibody to platelets containing, but not to those lacking, a specific antigen. This is generally accomplished by an antiglobulin test such as immunofluorescence assay or ELISA, or by demonstrating lysis of stored, frozen platelets obtained from known antigen positive donors. Upon recovery, the patients platelets can be phenotyped using reference sera that contain antibodies of known specificity. Typically, platelets obtained from the patient upon recovery will not aggregate or lyse when incubated with plasma obtained during the acute phase. This inability to reproduce the syndrome in vitro, the sine qua non of the PTP syndrome, is the basis of the uncertainty as to the pathogenesis of this syndrome discussed in the previous section.

Treatment

The clinical course of untreated or nonresponsive patients is typically prolonged. In the series cited earlier, bleeding lasted a mean of 10.2 days. [326] It took a mean of 14.6 days until the platelet count exceeded 50,000/l (range 390), and 19.5 days until it exceeded 100,000/l (3130). Thrombocytopenia has been reported to last as long as 60120 days.[330] [369] [370] Fatality rates as high as 10% were reported before effective therapy was identified. [276] [336] [371] [372] [373] Therefore, immediate diagnosis and intervention must be made once the disorder is suspected clinically.

The treatment of choice is intravenous immunoglobulin

(IVIG) 1 g/kg/day for 2 days, although a second course may be required in some patients.[374] Over 90% of the reported patients have responded, generally beginning within 23 days of treatment.[326] [370] [374] Therefore, IVIG has replaced plasmapheresis [375] and exchange transfusion[325] [376] as the initial treatment of choice, both because of its somewhat higher response rate and its ease of administration. Although occasional patients respond to corticosteroids given as a single agent, [377] [378] [379] [380] most do not,[326] [371] and steroids should be considered to have an adjunctive role, if any, in treatment. A single response to splenectomy in a refractory patient has been reported.[381] Recurrent thrombocytopenia may occur within days of stopping treatment; however, these relapses are generally milder and more easily managed than the initial episode. [357] [370] [374]

The role of prophylactic platelet transfusions in patients with profound thrombocytopenia but non-life-threatening bleeding is unclear. Sera from affected patients commonly contains antibodies to multiple HLA determinants, making provision of antigen matched platelets problematic. Administration of random donor platelets, which is commonly associated with moderate to severe transfusion reactions including bronchospasm and hypotension, rarely succeeds in raising the platelet count, and theoretically may perpetuate the disease. [323] [324] [325] [326] [382] Even when antigen-matched platelets can be procured in time, they may[276] [336] [383] or may not[384] [385] suffer the same fate as the patients own antigen-negative cells.

Anti-HPA-1a antibodies may persist for over a year after the initial episode. [386] It has been theorized by some that persistence of high antibody titers may protect against recurrence by immediately destroying potentially sensitizing platelets, thereby precluding coincidence of circulating antigen at the time of an anamnestic response.[276] Exposure [350] or re-exposure[325] [357] to blood products containing the relevant antigen does not invariably provoke PTP, but recurrences have been reported.[330] [337] [357] [387] Therefore, most experts recommend limiting the exposure of affected individuals by transfusing only antigen-matched (including autologous) blood products on subsequent occasions.[326] Whether current techniques of washing and filtering erythrocytes or the use of frozen, thawed, and washed red cells remove sufficient platelet antigen to prevent recurrence is unknown. [387] [388] It is not known whether the risk of PTP developing in unaffected multiparous or previously transfused siblings that share HLA haplotypes is sufficient to recommend similar restrictions on the source of transfused blood products. The risk of PTP developing in women whose pregnancies were complicated by NAIT appears sufficiently low that only awareness and close monitoring of platelet counts after transfusion appears warranted.

Chapter 127 - Thrombocytopenia Due to Decreased Platelet Production

Samuel A. Burstein

An estimated 15×10^6 megakaryocytes/kg body weight, averaging 12×10^3 fl in volume, produce approximately 1,0001,500 platelets each. [1] When measured as platelet turnover (calculated by dividing the platelet count by the platelet survival time and correcting for splenic pooling), most of the megakaryocyte cytoplasm is delivered to the circulation as platelets (effective platelet production). [2] In disease states, decreased platelet production is due either to a decrease in the megakaryocyte mass (virtually always a decrease in the number of megakaryocytes) or to a failure of delivery of an appropriate number of viable platelets by an adequate megakaryocyte cytoplasmic mass, a process termed *ineffective platelet production*[2] (Fig. 127-1). Table 127-1 shows typical kinetic characteristics for some of these disorders.

A decrease in numbers of megakaryocytes may be due to direct toxicity or damage to their immediate progenitors, the megakaryocyte colony-forming unit (CFU-Mk) or their precursors, the megakaryocyte burst-forming unit (BFU-Mk; see Chap. 17). Damage to more primitive stem cells (or to the regulatory mechanisms promoting their growth) would give rise to multilineage cytopenias (see Chap. 19).

Abnormalities of growth factors or growth factor pathways that promote commitment, proliferation, or differentiation of BFU-Mk, CFU-Mk, or their progeny may also be involved in the pathogenesis of platelet production abnormalities. The

Figure 127-1 Ineffective platelet production. In thrombocytopenia, the relationship between marrow megakaryocyte cytoplasmic mass and the turnover of platelet mass in the peripheral blood is usually direct. Platelet mass turnover represents the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes. The results in normal subjects are indicated by the arrow, and the stippled area represents 95% confidence limits in thrombocytopenic patients with effective production. Ineffective thrombocytopoiesis is identified as a disparity between available marrow substrate (megakaryocyte cytoplasmic mass) and delivery of platelet mass to the peripheral blood (platelet mass turnover). Results in patients with autosomal dominant thrombocytopenia (open circles), Wiskott-Aldrich syndrome (open triangles), megaloblastic anemia (open squares), and preleukemia (closed triangles) are characterized by ineffective platelet production. *(From Thompson A, Harker L: Quantitative platelet disorders. In Manual of Hemostasis and Thrombosis. FA Davis, Philadelphia, 1983, p. 65, with permission.)*

availability of assays for thrombopoietin (TPO) and other cytokines that may be involved in platelet production permits a better assessment of humoral involvement in production thrombocytopenia.[3] [4] For example, recent studies have suggested that the thrombocytopenia often accompanying cirrhosis may in part be due to TPO deficiency, although the data remain equivocal. [5] [6] [7]

Classically, the diagnosis of thrombocytopenia due to decreased platelet production depends on a bone marrow examination to assess the quantity and quality of the megakaryocytes. Noninvasive methods to assess platelet production have been described, although they are not in common use. The serum concentration of the glycocalicin fragment of glycoprotein (GP) Ib, released into the plasma at thrombocytopoiesis, has been shown to be significantly below the normal range in patients with production thrombocytopenia.[8] [9] Another method is theoretically based on the content of residual RNA in platelets that have recently entered into the circulation (analogous to the reticulocyte count). This may be detectable by flow cytometry using fluorescent dyes, such as thiazole orange, that bind to the RNA. Thus, fewer platelets would be expected to be positive for RNA if platelet production were decreased. [10] [11] Another approach to measure platelet production indirectly is measurement of TPO levels. TPO would be expected to be increased in patients with a platelet production deficit, and several studies have shown this to be the case.[9] [12] [13] [14] [15] Concurrent measurements of TPO concentration together with glycocalicin or thiazole orange binding may prove to be of value. [9] However, significant technical constraints remain in the reliable quantitation of thiazole orange binding to platelet RNA, and the physiology and normal range of blood TPO levels in various disease states remain to be elaborated.

ACQUIRED PRODUCTION DISORDERS

Platelet production abnormalities may be divided arbitrarily into acquired and hereditary disorders.

Marrow Infiltration

Production disorders are commonly observed when the marrow is involved with metastatic cancer, lymphoma, or leukemia. Table 127-2 categorizes the infiltrative processes associated with thrombocytopenia. Although physical replacement of marrow is the etiology of the thrombocytopenia in many cases, it is also possible that inhibitory factors produced by the infiltrating cells are toxic to the cells of the megakaryocytic lineage or interfere with normal regulatory mechanisms. The diagnosis of infiltrative disease is made by marrow examination, although diagnostic clues are usually provided by history, physical examination, and a leukoerythroblastic blood smear. The marrow shows decreased megakaryocytes, which may be larger than normal because of a compensatory physiologic response to the thrombocytopenia. The treatment approach is specific to the infiltrative process.

Chemotherapy and Irradiation

Direct destruction of megakaryocytes, their progenitors, or both can be observed after administration of chemotherapeutic

TABLE 127-1 -- Typical Kinetic Profiles in Patients with Thrombocytopenia Due to Production Abnormalities

Category	Megakaryocytes			Platelets			
	Cell No. ($\times 10^6$ /kg)	Cytoplasmic Volume (fl)	Cytoplasmic Mass ($\times$ 1011 fl/kg)	Concentration (platelets/mm^6)	Volume (fl)	Survival (days)	Mass Turnover ($\times 10^5$ fl/mm^3 /day)
Normal	15 ± 4	12,000 ± 1,700	1.8 ± 0.4	250,000 ± 40,000	8.7 ± 0.8	9.6 ± 0.6	3.2 ± 0.5
Decreased megakaryocytopoiesisdamaged marrow	r2	14,000	0.3	22,000	9.1	5.2	0.7
Ineffective production							
Autosomal dominant	49	9,400	4.6	64,000	8.9	8.4	1.1

agents or irradiation. Thrombocytopenia is one of the most frequent adverse effects of total body irradiation. [16] After either allogeneic or autologous marrow transplantation, thrombocytopenia may persist despite resolution of leukopenia and anemia. The etiology of prolonged thrombocytopenia after transplantation is unclear; it may be multifactorial (e.g., graft-versus-host disease, infections), but decreased production is likely important in some cases. [17] Transplantation with peripheral blood stem cells may improve the rate of platelet recovery compared with marrow transplantation, but thrombocytopenia remains a problem. [18] Transplantation of umbilical cord stem cells is associated with delayed platelet recovery; in 39 pediatric patients receiving such transplants, the median time to recovery was 49 days (range, 15117 days).[19]

Isolated thrombocytopenia with decreased megakaryocytes has been reported after chemotherapy for acute myeloid leukemia. Cyclosporine may augment the platelet count in such patients.[20]

Agents that are more likely to induce leukopenia usually induce thrombocytopenia as well. Alkylating agents in general produce more prolonged thrombocytopenia than do antimetabolites. Although it has been claimed that some alkylating agents are sparing of the megakaryocytes (e.g., cyclophosphamide), this is a relative phenomenon; conceivably, agents such as busulfan, the nitrosoureas, or platinum cause cumulative damage in the more primitive progenitors. Other chemotherapeutic agents, such as the vinca alkaloids, may not decrease the platelet count significantly.

Reducing the intensity of the chemotherapy dose remains the most appropriate approach to management, although in the near future hematopoietic growth factors that enhance thrombocytopoiesis may prove to be of value in these patients. A TPO derivative, pegylated megakaryocyte growth and development factor (MGDF), has been administered to 38 patients with lung cancer who received the agent after treatment with carboplatin

Osteopetrosis

and paclitaxel in a randomized, double-blinded trial. In the treated patients, the nadir platelet count was 188,000/mm ^{3} , whereas it was 111,000/mm^3 in 12 control patients receiving placebo. The platelet count returned to baseline levels in the treated patients in 14 days, whereas the control patients required 21 days. [21] Another study using the same TPO derivative was performed in 41 patients with a variety of advanced cancers treated with carboplatin and cyclophosphamide. In this study, patients also received granulocyte colony-stimulating factor. The platelet nadir occurred earlier in patients given MGDF, although there was no difference in the depth of the nadir. Recovery to the baseline platelet count was observed by day 17 in the treated patients, compared with day 22 in the placebo group. Moreover, patients who had previously received MGDF recovered their platelet counts more rapidly. [22]

Other cytokines, including interleukin-1 (IL-1), [23] IL-3,[24] IL-6,[25] IL-11,[26] and IL-3/granulocyte/macrophage colony-stimulating factor (GM-CSF) fusion protein [27] have been shown to enhance the platelet count in patients receiving chemotherapy. It is possible that these broadly acting cytokines may prove to be of value in augmenting hemostasis and reconstituting other cell lineages. Nonetheless, it has not yet been shown that the capacity of TPO and other cytokines to augment the platelet count after chemotherapy will diminish bleeding in patients with marked thrombocytopenia.

It is possible that drugs other than growth factors may ameliorate chemotherapy-induced thrombocytopenia. Studies with amifostine, a precursor of a thiol compound, suggest a reduction in thrombocytopenia in some patients. [28] Additional clinical trials are required to investigate the general utility of this approach, whose mechanism of action is unclear. Beyond attempts to raise the platelet count with cytokines or other drugs, amelioration of the bleeding tendency may be achievable by augmentation of other aspects of the hemostatic system. epsilon-Aminocaproic acid may be of benefit in some patients with refractory thrombocytopenia and bleeding.[29]

Ethanol-Related Disorders

Thrombocytopenia is the most common hematologic abnormality in severe alcoholism [30] (see Chap. 148). In one analysis, alcohol was a contributing factor in 26% of patients admitted to hospitals with a platelet count of <100,000/mm ^{3} . Alcohol abuse may result in thrombocytopenia due to several mechanisms, including ineffective production related to folate deficiency (which may lead to severe thrombocytopenia) and increased splenic pooling due to portal hypertension (which usually results in a modest decline in platelets). Ingestion of alcohol inhibits the expected response to thrombocytopenia induced by plateletpheresis. [31] A mild shortening of platelet survival has

been reported.[32] However, ethanol itself can be directly toxic to the marrow. [33] [34] In vitro studies have shown that alcohol concentrations achievable in vivo inhibit megakaryocyte maturation but do not inhibit megakaryocyte colony formation. [34] [35] Megakaryocyte numbers usually are normal, but markedly decreased megakaryocytes have been observed. In one such case, labeling with platelet-specific antibodies demonstrated that numerous, small, unidentifiable cells were immature megakaryocytes.[35] Rarely, marrow panhypoplasia has been observed in association with alcohol ingestion. [36] Anemia and macrocytosis accompanied by megaloblastic changes and ringed sideroblasts in the erythroid marrow are commonly noted in association with ethanol abuse. However, the severity of the anemia shows no correlation with the thrombocytopenia.[30] Treatment consists of withdrawal of ethanol and administration of a normal diet. Recovery of the platelet count, often with a rebound thrombocytosis, usually occurs within 2 weeks.

Viruses

Mild thrombocytopenia is frequently associated with viral infection. [37] Although the pathophysiologic mechanisms have not been systematically sought, a production deficit is probably important in the etiology of many of the cases. Megakaryocytes are capable of harboring a variety of viruses, although viral entry into megakaryocytes is not well understood. Infected marrow may exhibit dysmorphic megakaryocytes containing inclusion bodies, vacuoles, or degenerating nuclei, or show naked nuclei. Thrombocytopenia has been reported in mumps, rubella, measles, varicella, cytomegalovirus, infectious mononucleosis, chickenpox, dengue and other hemorrhagic fevers, hepatitis, and parvovirus infections. [38] [39] [40] [41] Live measles virus vaccination can also induce thrombocytopenia due to decreased production.[42]

Human Immunodeficiency Virus (HIV)

Thrombocytopenia after human immunodeficiency virus (HIV) infection is a common complication (see Chap. 155). Almost one half of adults and one fourth of children with hemophilia exhibit a decreased platelet count within 10 years after seroconversion. [43] The thrombocytopenia may be due both to immune mechanisms and to a decrease in platelet production (see Chap. 129). Production thrombocytopenia may be related directly to HIV infection, adverse effects of drug therapy, or to secondary malignancy or myelodysplasia. Platelet kinetic studies have shown that patients infected with HIV have a moderate reduction in platelet survival, but all have decreased platelet production regardless of the degree of thrombocytopenia. [44] A retrospective study of 85 patients with HIV and thrombocytopenia suggested that in early stages of infection, platelet destruction is predominant, whereas in patients with full-blown acquired immunodeficiency syndrome, thrombocytopenia is more often due to a production deficit. [45] Based on the finding of HIV mRNA and p24 antigen in megakaryocytic cytoplasm, [46] [47] [48] HIV has been shown to infect megakaryocytes directly, perhaps through megakaryocyte surface CD4. [49] [50] Morphologic abnormalities of megakaryocytes, including denuded nuclei, [51] together with growth anomalies of progenitor cells in culture have also been observed in patients with HIV, [52] [53] supporting a direct effect of the virus on megakaryocytopoiesis. Apoptosis of GP IIb/IIIa+ marrow cells has been suggested as an additional mechanism of impaired platelet production that may be independent of either direct megakaryocyte infection or CD4 count. [54] Isolated amegakaryocytic thrombocytopenia has been observed in a child with HIV. [55] Treatment with zidovudine has been shown to increase platelet production in some patients with HIV. [56] [57] The mechanism for this effect is controversial, with one kinetic study suggesting that the drug augments

INVESTIGATION OF DECREASED PLATELET PRODUCTION

Suspicion of thrombocytopenia due to decreased production should be provoked by a history of irradiation or chemotherapy, thrombocytopenia present at birth or in early infancy in the presence of a normal maternal platelet count, a family history of thrombocytopenia, concurrent anemia, leukopenia, or both, and alcohol abuse. A careful physical examination may suggest a production disorder if signs of alcohol-related liver disease or a hematologic malignancy are present. Although the thrombocytopenia due to splenomegaly is not related to a production abnormality, splenomegaly is often observed as a feature of portal hypertension, lymphoma, or other processes associated with marrow damage, and it may be a concurrent pathophysiologic mechanism of the thrombocytopenia.

The peripheral blood smear is critical to rule out pseudothrombocytopenia (see Chap. 126). Moreover, the blood smear provides additional clues to both the pathophysiologic mechanism of the thrombocytopenia and the diagnosis. For example, giant platelets suggest a hereditary or myelodysplastic syndrome; oval macrocytosis and hypersegmented neutrophils suggest folate or vitamin B_{12} deficiency; and a leukoerythroblastic smear points to an infiltrative process.

A marrow examination is required to evaluate the megakaryocytes. A biopsy is more reliable than an aspirate to determine whether megakaryocytes are decreased. However, an aspirate showing abundant megakaryocytes in the presence of thrombocytopenia is sufficient to suggest platelet destruction or ineffective production. Unfortunately, no clear guidelines are available to determine precisely what defines a decreased or increased number of megakaryocytes. Megakaryocyte morphology is occasionally valuable. The normal compensatory response to thrombocytopenia is enlargement of the cells with increased ploidy. Small, microlobulated, or hypolobulated megakaryocytes may be seen in myelodysplastic syndromes. Dysmorphic megakaryocytes may be also observed in viral infections, including HIV. In the future, flow cytometry may provide a more objective analysis of megakaryocytes.

Establishment of the pathologic process of ineffective production is one of exclusion. The marrow examination reveals quantitatively normal megakaryocytes, and the apparent absence of peripheral platelet destruction together with the appropriate clinical circumstances (e.g., folate or vitamin B_{12} deficiency) often points to this mechanism. The bleeding time, although not a useful measurement to predict the propensity for bleeding, may be helpful in distinguishing ineffective production from platelet destruction. In destructive processes such as immune thrombocytopenia, the bleeding time may be shorter than predicted on the basis of the platelet count alone, whereas in ineffective platelet production, the bleeding time is more often related to the platelet count. In complex cases, platelet survival studies may be necessary to show that consumption or splenic pooling are not significant contributors to the thrombocytopenia; however, survival studies are rarely required for clinical purposes. In the future, flow cytometric estimation of platelet production rate and measurement of TPO levels may permit a more facile approach to the differential diagnosis of thrombocytopenia.

platelet production,[44] and another claiming that it decreases production.[45] The specific role of other antiretroviral agents in HIV-related production thrombocytopenia has not been elucidated. Interferon- has been shown to increase the platelet count in zidovudine-resistant HIV-related thrombocytopenia.[58]

Drug-Related Disorders

A variety of drugs and toxins have been implicated in the etiology of aplastic anemia (see Chap. 19); several have been implicated in isolated thrombocytopenia believed to be due to a production deficit. Estrogen was reported to decrease platelet counts;[59] although megakaryocytes possess the estrogen receptor,[60] detailed thrombokinetic studies have not been carried out. Thrombocytopenia due to thiazide diuretics has been reported frequently.[61] Although the etiology in most cases is probably destructive, decreased megakaryocytes have been noted.[62] Chemotherapy may result in prolonged thrombocytopenia that may be isolated.[63] Interferons and IL-2 may induce thrombocytopenia, perhaps the result of inhibited megakaryocytic colony formation.[64] [65] Anagrelide, an agent used to lower the platelet count in patients with malignant thrombocytosis, appears to operate by reducing megakaryocyte size and ploidy, and by disrupting maturation.[66]

Folate and Vitamin B12 Deficiency

Varying degrees of thrombocytopenia may be observed with either folate or vitamin B_{12} deficiency; in some cases it may be severe[67] [68] (see Chap. 28). The pathophysiologic mechanism is ineffective production[1] because megakaryocyte numbers are normal or increased in the marrow, and platelet survival is normal or slightly shortened.[69] Amegakaryocytic thrombocytopenia has been reported in vitamin B_{12} deficiency.[70] Folate deficiency is frequently associated with ethanol abuse; the etiology of the thrombocytopenia may be more complex in these patients.

The blood may show macrocytosis and hypersegmented neutrophils in addition to the thrombocytopenia. Platelets are morphologically normal, but the count is variably decreased. Extremely severe thrombocytopenia may be observed. Often (but not necessarily), the marrow shows megaloblastic changes in the erythroid and myeloid lineages, as well as normal numbers of megakaryocytes, some of which may appear large. Although multiple disconnected nuclear lobulations have been described,[71] distinctive morphologic abnormalities of the megakaryocytes are not often apparent. Rapid recovery of the platelet count can be achieved with administration of the appropriate vitamin or by abstention from ethanol intake.

Iron Deficiency

Although thrombocytosis develops in most patients with iron deficiency, rare patients become thrombocytopenic.[72] In some instances, this is accompanied by decreased megakaryocytes.[73] Recovery of the platelet count has been observed with iron replacement,[73] [74] whereas induction of thrombocytopenia during iron therapy has been reported.[75] Hypotheses have been presented concerning the role of iron in platelet production,[76] but little investigation has been performed in this area.

Acquired Aplastic Anemia

Aplastic anemia involves multiple hematopoietic lineages, although isolated thrombocytopenia can be the presenting feature.[77] Many of the same pathogenetic

mechanisms seem to be operative in aplastic anemia and isolated amegakaryocytic thrombocytopenia (see later). TPO levels have been shown to be elevated in patients with aplastic anemia[12] (aplastic anemia is discussed in Chap. 19).

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal disorder resulting from mutations in the X-linked gene *PIG-A* that encodes for an enzyme required in the initial step of biosynthesis of glycosylphosphatidylinositol anchors (PNH is discussed in Chap. 20). Approximately 25% of patients with PNH have significant marrow aplasia.[78] Thrombocytopenia at diagnosis is a poor prognostic indicator. [79] Because platelet survival is usually normal in PNH, [80] the mechanism of the thrombocytopenia is decreased or ineffective production. Megakaryocyte progenitors show decreased proliferative activity and exhibit increased sensitivity to complement.[81] [82] Treatment with antithymocyte globulin or granulocyte colony-stimulating factor and cyclosporine has ameliorated the thrombocytopenia in some patients,[83] [84] whereas marrow transplantation has resulted in long-term remissions in patients with aplasia associated with PNH. [85]

Acquired Pure Amegakaryocytic Thrombocytopenic Purpura

Acquired pure amegakaryocytic thrombocytopenic purpura is a rare disorder that may be analogous to other isolated unicellular marrow aplasias. The pathognomonic finding is a normal bone marrow biopsy with markedly decreased or absent megakaryocytes. Platelet survival is normal in these patients, and the platelet counts reflect the degree of megakaryocytic hypoplasia. Amegakaryocytic thrombocytopenia may be a harbinger of aplastic anemia [86] or a presenting finding of lymphoma.[87] The pathogenetic mechanisms underlying this disorder are diverse and may be related to drugs or toxins, viruses, cytokine anomalies, and humoral or cell-mediated megakaryocyte suppression.[88] [89] [90] The Philadelphia chromosome has been described in a patient with this disorder in whom marrow aplasia subsequently developed.[91] TPO levels in pure amegakaryocytic thrombocytopenia have been reported as high. [92]

Patients present with bleeding manifestations due to severe thrombocytopenia. Macrocytosis is seen in almost all patients, presumably due to reticulocytosis, related to acute blood loss anemia, but other abnormalities of the peripheral blood are not typically seen. Except for the absence of megakaryocytes, the marrow shows normal cellularity. A decrease in megakaryocytic colony growth may be noted; it may be corrected by removal of an inhibitory cell population or antibody. [89] [90]

Because the causes of this disorder are multiple, the natural history and therapeutic approach depend on the specific etiology. Determination of the pathophysiologic mechanisms with megakaryocyte progenitor cell assays may be useful in guiding treatment because humoral or cell-mediated abnormalities may be discerned with these methods.[89] [93] In the absence of these uncommonly available laboratory studies, management is approached on an empiric basis.

If the etiology is viral, intravenous IgG or anti-HIV therapies are indicated. [88] In the rare patient with isolated amegakaryocytic thrombocytopenia due to ethanol or drugs, avoidance of the offending agent is indicated. Cytotoxic antibodies directed toward the CFU-Mk may be approached with corticosteroids, plasmapheresis, intravenous IgG, danazol, cyclosporine, or cyclophosphamide. [88] In a patient in whom an IgG antibody was found to be blocking GM-CSF action, a complete response to cyclophosphamide was observed.[93] Patients with T-cell mediated inhibition of megakaryocytopoiesis may respond to antithymocyte globulin, cyclosporine, or hematopoietic growth factors.[88] Despite the varied etiologies of this disorder, a review

of 30 patients found that sustained remissions were achieved in 8 patients with immunosuppressive agents. [94] Nonetheless, most patients do not respond to treatment, and intensive immunosuppressive therapy may not prevent progression to aplastic anemia. [86]

Refractory Thrombocytopenia Due to Myelodysplasia

A small proportion of patients (as low as 0.6%) with the myelodysplastic syndrome present with isolated thrombocytopeniadesignated *refractory thrombocytopenia*.[95] Clonal chromosomal abnormalities are required to confirm the diagnosis, with chromosomes 3, 5, 8, or 20 most commonly involved, but partial deletions of other chromosomes have been reported.[96] The usual laboratory findings include macrocytosis of platelets and red cells. Abnormal megakaryocyte morphology, typically mononuclear megakaryocytes, is often observed,[95] sometimes in combination with an increased number of megakaryocytes.[97] Dysmorphic erythroblasts or myeloid cells may also be noted. The clinical course of these patients is the progressive development of additional cytopenias and the myelodysplastic syndrome, with a significant number evolving into acute myeloid leukemia. [95] Therapy has not been shown to be beneficial. Some patients with a full-blown myelodysplastic syndrome associated with marked thrombocytopenia and <10% blasts have shown an increase in platelet count after androgen therapy. [98] Because some of these cases have been misdiagnosed and treated for idiopathic thrombocytopenic purpura (ITP), recognition of this uncommon syndrome is important. [97]

Cyclic Thrombocytopenia

Cyclic oscillations in the platelet count have been observed occasionally. Occurring predominantly in women, these fluctuations can result in thrombocytopenia sufficiently severe to result in bleeding. [99] Most frequently, the cycling occurs in association with the menstrual cycle. It is likely that a production abnormality is not the pathophysiologic mechanism for the thrombocytopenia in most patients with this disorder, and that circulating autoantibodies may be important. [100] [101] A study of 10 patients with cyclic thrombocytopenia suggested varied etiologies of the thrombocytopenia, with cyclic variations in platelet production being responsible for some cases, including the two male patients in that group.[102] The possibility that fluctuating cytokine levels may contribute to the pathogenesis of the disorder has been raised by several studies, although it is difficult to discern cause from effect. [103] [104] [105] Cyclic thrombocytopenia may rarely be a presenting manifestation of myelodysplasia. [106] Treatment has been variable; responses to low-dose contraceptives and intravenous gamma-globulin have been reported. [101] [107]

CONGENITAL OR HEREDITARY PRODUCTION DISORDERS

Thrombocytopenia due to decreased platelet production in the newborn is uncommon, accounting for <5% of neonatal thrombocytopenia. [108] Most of the thrombocytopenic disorders that are referred to as congenital have a genetic basis, although some may be acquired in the perinatal period (e.g., congenital rubella). [109]

Congenital Aplastic Anemia Syndromes

Congenital aplastic anemia, Fanconis anemia, and other syndromes associated with failure of several hematopoietic lineages are discussed in Chapters 18 , 19 , 20 . These syndromes occasionally present with thrombocytopenia, [110] but it soon becomes apparent that other lineages are involved.

Congenital Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia is a rare disorder of infancy and early childhood of unknown etiology. The inheritance pattern is mixed, with some of the cases being X-linked; others are autosomal recessive. [110] Approximately 40% of affected patients have somatic anomalies fitting no other congenital syndrome. [110] Patients present with isolated severe thrombocytopenia with normal marrow cellularity, but scant or no megakaryocytes. Platelet survival is normal. Anemia and macrocytosis are commonly observed; occasionally hemoglobin F is elevated. [111] The disorder may be an intrinsic stem cell defect because the marrow microenvironment appears to be normal. [112] In four of five cases analyzed, CFU-Mkderived colonies were very low in number, but increased in the presence of IL-3, GM-CSF, or both, although not to normal levels. [113] Studies in a single patient suggest that the response of megakaryocytic progenitors to TPO is defective (despite an elevation in serum TPO level), perhaps due to impaired expression of the TPO receptor mpl. [114] These findings suggest that therapeutic use of TPO would not be of benefit, but this remains to be tested. The natural history of the disorder is not well defined, but most patients with isolated thrombocytopenia either die of bleeding complications, progress to aplastic anemia, or acquire leukemia. [110] Projected survival is poor6 years for those who do not have associated physical anomalies and 2 years for those who do. [110]

Treatment with corticosteroids with or without androgens has been useful in some cases, but most patients relapse. [110] Splenectomy is ineffective. Bone marrow transplantation may be useful for these patients if a suitable donor is available. [115] Administration of IL-3, but not GM-CSF, was shown to augment the platelet count and decrease bleeding complications in five patients. [113]

Thrombocytopenia with Absent Radius Syndrome

Thrombocytopenia with absent radius syndrome (TAR) is an autosomal recessive disorder manifest by hypomegakaryocytic thrombocytopenia and absent radii. The general lack of consanguinity for this uncommon syndrome suggests that the gene may be more prevalent than previously suspected, or that other modes of inheritance occur. [116] [117] Chromosomal abnormalities are absent. Bone marrow culture studies of a patient with TAR showed absence of megakaryocyte colony formation accompanied by high levels of megakaryocyte colony-stimulating activity. [118] This activity declined as the patients platelet count increased, accompanied by an increase in megakaryocytic colonies. No significant abnormalities of colony formation or colony-stimulating activity were observed in the patients parents. [118] In five patients with this syndrome, TPO levels were measured and found to be elevated. [119] The TPO receptor mpl was found to be expressed normally on the platelet surface of these patients, and to be of the same molecular weight as in normal control subjects. Although platelet responsiveness to adenosine diphosphate and thrombin receptor agonist peptide was normal, addition of TPO to these agonists did not induce synergy as is normally seen. Moreover, TPO-induced tyrosine phosphorylation of platelet proteins was markedly reduced or absent. These data suggest that the TPO signal transduction pathway is abnormal in the TAR syndrome. [119]

Absence of the radii with thumbs present is pathognomonic of the syndrome (Fig. 127-2), and the diagnosis should not be considered unless these findings are present. [120] The muscles that normally attach to the radius are inserted into the carpal bones. Short stature accompanied by other skeletal malformations, including absence or malformation of the ulnar bones, and abnormalities of the humerus, shoulder joint, and lower extremities, are frequent. [110] Tetralogy of Fallot and atrial septal defects occur in one third of patients. [121] Symptomatic milk allergy has been observed frequently and may cause severe bloody diarrhea. [120] [122]

Thrombocytopenia is noted at birth, at which time it is most severe, ranging from 15 to 30,000/mm ^{3} . Intercurrent infection, surgery, gastrointestinal disturbances, and other types of stress are associated with even lower counts, and these are often accompanied by a myeloid leukemoid reaction, noted in two thirds of patients. Eosinophilia, seen in one half of the patients, is common in those with milk allergy. [120] Many patients have anemia related to bleeding and hemolysis, the latter observed in the first year of life. The bone marrow shows decreased or absent megakaryocytes, sometimes accompanied by erythroid hyperplasia. Megakaryocytes are often small, basophilic, and vacuolated. [120]

The diagnosis is suspected by the typical somatic abnormalities. Prenatal diagnosis is possible using ultrasonography, skeletal radiography, and fetal blood sampling. [123] [124] [125] TAR is distinguished from Fanconis syndrome by the presence of the thumbs and by the lack of chromosomal abnormalities. The platelet count and clinical course of these patients tend to improve with age. If patients survive the initial 12 years of life, survival appears to be normal. [120] Thrombocytopenia is best managed by platelet transfusions; orthopedic surgery should be postponed during the first few years of life. Steroids, splenectomy, and intravenous IgG treatments are usually ineffective. [121] [126] Rarely, thrombocytopenia develops when the patient is an adult; in such cases, splenectomy may be effective. [127] [128] Marrow transplantation is an option for the rare patients who continue to remain severely thrombocytopenic with bleeding symptoms throughout childhood. [129]

Other Autosomal Recessive Thrombocytopenias

The Bernard-Soulier syndrome is associated with moderate thrombocytopenia, but it occasionally may be severe. It is not clear whether a production deficit is involved in the etiology of the thrombocytopenia in most patients because platelet survival study results may be shortened or normal, [130] [131] [132] whereas megakaryocyte numbers have been reported to be increased or decreased. [130] [132] [133] Platelet functional defects are likely more important in the pathogenesis of bleeding in this disorder, as in other giant platelet syndromes (see Chap. 130). Nonetheless, it is clear that there are megakaryocytic abnormalities in the

Bernard-Soulier syndrome, including failure to express the GPIb-IX complex.[132] [134] Although in most cases the megakaryocytes are not enlarged despite the marked increase in platelet size, there is abnormal development of the membrane system. Conceivably, deficiency or mutations of the GPIb-IX complex may be important in the formation of platelet territories.[134]

A production deficit may contribute to the thrombocytopenia often noted in the gray platelet syndrome, a disorder in which megakaryocytes are unable to package endogenously synthesized proteins into developing granules [135] (see Chap. 130).

Familial Thrombocytopenia with Micromegakaryocytes

Several members of a family initially believed to have ITP exhibited thrombocytopenia with decreased megakaryocytes. Marrow examination showed a decrease in mean megakaryocyte diameter and the presence of numerous micromegakaryocytes.[136] Another family has been described that also exhibited numerous micromegakaryocytes.[137] Modest thrombocytopenia accompanied by giant granules (15% of all platelets) and a mild hemorrhagic tendency was observed. Platelet survival was normal. Despite a threefold increase in megakaryocytes, platelet production was calculated as 30% of normal. Although platelet function was normal globally, the abnormal population of platelets with giant granules failed to release their contents on stimulation. Culture of megakaryocyte progenitors showed a normal number of colonies, but micromegakaryocytes were always noted. Cell death was observed at the end of the culture period due to lysis, apoptosis, or cell activation. The major distinguishing features between this family (designated Paris-Trousseau thrombocytopenia) and the formerly described family was the presence of a deletion in the long arm of chromosome 23 in the latter (del[11]q23.3qter). That this genetic locus may be important in thrombocytopoiesis is supported by a case of severe thrombocytopenia associated with micromegakaryocytes,[138] and 35 cases of children with a similar chromosomal deletion, 47% of whom also exhibited thrombocytopenia associated with a wide variety of somatic abnormalities.[139]

Autosomal Dominant Thrombocytopenias

May-Hegglin Anomaly

May-Hegglin anomaly is an autosomal dominant disorder characterized by giant platelets, moderate thrombocytopenia (40,00080,000/mm ^{3}), and leukocyte inclusion bodies[140] (Fig. 127-3). Patients may have easy bruising or menorrhagia, but 40% are asymptomatic. No deaths due to bleeding have been

Figure 127-3 Peripheral blood in the May-Hegglin anomaly. Note the giant platelet and the typical basophilic inclusion in the neutrophil. *(Adapted from Hoffbrand A, Pettit J: Sandoz Atlas of Clinical Hematology. Gower Medical, London, 1988, with permission.)*

reported.[141] A variety of overlap syndromes manifest characteristics of Alports syndrome[142] [143] (see later).

The pathognomonic feature is the Döhle-bodylike inclusion bodies found in neutrophils and eosinophils and occasionally in monocytes. These bright blue, spindle-shaped inclusions are composed of parallel 7- to 10-nm filaments.[141] The platelets are large but exhibit no intrinsic structural abnormalities and have normal surface membrane proteins.[144] Platelet volume may exceed that of red cells, with one third at 3080 fl.[144] The mechanism by which the giant platelets are formed in the May-Hegglin anomaly and in other macrothrombocytopenias is unknown, but presumably involves abnormal megakaryocyte fragmentation.[145] Bleeding times are variable.[141] [145] Because marrow megakaryocytes appear normal and platelet survival has been shown to be normal or modestly decreased in most cases,[131] [145] [146] ineffective production is the likely etiology of the thrombocytopenia.

Owing to the modest thrombocytopenia, treatment is not usually required. Platelet transfusions have frequently been given for thrombocytopenia, but their requirement is not clear.[141] [146] [147] Pregnancy and normal vaginal delivery in patients with this disorder can be managed uneventfully.[148] Two patients with symptomatic thrombocytopenia underwent splenectomy without significant response.[149]

Alports Syndrome Variants

The syndrome of hereditary interstitial nephritis, cataracts, and high-frequency sensorineural deafness, designated Alports syndrome,[150] has been associated with thrombocytopenia and giant platelets in a number of families, referred to as Epsteins syndrome.[151] Ultrastructural abnormalities have been described in megakaryocytes.[134] This syndrome has been seen in association with leukocyte inclusions (resembling those in the May-Hegglin anomaly), and designated Fechtners syndrome.[152] [153] The Sebastian platelet syndrome is a variant of Fechtners syndrome without the other defects seen in Alports syndrome.[154] [155] A family with macrothrombocytopenia, late-onset hearing loss, and expression of glycophorin A on half of the giant platelets has been described that appears to be distinct form other variants.[156] The genetic defects in Alports syndrome are deletions or rearrangements in the collagen IV gene located on Xq22,[157] [158] and may be involved in the abnormalities in some Alports syndrome variants. However, whether the platelet and megakaryocyte abnormalities are related to these gene defects remains unknown.

In these autosomal dominant disorders, platelet counts are variable, although thrombocytopenia to levels of 20,000/mm ^{3} may be seen. The mean platelet volume ranges between 20 and 27 fl.[151] [152] [159] Platelet ultrastructure is normal, as is the bleeding time.[151] [159] [160] Platelet aggregation has been claimed to be normal in some reports and abnormal in another.[151] [152] [161] Marrow megakaryocytes are normal, but one report suggests that this may not always be the case.[151] [159] [162]

Cases are most often diagnosed in adult patients. Many were frequently misdiagnosed as having ITP, and failed to respond to treatment with corticosteroids or splenectomy.[151] [159] [162] Bleeding tends to be mild or moderate and is manifested as bleeding after dental extraction, easy bruising, postoperative bleeding and hematoma formation, and postpartum hemorrhage.[163] Fatalities have been observed in patients with Sebastian syndrome.[154] Nevertheless, renal failure, rather than thrombocytopenia, is the usual etiology of the morbidity and mortality in Alports syndrome variants.

Other Autosomal Dominant Thrombocytopenias

Thrombocytopenia without other congenital abnormalities has been reported in a number of kindreds with an autosomal dominant inheritance pattern.[164] [165] Most of these patients have modest thrombocytopenia with few clinical symptoms, normal platelet morphology, and normal numbers of megakaryocytes, but there are exceptions.[1] [164] [166] [167] Some patients exhibit abnormal megakaryocytic lobulations.[168] Families exhibiting macrothrombocytopenia have been described.[167] [168] [169] Platelet function is variable.[164] [165] [168] [169] [170] [171] Platelet survival has been reported to be normal in most families, suggesting ineffective production.[1] [164] However, in one kindred, platelet survival was short; this was demonstrated to be an intrinsic platelet abnormality.[170] In one pedigree with macrothrombocytopenia, an abnormality of GPIV (CD36) was identified.[172] Mediterranean macrothrombocytopenia has been defined as a syndrome of asymptomatic thrombocytopenia and large platelets in people of Mediterranean descent.[173] [174] Their inheritance pattern is not well defined, and little published information is available.[173] [174]

Patients with autosomal dominant thrombocytopenia may be relatively more common than previously believed. Most cases are not diagnosed until adulthood; these patients usually are asymptomatic, although exceptions have been reported.[165] Many may be misdiagnosed as having ITP and treated for that disorder.[166] [171] Family studies of 54 patients referred with the diagnosis of refractory ITP showed that these patients had autosomal dominant thrombocytopenia with large platelets, normal megakaryocytes, and normal platelet survival.[175] Treatment is usually not indicated. Corticosteroids are ineffective, although splenectomy occasionally results in a modest response.[170] [171] Conceivably, the poor responses to standard therapy in some patients with presumed ITP may reflect the possibility that some of those patients have misdiagnosed hereditary thrombocytopenia.

Wiskott-Aldrich Syndrome

The syndrome of immunodeficiency, microthrombocytopenia, and eczema defines the Wiskott-Aldrich syndrome (WAS), a rare X-linked disorder. At the level of the peripheral blood, the syndrome is characterized by depletion of the protease calpain in platelets, decreased mitogenic responsiveness of lymphocytes, decreased surface microvilli in T cells, a loss of cell surface sialoglycoproteins, and abnormal glycosyl transferases.[176] The gene involved in the pathogenesis of the syndrome

has been identified to be on the short arm of the X chromosome (Xp11.22), cloned and designated *WASP*.[177] The mechanism by which the product of this gene, a 53-kd, proline-rich protein, induces its pathologic sequelae remains speculative. One hypothesis is that WASP is important in cytoskeletal structure or cell signaling,[178] and that defects or absence of WASP lead to instability or abnormal assembly or function of the cytoskeleton in platelets and T cells.[176]

Analysis of the X-chromosome inactivation pattern in female heterozygotes (who have no abnormalities) has revealed nonrandom inactivation of the defective gene in multiple hematopoietic lineages, including CD34+ progenitors.[179] This finding suggests that WASP plays a crucial function in cell development. There are a variety of mutations involving the *WASP* gene leading to either absent or mutated protein,[180] [181] [182] [183] but the relationship between these mutations and the wide range of clinical symptomatology is yet to be explained.[184]

Platelet survival time in these patients is approximately half-normal;[185] [186] however, this moderately reduced survival time does not explain the degree of thrombocytopenia in all patients. Platelet turnover is approximately one-fourth normal and is associated with a normal megakaryocyte mass;[1] [187] thus, ineffective production appears to be an important pathophysiologic defect. Because survival time is shortened and splenectomy results in improvement of the platelet count in many patients, platelet destruction contributes substantially to the thrombocytopenia.

Platelets are abnormally small, approximately one-half normal size,[185] [188] but thrombocytopenia is usually moderate. Platelet function is variable;[186] [189] [190] an abnormality of GPIb may be observed in some patients, but not in others.[191] [192] Calpain in affected platelets is reduced relative to normal platelets, but not in affected lymphocytes.[193] The role of this deficiency in the shortened survival of WAS platelets is unclear, but may be involved in inappropriate platelet stimulation followed by clearance from the circulation.[193] Megakaryocytes are normal or increased in number.[1] [187] It has been proposed that WASP is involved in megakaryocytopoiesis and in the assembly of actin filaments.[194] [195]

Diagnostically, the X-chromosomal inactivation pattern, probe hybridization, and direct sequencing can be used for prenatal diagnosis and for detection of the carrier state.[181] [182] [196] [197] The classic triad of infections, thrombocytopenia, and eczema is seen in approximately one fourth of patients at diagnosis.[198] One third of cases have no family history. The diagnosis is often suspected on the basis of the small platelets. Patients usually present with bleeding within the first few months of life. Bloody diarrhea and epistaxis are the common manifestations, but intracranial hemorrhage may also occur. As might be expected, patients having the highest risk for bleeding are those with a platelet count of <10,000/mm^3 at diagnosis.[198] Within 6 months, eczema and infections ensue. Beyond the complications of infections and bleeding, there is a 2%/year risk of the development of a malignancy.[199] Acute myeloblastic leukemia and large cell non-Hodgkin lymphomas, often occurring in the brain and gastrointestinal tract, are the malignancies usually observed. Enlarged lymph nodes and hepatosplenomegaly resulting from lymphoid hyperplasia occur commonly and must be distinguished from the development of a lymphoid malignancy. One half of deaths associated with this syndrome are infectious, one fourth related to hemorrhage, and 5% to malignancy.[199] Life expectancy is usually <10 years.

Corticosteroids are of no benefit and may be deleterious because of the propensity for recurrent infections. Patients who exhibit significant bleeding have benefited from splenectomy, which has been shown to augment platelet number, size, and function in many cases.[188] [200] [201] Median survival in 39 untransplanted, splenectomized patients was 25 years.[201] Nevertheless, thrombocytopenia recurs in a number of patients.[202] Antibiotic prophylaxis and intravenous gamma-globulin are useful in preventing infections but generally do not improve the thrombocytopenia.[202] Should a human leukocyte antigen (HLA)-compatible sibling donor be available, allogeneic marrow transplantation is the most appropriate therapy.[201] [203] [204] Umbilical cord blood infusion from a HLA-identical sibling has been shown to be effective in WAS.[205]

Wiskott-Aldrich Syndrome Variants and Other X-Linked Recessive Thrombocytopenias

A number of kindreds with a WAS-like picture or with X-linked thrombocytopenia have been described.[196] [206] [207] Family studies of a girl with the phenotype of WAS suggested an autosomal recessive mode of inheritance.[208] One family has been described with a WAS variant that appears to be transmitted in an autosomal dominant fashion.[209] Some WAS variants have X-linked microthrombocytopenia and no associated abnormalities, whereas others have variable degrees of eczema and immunologic defects.[207] A WAS-like syndrome associated with renal disease has been described, although the kidney disease may be secondary to the underlying immune defect of the WAS, rather than a separate entity.[210] Lymphocyte mitogenic response to periodate is abnormal in WAS variants, as it is in classic WAS, and this abnormality may be a useful diagnostic test in distinguishing variant WAS from other congenital thrombocytopenias.[211] It is now apparent that X-linked isolated thrombocytopenia and WAS represent varying clinical manifestations consequent to mutations of *WASP*,[181] [212] [213] [214] and thus molecular analysis would provide the precise diagnosis if a WAS variant is considered in the differential diagnosis. The thrombocytopenia usually is mild in these families; most cases have been discovered incidentally.[214] Marrow megakaryocytes are normal or increased.[206] [215] [216] In those few patients reported in whom thrombocytopenia was severe and associated with bleeding, responses to splenectomy have been noted.[206] [215]

Chapter 128 - Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Keith R. McCrae
Douglas Cines

INTRODUCTION

In 1924, Moschowitz described a 16-year-old girl who died of a previously undescribed illness characterized by microangiopathic hemolytic anemia, petechiae, hemiparesis, and fever, which he termed acute febrile pleiochromic anemia with hyaline thrombosis of terminal arterioles and capillaries. [1] Postmortem examination revealed numerous hyaline thrombi, most prevalent in the terminal arterioles and capillaries of the heart and kidneys. [1] In 1936, four similar cases were reported by Baehr et al., who proposed that the hyaline thrombi were secondary to agglutinated platelets. [2] In 1947, Symmers[3] suggested that the term thrombotic microangiopathy be used to describe this disorder, and in 1955 Gasser used the term hemolytic uremic syndrome to describe a related syndrome that consisted of Coombs negative hemolytic anemia, thrombocytopenia, and renal failure. [4]

For many years, thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) were considered separate disorders. More recently, overlap in the pathogenesis and clinical features of these syndromes has been appreciated, [5] leading some to adopt the term TTP-HUS to describe both. These disorders are also referred to as thrombotic microangiopathies (TMA), based on their characteristic microvascular thrombotic lesions. [3] In our view, TMA is best considered as a family of related disorders with overlapping clinical and pathologic features. Such considerations have led to a newly proposed classification scheme, [5] [6] [7] which we have modified for use in this chapter (Table 128-1). In this scheme, the category of idiopathic TMA includes cases commonly referred to as either TTP or sporadic HUS. Other TMA syndromes are designated either by their etiology (when known) or the clinical situation with which they are associated. The utility of this scheme is that it highlights differences in the natural history, prognosis, and response to therapy of TMA syndromes of diverse etiology.

TABLE 128-1 -- Terminology for Syndromes of Thrombotic Microangiopathy

Idiopathic TMA
Thrombotic thrombocytopenic purpura (TMA-TTP)
Sporadic hemolytic uremic syndrome (TMA-HUS)
Toxin-associated TMA
Verocytotoxin-producing *Escherichia coli*-associated TMA (VTEC-TMA)
Shigella dysenteriae-associated TMA (Shigella-TMA)
Familial TMA
Autosomal recessive
Autosomal dominant
Quinine and miscellaneous drug-associated TMA
Transplantation and cyclosporine A-associated TMA
Malignancy and chemotherapy-associated TMA
Neuraminidase-associated TMA (*Streptococcus pneumoniae*-TMA)
Human immunodeficiency virus-associated TMA
Pregnancy-associated TMA

Modified from Kaplan BS: Thrombotic microangiopathy: a proposal for a new terminology for hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. J Nephrol 8:3, 1995, with permission.

GENETIC ASSOCIATIONS AND FAMILIAL TMA

Little information concerning the genetics of TMA is available. Recent reports indicate that HLA-B40 and the related antigens B60, 61, 41, and 47 predispose to development of verocytotoxin-producing *Escherichia coli* (VTEC) associated TMA.[8] [9] Although no specific haplotypes have been implicated in the development of idiopathic TMA, the presence of the supertypic class II antigen, DR53 may be protective, [10] possibly due to inability of the corresponding DRB4 chain to bind a relevant antigen or toxin. [10]

Two distinct patterns of familial TMA have been defined. [11] In the first, the disease begins simultaneously in family members of different ages, who often reside in areas where VTEC infection is endemic. Recovery exceeds 80%, and relapses are uncommon. [11] [12] An example is the simultaneous development of VTEC-TMA in five siblings following VTEC-induced gastroenteritis. [12] In the second, affected siblings develop the disease at similar ages but different times. [11] [13] Some of these have occurred during or soon after pregnancy, concomitant with the use of oral contraceptives, [14] or in association with consanguinity [15] or chronic hypocomplementemia. [16] Families with this pattern may be subdivided into those in which TMA follows an autosomal recessive mode of inheritance, usually developing more commonly during infancy or childhood, [11] [15] or an autosomal dominant pattern, in which the age of onset is more variable. [11] [13] [14] [17]

CLINICAL PRESENTATION

Idiopathic TMA

Idiopathic TMA-TTP

Clinical Manifestations

The clinical manifestations of TMA-TTP have been the subject of extensive review. [18] [19] This disorder occurs with an annual incidence of 3.7 cases per 100,000 residents, [20] is slightly more common in females (female/male ratio of 3:2), [18] [19] [21] [22] and has a peak incidence in the third decade. [18] [19] [22] Ten to 40% of patients complain of an upper respiratory tract infection or flulike syndrome in the 2 weeks preceding the diagnosis. [18] Occasional patients present with malaise, fatigue, fever, or other nonspecific symptoms of days to weeks duration that are unresponsive to antibiotics or symptomatic management. [18] [19] The diagnosis of TMA may be overlooked until these prodomal symptoms become unrelenting or neurologic dysfunction develops.

The classic pentad of symptoms associated with TMA-TTP include microangiopathic hemolytic anemia (MAHA), thrombocytopenia, neurologic symptoms, fever, and renal dysfunction. [18] However, only 40% of patients develop the complete pentad, [18] whereas 75% present with a triad of MAHA, neurologic symptoms, and thrombocytopenic purpura [18] [19] (Table 128-2). In data collected from patients during the last decade,

TABLE 128-2 -- Clinical Presentation of Patients with TMA

Study	Parameters (% of episodes)

Abbreviation: NS, data not stated.

Modified from Thompson et al., with permission.[23]

[a] Historical triad of anemia, thrombocytopenia, and renal dysfunction.
[b] Classic pentad of anemia, thrombocytopenia, neurologic dysfunction, fever, and renal dysfunction.

the incidence of symptoms such as fever appears to have diminished, perhaps due to earlier diagnosis. [23]

Neurologic symptoms ranging from headache and confusion, to somnolence, seizures, aphasia, or coma often dominate the clinical picture in TMA-TTP, [18] [19] [23] [24] [25] and may fluctuate in severity, a characteristic attributed to the repetitive formation and dissolution of microthrombi in the cerebral microvasculature. [26] [27] Thrombocytopenia may be severe, with 25% of patients presenting with platelet counts below 20,000/l. [18] [25] Approximately 90% of patients experience bleeding complications, [18] [19] [24] which may be disproportionate to the severity of thrombocytopenia, perhaps because of concomitant damage to the microvasculature. Despite bleeding events, the prothrombin time, partial thromboplastin time, and fibrinogen levels are usually normal or only mildly perturbed. [28] However, mild elevations in the levels of fibrinogen degradation products occur in 50% of patients, [28] and the use of more sensitive assays, such as those for prothrombin fragment 1+2, thrombin-antithrombin, and plasmin-antiplasmin complexes and fibrin D dimers, demonstrates activation of coagulation and fibrinolytic pathways. [29] Evidence of renal involvement, such as hematuria, proteinuria, or mild azotemia is common, though on presentation the severity is generally mild. [19] MAHA, resulting from fragmentation of red blood cells traversing fibrin strands in the microvasculature [18] [19] or oxidant damage to the red blood cell membrane, is a sine qua non of this disorder. This results in the schistocytes or helmet cells seen on the peripheral blood smear, which are characteristic of TMA (Fig. 128-1), as well as markedly elevated levels of plasma lactate dehydrogenase (LDH). Nucleated red blood cells are present in most patients, and their number may be disproportionately increased in comparison to the degree of reticulocytosis, [18] suggesting an element of marrow injury. With rare exceptions, the direct antiglobulin test is negative. [19] Other less common symptoms include abdominal pain and respiratory distress (see box, Approach to the Patient with TMA).

Pathogenesis

The factors that initiate idiopathic TMA are unknown. However, extensive evidence suggests that endothelial cell damage resulting in accelerated platelet/vessel wall interactions is a critical intermediary in the pathogenesis of this disease.

Pathology.

The prototypic vascular lesions are characterized by platelet-rich thrombi within or beneath a damaged endothelium. [30] Involved microvascular endothelial cells are swollen and in some cases detached. The subendothelium contains fibrinoid material composed, in part, of fibrin(ogen), von Willebrand factor (vWF), and platelet

remnants.[30] [31] Involved vessel walls characteristically display a paucity of mononuclear leukocytes; fibrinoid necrosis, aneurysm formation, and other evidence of vasculitis are absent in primary cases. Medium and large-sized arteries show less extensive involvement and the venous system is typically spared. The most commonly involved organs are the brain, kidney, pancreas, heart, and adrenal glands. [18] Involvement of other sites such as the spleen, gingiva, bone marrow, and skin (Fig. 128-2) also occur.[25]

Endothelial Injury.

Plasma from patients with TTP and other forms of TMA often contain elevated concentrations of endothelial-derived proteins such as thrombomodulin, P-selectin, plasminogen activator inhibitor type 1 (PAI-1), and vWF. [27] [32] Circulating endothelial cells, as well as decreased levels of tissue factor pathway inhibitor, have also been reported.[27] [32] Antiendothelial cell antibodies, some directed at CD36, have been described, but their role has not been delineated. [33] [34] It has also been reported that plasma from patients with idiopathic and human immunodeficiency virus (HIV)-associated, but not VTEC-TMA, induce apoptosis of dermal microvascular, renal, and cerebral endothelial cells, but not those of pulmonary or hepatic origin, through a pathway involving induction of Fas (CD95). [35]

Abundant evidence indicates that the capacity of endothelial cells to inhibit platelet activation and mediate vasodilatation through the elaboration of prostacyclin may be impaired.[36] Plasma levels of the prostacyclin metabolite, 6-keto-PGF_{1}, are

Figure 128-1 This peripheral blood film was obtained from a 28-year-old woman who presented with fever, epistaxis, and altered mental status. Note the absence of platelets and the presence of a nucleated erythrocyte and schistocytes (arrows), consistent with a microangiopathic process.

Figure 128-2 This skin biopsy was obtained from a 54-year-old woman who presented with low-grade fever, MAHA, and thrombocytopenia. The biopsy was performed at the site of a petechial lesion. Note the numerous thrombotic lesions in dermal arterioles (arrows). Petechial hemorrhage is noted in the upper dermis. Inspection of the arteriolar walls reveals prominent, swollen endothelial cells with no evidence of infiltrating leukocytes. Hematoxylin and eosin, original magnification × 100. (Photograph courtesy of Dr. I. Bruce Elfenbeim, Department of Pathology, and Dr. Alexander Zweibach, Division of Hematology, Temple University School of Medicine.)

reduced during the acute phase of the disease and normalize on remission. [37] Impaired renal generation of prostacylin has been observed in children with VTEC-TMA.[38] Vein biopsies from patients with TMA-TTP are deficient in prostacyclin synthesis in vitro, a finding attributed to inhibition of cyclo-oxygenase by free radicals or enhanced lipid peroxidation.[37] Plasma from patients with idiopathic, but not VTEC-TMA, has been reported to lack a 300400 kDa cyclo-oxygenase cofactor that is present in normal plasma, and stimulates vascular prostacyclin production. [39] It is presumed this factor is replenished by plasma therapy.[39] Defects in serum prostacyclin binding and enhanced prostacyclin degradation by TMA sera have also been described. [37] [39] Treatment of patients with TMA with intravenous prostacyclin, however, has met with limited success to date.[40]

Endothelial cell injury may also promote platelet adhesion to the vasculature by disrupting the production or processing of vWF. [32] Pioneering studies by Moake et al. demonstrated the presence of unusually large multimeric forms of vWF (ULvWF) in the plasma of four patients with chronic relapsing TMA (CR-TMA) during remission.[41] These ULvWF, which are exceedingly potent in supporting shear stress-induced platelet aggregation, [42] disappeared during relapse, presumably due to proteolysis under the high shear stress conditions within the partially occluded microvasculature of patients with TMA, [43] or consumption during systemic platelet aggregation.[41] Since these reports, both increased as well as diminished levels of ULvWF have been reported in a variable percentage of patients with idiopathic, VTEC- and drug-associated TMA.[32] These inconsistent results may reflect differences in the sampling time and method of plasma collection, resulting in ex vivo proteolysis.[44]

Several mechanisms may contribute to the accumulation of ULvWF in TMA plasma. Larger multimeric forms of vWF are normally processed at high shear forces by a plasma vWF-cleaving protease.[45] It is possible that the amount of ULvWF released by damaged endothelium may exceed the processing capacity of this metalloprotease, or that the protease may be deficient in individuals with CR-TMA. [46] Deficient protease activity, due to the presence of neutralizing IgG antibodies, has been recently reported in approximately 80% of patients with idiopathic, non-familial TMA (TMA-TTP). [46A] [46B] In patients with familial TMA syndromes with clinical manifestations most closely resembling those of TTP, protease activity was not detectable, though no inhibitor was demonstrated. [46B] Protease

APPROACH TO THE PATIENT WITH TMA

The diagnosis of TMA must be made in a timely manner because delay carries with it the attendant risk of sudden death. The disorder should be considered when prodromal symptoms such as malaise, fatigue, gastrointestinal distress, or low-grade fever persist or progress in the face of symptomatic therapy. A complete blood count and an analysis of the peripheral blood smear are indicated in any patient with a protracted course. Suspicion should be heightened in women who are or were recently pregnant, in patients who are infected or are at risk for infection with human immunodeficiency virus (HIV), in allograft recipients, and in those with a history of underlying vasculitis or exposed to specific drugs described in the text. Patients with early, idiopathic TMA-TTP may present without the classic triad or pentad of signs and symptoms (Table 128-2). Thus, it is the authors opinion that a provisional diagnosis of TMA should be made, and plasma-based therapy instituted, in any patient with the above-mentioned prodromal symptoms in whom MAHA and thrombocytopenia are discovered, unless an alternative diagnosis is evident. We consider an average of one or more schistocytes per high-power field to be of concern, especially when accompanied by thrombocytopenia and nucleated red blood cells, or an increased serum LDH level. The differential diagnosis of TMA-TTP, MAHA, and acquired thrombocytopenia is extensive and can be extraordinarily difficult in some cases. Vascular damage secondary to systemic lupus erythematosus, scleroderma, septic or tumor emboli, immune complex-mediated vasculitis (e.g., infective endocarditis), malignant hypertension, cryoglobulinemia, or infection with rickettsial or, more rarely, hemorrhage-inducing viral organisms, may mimic TMA. TMA may also be superimposed on pre-existing immune vascular disorders such as systemic lupus erythematosus or the antiphospholipid syndrome; in such patients, plasma exchange should be added to existing anti-inflammatory and immunosuppressive therapy. Occasional patients with disseminated intravascular coagulation secondary to malignancy or sepsis (e.g., purpura fulminans in the setting of protein C deficiency) present with occlusive microangiopathy of sufficient severity to be confused with TMA. In the setting of renal transplantation, there are occasions in which a biopsy may be required to distinguish TMA from allograft rejection or recurrence of a pre-existing renal vascular disorder. Occasional patients with TMA present with acute pancreatitis, acute respiratory distress syndrome, or memory and personality changes or other poorly defined neurologic symptoms that themselves have a broad differential diagnosis. Again, the finding of MAHA and thrombocytopenia provides important clues to the underlying problems and the urgent need for intervention with plasma-based therapy.

activity, however, was normal in the majority of patients with either sporadic or familial variants of HUS. [46B] These intriguing observations may provide insight into the greater therapeutic efficacy of either fresh frozen plasma (FFP) or cryosupernatant, sources of the vWF-cleaving protease, [32] [46C] in TTP versus HUS (see later). Further definition of the role of the protease in TMA awaits its cloning and molecular characterization. It has also been proposed that calpain or a related protease, present in elevated levels in TMA plasma, may generate novel fragments of vWF with enhanced affinity for the platelet glycoprotein (GP) IIb/IIIa complex. [47]

Platelet Activation.

In addition to alterations in endothelial cell function, TTP plasma may promote platelet aggregation directly. [48] Platelet microparticles have been detected in essentially all patients with TMA, their number correlating inversely with the platelet count and their disappearance with clinical improvement. [49] Platelet aggregation has been attributed by one group to a 37-kDa protein that binds specifically to platelet glycoprotein IV (CD36), [50] whereas others have implicated a lysosomal, cathepsin-type cysteine protease present in the plasma of patients with TMA. [51] However, Kelton et al. have argued that this latter activity is more likely attributable to the calcium-dependent, cytosolic protease, calpain. [52] Calpain was detected on the surface of platelet microparticles isolated from patients with TMA, [53] an environment that might protect the enzyme from its plasma inhibitors. [52]

Other Mechanisms.

Plasminogen activator activity is reportedly absent from vessels at sites of microthrombi in TMA. [54] In addition, plasma levels of PAI-1 are markedly elevated, [55] [56] far exceeding those measured in patients with disseminated intravascular coagulation (DIC). Plasma concentrations of PAI-1 have prognostic significance in children with TMA-HUS, and the recovery of renal function in a cohort of children with TMA correlated with the removal of PAI-1 by peritoneal dialysis. [57] Elevated levels of the vasoconstrictor, endothelin, have been reported in a few patients with idiopathic and VTEC-TMA. [58] Increased levels of nitric oxide metabolites are present in the plasma of patients with acute TMA, [59] perhaps generated following nitrous oxide release in response to elevated shear stress. [30] Nitrous oxide, however, may interact with neutrophil-derived superoxide anions to form lipid peroxides, as well as cytotoxic peroxynitrite and hydroxyl radicals. [59] Other products of activated leukocytes, such as elastase and cathepsin G, [60] have also been detected in patients with TMA. [61]

Therapy

The mortality rate of TTP-TMA approaches 100% without therapy. Through the mid-1970s, splenectomy remained the only modality with more than an anecdotal response rate. [19] Since that time, however, there has been a dramatic reversal of this grim prognosis with the advent of empiric, plasma-based therapy, such that long-term survival now approaches 90%. [62]

Plasma Therapy.

Anecdotal reports of responses to whole blood infusion have existed since Moschowitzs initial description of the disease. [63] Yet, the remarkable benefit of plasma therapy was not appreciated until 1976, when Bukowski et al. reported a 50% survival rate in 16 patients with TMA treated by exchange transfusion. [64] The following year, Byrnes and Kharuna reported that the active component in whole blood was contained in plasma, an observation that led to the widespread use of plasma infusion. [65] Thereafter, others began to explore the efficacy of plasma exchange under the assumption that the response rate might be improved by removing a toxic substance from patient plasma. [66] Numerous confirmatory studies followed, [26] [62] based on which plasma has become the therapy of choice for TMA-TTP.

The results of a prospective trial reported in 1991 appeared to resolve the long-debated issue of the relative efficacy of plasma exchange versus infusion in favor of the former. [67] At 6 months, complete remissions were seen in 78% of patients treated with exchange versus 31% in those treated with plasma infusion alone. [67] It has been argued, however, that patients in the plasma exchange arm of this study received a threefold greater volume of plasma, obscuring the question as to whether removal of a disease-inciting agent accounts for the apparently superior response. In support of this, no significant difference in outcome was observed in a retrospective analysis of patients who received equal volumes of plasma given by exchange or infusion. [68] Plasma infusion has also been effective in well-documented cases of chronic relapsing TMA. [69] Nevertheless, from a practical perspective, large volumes of plasma may be more easily administered by plasma exchange, which is, therefore, the standard initial therapy in almost all situations. [26] Exchange should be performed daily with the goal of exchanging 11.5 plasma

volumes (4060 ml/kg) with each procedure. Neurologic improvement occurs most rapidly, often within hours to days. [23] The serum LDH level typically falls by 50% within 3 days in responders, and the platelet count begins to rise in a mean of 5 days, though normalization may take several weeks. [23] Impaired renal function is generally the last to improve.

Fresh frozen plasma remains the most commonly used replacement product. However, up to 50% of patients seemingly refractory to exchange with FFP may respond subsequently to exchange with cryosupernatant, [70] which is essentially FFP from which vWF, fibrinogen, fibronectin, and factor XIII have been depleted. [62] As with all secondary treatments, the response to a newly introduced agent, a delayed response to a previously used modality and the natural history of the disease cannot be distinguished.

Plasma exchange should be continued until neurologic symptoms have resolved and both a normal serum LDH and platelet count have been maintained for 3 days; a shorter duration of therapy risks immediate and occasionally fatal relapse. Approximately 90% of patients will show a clinical and laboratory response to plasma exchange within 3 weeks, most by 10 days. Even with optimal therapy, approximately 30% of patients will relapse, half within 6 weeks of initial treatment (see box, Relapsing TMA). The decision to switch from FFP to cryosupernatant or to introduce another form of therapy remains a matter of clinical judgment but, in general, is not considered until the patient has received a minimum of 1014 days of daily exchange with FFP, unless extraordinary circumstances intervene.

Auxiliary Treatments and Management of Refractory Patients

Corticosteroids.

The rationale for the use of corticosteroids is uncertain. Corticosteroids are of little benefit on their own, [26] [62] and retrospective studies do not suggest that they improve the response to plasma exchange. [62] However, Bell et al. recently reported a response rate of 30% in patients with mild, idiopathic TMA (minimal symptoms, no neurologic abnormalities) treated with 200 mg prednisone daily. [71] It is the authors opinion that patients with seemingly asymptomatic TMA-TTP can die suddenly, and that corticosteroids as the sole modality of therapy is neither sufficient nor appropriate until these findings can be confirmed.

Splenectomy.

Before the introduction of plasma therapy, splenectomy was considered first-line treatment for TMA-TTP, inducing remission in up to 50% of patients when used in conjunction with other agents. [62] The use of splenectomy is now confined to refractory patients, with variable response rates reported. [23] [71] [72] Some series suggest that splenectomy induces an enhanced response to plasma exchange in patients initially refractory to this modality. [23] [26] In the authors opinion, splenectomy should be considered in patients refractory to large volume plasma exchange, perhaps after a trial of cryosupernatant. Exchange should be continued after surgery until the remission

---

RELAPSING TMA

More than 80% of patients presenting de novo with TMA-TTP can now be treated successfully with plasma-based therapy, with a concomitant increase in long-term survival. However, with the advent of effective therapy, it has become apparent that at least 30% of successfully treated adult patients will experience one or more relapses. Approximately half of these occur within the first 2 months after therapy has been discontinued, although some prefer to characterize these episodes as incomplete responses. The remainder can occur from a few months to many years after the initial episode. Approximately half the patients experience multiple relapses with no periodicity or obvious inciting event, with the possible exception of pregnancy in a few cases. There are also rare infants, children, and adults in whom relapses occur at regular intervals in the absence of therapy. Unusually large von Willebrand factor multimers may be found in the plasma of some of these patients, and relapses have been successfully pre-empted by regularly timed infusions of plasma. Recent reports suggest that a decrease in plasma vWF-cleaving protease activity may also portend relapse in some patients. In contrast, no serologic markers of relapse have been identified in adults with sporadic TMA-TTP, and no therapy (including antiplatelet agents, corticosteroids, or immunosuppressants), with the possible exception of splenectomy, has been shown to clearly reduce the incidence of recurrence outside the setting of pregnancy. However, patients often recognize the prodomal symptoms and bring themselves to medical attention promptly. The physician should respect these self-evaluations and investigate the possibility of recurrent TTP immediately. The prognosis of relapsed TTP is excellent if management is initiated promptly, but every episode carries the potential for irreversible tissue injury.

criteria mentioned above are attained. Splenectomy during hematologic remission may reduce the incidence or extend the duration between relapses in patients with chronic relapsing TMA. [73]

Other Modalities.

The response rate to *antiplatelet agents* such as aspirin, dipyridamole, sulfinpyrazone, or ticlopidine is 10%, [26] [62] essentially indistinguishable from the natural history of TMA. Antiplatelet agents have also not been convincingly shown to increase the response to plasma exchange, [67] [71] and may promote bleeding in the setting of severe thrombocytopenia. [26] Hence, their use as first-line therapy cannot be recommended, [26] though the role of ticlopidine in preventing TMA relapse is currently under investigation. [74] Some authors also recommend the use of aspirin to prevent thrombosis in patients who exhibit a rapid rise in the platelet count in response to plasma therapy. [26] [62] The use of *intravenous immunoglobulin* is predicated on the observation that IgG from healthy individuals inhibits the capacity of TTP plasma to agglutinate platelets in vitro, [75] a finding that others have failed to reproduce. Most reports supporting the efficacy of intravenous immunoglobulin [76] are compromised by the delay in the initiation of treatment or concomitant administration of other agents, [26] [62] and others have failed to demonstrate clinical responses to intravenous immunoglobulin after failure of plasma exchange. [26] There are anecdotal reports of favorable responses to *vincristine*, [26] [62] [77] as well as other immunosuppressive therapies such as azathioprine, cyclophosphamide, cyclosporine, and staphyloccal protein A immunoadsorption. [78]

Idiopathic TMA-HUS

Idiopathic TMA-HUS is a variant of TMA in which severe renal failure, developing in the absence of an obvious precipitating factor, is the predominant disturbance. This disorder encompasses the adult, atypical, or sporadic hemolytic uremic syndromes and may account for up to 10% of cases of pediatric HUS. In some instances, sporadic cases have occurred in more than one family member, [79] suggesting a cryptic autosomal recessive inheritance. [80] Though TMA-HUS is considered a rare disorder, up to 16% of patients in large series of idiopathic TMA (TTP and HUS) have required dialysis. [81] On the other hand, the incidence of idiopathic TMA-HUS in adults is decreasing as it becomes apparent that VTEC-TMA may account for a greater percentage of adult cases than previously appreciated. [82]

Most patients with TMA-HUS experience a prodrome suggestive of an upper respiratory tract infection, or nonspecific symptoms of malaise and fatigue, but severe

abdominal pain and bloody diarrhea, typical of VTEC-TMA, is notably absent. Hence, idiopathic TMA-HUS is sometimes also referred to as D(-)HUS. The occurrence of idiopathic TMA-HUS does not display the seasonal variability characteristic of VTEC-TMA. [83] Renal involvement is more severe than in TMA-TTP, with up to 60% of patients requiring dialysis. [84] MAHA is universal, and the reticulocyte count and LDH concentration are elevated. [85] The severity of thrombocytopenia is generally less than that seen in patients with TTP. [85] [86] Neurologic manifestations are also typically less common and severe than in TMA-TTP, and rarely dominate the clinical course, [82] though cerebral microthrombi are frequently detected at autopsy. [87]

The response to therapy of patients with TMA-HUS is ill-defined, due to its rarity, lack of clear diagnostic criteria, and the inclusion of patients with TMA-HUS in series consisting primarily of patients with TMA-TTP. This disorder is also frequently grouped with pregnancy, cancer, and chemotherapy-associated TMA, which may have different natural histories. Nevertheless, TMA-HUS is associated with a poor prognosis, with a mortality rate approaching 25%, and 50% of surviving patients developing chronic renal insufficiency. [83] Responses to plasma exchange have been documented, but their frequency is difficult to assess. Likewise, whether this disorder responds to the above-mentioned ancillary agents used in TTP-TMA has not been established. Older age and severity of renal dysfunction are associated with a poorer prognosis. [84] Nevertheless, a trial of plasma exchange is appropriate in patients able to undergo the procedure safely.

Verotoxin-Associated TMA (VTEC-TMA)

Epidemiology

This variant is commonly referred to as typical, epidemic, childhood, or D(+) HUS. Although the incidence is highest in children <5 years old, [88] cases have been reported in individuals of all ages. [88] [89] The pathogenesis of this form of HUS, and in particular its association with verotoxin-producing *E. coli*, [83] has been investigated extensively. The relationship of verotoxin-producing organisms to human disease was first recognized in 1983, based on an association of *E. coli* strain 0157:H7 with two outbreaks of hemorrhagic gastroenteritis. [90] VTEC were first implicated in the development of TMA following the detection of these organisms in the stools of 11 of 15 Canadian children with HUS. [91] Additional studies have demonstrated an association of other verotoxin-producing strains of *E. coli*, [92] of which >100 have now been identified, with epidemics of TMA. [93] VTEC are also associated with sporadic cases of TMA, [88] [93] [94] although molecular subtyping may be required when an association between apparently isolated cases is sought. [95] The disease occurs more frequently during summer months in temperate climates. [83]

The major reservoir of verotoxin-producing *E. coli* is domestic

cattle, approximately 1% of which harbor *E. coli* in their gastrointestinal tract. Outbreaks of VTEC-TMA are associated most frequently with ingestion of inadequately cooked ground beef from an identified source, [88] [94] though contamination of other food sources, such as poultry and cheese, has been reported. Other cases have been attributed to ingestion of contaminated water [96] or unpasteurized milk. [97] Person-to-person transmission may contribute to outbreaks of VTEC-TMA in settings such as day care centers, institutions, [98] and nursing homes. [99] A few instances of asymptomatic carriage of VTEC have been reported. [100]

Clinical Manifestations

This variant occurs most commonly after an episode of *E. coli* 0157:H7-induced gastroenteritis, [101] [102] although rare cases have been reported after infection of the urinary tract or skin. The disease begins with the sudden onset of abdominal pain and watery diarrhea 1 to 9 days after toxin exposure. [93] In some individuals, abdominal pain may be severe and precede the onset of diarrhea; this presentation, particularly in the absence of fever, may be difficult to differentiate from inflammatory bowel disease, appendicitis, ischemic colitis, or intussception. Bloody diarrhea ensues on the second day, accompanied in some cases by nausea and vomiting. [93] Fever is absent or mild. Colonoscopy shows an edematous colonic mucosa, with occasional ulceration and pseudomembrane formation. Thumbprinting in the distal ascending and proximal transverse colon, suggesting an ischemic colitis, may be seen on barium enema, and is caused by exotoxin-induced thrombi in the microvasculature of the bowel wall. [93]

It has been estimated that 930% of individuals with VTEC-associated hemorrhagic gastroenteritis develop HUS. [24] Young children and the elderly are at greatest risk for progression, [88] perhaps due to a slower rate of clearance of the organism from the gastrointestinal tract. Antimotility agents further delay clearance and may increase the risk of progression to TMA. [103] Antibiotics do not diminish progression and may theoretically increase the risk of progression by enhancing exotoxin production or release. [103] Patients who develop TMA present 2 days to 2 weeks after the onset of bloody diarrhea with oliguria or other evidence of renal impairment; [93] [101] 60% of patients ultimately require dialysis, at least temporarily. [101] The extent of MAHA varies considerably. Thrombocytopenia is common, but is mild or absent in 30% of cases at presentation. Thirty to 50% of patients develop neurologic manifestations, which may include irritability and somnolence, and less commonly, confusion, paresis, and seizures. [93] [104]

The disease should be suspected in a patient who presents with the characteristic clinical manifestations after an episode of bloody diarrhea, though the prototypic history of a preceding hemorrhagic gastroenteritis is absent in approximately 10% of cases. [101] [105] The diagnosis may be verified by a positive stool culture. [101] *E. coli* 0157:H7 ferment sorbitol slowly, and thus appear as colorless colonies on sorbitol-MacConkey agar; sorbitol-negative cultures may be characterized further using commercially available 0157:H7-specific antisera. [106] Methods to detect Shiga-like toxins or their structural genes [93] improve diagnostic sensitivity. Demonstration of a fourfold or greater rise in antibody titer to either Shiga-like toxins or 0157 lipopolysaccharide may be used to confirm a diagnosis of VTEC-TMA. [93] Serologic assays are of particular value when stool cultures are not performed within 7 days after the onset of diarrhea, because cultures obtained after this time are frequently negative. [107] However, methods to identify non-0157:H7 strains of verotoxin-producing *E. coli*, which account for up to 25% of cases of VTEC-TMA, are not widely available.

Pathogenesis

Pathology

Examination of renal biopsy material, though rarely required for diagnosis in endemic areas, suggests that endothelial damage is central to the pathogenesis of VTEC-TMA. Involved glomeruli show widening of the subendothelial space, which is filled with cellular debris and fibrin. Concurrent thickening of the capillary wall results in a double contour appearance. [30] In some specimens, infiltration of glomeruli by monocytes, and, to a lesser extent, neutrophils has been observed, perhaps as a result of the elevated urinary levels of monocyte chemoattractant protein-1 (MCP-1) and interleukin 8 in these patients. [108A] Mesangiolysis is present in most cases. Glomerular capillary endothelial cells are swollen and occasionally detached, leading to obliteration of the capillary lumens. [108] Thrombi in glomerular capillaries may be sparse, [39] though thrombotic occlusion of afferent arterioles occurs in some cases (Fig. 128-3A (Figure Not Available)). The presence of glomerular involvement with sparing of larger arterioles and arteries is generally associated with a good prognosis. [109] In older children and adults (who primarily develop idiopathic or familial TMA), involvement of arterioles and interlobular arteries, with relative sparing of glomeruli, is observed more commonly. These lesions are characterized by edema and myointimal proliferation, necrosis of the vascular wall, and patchy cortical necrosis. Glomeruli exhibit ischemic changes, characterized by collapse, retraction, and wrinkling of the capillary loops (Fig. 128-3B (Figure Not Available)). This pattern is associated with a poor prognosis and a high incidence of chronic renal insufficiency. [109]

Toxins

Escherichia coli verotoxin is a 70-kD bacterial exotoxin, [110] named for its cytotoxicity against African green monkey kidney (Vero) cells. Verotoxin is homologous to Shigella toxin [88] [110] and is therefore also referred to as Shiga-like toxin 1 (SLT-1). Many strains of pathogenic *E. coli* also produce a second, less closely related toxin, SLT-2, usually in conjunction with SLT-1. [111] The intact, 70-kD SLT holotoxins consist of a 32-kD A subunit and five 7.7-kD B receptor-binding subunits. [111] The toxin binds to Gala1-4Galb (galabiose) residues on globosyltriaosylceramide (Gb_3; also known as CD77, Burkitts lymphoma antigen, and the human blood group P^k antigen). [112] Receptor-bound toxin is internalized, [113] and transported to the endoplasmic reticulum, [114] where the A subunit is cleaved to a 27-kD A1 subunit, which binds and inactivates the 60s ribosomal subunit and prevents elongation factor 1-dependent binding of aminoacyl tRNA. [115] This blocks peptide elongation and leads to endothelial cell death.

The predilection of children exposed to verotoxin to develop renal disease may relate to the greater expression of Gb_3 by glomerular capillary endothelium in children compared to adults, [116] as well as the relatively greater expression of Gb_3 by glomerular endothelium versus other vascular beds. [116] [117] This pattern of expression

may account for the 1,000-fold greater cytotoxicity of SLTs toward human renal, compared with umbilical vein, endothelial cells in vitro. [116] The predilection of rabbits injected with SLT-1 to develop neurologic dysfunction with sparing of the kidneys may likewise be due to enhanced expression of Gb_3 by brain endothelial cells in this species.[118] The expression of Gb_3 and cytotoxicity of SLT-1 are enhanced by tumor necrosis factor-alpha (TNF-) and interleukin-1 (IL-1), which are released by monocytes following stimulation by *E. coli* lipopolysaccharide and SLT.[119] SLTs also induce the expression of TNF- within the kidney,[120] potentially increasing the expression of their own receptor through a positive feedback loop.

Therapy

Verotoxin-associated TMA may be the most common cause of acute renal failure in children[83] [105] Although approximately 60% of children require dialysis initially, the disorder is typically self-limited and the mortality rate has been reduced to 56% with appropriate supportive care. [83] Renal insufficiency

Figure 128-3 (Figure Not Available) **(A**)3-year-old boy who died 3 days after the onset of fulminant TMA following hemorrhagic colitis. Note thrombi in afferent arteriole and glomerular capillaries. Periodic acid-Schiff, × 400. **(B)** Transplanted kidney from a 3-year-old girl who had presented with idiopathic TMA-HUS at age 7 months. She received this cadaveric transplant at age 3 years. During the first 2.5 days post-transplant, she developed progressive thrombocytopenia and anemia followed by tonic-clonic seizures due to a diffuse cerebral infarction involving the left hemisphere. Note double contouring of the capillary wall (arrow) and collapsed, ischemic glomerulus. Periodic acid-Schiff, × 400. (Photos courtesy of Dr. Laura Finn, Department of Pathology, and Bernard S. Kaplan, M.B., B.Ch., Division of Nephrology, The Childrens Hospital of Philadelphia. From Meyers and Kaplan, [201] with permission.)

generally resolves within 23 weeks, although some patients have prolonged anuria, requiring several months before renal function returns to normal. Despite a favorable short-term outcome, it has become apparent that many patients with VTEC-TMA develop chronic renal insufficiency over time. [109] In one report of 29 patients with typical childhood TMA followed for 1528 years, 7 developed chronic renal failure and 12 developed related symptoms (hypertension, proteinuria, or mildly reduced glomerular filtration rate), whereas only 10 had no residual abnormalities. [109] Thus, complete recovery and long-term preservation of renal function approximates 5060%.[121] Presenting features associated with a poorer long-term outcome include prolonged anuria, [122] an elevated leukocyte count,[123] and the severity of the preceding gastroenteritis. There is also a relationship between the extent of histologic damage on presentation and eventual outcome; virtually all patients with cortical necrosis are left with significant chronic renal disease. [109] Recent studies demonstrate that persistent proteinuria more than 1 year after the initial episode of TMA is also associated with progressive renal disease. [105]

In randomized trials, neither plasma infusion nor exchange have been shown to benefit children with VTEC-TMA. [121] In one study of older children with TMA at high risk for poor outcome, plasma exchange did not prevent the development of renal insufficiency,

although all patients requiring long-term dialysis were in the nontreated group. [124] Likewise, treatment with heparin, urokinase, aspirin, or dipyridamole has not been beneficial. The utility of protein restriction and angiotensin-converting enzyme inhibitors to reduce the progression of renal disease in patients with persistent proteinuria after their initial episode of TMA is under investigation. [105]

Transplantation and Cyclosporine A-Associated TMA

Thrombotic microangiopathies occur most commonly in three transplant-related settings: (1) in association with the use of cyclosporine A (CyA), (2) as recurrent disease after transplantation for a TMA-related disorder, and (3) in the setting of bone marrow transplantation.

Cyclosporine A is the most common cause of drug-induced TMA.[125] TMA occurs in 35% of renal transplant recipients, [126] [127] [128] as well as in occasional heart[129] and liver [130] recipients treated with CyA. CyA-induced TMA typically develops insidiously with progressive, otherwise unexplained renal insufficiency. [126] MAHA or thrombocytopenia develops in only half the patients and is typically mild. [126] [127] The appearance of the glomerular capillary and arteriolar thrombotic lesions is similar to de novo cases of TMA.[131] The distinction of CyA-TMA from acute tubular necrosis or rejection can often be made only by biopsy, and not in every case can an unequivocal distinction be established. [132] Broad alloantibody reactivity,[126] [133] coinfection with cytomegalovirus,[128] and the use of non-heart-beating renal donors[134] may predispose to CyA-associated TMA.

Cyclosporine A is cytotoxic to cultured endothelial cells at concentrations similar to the peak plasma levels and tissue concentrations achieved in vivo. [135] CyA acts synergistically with interleukin-1 (IL-1), IL-1, and TNF- to induce endothelial cell tissue factor expression [136] and inhibit thrombomodulin activity.[137] CyA also enhances the secretion of prostacyclin and thromboxane by cultured endothelial cells [135] and inhibits the production or activity of a putative plasma prostacyclin stimulating factor in vivo.[138] Plasma levels of vWF[139] and endothelin-1[140] are elevated during episodes of CyA-induced nephrotoxicity, consistent with endothelial cell injury. CyA also enhances platelet aggregation and thromboxane release. [141] Therapy for CyA-induced TMA involves reduction of the dose or discontinuation of CyA. The prognosis is generally good, although occasional patients develop permanent renal failure. [125] In some patients, CyA can be reintroduced later at a lower dose[126] ; in others, FK 506 has been substituted successfully,[142] although the latter may also precipitate TMA on occasion. [143]

Approximately 50% of patients with idiopathic TMA-HUS develop end-stage renal insufficiency, becoming candidates for renal transplantation. TMA can recur in the transplanted kidney, even in the absence of CyA. The reported frequency of this complication varies widely. [144] [145] [146] A careful, multigenerational history must be taken to exclude the possibility of familial TMA when a living related donation is being considered. [80]

Thrombotic angiopathies also occur in at least 4% [147] of patients who undergo autologous or allogeneic bone marrow transplantation. [148] [149] [150] The use of total body irradiation as part of the pretransplant conditioning regime, [151] immunosuppression with CyA post-transplant, [147] [148] and the development of graft-versus-host disease[147] increase the incidence and severity of TMA. TMA can be particularly difficult to diagnose in this setting [148] because most marrow recipients develop thrombocytopenia, microangiopathic red cell changes, and mild renal insufficiency at some point in their course. [152] It has been proposed that bone marrow transplant recipients with TMA can be stratified into three groups for prognostic purposes, based on a number of identified risk factors that include: (1) the development of signs/symptoms within 120 days of transplant, (2) exposure to CyA or FK 506, and (3) the presence of neurologic symptoms. [150] Mortality exceeds 50% in high-risk patients (two or three risk factors), [150] for whom aggressive therapy with plasma exchange is indicated.[153] No controlled trials, however, have been performed to establish the benefit of intervention. In contrast, isolated mild renal insufficiency and microangiopathy developing insidiously months to years after transplant may result from radiation nephritis, perhaps exacerbated by chemotherapy, and often resolves or stabilizes with supportive care alone. [154]

Cancer and Chemotherapy-Associated TMA

Thrombotic angiopathies may terminate the course of some patients with disseminated malignant neoplasms and large tumor burdens, most commonly adenocarcinoma of gastrointestinal tract origin. [155] Patients present with the abrupt onset of moderate to severe MAHA and thrombocytopenia. [155] Renal insufficiency and neurologic dysfunction occur less commonly than in idiopathic or chemotherapy-induced TMA, [156] and may result from concurrent metabolic disturbances, central nervous system metastases, or hemorrhage.

The pathogenesis of cancer-associated TMA remains poorly understood. Laboratory evidence of disseminated intravascular coagulation (DIC) is found in 2580% of patients based on findings of elevated fibrin split products [155] [156] [157] or more sophisticated measurements of fibrinogen turnover.[155] However, the observation that TMA occurs in only 5% of patients with disseminated malignancy and DIC [158] suggests that additional factors, such as microvascular occlusion or intimal proliferation induced by tumor emboli within the pulmonary vasculature, [156] [159] [160] or formation of an incompletely endothelialized tumor vasculature that predisposes to platelet adhesion, must be involved in its development. The survival of patients with cancer-associated TMA is generally measured in weeks. The only effective therapy is reduction of the tumor burden, a goal that is not often attainable. A role for plasma exchange has not been established.

Specific cancer chemotherapeutic agents have also been implicated in the development of TMA (see references 159 161 for reviews). Most patients with this disorder had been receiving therapy for an adenocarcinoma when TMA developed, [162] [163] but the syndrome has been reported in individuals with other histologic types of neoplasms.[162] [164] Unlike cancer-associated TMA, most patients with chemotherapy-associated TMA do not carry a high tumor burden. [159] [161] [162] Mitomycin-C,[162] a known nephrotoxin,[165] is the most commonly reported cause. Other cases have been reported in patients treated with cis-platininum, [163] either alone or in combination

with other agents.[164] Most patients who develop TMA do so after having received a cumulative dose of mitomycin-C in excess of 60 mg,[162] but the syndrome has been reported after minimal exposure.[164] Most (77%) cases occur within 4 months of the last exposure to chemotherapy, and it is uncommon for cases to develop beyond 1 year.[162]

Patients with chemotherapy-associated TMA present with moderate to severe MAHA, thrombocytopenia, and renal insufficiency (median creatinine value of 4.2 mg/dl).[162] Approximately 1520% of patients develop neurologic dysfunction, which may include confusion, headache, and seizures. [162] [163] A unique feature is the development of noncardiogenic pulmonary edema in over 50% of patients. [163] Pulmonary function may also deteriorate rapidly after red blood cell or platelet transfusion,[162] which should be used with extreme caution in this setting.

Chemotherapy-associated TMA is presumed to result from direct toxicity to the endothelium. Mitomycin has been reported to inhibit the production of prostacyclin by umbilical vein endothelium, and the infusion of mitomycin-C into the rat kidney induces histologic changes similar to those of chemotherapy-induced

TMA.[166] Plasma levels of vWF increase after platinum-based chemotherapy, [167] and some,[168] but not all investigators,[169] have observed increased levels of ULvWF in affected patients. Chemotherapy-induced TMA confers a grave prognosis. Fewer than 20% of affected patients respond to plasma exchange and corticosteroids, [159] [162] and >50% die within 2 months. [162] More recently, however, responses to immunopheresis with staphylococcal protein A columns (ProSorba) have been reported in up to 50% of treated patients, typically those with no clinically evident tumor. [162] [170]

Miscellaneous, Drug-Associated TMA

Numerous anecdotal reports link the ingestion of specific drugs with the development of TMA. However, in only a few cases, such as quinine and possibly ticlopidine, can the association be considered confirmed. Quinine and its stereoisomer quinidine are common causes of drug-induced immune thrombocytopenia. [171] However, an association of quinine with TMA was first reported by Gottschall et al. in 1991, who described the course of three patients with a syndrome resembling idiopathic TMA-HUS.[172] Patients generally present with severe MAHA, platelet counts <50,000/l, and renal insufficiency, usually requiring dialysis. [173] Neurologic dysfunction occurs in a minority of patients, but can be severe, and occasional patients develop granulocytopenia and lymphopenia. [174] Although this disorder most commonly occurs after the ingestion of quinine tablets, cases have been reported after exposure to quinine in beverages such as tonic water. [175] Though the pathogenesis of this disorder is not well understood, quinine-dependent antibodies reactive with platelet-endothelial cell glycoproteins IIb/IIIa and Ib/IX are found in the serum of some patients,[172] [173] [174] and antibodies to neutrophil and T-lymphocyte membrane proteins occur in others. [173] [174] Antibodies reactive with an endothelial cell protein of similar size to platelet glycoprotein IIIa were reported in one study, [176] whereas in another, patient sera induced neutrophil aggregation and binding to cultured endothelial cells in a quinine-dependent manner. [174] The prognosis is favorable once quinine is withdrawn and plasma exchange instituted. [173] Symptoms may recur on re-exposure to quinine.[175]

Anecdotal evidence suggests an association between other drugs, including ticlopidine, [177] [177A] histamine H_2 -receptor antagonists,[178] and the Norplant contraceptive[179] with TMA. A thorough review of this topic has recently appeared. [161]

HIV-Associated TMA

An association between HIV infection and TMA has been recognized since 1984, [180] with a marked increase in the number of reported cases in recent years. HIV infection occurs in 1420% of patients presenting with TMA in retrospective series, [181] [182] and the association has been confirmed in a case-control study. [181] The prevalence of HIV infection in patients with TMA may be as high as 50% in some geographic regions. [183]

The presentation of HIV-associated TMA and idiopathic TMA are similar. [23] [183] [184] Initial diagnosis may be difficult because fever, anemia, [185] thrombocytopenia,[186] nephropathy, neurologic dysfunction, and elevated LDH levels secondary to lymphoma, drug reactions, or pulmonary infection with *Pneumocystis carinii* occur commonly in this population.[183]

The pathogenesis of HIV-associated TMA is not well understood. It has been speculated that the function of the microvascular endothelium is disrupted by opportunistic organisms, drugs such as fluconazole,[187] infection with HIV and alterations in plasma cytokine levels. [183] A single case of VTEC-TMA in a patient with HIV has been reported.[188]

Although HIV-TMA responds to plasma exchange,[23] [183] the role of antiplatelet agents or splenectomy is less certain. A case of TMA responding to therapy with zidovudine has been reported.[189] Most patients have advanced HIV infection on presentation and die within 1 year of their underlying disease. [23] [183]

Neuraminidase-Associated TMA

Neuraminidase-associated TMA is a rare disorder that occurs primarily in children in the setting of pneumonia and bacteremia caused by *Streptococcus pneumonia*.[190] All pathogenic pneumococci synthesize neuraminidase, which cleaves terminal sialic acid groups from carbohydrate residues expressed on the surface of erythrocytes, platelets, and glomerular cells, thereby exposing the Thomsen-Friedenreich (T-F) antigen. [24] [190] The exposed antigen is recognized by naturally occurring IgM antibodies leading to complement fixation and cellular damage. [24] [191] The renal tissue of affected individuals bind peanut agglutinin, indicative of exposed T-F antigen.[190] [191] Neuraminidase is also expressed by myxoviruses, influenza 2, *Streptococci, Bacteroides, Pseudomonas, Vibrio cholera, Clostridia*, and *Corynebacterium*. [24] Patients present with MAHA, thrombocytopenia, and acute renal failure in the setting of pneumonia. [190] Neurologic symptoms similar to those in other TMA syndromes may be present. Exposure of the T-F antigen also leads to difficulty in ABO cross-matching and may cause a positive direct antiglobulin test, providing additional clues to the diagnosis. [24] Few reports concerning treatment are available. Some cases resolved with supportive care alone. [190]

Pregnancy-Associated TMA

The differential diagnosis of MAHA in association with gestation is complex and has been the subject of recent review. [192] In some cases, TMA may be difficult to distinguish from other causes of MAHA unique to pregnancy, such as pre-eclampsia, the syndrome of hemolysis-elevated liver function tests and thrombocytopenia (HELLP), and acute fatty liver of pregnancy associated with DIC, each of which is managed differently. [192] The severity of the renal and neurologic abnormalities and the time during gestation at which the signs and symptoms of TMA first appear often provide clues needed to prevent critical delays in therapy. [192] [193]

Approximately 10% of cases of idiopathic TMA-TTP occur in association with pregnancy. [18] [194] In one series, 40 of 45 cases of TMA occurred antepartum; the mean gestational age at the onset of symptoms was 23.5 weeks.[195] In the absence of appropriate therapy, maternal and fetal mortality approach 90% and there is no evidence that uterine evacuation, by itself, leads to resolution. [196] [197] On the other hand, the prognosis has improved dramatically since the advent of plasma exchange, and there is no evidence that continuing pregnancy impairs the rate of response. [194] [195] Many patients carry to term successfully, although the overall risk of fetal loss remains appreciable.[196] Some patients with chronic, relapsing TMA develop recurrent episodes during pregnancy. [194] Anecdotal evidence suggests that prophylactic treatment with antiplatelet agents or corticosteroids may reduce the frequency and severity of these relapses. [194] Other patients have been managed with periodic transfusion of plasma or plasma fractions.[198] For the woman with a single episode of idiopathic TMA-TTP during pregnancy, the risk of recurrence appears small.

A second variant of TMA, previously termed malignant nephrosclerosis, irreversible postpartum renal failure, or postpartum intravascular coagulation, [193] also occurs in association with pregnancy. The disorder primarily affects primiparas who present with MAHA, thrombocytopenia, renal insufficiency, and hypertension beginning a minimum of 48 hours after an otherwise normal pregnancy. Neurologic symptoms are less frequent and severe. [192] In one series, the mean time to onset of symptoms was 26.6 days after delivery,[195] a finding that helps to distinguish TMA-HUS from other causes of pregnancy-associated

TRANSFUSION THERAPY IN TMA

Patients with TTP often develop symptomatic anemia because of bleeding and partially compensated hemolytic anemia. Packed red blood cells can be transfused safely in this setting. In elderly patients and in those with an impaired cardiovascular system, it may be prudent to provide some margin of safety when choosing a threshold for transfusion. In contrast, platelet transfusions are generally considered to be contraindicated in TTP. There are several published reports of patients under treatment for idiopathic TMA whose clinical situation deteriorated markedly within 124 hours of receiving allogeneic platelets; the authors are aware of similar experiences. Clinical deterioration after platelet transfusion can also occur in patients with VTEC-associated and drug-induced TMA. Postmortem examination of such patients has revealed widespread microthrombi involving the brain, heart, lung, kidney, and multiple other organs. Many of these lesions appeared fresh, in that they showed no evidence of overgrowth by proliferative endothelial cells. Sudden death has also been reported on rare occasions in patients who responded to plasma therapy with a rapid rise in the platelet count. Thus, we consider platelet transfusions to be contraindicated in patients with TMA in the absence of overt life-threatening bleeding or a comparable hemostatic challenge.

MAHA and thrombocytopenia such as pre-eclampsia, HELLP, and TMA-TTP. Occasional patients with familial TMA display clinical manifestations for the first time during pregnancy, and occasional cases associated with VTEC infection have occurred intrapartum. [199] The prognosis of pregnancy-associated TMA-HUS remains relatively poor. In older series, the mortality rate approached 50% and an additional 1015% were left with chronic renal insufficiency. [200] More recently, responses to plasma exchange or infusion have been reported, [192] though their frequency is uncertain (see box on transfusion therapy). Uterine evacuation does not lead to remission, and fetal outcome depends on successful treatment of the mother. [192]

FUTURE DIRECTIONS

The TMA syndromes remain relatively uncommon. However, the incidence and mortality associated with idiopathic and VTEC-associated TMA are increasing, [20] despite the fact that effective therapy for these syndromes has been available for two decades. [26] [62] [64] Further, the etiology and the pathogenesis of TMA remain poorly understood. Additional insight into the biology of TMA may result from cloning and molecular characterization of the vWF-cleaving protease and a clearer definition of the causes of endothelial damage and apoptosis. Nevertheless, a disorder universally fatal 30 years ago has a far better prognosis today, though, remarkably, treatment remains largely empiric.

Chapter 129 - Thrombocytopenia Due to Platelet Destruction and Hypersplenism

Theodore E. Warkentin
John G. Kelton

INTRODUCTION

Thrombocytopenia is defined as a platelet count below the lower limit of the normal range (150×10^9/L). Sometimes, an expanded definition of thrombocytopenia is appropriate. For example, an abrupt drop in the platelet count can signify the onset of a platelet-destructive process such as heparin-induced thrombocytopenia or bacteremia even if the platelet count remains $>150 \times 10^9$/L.

When a clinician is faced with a thrombocytopenic patient, three questions must be asked. First, could the patient have pseudothrombocytopenia? Second, what is the most likely explanation for the thrombocytopenia? And third, what are the likely risks to the patient suggested by the cause and severity of the thrombocytopenia? For example, very severe thrombocytopenia caused by drug-dependent antibodies or platelet-reactive autoantibodies is usually associated with bleeding. In contrast, mild to moderate thrombocytopenia caused by heparin-dependent antibodies or attributable to disseminated intravascular coagulation (DIC) secondary to adenocarcinoma is strongly associated with thrombosis. Often, the underlying cause of the thrombocytopenia (e.g., bacteremia, cancer, cirrhosis), rather than the thrombocytopenia itself, poses the greatest risk.

Thrombocytopenia can be caused by four general mechanisms: (1) platelet underproduction; (2) increased platelet destruction; (3) platelet sequestration; and (4) hemodilution. Platelet underproduction usually occurs with underproduction of other blood cell lines, and is therefore often accompanied by pancytopenia. Thrombocytopenia caused by increased platelet destruction develops when the rate of platelet destruction surpasses

TABLE 129-1 -- General Mechanisms of Platelet Destruction

Type of Thrombocytopenia	Specific Examples
Immune-mediated	
Autoantibody-mediated platelet destruction via reticuloendothelial system (RES)	ITP; secondary ITP (e.g., immune thrombocytopenia associated with lymphoproliferative disease, collagen vascular disease, infections such as infectious mononucleosis,[a] HIV)
Alloantibody-mediated platelet destruction via RES	Neonatal alloimmune thrombocytopenia;[a] post-transfusion purpura; passive alloimmune thrombocytopenia; alloimmune platelet transfusion refractoriness[a]
Antibodies against microbial antigens adsorbed onto platelets	Malaria-associated thrombocytopenia
Drug-dependent, antibody-mediated platelet destruction via RES	Drug-induced immune thrombocytopenic purpura (e.g., quinine, quinidine, sulfa drugs, vancomycin, etc). See Table 129-6
Platelet activation by binding of IgG Fc of drug-dependent IgG to platelet FcRIIa receptors	Heparin-induced thrombocytopenia
Non-immune mediated	
Platelet activation via thrombin or inflammatory cytokines	Disseminated intravascular coagulation (DIC);[a] septicemia and other systemic inflammatory response syndromes (e.g., adult respiratory distress syndrome, fat embolism syndrome, pancreatitis)
Platelet destruction via ingestion by macrophages (hemophagocytosis)	Infections, malignant lymphoproliferative disorders
Platelet destruction via uncertain mechanisms (e.g., possible platelet-activating proteinase)	Thrombotic thrombocytopenic purpura (TTP);[a] hemolytic-uremic syndrome (HUS)[a]
Platelet losses on artificial surfaces	Cardiopulmonary bypass surgery; use of intravascular catheters
Decreased platelet survival associated with cardiovascular disease	Congenital and acquired heart disease; cardiomyopathy; pulmonary embolism

[a] See chapters 126 and 128 for a discussion of thrombocytopenia in these disorders.

the ability of the bone marrow to produce platelets, and can be caused by immune or nonimmune mechanisms (Table 129-1). Thrombocytopenia caused by platelet sequestration involves platelet redistribution, usually resulting from an increase in the splenic platelet pool. Hemodilution is characterized by a decrease in the numbers of red cells, white cells, and platelets caused by the administration of colloids, crystalloids, or blood products.

This classification can be helpful for all thrombocytopenic patients, including those who develop thrombocytopenia in pregnancy. However, in pregnant patients, the differential diagnosis must be expanded to include causes unique to these patients (Table 129-2).

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

APPROACH TO THE THROMBOCYTOPENIC PATIENT

History and Physical Examination

Certain questions should be asked, including (1) the location and severity of bleeding (if any); (2) the temporal profile of the hemostatic defect (acute, chronic or relapsing); (3) symptoms of a secondary illness, such as a neoplasm, infection, or systemic lupus erythematosus (SLE); (4) a history of recent medication use, alcohol ingestion, or a transfusion; (5) risk factors for infection with human immunodeficiency virus (HIV); and (6) family history of thrombocytopenia.

TABLE 129-2 -- Differential Diagnosis of Thrombocytopenia in Pregnancy

Incidental thrombocytopenia of pregnancy (gestational thrombocytopenia)
Pre-eclampsia/eclampsia[a]
Thrombotic microangiopathy
Thrombotic thrombocytopenic purpura (TTP)
Hemolytic-uremic syndrome (note: post-partum HUS syndrome)
Disseminated intravascular coagulation (DIC) secondary to
Endometritis
Amniotic fluid embolism
Retained fetus
Abruptio placentae
Pre-eclampsia/eclampsia

[a]Pre-eclampsia/eclampsia usually is not associated with overt DIC.

During the physical examination, evidence of hemostatic impairment should be sought. The signs of platelet bleeding include petechiae and purpura. Petechiae typically occur on the dependent regions of the body or on traumatized areas. Spontaneous mucous membrane bleeding (wet purpura), epistaxis, and gastrointestinal bleeding indicate more serious hemostatic defects. Although petechiae are common in patients whose platelet count is <1020 × 10^9 /L, most patients whose platelet count is >50 × 10^9 /L do not exhibit any signs of hemostatic impairment. The physical examination often suggests an explanation for the thrombocytopenia. For example, enlarged lymph nodes can indicate a viral infection, such as infectious mononucleosis or HIV, or a neoplastic lymphoproliferative disorder. An enlarged spleen suggests hypersplenism.

Laboratory Evaluation

Laboratory tests used for the investigation of a patient with thrombocytopenia are summarized in Table 129-3 . The blood film is examined to exclude pseudothrombocytopenia, which is characterized by in vitro platelet clumping. This phenomenon, which occurs in about 1 in 1,000 blood samples examined, is caused by naturally-occurring, platelet GPIIb/IIIa-reactive autoantibodies that produce aggregation of platelets in the presence of the calcium-chelating anticoagulant, ethylenediaminetetraacetate (EDTA).[1] [2] The platelet aggregates are not counted by the electronic particle counter, so the automated platelet count appears falsely low. The correct platelet count can usually be determined by collecting the blood into sodium citrate or heparin anticoagulants or performing a count of non-anticoagulated fingerprick samples; maintaining the blood sample at 37°C will also reduce platelet clumping in many instances. [2] EDTA-dependent pseudothrombocytopenia has no

TABLE 129-3 -- Laboratory Tests Used to Investigate a Patient with Thrombocytopenia

Test	Rationale
Common tests	
Complete blood count (CBC)	Isolated thrombocytopenia is usually caused by platelet destruction, whereas involvement of all cell lines suggests underproduction or sequestration
Examination of the blood film	Pseudothrombocytopenia
	Toxic changes and granulocyte left shift suggest septicemia
	Atypical lymphocytes suggest viral infection
	Red cell fragments suggest TTP or HUS
	Parasites (e.g., malaria)
	White cell inclusions suggest hereditary macrothrombocytopenia
Blood cultures	Bacteremia, fungemia
Antinuclear antibody	Systemic lupus erythematosus (SLE)
Thyroid stimulating hormone (TSH) level	Thyroid dysfunction can accompany ITP

Direct antiglobulin test	Exclude concomitant immune hemolysis and ITP (Evans syndrome)
Coagulation tests	
Activated partial thromboplastin time, prothrombin time (INR), thrombin time, fibrinogen, D-dimer	Disseminated intravascular coagulation (DIC)
Lupus anticoagulant assay	Lupus anticoagulant syndrome
Anticardiolipin antibody assay	Antiphospholipid antibody syndrome
Serum protein electrophoresis; quantitative immunoglobulins	ITP associated with lymphoproliferative disorders (monoclonal); hypersplenism associated with chronic hepatitis (polyclonal)
HIV serology	HIV-associated thrombocytopenia
Bone marrow aspirate, biopsy	Assess megakaryocyte numbers and morphology; exclude primary marrow disorder
Specialized tests	
Glycoprotein-specific platelet antibody assays (e.g., MAIPA)	Specific assay for primary and secondary ITP
Drug-dependent platelet-associated IgG	Specific assay for drug-induced immune thrombocytopenic purpura (DITP)
Drug-dependent platelet activation (e.g., platelet serotonin release assay)	Heparin-induced thrombocytopenia (HIT)
Heparin/platelet factor 4 ELISA	Heparin-induced thrombocytopenia (HIT)
Radionuclide platelet lifespan studies (e.g., ^{111}In platelet survival study)	Define the mechanism of thrombocytopenia; identify an accessory spleen post-splenectomy

Abbreviations: ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; IgG, immunoglobulin G; INR, international normalized ratio; ITP, idiopathic (immune) thrombocytopenic purpura; MAIPA, monoclonal antibody immobilization of platelet antigens; TTP, thrombotic thrombocytopenic purpura.

pathologic significance, other than potentially placing a patient in jeopardy for inappropriate treatment for thrombocytopenia that does not exist. A much less common (1 in 10,000 blood samples), antibody-mediated pseudothrombocytopenic disorder is platelet satellitism, in which rosette-like clusters of platelets are seen around neutrophils.[3] This entity is produced by IgG antibodies that recognize EDTA-induced cryptic epitopes both on platelet GPIIb/IIIa complexes and neutrophil FcIII receptors.

Bone marrow examination can be helpful in assessing platelet production, particularly if megakaryocytes are reduced or abnormal in appearance. Examination of the bone marrow can be diagnostic in a few disorders (e.g., leukemia, metastatic tumor, megaloblastic anemia).

Elevated platelet-associated IgG (PAIgG) is observed in patients with either immune or non-immune thrombocytopenia; [4] therefore, these assays are not useful. There is evidence that glycoprotein-specific platelet antibody assays, such as the monoclonal antibody immobilization of platelet antigens (MAIPA) assay, [5] are relatively specific for autoimmune thrombocytopenic disorders.[6]

In patients in whom the mechanism of chronic thrombocytopenia is unclear, an ^{111}In-labeled autologous platelet survival study is performed. Three patterns can be seen: (1) a normal platelet survival and recovery (underproduction); (2) a marked reduction in the platelet life span (increased destruction); and (3) a reduced recovery, but a normal or near normal life span (sequestration). ^{111}In-labeled platelets can also be used to image accessory splenic tissue in patients with idiopathic thrombocytopenic purpura (ITP) who fail splenectomy or develop post-splenectomy relapse.

Therapy

Bleeding risk for thrombocytopenic patients can be reduced by avoiding drugs that can impair hemostasis (e.g., alcohol, antiplatelet agents, anticoagulants) and invasive procedures (intramuscular injections). If drug-induced thrombocytopenia is suspected, as many medications as possible should be stopped. Life-threatening bleeding episodes should be treated with platelet transfusions regardless of the mechanism of the thrombocytopenia.

The underlying cause and anticipated natural history of the thrombocytopenic disorder influences the decision of whether to transfuse platelets for prophylaxis against bleeding. As a general rule, patients with chronic thrombocytopenic disorders characterized by increased platelet destruction (e.g., chronic ITP) or chronic underproduction (e.g., aplastic anemia, myelodysplasia) can often tolerate long periods of severe thrombocytopenia without major bleeding. In addition, a prophylactic transfusion can trigger alloimmunization against HLA or platelet antigens and thereby jeopardize future therapeutic platelet transfusions. Therefore, prophylactic platelet transfusions are seldom indicated for these patients. However, when such patients have a transient but major hemostatic risk such as a significant head injury, trauma or following major surgery, platelet count should be maintained above 50×10^9 /L. Invasive procedures

such as thoracentesis, paracentesis, and liver biopsy are usually not associated with excess bleeding if the platelet count is >50×10^9 /L. [7] [8] Although a platelet count trigger of 20×10^9 /L has traditionally been used at many centers to guide prophylactic platelet transfusions in leukemic patients, most physicians now use a lower threshold.[9]

Prophylactic platelet transfusions should not be given to patients with heparin-induced thrombocytopenia, thrombotic thrombocytopenic purpura, or hemolytic-uremic syndrome, since platelet transfusions could exacerbate platelet-mediated thrombotic complications.

ANATOMY AND PHYSIOLOGY

The Spleen: Anatomy and Function

The spleen is a small, well-perfused organ receiving about 5% of the cardiac output. [10] Its anatomy is uniquely suited for its function; the progressive branching of the splenic artery into the trabecular and then central arteries helps separate the plasma from the cellular elements. [10] The central arteries arise perpendicularly from the trabecular arteries and skim off the plasma layer from the cells. Soluble antigens in the plasma are delivered to the white pulp, where phagocytic cells process the antigens and initiate antibody production.

The cellular-rich hemoconcentrated fraction of the blood is delivered to the red pulp. A small percentage of this blood flows directly to the splenic veins (the closed system), but most moves into the splenic cords (the open system). Here the cellular elements percolate through a meshwork of reticulum fibers, reticuloendothelial cells, and supporting cells to reach the splenic sinuses. The cells enter the sinuses by passing through fenestrations in the basement membrane of the endothelial cells lining the sinuses. The blood exits through the splenic vein into the portal system. Because the veins in the portal system lack valves, any increase in portal pressure is transmitted to the splenic microcirculation.

The spleen has a number of important roles. [10] It is the largest lymphoid organ in the body and plays a pivotal role in host defense by clearing microorganisms and antibody-coated cells. The spleen is also important for antibody synthesis, especially against soluble antigens. The filtering function of the spleen includes (1) culling (removal of damaged or senescent cells and bacteria), (2) pitting (removal of red cell inclusions and parasites), and (3) remodeling (reticulocyte sequestration and maturation). The spleen also acts as a (4) large reservoir for platelets (about one-third of the platelet mass). [11] In contrast, the human spleen contains <2% of the total red blood cell mass, although in some animals (dogs and cats), the spleen is a much more important red cell reservoir.

Physiologic Platelet Sequestration

Radiolabeled platelet studies have shown that approximately 30% of the total platelet mass exists as a freely exchangeable pool in the spleen. [11] Since the normal platelet life span is 910 days, a platelet spends about one-third of its life, or 3 days, within the spleen. In patients with hypersplenism, as many as 90% of platelets are found in the spleen.

After the labeled platelets are injected, accumulation is apparent in both the liver and spleen. [12] [13] An initial, irreversible phase of hepatic uptake occurs. This equilibrates during the first 5 minutes and may reflect hepatic clearance of platelets damaged in the labeling procedure. Simultaneously, there is a slow rise in activity in the spleen that peaks in about 20 minutes. Splenic platelet uptake is thus dependent on input (spleen blood flow) and output (clearance).

The splenic platelet pool size can be decreased and the platelet count increased with intravenous infusions of epinephrine in normal individuals and patients with splenomegaly. [11] In contrast, isoproterenol (a $_1$ - and $_2$ -agonist) increases the pool size. [14] Splenic blood flow increases with increasing spleen size, although perfusion (flow per unit tissue volume) falls. [15] Blood flow can be increased in some inflammatory disorders (e.g., SLE) without an increase in spleen size. A marked increase or decrease in splenic perfusion alters the proportion of platelets within the spleen.

The most important determinant of the splenic platelet pool is the spleen size. [15] The measurement of spleen size can thus be helpful in predicting the degree of thrombocytopenia expected from excess platelet pooling in the spleen. For example, if the splenic platelet pool is 90% (i.e., 10% outside the spleen), the platelet count will be reduced by a factor of 7 (since normally 70% of platelets lie outside the spleen). Consequently, and as a general rule, even if the spleen is massively enlarged, very severe thrombocytopenia is virtually never seen. On the other hand, mild splenomegaly that may not be detectible on physical examination can explain mild thrombocytopenia.

PATHOLOGIC PLATELET SEQUESTRATION: HYPERSPLENISM

Definition

Hypersplenism is a syndrome characterized by splenomegaly and any or all of the following cytopenias: anemia, leukopenia, or thrombocytopenia. Implicit in the definition is that the cytopenias will be corrected following splenectomy. Although splenomegaly is almost always present in hypersplenism, many patients with splenomegaly do not have hypersplenism. Almost always, the hypersplenism is the result of an identifiable pathologic process, but in some cases the cause of the splenomegaly remains elusive and is termed *primary*.

Pathogenesis

A list of many of the disorders producing splenomegaly and hypersplenism is presented in Table 129-4 . An increase in the size of the spleen can be caused by several mechanisms. An increase in the workload of the spleen can result from immunologic stress (infection, inflammation, or an autoimmune disorder) or from increased red cell removal (red cell membrane disorders, hemoglobinopathies). Portal hypertension will also increase the size of the spleen, and is termed congestive splenomegaly. Benign and malignant infiltrative disorders can also increase splenic size (infiltrative splenomegaly) and cause hypersplenism. Some of these disorders produce thrombocytopenia by more than just hypersplenism: e.g., marrow replacement by tumor, immune-mediated platelet clearance. Thus, the demonstration of an enlarged spleen does not necessarily mean that the cytopenias are caused by hypersplenism.

Cytopenias

The thrombocytopenia of hypersplenism is caused primarily by increased splenic platelet pooling. [11] [15] A massively enlarged spleen can hold >90% of the total platelet mass. In the absence of pathologic platelet overproduction, the total body platelet mass is usually normal and the platelet life span is near-normal. [11] Usually, the splenic transit time remains normal (approximately 10 minutes), but the absolute number of platelets retained within the enlarged spleen is increased. All these platelets remain part of the exchangeable pool. In hypersplenism, the platelet count is usually between 50150 × 10^{9} /L, and almost never <20 × 10^{9} /L. Therefore, patients with hypersplenism almost never have evidence of hemostatic impairment

TABLE 129-4 -- Differential Diagnosis of Splenomegaly and Hypersplenism

Infections

attributable to thrombocytopenia, nor do they need specific interventions to raise the platelet count. Plasma volume expansion occurs in hypersplenism, but hemodilution plays a relatively minor role in the thrombocytopenia. Similarly, some patients have evidence of marrow suppression, but, again, its contribution to the thrombocytopenia tends to be modest.

Sequestration and hemodilution combine to produce the anemia of hypersplenism. [16] An expansion of the plasma volume accompanies hypersplenism; the degree of expansion is proportional to the size of the spleen. In the absence of persistent portal hypertension, this expansion can be improved or corrected by splenectomy.

The neutropenia of hypersplenism is caused by an increase in the marginated granulocyte pool, a portion of which is located in the spleen. [17] Neutropenia of hypersplenism is usually asymptomatic.

Diagnosis

Thrombocytopenia is likely to be caused by hypersplenism when (1) splenomegaly is present; (2) the thrombocytopenia is mild to moderate in severity; (3) moderately-reduced or low-normal neutrophil and hemoglobin levels are found; and (4) no or minimal evidence for impaired hematopoiesis is observed on bone marrow examination. Ultrasonography and radionuclide imaging are of comparable sensitivity in documenting splenomegaly, [18] and either test should be performed when suspected splenomegaly is not evident on clinical examination. The mean platelet volume is usually slightly decreased in hypersplenism, but this finding is not sufficiently specific to be diagnostically useful. An ^{111} In-labeled platelet survival study can be diagnostic of hypersplenism, demonstrating reduced platelet recovery and a normal platelet life span. Determining the cause of the splenomegaly is usually the most important issue.

Therapy

Several maneuvers can improve or correct the cytopenias attributable to hypersplenism, including total or partial [19] [20] splenectomy, partial splenic embolization, [21] [22] [23] andin patients with congestive splenomegalysurgical [24] or transjugular intrahepatic portosystemic shunting. [25] However, cytopenias secondary to hypersplenism, per se, are almost never sufficiently severe to justify treatment. Consequently, the decision to perform one of these interventions usually depends upon other considerations. For example, splenectomy should be considered for relief of pain or early satiety associated with massive splenomegaly (e.g., myelo- or lymphoproliferative disorders [26]), or for splenomegaly of unknown origin (investigation of possible splenic lymphoma [27]).

Short-term complications from splenectomy include infections, bleeding, and thromboembolism. The major long-term risk of splenectomy is overwhelming septicemia, which can be reduced by vaccination. All patients should be vaccinated against pneumococcus, meningococcus, and hemophilus, preferably at least 2 weeks prior to splenectomy. [28] Splenectomy for congestive hypersplenism in the setting of portal hypertension has a high morbidity and mortality; consequently, splenectomy is generally considered contraindicated for cytopenias in these patients. [29] Splenectomy is also associated with a high morbidity (50%) and mortality (1015%) in myeloid metaplasia, and does not alter the natural history of this disorder. [30] Thus, splenectomy is usually performed for palliation of intractable symptoms in these patients.

Splenectomy in Gaucher disease usually corrects the cytopenias, relieves abdominal discomfort, and in children, improves growth. [31] Partial rather than total splenectomy has been used in an attempt to avoid shifting the deposition of glucocerebroside from spleen to bones. Often, however, recurrence of splenomegaly and hypersplenism results after partial splenectomy, [19] and this technique should still be considered experimental. [31] Enzyme replacement therapy can reduce the morbidity from hypersplenism.

DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Many drugs can cause thrombocytopenia. Some drugs (e.g., anticancer chemotherapy, valproic acid [32]) cause dose-dependent thrombocytopenia, generally via myelosuppressive mechanisms. An important disorder encountered by hematologists is

unexpected thrombocytopenia caused by immunologic (idiosyncratic) mechanisms. The frequency of these reactions varies considerably among drugs, and ranges from very rare (<1/10,000) for commonly used drugs such as acetaminophen, aspirin, quinine/quinidine, and trimethoprim/sulfamethoxazole, [33] to common (13%) for other drugs such as gold[34] and unfractionated heparin. [35] [36] [37]

Immunologic drug-induced thrombocytopenia can be divided into two general groups. One group, which represents the largest number of drugs implicated, is exemplified by quinine- and quinidine-induced thrombocytopenia. These disorders are mediated by the binding of the Fab terminus of IgG to a complex comprised of drug (or drug metabolite) and a platelet membrane component (typically platelet GPIb/IX or GPIIb/IIIa) (Fig. 129-1). The Fc portions of the IgG molecules are not involved in the binding to platelets, but are available for interaction with the Fc receptors on phagocytic cells of the reticuloendothelial system. Severe thrombocytopenia (platelet count usually <20 × 10^9 /L) is often observed in these patients, and they generally present with the abrupt onset of bleeding.

The other general type of drug-induced thrombocytopenia is exemplified by heparin-induced thrombocytopenia (HIT). In this disorder, the Fab portion of the pathogenic IgG binds to platelet factor 4 (PF4), an -granule protein that is immunogenic when complexed to heparin or other sulfated polysaccharides. The Fc portions of the IgG molecules bind to the platelet FcIIa receptors, triggering platelet activation. Because the Fc portion of the IgG molecules are bound to the platelet Fc receptor, they may not be available to the Fc receptors of the reticuloendothelial system, which may explain the less-severe thrombocytopenia that characterizes HIT.

Heparin-Induced Thrombocytopenia

Heparin is the most important cause of immune-mediated drug-induced thrombocytopenia for several reasons. First, heparin is a widely used anticoagulant. Second, HIT is relatively common, occurring in 13% of patients who receive unfractionated heparin for 714 days, respectively. [35] [36] Third, HIT paradoxically can cause life- or limb-threatening venous or arterial thrombosis.[35]

Pathogenesis

Heparin binds reversibly and saturably to platelets and can weakly activate platelets in vitro. [36] In general, the direct platelet-activating effects of heparin, as well as its immunogenicity, are proportional to its size and degree of sulfation; consequently, low-molecular-weight heparin is less likely to cause HIT than is unfractionated heparin (see Fig. 129-2). [35]

HIT is caused by heparin-dependent IgG that activates platelets via their FcIIa receptors. [38] The antigen is a complex between heparin and platelet factor 4. [39] [40] [41] HIT antibodies can also recognize PF4-related chemokines, such as interleukin-8 and neutrophil-activating peptide-2, [42] but the relevance of this fact is unknown. Some patients form IgM and IgA heparin-dependent antibodies,[43] but the clinical significance of this is uncertain. A unique laboratory characteristic of HIT is that large heparin concentrations (10100 U/ml) inhibit platelet activation by the pathogenic IgG, [44] most likely by displacing the pathogenic IgG from surface-bound heparin/PF4 complex. This laboratory feature is exploited in diagnostic testing for HIT (see the section, Diagnosis).

In vivo thrombin generation contributes to the pathogenesis

Figure 129-1 Proposed binding of quinine/quinidine-induced thrombocytopenia.

Figure 129-2 Pathogenesis of heparin-induced thrombocytopenia. Heparin produces mild platelet activation, resulting in release of platelet factor 4 (PF4) from platelet granules, and the formation of immunogenic heparin/PF4 complexes. B lymphocytes generate IgG that recognize the heparin/PF4 complexes; the Fc tails of the IgG bind to platelet FcII receptors, resulting in Fc receptor clustering and consequent strong platelet activation. Platelet-derived microparticles are generated that accelerate thrombin generation. The HIT antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to immunoinjury that causes endothelial activation. Tissue factor expressed on the endothelial surface further produces thrombin generation. This model of thrombin generation in HIT helps explain some of the unusual clinical manifestations of HIT (e.g., venous limb gangrene, DIC) and provides a rationale for treatment that reduces thrombin generation (e.g., danaparoid, recombinant hirudin, argatroban).

of some of the unusual sequelae of HIT,[37] which can include venous thrombosis,[35] warfarin-associated venous limb gangrene,[45] [46] and DIC.[36] Thrombin generation in HIT results from the generation of procoagulant microparticles from platelets activated by HIT antibodies, [47] as well as via expression of tissue factor by endothelial cells that have been activated by HIT antibody that recognizes PF4 bound to endothelial heparan sulfate. [41] [48]

Only a minority of patients who generate HIT antibodies develop thrombocytopenia. [35] Differing risk for HIT results from variability among platelets in their ability to be activated by HIT IgG,[49] [50] as well as varying titres of HIT antibodies. Clinical factors also appear to explain differences in risk for sequelae: e.g., postoperative orthopedic patients are at high risk for venous thrombosis, whereas postoperative cardiovascular patients are at relatively high risk for arterial thrombotic events. [35] [51]

Clinical Features

Most patients with HIT develop mild to moderate thrombocytopenia: the mean platelet count nadir in many series is approximately 50 × 10^9 /L. [36] Very rarely, the platelet count is as low as 5 × 10^9 /L. DIC and red cell fragmentation may be present in these patients with severe thrombocytopenia. Thrombosis in HIT can

complicate a relative platelet count fall of >30%, but prior to the development of thrombocytopenia as conventionally defined (<150 × 10^9 /L).[35] A high heparin requirement to maintain a therapeutic partial thromboplastin time (heparin resistance) is a common, but nonspecific, finding in patients with HIT.

The thrombocytopenia almost always begins 510 days after the initiation of heparin therapy. [35] HIT is prothrombotic: at least 3050% of patients will develop a thrombosis in association with HIT.[35] [36] [52] Both venous (deep vein thrombosis, pulmonary embolism) and arterial (especially aortic and iliofemoral arterial thrombosis, cerebrovascular accidents, myocardial infarctions) thrombi occur. Other complications include painful dermal erythema or necrosis at the sites of subcutaneous heparin injection,[53] and acute inflammatory [54] or transient memory disturbances[55] following heparin bolus injections to sensitized individuals. Unexplained hypotension or abdominal pain in a HIT patient suggests bilateral adrenal hemorrhagic infarction, which can lead to acute adrenal failure; this hemorrhagic necrosis appears to result from adrenal vein thrombosis. [56]

Diagnosis

Sensitive and specific assays for HIT antibodies have been developed based on the observation that the pathogenic IgG activates washed platelets. [44] [49] [57] These assays are more sensitive and specific than the simpler and more widely-used citrated platelet-rich plasma methods. [58] Important quality control maneuvers include the selection of platelet donors whose platelets respond well to Fc receptor stimulation, as well as the inclusion of negative

and positive HIT sera of varying reactivity to ascertain that the test platelets can identify weaker HIT sera. [49] A characteristic activation profile is produced by HIT serum: increased platelet activation at low heparin concentrations (0.050.3 U/ml), but background platelet activation at high heparin concentrations (10100 U/ml). [44] [49] [57] A gold standard assay (the ^{14}C-serotonin release assay[44] [49]) has been shown to have high sensitivity and specificity (>95%) for HIT antibodies in a blinded investigation.[35] Sometimes, heparin-independent platelet activation can be triggered by HIT serum ("indeterminate" result); for these sera, an enzyme-linked immunosorbent assay (ELISA) utilizing a heparin/platelet factor 4 target can be diagnostic. [37] Conversely, HIT antibodies that do not recognize the major antigen, heparin/PF4, require an activation assay, such as the serotonin release assay, for diagnosis. Thus, reference laboratories should be able to perform both activation and antigen assays.[37] [59]

Management

Heparin should be discontinued in patients with suspected HIT. However, there appears to be a high risk (approximately 50%) for subsequent thrombosis in patients with serologically confirmed HIT in whom heparin is simply discontinued. [52] Some physicians therefore consider continued use of anticoagulant agents even in patients with isolated thrombocytopenia attributable to HIT. [37] The recognition for an important role for thrombin generation in the pathogenesis of HIT has provided a rationale for the use of anticoagulant agents that reduce thrombin generation. Currently, three such anticoagulantsdanaparoid, recombinant hirudin, and argatrobanappear to be effective for the treatment of HIT. Differing pharmacokinetic and other considerations ensure that no single agent is ideal for all patients.

Danaparoid sodium (Orgaran), formerly known as Org 10172, is a mixture of anticoagulant glycosaminoglycans with predominant anti-factor Xa activity. In 1993, an uncontrolled report[60] of 230 HIT patients treated with danaparoid suggested that about 90% of patients respond favorably, as defined by platelet count recovery without new or progressive thrombosis during treatment. The authors have used this drug successfully in HIT patients, and have observed that a marker of in vivo thrombin generation (thrombinantithrombin complexes) falls during danaparoid treatment. [61] Anticoagulant monitoring can be performed using anti-factor Xa levels, although this is usually not necessary because of predictable anticoagulant effects with standard dosing (see Table 129-5). Danaparoid levels can accumulate in patients with renal failure, and monitoring should be performed in these patients. Anywhere from 1040% of HIT patient sera exhibit some degree of in vitro cross-reactivity with danaparoid; however, clinically-significant cross-reactivity

TABLE 129-5 -- Treatment Protocols for HIT Complicated by Thrombosis

Danaparoid
Loading dose: 2,250 U IV bolus,[a] followed by 400 U/hour × 4 hours, then 300 U/hour × 4 hours. *Maintenance*: 150200 U/hour, with subsequent dose adjustments made using anti-Xa levels (target range 0.50.8 anti-Xa U/mL), if assay available [b]
Recombinant hirudin
Loading dose: 0.4 mg/kg bolus. *Maintenance*: 0.15 mg/kg/hr infusion, with dose-adjustments to maintain APTT 1.53.0 times the median of the normal laboratory APTT range.

Modified from Warkentin, et al.,[37] with permission.

[a]Adjust bolus for body weight: <60 kg, 1,500 U; 6075 kg, 2,250 U; 7590 kg, 3,000 U; >90 kg, 3,750. The recommendations are based on 750 U ampule availability; for 1,250 U ampules, the loading dose would be 2,500 U, etc.
[b]The calibration curve for anti-Xa testing must be derived using danaparoid rather than low-molecular-weight heparin.

is uncommon (<5%). Our practice is to use danaparoid for its immediate anticoagulant effect in HIT patients without delaying treatment to perform in vitro cross-reactivity testing.[59] Danaparoid has been approved for the treatment of HIT in some countries (e.g., the Netherlands, New Zealand), although it is often used off-label in other countries (e.g., United States, Canada) where it has been approved for antithrombotic prophylaxis. [59]

The recombinant hirudin derivative, lepirudin (Refludan), is a 65-amino acid polypeptide that inactivates thrombin by forming a tight, noncovalent 1:1 complex with it. Evaluation of a standard lepirudin protocol (Table 129-5) to treat HIT complicated by thrombosis in a historically controlled study in Germany [62] led to its approval for this indication first in the European Union (March 1997), and then in the United States (March 1998). Hirudin is metabolized and excreted by the kidney, and the drug must be avoided or the dosage reduced in patients with renal failure. Anticoagulant monitoring is performed using the partial thromboplastin time (target PTT, 1.53.0 times the median of the laboratory normal range).

Argatroban is a synthetic antithrombin that has been used to treat HIT in Japan and the United States. [63] A recent, historically-controlled study suggested that this agent reduces the frequency of thrombosis in patients with HIT. Argatroban is metabolized by the liver, and may be used in patients with renal failure.

Warfarin and other oral anticoagulants should not be used to treat patients with active HIT. [37] [45] [46] HIT associated with deep vein thrombosis (DVT) is a high-risk situation; this is because DVT in a HIT patient treated with warfarin can progress to venous limb gangrene. [45] The laboratory marker of this unusual syndrome is a high INR (generally, >4.0), which corresponds to the combination of a marked reduction of protein C together with persisting thrombin generation (as shown by elevated thrombinantithrombin complex levels) during warfarin therapy. [45] [46] However, warfarin can be given safely to patients whose thrombin generation is controlled (e.g., using danaparoid or hirudin), or following resolution of the HIT.

A defibrinogenating snake venom, ancrod (Arvin), has been used in uncontrolled studies to treat HIT, [64] and is approved in Canada for this indication. The drug, given at a dose of 1 U/kg over 1224 hours, reduces the fibrinogen to low levels (<0.1 g/L), thereby reducing plasma viscosity. Ancrod does not reduce, and may even increase, thrombin generation in HIT; [61] this may explain why some patients have developed venous limb gangrene during combined treatment with ancrod and warfarin.[45] Ancrod should not be used in HIT patients with evidence of increased thrombin generation.

Using sensitive assays, all low-molecular-weight heparin preparations are as capable of activating platelets in the presence of HIT serum as unfractionated heparin (i.e., 100% in vitro cross-reactivity). Further, because many patients with HIT who are treated with low-molecular-weight heparin also develop progressive or recurrent thrombocytopenia or thrombosis (i.e., in vivo cross-reactivity), these agents are not recommended to treat HIT. [37] [59]

Although primary treatment for HIT should include an anticoagulant that reduces thrombin generation, certain treatment adjuncts [37] can benefit selected patients, including thromboembolectomy, thrombolytic therapy, high-dose intravenous gammaglobulin, aspirin, or plasmapheresis.

Prevention

Platelet monitoring in patients treated with heparin should reflect the overall risk of HIT (i.e., the preparation, the dose, and the clinical situation). The authors recommend daily platelet count monitoring in patients at relatively high risk for developing HIT (e.g., postoperative orthopedic and cardiovascular

patients receiving prophylactic-dose unfractionated heparin, and medical patients receiving therapeutic-dose unfractionated heparin). The frequency of HIT is much lower with low-molecular-weight heparin,[35] and no consensus exists regarding frequency of platelet count monitoring in patients receiving these preparations. The patient with a past history of HIT who requires future anticoagulation presents a problem, since the risk of recurrence is unknown. Danaparoid has been used successfully in these patients.[60] HIT antibodies are transient, and are usually undetectable even using a sensitive assay two months after an episode of HIT. [37] Thus, if HIT antibodies are not detectable, it may be acceptable to use heparin for a brief indication (e.g., heart surgery using cardiopulmonary bypass). Patients requiring urgent heart surgery during acute HIT have been successfully anticoagulated with alternate anticoagulants (e.g., danaparoid, [65] lepirudin[66]), but each of these approaches has certain drawbacks.

Drug-Induced Immune Thrombocytopenia

A large number of drugs can cause a syndrome that mimics acute ITP,[33] [67] [68] [69] [70] (Table 129-6 [33] [34] [69] [70] [71] [72] [73] [74] [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] [91] [92] [93] [94] [95] [96] [97] [98] [99] [100]). Typically, these patients develop severe thrombocytopenia (platelet count usually <20 × 10^9 /L) with petechiae and purpura, usually within weeks, but occasionally much longer after starting drug therapy. Drug-induced immune thrombocytopenia is much less common than HIT. Perhaps the most common cause of this syndrome is trimethoprim/sulfamethoxazole (co-trimoxazole), even though it occurs in only approximately 1 in 25,000 patients treated with this drug combination.[33]

Pathogenesis

Drug-dependent binding of the Fab component of IgG to platelet glycoproteins leads to platelet destruction. This occurs because the IgG-sensitized platelets are recognized by the Fc receptors of reticuloendothelial macrophages. For quinine- and quinidine-induced immune thrombocytopenia, both the GPIIb/IIIa and GPIb/IX complexes have been implicated as targets for the drug-dependent IgG.[69] In contrast, for sulfa antibiotic-induced immune thrombocytopenia, the GPIIb/IIIa complex is predominantly involved.[82] Sometimes, drug metabolites rather than the parent drug form the antigen.[83] [88] A trimolecular complex is formed among IgG-Fab, the drug (or metabolite), and the platelet glycoprotein. In contrast to HIT, platelet Fc receptors are not involved. Drug-dependent IgG binding is remarkably heterogeneous with respect to binding affinity, number of binding sites per platelet, and the range of drug concentration required.

Clinical Features

Patients with drug-induced immune thrombocytopenia typically present with petechiae, purpura, and severe thrombocytopenia (platelet count often <20 × 10^9 /L). Sometimes systemic symptoms such as fever and chills occur in patients with abrupt-onset thrombocytopenia. Usually, the thrombocytopenia becomes clinically apparent 12 weeks after starting the drug, but the thrombocytopenia can begin even after a patient has been taking a drug for several years. Usually the platelet count begins to rise within a few days of discontinuing the implicated drug, but occasionally several weeks are required for recovery, possibly because of generation of drug-independent IgG (platelet autoantibodies). [70]

Rarely, distinct drug-dependent IgG destroy red and/or white cells in addition to platelets. For example, both platelet- and leukocyte-reactive quinidine-dependent IgG have been reported in a patient with quinidine-induced bicytopenia. [71] Sometimes, the immune process is directed against a pluripotent hematopoietic stem cell, resulting in pancytopenia accompanied by marrow aplasia or hypoplasia (e.g., gold-, carbamazepine-, or quinidine-induced pancytopenia). A bone marrow should be performed in patients with suspected drug-induced bicytopenia or pancytopenia, as a hypoplastic marrow can indicate the serious complication of drug-induced aplastic anemia.

Diagnosis

A high index of clinical suspicion is often required to make the diagnosis. Quinine is widely available, e.g., as an ingredient in tonic water, or as an additive to street drugs. Demonstration of drug-dependent binding of IgG to platelets in vitro is important in diagnosis. Labeled immunoglobulin-specific probes (phase II assays) or glycoprotein capture techniques (phase III assays) appear to have the highest sensitivity and specificity. Investigators have reported that a commercially available solid-phase red cell adherence system can be modified to detect drug-dependent platelet antibodies, [100] but the predictive value of these assays is uncertain. A number of detection systems including flow cytometry can be used.[68] [82]

There are certain caveats in diagnostic testing. First, metabolites rather than parent drug must sometimes be used to detect the IgG. [83] [88] Second, wash buffer in these assays must include the target drug (or metabolite). Third, even despite these maneuvers, the sensitivity of in vitro assays is relatively low, and the diagnosis of drug-induced immune thrombocytopenia often must be made on clinical grounds alone. Sometimes the diagnosis is confirmed by inadvertent or deliberate re-exposure to the suspected drug. However, deliberate drug rechallenge is not recommended because of the potential hazard.

Management

As many drugs as possible should be discontinued in patients with suspected drug-induced immune thrombocytopenia. If further drug treatment is necessary, an alternate, immunologically non-cross-reactive substitute should be prescribed. Platelet transfusions should be given to patients with life-threatening bleeding. High-dose intravenous -globulin, 1 g/kg given over 68 hours for 2 consecutive days, usually is effective. [72] [95] Corticosteroids appear to be relatively ineffective in treating drug-induced immune thrombocytopenia.[101]

Gold-Induced Thrombocytopenia

Gold-induced immune thrombocytopenia occurs in as many as 13% of treated patients.[34] A genetic predisposition is suggested by the association with HLA-DR3, which is found in approximately 85% of affected patients.[34] The thrombocytopenia typically occurs during the first 20 weeks of therapy, before 1,000 mg of gold has been given. Rarely, the thrombocytopenia begins much later, sometimes even several months after discontinuation of the gold. Although the onset of thrombocytopenia is typically abrupt, regular platelet count monitoring is important because an early diagnosis can be made in some patients. The thrombocytopenia often persists for several months despite discontinuation of the gold. It is uncertain whether this is caused by gold-induced autoimmune thrombocytopenia [74] or whether prolonged release of gold from tissue stores produces long-term drug-dependent thrombocytopenia.[73] Although most patients will eventually respond to corticosteroids, immediate albeit generally transient correction of severe thrombocytopenia can usually be achieved with high-dose intravenous -globulin. [72] Some patients with persisting thrombocytopenia benefit by splenectomy or gold-chelating agents (dimercaprol, *N*-acetylcysteine).

TABLE 129-6 -- Drug-Induced Immune Thrombocytopenia[a]

	Platelet Count x<20 × 10^9 /L	Drug Rechallenge	Drug-Dependent in Vitro Testing		Platelet Count <20 × 10^9 /L	Drug Rechallenge	Drug-Dependent in Vitro Testing
Quinine/Quinidine Group				Procainamide[91]	Y	Y	Y[I]

Amiodarone	Y	Y		Ticlopidine			Y[II]

[a] Key evidence implicating the various drugs is shown, including documentation of severe thrombocytopenia, drug rechallenge (deliberate or inadvertent), and in vitro testing. In vitro testing is classified as phase I (IgG-nonspecific endpoints such as platelet aggregation, platelet factor 3 generation, clot retraction inhibition, and so forth), phase II (increase in drug-dependent platelet-associated IgG by patient serum), and phase III (drug-dependent binding to specific platelet glycoproteins). A recent report [100] that did not provide detailed clinical information used a phase I assay to suggest the following additional drugs might also cause immune thrombocytopenia: acyclovir, albuterol, amlodipine, amoxicillin, amphotericin, atenolol, axid, cefazolin, ceftriaxone, cephalexin, clindamycin, diltiazem, famotidine, fluoxetime, imipenem, metronidazole, nafcillin, normodyne, prilosec, and tobramycin. Other references for this table can be found in previous editions of this textbook.

[d] Although classified here as an antihypertensive, note that diazoxide is a thiazide derivative.

[e] Although classified here as a diuretic, note that acetazolamide is a sulfonamide derivative.

[b] Several other sulfa antibiotics have been implicated in DITP.

[c] Metabolites of the drug have been implicated in the pathogenesis of DITP.

Drug-Induced Autoimmune Thrombocytopenia

Certain drugs besides gold have been reported to initiate autoimmune thrombocytopenia, e.g., procainamide. [102] However, as the pathogenic antibodies are by definition drug-independent, it is difficult to establish causation. The mumps-measles-rubella vaccine can cause a severe, but generally self-limited thrombocytopenia that is clinically and serologically indistinguishable from childhood acute ITP. [103]

MISCELLANEOUS DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Drug-Induced Thrombotic Microangiopathy

Several drugs can trigger a syndrome of thrombocytopenia, fragmentation hemolysis, and renal failure (drug-induced hemolytic-uremic syndrome) (see Chap. 128). This syndrome has been established for quinine: multiple quinine-dependent antibodies reactive against platelets, red cells, leukocytes, and endothelial cells have been reported.[104] Patients treated with plasmapheresis usually recover, although some also require short-term hemodialysis. [104] Although a similar syndrome may be caused by mitomycin C,[105] cyclosporine, and penicillamine, it should be noted that many patients who receive these drugs have underlying illness (gastric adenocarcinoma, bone marrow transplantation, collagen vascular disease, respectively) that are themselves associated with hemolytic uremic syndrome. Growing evidence indicates that thrombotic thrombocytopenic purpura (TTP) rarely can be caused by the antiplatelet drug, ticlopidine. [106]

Nonidiosyncratic Drug-Induced Thrombocytopenia

Most antineoplastic drugs produce a dose-dependent pancytopenia caused by injury to hematopoietic cells, including megakaryocytes and their progenitor cells. Typically, the platelet count nadir occurs at a predictable point following treatment and then quickly recovers. Unexpectedly severe or prolonged thrombocytopenia in patients receiving chemotherapy should suggest alternate explanations for the thrombocytopenia (e.g., idiosyncratic thrombocytopenia caused by another drug).

Approximately 20% of patients who receive valproic acid (an anti-epileptic agent) develop mild to moderate thrombocytopenia; bleeding symptoms are uncommon. [32] This mechanism of thrombocytopenia is unknown, but appears to be nonidiosyncratic, as the risk of thrombocytopenia correlates strongly with serum concentrations of valproic acid metabolite.[32] Amrinone is another agent that can cause mild, dose-dependent thrombocytopenia. [107]

Rapid Drug-Induced Thrombocytopenia

Some drugs produce rapid but generally mild and transient drops in the platelet count. These include heparin, [36] protamine, bleomycin, hematin, ristocetin (no longer clinically used), desmopressin (particularly in patients with type 2B von Willebrand disease [108]), and porcine factor VIII. The mechanism(s) for thrombocytopenia in these syndromes is obscure. Occasionally acute thrombocytopenia is IgG-mediated: for example, some rapid-onset thrombocytopenic reactions to heparinparticularly when accompanied by systemic inflammatory symptoms and signsare attributable to IgG-mediated HIT in patients who were recently sensitized to heparin. [54]

Abciximab (c7E3, or ReoPro) is a humanized chimeric Fab fragment of a murine monoclonal antibody (7E3) directed against GPIIb/IIIa. This agent reduces restenosis following percutaneous transluminal coronary angioplasty. About 0.5% of patients develop severe thrombocytopenia within several hours of treatment with abciximab.[109] [110] Most patients do not have associated bleeding complications, but platelet transfusions can be used if bleeding occurs. The mechanism of the thrombocytopenia is uncertain, although the abrupt onset of severe thrombocytopenia suggests an immune pathogenesis.

Drug Hypersensitivity Reactions

Mild to moderate thrombocytopenia is sometimes observed in patients with systemic drug hypersensitivity reactions. Comorbid clinical features can include generalized rashes, fever, cholestasis, and leukopenia. Allopurinol, isoniazid, sulphasalazine, and phenothiazine drugs, among others, have been implicated in these reactions.

Thrombocytopenia Secondary to Biologic Response Modifiers

Use of purified or recombinant biologic response modifiers such as interferon, [111] interleukin-2, [112] and certain colony-stimulating factors [113] has resulted severe, reversible thrombocytopenia in some patients. Anti-lymphocyte globulins can also produce severe thrombocytopenia in some patients. [114] The mechanism of causation of this thrombocytopenia is uncertain.

OTHER CAUSES OF DESTRUCTIVE THROMBOCYTOPENIA

Incidental Thrombocytopenia of Pregnancy

Maternal thrombocytopenia occurs in 57% of pregnancies.[115] [116] [117] Most of these women are healthy, have no prior history of thrombocytopenia, and are detected by routine blood testing. The cause of the mild reduction in platelet count (usually 75150 × 10^9 /L) is unknown. This condition is benign, without an increased risk for maternal bleeding or neonatal thrombocytopenia.[115] [116] Accordingly, no special treatments are indicated in these women, and the route of delivery should be determined by obstetrical indications.

Pre-eclampsia/Eclampsia

Pre-eclampsia is characterized by the onset of hypertension and proteinuria during pregnancy, especially in a primigravida near term. Pre-eclampsia complicates approximately 5% of pregnancies. Thrombocytopenia occurs in about 20% of pre-eclamptic patients, and almost half of all patients with eclampsia.[117] [118] [119] In addition, some patients have evidence for a platelet function defect, exhibiting a prolonged bleeding time despite a normal platelet count.[120] A subset of patients with pre-eclampsia have microangiopathic *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets (HELLP syndrome).[121] This condition usually indicates severe pre-eclampsia, and is associated with a higher risk of maternal and fetal complications.[121] [122] [123] Repeated clinical and laboratory assessment of these patients is important, as this syndrome can mimic other life-threatening complications of pregnancy, such as overt DIC, thrombotic thrombocytopenic purpura, septicemia, or acute fatty liver of pregnancy.[124]

Increased platelet destruction is the mechanism for the thrombocytopenia in pre-eclampsia.[125] However, activation of the coagulation system is relatively modest,[126] [127] suggesting that thrombin generation may not be a major factor in the thrombocytopenia. Endothelial dysfunction is another potential explanation for increased platelet turnover in pre-eclampsia.[128]

Pharmacologic control of hypertension and rapid delivery are the treatments of choice for pre-eclampsia, and will usually result in resolution of the thrombocytopenia within a few days. Because of the associated platelet function defects, some physicians recommend demonstrating a normal bleeding time in moderately thrombocytopenic patients before performing epidural

anesthesia in these patients.[119] However, epidural anesthesia is considered to be relatively safe even in patients with moderate thrombocytopenia.[129] In patients in whom delivery is not an option (i.e., premature fetus), treatment with bed rest and aggressive antihypertensive therapy has been reported to result in an improved platelet count. However, the clinical course is markedly variable, and some patients develop life-threatening organ failure.[122] Plasmapheresis has been used in some patients, especially if there is evidence of thrombotic microangiopathy and organ dysfunction.[130] The authors would perform plasma exchange in such a patient whose clinical picture has features that overlap with TTP.

Infection

Infection is a common cause of thrombocytopenia, occurring in approximately 5075% of patients with bacteremia or fungemia, and almost all patients with septic shock or DIC.[131] Even when caused by bacteremia, the thrombocytopenia is generally mild to moderate in severity, and usually not accompanied by significant coagulation abnormalities or bleeding. However, the likelihood of laboratory evidence for DIC increases as the platelet count falls to <50 × 10^9 /L. The mechanism(s) for thrombocytopenia in septicemia in the absence of DIC is uncertain, but could include chemokine-induced macrophage ingestion of platelets (hemophagocytosis) and direct activation of platelets by endogenous mediators of inflammation (e.g., platelet-activating factor[132]) or certain microbial products.[133] Various explanations for thrombocytopenia among different types of infection are listed in Table 129-7 .[134] [135] [136] [137] [138] [139] [140] [141] [142] [143] [144] [145] [146]

Unexplained thrombocytopenia in any hospitalized patient

TABLE 129-7 -- Mechanisms for Thrombocytopenia Complicating Infections

Mechanisms for Thrombocytopenia	Selected Examples
Increased platelet destruction	
Disseminated intravascular coagulation	Meningococcemia[134]
Hemophagocytosis	Septicemia,[135] Epstein-Barr virus[136]
Platelet-reactive autoantibodies: acute	Varicella[137]
Platelet-reactive autoantibodies: chronic	HIV[138]
Hemolytic-uremic syndrome	Verocytotoxin-producing*e. coli,*[139] HIV[140]
Antibodies against platelet-adsorbed microbial antigens	Malaria[141]
Hypersplenism	
Acute	Disseminated mycobacterium avium in HIV[142]
Chronic	Viral chronic active hepatitis, malaria
Decreased platelet production	
Replacement of marrow by granulomata	Ehrlichiosis,[143] tuberculosis
Infection of megakaryocytes	HIV [144]
Transient virus-induced aplastia	Parvovirus B19[145] (erythroblastopenia predominates)
Multiple mechanisms	

e.g., platelet destruction + hypersplenism	Recurrent malaria
e.g., increased platelet destruction, decreased platelet production, hypersplenism	Chronic HIV infection [146]

warrants studies, such as blood cultures, to exclude infection. Prompt recognition and treatment of the infection is most important, as platelet count recovery tends to parallel the resolution of the infection. Prophylactic platelet transfusions are generally not required unless the platelet count falls to <1020 × 10 ^{9} /L, or unless comorbid clinical features increase the likelihood of serious bleeding (e.g., concomitant coagulopathy, an invasive procedure, uremic platelet dysfunction). The use of heparin for patients with septic shock and DIC is controversial. However, heparin may benefit a subset of patients with clinical evidence of DIC and microvascular thrombosis (e.g., meningococcemia with acral tissue necrosis). The possibility of acquired protein C deficiency complicating acute DIC should also be considered in septic patients with limb ischemia (e.g., meningococcemia), as treatment with vitamin K, plasma, and, possibly, protein C concentrates, [134] could be beneficial.

Patients infected with HIV pose a special diagnostic problem, as many potential causes of thrombocytopenia often coexist in these patients (Chap. 155).[146] These include: immune platelet destruction, impaired platelet production secondary to HIV infection of megakaryocytes, drug-induced myelosuppression (commonly, zidovudine, ganciclovir, and trimethoprim/sulfamethoxazole), HIV-associated thrombotic microangiopathy, hypersplenism, and marrow infiltration by tumor or opportunistic infections. Platelet kinetic studies have shown a complex interaction of decreased platelet production, increased platelet destruction, and splenic platelet sequestration. Immune platelet destruction may be related to antibodies that cross-react with GPIIb/IIIa complexes. [135] Zidovudine often raises the platelet count in patients with HIV-associated thrombocytopenia. Most patients with HIV-associated thrombocytopenia respond to conventional treatments for ITP, including corticosteroids, splenectomy, and gammaglobulin.[136]

Systemic Lupus Erythematosus

Thrombocytopenia occurs in as many as 25% of patients with systemic lupus erythematosus (SLE), generally because of immune mechanisms.[147] Many different types of platelet-IgG interactions are described (anti-glycoprotein, [148] antiglycolipid,[149] antiphospholipid, platelet-reactive immune complexes) and the predominant explanation for thrombocytopenia is unknown.

Several thrombocytopenic syndromes are seen in SLE patients. For many patients, the thrombocytopenia is chronic, resembling ITP, and is the predominant clinical manifestation of the lupus.[147] Often, these patients have a prolonged bleeding time and platelet function abnormalities despite the relatively mild thrombocytopenia.[150] Some thrombocytopenic SLE patients have antiphospholipid antibodies and are at increased risk for thrombotic rather than bleeding complications.[151] Acute, severe thrombocytopenia can be a prominent feature of patients with a severe multisystem exacerbation of lupus. [147] Rarely, patients with SLE develop an illness that closely resembles TTP or HUS; these patients should be treated with plasma exchange. [152]

Treatment of the thrombocytopenia of SLE is similar to that of ITP (see Chap. 126). Corticosteroids are the first line of therapy, but many patients do not respond or require high doses. This can produce serious adverse effects such as avascular necrosis of the femoral head. Before proceeding to splenectomy, we usually try danazol (an attenuated androgen), in doses of 2001,200 mg/day. [153] Usually, several weeks are required before results are visible. The efficacy of splenectomy in SLE is controversial. Although many patients respond, the overall success rate appears to be lower than that for ITP, with a higher operative morbidity. [154] Patients with refractory thrombocytopenia can benefit with more aggressive therapies, including high-dose intravenous -globulin, [155] azathioprine, cyclophosphamide combined with plasmapheresis,[156] and cyclosporine.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome is a clinicopathologic disorder characterized by a wide spectrum of clinical events (particularly thrombosis and recurrent miscarriages) associated with antibodies that recognize a complex of negatively charged phospholipid and various protein cofactors such as $_{2}$ -glycoprotein I, prothrombin, protein C, protein S, and annexin V.[157] [158] [159] Many patients with this syndrome have thrombocytopenia, [160] which is typically mild and intermittent. The antiphospholipid antibody syndrome should be considered in patients who develop cardiac valvulitis, idiopathic lower limb or abdominal vein thrombosis, dural sinus thrombosis, non-atheromatous arterial thrombosis, or microvascular thrombosis (e.g., acrocyanosis, digital ulceration or gangrene, livedo reticularis). [161] [162] [163] [164] The mechanism of the prothrombotic tendency in patients with antiphospholipid antibody syndrome remains elusive, but interference with endothelial cell function, impaired fibrinolysis, interference with the protein C anticoagulant pathway, and antibody-mediated platelet activation have all been described. [159]

Antiphospholipid antibodies are detected using solid-phase enzyme-linked immunoassays (ELISA) with purified phospholipids (usually cardiolipin) as target antigens. Lupus anticoagulant activity is shown by demonstrating inhibition of certain phospholipid-dependent coagulation assays. Although antiphospholipid antibodies are frequently detected in patients with SLE, they can also be found in patients with other autoimmune disorders, malignancy, infections, or as a complication of certain drugs (e.g., procainamide). Often no associated condition is identified (primary antiphospholipid antibody syndrome). [165] Evidence indicates that thrombocytopenia in patients with antiphospholipid antibody syndrome is associated with platelet glycoprotein-reactive autoantibodies. [148] [166]

Specific treatment for the thrombocytopenia is not usually required. For many patients, long-term anticoagulant or antiplatelet therapy, or both, are needed to prevent recurrent thromboses. Some clinical observations suggest that corticosteroid treatment may exacerbate certain thrombotic complications, [167] although others have noted benefit from corticosteroids. Anticoagulant therapy for asymptomatic patients without a prior history of thrombosis is not currently recommended.

Malignancy

Thrombocytopenia complicating malignant disorders most frequently results from antineoplastic treatment or marrow replacement by tumor. However, certain thrombocytopenic syndromes have been associated with malignancy, including autoimmune thrombocytopenia, DIC, and thrombotic microangiopathy.

Thrombocytopenia attributable to platelet glycoprotein-reactive autoantibodies can complicate neoplastic lymphoproliferative diseases such as Hodgkin disease, non-Hodgkin lymphoma, and chronic lymphocytic leukemia.[168] [169] Sometimes the thrombocytopenia responds to treatment of the neoplasm, although in some patients (particularly those with Hodgkin disease) the thrombocytopenia is indistinguishable from ITP and is not related to the activity of the lymphoma (see Chap. 126).

DIC occurs in certain malignancies, particularly adenocarcinomas of the pancreas, stomach, lung, colon, breast, and prostate. [170] [171] Some patients present with venous or, less commonly, arterial thrombosis as the first clinical manifestation of their malignancy. In these patients the presence of thrombocytopenia is an important clue that should prompt specific investigations for DIC. The platelet count typically rises to normal or even elevated levels during heparin therapy; however, recurrent thrombocytopenia and thrombosis can occur within hours or days of discontinuing the heparin therapy. Cancer patients with DIC and DVT are also at risk for warfarin-associated venous limb gangrene (HIT complicated by DVT). Thus, cancer patients with DIC should receive heparin rather than warfarin anticoagulation.

DIC with hemorrhagic manifestations is characteristically seen in some patients with prostate adenocarcinoma, and in most patients with acute promyelocytic leukemia. It is crucial to recognize promyelocytic leukemia, since treatment with all-trans retinoic acid produces differentiation of the malignant cells, and rapidly reduces the life-threatening bleeding risks attributable to hyperfibrinolysis in this disorder (see Chaps. 53 and 54).[172]

A destructive thrombocytopenic disorder that resembles hemolytic uremic syndrome or thrombotic thrombocytopenic purpura has been described in patients with adenocarcinoma of the breast and colon.[105] This syndrome has a high prevalence in females, frequently those with a history of therapy with mitomycin C. DIC is not usually present. Some patients respond transiently to plasmapheresis or protein A immunoadsorption. [173]

Hemophagocytic Syndrome

The hemophagocytic syndrome is characterized by pancytopenia and morphologic evidence of phagocytosis of red cells, granulocytes, and platelets by reactive macrophages. Some adult patients have a fatal disease process characterized by high fever, weight loss, prominent hepatosplenomegaly, severe pancytopenia, elevated liver enzymes, and a terminal infection.[174] A T-cell lymphoma is the usual explanation for this dramatic illness. [174] [175] However, similar patients with fulminant

illness have been described following otherwise unremarkable bacterial [176] or viral infections (particularly the Epstein-Barr virus [136] [177] [178]). In some cases, the viral infection could have initiated the lymphoma;[177] in others, the infection may represent the initial manifestation of a lymphoma accompanied by a severe immunocompromised state. In children, the high mortality associated with hemophagocytic lymphohistiocytosis warrants aggressive treatment, including antineoplastic chemotherapy and bone marrow transplantation.[136]

Severe, but potentially reversible, hemophagocytosis can be seen in patients with certain unusual infections (e.g., babesiosis, [179] ehrlichiosis[180]). Hemophagocytosis has also been observed in patients with SLE,[181] Still disease, and HIV infection.[182] Treatment should be directed at the underlying illness, with blood product support as needed.

Solid Organ and Bone Marrow Transplantation

Thrombocytopenia commonly occurs during episodes of solid organ allograft rejection. [183] It is possible that platelet activation and deposition in the transplanted organ vasculature contribute to the rejection process. Anti-rejection therapies also can cause thrombocytopenia via increased platelet destruction (antilymphocyte globulin[114] [184]) or marrow suppression (azathioprine[184]). About 5% of renal transplant recipients,[185] [186] and even fewer recipients of liver or heart transplants,[186] develop post-transplant HUS. Although HUS is often attributed to cyclosporine treatment in these patients, it has been noted that cyclosporine usually can be safely resumed following graft recovery.[185]

Early, severe thrombocytopenia caused by marrow ablative therapy invariably accompanies bone marrow transplantation (BMT). Platelet count recovery to >50 × 10^9 /L is more rapid (16 vs. 35 days) in patients receiving autologous mobilized peripheral blood progenitor cells compared with autologous BMT. [187] Severe, persistent thrombocytopenia despite recovery of red and white cells is relatively common following marrow or peripheral blood transplantion; [188] autoimmune thrombocytopenia has been implicated in some patients.[189] Late-onset thrombocytopenia following BMT that responds to corticosteroids, intravenous -globulin, and splenectomy has also been attributed

to autoimmune thrombocytopenia. Rarely, transplantation-associated alloimmune thrombocytopenia can be caused by donor/recipient incompatibility involving platelet-specific alloantigens such as Pl^{A1} or Br^a . [190]

A syndrome of thrombocytopenia, red cell fragmentation, and renal impairment can occur in as many as 10% of BMT patients, usually beginning 312 months following transplantation (BMT-associated hemolytic uremic syndrome).[191] The hematologic abnormalities can be mild and remit spontaneously, although patients often have residual azotemia and hypertension. More severely affected patients can benefit from plasmapheresis.Unfortunately, the syndrome has a poor overall prognosis and many patients will die despite any interventions.

Cardiopulmonary Bypass Surgery

Excess bleeding is an important problem in patients who undergo heart surgery utilizing cardiopulmonary bypass. [192] Most of these patients receive blood transfusions, and approximately 5% require urgent reoperation for postoperative bleeding.

Thrombocytopenia and transient platelet dysfunction are observed in virtually every patient. Typically, the platelet count falls by 3350%, primarily due to hemodilution, but also as a result of bleeding and losses within the extracorporeal perfusion device. The bleeding time rises markedly during heart surgery (>30 minutes), but usually improves to <15 minutes shortly after surgery, and to normal several hours later. In contrast, the thrombocytopenia persists for 34 days, followed by recovery of the platelet count to values exceeding the preoperative baseline.

The pathogenesis and clinical significance of the hemostatic defect in these patients remain uncertain, but it is probably multifactorial. Studies have described transient, *intrinsic* defects in platelet function[192] [193] [194] (see Chap. 131). These include decreased in vitro platelet aggregation, decreased platelet surface membrane proteins,[195] selective depletion of platelet -granules, and evidence of in vivo platelet activation [196] and platelet vesiculation. [196] The platelet dysfunction in heart surgery is also attributable to an *extrinsic* platelet defect resulting from thrombin inhibition by the high doses of heparin. [197] Further, an important role for hyperfibrinolysis in the pathogenesis of bleeding is shown by elevated D-dimers levels in bleeding patients, [198] as well as the efficacy of antifibrinolytic agents [199] [200] in the prevention and treatment of heart surgery-associated bleeding. Other factors in some patients include residual heparin effect post-bypass (including heparin rebound[201]) and preoperative use of aspirin. Treatment of platelet dysfunction after cardiopulmonary bypass is discussed in Chapter 131 .

Thrombocytopenia Associated with Cardiovascular Disease

Congenital Cyanotic Heart Disease

Thrombocytopenia caused by a decrease in platelet life span occurs in some patients with severe cyanotic congenital heart disease, and is approximately related to the severity of the polycythemia. Bleeding occurs in a few patients and can be related to platelet function defects, coagulopathy, or hyperfibrinolysis. Reducing the hematocrit by phlebotomy sometimes improves the hemostatic defects.

Valvular Heart Disease

Although increased platelet turnover is common in valvular heart disease, mild thrombocytopenia occurs infrequently. The pathogenesis of the platelet consumption is not well understood, but could be related to increased plateletvon Willebrand factor interactions at high shear. [202] Indeed, high-molecular-weight multimers of von Willebrand factor are reduced in some of these patients,[203] suggesting a possible explanation for the characteristic bleeding from gastrointestinal angiodysplasia observed in some patients with aortic stenosis or hypertrophic cardiomyopathy.[204]

Pulmonary Vascular Disorders

Disorders characterized by pulmonary hypertension can be accompanied by thrombocytopenia, the pathogenesis of which is poorly defined. [205] Thrombocytopenia has also been reported to occur in association with pulmonary embolism,[206] possibly as a result of mild DIC. When evaluating such a patient, the clinician should inquire about current or recent heparin exposure, as HIT and pulmonary embolism are strongly associated. [35] [52]

Chapter 130 - Hereditary Disorders of Platelet Function

Joel S. Bennett

INTRODUCTION

A prolonged bleeding time in a patient with a normal platelet count implies a diagnosis of von Willebrand disease or a disorder of platelet function. von Willebrand disease is discussed in Chapter 114 and acquired disorders of platelet function are discussed in Chapter 131 . Hereditary disorders of platelet function can be subclassified into disorders of platelet adhesion, aggregation, secretion, or procoagulant activity according to the predominant phase of platelet function affected.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DISORDERS OF PLATELET ADHESION

Bernard-Soulier Syndrome (Glycoprotein Ib-IX Deficiency)

The Bernard-Soulier syndrome, described in 1948 by Bernard and Soulier, is a rare disorder of platelet function characterized by a prolonged bleeding time, very large platelets, and thrombocytopenia.[1] Individuals with the Bernard-Soulier syndrome have a bleeding diathesis because their platelets are unable adhere to von Willebrand factor (vWf) in the subendothelial matrix. [2] The basis for this abnormality is deficiency or dysfunction of the glycoprotein Ib-IX (GPIb-IX) complex. [3] [4]

Biology and Molecular Aspects

Following disruption of the endothelial lining of the vasculature, circulating platelets adhere to exposed subendothelial connective tissue. At low rates of shear in the blood, platelets adhere to subendothelial collagen, fibronectin, or laminin. However, at higher rates of shear, such as those present in arterioles and in the microcirculation, platelet adhesion requires the presence of subendothelial vWf. [5] [6] vWf is an elongated multimeric glycoprotein, each monomer of which contains two domains that interact with platelets.[7] [8] One domain binds to the glycoprotein IIb-IIIa complex (GPIIb-IIIa) on activated platelets. [9] The other binds to GPIb-IX, thereby mediating the adhesion of unactivated platelets to subendothelial vWf. [10] vWf is also present in plasma but is not found on the platelet surface. There is as yet no adequate explanation for this paradox. Exposing vWf to the antibiotic ristocetin or the snake venom protein botrocetin in vitro induces binding to GPIb-IX. [11] [12] However, the factors that induce vWf binding to GPIb-IX in vivo are uncertain. One possibility is that the conformation of vWf changes when it is present in the subendothelium, allowing it to bind to GPIb-IX. [8] [13] [14] A second possibility is that shear stress induces vWf binding by changing the conformation of GPIb-IX, vWf, or both.[15] [16] [17]

The protein GPIb-IX, affected in Bernard-Soulier platelets, is a non-covalent heterodimer, consisting of the heavily glycosylated 165,000-molecular weight GPIb and the 20,000-molecular weight GPIX.[15] [18] There are approximately 25,000 copies of GPIb-IX on the platelet surface. [15] GPIb itself is a disulfide-linked heterodimer containing a 143,000-molecular weight -subunit (GPIb) and 22,000-molecular weight -subunit (GPIb). [15] GPIb can be cleaved by trypsin and a calcium-dependent platelet protease, giving rise to a soluble 135,000-molecular weight heavily glycosylated amino terminal fragment termed glycocalicin [15] and a membrane-associated 25,000-molecular weight remnant that remains disulfide-linked to GPIb and associated with GPIX. [18] The amino terminal portion of glycocalicin contains binding sites for both vWf and thrombin[15] and its carboxyl-terminal portion contains multiple sialic acid-rich hexasaccharides O-linked to serine and threonine residues. [19] The latter consists of several tandem repeats of a mucin-like sequence and is polymorphic due to differences in the number of repeats of a 13 amino acid motif. [20] GPIb extends into the platelet cytoplasm where it is linked to the platelet cytoskeleton [21] via actin-binding protein [22] and possibly to platelet signaling pathways via the protein 14-3-3.[23] The cytoplasmic portions of GPIb and GPIX are acylated with palmitic acid through thioester linkages, probably at a free cysteine residue. [24] This modification likely stabilizes the interaction of these subunits with the membrane lipid bilayer or with other membrane proteins. In addition, the cytoplasmic portion of GPIb can be phosphorylated at Ser 166 by the cyclic adenosine monophosphate (AMP)-dependent protein kinase, [25] a reaction that inhibits collagen-induced platelet actin polymerization.[26]

The GPIb, GPIb, and GPIX each contain leucine-rich motifs (LRMs) with the consensus sequence L-LN-LLPPGLL-GL-. [19] [27] [28] Similar sequences were first noted in the plasma protein leucine-rich $_2$ glycoprotein and have now been detected in 13 other proteins. [15] There are seven LRMs in GPIb and GPIb and GPIX each contain a single LRM. The amino acids flanking the LRMs are also conserved. [15] The function of the LRMs is not known. The presence of multiple leucine residues suggests that they could act like leucine-zippers involved in protein oligmerization. [15] However, the classic leucine zipper motif consists of an amphipathic -helix, whereas the LRM appears to be an amphipathic -sheet.[29] Moreover, the motifs in GPIb, GPIb, and GPIX are not located in regions known to be involved in intermolecular associations.[15] On the other hand, they could be involved in intramolecular associations that contribute to the tertiary structure of each molecule.

A fourth protein, glycoprotein V (GPV), is also missing from Bernard-Soulier platelets. [3] [30] GPV is an 82,000-molecular weight substrate for thrombin. [31] [32] However, GPV cleavage is not required for thrombin-induced platelet activation [32] nor is it required for GPIb-IX function. [33] GPV contains 15 tandem LRMs homologous to those of GPIb, GPIb, and GPIX,[34] but they do not appear to be involved in the formation of a GPIb-IX-V complex. [35] The association of GPV with GPIb-IX is mediated by GPIb.[36] Because there are only half as many GPV molecules on the platelet surface as there are GPIb-IX complexes, [35] it is likely that GPIb-IX-V is a trimer with a stoichiometry of 2:2:2:1 for GPIb, GPIb, GPIX, and GPV, respectively. [36]

Studies of GPIb-IX biosynthesis indicate that although GPIb and GPIb can be expressed independently on the cell surface, their expression is much more efficient in the presence of GPIX.[33] Further, GPIb is the subunit that links GPIb to GPIX. [37] Thus, mutations that result in the deficient expression of any one of the three components of GPIb-IX can produce the Bernard-Soulier syndrome. On the other hand, GPV is not required for GPIb-IX expression and the basis for its absence from Bernard-Soulier platelets is not known.

Etiology and Pathogenesis

The effects of GPIb-IX deficiency are not limited to the inability of affected platelets to adhere to vWf. The majority of Bernard-Soulier platelets are large when observed on peripheral blood smears. However, there is contradictory evidence about the size of the platelets in the circulation. It has been reported that circulating Bernard-Soulier platelets are of normal size, [38] but have increased membrane, perhaps located in the surface-connected open-canalicular system and extruded when platelets spread during the preparation of a blood smear. [39] Others have found that circulating Bernard-Soulier platelets have an increased volume, [40] a more spherical shape,[40] and a more deformable membrane than normal platelets.[41] Although the serum prothrombin time has been reported to be shortened in the Bernard-Soulier syndrome[42] and collagen-induced platelet procoagulant activity and factor XI binding to be absent, [43] prothrombin consumption, measured by a two-stage assay, is normal[44] and the expression of platelet factor 3 [44] and prothrombinase activity by Bernard-Soulier platelets is increased. [45] An unexplained decrease in thrombin-, trypsin-, and thromboxane-stimulated phospholipase C activity has also been reported. [46] GPIb-IX is a target for some drug-dependent antiplatelet antibodies induced by quinidine and quinine [47] [48] [49] and as expected, these antibodies fail to bind to Bernard-Soulier platelets. [50]

Genetic Aspects

The Bernard-Soulier syndrome is an autosomal recessive disorder. [51] In most instances, GPIb-IX is not detectable on the surface of Bernard-Soulier platelets, but in a few cases, 747% residual

GPIb or GPIb-IX has been detected.[3] [30] [52] When it has been possible to study heterozygotes, most have had platelets that were larger than normal and a GPIb

content intermediate between normals and affected individuals. [30] [53] Consistent with the rarity of the syndrome, consanguinity has often been noted in affected families.

The gene for each component of the GPIb-IX-V complex has been localized and characterized. The GPIb gene is located on chromosome 17p12-ter, [54] the GPIb gene on chromosome 22q11.2,[55] [56] the GPIX gene on chromosome 3q21,[57] [58] and the GPV gene on chromosome 3q29.[58] Each gene has a compact intron-depleted structure, such that the genes for GPIb, GPIb, and GPV contain two exons and the gene for GPV contains three. [58] Moreover, the open reading frame and 3 untranslated region of each is encoded by a single exon except for the GPIb gene where its single intron is inserted into the codon for the fourth residue of its signal peptide.[55] The genes are also similar in that their 5 flanking regions contain potential binding sites for the GATA, *ets*, and Sp-1 transcription factors like other genes expressed by megakaryocytes.[58] [59] [60] [61] Although potential TATA elements are located in the GPV 5 flanking region, it is uncertain whether these are utilized. [58]

A number of mutations responsible for the Bernard-Soulier syndrome have been identified (Table 130-1). As would be expected from the studies of GPIb-IX-V biosynthesis discussed previously, these mutations involve the genes for either GPIb, GPIb, or GPIX. Most of the detected mutations have been missense mutations or frameshifts resulting in premature stop codons. However, two unique mutations were identified in the GPIb genes of a patient with the velo-cardio-facial syndrome and consisted of deletion of a portion of chromosome 22q11.2 including the GPIb locus [62] and a mutation in a GATA binding site in the promoter of the remaining GPIb allele resulting in decreased GPIb gene transcription. [61] It is noteworthy that seven mutations are located in the LRMs of either GPIb or GPIX (Table 130-1). Those involving GPIb produced dysfunctional GPIb-IX complexes, [63] [64] [65] [66] whereas those involving GPIX decreased GPIb-IX expression. [67] In addition, a Asn 45 Ser mutation in GPIX has been detected in separate kindreds from the United Kingdom, [68] Austria,[69] and Sweden,[70] a Cys 73 Tyr mutation in GPIX has been identified in two kindreds in Japan, [71] and a dinucleotide deletion involving codon 492 of GPIb has been identified in a Caucasian [72] and an African-American kindred in the United States,[73] suggesting that these sites may be hot spots for mutation in the GPIX and GPIb genes.

Clinical Presentation

The Bernard-Soulier syndrome presents in infancy or childhood with bleeding characteristic of defective platelet function: ecchymoses, epistaxis, and gingival bleeding.[51] Later manifestations include menorrhagia and postpartum, gastrointestinal, and post-traumatic hemorrhage. [81] [82] Hemarthroses and expanding hematomas are unusual. Although the severity of hemorrhage among affected individuals is variable, it may require frequent transfusions and suppression of menses. In a report of 59 cases, there were 10 deaths.[83] In some patients the severity of hemorrhage inexplicably declines over the course of the disease. [83]

Laboratory Findings

The bleeding time in patients with the Bernard-Soulier syndrome is markedly prolonged to >20 minutes. [44] Platelet counts may vary within kindreds and in a given patient. Most patients are thrombocytopenic to some degree and patients with platelet counts <20,000/l have been reported. [84] Platelets seen on stained peripheral blood smears are large, with 3080% having a mean diameter >3.5 m.[53] Occasional platelets are as large as 2030 m in diameter. The red blood cells and white blood cells are normal and distinctive abnormalities have not been observed in marrow megakaryocytes by light microscopy, [85] although abnormalities in the demarcation membrane system have been observed by electron microscopy.[86] The laboratory tests that distinguish Bernard-Soulier from normal platelets are the failure of Bernard-Soulier platelets to agglutinate in the presence of ristocetin and decreased [87] or absent agglutination[88] after exposure to botrocetin. In contrast to von Willebrand disease, these abnormalities cannot be corrected by the addition of normal plasma. [84] Absent ristocetin-induced agglutination and normal platelet aggregation can be reproduced in the whole blood aggregometer, obviating the difficulty of preparing platelet-rich plasma containing a sufficient number of Bernard-Soulier platelets for conventional aggregometry. [89] Aggregation of Bernard-Soulier platelets induced by agonists such as adenosine diphosphate (ADP), collagen, thrombin, and epinephrine is normal (Fig. 130-1).[51] Although a defect in prothrombin consumption, manifested by a short serum prothrombin time, has

TABLE 130-1 -- Mutations Resulting in the Bernard-Soulier Syndrome

Affected Protein	Mutation	Consequence	Reference

[a]Mutation involving a LRM or a flanking region.

Figure 130-1 Platelet aggregation in response to ADP. Following the addition of ADP to stirred aliquots of platelet-rich plasma in an aggregometer, there is a brief decrease in light transmission indicated by the solid arrow, due to platelet shape change. When normal (NRML) or Bernard-Soulier platelets (BSS) are examined, shape change is followed by either a single continuous wave of aggregation at high ADP concentrations or two waves of aggregation at lower ADP concentrations. The hatched arrow at the inflection point between the first and second waves of aggregation is the point at which platelet secretion occurs. -Storage pool deficient platelets (SPD) generally undergo only a first wave of aggregation and the aggregates may dissociate. Thrombasthenic platelets (TSA) undergo shape change but do not aggregate.

been reported,[44] expression of platelet factor 3 activity by Bernard-Soulier platelets is normal or increased. [44]

Differential Diagnosis

Conditions associated with thrombocytopenia and large platelets can be differentiated from the Bernard-Soulier syndrome because Bernard-Soulier platelets fail to agglutinate in the presence of ristocetin. Giant platelets, thrombocytopenia, and Döhle bodies in leukocytes are seen in the *May-Hegglin anomaly*.[90] The function and membrane proteins of May-Hegglin platelets are normal. [91] When hemorrhage does occur in these patients, it correlates with the extent of thrombocytopenia. [90]

Several variants of Alports syndrome have been described with large platelets, thrombocytopenia, hereditary nephritis, sensorineural deafness plus (*Fechtner syndrome*)[92] or minus leukocyte inclusions (*Epsteins syndrome*). [93] A third variant with only macrothrombocytopenia and characteristic leukocyte inclusions has been observed (*Sebastian syndrome*). [94] Platelet function in some affected individuals is normal, [92] [95] in others platelet aggregation and secretion induced by ADP, collagen, and epinephrine is defective. [93] [96] The *gray platelet syndrome* due to a deficiency of platelet -granules is associated large platelets and thrombocytopenia.[97] In contrast to Bernard-Soulier platelets, these platelets are pale gray on Wright-stained blood smears and agglutinate normally in the presence of ristocetin.[96] In the autosomal dominant *Montreal platelet syndrome* giant platelets, thrombocytopenia, and a prolonged bleeding time are associated with spontaneous platelet aggregation at pH 7.4 and normal agonist-induced platelet aggregation. [95] So-called *Mediterranean macrothrombocytopenia*[100] is not a unique entity, but refers to a putative difference in platelet count and platelet size among Europeans of northern and Mediterranean origin. There are also anecdotal reports of thrombocytopenia and giant platelets, often associated with a mild bleeding diathesis, but lacking the features of either Bernard-Soulier syndrome or the May-Hegglin anomaly.[101] [102] [103] [104] In *platelet-type von Willebrand disease*, mutations within the vWf binding domain of GPIb produce spontaneous vWf binding and the clinical picture of type 2B von Willebrand disease. [105] [106] [107]

Acquired Bernard-Soulier-like disorders can be differentiated from the congenital Bernard-Soulier syndrome by history. Antibodies to GPIb occur in some patients with idiopathic thrombocytopenic purpura,[108] [109] [110] but it has not been possible to determine if the antibodies are responsible for bleeding because of the concomitant thrombocytopenia. Two patients with myelodysplasia and an acquired Bernard-Soulier-like syndrome have been reported. [111] [112] A patient has been reported with a lymphoproliferative disorder and clinical bleeding who had a prolonged bleeding time, normal platelet count and platelet morphology, and a circulating IgG antibody that inhibited ristocetin-induced platelet agglutination but was directed against an unidentified 210,000-molecular weight platelet protein. [113]

Therapy

Treatment of hemorrhage in patients with the Bernard-Soulier syndrome usually requires platelet transfusion (Table 130-2). Hormonal control of menses has been effective in managing menorrhagia.[114] Splenectomy has been attempted to increase the platelet count, [115] but has resulted in only transient increases and has not ameliorated the platelet function defect. Corticosteroids are not beneficial in this disorder. Desmopressin acetate (DDAVP) has been reported to shorten the bleeding time in several affected individuals, [116] [117] [118] but its efficacy in patients with hemorrhage has not been reported.

Deficiency of Platelet Collagen Receptors

Collagen is a substrate for platelet adhesion and an agonist for platelet aggregation and secretion. A number of platelet proteins

TABLE 130-2 -- Treatment of Inherited Disorders of Platelet Function

Disorder	Defect in Platelet Function	Structural Defect	Treatment Options		
			Platelet Transfusion	DDAVP	Corticosteroids

Abbreviations: Y, yes; N, No; ?, may be effective in some cases; DDAVP, desmopressin.

that interact with collagen have been identified, including GPIIb, [119] GPIV,[120] GPVI,[121] the GPIa-IIa (21) complex,[122] a 65,000-molecular weight protein that binds to type 1 collagen[123] and a protein with a molecular weight of 85,00090,000.[124] It is unclear which of these proteins functions as a physiologic receptor for collagen. However, several clinical reports suggest that GPVI and the GPIa-IIa complex can function in this manner.

GPVI

A 62,000-molecular weight protein, GPVI, is stably associated with the Fc receptor -chain in the plasma membrane of human platelets. [125] [126] Exposure of normal platelets,[126] [127] but not GPVI-deficient platelets,[125] to collagen or collagen-like peptides results in the phosphorylation of the Fc receptor -chain on tyrosine residues, followed by the tyrosine phosphorylation of tyrosine kinase Syk and phospholipase C2. [127] Moreover, murine platelets lacking either the Fc receptor -chain or Syk are unable to respond to collagen stimulation,[128] whereas the interaction of GPVI-deficient human platelets with either immobilized [129] or soluble[130] collagen is markedly impaired. Thus, it appears that platelet function can be induced by a collagen-stimulated pathway consisting of GPVI, the Fc receptor -chain, Syk, and phospholipase C2.

The description of three patients with mild bleeding disorders whose platelets specifically lacked GPVI is additional evidence that GPVI is a functional receptor for collagen on platelets.[121] [131] [132] The platelets of each patient failed to aggregate following stimulation with collagen, despite the presence of normal amounts of GPIa-IIa, although the platelets of two retained some ability to adhere to collagen-coated surfaces. [131] [132] Further, an antibody against GPVI has been reported in a patient with idiopathic thrombocytopenic purpura that inhibits collagen-induced platelet function. [133]

GPIa-IIa

The GPIa-IIa complex is indistinguishable from the VLA-2 complex on lymphocytes and the integrin 21 present on a variety of cells. [134] [135] In many of these cells (including platelets), 21 functions as a Mg^{2+} -dependent receptor for collagen.[122] [136] [137] [138] In platelets, the collagen-stimulated phosphorylation of Syk [139] [140] and phospholipase C2[139] can be blocked by an anti-GPIa-IIa antibody, whereas cross-linking GPIa-IIa with a monoclonal antibody induces the FcRII-dependent phosphorylation of these proteins.[139] Moreover, two patients with histories of bleeding have been reported whose platelets failed to respond normally to collagen and lacked GPIa-IIa. The platelets of the first contained æ1525% of the normal amount of GPIa and failed to aggregate in response to collagen, to adhere to collagen under static conditions,[141] and to adhere and spread on collagen under conditions of flow. [142] The platelets of the second completely lacked GPIa plus the -granule protein thrombospondin, failed to aggregate in response to low concentrations of collagen and adhered to, but did not spread on, collagen-coated surfaces. [143] A third patient has also been reported with a myeloproliferative disorder, a prolonged bleeding time, and no bleeding symptoms whose platelets were unresponsive to collagen and contained GPVI but no GPIa-IIa.[144] Thus, GPIa-IIa appears to play a role in the platelet response to collagen. On the other hand, the inability of platelets lacking GPVI to respond to collagen despite the presence of GPIa-IIa, and vice versa, suggests that both proteins may be required for normal platelet responsiveness to collagen.

GPIV

A single chain 88,000-molecular weight protein, GPIV (CD36), is present on the surface of a variety of cells and functions as a receptor for red blood cells parasitized by *Plasmodium falciparum* on endothelium,[145] a binding site for thrombospondin, [146] [147] a receptor for oxidized low-density lipoprotein, [148] and a signal transduction molecule.[149] Because monoclonal anti-GPIV antibodies inhibit collagen-mediated platelet adhesion [150] and purified GPIV binds to collagen and inhibits collagen-induced platelet aggregation, [120] it has been suggested that GPIV is a platelet receptor for collagen. [120] GPIV carries the platelet antigen Nak^{a151} and platelets of Nak^{a} -negative individuals lack GPIV[152] as a result of one of several mutations. [153] [154] [155] However, GPIV-deficient individuals, usually identified because their platelets lack Nak^{a} , are asymptomatic and in most,[156] [157] [158] [159] but not all,[160] [161] studies, their platelets interact normally with collagen. [156] Thus, GPIV does not appear to be a physiologically relevant platelet receptor for collagen.

DISORDERS OF PLATELET AGGREGATION

Glanzmann Thrombasthenia (Glycoprotein IIb-IIIa Deficiency)

Glanzmann thrombasthenia is a rare disorder characterized by a prolonged bleeding time, normal platelet count, and absent macroscopic platelet aggregation. [51] Thrombasthenia was originally described by Glanzmann in 1918 as a bleeding disorder with a normal platelet count and abnormal clot retraction. [162] Affected platelets in Glanzmann thrombasthenia are unable to aggregate. The basis for their defective function is deficiency or dysfunction of the GPIIb-IIIa complex. [163]

Biology and Molecular Aspects

Platelet aggregation follows platelet adhesion to form a hemostatic plug. [164] In contrast to adhesion, however, aggregation is an active metabolic process in which agonists such as thrombin or ADP bind to their cognate receptors to stimulate the exposure of a fibrinogen or vWf binding site on the platelet membrane GPIIb-IIIa complex.[165] [166] [167] [168] [169] Fibrinogen or vWf bound to GPIIb-IIIa then cross-links adjacent platelets into an occlusive plug. GPIIb-IIIa is already present on the surface of resting platelets. Thus, the signals induced by platelet stimulation cause a change in GPIIb-IIIa that exposes its ligand binding site. [170] Following ligand binding, the cytoplasmic tails of GPIIb-IIIa associate with submembranous actin filaments via intermediary cytoskeletal proteins. [171] This provides a mechanism for transmitting the force of cytoskeletal contraction to the fibrin clot resulting in clot retraction. [172] [173] GPIIb-IIIa can also bind to vWf and fibronectin in the subendothelial matrix, resulting in the spreading of adherent platelets. [174] [175] There are approximately 40,00080,000 GPIIb-IIIa complexes on the surface of resting platelets [176] and additional complexes, present in the membrane of the platelet -granules, can be translocated to the platelet surface by platelet stimulation. [177] [178] Glanzmann thrombasthenia results when platelets lack sufficient numbers of functional GPIIb-IIIa complexes on their surface to support platelet aggregation. [163] Because the platelets of obligate heterozygotes aggregate normally, but contain one-half the normal number of GPIIb-IIIa complexes, 50% of the normal number of GPIIb-IIIa complexes per platelet is at least sufficient to support platelet aggregation. [179]

The GPIIb-IIIa complex is a calcium-dependent heterodimer and dissociates into GPIIb and GPIIIa monomers in the presence of calcium chelators. [180] By electron microscopy, it appears as a 12 × 8 nm globular head with two 18-nm tails extending from one side. [181] When incorporated into phospholipid vesicles, the globular head extends æ20 nm above the vesicle surface with the tips of the tails inserted into the phospholipid. [182] GPIIb-IIIa is a member of the integrin superfamily of adhesion receptors that mediate a variety of cell-cell and cell-extracellular

matrix interactions.[183] Integrins are /-heterodimers with -subunits homologous to GPIIb and -subunits homologous to GPIIIa. Because each integrin -subunit interacts with a restricted number of -subunits, integrins can be classified into subfamilies. GPIIb-IIIa belongs to a small subfamily consisting of GPIIb-IIIa or IIb3 and the vitronectin receptor v3. The expression of GPIIb-IIIa is restricted to cells of the megakaryocytic lineage because the GPIIb gene is only active in these cells, [184] whereas v3 is expressed by a variety of cells including endothelium and platelets. [185]

GPIIb has a molecular weight of 136,000 and is composed of disulfide-linked heavy (GPIIb) and light (GPIIb) chains with molecular weights of 125,000 and 23,000, respectively.[180] The light chain anchors the protein in the platelet membrane [186] and the heavy chain interacts with GPIIIa.[187] GPIIb is synthesized as single chain precursor (Pro-GPIIb).[186] In association with GPIIIa, Pro-GPIIb is transported to the Golgi complex where it is cleaved into heavy and light chains. [188] A feature of GPIIb is the presence of four domains in the heavy chain that are similar to the calcium-binding domains of calmodulin [186] and likely bind calcium in the mature protein.[189] A region proximal to the second of these domains (amino acids 294314) can be cross-linked to a peptide corresponding to the carboxyl terminus of the fibrinogen -chain, suggesting that these amino acids are part of GPIIb-IIIas ligand binding site. [190] [191] [192] Studies in vitro suggest that GPIIb plays a major role in determining which protein ligands bind to GPIIb-IIIa. [193] [194]

GPIIIa is a single-chain transmembrane protein that contains 56 cysteine residues and 28 disulfide bonds. [184] [195] Accordingly, its apparent molecular weight of 90,000 on unreduced sodium dodecyl sulfate gels increases to 110,000 following disulfide bond reduction. [180] Disulfide bonds in GPIIIa are distributed in three regions in the extracellular portion of the molecule: a cysteine-rich, protease-resistant amino terminus (residues 162), a protease-sensitive central region (residues 101422), and a disulfide-rich, protease-resistant core (residues 423622). [196] In addition, there is a long-range disulfide bond between cysteine residues 5 and 435 that results in a large protease-sensitive loop in the molecule. [196] [197] [198]

The GPIIb-IIIa heterodimers are assembled in the calcium-rich milieu of the endoplasmic reticulum. [199] In the absence of heterodimer formation, GPIIb and GPIIIa are retained eventually degraded in this organelle. [199] The factors responsible for the retention of GPIIb and GPIIIa monomers in the endoplasmic reticulum are unknown. However, it is clear that formation of GPIIb-IIIa heterodimers alone is not sufficient to guarantee egress because mutations that distort the conformation of the assembled heterodimers also result in their retention. [199] [200]

Etiology and Pathogenesis

The fundamental defect of thrombasthenic platelets is their inability to aggregate. However, GPIIb-IIIa deficiency is responsible for additional abnormalities of platelet function. Thrombasthenic platelets do not spread normally on the subendothelial matrix, an aspect of platelet adhesion that is mediated by GPIIb-IIIa binding to fibronectin and vWf. [174] [201] The amount of fibrinogen in the -granules of thrombasthenic platelets is decreased to absent. [202] Megakaryocytes do not synthesize fibrinogen,[203] [204] [205] consequently, -granule fibrinogen results from the endocytosis of plasma fibrinogen. [206] [207] Kistrin and barbourin, snake venom proteins that inhibit fibrinogen binding to GPIIb-IIIa, also inhibit the endocytosis of fibrinogen by guinea pig megakaryocytes. [208] [209] Thus, the absence of functional GPIIb-IIIa on thrombasthenic platelets likely accounts for their deficit in -granule fibrinogen. [210] A number of biochemical reactions in platelets require the presence of GPIIb-IIIa or platelet aggregation and are impaired in thrombasthenic platelets. For example, phosphorylation on tyrosine of multiple platelet proteins including proteins with molecular weights of 140,000 and 50,00068,000 depends on ligand binding to GPIIb-IIIa and the tyrosine phosphorylation of proteins such as pp125 ^{FAK} as well as proteins with molecular weights of 95,00097,000 requires platelet aggregation. [211] [212] [213] [214] Calpain, a calcium-dependent thiol protease, is activated by thrombin-stimulation of stirred normal platelets, but not following similar treatment of thrombasthenic platelets. [215] The redistribution of a number of proteins, including spectrin, talin, vinculin, pp60 ^{src} and p62^{yes} , to the detergent-insoluble platelet cytoskeleton follows thrombin-stimulated platelet aggregation, but is not detected when thrombasthenic platelets are studied. [216] The kinetics of calcium exchange in unstimulated thrombasthenic platelets is decreased. [217] However, it is still unclear whether GPIIb-IIIa plays a direct role in calcium transport. [218] [219] [220] Clot retraction in blood containing thrombasthenic platelets is either absent or reduced, [221] a finding consistent with the ability of GPIIb-IIIa to link the fibrin clot to the contractile elements of the platelet cytoskeleton. [172] [173]

On the other hand, those aspects of platelet function that do not depend on GPIIb-IIIa are normal in thrombasthenia. Thrombasthenic platelets interact normally with collagen fibrils[221] and undergo secretion when stimulated by strong agonists such as thrombin. [202] Incubation of thrombasthenic platelets with ristocetin induces vWf

binding to GPIb-IX[11] and thrombasthenic platelets adhere to vWf in the subendothelium. [174] [201] Thrombasthenic platelets express normal amounts of procoagulant activity following lysis,[45] but expression may[202] or may not [222] be decreased under conditions that require platelet aggregation.

Genetic Aspects

The genes for GPIIb and GPIIIa are both located on the long arm of chromosome 17 at q21 23. [223] [224] [225] The GPIIb gene spans 18 kb and is located in a region that contains at least seven complete and three incomplete Alu repeats. [226] The gene consists of 30 exons ranging in size from 46 bp to 220 bp. [226] Like the genes for other proteins expressed in megakaryocytes, its 5 flanking region lacks TATA or CAAT boxes. Instead it contains a linear array of regulatory elements including two motifs recognized by the GATA-binding transcription factors, [227] [228] a sequence recognized by a member of the Ets family of transcription factors, [229] and a binding site for the transcription factor Sp1. [230] In addition, a repressor element located between the GATA motifs may be involved in controlling the tissue specificity of GPIIb gene expression. [231] The gene for GPIIIa spans 63 kb and contains 15 exons. [232] [233] Like the GPIIb gene, the 5 flanking region of the GPIIIa gene lacks TATA or CAAT boxes. [234] However, specific regulatory motifs in this region that might control GPIIIa gene expression have not yet been identified. Although the organization of exons in many genes reflects the distribution of functional domains in the proteins they encode, [235] this does not appear to be true for either the genes for GPIIb or GPIIIa.

Glanzmann thrombasthenia is inherited as an autosomal recessive disorder with clusters of disease in populations where consanguinity is common. [236] [237] [238] It has been classified into three types based on the amount of GPIIb-IIIa present and the presence or absence of -granule fibrinogen and clot retraction. [202] In type I, platelets contain <5% of the normal amount of GPIIb-IIIa and clot retraction and -granule fibrinogen are absent. In type II, platelets contain 1020% of the normal amount of GPIIb-IIIa, clot retraction is decreased, and -granule fibrinogen is present. [239] In variant thrombasthenia, the platelet content of GPIIb-IIIa is 50% of normal so that the GPIIb-IIIa abnormality is qualitative, rather than quantitative. [239]

Expression of GPIIb-IIIa on the cell surface requires that both GPIIb and GPIIIa are present in the endoplasmic reticulum. [240] Thus, a mutation in the gene for either protein will produce thrombasthenia. On occasion, it has been possible to determine which gene is affected by measuring the number of v3

TABLE 130-3 -- GPIIb Mutations Resulting in Glanzmann Thrombasthenia

Mutation	Type	Comments	Reference
4.5 kb deletion in GPIIb gene	I	Deletion between Alu repeats in introns 1 and 9 no detectable protein	[244]
Deletion of amino acids 106111	I	Alternative splicing due 13-base deletion including splice acceptor site of exon 4	[245]
Arg 584 stop	I	Unstable mRNA	[247] [253] [254]
Mutation of splice acceptor for exon 26	I	Alternative splicing loss of exons 2527 and synthesis of single-chain truncated protein	[247]
Mutation of splice acceptor for exon 28	I	Alternative splicing loss of exon 28, intracellular degradation of GPIIb-IIIa	[248]
Gly 273 Asp	I	Intracellular retention of malfolded GPIIb-IIIa	[200]
Gly 418 Asp	I	Intracellular retention of malfolded GPIIb-IIIa	[256]
Deletion of 6 bp and insertion of 31 bp in exon 25	I	Alternative splicing at a cryptic acceptor site in the inserted sequence	[249]
Arg 327 His	II	GPIIb-IIIa expression 710% of normal, clot retraction decreased	[242] [243]
Mutation in exon 17 disrupting a splice donor site	I	Use of cryptic donor site within exon 17 leading to the synthesis of an unstable mRNA	[250]
Mutation of splice donor site in intron 15	I	Use of cryptic donor site in exon 15 frame shift and premature stop codon	[251] [252]
Ser 870 stop	I	Intracellular retention of malfolded GPIIb-IIIa	[255]
Deletion of Val 425 and Asp 426	I	Intracellular retention of malfolded GPIIb-IIIa	[246]

complexes per platelet, because they are increased when the GPIIb gene is affected and decreased when the GPIIIa gene is affected. [241]

A variety of mutations in the genes for GPIIb and GPIIIa have been detected in patients with thrombasthenia (Tables 130-3 and 130-4). Except for one example of type II thrombasthenia,[242] [243] all reported mutations of the GPIIb gene have produced type I disease. The identified mutations have included large [244] and small deletions,[245] [246] mRNA-splicing abnormalities leading to shifts in the GPIIb reading frame and aberrant GPIIb proteins, [247] [248] [249] [250] [251] [252] nonsense mutations,[247] [253] [254] [255] and missense mutations.[200] [242] [243] [253] Six mutations[200] [242] [246] [248] [255] [256] are of particular interest because the translated product of the mutant gene is able to associate with GPIIIa in the endoplasmic reticulum, but the conformation of the resulting heterodimers is sufficiently perturbed to impair their egress from the endoplasmic reticulum to the Golgi apparatus. Four of the latter mutations [200] [242] [246] [256] are located in the putative calcium-binding region of GPIIb, suggesting that folding of this portion of GPIIb makes an important contribution to the overall conformation of GPIIb-IIIa. It is also noteworthy that examples of variant thrombasthenia due to mutations in GPIIb have not yet been identified.

In contrast, GPIIIa mutations have produced all three types of thrombasthenia. Type 1 disease has resulted from complex

TABLE 130-4 -- GPIIa Mutations Resulting in Glanzmann Thrombasthenia

Mutation	Type	Comments	Reference
Complex gene rearrangement	I	Homologous recombination among 3 Alu sequences causing a 15 kb-inversion and 1 kb-deletion	[257] [258]
Asp 119 Tyr	V[a]	Perturbed ligand binding domain in GPIIb-IIIa	[268]
Deletion of 11 bp in exon 12	I	Frameshift premature stop codon and the synthesis of a truncated protein	[245]
Arg 214 Gln	V	Decreased ligand binding to GPIIb-IIIa	[275]
Ser 752 Pro	V	Defective agonist-stimulated GPIIb-IIIa activation	[267]
Arg 214 Trp	V	Decreased ligand binding to GPIIb-IIIa, corrected by incubating platelets with dithiothreitol	[269] [273] [275]
Mutation of splice donor site in intron 1	I	Frameshift premature stop codon and synthesis of a severely truncated protein	[261]
34 kb insertion into intron 8	I	Abnormal mRNA splicing decreased mRNA stability	[260]
Arg 62 stop	I	Nonsense mutation truncated protein	[254]
G A mutation 6 bp upstream from exon 9 splice donor site	I	Alternative splicing of exon 9 frameshift, premature stop codon, and mRNA instability	[262]
Cys 374 Tyr	II	Reduced GPIIb-IIIa expression on the platelet surface	[266]
Dinucleotide deletion affecting codons 210 and 211 in exon 4		Frameshift premature stop codon and synthesis of a severely truncated protein. Patient is carrier for type I thrombasthenia.	[263]
Leu 117 Trp	I	Intracellular retention of malfolded GPIIb-IIIa	[264]
11.2-kb deletion between Alu repeat in intron 9 and exon 13	I	Mutant mRNA lacked exons 10, 11, 12, and 13 and contained a frameshift premature stop codon	[259]
Deletion of IIe 325, Pro 326, and Gly 327	I	Mutant GPIIIa unable to associate with v when expressed in CHO cells	[265]

Arg 724 stop	V	Truncation deleting 39 C-terminal amino acids of the GPIIIa cytoplasmic tail defective agonist-stimulated GPIIb-IIIa activation	[274]

[a]V, variant.

rearrangements in the GPIIIa gene;[257] [258] deletions,[259] insertions,[260] and point mutations[261] [262] affecting mRNA splice donor or splice acceptor sites; deletions or point mutations producing frameshifts and premature stop codons;[245] [263] nonsense mutations;[254] and missense mutations.[264] Type 1 disease has also resulted from the deletion of three amino acids (IIe 325, Pro 326, Gly 327), thereby impairing the ability of GPIIIa to associate with an -subunit. [265] One missense mutation (Gys 374 Tyr) has produced in type II disease. [266] Five mutations have produced variant thrombasthenia in which platelets contain nearly normal amounts of nonfunctional GPIIb-IIIa. Four of the mutations are missense mutations. In one kindred, a Ser 752 Pro substitution in the cytoplasmic domain of GPIIIa prevented GPIIb-IIIa activation by cellular agonists.[267] In each of the remaining kindreds, a charged amino acid in the extracellular domain of GPIIIa was converted to an uncharged residue. These mutations (Asp 119 Tyr;[268] Arg 214 Trp;[269] Arg 214 GIn[270]) are located in regions of GPIIIa that have been implicated in ligand binding. [271] [272] However, incubation of platelets containing the Arg 214 Trp mutant with the reducing agent dithiothreitol restored platelet aggregation, [273] suggesting that Arg 214 is necessary to maintain the conformation of the ligand binding site in GPIIIa. The fifth mutation is a nonsense mutation in which the codon for Arg 724 is converted to a stop codon.[274] This results in the synthesis of a truncated GPIIIa molecule lacking the carboxyl terminal 39 amino acids of its cytoplasmic domain and the presence of GPIIb-IIIa heterodimers that are unable to transduce either inside-out or outside-in signals.

Additional cases of thrombasthenia, have been reported in which abnormalities in GPIIb or GPIIIa structure or distribution have been detected, but the responsible mutations have yet to be identified. In one patient with variant thrombasthenia, GPIIb-IIIa was present, but dissociated abnormally in the presence of low concentrations of ethylenediamine titra-acetic acid (EDTA). [276] The GPIIb-IIIa of the second patient was also more sensitive to EDTA and failed to react with a anti-GPIIb-IIIa monoclonal antibody, suggesting that its conformation was abnormal. [277] The platelets of a third patient contained decreased amounts of both normal and an abnormal form of GPIIb.[278] Finally, the platelets of the fourth patient with a mild thrombasthenia-like illness aggregated poorly in response to ADP and other agonists and had a deficit in the surface pool, but not the internal pool, of GPIIb-IIIa. [279]

Clinical Presentation

The clinical manifestations of thrombasthenia in a large cohort have been described in detail. [239] Thrombasthenia typically presents with mucocutaneous bleeding in the neonatal period or infancy, occasionally with bleeding following circumcision. Spontaneous petechiae are uncommon and bleeding generally results from a condition that would cause bleeding in an otherwise normal individual. Next to purpura, epistaxis is the most frequent type of bleeding, especially in childhood. Gingivalbleeding, often related to poor dental hygiene, and menorrhagia are frequent. Bleeding at menarche may be severe and require transfusion. Similarly, parturition represents a severe hemorrhagic risk. Other hemorrhagic manifestations include gastrointestinal bleeding and hematuria, but hemarthroses and deep hematomas are unusual. Serious bleeding may follow trauma or surgery in patients not prepared with normal platelets. The severity of the hemorrhagic diathesis is not predictable, even within single kindreds, and does not correlate with the extent of GPIIb-IIIa deficiency. Thus, one sibling may experience life-threatening bleeding requiring frequent transfusion, whereas another will suffer only mild bruising and epistaxis. The apparent decline in the clinical severity of thrombasthenia with age is likely due to a decrease in the incidence of conditions such as epistaxis with aging.

Laboratory Findings

Platelet counts and platelet morphology on peripheral blood smears are normal. The bleeding time of affected individuals is markedly prolonged. [221] [236] [237] The diagnosis thrombasthenia is usually suspected after platelet aggregometry. In contrast to normal platelets, addition of agonists (except for epinephrine) to a stirred suspension of thrombasthenic platelets results in only platelet shape change and platelet aggregation is absent (Fig. 130-1).[51] Platelet secretion induced by strong agonists such as thrombin is normal, but secretion in response to weak agonists such ADP and epinephrine is absent. Coagulation tests, such as the prothrombin time and the partial thromboplastin time, are normal in thrombasthenia. Clot retraction in the presence of thrombasthenic platelets is either absent or reduced.

Differential Diagnosis

A history of lifelong bleeding, a prolonged bleeding time, and absent platelet aggregation are diagnostic of thrombasthenia and differentiate it from other disorders of platelet adhesion and secretion. Instances of acquired thrombasthenia have been reported and can be differentiated from congenital thrombasthenia by history. Although autoantibodies against GPIIb-IIIa have been detected frequently in patients with idiopathic thrombocytopenic purpura, [280] [281] autoantibodies that induce a thrombasthenic-like state are unusual.[282] [283] [284] A patient with multiple myeloma has also been reported whose IgG_1 paraprotein was directed against GPIIIa and inhibited GPIIb-IIIa function.[285] Congenital afibrinogenemia may be associated with a prolonged bleeding time and decreased in vitro platelet aggregation due to the absence of sufficient fibrinogen to support platelet aggregation. [286]

Therapy

Bleeding in thrombasthenia requires the transfusion of normal platelets. (Table 130-2). Because bleeding is a lifelong problem, the use of human leukocyte antigen-matched platelets should be considered to lessen the chance of refractoriness to transfusion due to platelet alloimmunization. In rare instances, thrombasthenic patients have developed antibodies against normal GPIIb and GPIIIa following transfusion. [287] [288] Such antibodies could potentially limit the effectiveness of transfused platelets. Oral contraceptives have been useful in controlling menorrhagia. Regular dental care is essential in minimizing gingival bleeding. Fibrinolytic inhibitors such as \?\-aminocaproic acid, in addition to platelet transfusions, may be useful in controlling bleeding after dental extractions. Corticosteroids are not efficacious in managing bleeding in thrombasthenic patients. [221] Although DDAVP shortened the bleeding time in a patient with thrombasthenia and had a beneficial effect during minor dental surgery, [116] this is the only report of an effect of DDAVP in thrombasthenia.[259] The thrombasthenia of two severely affected children has been corrected by bone marrow transplantation. [290] [291] Prenatal diagnosis of Glanzmann thrombosthenia is discussed in Chapter 159 .

DISORDERS OF PLATELET SECRETION

The platelet cytoplasm contains four types of granules: dense granules containing ADP, adenosine triphosphate (ATP) calcium, serotonin, and pyrophosphate; -granules containing a variety of proteins, some derived from the plasma, others synthesized by the megakaryocyte; lysosomes containing acid hydrolases; and microperoxisomes containing a peroxidase activity.[292] Following platelet activation, the contents of these granules are extruded in a process known as platelet secretion. Inherited disorders of platelet secretion result from a deficiency

of one or more of the types of platelet granules or from abnormalities in the platelet secretory mechanism. Secretion disorders are a frequent cause of mild to moderate bleeding manifested by easy bruising, menorrhagia, and excessive postoperative and postpartum blood loss.[293] In one group of 145 patients presenting with such symptoms, 18% were found to have a deficiency of platelet granules, 19% to have an abnormality in the platelet secretory mechanism, and 36% to have von Willebrand disease.[294] No explanation for the bleeding diathesis could be found in 27% of the patients. Patients with disorders of platelet secretion usually have a prolonged bleeding time, absence of the second wave of platelet aggregation when platelets are stimulated by ADP and epinephrine, and decreased aggregation when platelets are stimulated by collagen.[293] These disorders must be differentiated from the acquired abnormalities of platelet secretion induced by drugs such as aspirin or systemic diseases such as uremia and multiple myeloma (Chap. 131) and from the various types of von Willebrand disease (Chap. 114).

Disorders of Secretion Due to Abnormalities of Platelet -Granules

The Gray Platelet Syndrome (-Granule Deficiency, -Storage Pool Disease)

The gray platelet syndrome, described by Raccuglia in 1971,[97] is a rare disorder that results from the specific absence of morphologically recognizable -granules in the platelets of affected individuals.

Biology and Molecular Aspects

Normal platelets contain æ50 spherical or elongated structures termed -granules that contain a variety of proteins, some of which are specific or relatively specific for platelets and others that are also found in plasma.[295] The former include platelet factor 4, (PF4), -thromboglobulin (TG) platelet-derived growth factor (PDGF), and thrombospondin (TSP) and the latter include fibrinogen, vWf, albumin, coagulation factor V (FV), IgG, fibronectin, and a number of protease inhibitors. [292] [295] [296] The platelet-specific proteins and several of the plasma proteins (vWf, [297] FV[298]) are synthesized by megakaryocytes. The others reach the -granules via endocytosis of circulating protein.[203] [206] [207] The -granule membrane contains many of the same proteins present in the platelet plasma membrane (GPIIb-IIIa[299] and GPIb-IX-V[300]) and others specific for -granules (P-selectin[301] [302] and osteonectin[303]). Each can be translocated to the platelet surface following platelet-activation. [177] [178] [301]

Etiology and Pathogenesis

Electron micrographs of megakaryocytes and platelets from patients with the gray platelet syndrome reveal absence of normal -granules and the presence of vacuoles and small -granule precursors containing material that stains for vWf and fibrinogen. [304] [305] The other types of platelet granules are present in normal numbers.[304] The outer membranes of the vacuoles and small -granule precursors contain P-selectin and GPIIb-IIIa, [299] [306] which can be translocated to the platelet surface after thrombin stimulation.[306] These observations indicate that -granules are present in gray platelets and suggest that the abnormality responsible for the gray platelet syndrome is an inability to target proteins to these structures. The inability to package and retain PF4, TG, and PDGF in -granules would account for the elevated plasma concentrations of PF4 and TG and the bone marrow fibrosis observed in patients with the syndrome. [307] [308] The abnormality responsible for the gray platelet syndromes appears to be restricted to megakaryocytes because electron micrographs of endothelial cells from affected patients reveal typical Weibel-Palade bodies suggesting that these cells are capable of packing vWf normally. [309]

Clinical Presentation and Laboratory Findings

Patients with the gray platelet syndrome present with a lifelong history of mild to moderate mucocutaneous bleeding, [97] [98] [309] [310] although one patient developed subgaleal and epidural hematomas following head trauma.[311] Patients also exhibit variably prolonged bleeding times, moderate thrombocytopenia, reticulin fibrosis of the bone marrow, and large platelets whose gray appearance on a Wright-stained blood smear gives the name to the disorder. [97] [309] Platelet counts vary from 25,000 to 150,000/l, but generally range between 60,000 and 100,000/l. Studies of platelet aggregation have produced variable results. Aggregation induced by ADP, epinephrine, arachidonic acid, and the calcium ionophore A23187 has generally been normal or nearly normal, [97] [307] but collagen-induced aggregation has been decreased to absent in some cases[98] [307] and normal in others.[97] [311] Responses to thrombin have also been variable, with reports of decreased aggregation and secretion in response to low thrombin concentrations, [98] [307] [310] impaired increments in intracellular calcium, [312] and decreased generation of IP_3 .[313] Gray platelets agglutinate normally when exposed to ristocetin and contents of their dense granules is normal. [98] [314] As expected, the PF4, TG, fibrinogen, vWf, FV, fibronectin, and thrombospondin content of their -granules is markedly decreased. Surprisingly, gray platelets contain substantial quantities of albumin and IgG, [306] [315] proteins normally present in -granules. The PF4 and TG concentrations in the plasma of affected individuals are normal or elevated. [96] [307]

Genetic Aspects

Although nearly 40 cases of the gray platelet syndrome have been reported,[316] the mode of inheritance of the gray platelet syndrome remains uncertain, but the presence of the disorder in males and females in the same family indicates that it is an autosomal disease.[314] A disorder resembling the gray platelet syndrome is present in the Wistar Furth strain of rat and is inherited in an autosomal recessive fashion. [317]

Therapy

Treatment of bleeding episodes, if severe, may require the transfusion of normal platelets (Table 130-2).[311] DDAVP shortened the bleeding time in one patient and was used as successful prophylaxis for a dental extraction.[318]

The Quebec Platelet Disorder (Factor V Quebec)

Two unrelated families with an autosomal dominant bleeding disorder of moderate severity have been identified in Quebec. [319] [320] Their disorder is characterized by

mild thrombocytopenia, defective epinephrine-induced platelet aggregation, a decrease in the concentration of multiple -granule proteins due to degradation, and bleeding unresponsive to platelet transfusion. The disorder of the index family was initially attributed to a decrease in platelet factor V, hence the name factor V Quebec.[321] In contrast to the gray platelet syndrome, the -granules in platelets of the Quebec platelet disorder appear to be morphologically normal. [320] However, many -granule proteins, including factor V, multimerin, fibrinogen, vWf, fibronectin, osteonectin, and TSP, are decreased in concentration and substantially degraded.[322] The pathogenesis of this disorder is unknown.

Disorders of Secretion Due to Deficiency of Platelet Granules

Dense Granule Deficiency (-Storage Pool Disease)

Biology and Molecular Aspects

Normal platelets contain three to six 200300-nm dense or -granules that serve as intracellular storage sites for ADP, ATP,

calcium, pyrophosphate, and serotonin.[323] Because of their high calcium content, -granules can be visualized in electron micrographs of unfixed, unstained platelet whole mounts.[323] They can also be visualized by electron microscopy of thin sections of fixed platelets after staining with uranyl ions (uranaffin reaction) and by fluorescence microscopy after staining the platelets with mepacrine (quinacrine). [323] The -granule membrane contains a 40,000-molecular weight protein named granulophysin that may be related to the synaptosomal membrane protein synaptophysin.[324] Granulophysin is translocated to the platelet surface following platelet activation.[325] The membrane may also contain P-selectin, GPIb, and GPIIb-IIIa.[325] [326] -Granules undergo exocytosis coincident with the second wave of platelet aggregation.[327] Although -granule ADP is thought to be involved in the propagation of the primary platelet response, [328] [329] the function of the other -granule contents is not known. The biogenesis of -granules in megakaryocytes is poorly understood. -storage pool deficiency occurs in two syndromes of tyrosinase-positive albinism in humans,[330] [331] in several pigment dilution syndromes in mice[332] and rats,[333] and as part of a Chediak-Higashi-like syndrome in cattle, [334] cats,[335] mink,[336] and foxes.[337] This suggests that the biogenesis of dense granules, melanosomes, and lysosomes is somehow related. The mechanism by which dense granules accumulate ATP and ADP is also not known. It is clear, however, that two pools of adenine nucleotides exist in normal platelets that exchange very slowly, if at all. [338] One pool is a metabolic nongranule pool in which the ratio ATP/ADP is 810:1. The second pool is present in the -granules and contains 65% of the platelet adenine nucleotides with an ATP/ADP ratio of 2:3. Thus, in normal platelets, the whole platelet ATP/ADP ratio is <2.5. On the other hand, serotonin is not synthesized by megakaryocytes, but is taken up from the plasma and stored in the -granules where it is protected from platelet monoamine oxidase. [339]

Etiology and Pathogenesis

-Storage pool disease represents a heterogeneous group of disorders with -granule abnormalities as the common feature. [323] The disorder can be subdivided into deficiency states associated with albinism and those in otherwise normal individuals. -Storage pool disease has also been observed in some patients with the Wiscott-Aldrich syndrome, [340] the syndrome of thrombocytopenia with absent radii,[341] the Ehlers-Danlos syndrome, [342] and osteogenesis imperfecta.[343] When -storage pool disease is associated with albinism, as in the Hermansky-Pudlack syndrome (oculocutaneous tyrosinase-positive albinism, platelet dense granule deficiency, and ceroid like inclusions in cells of the reticuloendothelial system) [330] and the Chediak-Higashi syndrome (partial oculocutaneous albinism, frequent pyogenic infections, and giant lysosomal granules in cells of hemotologic and nonhematologic origin), [344] there is a quantitative deficiency of -granules.[324] [345] In the platelets of nonalbinos, however, the number of uranaffin-positive and mepacrine-positive granules is normal to only slightly decreased, suggesting an inability to package the -granule contents in these patients.[323] [346] The platelet content of granulophysin also parallels the apparent number of -granules in storage pool-deficient patients, being low in patients with the Hermansky-Pudlack and Chediak-Higashi syndromes, but normal in nonalbinos. [345] [346] In some nonalbino patients, the -granule abnormality is associated with a variable deficiency of -granules (-storage pool disease). [347] [348] The nature of the -granule deficiency in these patients is also heterogeneous. For example, in one patient with severe -storage pool disease, a decrease in the platelet content of P-selectin suggested that a defect in -granule formation accompanied the deficit in -granules. In a family with less severe disease, however, the platelet content of P-selectin was normal, suggesting that the -granule abnormality might be similar to that seen in the gray platelet syndrome.[348] The content of lysosomal acid hydrolases in platelets from patients with -storage pool disease is normal,[329] but thrombin-induced acid hydrolase secretion may be impaired in severely affected individuals, an abnormality that can be corrected in vitro by the addition of ADP.[329] The ability of -storage pool-deficient platelets to form thrombi on subendothelium has been studied ex vivo under various conditions of shear.[201] It was found that thrombus dimensions were reduced in proportion to the magnitude of the dense granule deficit and were reduced even further when -storage pool disease platelets were examined. These studies suggest that the contents of the -and -granules either potentiate the growth of thrombi on the subendothelium or help to stabilize the thrombi in the presence of high shear stress.

Clinical and Laboratory Findings

Patients with -storage pool disease present with a mild to moderate bleeding diathesis characteristic of patients with platelet secretion defects. [293] Platelet counts and morphology are usually normal, but bleeding times are usually, but not always, prolonged. [294] Moreover, the volume of blood that emerges from the bleeding time wounds in these patients is increased over normal, particularly at early time points, suggesting that -granule contents are involved in the contraction that follows vascular-transection.[349] The quantity of thromboxane B_2 , a metabolite of thromboxane A_2 , in the collected blood is also decreased, especially in patients with -storage pool disease, a finding consistent with the impaired agonist-induced prostaglandin and thromboxane synthesis often detected in these platelets. [350] In the aggregometer, -storage pool deficient platelets usually lack a second wave of aggregation when stimulated by agonists such as ADP and epinephrine (Fig. 130-1).[351] Responses to low concentrations of collagen are also diminished to absent, but responses to high collagen concentrations may be normal or nearly normal. [351] [352] Although this pattern of aggregation is typical for -storage pool disease, patients have been reported with normal aggregation studies. [294] Although the steady-state serotonin content of -storage pool-deficient platelets is decreased, the rate of uptake of serotonin is normal. [338] Without storage sites, however, the serotonin either leaks out of the platelet or is metabolized by platelet monoamine oxidase. [352] [353] In -storage pool deficiency, the dense granule pool of ADP no longer contributes to the whole platelet content of ADP and the ATP:ADP ratio of -storage pool deficient platelets is 3.0. [293] This alteration in ATP:ADP ratio is extremely helpful in the diagnosis of -storage pool deficiency, especially when typical aggregation abnormalities are absent. [294] Flow cytometry of mepacrine-labeled platelets may be a rapid method to detect -storage pool-deficient platelets,[354] [355] but its sensitivity compared to measurement of ATP:ADP ratios has not been tested.

Genetic Aspects

The Hermansky-Pudlak and Chediak-Higashi syndromes are inherited as autosomal recessive disorders. [331] [345] Although studies of the inheritance of -storage pool disease in patients without albinism are limited, examination of three generations of one family with this disorder suggest that it is transmitted in autosomal dominant fashion.[356] The nature of the mutations responsible for -storage pool disease is unknown. A number of murine mutations result in the disorder, [332] [357] [358] [359] [360] indicating that multiple genetic loci are involved. Studies of patients in Puerto Rico and Switzerland have localized the gene for the Hermansky-Pudlak syndrome to human chromosome 10q23.123.3.[361] It is noteworthy that this region is syntenic to the region of murine chromosome 19 that includes the mutations *pale ear* and *ruby-eye*.[362] Although the gene for the erythrocyte protein 4.2 was initially thought to be a candidate for the murine *pallid* mutation, [363] they are now thought to be distinct loci. [364]

Therapy

Bleeding can be controlled by the transfusion of normal platelets (Table 130-2). However, this is seldom necessary because the potential risks of platelet transfusion far outweigh the benefits when bleeding is not life-threatening. Moreover, other methods to readily improve hemostasis without the risks of transfusion are available. Bleeding has been controlled by the administration of cryoprecipitate [365] or DDAVP.[366] [367] The latter avoids the transfusion of blood products and should be regarded as the initial therapy of choice. DDAVP is a vasopressin analog whose pressor effects (V_1 vasopressin receptors) are substantially less than its antidiuretic effects (V_2 vasopressin receptors). Infusion of the drug releases large multimers of vWf and tissue plasminogen activator from tissue stores. [368] The released vWf accounts for the beneficial effect of the drug on the bleeding time in some forms of von Willebrand disease. The precise mechanism of its ability to shorten the bleeding time in patients with platelet function disorders is uncertain. Nonetheless, in several series of patients with platelet disorders, shortening of the bleeding time in response to

DDAVP occurred in 43100% of patients.[366] [367] [369] This variability in response rate indicates that if DDAVP is to be used for surgical prophylaxis, a bleeding time must be obtained after the DDAVP infusion to ensure that the bleeding time has responded.

In a single study, prednisone at doses of 2050 mg for 34 days was used to improve hemostasis in patients with inherited platelet disorders. [370] Shortening of the bleeding time was seen within 3 days and persisted for up to 37 days after the prednisone was stopped. However, prednisone treatment was ineffective in shortening the bleeding time in patients with thrombasthenia [221] or in normal individuals given aspirin. [371]

Disorders of Secretion Due to an Abnormal Secretory Mechanism

Platelet function in this group of disorders resembles that of individuals who have been given platelet inhibitory drugs such as aspirin. [372] There is marked impairment of aggregation and secretion in response to weak platelet agonists such as ADP, epinephrine, and low concentrations of collagen, whereas responses to stronger agonists such as higher concentrations of collagen may be normal or near normal. The bleeding time of patients with this type of secretion defect is usually prolonged. However, when it is normal or only slightly prolonged, it may become markedly prolonged 2 hours after the ingestion of three aspirin tablets. [373]

Biology and Molecular Aspects

Stimulated platelets secrete the contents of their cytoplasmic granules by a process that involves granule convergence at the center of the platelet, fusion of the granule membranes with the membranes of the surface-connected open canalicular system, and extrusion of the granule contents into the platelets external milieu. [374] [375] This process requires coupling agonist receptors on the platelet surface to the effector systems responsible for platelet aggregation and secretion and is discussed in detail in Chapter 100 . Briefly, platelet stimulation results in the activation of the phospholipases C and A2 and the serine/threonine kinases protein kinase C, calcium-calmodulin dependent protein kinase, and myosin light chain kinase. [376] Phospholipase C activation in platelets is a G protein-mediated process [376] and generates of diacylglycerol and inositol 1,4,5-triphosphate (IP3) from phosphatidylinositol 4,5-bisphosphate. [377] Diacylglycerol is a protein kinase C activator and IP3 is responsible for the rise in intracellular calcium that accompanies platelet activation induced by most platelet agonists. [378] Platelets contain high levels of the protein tyrosine kinase pp60$^{c\text{-}src}$, [379] the src-related kinases Fyn, Lyn, Hck, and Yes,[380] and the protein kinases p72^{syk} and CPTK71[381] and platelet activation results in the phosphorylation of a number of intracellular proteins on serine, threonine, and tyrosine residues. [382] [383] [384] Which phosphorylated proteins are directly involved in platelet secretion remains to be determined.

Etiology and Pathogenesis

These disorders constitute a heterogeneous collection of abnormalities of stimulus-response coupling in platelets. In many instances, the evidence linking observed biochemical abnormalities to defective platelet secretion is not definitive. Patients have been reported whose platelets display abnormalities in arachidonic acid metabolism including impaired coupling of the thromboxane A_2 receptor and phospholipase C[385] and deficiencies of cyclo-oxygenase[386] [387] [388] [389] [390] [391] and thromboxane synthetase.[392] [393] Diminished platelet responsiveness to endogenous and exogenous thromboxane A_2 has been attributed to abnormalities of platelet endoperoxide/thromboxane A_2 receptors.[394] [395] [396] Impaired platelet responsiveness to the ionophores A23187 [395] [397] and ionomycin[398] has been observed, as well as diminished IP3 production and calcium mobilization due to defective activation of phospholipase C-2. [399] [400] [401] Impaired GPIIb-IIIa activation and pleckstrin phosphorylation following platelet stimulation by multiple agonists has been noted. [402] A patient whose platelets were initially reported as having impaired receptor-mediated release of arachidonic acid from phospholipids and calcium mobilization [403] was subsequently found to have decreased platelet membrane GTPase activity and decreased Gq. [404] This is a notable observation in view of the report that Gq-deficient mice fail to aggregate in response to thrombin, ADP, collagen, arachidonic acid, and U46619. [405] Patients have been reported whose platelets respond poorly to ADP likely due to a decrease in the number of ADP receptors.[406] [407] Others show decreased responsiveness epinephrine [408] [409] [410] [411] and platelet aggregating factor.[410] [411] In one group of 11 patients with impaired platelet responses to low concentrations of collagen, 8 were noted to have abnormal responses to other weak-agonists, such as ADP, epinephrine, thromboxane A_2, and the prostaglandin endoperoxide analog U44069, but normal responses to strong agonists such as thrombin and high concentrations of collagen. [412] This suggests a defect in coupling stimulation by weak agonists to secretion, rather than a defect in the secretory mechanism itself. In remaining patients, responses to strong agonists were abnormal and the platelets appeared unable to synthesize thromboxane A_2. Finally, in patients with the neuropsychiatric attention deficit disorder and easy bruising, abnormal dense granule and lysosome secretion was inexplicably observed when gel-filtered platelets, but not platelets in platelet-rich plasma, were stimulated with thrombin or the ionophore A23187.[413]

Genetic Aspects

Most reports have been of individual patients so that determination of the mode of inheritance has not been possible. Where families have been studied, the mode of inheritance appeared to be autosomal dominant. [388] [390] [393] [394] [408]

Therapy

The approach to therapy in patients with these disorders is identical to that described above for patients with storage pool disease.

DISORDERS OF PLATELET PROCOAGULANT ACTIVITY

The plasma membrane of activated platelets provides a surface for the assembly of the tenase and prothrombinase complexes that activate coagulation factor X and prothrombin, respectively (see Chap. 102 for a detailed discussion). This procoagulant activity was previously termed platelet factor 3. Although it is uncertain whether specific membrane structures

serve as receptors for this activity, it is clear that it is associated with a calcium-induced exposure of anionic phospholipids on the platelet surface. The phospholipid composition of the platelet plasma membrane, like that of other cells, is asymmetric with phosphatidylcholine and sphinomyelin localized predominantly in the outer membrane leaflet and phosphatidylserine and phosphatidylethanolamine concentrated in the inner leaflet. This asymmetry is catalyzed by an aminophospholipid translocase, an Mg^{82+} -dependent ATPase.[414] [415] Following an agonist-stimulated rise in intraplatelet Ca^{2+} , however, membrane asymmetry is lost with exposure of anionic phospholipids on the platelet surface [416] and with membrane vesiculation.[417] A similar response to increased intracellular calcium has been detected in erythrocytes[418] and lymphocytes.[419] The rapid Ca^{2+} -induced movement of phospholipids between membrane leaflets is mediated by a membrane-associated phospholipid scramblase.[420] The phospholipid scramblase, cloned from a human K562 cell cDNA library, is a proline-rich 37,000-molecular weight type II membrane protein present not only in erythrocytes and platelets, but in a variety of hematologic and nonhematologic tissues and cell lines as well. [421]

Isolated deficiency of platelet procoagulant activity is exceedingly rare. In addition to the one well-studied patient after whom the disorder was named (Scott syndrome),[422] data on three additional patients have been reported. [222] [423] The initial patient presented with bleeding after surgery and dental procedures and a spontaneous retroperitoneal hematoma.[422] Although prothrombin and partial thromboplastin times, bleeding times, and platelet function studies were normal, serum prothrombin times were short and the patients platelets were unable to express normal procoagulant activity. Moreover, although the patients platelets secreted normal quantities of factor Va activity, they expressed only 2025% of the normal number of factor Xa binding sites. [424] In addition, factor X activation by factor IXa and factor VIIIa was impaired, suggesting a concomitant deficiency of factor IXa and factor VIIIa binding sites. [425] When stimulated with the combination of thrombin and collagen, there was decreased exposure of anionic phospholipids on the platelet surface [426] and decreased membrane vesiculation.[427] Similarly, there was decreased membrane vesiculation and procoagulant activity when the patients erythrocytes were treated with the ionophore A23187. [418] However, whereas membrane-associated phospholipid scramblase activity in the patients platelets, erythrocytes, and lymphocytes was impaired, Ca^{2+} -induced function of the isolated scramblase incorporated into proteoliposomes was indistinguishable from normal, [420] suggesting that another membrane component affecting the function of the scramblase may be responsible for the syndrome.

Chapter 131 - Acquired Disorders of Platelet Function

James N. George
Sanford J. Shattil

INTRODUCTION

The acquired disorders of platelet function are among the most common of all hematologic abnormalities, an observation supported by the predictable effect on platelet function of the ubiquitous drug, aspirin. This chapter discusses the clinical disorders associated with acquired defects in platelet function (Table 131-1). A major goal is to attempt to provide a balanced view of the clinical importance of each acquired platelet defect. This task may not be possible in all cases. An illustration of the real difficulty in predicting the risk for hemorrhage is the clinical experience with Glanzmann thrombasthenia, a congenital platelet disease that is defined by a long bleeding time and absent platelet aggregationabnormalities similar to but typically more severe than those found in many acquired disorders. Among thrombasthenic patients who have equally severe abnormalities of platelet function the range of bleeding symptoms is great, and some patients experience no excessive bleeding throughout their lives. In most patients, severe hemorrhagic episodes are sporadic and unpredictable. [1] Therefore, since acquired platelet function defects generally produce milder symptoms than Glanzmann thrombasthenia, it should be expected that bleeding in patients with acquired defects will be even less predictable and may occur only when additional hemostatic defects are present. The preservation of normal hemostasis despite diminished platelet function is consistent with the observation that spontaneous bleeding does not usually occur in thrombocytopenic patients until the platelet count is <10,000/ml, or <5% of the normal value.[2]

Part of the problem in the clinical assessment of these disorders is the difficulty in interpreting the laboratory measures of

platelet function by which they are defined: platelet aggregation and the bleeding time. These diagnostic procedures are discussed more fully in Chapter 106 , but their interpretation requires emphasis here. There are several reasons why it cannot be assumed that abnormal in vitro platelet aggregation or a prolonged bleeding time predict an increased risk for bleeding. First, it is difficult to accurately express results of aggregation studies in quantitative terms, and there is no universally accepted definition of a normal range of values. Second, aggregation studies can be inconsistent and abnormal in normal subjects who have ingested no medication [3] and may vary with the age of the subject.[4] Third, aspirin ingestion is widespread in our society, and this drug causes abnormal patterns of aggregation (see below). Fourth, the secondary wave of aggregation following adenosine diphosphate (ADP) stimulation occurs in citrate-anticoagulated platelet-rich plasma, but not in the presence of physiologic concentrations of calcium, which suggests that this normal aggregation pattern occurs in vitro but may not occur in vivo. [5] Even with these limitations, platelet aggregation studies can be useful in the diagnostic evaluation of selected patients, but the ability of abnormal results to predict an increased risk for bleeding is unknown. Finally, although the bleeding time is an important aid in the diagnosis of selected congenital disorders, [6] its value in predicting a risk for hemorrhage is unproved.[7]

Despite difficulty in assessing individual risks, acquired platelet function disorders do have a clear effect on hemostasis and thrombosis in large studies. Again the case of aspirin is pertinent, as recent data demonstrate that a small but sustained dose of aspirin (325 mg every other day) may cause a reduction in the risk for myocardial infarction in a selected study group but may also increase the risk for hemorrhage. [8]

DRUGS THAT AFFECT PLATELET FUNCTION

A vast array of drugs are known to affect platelet function (Table 131-2). [9] Some of the agents listed in Table 131-2 are used specifically for their antithrombotic activity, with diminished platelet function being the therapeutic goal. [10] These agents are also discussed in Chapter 125 . For the others, the occurrence of abnormal platelet function is an unwanted side effect. For all of these drugs, their effect on platelet function is defined by an abnormality of platelet aggregation or of the bleeding time, but whether they contribute to a risk of excessive bleeding is definitively established only for aspirin.

Aspirin

Aspirin has become a common household drug since its introduction nearly 100 years ago, and estimates of its current use in the United States are staggering: 10,00020,000 tons annually, [11] which is equivalent to almost one tablet for every person every day.

Definition of the Aspirin-Induced Platelet Defect

The mechanism of aspirin impairment of platelet function is the acetylation and irreversible inhibition of platelet cyclooxygenase. [10] [12] For platelets, which have minimal protein synthetic capacity, a single small dose of aspirin, 40100 mg, or as little as 10 mg taken daily for a week, can totally inhibit thromboxane production and therefore impair the function of a cohort of platelets for its entire circulating life span of 10 days. These observations are consistent with data suggesting a therapeutic antithrombotic effect of aspirin at doses as low as 30 mg/day. [12] Although the effect of aspirin on platelet cyclooxygenase function is clear, it may not be the only mechanism by which aspirin interferes with hemostasis. Aspirin depresses thrombin formation in clotting blood, possibly by acetylating prothrombin, and the acetylation of fibrinogen after therapeutic doses of aspirin significantly interferes with fibrin formation and allows accelerated fibrinolysis. [13]

Aspirin also acetylates cyclooxygenase in endothelial cells, blocking synthesis of the final product of endothelial cell eicosanoid metabolism, prostacyclin, which is a strong inhibitor of platelet function. However, the endothelial enzyme is less sensitive than platelet cyclooxygenase to low doses of aspirin, and, in contrast to platelets, endothelial cells can recover cyclooxygenase activity by synthesizing new enzyme. [12] [13] Therefore, a consideration for therapeutic trials with aspirin has been to use a low dose, minimizing the inhibition of endothelial cell prostacyclin synthesis, which could have a prothrombotic effect. A significant portion of aspirins effect on platelets occurs in the portal circulation; [14] half of an oral dose is deacetylated in the liver to form inactive salicylic acid. This provides an additional therapeutic advantage by allowing small oral doses of aspirin to react more effectively with circulating platelets than with endothelial cells in the systemic circulation.

Aspirin and Platelet Aggregation

A predictable abnormality after exposure of platelets to aspirin either in vivo or in vitro is impaired aggregation with epinephrine, ADP, arachidonic acid, and low concentrations of collagen and thrombin. [15] These abnormalities are a direct result of inhibition of cyclooxygenase, with the resulting deficient synthesis of the final product of platelet arachidonic acid metabolism, thromboxane A_2 . [10] Thromboxane A_2 diffuses out of the platelet, binds to specific platelet membrane receptors, and reinforces aggregation by promoting alpha-granule and dense granule secretion. With cyclooxygenase inhibition, only a primary, reversible wave of platelet aggregation without platelet secretion occurs following stimulation by epinephrine and low concentrations of ADP, thrombin, and collagen. The aspirin-induced abnormality of platelet aggregation is so characteristic that abnormal platelet aggregation patterns of any cause are often designated as aspirin-like. Stronger agonists (high concentrations of thrombin and collagen) do not require thromboxane A_2 synthesis to cause platelet secretion and irreversible aggregation. The occurrence of a complete platelet response in the presence of total inhibition of the enzyme cyclooxygenase demonstrates the presence of multiple pathways of platelet activation, and this may explain why normal subjects almost always have normal hemostasis while taking aspirin.

Aspirin and the Bleeding Time

Aspirin also prolongs the bleeding time, but in individual subjects this is less consistent than the platelet aggregation abnormality. Initial studies demonstrated that 2 hours after ingestion of two to three aspirin tablets (650975 mg), the mean template bleeding time of a group of normal subjects was significantly increased. [6] [16] Prolongation of the bleeding time can be demonstrated for as long as 4 days after a single dose of aspirin, [17] until normal platelet turnover results in the appearance of new platelets with normal function. However, aspirin actually prolongs the bleeding time to a value greater than the normal range in only about half of normal subjects. [6] [16] It is assumed, but has not been clearly demonstrated, that individual subjects have a consistent bleeding time response to aspirin on repeated challenges. [6] [17] Smaller single doses of aspirin (150160 mg) that consistently cause abnormal platelet aggregation do not cause a prolonged bleeding time; however, daily ingestion of 30 mg of aspirin (but not 10 mg) does cause an increased bleeding time. [18]

The bleeding time has a reputation for being the most direct test of platelet function, because it is performed directly on the patient and because it correlates with the platelet count in selected patients. [19] However, its limitations need to be

TABLE 131-2 -- Drugs That Inibit Platelet Functiona [a]

Nonsteroidal anti-inflammatory drugs	Nifedipine (Procardia)
Aspirin [b]	Verapamil (Calan, Isoptin)
Sulfinpyrazone (Anturane) [b]	Diltiazem (Cardizem)
Indomethacin (Indocin)	Quinidine
Ibuprofen (Advil, Motrin, Nuprin)	Psychotropic drugs
Sulindac (Clinoril)	Tricyclic antidepressants
Naproxen (Naprosyn)	Imipramine (Tofranil)
Phenylbutazone (Butazolidin)	Amitriptyline
Meclofenamic acid (Meclomen)	Nortriptyline (Pamelor)

Mefanamic acid (Ponstel)	Phenothiazines
Diflunisal (Dolobid)	Chlorpromazine (Thorazine)
Piroxican (Feldene)	Promethazine (Phenergan)
Tolmetin (Tolectin)	Trifluoperazine (Stelazine)
Zompirac (Zomax)[c]	Anesthetics
	Local
-Lactam antibiotics	Dibucaine (Lidocaine)
Penicillin G	Tetracaine (Carbocaine)
Penicillin G	Cyclaine
Carbenacillin (Geopen)	Butacaine
Ticarcillin (Ticar, Timentin)	Nepercaine
Methicillin (Staphcillin)	Procaine
Ampicillin (Polycillin, Omnipen)	Cocaine
Nafcillin (Nafcil, Unipen)	Plaquenil
Piperacillin (Pipracil)	General
Azlocillin (Axlin)	Halothane (Fluothane)
Mezlocillin (Mezlin)	Narcotic
Apalcillin	Heroin
Sulbenicillin	Oncologic drugs
Temocillin	Mithramycin
Cephalosporins	Daunorubicin
Cephalothin (Keflin, Seffin)	BCNU
Moxalactam (Moxam)	Miscellaneous drugs
Cefoxitin (Mefoxin)	Ticlopidine
Cefotaxime (Claforan)	Clofibrate (Atromid-S)
Cefazolin (Ancef, Kefzol)	Ketanserin
Other drugs	Antihistamines
Antibiotics	Diphenhydramine (Benadryl, Allerdryl)
Nitrofurantoin (Furadantin, Macrodantin)	Chlorpheniramine (Donatussin, Probahist)
Drugs that increase platelet cAMP concentration	Mepyramine
Prostacyclin	Radiographic contrast agents
Iloprost	Renografin-76
Dipyridamole (Persantin)[b]	Renovist II
Anticoagulant	Conray-60
Heparin	
Fibrinolytic agents	Foods and food additives
Plasma expanders	-3 Fatty acids (eicosapentaenoic acid)
Dextrans	Ethanol
Hydroxyethyl starch (hetastarch)	Chinese black tree fungus
Cardiovascular drugs	Onion extract
Nitroglycerin	Ajoene (garlic component)
Isosorbide dinitrate (Isordil, Diltrate)	Cumin
Propranolol (Inderal)	Turmeric
Nitroprusside (Nitropress)	Clove

[a] Of these drugs, only aspirin has been demonstrated to cause a significant increase in bleeding (Table 1313). The other drugs are described as affecting platelet aggregation or the bleeding time, and case reports have suggested an association with increased bleeding. Brand names for these agents are given in parentheses when they may be more familiar.
[b] Used as a therapeutic antithrombotic agent.
[c] Withdrawn from the U.S. market in 1983.

recognized.[7] For example, to demonstrate an effect of aspirin on the template bleeding time, certain technical details must be followed. If the bleeding time test is performed using a vertical rather than the traditional transverse skin incision and without the usual venostasis, there is no prolongation after aspirin treatment, despite the characteristic changes in platelet aggregation and secretion.[17] An older bleeding time technique, the Duke earlobe puncture, is insensitive to aspirin treatment.[16] It is usually assumed that the skin bleeding time can be used to assess the risk for bleeding from other organs. However, in one study of patients taking aspirin for rheumatic disease and who were undergoing gastric endoscopic biopsy, this assumption was shown not to be true.[20] These data emphasize that the bleeding time cannot be automatically accepted as an accurate representation of systemic hemostasis.[7]

The most dramatic demonstrations of the aspirins effect on the bleeding time have been in patients with severe hemophilia.[21] The bleeding time is already slightly prolonged in some patients with severe hemophilia A.[22] However, following the administration of two or three aspirin tablets, sustained hemorrhage from the bleeding time incision was observed in five of 11 patients with severe hemophilia A, and this ultimately required an infusion of plasma or factor VIII to arrest the bleeding.[21] Patients with mild hemophilia appeared to have less risk

from aspirin, as in none of 16 patients was the bleeding time prolonged greater than values in the normal control group.[21] Also, small doses of aspirin cause a greater than normal prolongation of the bleeding time in patients with chronic renal failure and have been associated with reports of major bleeding.[23] The combination of ethanol and aspirin has a synergistic effect on increasing the bleeding time in normal subjects.[24]

Clinical Importance of the Aspirin-Induced Defect in Platelet Function

In contrast to its antithrombotic effect, which appears not to be dose related above small threshold doses, aspirin-induced gastrointestinal (GI) mucosal toxicity is dose related.[25] The mechanism of mucosal injury appears to be separate from the effect on hemostasis. The risk for GI bleeding with aspirin, from both the upper and lower GI tract and from both discrete ulceration and more diffuse mucosal damage, is increased 1.52.0-fold, [26] even with low doses of aspirin, 100 mg/day.

The overall clinical importance of aspirin on hemostasis was demonstrated by the administration of a low dose of aspirin (325 mg every other day) or a placebo to 22,071 physicians over the course of 5 years (Table 131-3).[8] Aspirin-treated subjects had a 44% decrease in the risk for myocardial infarction. Aspirin treatment was also associated with a small but significant increase in the risk for serious hemorrhage. Some 2,979 subjects in the aspirin group and 2,248 of those taking placebo reported problems such as easy bruising, hematemesis, melena, and epistaxis (relative risk, 1.32; $P < 0.00001$), and 48 in the aspirin group, compared to 28 in the placebo group, required a blood transfusion during the 5-year period ($P = 0.02$). Therefore, in spite of the difficulty in assessing the effect of aspirin on the hemostatic function of individual normal subjects, the clinical importance of aspirin-induced impairment of hemostasis is certain. Aspirin may cause more bleeding symptoms in patients with other hemostatic defects. The risk of bleeding is increased if aspirin is given simultaneously with warfarin in high-intensity regimens (INR 3.04.5), although the occurrence of major hemorrhagic events may not be increased.[27] On the other hand, aspirin given during treatment of acute coronary syndromes in combination with fibrinolytic and other antithrombotic agents does not appear to increase the incidence of major bleeding episodes. [13] [28]

TABLE 131-3 -- Effect of Aspirin on the Risk of Bleeding in Normal Subjectsa[a]

	Aspirin	Placebo	Relative Risk	*P* Value
No. of subjects	11,037	11,034		
No. with hemorrhagic complications	2,979	2,248	1.32	<0.00001
Easy bruising	1,587	1,027	1.55	<0.0001
Epistaxis	862	640	1.35	<0.0001
Melena	364	246	1.48	<0.00001
Hematemesis	38	28	1.36	0.22
Nonspecific gastrointestinal bleeding[b]	440	422	1.04	0.55
Other bleeding[c]	724	596	1.21	0.0004
Number of requiring blood transfusion	48	28	1.71	<0.02

[a] These data are adapted from the Physicians Health Study Research Group,[g] and they represent the only definitive documentation of a hemorrhagic risk from drug-induced platelet dysfunction, other than the direct platelet GPIIb/IIIa receptor antagonists. The subjects were healthy male physicians, treated with one aspirin tablet (325 mg) every other day or a placebo, and followed for an average of 60.2 months.
[b] No further defined.
[c] Hemorrhagic complications described as other bleeding: 29% were related to shaving or brushing the teeth (32% in the aspirin group and 27% in the placebo group), and 72% were hematuria (70% in the aspirin group and 75% in the placebo group).

MANAGEMENT OF PATIENTS TAKING ASPIRIN

The therapeutic recommendations for management of a patient taking aspirin are straightforward. In a patient with a clear therapeutic indication for aspirin, whether it be a headache or unstable angina, and no apparent increased risk for bleeding, aspirin is one of the safest drugs. In patients who already have greatly increased hemorrhagic risks, such as severe hemophilia, aspirin must be avoided.[21] When a hemostatically normal patient who is taking aspirin is scheduled for an invasive procedure, aspirin should be discontinued for at least 5 days.[35] This period of time is sufficient for about half of the circulating platelets to be replaced by platelets from megakaryocytes that were not exposed to aspirin, and half of the normal number of platelets (e.g., approximately 100,000/l) is sufficient for normal hemostasis during any surgical procedure. However, since aspirin use is so common[11] and since the drug is present in hundreds of pharmaceutical products, it may not be feasible to discontinue aspirin and wait 5 days for a procedure in most patients. Then only careful observation is necessary. Significant excessive bleeding due to aspirin is rare, and any serious bleeding that does occur during an operative procedure is likely due to a surgically correctible lesion. If severe hemorrhage due to deficient platelet function is suspected, a platelet transfusion would be promptly effective, but this will be indicated only very rarely. Perhaps the recommendations for surgery in a patient who has taken aspirin should parallel the recommendations for surgery in patients taking prophylactic subcutaneous heparin. [36] [37] With both aspirin and the conventional fixed doses of subcutaneous heparin (5,000 units twice daily), the risk for increased bleeding during and after surgery is significant in large studies but is negligible in any individual patient. Therefore, except for those patients in whom the nature of the surgical procedure requires the absolute minimum risk for excessive bleedingas in some plastic surgical, neurosurgical, or ophthalmologic proceduresthe increased risk for bleeding with aspirin use does not appear to be a reason to delay necessary surgery. The use of prophylactic platelet transfusions in this clinical setting is discouraged.

Furthermore, relatively low doses of aspirin (60 mg/day) given during pregnancy did not increase maternal or neonatal bleeding complications. [29]

On balance, the hemostatic risks of aspirin treatment may be similar to those observed in patients with Glanzmann thrombasthenia, in which the hemorrhagic complications are greater when there is an additional cause for bleeding. [1]

Several studies have addressed the risk of postoperative hemorhage in patients taking aspirin. The results, as may be expected with a very mild hemostatic defect, are not consistent. Some studies report increased blood loss in patients taking aspirin who undergo cardiac surgery, but others do not. [9] Reports of increased chest tube blood loss in aspirin-treated patients are not associated with worse clinical outcomes, such as a need for reoperation or greater numbers of units of blood transfused.[30] [31]

In studies of patients undergoing elective total hip replacement by a single surgeon, aspirin treatment (1.23.6 g/day) was begun the day before surgery and continued for 7 days.[32] The blood loss was 20% greater in the treated group in one study, but this was considered clinically unimportant and required no additional care. [32] A study of 200 patients undergoing general

or gynecologic surgery also suggested that there was greater operative blood loss in patients who had taken aspirin. [33] The surgeon and the anesthesiologist observed greater than expected bleeding in 12 of 55 patients who had taken aspirin and had abnormal results on platelet aggregation studies, compared to 7 of 97 patients who had not taken aspirin and had normal aggregation studies. The other 48 patients in this study either claimed they had not taken aspirin but were found to have abnormal platelet aggregationa frequent occurrence in many studies owing to habitual and forgotten aspirin use (33 patients)or had taken aspirin but their platelet aggregation was normal (15 patients). Eight of these 48 patients were thought to have excessive bleeding at surgery. Although the results were interpreted as demonstrating increased operative bleeding following aspirin treatment, it is important to note that greater than expected bleeding also occurred in the control patients. This observation is inevitable in all subjective evaluations of bleeding, either surgical or medical. The observer always expectshopes forthe normal bleeding response to be minimal, but the range of normal bleeding is great, and patients with more bleeding are often viewed with concern.

It may be concluded from the sum of these reports that aspirin has a small, inconsistent, but sometimes important effect on surgical bleeding. Minimally invasive trauma, such as spinal or epidural anesthesia, is not associated with increased bleeding in patients taking aspirin. [29] [34] These data on aspirin represent well the clinical paradigm for acquired disorders of platelet function: (1) their occurrence is common; (2) the defect is usually mild; (3) normal individuals vary in their sensitivity to aspirin; (4) platelet aggregation and the bleeding time are subject to technical vagaries; (5) the risk for increased bleeding in the individual subject who is otherwise normal is minimal and unpredictable; (6) however, a definite risk for increased bleeding with aspirin can be demonstrated when large groups of normal subjects are analyzed or when individuals are studied who have concomitant pathologic (e.g., hemophilia) or physiologic (e.g., childbirth) conditions that can predispose to hemorrhage.

Other Nonsteroidal Anti-inflammatory Drugs

In addition to aspirin, many other drugs used for their anti-inflammatory and analgesic properties can cause decreased platelet function (Table 131-2).[9] As with aspirin, their mechanism of action appears to be the inhibition of the activity of platelet cyclooxygenase. In contrast to aspirin, each of these agents has only a temporary effect on cyclooxygenase function, causing enzyme inhibition only as long as the active drug is present in the circulation. Therefore, among these agents only drugs such as piroxicam, which has a plasma half-life of >2 days, [38] affect platelets for more than a few hours. As with aspirin, the most sensitive indication of impaired platelet function is the inhibition of in vitro aggregation and secretion. These agents prolong the bleeding time minimally and transiently or not at all, consistent with the bleeding time being a less sensitive measure of the aspirin-induced defect. [9]

Clinical reports are consistent with the observations on platelet function and suggest that these drugs cause less risk for increased bleeding than aspirin. As with aspirin, they may increase the bleeding time in patients with severe hemophilia, [35] although in two studies therapeutic doses of ibuprofen had no effect on the bleeding time in 19 of 20 patients with hemophilia. [39] Therefore, the clinical approach to patients taking any drug that can inhibit platelet cyclooxygenase should be similar, although the hemostatic risk with drugs other than aspirin usually disappears a few hours after the drug is stopped. The additional risk for bleeding with surgery should be negligible, but a prudent course would be to discontinue these drugs the day before a procedure. Analgesics such as acetaminophen and sodium or choline salicylate do not inhibit platelet function and have no adverse effect on hemostasis. [39]

Ticlopidine and Clopidogrel

Ticlopidine is a thienopyridine that is used to reduce the risk of thrombotic strokes in patients who have cerebrovascular disease, and for the prevention of myocardial infarction.[10] [40] The degree of prolongation of the bleeding time is equivalent to that seen with aspirin. Ticlopidine impairs fibrinogen binding to GPIIb/IIIa and inhibits platelet aggregation to many agonists, particularly ADP. The major site of action appears to be on the pathway providing stimulusresponse coupling between the ADP receptor and fibrinogen binding. The effects of ticlopidine on platelet function appear within 2448 hours after ingestion, are maximal in 46 days, and continue for 410 days after the drug has been discontinued.[40] Ticlopidine may be associated with a small increased risk for bruising and epistaxis, but the major complications are neutropenia, aplastic anemia, and thrombocytopenia.[40] It is recommended that ticlopidine be discontinued at least 10 days before elective surgical procedures. Clopidogrel is a congener of ticlopidine that has similar effects on platelet function and similar antithrombotic efficacy in atherosclerotic vascular diseases, although with a reduced tendency to cause cytopenias.[41]

Platelet GPIIb/IIIa Receptor Antagonists

A new class of agents has been developed for use in acute coronary syndromes; these agents block the fibrinogen receptor function of platelet GPIIb/IIIa, essentially creating a phenotype of Glanzmann thrombasthenia.[28] [42] The first agent that was approved for use in 1996, abciximab (ReoPro), is a human-murine chimeric monoclonal antibody to human platelet GPIIb/IIIa, and it also reacts with another $_3$ integrin, $_v{}_3$. Agents developed subsequently are highly selective for GPIIb/IIIa and include RGD- (or KGD)-containing peptides or small peptidomimetic molecules.[43] Abciximab and the recently approved agents, integrilin and tirofiban, are given by intravenous infusion; some of the subsequent agents will be orally administered. Initial clinical trials have demonstrated efficacy in preventing restenosis after coronary angioplasty and in the treatment of unstable angina. [28] [43] [44] Bleeding complications were significantly greater with abciximab plus heparin than with conventional treatment with heparin alone in initial trials, but this adverse effect was reduced by decreasing the heparin dose in subsequent trials. [44] An important complication of use of these agents is the occurrence of acute, profound thrombocytopenia, which occurs in 1% of patients. [42] [45] The cause of the thrombocytopenia is unknown, but the clinical course suggests that these patients have a preformed, naturally occurring antibody against epitopes on GPIIb/IIIa that is exposed by binding of the receptor antagonist molecules. Drugs of this class in general have a high affinity for circulating platelets, and their clearance when dissociated is rapid. As might be expected, therefore, platelet transfusions are effective in the management of bleeding in these patients, either in the presence or in the absence of thrombocytopenia.

-Lactam Antibiotics

Antibiotics are the other major category of therapeutic agents, along with the nonsteroidal anti-inflammatory drugs (NSAIDs), that affect platelet function (Table 131-2).[9] Like NSAIDs, antibiotics are widely used. The antibiotics that affect platelet function all share a common -lactam ring structure, a characteristic of the penicillins and cephalosporins. Some of the antibiotics listed in Table 131-2 have a predictable dose- and duration-related effect on the bleeding time. [46] [47] Because the effect on bleeding time is seen only in patients who are receiving large parenteral

doses of antibiotics, this is a potential problem only for hospitalized patients. In a study of 74 hospitalized patients with a consistently prolonged bleeding time, the likely cause was penicillin in 39 patients (30 patients were receiving penicillin G, more than 15,000,000 U/day, and 9 were receiving ampicillin, 68 gm/day) and aspirin or related drugs in 7 patients.[48]

The structural properties that cause some, but not all, of the penicillins and cephalosporins to affect platelet function are unknown. The diversity of side chain structure alters the antibacterial and pharmacologic properties of the penicillins and cephalosporins and may also determine their effect on platelet function. It is postulated that the antibiotic associates with the platelet plasma membrane by a lipophilic mechanism, causing a perturbation that blocks multiple receptoragonist interactions or stimulusresponse coupling.[49] The characteristic laboratory observation is the occurrence of a prolonged bleeding time and abnormal platelet aggregation after several days of high-dose parenteral therapy. [46] [47] These abnormalities do not subside until several days after the antibiotic is discontinued.

The frequency of clinically important bleeding in patients taking -lactam antibiotics appears to be low and is not predicted by a prolonged bleeding time, and the causal relationship to antibiotic treatment is unproved. [50] Certainly many patients who need to receive high doses of these antibiotics have risk factors for hemorrhage, such as thrombocytopenia, sepsis, malignancy, and renal failure. Typical case reports suggesting antibiotic-related hemorrhage (e.g., with the use of carbenicillin and nafcillin [51] [52]) occur in such complicated patients. In these cases, the antibiotic was assumed to have contributed to the bleeding because the diagnostic bleeding times were markedly abnormal. An alternative explanation is that the bleeding time is not related to a risk for hemorrhage [7] and that the antibiotics were innocent. For each report implicating an antibiotic as a cause of hemorrhage, many more patients receive the same antibiotics in large doses without bleeding complications.[50] In conclusion, antibiotic-induced platelet dysfunction appears to have little clinical importance, and the potential effect on platelet function should not

be considered in the decision to use any antibiotic in any clinical situation.

An exception to this conclusion may be moxalactam. The frequency of clinically important hemorrhagic complications with moxolactam appears to be greater than with other antibiotics.[50] Its effect on the bleeding time and platelet aggregation are no different from that of other antibiotics, [47] so it probably has no more profound effect on platelet function. However, unlike most other -lactam antibiotics, moxalactam contains a methylthiotetrazole-leaving group that has been implicated in the inhibition of synthesis of vitamin K-dependent proteins.[53] Therefore, moxolactam-induced bleeding may be due to the combination of deficiencies in coagulation factors II, VII, IX, and X and impaired platelet function.

Other Drugs

Antibiotics

Nitrofurantoin, an antibiotic structurally unrelated to the -lactam antibiotics, may cause a mild prolongation of the bleeding time and impair platelet aggregation when blood levels of the drug are >20 M.[54] Nitrofurantoin is not known to cause clinical bleeding.

Drugs That Increase Platelet Cyclic AMP Concentration

Elevation of the platelet concentration of cyclic adenosine monophosphate (cAMP) by any mechanism inhibits platelet function. Prostacyclin and its analogs increase cAMP synthesis by stimulation of adenyl cyclase, and they have been studied as antithrombotic substitutes for heparin in cardiopulmonary bypass surgery and hemodialysis.[10] [55] In spite of the potent inhibition of platelet aggregation by prostacyclin in vitro, the effects on the bleeding time are minimal and inconsistent. [55] Dipyridamole increases cAMP concentration by inhibition of the cAMP phosphodiesterase; it has been used extensively as an antithrombotic agent despite the lack of clearly documented efficacy.[10] There are no data to suggest that dipyridamole causes increased bleeding.

Anticoagulants

Although heparin is best known for its anticoagulant effect and its adverse effect in causing thrombocytopenia (see Chaps. 122 and 129), it has the potential to affect platelet function. Heparin can bind to the platelet surface, [56] cause platelet aggregation and secretion, [57] and impair von Willebrand factor (vWF)-dependent platelet function.[58] Heparin can also cause a prolonged bleeding time.[59] Whether these phenomena are related to the bleeding complications of heparin use is unknown. The prolonged bleeding time is probably due to heparins inhibition of thrombin generation, analogous to the slight but significant increase in bleeding time in patients with hemophilia.[22]

Fibrinolytic Agents

Bleeding during therapy with plasminogen activators is predominantly due to the effects of hypofibrinogenemia and increased fibrin(ogen) degradation products on fibrin clot formation, usually combined with a structural lesion in the blood vessel wall (see Chap. 123). Pharmacologic doses of streptokinase, urokinase, and tissue plasminogen activator (t-PA) may impair platelet function.[60] Several mechanisms may be involved. First, very high levels of fibrin(ogen) degradation products coupled with very low levels of fibrinogen may impair platelet aggregation. Second, plasminogen can bind to the platelet surface where it is converted to the proteolytic enzyme, plasmin, by plasminogen activator.[61] On the platelet surface, plasmin can degrade both GPIb (thereby impairing the interaction of the platelet with vWF [62]) and fibrinogen (thereby dispersing platelet aggregates [63]). Third, plasmin can inhibit platelet aggregation by blocking the release of arachidonic acid from platelet membranes, thereby limiting thromboxane production.[64] The clinical importance of these observations is unknown.

Plasma Expanders

Dextrans are partially hydrolyzed branched polysaccharides of glucose. The two preparations in clinical use have average molecular sizes of 70,00075,000 (often termed dextran 70) and 40,000 (termed dextran 40, or referred to as low-molecular-weight dextran). Both preparations are effective plasma expanders and both can affect platelet function, though there are some data to suggest that the high-molecular-weight molecules have a greater effect on hemostasis. [65] An infusion of a liter of 6% dextran solution over 1 hour prolonged the bleeding time in about half of 163 normal subjects, with some bleeding times prolonged to >30 minutes. [65] Dextran infusion also impairs platelet aggregation and platelet procoagulant activity and can cause a modest reduction in plasma vWF concentration. However, dextran has no effect on platelet function when added directly to platelet-rich plasma in vitro. [66] Because of these effects on platelet function, dextran has been used as an antithrombotic agent, and its efficacy in preventing fatal postoperative pulmonary emboli appears to be equivalent to that of subcutaneous heparin. [67] This therapeutic effect is achieved without any increased risk for bleeding, as demonstrated in a large double-blind trial comparing dextran and placebo during general surgery. [68] Therefore dextran infusions represent yet another example of an agent that can alter platelet function and prolong the bleeding time without an apparent increased risk for hemorrhage. Hydroxyethyl starch, known as hetastarch, is a synthetic

glucose polymer with an average molecular weight of 450,000 (range, 10,0001,000,000) that is also used for plasma expansion. Like dextran, it may prolong the bleeding time, particularly if administered in doses of >20 ml/kg of a 6% solution, and may predispose to bleeding if administered simultaneously with heparin or used in a patient with a preexisting hemostatic defect.[69]

Cardiovascular Drugs

Administration of nitroglycerin, isosorbide dinitrate, propranolol, or nitroprusside can decrease platelet aggregation and secretion, although the effects are minimal and inconsistent in some studies.[9] Some of the observed effects may also be mediated by desensitization of platelets by increased plasma concentrations of epinephrine.[70] There are also numerous reports on the effect on platelets by drugs used clinically for their ability to inhibit the influx of calcium ions across the membranes of excitable cells, known as calcium channel blockers: nifedipine, verapamil, and diltiazem. [9] These studies have demonstrated inhibition of platelet aggregation in vitro when high concentrations (micromolar) of the drug were used with washed platelets. [71] This effect is seen primarily with epinephrine as the agonist and it does not appear to be related to inhibition of calcium ion flux. The proposed mechanisms of action include inhibition of epinephrine binding to $_2$ -adrenergic receptors, inhibition of the platelet response to thromboxane A_2 , and inhibition of serotonin-induced aggregation. In therapeutic doses, the calcium channel blockers do not prolong the bleeding time. Quinidine, an anti-arrhythmic drug, can act as an antagonist at platelet $_2$ -adrenergic receptors when in high concentrations. In a single report, a patient taking 800 mg of quinidine and 650 mg of aspirin daily developed melena and generalized petechiae with a normal platelet count and a bleeding time of >35 minutes.[72] Subsequent studies on two normal volunteers showed that quinidine caused a mild increase in the bleeding time that was apparently potentiated by aspirin.

Psychotropic Agents

Platelets from patients taking tricyclic antidepressent drugs (imipramine, amitriptyline, nortriptyline) or phenothiazines (chlorpromazine, promethazine, trifluoroperazine) may have impaired in vitro aggregation and secretion responses to ADP, epinephrine, and collagen, but this effect is not associated with an increased risk for bleeding.[9]

Anesthetics

Both local and general anesthetics may impair in vitro platelet aggregation. Halothane may cause a slight prolongation of the bleeding time, but it has no adverse effect on surgical hemostasis. Cocaine may increase platelet responsiveness to ADP. [9]

Heroin

A study of ten patients admitted to a methadone program who denied intake of any other drugs for the previous 2 weeks demonstrated a long bleeding time in two and abnormal platelet aggregation in eight.[73] None of these patients had any evidence of a clinically important hemostatic defect, and the cause of the abnormalities is

unclear.

Oncologic Drugs

Administration of mithramycin to a total dose of 621 mg has been associated with decreased platelet aggregation, an increased bleeding time, and mucocutaneous bleeding. Daunorubicin and BCNU can each inhibit platelet aggregation and secretion when added to platelet-rich plasma, but there has been no suggestion of clinically important bleeding caused by defective platelet function. [9]

Miscellaneous Drugs

Clofibrate, a drug that can lower the plasma concentration of lipoproteins, diminishes platelet responsiveness to ADP, collagen, and epinephrine when given to patients with type II hyperbetalipoproteinemia, and can diminish the responsiveness of normal platelets to ADP and epinephrine in vitro. Ketanserin, which has been studied for its potential to prevent atherosclerotic complications, causes decreased platelet aggregation in response to serotonin. Antihistamines and some radiographic contrast agents can also impair platelet aggregation. The mechanism of action of these agents is not known. [9]

Foods and Food Additives

In our nutrition-conscious society, the effect of certain food components on platelet function is an increasingly important issue. A diet rich in fish and other marine oils, that contain a high concentration of -3 fatty acids (eicosapentaenoic acid, EPA, C20:5-3; and docosahexaenoic acid, DCHA, C22:6-3) may decrease the development of atherosclerosis and the occurrence of myocardial infarction. [10] One proposed mechanism of this effect is inhibition of the platelets role in the pathogenesis of atherosclerosis. Subjects ingesting a diet rich in marine oils or supplemented with -3 fatty acids have a slight prolongation of the bleeding time. These lipids act by reducing the platelet content of arachidonic acid and by competing with arachidonic acid for cyclooxygenase, thereby reducing thromboxane production. [10] Whether these subjects have any increased risk for clinically important bleeding is unknown.

Ethanol is a commonly imbibed substance that acts synergistically with aspirin to prolong the bleeding time. [24] Ethanol can itself significantly impair platelet function in vitro, and a blood level as low as 0.05% can impair platelet adhesion to vessel subendothelium in an in vitro perfusion system. [74]

Other food components or additives may affect platelet function and have been suspected of increasing the risk for minor bleeding. Easy bruising noted after eating Chinese food has been attributed to an effect on platelets by a black tree fungus. [75] A component of onion extract can inhibit platelet arachidonic acid metabolism. [76] Ajoene, a component of garlic, is an inhibitor of fibrinogen binding to platelets and platelet aggregation. [77] Extracts from frequently consumed spices, cumin, turmeric, and clove can decrease platelet thromboxane production and inhibit platelet aggregation. [78]

It can be concluded that platelets are sensitive to an enormous variety of therapeutic and dietary compounds. [9] The inhibition of platelet aggregation is a common observation in patients receiving a wide variety of agents; prolongation of the bleeding time is less common. However, an increased risk for clinically important bleeding has been demonstrated only for aspirin (Table 131-3).[8] Reports of increased bleeding with all other agents must be viewed with caution. Despite this qualification, it would be prudent for the clinician to have a thorough understanding of the antiplatelet effects of drugs prescribed, and to always consider the potential impact of drug-induced platelet dysfunction, particularly in patients with coexisting hemostatic defects.

SYSTEMIC DISORDERS THAT AFFECT PLATELET FUNCTION

Chronic Renal Failure

Clinical Features

The clinical importance of bleeding in chronic renal failure is difficult to assess. The recognition of severe hemorrhage as a distinct complication of renal failure is generally attributed to Reismans description in 1907 of two patients with Brights disease who had severe and generalized bleeding. [79] Reisman proposed

that the cause was a toxin analogous to the hemorrhagins of snake venom. However, there could have been multiple causes of the observed bleeding problems in both of Reismans patients.[79] Others observed a tendency to hemorrhage in patients with chronic glomerulonephritis in the predialysis era, and the descriptions of epistaxis and menometrorrhagia[80] are similar to the symptoms of patients with a primary platelet abnormality.[1] Chronic nephritis was also noted to be one of the common causes of cerebral hemorrhage in young people.[80] However before dialysis, death occurred primarily from hyperkalemia and pulmonary edema. [81] After dialysis became established treatment, the major causes of death became infection and the underlying cause of the renal failure. Hemorrhage caused six of 100 deaths in one series, but additional factors could have contributed in each patient. [81] Others noted that management with dialysis, allowing better nutrition and improved general health, appeared to diminish the occurrence of hemorrhagic symptoms.[82] The current prognosis for patients with end-stage renal disease is excellent. Patients who are <46 years old have a 97% 5-year survival rate with no medical complications; for patients <61 years old, the 5-year survival rate is 84%. [83] Bleeding problems were not mentioned in this discussion,[83] and bleeding was not considered in reviews published in the past 25 years on the clinical course and management of patients with chronic renal failure. However, bleeding and thrombosis in chronic uremia continue to be discussed. [84]

More objective indication of the rarity of a significant bleeding diathesis in patients with renal failure is the extensive experience with percutaneous renal biopsy. A study of 1,000 consecutive percutaneous renal biopsies performed at the Mayo Clinic reported that 69 patients had hematuria, of whom 50 experienced clearance within 2 days and two needed blood transfusions. [85] Fourteen patients had clinically detectable perirenal hematomas, and two underwent surgical exploration and evacuation. A bleeding time was determined in 707 of these patients before biopsy; it was abnormal in 24 (3%), and one of these patients had a perirenal hematoma. The other 13 patients with perirenal hematomas had a normal bleeding time. Hypertension was a more significant factor than the bleeding time in predicting the occurrence of complications.[85] Another study of 183 consecutively performed renal biopsies reported three hemorrhagic complications that required surgical intervention; all were the result of needle lacerations of the kidney or spleen. [86] In a discussion of 5,120 renal biopsies performed at 15 institutions, there were no deaths, and the severe bleeding complications appeared to be related to anomalous vessels, heparin anticoagulation, or the presence of amyloid in the kidney. [87] The incidence of small perirenal hematomas after percutaneous renal biopsy, as diagnosed by computed tomography, is high, 85%, [88] but this may not be unexpected for the puncture of an organ that receives 20% of the cardiac output. The reports with other invasive procedures in patients with chronic renal disease are few, but they suggest that bleeding complications after abdominal surgery, liver and bone marrow biopsies, and tooth extractions may be rare. [89]

By contrast, GI tract hemorrhage is a common complication and frequent cause of death in patients with acute renal failure, and patients with chronic renal failure account for a significant proportion of patients undergoing endoscopy for upper GI bleeding. [90] Experimental data suggest that chronic uremia causes increased susceptibility of gastric mucosa to acid injury.[91] More than 90% of patients with renal failure and GI bleeding have an anatomic diagnosis at endoscopy: angiodysplasia is most common, with peptic lesions (gastric or duodenal ulcer, erosive esophagitis, gastritis, or duodenitis) also very common. [90] Rectal ulcers can also cause sudden, massive lower GI hemorrhage.

These observations suggest that serious, spontaneous hemorrhage is very uncommon in patients with chronic renal failure. However, the many individual case reports of serious, spontaneous hemorrhage support the existence of a hemostatic defect in at least some uremic patients. Patients have been described with subdural hematoma, subarachnoid hemorrhage, hemorrhagic pericardial effusion, hemorrhagic pleural effusion, subcapsular liver hematoma, retroperitoneal hematoma, mediastinal hemorrhage, and bleeding into the anterior chamber of the eye.[9] In these patients the heparin therapy used for hemodialysis could have been a factor in the bleeding because the nature of the bleeding, primarily visceral hematomas, is more consistent with a heparin-induced coagulopathy than with the typically mucocutaneous bleeding of a platelet function disorder. [1]

The primary hemostatic abnormality in uremia is thought to be a defect in platelet function. [9] Descriptions of bleeding in uremia often focused on the laboratory phenomena of abnormal platelet aggregation or a prolonged bleeding time, rather than actual hemorrhagic episodes in patients. [84] As with the drug-induced disorders of platelet function discussed above, abnormal platelet function in uremia is far more common than clinically important bleeding. Furthermore, laboratory evaluation of platelet function may not be a good predictor of the risk of hemorrhage.

Tests of Hemostasis and Platelet Function in Uremia

Platelet aggregation studies are frequently abnormal in uremic patients, but the occurrence of the abnormality does not appear to correlate with the severity of the renal failure or the occurrence of bleeding. [92] The bleeding time may also be prolonged in uremia and does appear to correlate with the severity of the renal failure [92] or the occurrence of clinically important bleeding. [7]

Anemia, which does correlate with the severity of renal failure, is an independent cause of a prolonged bleeding time. [93] [94] [95] [96] The relationship of the hematocrit to the bleeding time was first discerned by Duke, in 1910, who found that the bleeding time in thrombocytopenic patients was corrected by transfusion of fresh whole blood, but when thrombocytopenia recurred the bleeding time was less abnormal in the presence of a higher hematocrit. Bleeding times can be prolonged with severe anemia due to vitamin B_{12} or iron deficiency, and are corrected when the anemia is corrected with transfusions of washed red cells. [93] Therefore it should be expected that severely anemic patients with chronic renal failure will have a prolonged bleeding time. The relationship of the bleeding time to hematocrit in these patients has been confirmed by correction of the bleeding time with the transfusion of washed red cells and by treatment with erythropoietin. [95] [97] There was a suggestion in these reports that bleeding symptoms also improved with the correction of the anemia. In other experiments, it has been shown that the presence of red cells displaces the less dense platelets to the periphery of the column of circulating blood, thereby increasing the interaction of platelets with the vessel wall. [98] Since a prolonged bleeding time, rather than clinical bleeding, has been the focus of concern and discussion in many studies of the hemostatic defect in uremia, it is likely that this issue will receive less emphasis as patients with chronic renal failure are routinely treated with erythropoietin.

In contrast to the studies of platelet function performed to understand the possible increased risk for bleeding in patients with chronic renal failure, coagulation and fibrinolytic activities have been investigated to understand the increased risk for thrombotic complicationsa major cause of mortality. [84] Although the data are

inconsistent, markers of activated coagulation are commonly present and suggest the presence of a prothrombotic state. [84] [99]

Pathogenesis of Abnormal Platelet Function in Uremia

Even though the anemia of renal failure appears to be the major cause of the prolonged bleeding time, there is other evidence of abnormal platelet function. Platelet aggregation abnormalities

MANAGEMENT OF PATIENTS WITH CHRONIC RENAL FAILURE AND ABNORMAL PLATELET FUNCTION STUDIES

The first principle of management is to determine if an increased risk for clinically important bleeding is present. This must be determined by a careful history and examination of the patient (see Chap. 105). Since abnormal platelet aggregation and a prolonged bleeding time are common in uremic patients and do not predict an increased risk for hemorrhage, they are not an indication for transfusion or therapeutic intervention. If a patient with abnormal platelet function and a long bleeding time requires an invasive procedure, for example a kidney biopsy, lung biopsy, or laparotomy, and there is no history to suggest an increased risk for bleeding, there is probably less risk to doing the procedure without specific treatment to correct the platelet defect than to delay and attempt to normalize a laboratory value.[85] [86] [87] [88] If bleeding does complicate a procedure, a surgical complication is the most likely cause and the initial management is no different than in patients without renal failure. If a patient with chronic renal failure presents with a hemorrhagic episode, the patient should be initially evaluated for the cause of bleeding without the physician assuming that uremia is the cause. Several treatment modalities may improve the bleeding time, and anecdotal observations suggest that they may also improve hemostasis. However, these modalities have not been uniformly effective, and prospective studies have not been performed. Therefore, therapy for bleeding in a patient with chronic renal failure should take into consideration the severity of bleeding, the anticipated severity of the hemostatic risk from surgery or trauma, and the risks of the therapy.

Dialysis with correction of the renal failure is often, but not always, effective in correcting the abnormal platelet function and the long bleeding time in uremia and diminishing the risk for clinical bleeding. For example, intensive dialysis decreases the occurrence of acute GI bleeding, a major cause of morbidity and mortality in patients with acute renal failure, probably by decreasing the ulcerative intestinal complication. [104] Peritoneal dialysis and hemodialysis are equally effective.

Infusion of DDAVP (1-deamino-8-D-arginine vasopressin desmopressin) avoids the risk of blood-borne infection and has been used in the management of bleeding in uremia.[105] DDAVP has less pressor effect than natural vasopressin, and side effects are uncommon. However, the reported complications of DDAVP therapy include facial flushing, mild tachycardia, water retention, hyponatremia severe enough to cause seizures, arterial thrombosis, and memory loss. DDAVP stimulates the release of von Willebrand factor from endothelial cells, and this may be the reason for its therapeutic effect in uremia, although other mechanisms may be involved. DDAVP, administered intravenously or subcutaneously in a dose of 0.3 mg/kg over 1530 minutes, shortens the bleeding time in 5075% of uremic patients. This correction occurs in 3060 minutes and lasts for 4 hours, correlating with an increase in the plasma concentration of von Willebrand factor and an increase in the proportion of the higher-molecular-weight multimers of von Willebrand factor. There are reports of the effectiveness of DDAVP in preventing bleeding at surgery in uremic patients, but no controlled trial has been performed, and the occurrence of excessive bleeding with surgery in uremic patients who have not received specific treatment may be negligible.

An increase in the hematocrit, either by red cell transfusion or by treatment with recombinant human erythropoietin, is associated with a correction of the bleeding time and a suggestion of diminished clinical bleeding. [94] [106] It seems unusual to suggest red cell transfusion as a therapeutic measure for correction of abnormal hemostasis, but if hemorrhage occurs and red cell replacement is required, transfusion up to a hematocrit of 30% may provide some improvement in hemostasis. However, the inevitable risk of infection associated with transfusion of blood products outweighs the potential benefit unless red cell replacement is required. Similarly, the use of cyroprecipitate infusions, which have been reported to shorten the bleeding time in some studies but not others, may have greater risk than benefit for patients with chronic renal failure.

Conjugated estrogens have also been reported to shorten prolonged bleeding times in uremic patients. One report suggests that oral conjugated estrogen (Premarin) is effective at a single dose of 50 mg.[107] The mechanism of this effect and its clinical relevance are unknown.

persist when the hematocrit is normalized by red cell transfusion [94] [95] or erythropoietin treatment.[100] Washed uremic platelets suspended in normal plasma do not adhere normally to de-endothelialized rabbit vessels at a high shear rate, and normal platelets suspended in uremic plasma acquire an adhesion defect that may be related to an abnormality of the interaction of vWF with GPIIb/IIIa. This has led to the suggestion that there may be an abnormality of vWF in uremia, but measurement of vWF antigen and activity (measured as ristocetin cofactor activity) demonstrates normal or elevated values. Other studies have found that vWF function is diminished relative to the amount of immunologic vWF present; however, no abnormalities of the interaction of vWF with its constitutive platelet membrane receptor, GPIb-IX, have been reported. [9] [96]

Platelets from uremic patients frequently exhibit reduced fibrinogen binding, aggregation, and secretion in response to a wide variety of agonists. This abnormality may be retained by the platelets after their separation from uremic plasma, and in some experiments uremic plasma has induced these defects in normal platelets. Uremic platelets may also exhibit a reduction in several of the biochemical responses necessary for aggregation and secretion, including the rise in cytoplasmic free calcium levels, release of arachidonic acid from membrane phospholipids, conversion of arachidonic acid to thromboxane A_2, and dense-granule and alpha-granule secretion. In addition, a decrease in the dense granule content of ADP and serotonin and an increase in cAMP have been demonstrated. However, others have noted increased mobilization of internal calcium stores in platelets from patients with chronic renal failure. [9] [96]

The pathogenesis of the diverse platelet function defects in uremia remains undefined. They may be caused by both dialyzable and nondialyzable substances present in uremic plasma.[96] For example, platelet aggregation can be inhibited by dialyzable substances, such as guanidinosuccinic acid or phenolic acids, and by poorly characterized substances of intermediate molecular sizes at concentrations found in uremic plasma. The reduced aggregation responses may improve after the uremia is corrected by dialysis. Venous and arterial segments from uremic patients produce more of the platelet inhibitor prostacyclin than normal vessels, and this abnormality is not corrected by dialysis. In rats, uremic plasma stimulates excessive prostacyclin production by endothelial cells. Endothelial cells from uremic

patients also generate more nitric oxide (NO), possibly related to higher plasma levels of the NO precursor, L-arginine, and NO may be responsible for the higher platelet concentrations of cGMP and deficient platelet function. [100] [101] Furthermore, the response of platelets from patients on hemodialysis to NO may be impaired. [100] Some substances found in high concentrations in uremic plasma, such as urea and parathyroid hormone, appear to have no role in inhibiting platelet function. Dialysis itself may be associated with alterations in platelet function, although the clinical importance of such changes is not known. For example, hemodialysis may cause transient increases in the bleeding time and reduced responsiveness to platelet agonists in vitro, [102] and both chronic hemodialysis and peritoneal dialysis are associated with an increase in reticulated platelets, suggesting accelerated platelet turnover. [103]

Procoagulant activity describes an important property of platelets to provide a catalytic membrane surface to accelerate the generation of thrombin. Congenital deficiency of platelet procoagulant activity is not associated with an abnormality of aggregation or of the bleeding time but may be associated with increased bleeding. Based on crude tests, the serum prothrombin time, and platelet factor 3 assay, this property of platelets is consistently diminished in patients with uremia. Insofar as optimal procoagulant activity requires platelet activation, decreased procoagulant activity in uremia may reflect the abnormalities of activation described previously. [9] [96]

Platelets from uremic patients may be unusually sensitive to medicines that decrease platelet function. Aspirin has been reported to be more effective in prolonging the bleeding time in uremic patients than in control subjects, and this effect may occur by mechanisms other than the irreversible inhibition of cyclooxygenase function. Similarly, -lactam antibiotics that prolong the bleeding time may have a greater effect in uremic patients and may increase the occurrence of bleeding,

particularly if renal clearance of the antibiotic is reduced. [9] [96]

Mild thrombocytopenia has been reported in chronic renal failure, in which setting it is probably due to a combination of diminished marrow production and diminished platelet survival.[96] However, a platelet count of <100,000/l should alert the physician to the possibility of thrombocytopenia due to a systemic disease, such as multiple myeloma, systemic vasculitis, the hemolytic-uremic syndrome, pre-eclampsia, renal allograft rejection, or an adverse reaction to a medicine such as heparin.

Cardiopulmonary Bypass Surgery

Clinical and Laboratory Features

Although cardiopulmonary bypass is accompanied by decreased plasma levels of coagulation factors and increased fibrinolytic activity, abnormal platelet function is a prominent observation in these patients. A fall in the platelet count and platelet dysfunction are seen in most patients undergoing bypass surgery with either a bubble or membrane oxygenator.[108] A prolonged bleeding time (longer than expected for the degree of thrombocytopenia), decreased platelet aggregation, decreased platelet agglutination in response to ristocetin, and a decreased concentration of alpha-granule and/or dense granule contents are typically found in patients following bypass surgery.[108] Despite these abnormalities, excessive bleeding is uncommon, occurring in only 5% of patients. Bleeding, usually manifesting as excessive chest tube blood loss (defined as >100 ml/hour), is due to multiple causes: surgical complications, excessive protamine dose, and possibly also platelet function abnormalities.[109] [110] [111] [112] [113]

Pathogenesis of the Platelet Disorder

The platelet defect caused by cardiopulmonary bypass is most likely due to the effects of platelet activation and fragmentation within the extracorporeal circulation. The severity of the platelet abnormalities correlates with the duration of the bypass procedure. [114] [115] Following uncomplicated surgery, platelet function returns to normal in 1 hour,[114] though a much longer time may be required in some patients[116] and the platelet count typically does not return to normal for several days. [113] Thrombocytopenia is caused by hemodilution, by accumulation of platelets within the bypass circuit, and to a lesser extent by sequestration of damaged platelets in the liver. Platelet dysfunction following bypass may be due to reversible adhesion and aggregation of platelets to fibrinogen adsorbed from plasma onto the bypass circuit material, mechanical trauma and shear stress, cardiotomy suction, trace concentrations of circulating thrombin and ADP, complement activation, hypothermia, blood conservation devices, bypass priming solutions, and, with bubble oxygenators, exposure of platelets to the bloodair interface. [9] Cardiopulmonary bypass also consistently causes the appearance of platelet fragments, or membrane microparticles, evidence that the platelet surface membrane is subjected to severe mechanical stress during the procedure.[115] Surface membrane alterations may play a significant role in platelet dysfunction. Other data suggest that the hemostatic abnormality is not intrinsic to platelets but rather is primarily due to reduced formation of the platelet agonist thrombin during heparin administration. Furthermore, abnormalities of hemostasis measured by laboratory studies are transient and do not correlate with clinical bleeding. [113]

Management

It is controversial whether to determine the bleeding time preoperatively in patients without a bleeding history in the hope of identifying those patients more likely to have excessive postoperative bleeding. In cardiac surgery as well as in other major surgery, the bleeding time should not be relied on as a good predictor of postoperative hemorrhage.[7] In fact, if a careful history is taken, few laboratory assays are helpful in the preoperative evaluation. [117] Prophylactic platelet transfusions are not routinely indicated for cardiopulmonary bypass surgery. However, patients who have a prolonged bleeding time and excessive blood loss in the postoperative period usually will respond to platelet transfusions. [114]

Postoperative blood loss may be diminished by the use of DDAVP after cessation of bypass but most clinical trials have not demonstrated a beneficial effect of DDAVP.[105] [118] In these studies, a benefit of DDAVP seemed more apparent in patients undergoing more complex cardiac surgical procedures. Potential risks of DDAVP include hyponatremia, hypotension, and thrombosis.[105]

Attempts have been made to prevent platelet activation during bypass surgery in both man and experimental animals by infusion of prostaglandin E_1 or prostacyclin. By increasing the platelet concentration of cAMP and reducing platelet responsiveness, these agents partially prevent the occurrence of thrombocytopenia and platelet function abnormalities.[55] However, the hypotensive properties of these agents limit their usefulness. Aprotinin (Trasylol), a peptide serine protease inhibitor, has been studied for its potential to protect platelets from activation by thrombin, plasmin, and other proteases generated during cardiopulmonary bypass and may decrease blood loss.[119] Allergic reactions preclude its use in patients who have previously been treated with aprotinin.

Anti-platelet Antibodies

Immunoglobulin molecules can bind to the platelet surface in several pathologic conditions, including idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), and platelet alloimmunization.[120] The common pathologic result

of antibody binding, with or without complement binding, is accelerated platelet destruction and thrombocytopenia. In most cases the surviving platelets appear to function normally; indeed, bleeding times in ITP may be shorter than expected for the degree of thrombocytopenia. On the other hand, some individuals with circulating antiplatelet antibodies appear to have impaired platelet function, although the frequency of this problem, compared to the occurrence of thrombocytopenia, must be very low. Immune thrombocytopenia is a common disease; significantly impaired hemostasis caused primarily by antibody-mediated platelet dysfunction has been demonstrated in only a few reports.

Clinical and Laboratory Features

In some patients with ITP or SLE, platelet dysfunction may be suspected because mucocutaneous bleeding symptoms occur at a platelet count that is usually sufficient for normal hemostasis (>50,000/l), and the bleeding time may be longer than expected for the degree of thrombocytopenia. Patients with antiplatelet antibodies may exhibit defective platelet function in vitro, even if they do not have a prolonged bleeding time or clinical symptoms of excessive bleedinga situation similar to that described above for the effects of aspirin ingestion and renal disease. For example, in two studies, 13 of 19 patients with ITP demonstrated impaired platelet aggregation to ADP, epinephrine, or collagen. [121] [122] In two other studies, 22 of 35 patients with SLE were found to have decreased platelet aggregation in response to these agonists.[123] [124] These platelet function abnormalities appeared to be antibody-mediated because IgG purified from the plasma or eluted from the platelets of some of the patients inhibited the aggregation of normal platelets.

Several aspects of platelet function may be impaired by antiplatelet antibodies. The most frequently observed abnormality is absence of platelet aggregation in response to low concentrations of collagen, and absence of the second wave of irreversible aggregation in response to ADP or epinephrine. This pattern is identical to the abnormalities caused by aspirin, described above. In ITP and SLE, the abnormal aggregation may be related to a decreased platelet content of dense-granule and alpha-granule contents or to an activation defect manifested by diminished conversion of arachidonic acid to thromboxane A_2. In addition, experiments using an ex vivo perfusion system indicated that some antiplatelet antibodies may inhibit the adhesion of platelets to subendothelial matrix. [125]

Pathogenesis

How autoantibodies or alloantibodies may impair platelet function is unknown. Antibody binding to specific platelet membrane proteins, lipids, or glycosphingolipids could affect the participation of these membrane components in stimulusresponse coupling. For example, antibodies against $_2$-microglobulin from the sera of patients with SLE or rheumatoid arthritis inhibit ADP-induced platelet aggregation, although the normal function of $_2$-microglobulin on the surface of platelets is unknown. Some HLA antibodies inhibit the uptake of serotonin by platelets. Anti-PI^{A1} alloantibodies bind to GPIIIa, and some inhibit aggregation by interfering with fibrinogen binding to the GPIIb/IIIa complex.[126] Autoantibodies with specificity for GPIIb/IIIa may cause a functional platelet disorder indistinguishable from Glanzmann thrombasthenia,[127] and autoantibodies reacting with glycoprotein Ib-IX-V may cause a functional disorder indistinguishible from Bernard-Soulier syndrome. [128]

Some antiplatelet antibodies can induce aggregation and secretion. In vitro, antibodies may activate platelets through the binding of IgG immune complexes to platelet

Fc receptors, with the deposition onto the cell of sublytic quantities of C5b9, the membrane attack complex of the complement system. [129] If bound antibody were to cause platelet secretion in vivo and the platelets continued to circulate, they might be expected to be refractory to platelet agonists and deficient in secretory granule contents. Although such activation of circulating platelets is an attractive hypothesis for the acquired storage pool deficiency seen occasionally in ITP or SLE, alternative mechanisms need to be considered. For example, some antibodies may affect the uptake of substances into platelet granules, either during megakaryocytopoiesis or in the circulation. [130]

Management

Antibody-mediated platelet dysfunction is a syndrome of only investigative interest and not of clinical importance, except in those instances where an acquired platelet disorder was responsible for bleeding symptoms. [127] [128]

Miscellaneous Disorders

Patients with disseminated intravascular coagulation (DIC) may have reduced platelet aggregation associated with a deficiency of secretory granule contents, a phenomenon termed acquired storage pool disease or, more graphically, exhausted platelets [131] and resulting from platelet stimulation by thrombin or other agonists. It has also been suggested that the elevated fibrin(ogen) degradation products and low fibrinogen levels that occur in DIC may inhibit platelet function. Although purified fibrin(ogen) degradation products can impair platelet aggregation in vitro, this requires high concentrations that are unlikely to occur in vivo. Furthermore, hypofibrinogenemia would contribute to a defect in platelet aggregation only in extreme cases in which the plasma fibrinogen is <10 mg/dl because that concentration is sufficient to saturate platelet membrane fibrinogen receptors. Chronic liver disease and hepatic cirrhosis of various causes have been reported to prolong the bleeding time and cause other platelet function abnormalities that may be related to a decrease in GDIb. [132] However, studies demonstrating that the bleeding time and platelet aggregation abnormalities correlated with the degree of thrombocytopenia [133] suggest that no specific platelet function defect exists in liver disease. Bartters syndrome, a disorder of primary renal potassium wasting and hypokalemic alkalosis, has been reported to be associated with a prolonged bleeding time and decreased platelet aggregation and secretion in response to ADP and epinephrine. [134] There are isolated reports of a slight prolongation of the bleeding time or of platelet aggregation defects in a number of other clinical conditions: nonthrombocytopenic purpura with eosinophilia, [135] atopic asthma and hay fever, [136] acute respiratory failure, [137] and Wilms tumor. [138] The clinical importance of these observations is unknown.

HEMATOLOGIC DISORDERS THAT AFFECT PLATELET FUNCTION

Chronic Myeloproliferative Disorders

Bleeding and thrombosis are important causes of morbidity and mortality in the chronic myeloproliferative disorders, which include essential thrombocythemia, polycythemia rubra vera, and myelofibrosis with myeloid metaplasia. Abnormal platelet function has been postulated as a contributing cause for these complications. Thrombocytosis is present by definition in thrombocythemia and may also occur in each of the other disorders. Bleeding manifestations are comparable to those seen in patients with platelet function disorders [1] but contribute to mortality in <3% of patients. [139] The incidence of thrombotic complications is 3.4% per year and is correlated with age.[139] Both arterial and venous thromboses can occur, and they may be in

unusual locations, such as the hepatic, portal, and mesenteric circulations. Patients with thrombocythemia can develop ischemia of the fingers and toes due to digital artery thrombosis, microvascular occlusion in the coronary circulation, and transient neurologic symptoms due to cerebrovascular occlusion. [140]

Pathogenesis of the Bleeding and Thrombosis

A number of intrinsic platelet function defects have been reported, but their clinical importance is uncertain. The bleeding time is prolonged in only a minority of patients and significant bleeding complications can occur in patients with a normal bleeding time. Elevation of the platelet count per se, correlates poorly with the risk for hemorrhage or thrombosis in some studies but spontaneous bleeding is rare in patients with platelet counts of <1,000,000/l. A clear risk factor for excessive bleeding, particularly after surgery, is the increased whole blood viscosity in patients with uncontrolled polycythemia vera and a high hematocrit. [140]

Platelets in these disorders may be larger or smaller than normal, abnormally shaped, and have a decreased number of secretory granules. Platelet survival may be decreased in essential thrombocythemia. The most common platelet abnormality is decreased aggregation and secretion in response to epinephrine, ADP, and collagen. These abnormalities are not due merely to the high platelet count, since patients with reactive thrombocytosis have functionally normal platelets. [141] In what may appear to be a paradox, some patients may demonstrate spontaneous in vitro platelet aggregation in platelet-rich plasma. The significance of this is unknown because it is also occasionally seen in normal individuals. Decreased platelet aggregation or secretion, and decreased procoagulant activity, may be caused by: (1) decreased agonist-induced release of arachidonic acid from membrane phospholipids; (2) decreased conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products; (3) decreased platelet responsiveness to thromboxane A_2; (4) decreased dense-granule or alpha-granule contents; or (5) decreased $_2$ -adrenergic receptors. Specific platelet membrane abnormalities have also been reported, including a deficiency of glycoproteins Ib and IX, causing an acquired form of the Bernard-Soulier syndrome; [142] a deficiency of receptors for the prostaglandin PGD_2; [143] a deficiency in the number of c-mpl receptors; [144] and an increased number of receptors for the Fc portion of IgG. [145] Myeloproliferative disorders are clonal in origin, and therefore the platelet abnormalities may develop from a clone of abnormal megakaryocytes. Acquired von Willebrand disease has also been reported in these patients. [146]

It is important to emphasize several features about the platelet function defects reported in myeloproliferative disorders. First, none has consistently predicted a risk for bleeding or thrombosis. Second, none is unique to a particular myeloproliferative disorder. Third, their relative frequency has varied widely in different reported series. Therefore the clinical importance of the described abnormalities of platelet function in myeloproliferative disorders is unknown.

Management

The most effective preventive treatment is to maintain the hematocrit at <45% in patients with polycythemia vera. Decreasing the platelet count with alkylating agents, such as hydroxyurea, or with anagrelide[147] is important in patients with signs of or risks for bleeding and thrombosis, [140] although there are reports documenting the lack of symptoms associated with untreated extreme thrombocytosis of long duration. Assuming a potential leukemogenic risk of alkylating agents, asymptomatic patients should probably not be treated with such drugs to decrease their platelet count, especially if they are young, except for specific indications of serious thrombotic or hemorrhagic complications. However, hydroxyurea has never been demonstrated to increase the risk for leukemic transformation in patients with chronic myeloproliferative syndromes.[148] Aspirin may be effective therapy for acute digital ischemia and for diminishing the risk for thrombosis, and in low doses (40 mg/day) it does not increase the risk for bleeding. [149]

Leukemias and Myelodysplastic Syndromes

Bleeding in these disorders is most always due to thrombocytopenia, though abnormalities of platelet function have been described. In acute myelocytic leukemia and its variants, platelets may be larger than normal, abnormally shaped, and have a marked variation in the number of granules. There may be decreased aggregation and secretion in response to ADP, epinephrine, or collagen, as well as decreased platelet procoagulant activity. Identical abnormalities can be seen in the myelodysplastic syndromes, although the platelets may be less uniformly affected, perhaps owing to the presence of normal platelets mixed with those produced by the neoplastic clone. Abnormal platelet function and acquired von Willebrand disease have been reported in hairy cell leukemia.

Dysproteinemias

Clinical Features

Platelet dysfunction is observed in approximately one-third of patients with IgA myeloma or Waldenström macroglobulinemia, in 15% of patients with IgG myeloma, and occasionally in patients with benign monoclonal gammopathy. [150] However, thrombocytopenia is much more likely to be a major cause of bleeding. Additional hemostatic problems in these patients can be due to the hyperviscosity syndrome, to a heparin-like coagulation inhibitor, [151] or to complications of amyloidosis (i.e., acquired factor X deficiency[152] or fibrinolysis[153]). A diagnostic problem in patients with myeloma can be the interpretation of laboratory assays of coagulation when the paraprotein interferes with fibrin polymerization and the function of other coagulation proteins. [150] Patients may have markedly abnormal results on laboratory tests (for example, the thrombin time) with no evidence of clinical bleeding. [150] Also, the bleeding time may be prolonged in patients with dysproteinemias in the absence of clinical bleeding.

Pathogenesis

Abnormalities of platelet function correlate with the concentration of the plasma paraprotein. Myeloma proteins can inhibit all platelet functionsaggregation, secretion,

procoagulant activity, and clot retractionand normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin. In some cases, specific interactions of the monoclonal protein have been described. One IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.[154] The bleeding time and bleeding symptoms of the patient from whom this paraprotein was isolated were corrected when the IgA myeloma protein was removed by plasmapheresis. In another patient, an IgG myeloma protein bound specifically to platelet membrane GPIIIa. [155] Both the intact IgG and its $F(ab')_2$ fragment inhibited binding of fibrinogen to activated platelets, thus inducing a defect comparable to thrombasthenia. This patient also had bleeding reminiscent of classic Glanzmann thrombasthenia[1] and died of hemorrhage from a gastric ulcer. [155] There are a number of reports of acquired von Willebrand disease in patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia. [156] In some the plasma concentration of

vWF was decreased, in others the larger multimers were deficient. The myeloma protein may interact with vWF and accelerate its clearance from plasma, or interfere with its binding to platelet GPIb.

Management

A high plasma concentration of myeloma protein can cause severe hemorrhagic symptoms, in part due to hyperviscosity and in part due to platelet dysfunction. Under these conditions, bleeding should be regarded as a medical emergency and treatment initiated by means of plasmapheresis to reduce the concentration of the myeloma protein. The goal of therapy is the cessation of bleeding. Chemotherapy for the underlying plasma cell neoplasm should be begun to effect a longer-lasting reduction of the paraprotein. DDAVP infusion, with or without plasmapheresis, may be transiently effective in patients with acquired von Willebrand disease. [156]

PART 1
Carbohydrates Determinants

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

INTRODUCTION

Biochemical studies demonstrated that many important blood group antigens are complex carbohydrates (i.e., glycoconjugates). These are grouped together in this section because they have some similarities in their biosynthesis, in the human immune response to these antigens, and in the outcome in vivo after transfusion of incompatible blood.

The biosynthetic pathways used in forming antigens in the ABH, Lewis, P, and I blood group systems are interrelated. These oligosaccharide antigens may exist free in solution. In addition, they may be covalently attached to lipid molecules (ceramides) to form glycosphingolipids, or to polypeptides to form mucins, integral membrane glycoproteins, or soluble glycoproteins. The formation of the relevant glycosidic linkages (i.e., the bonds between monosaccharides) are specifically catalyzed by various glycosyltransferases. Some glycosyltransferases, found in all individuals, form framework structures. The genes encoding other glycosyltransferases are allelically inherited and the resulting enzymes specify the synthesis of variable structures. Because of their variable inheritance and expression, the latter may form blood group antigens. As described below, antigens in the ABH, Lewis, P, and I blood group systems are synthesized on common precursor framework molecules. Competition between genetically inherited blood group-specific glycosyltransferases results in a rich mixture of antigenic molecules. In addition, a single oligosaccharide may contain several different blood group specificities (epitopes). The absence of particular blood group antigens in certain individuals may result in specific antibody production after stimulation by the foreign antigen.

The immune response to carbohydrate antigens, particularly when presented as repetitive epitopes, is usually thymus independent (for review, see reference [1]). . In this case, multivalent antigens directly stimulate B cells to synthesize antibodies without the aid of helper T cells. Thymus-independent immune responses classically result in the production of IgM antibodies, and most antibodies to carbohydrate blood group antigens are, in fact, of the IgM class. Surprisingly, individuals lacking a carbohydrate blood group antigen on their red blood cells (RBCs) often have naturally occurring IgM antibodies to that particular antigen in their serum, even if they have not been previously exposed to human blood products. The current understanding of this phenomenon is not that these antibodies spontaneously arise without prior antigenic stimulation, but that cross-reacting antigens present in the environment, such as on gut bacteria, stimulate specific IgM production. By contrast, high-titered IgG antibodies to carbohydrate antigens can be found in certain individuals. The latter may be stimulated by a thymus-dependent form of these oligosaccharides, perhaps as individual epitopes on glycoproteins, in which T-cell help leads to an isotype switch from IgM to IgG production. A complete understanding of this phenomenon is not yet available, however.

Because carbohydrate-specific blood group antibodies are predominantly IgM, these pentameric decavalent molecules directly agglutinate antigen-positive human RBCs without the aid of an antiglobulin reagent. These antibodies, for unclear reasons, often cause more significant agglutination in vitro at temperatures <37°C. Because most IgM molecules directly fix complement, these antibodies can cause immediate intravascular hemolysis after transfusion of incompatible, antigen-positive RBCs. In unusual cases, high-titered IgG carbohydrate-specific antibodies coat RBCs and lead to extravascular hemolysis after incompatible transfusion. Alternatively, the latter may cross the placenta resulting in hemolytic disease of the newborn.

ABH, SECRETOR, AND LEWIS SYSTEMS

ABH Antigens

At the turn of the 20th century, Karl Landsteiner discovered the ABO blood group system, which is the most important one with respect to blood transfusion and renal transplantation. He was fortunate to discover the first human alloantigens by using a conceptually simple experiment (Table 132-1). The RBCs of each individual were found either to lack or to have one or both of the two antigens, A and B. In addition, the serum of each subject contained naturally occurring directly agglutinating antibodies that recognized the antigens absent from their own RBCs. This experiment can be explained in modern terms as follows: cross-reacting carbohydrate structures on environmental agents stimulate the thymus-independent production of IgM anti-A and/or anti-B antibodies in individuals not tolerant to these antigens. The IgM antibodies then directly agglutinate the appropriate antigen-positive RBCs, preferentially at room temperature. There are interesting variations in the frequencies of these blood types in different human populations (Table 132-2).[2] [3]

Although the ABH antigens (the H antigen is the relevant carbohydrate structure present on group O RBCs) are typically described as blood group antigens because of their presence on RBCs, they are also found on other tissues and may be more appropriately termed histo-blood group antigens. [4] In blood they exist in both a cellular form on platelets and a soluble form as blood group-active glycosphingolipids inserted into plasma lipoprotein particles. They exist as membrane antigens on such diverse cells as vascular endothelial cells and intestinal, cervical,

TABLE 132-1 -- ABO Blood Group Antigens and Antibodies

Lapps (324)	18	36	19	15	6	6

Data from Mourant et al.[2] and Walker.[3]

[a] Figures are for selected populations and do not necessarily apply to the racial group as a whole.

urothelial, and mammary epithelial cells. Soluble forms are also found in various secretions and excretions, such as saliva, milk, urine, and feces. In some tissues, their appearance is developmentally regulated. Despite their wide distribution, genetic inheritance, developmental regulation, and importance in transfusion and transplantation, their normal physiologic function, if any, remains a mystery.

To appreciate fully the structure and antigenicity of ABH antigens and their relationship to other blood group systems, it is necessary to understand the underlying biochemistry.

Early studies indicated that anti-A, anti-B, and anti-H specifically recognize epitopes composed of the terminal trisaccharides or disaccharides illustrated in Figure 132-1 . From these results it is possible to conclude that the A, B, and H antigens are not directly encoded by the corresponding genes, but rather the genes code for particular glycosyltransferases, commonly

Figure 132-1 Biochemical structures of the immunodominant oligosaccharides of the H, A, and B antigens. The monosaccharides are abbreviated as follows: D-galactose is Gal; D-*N*-acetylgalactosamine is GalNAc; and L-fucose is Fuc.

called the A, B, and H transferases, or equivalently, the A, B, and H enzymes. The H enzyme is a fucosyltransferase that specifically adds in an (12) linkage to a terminal galactose. The A or B enzymes then add *N*-acetylgalactosamine or galactose, respectively, an (13) linkage to the same terminal galactose. However, the substrate for the A or B enzymes is a terminal H antigen sequence; these enzymes do not transfer the appropriate sugar to galactose in the absence of (12)-linked fucose. Similarly, the H enzyme does not function if this galactose is substituted with a different sugar. Thus, the biosynthetic pathway is:

where reaction 1 is catalyzed by the H enzyme and reaction 2 by the A or B enzyme.

The finding that the *A* and *B* genes code for glycosyltransferases explains some results obtained from classic genetic analysis of family pedigrees. In particular, the *A* and *B* genes are inherited in a strict mendelian fashion and are dominant compared to *O*, but the *A* and *B* genes are co-dominant with each other. That is, an individual with the genotype *AO* (or *BO*) is phenotypically A (or B), an individual of genotype *AB* is phenotypically AB, and an individual of genotype *OO* is phenotypically group O. Because the A and B enzymes both use the H antigen as substrate, even the presence of only 50% of these enzymes in an *AO* (or *BO*) heterozygote is sufficient to convert the RBCs to the corresponding A (or B) phenotype. Similarly, if both the A and B enzymes are present, they each convert 50% of the available H antigen substrate, yielding RBCs expressing both the A and B antigens.

Recent studies have begun to elucidate the biology of the ABH system at the level of the gene. The allelic genes encoding the A and B enzymes are located on chromosome 9[5] [6] (Table 132-3). They encode membrane-bound glycosyltransferases containing 354 amino acids (Fig. 132-2). Interestingly, these two enzymes exhibit a great degree of mutual homology and, at the amino acid level, differ at only four residues. [7] [8] Their substrate specificity is primarily determined by the two adjacent residues near the C-terminus of the protein, amino acids 266 and 268 [9] [10] (Fig. 132-2). The predominant allele corresponding to blood group O, O_1, contains a single nucleotide deletion near the N-terminus of the protein. This leads to a shift in reading frame and a prematurely terminated translation product lacking enzymatic activity.[8] (Fig. 132-3). Recently several other *O* alleles have been identified [11] [12] [13] [14] [15] (Fig. 132-3). For example, the O_2 allele has a missense mutation that abolishes enzyme activity.[11] [12] [13]

Not only do these findings using molecular biology confirm and extend the results obtained from carbohydrate biochemistry and enzymology, but they also suggest new ways of blood typing using molecular biology techniques. [16] [17] [18]

TABLE 132-3 -- Chromosomal Assignment of Cloned Genes in the ABH, Se, Le, I, and P Blood Group Systems

Gene	Gene Product	Location	Reference
H (*FUT1*)	(12) fucosyltransferase	19q13.3	[24]
Se (*FUT2*)	(12) fucosyltransferase	19q13.3	[24]
Le (*FUT3*)	(13/4) fucosyltransferase	19p13.3	[24] [33]
A	(13) *N*-acetylgalactosaminyl transferase	9q34.1-q34.2	[5] [6]
B	(13) galactosyltransferase	9q34.1-q34.2	[5] [6]
I	(16) *N*-acetylglucosaminyl transferase	9q21	[60]
P_1	(14) galactosyltransferase	22q12.3-q13.1	[68] [69] [70]

The *A* and *B* genes are allelic. The *H* and *Se* genes are encoded at distinct, but closely linked, loci and are not alleles of each other. The *H*, *Se*, *Le*, *A*, *B*, and *I* cDNA sequences and some genomic sequences have been determined. Neither the P_1 gene nor its cDNA have yet been cloned.

Figure 132-2 cDNA structures and amino acid sequences of the A, B, and related glycosyltransferases. The A_1 and B transferases are 354 amino acid, type II, membrane glycoproteins. All sequences in this figure are compared with the A_1 sequence. Above each bar is the relevant nucleotide sequence; uppercase letters indicate the existence of a mutation leading to a change in amino acid sequence, and lowercase letters indicate that a mutation does not lead to a change in amino acid sequence. Below each bar is the relevant amino acid sequence using the single letter code for amino acids. The hatched portions of the bar indicate that a frameshift mutation resulted in translation of a significant length of amino acid sequence that differs from the A_1 sequence. The designation del indicates that there is a one nucleotide deletion; ins indicates that there is a one nucleotide insertion.

Secretor Gene

The ABH antigens are found not only on RBCs but also in secretions, particularly saliva and plasma. The ability to secrete ABH antigens is genetically inherited: 80% of whites are secretors and 20% are nonsecretors. This trait is inherited as a single locus gene in simple mendelian fashion. The secretor gene (*Se*) is dominant; nonsecretor (*se*) is recessive. The terminal carbohydrate sequences of the ABH antigens in saliva and plasma are identical to those on RBCs. However, the backbone or framework carbohydrate structures are different. ABH antigens on glycosphingolipids and glycoproteins synthesized by RBC precursors are primarily coupled to framework type 2 chains (Gal(14)GlcNAc-R); the same antigens on plasma glycosphingolipids and salivary mucins are coupled to type 1 chains (Gal(13)GlcNAc-R) (Table 132-4). Because ABH blood group-active glycosphingolipids on plasma lipoproteins are also passively transferred onto RBCs, the RBCs of secretors have ABH antigens on both type 1 and type 2 precursor chains, but RBCs of nonsecretors only have ABH antigens on type 2 chains.

Initially, it was thought that the *H* gene was a structural gene coding for the H enzyme and the secretor locus encoded a regulatory gene that permitted expression of the *H* gene in the appropriate tissues. This hypothesis suggested that a single H enzyme transferred fucose residues onto either type 1 or type 2 precursor chains. In this model, the H enzyme is always expressed in RBC precursors, but its expression in secretory tissues (e.g., salivary epithelium) comes under the control of the secretor locus. However, this model does not explain all the available information, and recent biochemical, immunologic, and genetic studies demonstrated that an alternative model is correct.[19] [20] The latter hypothesizes that there are two different H transferases: one that adds fucose to type 1 chains (H type 1 enzyme) and one that acts on type 2 chains (H type 2 enzyme). Therefore, the H type 1 enzyme is the structural protein coded for by the secretor gene (*Se*) and is expressed in secretory tissues. In the last several years the genes encoding multiple fucosyltransferases have been cloned. These results indicate that the *Se* gene is equivalent to the *FUT2* gene and that the product of the *Se* gene, the H type 1 enzyme, is the same as the FUT2 enzyme.[21] [22] At least one copy of the *Se* gene is found in 80% of the population and leads to the expression of ABH antigens in secretions. By contrast, the traditional H locus is a structural gene for the H type 2 enzyme; the latter is equivalent to the FUT1 fucosyltransferase.[23] This gene (*H* or *FUT1*) is active in virtually all individuals (see later) and leads to the formation of ABH antigens on RBCs and other tissues. These two enzymes, FUT1 (or, equivalently, the H type 2 enzyme) and FUT2 (or, equivalently, the H type 1 enzyme) are encoded by genes at two closely linked loci on chromosome 19[24] (Table 132-3).

Following the cloning of the *Se* gene in 1995,[21] [22] multiple variants and mutations of this gene have been described. For example, many individuals, particularly of Asian descent, have a normally functioning variant, Se^1, that contains a silent mutation [25] [26] [27] [28] (Fig. 132-4). In addition, the Se^w mutant encodes a functional, but less active, enzyme, also primarily in individuals of Asian descent. [25] [27] [29] This mutation leads to the partial expression of the secretor phenotype. As described below, this results in individuals whose RBCs have the Lewis blood group phenotype of Le(a+b+). Finally, at least six nonenzymatically active variants of the *Se* gene have been described (Fig. 132-4). Most (se^1-se^5) are caused by premature stop codons that result in the expression of truncated, nonfunctional enzyme proteins; [22] [26] [27] [28] [30] one (se^6) is the result of a fusion gene between *Se* and an adjacent pseudogene.[28]

Lewis System

The two Lewis blood group antigens Le^a (Lewis a) and Le^b (Lewis b) were discovered in the 1940s (for review, see reference 31). . Virtually all individuals fall into one of three different Lewis types: Le(a+b), Le(ab+), and Le(ab) (Table 132-5). These molecules are not intrinsic RBC antigens; they are synthesized in another tissue (probably the intestinal epithelium), circulate in plasma attached to lipoproteins, and then passively transfer onto RBCs. [32] Biochemical studies demonstrated that these are carbohydrate antigens on glycosphingolipids (Fig. 132-5). They are structurally similar to the type 1 ABH antigens found on plasma glycosphingolipids; the latter also transfer onto RBCs. The Lewis gene (*Le*) resides on chromosome 19,[24] [33] and its locus is distantly linked to the H and Se loci (Table 132-3). The gene codes for an enzyme, an (14) fucosyltransferase

Figure 132-3 cDNA structures and amino acid sequences of the *O* alleles of the A and B transferases. As in Figure 132-2 , all sequences in this figure are compared with the A_1 sequence. The hatched portions of the bar indicate that a frameshift mutation resulted in translation of a significant length of amino acid sequence that differs from the A_1 sequence. When a frameshift mutation leads to a stop codon resulting in premature termination of translation, the unshaded portions of the bar indicate that this section of the nucleotide sequence is not translated.

denoted FUT3, and thus behaves in a dominant fashion. A human cDNA derived from the *Le* gene, the *FUT3* gene, has recently been cloned and encodes a 361 amino acid type II membrane-bound enzyme[34] (Fig. 132-6). Approximately 95% of whites and 75% of blacks have at least one *Le* allele.

The transfer of fucose to a type 1 precursor by the Lewis

TABLE 132-4 -- Biochemical Structures of ABH Antigens

Blood Group	Secretions (Type 1 Chain)	RBCs (Type 2 Chain)

enzyme results in the formation of the Le^a antigen; the addition of (14)-linked fucose to the H type 1 structure leads to the formation of the Le^b antigen. Thus, the latter is formed through the cooperation of two glycosyltransferases encoded by the two genes, one gene from the Lewis system (*Le* on chromosome 19) and one from the ABH system (*Se* at a different, unlinked locus on chromosome 19). The biosynthetic pathways demonstrating the connections of the ABH, secretor, and Lewis systems (encoded by genes at three distinct loci on two chromosomes, 9 and 19) are illustrated in Figure 132-7 . Interestingly, cooperation of the *Le, Se*, and *A* (or *B*) genes leads to the formation of a minor antigen, ALe^b (or BLe^b), recognized by both anti-A (or anti-B) and anti-Le^b antibodies. Because the H type 1 enzyme converts virtually all type 1 precursor chains into H type 1, whether or not the Lewis enzyme is present, Lewis-positive secretors have virtually no Le^a antigen and their RBCs type as Le(ab+). By contrast, Lewis-positive nonsecretors have Le(a+b) RBCs. This is summarized in Table 132-6 .

Individuals whose RBCs type as Le(a+b+) are rarely identified in Caucasian populations, but are reasonably common in Asian populations. In these individuals the *Le* gene is normal but the secretor gene is partially defective due to an Ile 129 Phe mutation (Se^w) [25] [27] [29] (Fig. 132-4). Because the resulting Se^w

Figure 132-4 cDNA structures and amino acid sequences of the functional and nonfunctional alleles of the secretor (*Se* or *FUT2*) gene. The H type 1 transferase (FUT2) is a 365 amino acid, type II membrane glycoprotein. All sequences in this figure are compared with the *Se* sequence. The hatched portion of the bar represents sequences derived from a homologous pseudogene. The open portion of the bar represents a length of sequence in which the pseudogene and the *Se* gene are identical; the fusion between these two genes occurred in this region.[28]

TABLE 132-5 -- The Lewis Blood Group System

Blood Group	RBC Antigens		Serum Antibodies	
	Le^a	Le^b	Anti-Le^a	Anti-Le^b
Le(a+b)	+			Very rarely
Le(ab+)		+	Very rarely	
Le(ab)			Occasionally	Occasionally

Figure 132-5 Biochemical structure of the Lewis-active glycosphingolipids. The monosaccharides are abbreviated as follows: D-glucose is Glc and D-*N*-acetylglucosamine is GlcNAc. Abbreviations are as in Figure 132-1 .

Figure 132-6 cDNA structures and amino acid sequences of the functional and nonfunctional alleles of the *Lewis* (*Le*) gene. The Le transferase is a 361 amino acid, type II membrane glycoprotein. All sequences in this figure are compared with the *Le* sequence.

Figure 132-7 Biosynthesis of blood group antigens with type 1 chains. The genes encoding the relevant glycosyltransferases are denoted in italics and the reactions catalyzed are indicated by arrows. The names of the individual blood group antigens are shown in boxes next to the relevant structures. The abbreviations for the monosaccharides are as described in Figures 132-1 and 132-5 .

enzyme has partial activity, some type 1 precursor chains are converted to H type 1 and are subsequently converted to Le^b by the normal Lewis enzyme, FUT3 (Fig. 132-7). In addition, some type 1 precursor chains avoid (12) fucosylation by the partially defective FUT2 transferase, Se^w , and are converted into Le^a by the normal Lewis FUT3 enzyme (Fig. 132-7). Thus, the RBCs of these individuals contain both the Le^a and Le^b antigens and type as Le(a+b+).

Subsequent to the cloning of the *Le* cDNA, at least six different defective alleles (le^1 -le^6) have been sequenced from individuals whose RBCs type as Le(ab) [35] [36] [37] [38] [39] [40] [41] (Fig. 132-6). Based both on family studies and expression of transfected chimeric cDNAs in vitro, the mutations at nucleotides 508, [36] [37] [39] 1067, [36] [38] [39] and 202[41] severely inhibit or abolish enzyme activity. Interestingly, the mutation at nucleotide 59, which changes an amino acid in the transmembrane domain, may affect the Golgi localization of this enzyme, but not its activity, yielding the paradoxical non-genuine Lewis-negative phenotype. [36] [37] [38] [39] The RBCs of these individuals lack the relevant blood group-active glycosphingolipids and type as Le (ab); however, the mucin glycoproteins in their saliva do contain Lewis antigens. [38]

Although hemolytic transfusion reactions and hemolytic disease of the newborn are rarely caused by antibodies to the Lewis blood group antigens, this blood group system may be important

in renal transplantation[42] and in infection by *Helicobacter pylori*.[43] [44]

Bombay and para-Bombay Phenotypes

The ABH system has several unusual but instructive antigen variants. The most striking is the Bombay phenotype (O_h)[45] . The RBCs of these individuals type as group O, and they are nonsecretors of ABH antigens. However, they do not express H antigens on their RBCs and their serum contains high-titered, hemolytic anti-H antibodies that lyse RBCs of individuals of any ABO group, except those from another individual of the Bombay phenotype. Based on the premise that the *H* gene codes for the H type 2 glycosyltransferase (FUT1), then the allelic *h* gene codes for a nonfunctional enzyme. In addition, because individuals of the Bombay phenotype are nonsecretors (i.e., they lack a functional H type 1 transferase [FUT2]), their genotype is *hh sese*. Interestingly some of these individuals do express active A and/or B enzymes, but the A (or B) antigen is not detected because the appropriate substrate for these enzymes (H type 1 or H type 2 chains) is not synthesized (Fig. 132-7). Nonetheless, the functional *A* or *B* genes can be transmitted to the next generation, yielding the apparently paradoxical pedigree O × O A (or B). On rare occasions, individuals are identified with ABH-deficient RBCs but with ABH antigens in their secretions; this is referred to as the para-Bombay phenotype.[46] Again, in terms of the model described above, these individuals have the *hh Sese* or *hh SeSe* genotype. That is, they are able to synthesize functional H type 1 transferase (FUT2), but not H type 2 transferase (FUT1). These variations are summarized in Table 132-7 .

Since the cloning and sequencing of the *H* gene in 1990, [23] various groups have investigated the molecular nature of the defective *h* alleles.[47] [48] [49] [50] [51] At least 20 different *h* alleles have been identified to date, variously containing missense, nonsense, and frameshift mutations. Interestingly, virtually every individual examined in these studies had a different mutation leading to

inactivation of FUT1 activity. In addition, one individual had a completely normal coding sequence, but defective enzyme activity, [51] suggesting a defect in transcriptional regulation rather than in protein structure. This latter result, in particular, also suggests that caution will be required if molecular approaches for blood typing based on *genotype* become widely used as a replacement for classical methods, which directly determine blood group *phenotype*.

Antigenic Variants of the ABH System

Some relatively common variations in the ABH system relate to the strength of the A antigen on group A cells. Several subgroups of A that have weak expression of the A antigen have been identified. The RBCs of most group A individuals (80% of whites) type as A_1 (Table 132-2) and correspond to the results originally described by Landsteiner. Most of the remaining group A individuals have weaker expression and are denoted A_2 . Other rarer subgroups of A (e.g., A_3 , A_x , A_m , A_{el}) have progressively weaker A antigen expression. Interestingly, many of these latter individuals produce an antibody, anti-A_1 , which does not agglutinate their own RBCs but does agglutinate A_1 RBCs. This phenomenon is explained by quantitative and qualitative differences in antigen expression. The number of A antigen sites per RBC varies from 800,000 sites for A_1 cells to 250,000 sites for A_2 cells to 700 sites for A_m cells.[52] The finding that A_2 individuals can synthesize A_1 -specific antibodies suggests that there are also qualitative differences. Recent biochemical investigations demonstrate that A antigens on A_1 RBCs differ from those on cells of the various subgroups of A.[53] In addition, the molecular biologic approach has identified mutations in allelic A transferase cDNA and genomic DNA sequences in individuals with RBCs expressing weak A activity[54] [55] [56] [57] [58] (Fig. 132-2). For example, the A transferase in A_2 individuals has a Pro156 Leu missense mutation and a frameshift mutation near the 3-end of the coding sequence.[54] In addition, A_3 individuals have an Asp 291 Arg mutation in the coding sequence.[56] These findings are summarized in Figure 132-2 . In some cases, transfection studies have been used to prove that these mutations result in weakened or variant enzyme activity of the encoded glycosyltransferases.[54]

By analogy with the subgroups of A, weak subgroups of B have also been described (e.g., B_3 , B_x , B_m , B_{el}). For example, the gene encoding the *B* allele responsible for the B_3 subgroup, has an additional Arg 352 Trp mutation in the coding sequence[56] (Fig. 132-2).

The B(A) and cis AB phenotypes are interesting and unusual variations in the ABH system. In each case, one chromosome in the affected individual apparently encodes for a gene (or genes) that leads to the synthesis of both the A and B antigens. In the B(A) phenotype, the RBCs predominantly have B antigens with small amounts of A antigens.[55] In the cis AB phenotype, the RBCs have equivalent amounts of the A and B antigens.[59] Recent molecular studies demonstrated that the coding sequence of the B(A) transferase is virtually identical to the B transferase, except that it lacks the Gly 235 Ser mutation [55] (Fig. 132-2). Thus, at three of the relevant amino acid positions the $B_{(A)}$ allele is identical to *B* and at one position it is identical to *A*; this allows the resulting glycosyltansferase to then create small amounts of A antigen in addition to large amounts of the B antigen.[55]

In the two cases of cis AB that have been studied, the *cisAB* allele has mutations resulting in two amino acid substitutions [59] (Fig. 132-2). The Pro 156 Leu mutation is identical to that found in A_2; the Gly 268 Ala mutation is a change that is important for conferring B transferase activity to the resulting enzyme. [9] [10] Thus, the *cisAB* allele seems to have arisen by point mutations of the A_1 transferase during evolution. These changes resulted in an enzyme that functions as an AB transferase chimera. Evidence for an alternative model, in which crossing-over results in one chromosome that contains both an intact A transferase and a separate, intact B transferase, is not yet available.

Ii BLOOD GROUP SYSTEM

The Ii blood group system has been intensively studied but is still not completely understood. The Ii antigens are oligosaccharides that form the type 2 chain precursors for the ABH antigens (Fig. 132-8). The best available evidence indicates that the difference between the I and i antigens relates to branching of the oligosaccharide chain; anti-i antibodies recognize an unbranched oligosaccharide chain, and anti-I antibodies recognize a similar chain that is also branched. Fetal and cord RBCs contain mostly i antigen with small amounts of I; adult RBCs demonstrate the opposite pattern. This suggests that the glycosyltransferase necessary for synthesis of the branched structure, a (16) *N*-acetylglucosaminyltransferase, is developmentally regulated. The availability of the cloned cDNA encoding this enzyme[60] (Table 132-3) will now allow this hypothesis to be tested.[61] Rare adults have RBCs that type as i; presumably their RBC precursors lack this glycosyltransferase. Antibodies specific for the Ii antigens are clinically relevant in the setting of cold type autoimmune hemolytic anemia. The sera of these patients typically contain high titers of a monoclonal antibody, usually with anti-I specificity. In patients demonstrating hemolysis in vivo, the antibodies bind to RBCs at or near 37°C in vitro and have the ability to fix complement. Surprisingly, almost all normal individuals have low titers of presumably polyclonal anti-I. These autoantibodies have a low thermal amplitude, agglutinating RBCs only at room temperature or below, and do not cause accelerated RBC destruction in vivo. Patients with particular infectious diseases such as infectious mononucleosis and mycoplasma pneumonia often develop cold agglutinins, typically with anti-i and anti-I specificity, respectively. [62] In unusual cases, this may result in immune-mediated hemolytic anemia. At present, no completely satisfactory explanation that describes, at a molecular level, the differences between cold agglutinins that cause hemolysis in vivo, and those that do not, is available. [63] [64]

P BLOOD GROUP SYSTEM

The P blood group system consists of three glycosphingolipid antigens: P^k, P, and P_1 (Table 132-8) (for review, see reference 65). . These carbohydrate chains are structurally and biosynthetically related [66] Each has a common precursor, Gal(14)Glc-ceramide (also called lactosylceramide); the P^k antigen is the biosynthetic precursor of the P antigen; both P^k and P_1 share a common disaccharide structure, Gal(14)Gal(14)-R, at the nonreducing end of the glycosphingolipid. These antigenic structures are not found on RBC membrane glycoproteins.[67] The glycosyltransferase that converts lactosylceramide to the P^k antigen is denoted as P^k synthase, that which converts P^k to P is denoted as P synthase, and that which converts paragloboside to P_1 is denoted as P_1 synthase (Table 132-8 and Fig. 132-9). Although none of the genes encoding these enzymes has yet been cloned, the gene encoding the P_1 synthase has been localized to chromosome 22[68] [69] [70] (Table 132-3).

Five different RBC phenotypes in which various combinations of these three antigens are present have been described (Table 132-9). The P_1 and P_2 phenotypes are common and account for almost all of the population. The serum of some P_2 individuals contains anti-P_1 antibodies. These antibodies are usually IgM low-titered cold agglutinins and are rarely of clinical significance. By contrast, the rare individuals with the P_1^k, P_2^k, and p phenotypes have naturally occurring high-titered IgM antibodies with specificity either for the P antigen (anti-P) or for all the antigens in the P blood group system (anti-P_1PP^k, or, equivalently, anti-Tj^a). These antibodies are clinically relevant in that they can cause severe hemolytic transfusion reactions. An unusual syndrome of recurrent spontaneous abortions has also been associated with these antibodies,[71] presumably due to the presence of P^k - and P-active glycosphingolipids on trophoblastic tissue. [72] In addition, the syndrome of paroxysmal cold hemoglobinuria, originally associated with

Figure 132-9 Biosynthetic pathway of antigens in the P blood group system. The biochemical structures of these glycosphingolipids are shown in Table 132-8 .

syphilis, is caused by Donath-Landsteiner antibodies. The latter are complement-fixing IgG antibodies with anti-P specificity that cause immune-mediated hemolysis in vivo.[73] Finally, recent studies have shown that the P blood group antigen is the receptor for parvovirus B19 on erythropoietic precursors. [74] [75] This virus causes both transient aplastic crises in patients with underlying hemolysis and anemia in immunocompromised patients. [76]

POLYAGGLUTINATION AND T AND Tn ANTIGENS

The major glycoproteins on RBC membranes, glycophorins A, B, and C, each carry 16, 11, and 12 O-linked oligosaccharides per molecule, respectively. [77] These oligosaccharides are disialylated tetrasaccharides with the structure shown in Figure 132-10 . In certain individuals, cryptic carbohydrate antigens are exposed by removing sialic acid residues from the mature tetrasaccharide (denoted T activation) revealing the T antigen. In other individuals, cryptic antigens are exposed by preventing enzymatic attachment of (13)-linked galactose (Tn activation) resulting in expression of the Tn antigen. [78] Interestingly, the T and Tn structures are also tumor-associated antigens.[79]

Red blood cells expressing the T or Tn antigens are polyagglutinable because they are agglutinated by IgM antibodies present in all adult sera. These naturally occurring anti-T and anti-Tn antibodies presumably arise after exposure of individuals to cross-reacting structures present on bacteria.

The T antigen is transiently exposed on RBCs in vivo by the action of microbial neuraminidases (sialidases), typically in individuals with a bacterial infection caused by organisms such as *Escherichia coli*.[80] However, T activation has also been reported to occur in normal individuals. Although this phenomenon causes serologic problems in blood banks, it rarely causes hemolysis in vivo.

The Tn phenotype is an acquired condition of unknown etiology that may be transient but is usually persistent. It is a clonal disorder resulting from diminished (13) galactosyltransferase activity arising in hematopoietic stem cells. [81] [82] Thus, the Tn antigen is not only expressed on RBCs but it is also found on platelets and granulocytes. In most affected individuals, two populations of RBCs are found: one normal and one polyagglutinable. Although this disorder may occur in healthy

INTRODUCTION

Numerous blood group antigens reside on membrane proteins and comprise determinants dependent primarily on amino acid sequence. The biochemical and genetic basis of many of these antigens has been elucidated in recent years (Table 132-10), and these advances have led to the use of molecular diagnostic techniques to predict risk of hemolytic disease of the newborn and even expression of recombinant blood group antigen proteins to define antigenic epitopes. Some protein antigens typically stimulate brisk thymus-dependent immune responses, and the resulting high-titer IgG antibodies to such antigens may often result in rapid extravascular clearance of antigen-positive cells. These IgG antibodies may also cross the placenta, resulting in hemolytic disease of the newborn. For unknown reasons, other antigens, however, only rarely stimulate antibody production.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

Rh BLOOD GROUP

The Rh blood group antigens are clinically the most important of the protein antigens. They are the most frequent targets of alloantibodies produced by transfusion recipients as well as by mothers alloimmunized to antigens expressed by fetal RBCs. The Rh antigen proteins are also frequent targets of autoantibodies responsible for idiopathic and drug-induced hemolytic anemias. Antibodies to Rh antigens are usually IgG and rarely fix complement. Nevertheless, they may induce rapid extravascular clearance of antibody-sensitized cells.

The Rh blood group comprises 45 individual antigens, of which 5 are routinely identified: D, C, c, E, and e. These reside on two proteins that are the products of two extremely closely linked and homologous genes. The first Rh antigen to be defined was the Rho, or D, antigen. This antigen may be expressed or absent, giving rise to the so-called Rh-positive (D-positive) and Rh-negative (D-negative) phenotypes, respectively. No antigen antithetical to D has ever been identified; however, the symbol d has sometimes been used to denote absence of the D antigen. The other four antigens comprise two antithetical pairs: C and c, and E and e. Because of the tight linkage between the D and CcEe loci, these five antigens are inherited en bloc. Certain genotypes encoding specific combinations of D and CcEe antigens are more common than others, although gene frequencies vary from one population to another (Table 132-11).[85]

The Rh blood group system also encompasses a large number of antigens that represent epitopes determined by rare Rh protein polymorphisms or epitopes common to most Rh proteins but recognized immunologically only by those rare persons who are deficient in Rh proteins or whose cells carry only

TABLE 132-10 -- Blood Group Antigens That Reside on Identified Erythrocyte Membrane Proteins

Blood Group System	Symbols for System and Major Antigens	Molecular Characterization, Other Nomenclature
Cartwright	Yt^a /Yt^b	Acetylcholinesterase

DCE	0.001	0.001
dCE	0.001	0.001

abnormal Rh protein molecules. These are the low- and high-frequency antigens of the Rh system. In addition, some Rh antigens exist only when certain antigens are encoded by the same gene. We now know that these cis antigens exist because the Cc and Ee epitopes constitute different immunogenic sites of the same protein. The most common example of a cis antigen is the f antigen, produced when the c and e antigens are encoded by the same gene. For example, f is expressed by the genotype *CDE/ce*, but not by the genotype *CDe/cDE*, even though both lead to expression of both the c and e antigens. Numerous other cis antigens have also been identified.

The null phenotype in the Rh blood group system has been extensively studied. Rh_{null} erythrocytes express no Rh antigens. Most interestingly, these cells also exhibit a wide range of abnormalities,[86] [87] [88] including stomatocytosis, reduced cation and water content, increased adenosine triphosphatase activity, abnormal membrane phospholipid distribution, reduced membrane stability, and shortened survival in vivo. Thus, individuals with this phenotype have a mild-to-moderate chronic hemolytic anemia.

Biochemistry

The proteins bearing Rh antigens were originally identified and characterized as 28,00033,000-d membrane proteins, all with common N-terminal sequences and a high degree of homology over the remaining protein domains (Fig. 132-11).[89] [90] [91] [92] These proteins are highly hydrophobic and lack any detectable glycosylation, a highly unusual trait for membrane proteins. The Rh proteins make up a large portion of the fatty acid acylated proteins of the plasma membrane [93] and may also interact with the cytoskeleton. [94] [95] Fatty acid acylation appears to be the result of a continuous on and off process of constant exchange of free palmitate for palmitate esterified onto cysteine residues within the portion of the molecule residing near the cytoplasmic border of the inner membrane leaflet.

Despite the marked abnormalities demonstrated by Rh_{null} erythrocytes, in which Rh peptides are not expressed, no function has yet been attributed to the Rh proteins. The multiple membrane spanning domains of the Rh peptides are reminiscent of transport proteins, but no transport function has been successfully demonstrated for Rh peptides. Rh peptides have been shown to be homologous to nonmammalian NH_4^+ transporters;[96] however, proteins with NH_4^+ transport function have thus far not been identified in animals.

When Rh proteins are deficient, abnormalities in the expression of other membrane proteins are also detected. These include reduced or absent expression of the U antigen, known to be at least partly dependent on expression of glycophorin B. Expression of another glycoprotein, CD47 (see later discussion), is also markedly reduced in Rh_{null} cells. Some human and murine monoclonal antibodies coprecipitate several membrane proteins, including the Rh peptides and either CD47 and/or another glycoprotein, Rh50.[97] This and additional evidence has led to the belief that the Rh peptides exist in the membrane as part of a multiprotein complex that may include the Rh peptides, the Rh50 protein, CD47, and glycophorin B. Serologic evidence suggests that expression of the Rh and Duffy proteins may also be associated.

Genetics

The two closely linked *RHD* and *RHCE* genes on chromosome 1p36.1334.3 encode the proteins bearing the D and CcEe

Figure 132-11 (A) Structure of the RhD and RhCE proteins. The RhD and RhCE proteins are highly homologous multipass integral membrane proteins that lack glycosylation. The upper figure indicates the individual amino acid positions at which the RhD and RhCE proteins differ. The lower figure indicates the polymorphisms that correspond to expression of the C/c and E/e antigen polymorphisms. **(B)** Examples of the genetic basis of variant Rh genes. A large number of complex variant *RHD* and *RHCE* genes have arisen, apparently due to the high homology between and close proximity of the *RHD* and *RHCE* genes. As shown by the variants illustrated here, many *RHD* and *RHCE* variants contain one or more exons derived from the other gene, leading to aberrant expression of Rh epitones and, in some cases, expression of rare novel antigens.

antigens, respectively.[98] [99] [100] In persons with the Rh-negative (D-negative) phenotype, the *RHD* gene is most often missing entirely, so that Southern blots of genomic DNA show absence of a set of bands corresponding to the *RHD* gene.[100] The *RHCE* gene encodes a protein that bears either E or e, along with either C or c. The difference between the coding regions of the D and CcEe cDNAs consists of scattered nucleotide differences encoding only a relatively small number of amino acid differences. Both the D and CcEe proteins have similar overall structure, including 30% hydrophobic amino acid residues and 12 predicted transmembrane domains (Fig. 132-10). The difference between the E and e proteins depends on a single amino acid polymorphism (proline versus alanine at position 226) in the fourth extracellular domain. The C and c proteins differ at four amino acids, although expression of either a serine or proline at position 103 in the second extracellular domain is probably the critical amino acid substitution on which the antigenic Cc epitopes depend. [101]

A large number of *D* and *CE* variant genes have been identified and are apparently derived from genetic events that occur because the *D* and *CE* genes are both highly homologous and physically close.[102] These genes frequently bear one or more exons deriving from the other gene (Fig. 132-11). For example, the *DVa* gene is normal except for the replacement of exon 5 of the *D* gene with exon 5 of the *CE* gene.[103] Some genes contain more extensive substitutions; one type of *DVI* gene contains three exons from *CE*,[104] and persons with the Dc-phenotype, who lack all Ee antigens, have a *CE* gene in which exons 49 are derived from the *D* gene.[105]

The cDNAs of two additional Rh-associated proteins have been cloned. The Rh-related glycoprotein Rh50 is encoded by chromosome 6, and its cDNA bears partial sequence homology to the Rh cDNAs encoded by chromosome 1.13. In addition, the predicted structure of the protein is analogous to that of the D and CcEe proteins. However, the Rh50 protein is glycosylated, unlike the Rh proteins. Thus far, it has been mutations in the *RH50* gene that have been identified as leading to the Rh_{null} phenotype, presumably because expression of Rh50 protein is necessary for normal expression of Rh proteins. [106]

The second Rh-related protein, which is more widely expressed by human tissues, has been described by several names. Identification on leukocytes via monoclonal antibodies has led to its designation as CD47, [107] while its association with integrins in certain tissues has led to its description as an integrin-associated protein. [108] Unlike the Rh50 protein, CD47 bears no significant homology to the Rh polypeptides. [109]

LW Antigens

The LW antigen, named for two pioneers in blood group antigens, Landsteiner and Weiner, is more strongly expressed by D+ than D RBCs. Indeed, LW is the Rhesus antigen originally identified by these investigators using heterologous antisera to rhesus monkey RBCs. Since its original identification, LW has been subdivided into LW^a and LW^b . Both antigens are borne by 3747-kd glycoproteins encoded by a gene on chromosome 19. [110] Structurally, the LW protein is related to the intercellular adhesion molecule subgroup of the Ig superfamily of molecules, [111] and LW has been shown capable of binding certain leukocyte integrins. [112] The molecular basis for the $LW^{a/t}$ polymorphism, as well as for the LW (ab) phenotype, have been defined. [113] [114] Although expression of LW antigens is abolished in the Rh_{null} phenotype, the full structural relationship between the LW antigens and the Rh system remains to be determined.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MNSs BLOOD GROUP ANTIGENS

The M, N, and S/s antigens reside on two highly related integral membrane glycoproteins most often called glycophorin A (GPA) and glycophorin B (GPB). [115] GPA is one of the two most abundant erythrocyte integral membrane proteins, each of which is expressed at about 1×10^6 copies per cell. GPB is somewhat less abundant (0.83×10^5 copies per cell). Together they account for 95% of the periodic acid-Schiff-staining material in the RBC membrane and bear the great majority of the sialic acid residues that confer a negative surface charge to erythrocytes.

Antibodies to the M and N determinants of GPA may be immune or naturally occurring and may be allo- or autoimmune. These antibodies are rarely of clinical significance in transfusion, hemolytic disease of the newborn, and autoimmune hemolysis. Antibodies to the S and s antigens, however, are most often IgG alloimmune antibodies that are capable of stimulating immune clearance of transfused or fetal RBCs. In addition, individuals lacking either GPA or GPB or only expressing rare variants of these proteins often produce clinically significant antibodies to epitopes expressed by normal GPA or GPB.

Biochemistry and Genetics

The glycophorin genes are highly homologous and lie close to each other on chromosome 4q2831, apparently having arisen through gene duplication. [116] GPB is smaller than GPA, because the region of the *GPB* gene corresponding to exon 3 of GPA is not used due to mutation of the intron-exon junction in the *GPB* gene. In addition, the cytoplasmic portion of the GPB molecule is truncated (Fig. 132-12).

Glycophorin A bears an M or N antigen at its N-terminus, depending on whether the N-terminus comprises Ser-Ser-Thr-Thr-Glyor Leu-Ser-Thr-Thr-Glu, respectively (Fig. 132-13).[115]

Figure 132-12 Structure of the *GPA* and *GPB* genes and some GPA and GPB variants. GPA is encoded by seven exons; while GPB is encoded by five exons. The genetic material corresponding to exon 3 of the GPA gene does not contribute to mature mRNA due to a splice junction defect. In addition, a stop codon in the GPB exon corresponding to exon 6 of GPA prevents extension of the cytoplasmic domain of GPB. Many so-called Miltenberger (Mi) phenotypes result from gene conversion events resulting in substitution of material from one glycophorin gene into the genetic structure of the other glycophorin gene.

Figure 132-13 The MN and Ss polymorphisms of GPA and GPB. Numbers indicate amino acid position, and small dark circles indicate O-linked glycosylation sites. Small circles indicate presence of additional amino acids.

However, human anti-M and anti-N, which are usually IgM antibodies, often depend both on primary amino acid structure as well as appropriate glycosylation of the second, third, and fourth amino acids (-Ser-Thr-Thr-).

The N-terminal structure of GPB is homologous to that of the N variant of GPA through residue 26. At amino acid 29, GPB is polymorphic; the existence of a methionine corresponds to expression of the S antigen, while a threonine at this site gives rise to the s antigen (Fig. 132-13).[115]

Null and Variant Phenotypes

Red blood cells may be totally deficient in either GPA or GPB, or both, without apparent shortening of RBC half-life or functional abnormalities. Lack of GPA or GPB, or both, is denoted as the En(a), S-s-U-, and MkMk phenotypes, respectively.

The *GPA* and *GPB* genes have also given rise to a large number of genetic variants, often associated with unique antigens. The variant phenotypes created by genetic events involving these genes have been designated Miltenberger phenotypes. These phenotypes arise from a number of different mechanisms. Some represent simple point mutations. Others appear to arise from formation of variant *GPA/B* genes via unequal crossing over,[117] [118] [119] a phenomenon apparently dependent on the close proximity to one another of the highly homologous *GPA* and *GPB* genes, along with a third homologous gene, denoted glycophorin E; thus, some molecules may consist of the N-terminal portion of GPA, along with the C-terminal portion of GPB, or vice versa (Fig. 132-13). Other variant glycophorin genes appear to result from gene conversion events that result in genes that have small internal segments that correspond to the homologous gene.

Antibodies to the En^a and U antigens made by En(a), U-, and M^k M^k individuals are almost always capable of markedly accelerating clearance of antigen-positive cells. Likewise, antibodies made to antigens carried by variant glycophorin molecules are frequently capable of causing hemolytic transfusion reactions and hemolytic disease of the newborn.

GERBICH ANTIGENS

Although antibodies to the Gerbich antigens are rarely encountered, their mention is appropriate because they reside on two molecules that also bear the name glycophorins and that are important to erythrocyte membrane integrity. Glycophorins C and D (GPC/D) are membrane glycoproteins that arise from a single gene by the use of alternate translation start sites (Fig. 132-14).[120] [121] Unlike GPA and GPB, to which they are unrelated, GPC/D are physiologically important membrane proteins that interact with the peripheral membrane protein band 4.1 to mediate attachment of the cytoskeleton to the membrane. [122] [123] [124] Complete lack of these glycoproteins, a phenotype designated Leach, results in absence of the Gerbich blood group antigens as well as a rare form of hereditary elliptocytosis. [125] [126]

A number of variant forms of GPC/D also exist and are occasional targets of clinically significant alloantibodies, but are not associated with elliptocytosis. Some of these variants arise from a deletion or duplication of one of two internal exons (Fig. 132-14), which are themselves highly homologous to one another.[120] This homology apparently leads to unequal crossing-over events. The resultant variant proteins may both lack some common Gerbich epitopes as well as present novel Gerbich antigens.

KELL BLOOD GROUP ANTIGENS

The Kell blood group system is extremely important from the point of view of transfusion medicine because antibodies to the K antigen are among the alloantibodies most often identified. Antibodies to K, as well as to other Kell system antigens (Table 132-12), are in general IgG antibodies that are capable of rapidly clearing antigen-positive cells. The Kell blood group system includes three sets of well-defined antithetical antigens that have been mapped to chromosome 7q33. [127]

Figure 132-14 Structure of the GP*C/D* gene and some variants. The GP*C/D* gene contains four exons that encode the mature protein. GPD, however, results from translation initiation at an alternative site, located near the 5 end of exon 2. The regions encoding the Ge:2 and Ge:3 antigens are indicated.

TABLE 132-12 -- Commonly Identified Kell System Antigens

Symbol and Original Name	ISBT Alphanumeric Symbol	Frequency
K (Kell)	K1	Low
k (Cellano)	K2	High
Kp^a (Penney)	K3	Low
Kp^b (Rautenberg)	K4	High
Js^a (Sutter)	K6	Low
Js^b (Matthews)	K7	High

Abbreviation: ISBT, International Society of Blood Transfusion.

Null and Variant Kell Phenotypes

Although most Kell system-related immune problems are caused by antibodies to antigens that belong to one of the three antithetical antigen pairs listed in Table 132-12 , the unusual Kell phenotypes are quite interesting from a number of viewpoints. Rare individuals have been found who fail to express all Kell antigens, apparently due to inheritance of two nonfunctional (amorphic) Kell alleles. This phenotype, designated Ko, is associated with no morphologic or physiologic RBC abnormalities.

Another phenotype, associated with weakened Kell antigens, presents with acanthocytosis and mild chronic hemolytic anemia. This latter phenotype is associated with absence of the Kx antigen, and is often designated the McLeod phenotype. The McLeod phenotype has now been shown to be part of the syndrome of neuroacanthocytosis and is associated with late-onset neurologic symptoms. [128] [129] The Kx antigen is encoded at Xp21, near the loci for X-linked chronic granulomatous disease and Duchenne muscular dystrophy.[130] Therefore, the Kell and Kx antigens have been recognized as distinct for some time. The serologic characteristics of the McLeod phenotype, namely the weakening of Kell blood group antigen expression and the absence of Kx antigen expression, are thought to result from failure of the normal interaction of the Kell and Kx proteins.

Biochemistry and Genetics

The protein carrying the Kell antigens has been purified and its cDNA isolated and cloned. [131] This protein of 93,000 daltons belongs to the family of zinc-binding neutral endopeptidases and is highly homologous to CD10 (CALLA, common acute lymphocytic leukemia antigen). The Kell protein comprises 732 amino acids, organized with one membrane-spanning domain, so that the C-terminus is extracellular and the N-terminus is in the cytoplasm. All Kell system antigens appear to reside on a single protein, so that the various antithetical antigen pairs represent polymorphic epitopes on this protein, usually determined by single amino acid substitutions.

Immunoprecipitation studies using antibody to Kell protein, however, also demonstrate co-precipitation of a second protein. This 34,000-dalton protein has been identified as the Kx protein, which is the *XK* gene product.[132] The *XK* gene encodes a membrane protein with structural similarity, but not amino acid homology, to a family of neurotransmitter transport proteins. [133] A function for KX has not yet been proven.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

KIDD BLOOD GROUP SYSTEM

The Kidd antigens are clinically important and often problematic antigens. Antibodies to these antigens are relatively common alloimmune antibodies that often fix complement. However, antibodies to Kidd antigens often wane to undetectable levels after primary or secondary exposure, making these antibodies frequent causes of delayed hemolytic transfusion reactions.

The two common antigens in this systemJk^a and Jk^b occur at about the same frequency in the white population. A rare allele that apparently encodes no Kidd protein is denoted *Jk*. Individuals homozygous for this amorphic allele express no Kidd antigens and may, after exposure to normal RBCs, make anti-Jk3, an antibody that reacts with all cells that express Jk antigens. The Jk(ab) phenotype is of added interest because it can be shown to have a defect in urea transport; unlike normal RBCs, Jk(ab) RBCs cells will not lyse in 2 M urea. [134] [135]

Biochemistry and Genetics

The Kidd antigens reside on a urea transport protein. [136] The gene encoding this protein, *HUT11*, has been mapped to chromosome 18q11q12. The *HUT11* gene product is also expressed in the kidney, and individuals lacking expression of *HUT11* have reduced urinary concentrating ability. [137] The Jk^a and Jk^b antigens arise from a single amino acid substitution. [138]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DUFFY BLOOD GROUP ANTIGENS

The Duffy (Fy) antigensFy^{a} and Fy^{b} occur with nearly similar frequencies in the white population, while approximately two-thirds of American and 90% of West African blacks are Fy(ab). Antibodies to Fy antigens are relatively common, most often IgG and immune in nature. Anti-Fy ^{a} is slightly more common that anti-Fy^{b} .

The Duffy antigens have been investigated with intense interest because of their relationship to malarial resistance. *Plasmodium vivax*, a cause of human malaria, and *Plasmodium knowlesi*, a causative agent of malaria in monkeys, cannot invade Fy(ab) RBCs, [139] although *Plasmodium falciparum*the malarial parasite causing the most serious human morbidity and mortalitycan both attach to and invade Fy(ab) RBCs.

Biochemistry and Genetics

The Fy antigens reside on a protein of 35,00046,000 daltons that has been shown to be part of the chemokine receptor family of proteins. [140] The RBC Duffy protein can bind a number of chemokines, including interleukin-8. Duffy protein is also expressed in other tissues, including endothelial cells. [141] Current investigations are examining whether Duffy protein may play a role in leukocyte migration across endothelium.

The Fy(ab) phenotype in people of African origin does not arise from nonfunctional *FY* alleles. Instead, it is caused by mutation of the promoter region of the *FY* gene.[142] This mutation disrupts the nucleotide sequence normally recognized by the GATA-1 transcription factor, a factor of critical importance in the expression of a large number of erythroid genes. The result of this mutation is that the *FY* gene is not transcribed in erythroid cells but is expressed in nonerythroid cells, in which other transcription factors presumably drive expression of the *FYB* gene.[143] Thus far, this promoter mutation has only been found in association with the *FYB* allele.

LUTHERAN ANTIGENS AND RELATED PROTEIN ANTIGENS

The Lutheran blood group system is another system that comprises a large number of individual antigens (18), of which eight comprise four antithetical pairs. Only Lu^a and Lu^b , however, are frequently identified. Lu^b is expressed by > 99% of individuals, while Lu^a is expressed by about 8%. In general, antibodies to Lutheran antigens are IgG in nature, although IgA and IgM antibodies

have been reported; most are not effective in causing accelerated clearance of antigen-positive RBC.

The Lutheran blood group system is of especial interest, however, because of the unusual genetic regulation of expression of Lutheran antigens. Although some Lu(ab) persons have inherited two amorphic (nonfunctional) Lutheran alleles, most examples of the Lu(ab) phenotype are due to inheritance of a single, dominant *In(Lu)* gene. This gene causes markedly reduced expression of Lutheran antigens, so that routine typing results in identification of a Lu(ab) phenotype. However, more sensitive techniques demonstrate expression of very small amounts of apparently normal Lutheran protein and antigens by these cells. In addition, the *In(Lu)* gene also suppresses expression of unrelated proteins, including the CD44 hyaluronan receptor, [144] a protein that carries another blood group, In. [145] [146] In addition, *In(Lu)* may affect expression of other antigens, including the Knops and AnWj antigens.

A third type of Lu(ab) phenotype has been shown to be due to an X-linked gene. Like in the *In(Lu)* phenotype, Lutheran antigens in the X-linked Lu(ab) phenotype are suppressed but not totally absent, while expression of antigens outside the Lutheran blood group system, such as CD44, is unaffected. This phenotype is inherited in an X-linked recessive manner,[147] [148] whereas the *In(Lu)* phenotype is inherited as an autosomal dominant trait.

Biochemistry and Genetics

Lutheran antigens reside on two related proteins of 78,000 and 85,000 daltons that are themselves products of alternatively spliced mRNA from a single gene. [149] [150] [151] The *LU* gene is at chromosome 19q13.2, a locus linked to that of the secretor (*Se*) gene. The Lutheran protein is an Ig superfamily molecule containing two V and three C2 type domains; it has been shown capable of mediating cell adhesion to laminin. [152] Although this function is only minimally demonstrable on normal RBCs, it is present on sickle RBCs, as well as in the diverse epithelial tissues in which Lutheran protein is also expressed. [152] Lutheran protein, in its 78,000-dalton form, has also been called the basal cell adhesion molecule. [153] Thus far, several Lutheran antigens have been mapped to the various IgSF domains of Lutheran protein, and the molecular basis for the Lu^a /Lu^b phenotype has been identified as a single nucleotide substitution leading to a single amino acid change in the IgSF domain nearest the N-terminus of the protein. [154] [155]

COLTON ANTIGENS

The Colton blood group system comprises antigens expressed by the water channel protein of erythrocytes, also known as channel-forming integral protein-1 or aquaporin-1.[156] [157] This protein accounts for >2% of the total membrane protein and facilitates rapid water transport across the erythrocyte membrane. It most likely occurs in the membrane as a tetramer, in which one of the four protein molecules is glycosylated and also carries ABH determinants on a polylactosaminoglycan moiety. The gene encoding aquaporin-1 is on chromosome 7p14, and weak expression of Colton antigens may sometimes occur in leukemias and myelodysplastic conditions in which there is monosomy 7. However, total absence of aquaporin-1, as seen in the Co(ab) phenotype, is not associated with clinically significant defects in circulating erythrocytes nor in renal function, despite the fact that aquaporin-1 is responsible for about 80% of the water reabsorption in normal kidneys. [158] [159]

DIEGO AND WRIGHT ANTIGENS

The Diego blood group system comprises two pairs of antithetical antigens (Di^{a} /Di^{b} and Wr^{a} /Wr^{b}), as well as a number of

Figure 132-15 The anion transport protein (band 3). The anion transport protein, also called AE1 or band 3, carries both Diego and Wright antigens. Band 3 also carries ABH and Ii antigens on a single highly branched N-linked oligosaccharide, represented by the branching structure on the fourth extracellular domain. As do many transport molecules, band 3 crosses the membrane multiple times. Band 3 is thought to occur in the membrane as a homodimer and form a pore through which anions are exchanged between the extracellular environment and the cytosol.

low-incidence antigens. Alloantibodies to these antigens are only occasionally encountered and are usually IgG; they vary widely in their ability to clear transfused incompatible RBCs and to cause hemolytic disease of the newborn.

Diego and Wright antigens reside on the erythrocyte anion channel protein, [160] [161] [162] long known as band 3, a nomenclature earned when RBC membrane proteins were first examined in Coomassie blue-stained gels (Fig. 132-15). This protein, which occurs in approximately 1,000,000 copies per RBC, is also known as AE-1 (anion exchanger-1), as it is a member of a family of anion exchange proteins expressed in many tissues. [163] [164] [165] The band 3 protein also subserves an important structural role in human erythrocytes by providing a means of connection between the cytoskeleton and the plasma membrane via its interactions with ankyrin, and abnormalities of this protein account for the Southeast Asian ovalocytosis syndrome, [166] [167] [168] as well as between one-tenth and one-third of all cases of dominantly inherited hereditary spherocytosis. [169] [170] Band 3 is also a frequent target of RBC autoantibodies in warm-type autoimmune hemolytic anemia. [171]

OTHER-BLOOD GROUP SYSTEMS

A large number of blood group systems and individual unrelated blood group antigens have been identified, and the genes for many of them have been cloned (Table 132-10). The reader should keep in mind that some proteins bearing blood group antigens are functionally important, and that somebut by no means allpolymorphisms or deficiencies of such proteins may be accompanied by physiologically significant changes in RBC morphology, function, or survival. Antibodies to blood group antigens will continue to serve as obstacles to transfusion, as well as tools for investigating the surface structure of the erythrocyte and other cell types.

LABORATORY METHODS FOR DETECTING BLOOD GROUP ANTIGENS AND ANTIBODIES

Manual methods based on agglutination of RBCs are still the most common serologic assays performed in blood banks. Automated assays based on agglutination, and manual or automated solid-phase assays adherence assays not based on agglutination, are used in large blood centers or in research environments.

The serologic behavior of RBC antibodies primarily relates to their immunoglobulin isotype. Thus most antibodies to carbohydrate antigens such as those in the ABO, Lewis II, and P blood group systems are naturally occurring and are of the IgM isotype. These multivalent antibodies optimally bind to RBCs at temperatures <37°C and directly agglutinate these cells suspended in saline. By contrast, antibodies occurring following immunization to protein antigens such as those in the Rh, Kell, and Duffy blood group systems, are of the IgG isotype. These bivalent antibodies optimally bind to RBCs at 37°C and will bind to, but not directly agglutinate, RBCs suspended in saline. The addition of an antiglobulin reagent (i.e., rabbit anti-human IgG) is required to induce agglutination.

ANTIGEN TYPING OF HUMAN RBC

Commercially available human polyclonal and mouse monoclonal IgM anti-A and anti-B antibodies are used to determine the ABO type of patient and donor RBCs. These antibodies will directly agglutinate RBCs at room temperature. To confirm a patients ABO type the presence of the corresponding serum isoagglutinins is also determined by incubating the serum at room temperature with commercially available group A and group B RBCs. In both cases, hemagglutination is macroscopically visible, and an antiglobulin reagent is not required.

Patient and donor RBCs are also routinely tested for the presence of the D antigen in the Rh system. A commonly used anti-D reagent is a chemically reduced IgG antibody that directly agglutinates D-positive RBCs suspended in saline at room temperature.

IDENTIFICATION OF SERUM ALLOANTIBODIES OR AUTOANTIBODIES DIRECTED AGAINST RBC

Most alloantibodies found in patient sera are of the IgG isotype and therefore do not directly agglutinate antigen positive RBCs. Thus,the most common assay used to detect these antibodies is the indirect antiglobulin test, formerly known as the indirect Coombs test. In this assay, patient serum is incubated at 37°C with commercially available reagent RBCs of known antigen type. Following incubation, unbound antibodies are removed from the RBCs by washing with saline, and an antiglobulin reagent containing either rabbit anti-human IgG or a mixture of rabbit anti-human IgG and anti-human complement is added. If the RBCs are agglutinated, this indicates the presence of an alloantibody or an autoantibody or both. The distinction between alloantibody and autoantibody and the determination of the specificity of the alloantibody are determined by performing this assay with a panel of 10 different reagent RBCs varying in antigen phenotype. Agglutination of all panel cells suggests the presence of an autoantibody; differential reactivity suggests the presence of an alloantibody to a specific RBC antigen.

The indirect antiglobulin test is also used to cross-match donor blood for transfusion into patients. In this case, patient serum is tested against RBCs from a donor with a compatible ABO and D antigen type. A positive reaction indicates the probable presence of an alloantibody in the recipient directed against a donor RBC antigen. The specificity of this alloantibody can be determined by the approach outlined previously.

DETECTION OF RBC COATED IN VIVO WITH IMMUNOGLOBULIN AND COMPLEMENT

The direct antiglobulin test, formerly known as the direct Coombs test, detects the presence of antibody or complement (or both) on the surface of RBCs. This technique is used in the analysis of delayed hemolytic transfusion reactions and in the evaluation of patients with suspected autoimmune hemolytic anemia. In this assay, unagglutinated patient RBCs are obtained from ethylenediaminetetraacetic acid anticoagulated blood, washed with saline, and then incubated with a commercially available antiglobulin reagent containing either rabbit anti-human IgG or a mixture of rabbit anti-human IgG and anti-human complement. The test is positive if agglutination is seen after the addition of the antiglobulin reagent. Antiglobulin reagents containing anti-IgM or anti-IgA are available in specialized centers to detect coating of RBCs in vivo by antibodies of these isotypes.

Chapter 133 - Human Platelet Antigens

Thomas J. Kunicki

INTRODUCTION

Platelet Membrane Glycoproteins

Among the variety of glycoproteins on the human platelet surface, there are several that contribute to the immunogenic makeup of the platelet (Table 133-1).

Integrins

The integrins are membrane glycoprotein heterodimers, each consisting of noncovalently associated and subunits. [1] [2] [3] [4] [5] [6] The specificity of an integrin is dictated in large part by the identity of its subunit, even though ligand binding per se may occur with a significant portion of the subunit. The number of possible combinations is apparently limited, however, and selective pairing in humans between 16 and 8 subunits has led to the discovery of 22 different integrins (Fig. 133-1). These ubiquitous receptors mediate a wide range of cell adhesion events that are important to every fundamental area of human biology, including embryonal development, immunocompetence, wound healing, and hemostasis. Two platelet membrane receptors that figure prominently in the antigenic profile of platelets, the cohesion receptor $_{IIb\ 3}$ and the collagen receptor $_{2\ 1}$, are integrins.[1]

The Platelet Cohesion Receptor, Integrin $_{IIb\ 3}$

The numerically predominant platelet integrin $_{IIb\ 3}$ (initially designated glycoprotein [GP] IIb/IIIa) mediates the common cohesive pathway that results from platelet activation in vivo, namely, platelet aggregation supported by the binding of adhesive proteins, such as fibrinogen and von Willebrand factor (vWF). The subunit of this integrin, $_{IIb}$, is synthesized exclusively by megakaryocytes. Consequently, $_{IIb\ 3}$ is a unique marker for platelets or cell lines with a megakaryocytic phenotype. Glanzmann thrombasthenia is an inherited disorder of platelet function characterized by an inability of platelets to bind fibrinogen and undergo agonist-induced aggregation.[7] The

TABLE 133-1 -- Functional Properties of Selected Membrane Glycoprotein (GP) Complexes

GP	Alternate Names	Receptor Function	Protein Ligands
Ib-IX-V		Adhesion	vWF
$_{IIb\ 3}$	GPIIb/IIIa, CD41/CD61	Adhesion Cohesion	Fibrinogen Fibrinogen Fibronectin Vitronectin vWF
$_{2\ 1}$	GPIa/IIa, VLA-2, CD49b/CD29	Adhesion	Collagen
$_{5\ 1}$	GPIc/IIa, VLA-5, CD49e/CD29	Adhesion	Fibronectin
$_{6\ 1}$	GPIc/IIa, VLA-6, CD49f/CD29	Adhesion	Laminin

Figure 133-1 The integrin receptor family. Integrin and subunits are paired to form functional receptors, as indicated by solid connecting lines. Those integrins that exist on human platelets are highlighted and include $_{2\ 1}$, $_{5\ 1}$, $_{6\ 1}$, $_{v\ 3}$, and $_{IIb\ 3}$.

molecular defect in this disease involves either a quantitative or a qualitative abnormality of $_{IIb\ 3}$. The $_{IIb\ 3}$ heterodimer complex is depicted schematically in Figure 133-2 .

The Platelet Collagen Receptor, Integrin $_{2\ 1}$

Another integrin that contributes significantly to platelet function is the collagen receptor $_{2\ 1}$ (GPIa/IIa).[8] [9] [10] [11] This integrin plays a fundamental role in adhesion of blood platelets to both fibrillar (types IIII and V) or nonfibrillar (types IV, VI, VII, and VIII) collagens. [8] [9] [12] [13] [14] [15] Unlike $_{IIb}$, the $_{2}$ subunit is a single-chain molecule[16] and, like several other integrin subunits, contains an additional 129-amino acid segment known as the I-domain (Fig. 133-3). Inherited platelet deficiencies of the $_{2}$ subunit have been described; affected individuals exhibit chronic mucocutaneous bleeding and prolonged bleeding times. [17] [18] The expression of $_{2\ 1}$ on platelets differs markedly between normal subjects and depends on the inheritance of at least three alleles of the $_{2}$ gene.[19] [20] Although the levels of the integrins $_{5\ 1}$ or $_{IIb\ 3}$ and the glycoprotein Ib-IX-V complex on platelets (molecules per platelet) certainly vary from one individual to the next, [19] [21] these differences never exceed a fraction of the mean population level. On the other hand, the number of $_{2\ 1}$ molecules per platelet varies by as much as an order of magnitude and correlates precisely with quantitative estimates of platelet adhesion to type I or type III collagens. [19]

Regulation of $_{2\ 1}$ expression could certainly modulate the antigenicity of this membrane receptor. It is also possible that similar factors influence expression of other

platelet integrins, including $_{IIb\ 3}$, but the extent to which that occurs remains to be determined. Two other integrins, the fibronectin receptor $_{5\ 1}$ [22] and the laminin receptor $_{6\ 1}$, [23] are expressed by platelets, but neither has yet been shown to contribute significantly to platelet immunogenicity.

Figure 133-2 The integrin $_{IIb\ 3}$, $_{IIb}$, and $_{3}$ form a noncovalently associated heterodimer. The hatched area of $_{IIb}$ represents the decapeptide recognition site. On $_{3}$, the stippled region represents the RGD recognition site; the hatched region, an alternative fibrinogen recognition site. Divalent cations (positively charged spheres) are required for both complex integrity and ligand binding. In this and subsequent figures, the locations of the polymorphisms that give rise to alloantigens are indicated by a black circle within which is the corresponding HPA designation (see Table 133-3). Regions that contain autoantigenic determinants are indicated by boxed areas and include two sequences on the cytoplasmic tail of $_{3}$ (721762), a portion of the cysteine-rich domain of $_{3}$ (479656), and the discrete epitope 2E7, located at residues 222238 of $_{IIb}$.

Figure 133-3 The $_{2}$ subunit. $_{2}$ belongs to the subfamily of subunits that are single-chain molecules with an additional I-domain (large open bar) sequence. Three putative calcium-binding repeats are indicated (small open bars), as is the site of the alloantigenic HPA-5 polymorphism. The locations of disulfide bonds (thin lines) are hypothetical.

The Receptor Complex Glycoprotein Ib-IX-V

The pattern of membrane glycoproteins existing as functional complexes is repeated in the case of the non-integrin adhesion receptor complex Ib-IX-V. [24] [25] The functional complex is actually a heptamer composed of one molecule of glycoprotein V associated with two molecules of each of three other gene products, glycoproteins Ib, Ib, and IX ((2)Ib:(2)Ib:(2)IX:(1)V) (Fig. 133-4).[26] This complex is a receptor for vWF and the initial mediator of transient platelet contact and attachment to the vessel wall under essentially all conditions of flow or shear stress. The vWF-binding site on the complex is located within the amino-terminal domain of GPIb.[25] [27] [28] Bernard-Soulier syndrome is an inherited disorder of platelet function characterized by defective platelet adhesion to subendothelium and a quantitative or qualitative defect in the Ib-IX-V complex caused by mutations in genes encoding either the GPIb or GPIX components. [29] [30] [31]

Platelet Glycolipids

Glycolipids play an important role in the structural and functional characteristics of the platelet membrane, as is true of all cell types. Less is known about platelet glycolipid structure and immunogenicity than about platelet glycoproteins, but important contributions have been made in this area, permitting the identification of a number of immunogenic glycolipid components of the membrane (Table 133-2). [32] The predominant glycolipid on human platelets is lactosyl ceramide, representing 64% of the neutral glycolipids. Other neutral glycolipids include trihexosyl ceramide, glycosyl ceramide, and globoside. The principal fatty acids associated with these neutral glycolipids are behenic acid (22:0), arachiditic acid (20:0), and lignoceric acid (24:0). Ganglioside I (identified as hematoside or GM3) represents 92% of the acidic glycolipids, and ganglioside II represents 5% of the platelet acidic glycolipid composition.

Figure 133-4 Glycoprotein Ib-IX-V complex. GPIb is composed of a heavy chain (Ib) and light chain (Ib) linked by a disulfide bond. The Ib molecule is noncovalently associated with glycoprotein IX. All three polypeptides span the membrane, are glycosylated (open diamonds or circles), and contain repetitive leucine-rich glycoprotein sequences (open areas). Two each of Ib, Ib, and IX are associated with one molecule of V. In the case of Ib, vWf binds at the amino-terminal region of the molecule, and five additional O-glycosylated repeats generate a carbohydrate-rich (macroglycopeptide) carboxy region. The positions of the Ib polymorphism that gives rise to the HPA-2 alloantigen system and the tandem 13-amino acid repeats (*) are indicated.

ALLOANTIGENS

The proliferation of serologically defined alloantigens on platelet glycoproteins has led to the development of a consensus nomenclature in which each of the alloantigens is prefixed by HPA-, for human platelet antigen.[33] These designations as well as the alternate (original) names are given in Table 133-3 . Unfortunately, the HPA nomenclature is not based on current knowledge of the linkage between several of these polymorphisms. As pointed out by Newman et al.,[34] [35] these polymorphisms really define a limited number of allelic variants (Table 133-4 (Table Not Available)), and it is important to understand the molecular basis for distinguishing the allelic variants of each immunogenic glycoprotein.

In the case of GPIb and integrin subunit $_{2}$, each is represented by two allelic variants. For $_{2}$, residue Glu_{505} defines the antigen HPA-5a, while Lys_{505} is defined as HPA-5b.[36] With GPIb, the Gly_{15} /Glu_{15} substitution gives rise to the antigens Iy^{b} and Iy^{a} , respectively.[37] The next highest degree of complexity is found with the integrin subunit $_{IIb}$. Three allelic variants of $_{IIb}$ have been defined that differ at either residue 837 (Val or Met) [38] or residue 843 (Ser or Ile).[39] When this kind of analysis is applied at the molecular level, it is apparent that the hypothetical variant Met_{837} , Ile_{843} does not exist. Consequently, the serologic phenotype HPA-3a, HPA-9b is not possible. For GPIb (the heavy chain), alloantigens HPA-2a and HPA-2b are distributed among five alleles that differ by the single amino acid replacement, Thr/Met, respectively, at residue 145 [40] and four polymorphic size variants, termed A, B, C, and D (ranging from largest to smallest), that are generated by differences in the number of tandem 13-amino acid repeats present in the macroglycopeptide portion of the molecule.[41] [42] The D isoform of GPIb contains one repeat, the C isoform contains two repeats, and so on. The most complex scenario occurs with the integrin subunit $_{3}$. Eight different alleles of the $_{3}$ can be distinguished that differ at six positions within the coding sequence. These dimorphic residues and their serologic designations are: Leu_{33} /Pro_{33} (HPA-1a/HPA-1b);[43] Arg_{62} /Gln_{62} (HPA-10wa/HPA-10wb);[44] Arg_{143} /Gln_{143} (HPA-4a/HPA-4b);[45] Pro_{407} /Ala_{407} (HPA-7a/HPA-7b);[46] Arg_{489} /Gln_{489} (HPA-6a/HPA-6b);[47] and Arg_{636} /Cys_{636} (HPA-8a/HPA-8b).[48] The eighth, rare HPA-1b allele characterized by the presence of Arg_{40} does not appear to be serologically distinguishable from the HPA-1b allele bearing the more common Leu_{40} .[49]

Immunochemistry of Platelet Alloantigens

HPA-1

The HPA-1 alloantigen system is defined by the Leu$_{33}$ /Pro$_{33}$ polymorphism that, according to the disulfide bonding scheme proposed by Calvete et al., [50] would be enclosed within a small 13-amino acid loop formed by the pairing of Cys$_{26}$ with Cys$_{38}$. This region of the molecule is held proximal to the distal cysteine-rich region in the middle of $_3$ by a long-range disulfide bond linking Cys$_5$ and Cys$_{435}$.[51] The importance of the three-dimensional structure imposed by the Cys$_{26}$ -Cys$_{38}$ disulfide bond constraint to expression of the HPA-1 determinants is indicated by the facts that linear peptides corresponding to the $_3$ (2638) sequence are not antigenic,[52] and the antigens are not lost following denaturation of $_3$ in ionic detergents. However, they are immediately destroyed on subsequent disulfide bond reduction. The complex structure of the $_3$ molecule and the sensitivity of the determinants to this structure are the likely explanation for the observed heterogeneity in binding properties of anti-HPA-1a alloantibodies. [53] [54] Although all alloantibodies would bind to the denatured molecule or to recombinant amino-terminal segments of the molecule expressed in *E. coli*,[55] [56] a subset of antibodies appear to require presentation of the antigenic loop within a more native environment, such as the nondenatured molecule.[53] [54]

Anti-HPA-1a antibodies inhibit clot retraction and platelet aggregationin the latter case, presumably because they block the binding of fibrinogen. [57] [58] Ryu et al.[59] have also reported that there is a dose-dependent stimulation versus inhibition of fibrinogen binding induced by anti-HPA-1a. A similar effect has been attributed to other platelet inhibitors, particularly the disintegrins, RGD peptides, and certain snake venoms. [60]

HPA-2

Two previously described polymorphisms of the Ib-IX-V complex, termed Ko and Sib, are now known to be reflections of two linked polymorphisms, one of which defines the diallelic system, HPA-2.[40] [61] [62] [63] [64] In the GPIb sequence, a Thr/Met polymorphism at residue 145 is associated with HPA-2a and HPA-2b epitopes, respectively (Fig. 133-4).

HPA-3

The HPA-3 system is associated with an Ile$_{843}$ /Ser$_{843}$ polymorphism of $_{IIb}$ (Fig. 133-5).[39] In addition, Take et al.[65] have reported that the binding of certain anti-HPA-3a antisera to $_{IIb}$ is decreased following desialation of $_{IIb}$, which raises the possibility that glycosylation of $_{IIb}$ may contribute to or influence the expression of the HPA-3 epitopes. Moreover, anti-HPA-3 alloantibodies do not bind to the precursor form of the $_{IIb}$ molecule, pro-$_{IIb}$.[39] Thus, O-glycosylation at the polymorphic Ser 843 may influence specificity or accessibility of HPA-3 determinants.

At this time, there has not yet appeared any report concerning the effect of antibodies specific for HPA-3a antigens on fibrinogen binding, platelet aggregation, or clot retraction. Because the $_{IIb}$ molecule is expressed only on platelets, megakaryocytes,

Figure 133-5 Schematic diagram of the $_{IIb}$ subunit. $_{IIb}$ is composed of two chains linked by a single interchain disulfide bond. The light chain is a transmembrane molecule. The open areas represent four putative divalent cation (calcium)-binding repeats, and the location of the binding site for the fibrinogen -chain carboxydodecapeptide is indicated by a large arrow. The positions of the polymorphisms that define the alloantigen systems HPA-3 and HPA-9 are indicated.

or cells with a megakaryocyte lineage, the HPA-3 epitopes are not found on other cell types.

HPA-4

Another diallelic human alloantigen system known as Pen (or Yuk) is found on $_3$ and is associated with an Arg$_{185}$ /Gln$_{186}$ polymorphism.[45] [58] [66] [67] Given the proximity of the Pen polymorphism to the RGD-binding domain (residues 109171) of $_3$, it is not surprising that anti-HPA-4a antibodies completely inhibit aggregation of HPA-4a homozygous platelets.[68]

Other cells that express $_3$ as the subunit of the vitronectin receptor, including endothelial cells, fibroblasts, and smooth muscle cells, also express HPA-1 and HPA-4 epitopes.[68] [69] [70] [71] This could contribute to the complexity of the clinical symptoms in alloimmune-mediated thrombocytopenia. At this time, little is known about the involvement of tissues other than platelets in these conditions.

HPA-5

The HPA-5 system is located on the integrin subunit $_2$ (Fig. 133-3).[72] [73] The detection of this system was facilitated by the development of a highly sensitive murine monoclonal antibody-based immobilization of platelet antigen (MAIPA) assay. [74] Like the preceding alloantigenic systems, the HPA-5 system is diallelic. Roughly 2002,000 copies of $_2$ are present on the surface of normal platelets, and each $_2$ molecule expresses a single HPA-5 epitope.[72] The integrin $_2$ is distributed on a wide variety of cells, but currently nothing is known about the antigenicity of the HPA-5 determinants on receptors expressed by cell types other than platelets.

HPA-6

This system, originally known as Ca or Tu, is defined by the $_3$ Arg$_{489}$ /Gln$_{489}$ polymorphism resulting from a G/A substitution at base 1564.[47] [75] [76]

HPA-7 and HPA-8

Two novel alloantigens, HPA-8b and HPA-7b, have recently been localized to $_3$.[46] [77] The alloantigen HPA-8b is classified as a private alloantigen because it appears to be inherited within a single family or family group but is not expressed by the general population. The unique feature of the HPA-8b polymorphism is that it is associated with an Arg$_{636}$ /Cys$_{636}$ substitution and thereby results in an additional unpaired cysteine residue. [77] Since its initial characterization, it has been accepted that all cysteine residues in $_3$ are involved in disulfide bridges. Despite the addition of this new sulfhydryl group, the HPA-8b-positive $_3$ subunit still associates with $_{IIb}$ and contributes to an expressed $_{IIb}$ $_3$ complex without apparent impairment of function. The alloantigen HPA-7b results from a C to G substitution at bp 1,267 of $_3$, resulting in replacement of Pro$_{407}$ by Ala$_{407}$.[46] HPA-7b is a very low-frequency alloantigen and has been detected in only one of 450 random donors outside of the birth family of the propositus.

HPA-9

The HPA-9 system, originally named Max, is the second system to be localized to the integrin $_{IIb}$ subunit. It is defined by the Val_{837} (Max^a)/Met_{837} (Max^b) polymorphism.[38]

HPA-10w

This system, initially named La, is defined by the $_3$ Arg_{62} /Gln_{62} polymorphism.[44]

Gov

The alloantigenic polymorphism Gov is uniquely expressed by a different protein receptor. Kelton et al. [78] initially described the Gov system, which is now known to be carried by the 175-kd glycosyl phosphatidylinositol-anchored glycoprotein CD109. Alloantibodies defining each of two alleles (Gov^a/Gov^b) were detected in two patients who had received multiple platelet transfusions [78] and, more recently, in three patients who had developed neonatal alloimmune thrombocytopenia. [79] The genotypic frequencies in the Canadian population are: for Gov^a, 81%; for Gov^b, 74%.

Additional Suspected Alloantigens

Five additional alloantigens have been serologically defined whose precise polymorphic residues or structures have not yet been identified (Table 133-3). Two are associated with the integrin $_3$ subunit: the private antigen Gro^a and the low-frequency antigen Oe^a. [80] [81] One additional low-frequency antigen, Va^a, is associated with the integrin $_{IIb\ 3}$, although it has not been determined which subunit bears the determinants. [82] The remaining two alloantigens are localized to the glycoprotein Ib-IX-V complex: Ly^a, found in one of 249 unrelated German donors and not yet precisely localized within the Ib-IX-V complex, [37] and PI^T, implicated in a single case of neonatal alloimmune thrombocytopenia, localized by Beardsley et al. [83] to glycoprotein V by immunoblot assay and expressed by platelets from all of 50 normal donors tested.

Neonatal Alloimmune Thrombocytopenia and Post-transfusion Purpura

Two clinically significant syndromes are the direct result of sensitization to platelet-specific alloantigens: neonatal alloimmune thrombocytopenia and post-transfusion purpura.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is caused by maternal sensitization to paternal alloantigens on fetal platelets (Table 133-5). It is intriguing that only a fraction of those mothers negative for the platelet antigen in question deliver infants affected with neonatal alloimmune thrombocytopenia. For example, in the western world, responsiveness to HPA-1a is most commonly the cause of neonatal alloimmune thrombocytopenia, yet the frequency of homozygous HPA-1b mothers in the general caucasian population is 2%, and estimates of the incidence of neonatal alloimmune thrombocytopenia are no greater than 0.05%. A key to understanding this discrepancy lies in the finding that responsiveness to HPA-1a shows an HLA restriction. [84] [85] [86] HPA-1a and HPA-1b are defined by the Leu_{33} /$Pro_{33\ 3}$ polymorphism.[43] [50] [87] [88] [89] Individuals who are homozygous for Pro_{33} (homozygous HPA-1b) and responsive to the predominant HPA-1a antigen are almost exclusively HLA DRB3*0101[85] or DQB1*02. [90] [91] In the case of DRB3*0101, the calculated risk factor is 141, a risk level equivalent to that of the hallmark of HLA restriction in autoimmune disease, ankylosing spondylitis, and HLA-B27. [91] In contrast, responsiveness of homozygous HPA-1a individuals to the HPA-1b allele is not linked to HLA.[91] [92] T cells are the likely candidates for providing HLA restriction in this case, and Maslanka et al. [91] provided elegant evidence that in one case of neonatal alloimmune thrombocytopenia, T cells that share CDR3 motifs are stimulated by peptides that contain the same Leu $_{33}$ polymorphism that is recognized by anti-HPA-1a alloantibodies. In the case of another, less frequent antigen, HPA-6b, there appears to be an association between responsiveness and the MHC genes *HLA-DRB1*1501, HLA-DQA1*0102*, or *HLA-DQB1*0602*.[93]

TABLE 133-5 -- Alloimmune Thrombocytopenias

Neonatal autoimmune thrombocytopenia
Incidence: 1 per 3,000 in a retrospective study, 1 per 2,200 births in one prospective study.
Maternal antibodies produced against paternal antigens on fetal platelets.
Similar to erythroblastosis fetalis, except that 50% of cases occur during first pregnancy.
Most frequently implicated antigens are HPA-1a and HPA-5b (United States/Europe).
In the case of responsiveness to HPA-1a, there is a high-risk association with *HLA-DRB3*0101* or *HLA-DQB1*02.*
In the case of responsiveness to HPA-6b, there is an increased association with *HLA-DRB1*1501*, *HLA-DQA1*0102,* or *HLA-DQB1*0602*.
Post-transfusion purpura
Nearly all of the reported patients have been females previously sensitized by pregnancy or transfusion (<5% were males).
Thrombocytopenia usually occurs 1 week after transfusion.
Homozygous HPA-1b individuals account for a majority (>60%) of cases.
High-risk association with *HLA-DRB3*0101* or *HLA-DQB1*02.*
Enigmatically, the recipients antigen-negative platelets are destroyed by autologous antibody.

Responsiveness to HPA-1a is not the sole cause of neonatal alloimmune thrombocytopenia. In a large study of 348 cases of clinically suspected neonatal alloimmune thrombocytopenia,[94] 78% of serologically confirmed cases were due to anti-HPA-1a and 19% to anti-HPA-5b. All other specificities accounted for no more than 5% of cases. In reports from other laboratories, the association of neonatal alloimmune thrombocytopenia with other alloantigens, such as HPA-3a, HPA-3b, HPA-1b, or HPA-2b, was noted but is rare.[95] [96] [97] [98] Obviously, differences in allelic gene frequencies between different racial or ethnic populations will have an important impact on the frequency of responsiveness to a particular alloantigen. Table 133-6 summarizes some of the known variation in allelic gene frequencies between different world populations. Thus, in the Japanese population, anti-HPA-1a has never been shown to be involved in neonatal alloimmune thrombocytopenia, and antibodies specific for HPA-4b play a dominant clinical role. [99] This is probably because the gene frequency for the HPA-1b allele among the Japanese (0.02) is much lower than that found in Western populations (0.15). Conversely, the gene frequency of the HPA-4b allele in Japan (0.0083) is higher than that observed in Western populations (<0.001).

Post-transfusion Purpura

Post-transfusion purpura follows 710 days after an immunogenic blood (platelet) transfusion (Table 133-5). It most often affects previously nontransfused, multiparous women. As with neonatal alloimmune thrombocytopenia, the risk for developing post-transfusion purpura is increased among HLA-DR3-positive individuals, and HPA-1a is the antigen most often implicated (in Western populations). [84] [100]

The exact mechanism by which the recipients antigen-negative platelets are also cleared from the circulation in post-transfusion purpura is not yet fully understood.

Proposed mechanisms include the following: (1) During the first phase of post-transfusion purpura, the recipient develops antibodies that recognize framework determinants (conserved protein structures surrounding the specific polymorphic sites), and these react with each of the allelic forms of the antigen, resulting in autoantibody formation (see Chap. 11); (2) recipient antibodies form immune complexes with soluble antigens from donor platelets, and these interact with autologous platelets via an Fc receptor-dependent mechanism; and (3) soluble antigen from the transfused product is adsorbed onto recipient platelets, rendering them passively positive for the antigen in question. Platelet membrane microparticles are known to be a constituent of fresh frozen plasma and platelet concentrates.[101] It is conceivable that the $_{IIb\ 3}$ complex could become adsorbed onto neighboring platelets via this process.

HPA-1b platelets had been reported to become HPA-1a-positive when incubated with plasma from HPA-1a-positive individuals. [102] [103] [104] Although this passive transfer of soluble antigen has been proposed as a mechanism for clearance of the recipient platelets in post-transfusion purpura, Ehmann et al. [105] contend that this is an in vitro artifact. These authors provided evidence in patients with post-transfusion purpura for the presence of immune complexes composed of donor antigen and recipient antibody. We have found that centrifugation, even at forces exceeding 10,000 times g, fails to remove antigen-positive material (residual platelets and/or fragments) from plasma preparations. However, clearance of antigen-positive material is reliably accomplished by the passage of such plasma through a 0.45-m filter (D. Warejka, R.H. Aster, and T.J. Kunicki, unpublished observations). These findings support the contention of Ehmann et al. that antigen transfer using nonfiltered plasmas is an in vitro artifact.

At this time, there remains no conclusive evidence to support

ISOANTIGENS

Isoantibodies are produced against an epitope that is expressed by all normal individuals and is not polymorphic. In the area of human platelet immunology, a classic example of isoimmunization can and does occur when a patient with an inherited deficiency of a membrane glycoprotein has received multiple platelet transfusions to correct a bleeding diathesis. Glanzmann thrombasthenia and Bernard-Soulier syndrome are examples of inherited disorders in which the individual either lacks or expresses an altered form of $_{IIb\ 3}$ (Glanzmann thrombasthenia) or Ib-IX-V (Bernard-Soulier syndrome), respectively. Isoantibodies developed by transfused patients do not distinguish any of the allelic forms of the glycoproteins (such as HPA-3 or HPA-1 alloantigens on $_{IIb\ 3}$) but react with the platelets of all normal persons tested. Because the propositus does not express the platelet glycoprotein that carries the epitope in question, these antibodies do not bind to their own platelets.

Isoantibodies in Glanzmann Thrombasthenia

Several cases have been documented in which patients with Glanzmann thrombasthenia produced antibodies specific for $_{IIb\ ,\ 3}$, or the $_{IIb\ 3}$ complex.[106] [107] [108] [109] [110] Recently, we defined an idiotype (OG) that is associated at high frequency with isoantibodies specific for integrin subunit $_{3}$ generated by patients with Glanzmann thrombasthenia.[108] [111] [112] [113] Patient O.G. suffered from persistent, often serious bleeding episodes as a result of both his Glanzmann thrombasthenia phenotype and the fact that he had generated a very high-titered, IgG isoantibody inhibitor of platelet cohesion. [108] [113] The study of the OG idiotype presented an excellent opportunity to compare and contrast disease-related, $_{IIb\ 3}$ inhibitors of human origin with other natural or synthetic inhibitors of this integrin receptor. Rabbit polyclonal anti-OG idiotype binds to IgG specific for $_{IIb\ 3}$ obtained from 11 nonrelated patients with Glanzmann thrombasthenia, including an unrelated patient, E.S., studied extensively by Coller et al., [107] who had developed isoantibodies of very similar specificity. On the other hand, anti-OG does not recognize $_{IIb\ 3}$ -specific antibodies produced by other unrelated patients with Glanzmann thrombasthenia, who had developed isoantibodies with specificities distinct from that of the OG isoantibody. Moreover, anti-OG does not recognize $_{IIb\ 3}$ -specific antibodies developed by any patients with idiopathic thrombocytopenic purpura or six representative patients with alloimmune thrombocytopenias, and anti-OG never binds to IgG from any of several nonimmunized control individuals.

Anti-OG binds to selected protein ligands of $_{IIb\ 3}$, namely, fibrinogen, vitronectin, and vWF, but not to other known protein ligands, such as fibronectin or type I collagen. The epitope(s) recognized by anti-OG on these three adhesive proteins are either very similar or identical, since each protein can inhibit the binding of anti-OG to any of the others. The epitope on fibrinogen recognized by anti-OG resides in the B chain and is likely contained within the first 42 amino acids from the amino-terminus.[114] Because OG IgG inhibits fibrinogen binding to $_{IIb\ 3}$, the specificity of the OG idiotype defines a novel binding motif for the integrin $_{IIb\ 3}$ that is shared by fibrinogen, vitronectin, and vWF but is distinct from previously described RGD-containing sites on the fibrinogen A chain or the fibrinogen -chain carboxyl-terminal decapeptide site. Moskowitz et al. [114] employed specific proteolytic forms of fibrinogen to confirm that the epitope recognized by anti-OG-2 is located within B 142. This represents an excellent example of molecular mimicry in which an antigen-selected, IgG inhibitor of $_{IIb\ 3}$ function shares a novel recognition sequence common to three physiologic protein ligands of that receptor.

Isoantibodies in Bernard-Soulier Syndrome

Because Bernard-Soulier syndrome is less frequently encountered than Glanzmann thrombasthenia, the isoantibodies produced in conjunction with this syndrome are also less frequently encountered. In the only clear case of such an isoantibody, [115] the isolated IgG impaired both normal platelet adhesion to subendothelial elements and in vitro aggregation in response to ristocetin and bovine factor VIII.

AUTOANTIGENS

Autoimmune (or idiopathic) thrombocytopenic purpura (AITP or ITP) is the most frequently encountered form of immune thrombocytopenia. [116] [117] This disorder can be classified as acute or chronic on the basis of the duration of the thrombocytopenia, the chronic form persisting >612 months (see Chap. 126). The acute, self-limiting form occurs predominantly in children, often following a viral illness or immunization, and affects males and females with equal frequency. The chronic form is mainly an adult illness and affects twice as many females as males. Life-threatening bleeding occurs in up to 1% of patients with ITP. The reason why some patients sustain severe hemorrhagic complications and others do not remains unexplained, but because of differences seen in the clinical expression of chronic and acute ITP, it has been theorized that the mechanisms of disease for each form are probably different.

Glycoproteins as Autoantigens

The integrin $_{IIb\ 3}$ was the first platelet membrane component to be identified as a dominant antigen in chronic ITP, [118] and subsequent studies from several laboratories have confirmed the important contribution of this receptor to the autoantigenic makeup of the human platelet. [96] [119] [120] [121] [122] [123] [124]

Attempts to further localize autoepitopes on either integrin subunit have been more successful with regard to $_{3}$. Early on, Kekomaki et al. [124] defined a prominent autoantigenic region as the 33-kd chymotryptic fragment of $_{3}$ located within the cysteine-rich region of $_{3}$ (Fig. 133-6) that was bound by both plasma autoantibodies and autoantibody eluted from patients platelets. Fujisawa et al. [125] [126] [127] subsequently determined that plasma autoantibodies in five of 13 patients with chronic ITP bound to peptides representing $_{3}$ residues 721744 or 742762, namely, the carboxy-terminal region of $_{3}$ that is presumed to be located in the cytoplasm of the platelet, while autoantibodies eluted from the platelets of additional ITP patients bound to other areas of $_{3}$ within the extracellular portion of the molecule (perhaps identical to the 33-kd region defined by Kekomaki et al. [124]). Most important, they determined that certain platelet-associated autoantibodies bind preferentially to cation-dependent conformational antigens on the $_{IIb\ 3}$ complex. [127]

More recently, additional autoantigenic epitopes have been identified on the $_{3}$ subunit. Nardi et al. [128] identified the peptide $_{3}$ (4966) as a site that is bound by a majority of affinity-purified antibodies isolated from serum immune complexes of immunologic thrombocytopenic HIV-1-infected patients. This is not a peptide that is bound by serum IgG antibodies from control subjects or patients with the classic form of ITP. Using random peptide phage display libraries, Bowditch et al. [129] determined that plasma antibody eluates from one ITP patient bound to two distinct hexapeptides, and the binding to one of these could be inhibited by the sequence $_{3}$ (734739).

Figure 133-6 Schematic diagram of the $_{3}$ subunit. The $_{3}$ subunit is a single-chain transmembrane molecule. Twenty-eight intrachain disulfide bonds are present, at least one of which is thought to bring the amino-terminal domain (N) proximal to the cysteine-rich domain at the carboxy (C) third of the molecule. The approximate positions of RGD- and fibrinogen (Fbg)-binding sites are indicated. The locations of the polymorphisms that give rise to alloantigen systems HPA-1, HPA-4, HPA-6, HPA-7, HPA-8, and HPA-10w are indicated.

Autoantibodies reactive with $_{IIb}$ were identified in two patients with chronic ITP, [122] [123] and in one of these patients the antibody was subsequently shown to react with a chymotryptic, 65-kd COOH-terminal fragment of the $_{IIb}$ heavy chain (Fig. 133-5). [123] Ethylenediaminetetraacetic acid (EDTA)-dependent autoantibodies represent a special category that are adsorbed by autologous platelets when whole blood is drawn in EDTA. [130] In one such case of EDTA-dependent pseudothrombocytopenia, an IgM antibody was shown to bind to $_{IIb}$ by immunoblot assay and crossed immunoelectrophoresis. [131] As a final note, it should be remembered that, although most autoantibodies apparently induce thrombocytopenia, a minority can induce platelet dysfunction without an increase in platelet clearance (see Chap. 126). [132] [133] The proportion of the two types of autoantibodyone leading to platelet clearance, one blocking platelet functionmay be an important factor controlling the unpredictable clinical severity of ITP.

$_{IIb\ 3}$ is not the only integrin implicated as the antigen target for human autoantibodies. Serum IgG autoantibodies specific for integrin subunit $_{2}$ were identified in a unique case of autoimmune platelet dysfunction following myasthenia gravis. [134] This autoantibody inhibited aggregation of normal platelets induced by collagen or wheat germ agglutinin. This is the first case in which autoantibodies to Ia were associated with a chronic hemorrhagic disorder, and this study provides strong indirect support for a role of this integrin in hemostasis in vivo.

Autoantibodies to components of the Ib-IX-V complex are also frequently encountered in adult chronic ITP. [135] He et al. [136] have made progress in the localization of selected autoantigenic epitopes on the glycoprotein Ib molecule. Epitopes were most frequently found on a recombinant fragment of Ib corresponding to residues 240485, and next most often on a fragment representing residues 1247. In the case of those antibodies reactive with the former sequence, further epitope mapping identified the dominant determinant as the 9-amino acid sequence TKEQTTFPP (residues 333341). [136] In some cases in which autoantibody to Ib-IX was detected, the clinical presentation proved to be particularly severe and refractory to therapy. [137] One case of pseudo-Bernard-Soulier syndrome (dysfunction of the Ib-IX-V receptor complex) was reported to be caused by an autoantibody to Ib. [138] Finally, in a subset of childhood ITP, that associated with varicella zoster infection, the glycoprotein V component of this receptor was found to be the dominant target of serum autoantibodies that do not cross-react with viral antigens. [139] At the same time, in another group of children with this disease, it was found that serum antibodies specific for viral antigens can cross-react with normal platelet antigens and thus may contribute to platelet clearance. [140]

It had been hoped that the antigenic targets in acute and chronic forms of ITP might be different so that antigen identity might one day be used as an early indicator of clinical outcome. Subsequent studies have shed more light on this issue and have demonstrated that autoantibody specificity in chronic and acute ITP is quite similar, particularly in children. [141] [142] Nonetheless, a distinction between antigen specificity and an acute versus chronic course in ITP may yet be found in the early stages of the autoimmune response. Prospective studies aimed at answering this question are warranted.

How large is the autoepitope repertoire on a given glycoprotein antigen? The answer to this important question will have an impact on the feasibility of developing therapeutic and diagnostic measures based on epitope specificity. Because the autoantibodies that react with a given epitope are likely to share idiotypes, one can approach this question from two angles, analyzing the epitope repertoire, the idiotype repertoire, or both. Two studies have addressed the extent of the autoantigen repertoire on $_{IIb\ 3}$ by analyzing the competitive binding between human autoantibodies and murine monoclonal antibodies. [143] [144] However, the limited number of studies that have used this approach have generated conflicting results, and there remain insufficient data to judge the size of the autoepitope repertoire on $_{IIb\ 3}$. Additional analyses aimed at epitope localization will be necessary, and perhaps novel approaches will expedite this task. One such novel approach is the

development of human monoclonal autoantibodies specific for $_{IIb\ 3}$ and other platelet glycoproteins.

Human monoclonal antibodies are an alternative tool in the search for glycoprotein epitopes that are autoimmunogenic in humans. The first human monoclonal antibody against a platelet glycoprotein was developed by Nugent et al., [145] derived from an individual with ITP who produced an antibody against $_{3}$. This human monoclonal antibody detects a neoantigen associated with $_{3}$ that is expressed only on stored or thrombin-activated platelets. A number of human monoclonal autoantibodies specific for the heavy chain of GPIb were generated from the lymphocytes of an ITP patient with serum autoantibody specific for Ib. [146] The heavy chain variable region genes of four of these antibodies have been sequenced and found to be markedly homologous to human immunoglobulin, germ-line, heavy chain variable region genes. [146] Most recently, another human monoclonal autoantibody was produced that is specific for the heavy chain of $_{IIb}$.[147] The epitope recognized by this antibody (2E7) has been identified as a contiguous amino acid sequence with residues 231238 with an immunodominant tryptophan residue at position 235 (Fig. 133-5). [148] This is the first time that the precise epitope on $_{IIb}$ or $_{3}$ recognized by a human antibody has been identified.

From the foregoing analysis, it is clear that further studies are required to determine the extent to which the production of human autoantibodies to platelet glycoproteins is clonally restricted. Given a selected number of idiotypes (Ids) related to autoimmunity to $_{IIb\ 3}$, one could potentially use the anti-idiotype (anti-Id) to modulate immunization to $_{IIb\ 3}$. Along these lines, it has been reported that intravenous immune globulin G (IVIgG), which is routinely used to reverse acute thrombocytopenia in ITP, may contain anti-Id directed to idiotypes of autoantibody but not alloantibodies that recognize $_{IIb\ 3}$.[149] Recently, Nugent et al.[137] defined a DM idiotype that is characteristic of human autoantibodies that are specific for the Ib heavy chain. The latter study clearly suggests that the repertoire

of idiotypes expressed by human autoantibodies specific for membrane glycoproteins, such as those of the human platelet, will be narrowly defined and, thus, amenable to study.

Glycolipids as Antigens

A number of reports have implicated cardiolipin, lactosyl ceramide and other glycosphingolipids as autoantigenic targets (Table 133-2).[150] [151] [152] [153] [154] [155] [156] van Vliet et al.[154] analyzed the binding of serum IgG/IgM antibodies from 30 patients with ITP to platelet glycosphingolipids separated by high-performance thin-layer chromatography (HPTLC). Acidic glycosphingolipids, namely sulfatides and gangliosides, were identified as the major targets of serum autoantibodies. Thirteen of the 30 sera, five with anticardiolipin antibodies, had antibodies that bound to sulfatides, while four sera showed antibody binding to gangliosides. Koerner et al. [150] employed a more efficient phase partition separation of acidic glycosphingolipids from neutral glycosphingolipids and were able to demonstrate that serum antibodies specific for neutral glycosphingolipids were more characteristic of ITP. Two classes of glycosphingolipid autoantigens were defined: those associated with general autoimmunity and detected in the sera of patients with either systemic lupus erythematosus (SLE) or ITP, and those peculiar to platelet-specific autoimmunity and detected only in the sera of ITP patients. Two glycosphingolipid forms belong to the platelet-specific group, but they are present at minute levels, and further characterization awaits large-scale purification. One-half (6/12) of patients with ITP had serum IgG or IgM antibodies that bound these platelet-specific glycosphingolipids. Sera from none of ten patients with nonimmune thrombocytopenia, none of ten patients with SLE, and only one of 18 normal subjects gave positive reactions with the platelet-specific glycosphingolipid group. The general glycosphingolipid antigen group includes globotriaosyl ceramide, globotetraosyl ceramide, and a third unidentified neutral glycosphingolipid. Antigens in the general group were bound by IgG or IgM antibodies in the sera of ten of ten patients with SLE, eight of 12 patients with ITP, and none of ten patients with nonimmune thrombocytopenia or 18 control subjects. These findings provide compelling support for a role of neutral glycosphingolipids as antigenic targets in selected cases of ITP.

Animal Models of ITP

Many investigators have searched in animals for clinical correlates of human ITP. These attempts have been largely unsuccessful, but an exception may have recently emerged from concerted studies in dogs. As pointed out in a recent series of reports by Lewis and Meyers, [157] there is now substantial evidence that ITP in dogs and ITP in humans are clinically analogous syndromes. In 32 cases of canine ITP, increased platelet-bound IgG was detected in a majority of the animals (30), and Ig eluted from the platelets of 11 of 19 affected dogs bound to homologous normal canine platelets. [157] Furthermore, Ig specific for integrin subunits $_{IIb}$ and/or $_{3}$ was detected in sera of four of 17 dogs tested. Lewis and Meyers concluded that, in canine ITP, Ig bound to the surface of platelets is directed against host antigens and that the target antigen is frequently $_{IIb\ 3}$. Given the similarities between these findings and the cumulative experience with human ITP, the canine model may prove to be a valuable tool to further understand the pathogenesis of the autoimmune response to platelet antigens.

Quinine/Quinidine Purpura

Although drug-induced thrombocytopenic purpura (DITP) may be a complication of therapy with a variety of drugs, it is most frequently seen in the United States with the administration of quinine and quinidine. [158] It has been proposed that the following criteria be met before an individual can be considered to have DITP: (1) the patient is not thrombocytopenic prior to administration of the drug; (2) thrombocytopenia follows drug ingestion and begins to reverse shortly after cessation of drug; (3) thrombocytopenia does not reoccur after cessation of drug treatment; and (4) all other causes of thrombocytopenia are ruled out. [159]

The exact mechanism for platelet clearance is not yet certain. However, cumulative evidence now favors a mechanism whereby the drug induces the expression of a neoantigen on the platelet surface[160] [161] [162] [163] [164] [165] that is recognized by circulating antibodies only in the presence of the drug. The observation that platelets from patients with Bernard-Soulier syndrome (lacking Ib-IX-V) failed to lyse in the presence of drug-dependent antibody, specific drug, and complement was the first indication that a specific platelet antigen is recognized by such antibodies. [165] This finding led other laboratories to confirm that purified Ib-IX would compete for drug plus antibody and was therefore likely to contain the antigenic epitope in question. Evidence of direct binding of such antibodies to Ib-IX was first provided by Chong et al.,[163] and Berndt et al.[162] established that the complex of Ib and IX is likely required for maximum antigen expression. Whereas it has been confirmed that Ib-IX-V is a major antigen in DITP,[165] [166] [167] [168] there is now ample evidence that the integrin $_{IIb\ 3}$ is also a dominant target for many quinine- and quinidine-dependent antibodies.[169] [170] Continued study of the drug-dependent autoimmune phenomena and their relationship to platelets is warranted, with particular attention to a comparison of the clinical significance of drug-dependent autoantibodies that bind to either Ib-IX or $_{IIb\ 3}$.

In order to understand the mechanism whereby drugs like quinine or quinidine induce neoantigen formation, one must first consider the direct effects of these drugs on platelet membrane components, a subject that has not received enough attention by those interested in DITP. Deykin and Hellerstein [171] were probably the first to show that quinidine inhibits in vitro platelet aggregation induced by adenosine diphosphate (ADP), collagen, or adrenaline. Lawson et al. [172] demonstrated that quinidine administration will induce the prolongation of the bleeding time without thrombocytopenia. Connellan et al. [173] extended these findings and showed that quinine, both ex vivo and in vitro, will inhibit platelet aggregation induced by weak agonists like ADP or adrenaline. Aggregation by strong agonists, for example, collagen, thrombin, or arachidonate, was inhibited only in vitro. The combination of ddAb and quinine inhibited the binding of two monoclonal antibodies, HuPlm1, specific for $_{3}$, and FMC25, specific for GPIX. On the other hand, the binding of another antibody, AN51, specific for GPIb, was enhanced. The studies clearly point to a general platelet dysfunction that can be attributed to exposure to these drugs. That this dysfunction should be the result of perturbations of specific membrane glycoprotein receptors is not surprising. Nor should it be surprising that one effect of such perturbations might be the development of neoantigens or the exposure of cryptic antigens.

In 12 patients with DITP, Chong et al.[170] used a panel of murine monoclonal antibodies in competitive binding assays to map the domains on Ib-IX-V that are bound by drug-dependent antibodies. The combined data showed that one quinine-dependent antibody binds to an epitope on the amino-terminal portion of Ib and five other quinine-dependent antibodies recognize a complex-specific epitope proximal to the membrane-associated region of Ib-IX. Each of six quinidine-dependent antibodies contained two specificities, one for the same Ib-IX complex epitope described above, the other for IX alone. Additional observations were that antibodies reactive with Ib-IX are more predominant (12/12 patients) than those that bind $_{IIb\ 3}$ (3/12 patients) and that antibodies specific for Ib-IX-V are present in titers 8- to 32-fold higher than the corresponding antibodies

that bind to IIb 3 in the same patient samples. In each case, those antibodies that bound to Ib-IX-V were distinct from those that recognized IIb 3 . The specificity of quinine- and quinidine-dependent antibodies for a conformation-sensitive epitope(s) on the GPIX component of the complex was confirmed by Lopez et al. [174] using monoclonal antibody inhibition assays.

Regions of IIb 3 that bind to quinine- or quinidine-dependent antibodies have also been further localized by Visentin et al. [175] Of 13 patient sera containing such antibodies, ten were reactive with both Ib-IX and IIb 3 , two reacted with Ib-IX alone, and one reacted with IIb 3 alone. Again, in those sera where both specificities were identified, the anti-Ib-IX-V antibodies were distinct from those that bound to IIb 3 . Seven sera containing anti- IIb 3 antibodies were further characterized: three bound only to the IIb 3 complex, one bound to IIb alone, and three bound to 3 alone. Those that recognized 3 alone were found to bind to epitopes on the major 61-kd chymotryptic fragment of 3 that are resistant to deglycosylation with endo-H. In the case of sulfonamide-induced immune thrombocytopenia, [176] the causative antibodies are almost exclusively specific for calcium-dependent (complex-specific) epitopes on the integrin IIb 3 .

One additional intriguing aspect of certain cases of DITP is worthy of mention, because it may have an important bearing on our understanding of the autoimmune response to platelets in general. Based on anecdotal evidence, it has been suspected that some cases of chronic ITP are initiated in clinical situations that, from all appearances, could be classified as DITP. [135] The only difference is that selected autoantibodies persist long after exposure to the insulting drug. Direct evidence to support of this contention was obtained by Nieminen and Kekomaki. [177] They reported that the DITP patients with Ib-IX specific antibodies, despite a very intense and acute thrombocytopenia, recovered promptly after drug removal. On the other hand, DITP patients with more prolonged thrombocytopenia and persistently elevated platelet Ig levels >1 month after drug removal had antibodies that reacted with additional target antigens, including integrin IIb 3 . To better understand the pathogenesis of both DITP and classic ITP, in the future it may become important to distinguish the acute but readily reversible clinical situation that we accept as DITP from the more complex disease situation that may be initiated by drug exposure but evolve into a more classic form of ITP.

Heparin-Associated Thrombocytopenia

Heparin-associated immune thrombocytopenia (HAT) is a life-threatening condition that results in thrombocytopenia and can be associated with thrombosis. [178] [179] [180] [181] Unlike quinine- or quinidine-dependent antibodies, the actual binding of heparin-dependent antibodies (HDAs) to the platelet surface appears to be of very low affinity and was difficult to demonstrate in earlier studies until the report of Lynch and Howe. [178] It was also determined that HDAs differ from other forms of drug-dependent antibodies in that they can often be *activating*, causing not only thrombocytopenia but also heparin-dependent platelet aggregation, thromboxane synthesis, and granule release that can be quantitated by preloading platelets with [^{14} C]serotonin. The consequences of HAT therefore are multiplied by often serious thrombotic complications. Approximately 30% of these patients die, with an additional 20% developing vascular occlusions that result in gangrene and subsequent amputation.[182]

Although the precise mechanism of HAD binding to platelets eluded investigators for many years, it was generally accepted that the activating properties of HAD must be mediated by Fc-dependent binding to platelets. In this regard, Kelton et al. [179] showed that the platelet release reaction induced by HDA could be blocked by pretreating platelets with human or goat IgG Fc fragments, Adelman et al. showed that the Fab regions of HDA alone are not sufficient to cause platelet activation, [183] Chong et al. [184] showed that purified rabbit IgG and its Fc, but not Fab, fragments markedly inhibited platelet aggregation induced by HDAs, and a number of groups observed that the monoclonal anti-Fc receptor antibody, IV.3, could block platelet activation by HDA. [179] [185]

Subsequent findings from several study groups have led to the consensus that the dominant pathologic factor in HAT is circulating antibody specific for a complex of heparin (H) and platelet factor 4 (PF4). [186] [187] [188] [189] [190] It is now accepted that H-PF4 complexes, which are detected in 85% of patients with HAT, [191] can bind to the membrane of platelets[187] [192] [193] or endothelial cells,[187] leading directly to thrombocytopenia in the former case. In those cases where the HDAs are IgG, the Fc portion can cross-link to the platelet FcRIIA receptor, inducing platelet activation, release, aggregation, and thrombosis. [187] [189] [190] However, HAT can also be associated with antibodies of IgM and IgA isotypes, [194] in which case the Fc()R of lymphocytes or the Fc()R of monocytes and neutrophils, as well as complement activation, may play a role in the pathology of this disorder.

Thus, it is now generally accepted that one of the major stimuli for the thrombosis associated with HAT is the Fc receptor-mediated immune complex-dependent activation of platelets. In support of this theory, Warkentin et al. [181] have pointed out that this likely involves and is complicated by the propensity of these immune complexes to generate procoagulant platelet-derived microparticles.

Alternative protein targets may be involved in selected cases of HAT. For example, in nine of 15 patients with HAT who lacked detectable antibodies to H-PF4 complexes, Amiral et al.[195] found evidence of autoantibodies specific for the chemokines neutrophil-activating peptide-2 (NAP2) or interleukin-8 (IL-8). PF4 is 60% homologous to NAP2 and 40% homologous to IL-8, leading to the proposal that HAT involving these proteins could proceed along a mechanism similar to that invoked for PF4.

Chapter 134 - HLA and Neutrophil Antigen and Antibody Systems

Glenn E. Rodey
Parviz Lalezari

INTRODUCTION

This chapter reviews human leukocyte antigen (HLA) and neutrophil-specific antigens and antibodies. The structure and function of the HLA genetic complex and some important clinical applications of HLA testing are discussed. Analysis of HLA gene products is used in four clinical settings: (1) to select compatible donor-recipient pairs for organ and bone marrow transplantation, (2) to select HLA-compatible single donor platelet products for thrombocytopenic patients who are refractory to random pooled platelets, (3) to analyze genetic factors that contribute to the expression of HLA-associated diseases, and (4) to resolve parentage disputes or forensic issues. Only HLA testing in the settings of organ transplantation and blood transfusion is discussed in this chapter. Neutrophil-specific alloantigen systems are reviewed and clinical neutropenic disorders associated with the production of specific antibodies induced through alloimmune, isoimmune, or autoimmune mechanisms are discussed.

HLA ANTIGENS AND ANTIBODIES

The HLA genetic system is the major histocompatibility complex (MHC) in humans. MHC gene products were initially defined in mice as transplantation antigens; [1] for several years, they were of interest primarily to transplantation immunologists. In the mid-1960s, two lines of evidence suggested that MHC genes might participate more broadly in immune responses. First, Lilly et al. [2] discovered that genetic susceptibility of inbred mice to Gross virus-induced leukemia was linked to the murine MHC, H-2. This observation was the basis for a major survey of HLA and disease associations that began in 1967 and has continued to the present time. [3] Second, certain inbred mouse strains were observed to respond poorly or not at all to selected simple antigens. [4] Studies demonstrated that the capacity to respond to specific antigens was genetically determined by factors linked to the H-2 complex, [5] giving rise to the concept of immune response (Ir) genes. In 1974, Zinkernagel and Dougherty identified the critical role of MHC genes in immune responses by demonstrating that antigen-primed T cells recognized a foreign antigen only when it was presented on cells sharing the same MHC antigens as the initial antigen-presenting cell. [6] This phenomenon became known as MHC restriction. The investigators shared the 1996 Nobel prize in medicine for this important observation. Finally, MHC molecules were found to direct the educational process, occurring in the thymus, that ultimately determines the repertoire of expressed T-cell receptors. [7] MHC studies now are an integral component of immunobiology. MHC genes, together with the B-cell and T-cell receptor genes, form a major triad of gene families responsible for genetic control of immune responses.

HLA NOMENCLATURE

HLA nomenclature in the 1950s consisted of multiple, locally formulated assignments. As the field matured and developed structure, a need for uniform nomenclature became apparent. In 1967, an HLA nomenclature committee, formed under the auspices of the World Health Organization (WHO), received responsibility to develop and update HLA nomenclature.[8] Major nomenclature revisions were made in 1967, 1975, 1984, and 1987. Currently, two nomenclature systems are used: one based on immunologically defined epitopes using either serologic or cellular techniques, and a second based on defined nucleotide sequences of allelic genes.

Immunologically Defined HLA Nomenclature

The current immunologically defined nomenclature, implemented in 1975 and modified in 1984, is based on the following principles: *HLA* followed by a hyphen designates the MHC, capital letters (e.g., *A, B, C, DR, DQ, DP*) designate segregant series, and a numeric designates a specific allele. Numerics for each locus, with the exception of the A and B loci, start with the number 1.[9] HLA-A and -B alleles are still considered as a single group for sequential numbering of new specificities. When the nomenclature was first developed, HLA-A and -B locus alleles were thought to be encoded by a single locus. Provisional allelic specificities originally were preceded by a *w*, but the letter is no longer used for that purpose. However, the *w* is used in four other circumstances. To prevent possible confusion between HLA-C locus alleles and complement components, the *w* prefix in all C locus alleles is permanently retained. DP and Dw alleles also retain a *w* to indicate that both series were originally defined by cellular techniques.[10] Finally, the public specificities, Bw4 and Bw6, retain the *w* to indicate the specificities are epitopes rather than allelic gene products.

A minor modification has been made since 1987. New serologically defined variant specificities that detect a single gene product of known nucleotide sequence receive an extended numeric that coincides with the molecular nomenclature of the allele.[11] For example, a unique serologic specificity that detects the class I gene product HLA-A*0203 is called HLA-A203.

Sequence-Defined Allelic Nomenclature

An additional nomenclature, based on nucleotide sequences, was recommended during the Tenth International Histocompatibility Workshop in 1987.[11] Refined gene mapping and nucleotide sequence data revealed that more than one locus could code for alternate protein chains in D region molecules. Further, many HLA allelic variants that are not detectable by traditional serologic techniques were discovered. This complexity necessitated development of the following nomenclature for HLA genes: (1) HLA designates the MHC, and (2) a series of capital letters, with or without a numeric, designates a specific locus (Table 134-1). Specific alleles (Table 134-2) are designated by an asterisk (*), followed by a two-digit number indicating the most closely associated serologic specificity, followed by a two-digit number defining the allele. For example, there currently are 25 officially recognized molecular variants of the serologically defined specificity HLA-A2. They are designated as HLA-A*0201 through 0225. Similarly, 24 molecular variants of HLA-DR4 are called HLA-DRB1*0401 through *0424. When a fifth digit appears in the nomenclature (e.g., *11041 and *11042), it identifies two alleles differing only by a single nucleotide that does not change the encoded amino acid. Occasionally, the capital letter N or L, with or without a preceding 3-digit number, such as

TABLE 134-1 -- Names for Class I and II Genes

Name	Previous Equivalents	Molecular Characteristics
HLA-A		Class I -chain
HLA-B		Class I -chain
HLA-C		Class I -chain
HLA-E	E, 6.2	Associated with class I 6.2-kb Hind III fragment
HLA-F	F, 5.4	Associated with class I 5.4-kb Hind III fragment
HLA-G	G, 6.0	Associated with class I 6.0-kb Hind III fragment
HLA-H	H, AR, 12.4	Class I pseudogene associated with 5.4-kb Hind III fragment
HLA-J	cda12	Class I pseudogene associated with 5.9-kb Hind III fragment
HLA-K	HLA-70	Class I pseudogene associated with 7.0-kb Hind III fragment
HLA-L	HLA-92	Class I pseudogene associated with 9.2-kb Hind III fragment
HLA-DRA	DR	DR -chain
HLA-DRB1	DRI, DR1B	DR_1 -chain determining specificities DR1, DR2, DR3, DR4, DR5, etc.
HLA-DRB2	DRII	Pseudogene with DR -like sequences
HLA-DRB3	DRIII, DR3B	DR_3 -chain determining DR52 and Dw24, Dw25, Dw26 specificities
HLA-DRB4	DRIV, DR4B	DR_4 -chain determining DR53
HLA-DRB5	DRIII	DR_5 -chain determining DR51
HLA-DRB6	DRBX, DRB	DRB pseudogene found on DR1, DR2, and DR10 haplotypes
HLA-DRB7	DRB1	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB8	DRB2	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB9	M4.2 exon	DRB pseudogene, isolated fragment
HLA-DQA1	DQ1, DQ1A	DQ -chain as expressed

HLA-DQB1	DQ1, DQ1B	DQ -chain as expressed
HLA-DQA2	DX, DQ2A	DQ -chain-related sequence, not known to be expressed
HLA-DQB2	DX, DQ2B	DQ -chain-related sequence, not known to be expressed
HLA-DQB3	DV, DQB3	DQ -chain-related sequence, not known to be expressed
HLA-DOB	DO	DO -chain
HLA-DMA	RING6	DM -chain
HLA-DMB	RING7	DM -chain
HLA-DNA	DZ, DO	DN -chain
HLA-DPA1	DP1, DP1A	DP -chain as expressed
HLA-DPB1	DP1, DP1B	DP -chain as expressed
HLA-DPA2	DP2, DP2A	DP -chain-related pseudogene
HLA-DPB2	DP2, DP2B	DP -chain-related pseudogene
TAP1	RING4, Y3, PSF1	ABC (ATP-binding cassette) transporter
TAP2	RING11, Y1, PSF2	ABC (ATP-binding cassette) transporter
LMP2	RING12	Proteasome-related sequence
LMP7	RING10	Proteasome-related sequence

101 or 102, may be added to the alleleic designation. *N* indicates a nonexpressed or null allele. *L* indicates a mutation in a noncoding region that causes significantly lower expression of the specific gene product. For example, there is a noncoding variant of A*2402. The normal allele is designated A*2402101, and the poorly expressed variant is A2402102L. If there is no normal counterpart to a null or poorly expressed gene product, it is designated with the letter *N* or *L* without the additional preceding three-digit number. [12]

To summarize, two HLA nomenclatures are in use: a nomenclature that is used to describe immunologically defined specificities (antigenic determinants) and a nomenclature that is used to define alleles, based on confirmed nucleotide sequences. Immunologically defined specificities are commonly used in organ transplantation and platelet donor selection. Molecular nomenclature is commonly used for defining HLA class II alleles in donors and recipients of unrelated hematopoietic stem cell transplants. As class I and II serology is replaced by molecular typing techniques, molecular nomenclature will increasingly replace the classical serologic nomenclature.

STRUCTURE OF THE HLA GENETIC COMPLEX

The HLA genetic complex, located on the short arm of chromosome 6, spans a distance of approximately 4,000 kilobases (kb).[13] The complex contains more than 100 genes. Thirty-three class I and class II genes are officially recognized by the WHO nomenclature committee (Table 134-1). Within the MHC, defined genes are physically grouped into three regions (Fig. 134-1). The class I region encodes genes for heavy chains of the classical transplantation molecules, HLA-A, -B, -C, the nonclassical class I genes, HLA-E, -F, and -G, several pseudogenes, and other genes of undetermined function. The class II region encodes both - and -chains of HLA-DR, -DQ, -DP, -DM, and -DO. At least four genes in the class II region code proteins that transport peptides into the endoplasmic reticulum for loading into class I molecules (TAP1, TAP2) or have proteasome-like structures that partially digest endogenously derived proteins (LMP2, LMP7).[14] The class III region encodes several structurally and functionally diverse molecules (C4, 21-hydroxylase [21-OH], C2, factor B, tumor necrosis factor [TNF], heat shock protein Hsp 70). DRA, the most telomeric class II locus, is separated from 21-OHB by about 400 kb; the position of TNF- and - loci is approximately 200 kb centromeric to the HLA-B locus, with the gene on the HLA-B locus side.[14]

Class I and II genes are the most polymorphic genetic systems known. More than 500 class I and II allelic gene products have been sequenced, of which 136 can be detected by serologic techniques.[12] [15] The true number of gene products is still underestimated, since a significant number of variant alleles remain to be sequenced in nonwhite populations throughout the world.[16] [17] The occurrence of the class III genes within the MHC is still puzzling. It is not clear if this group of somewhat unrelated genes is located in the MHC complex by chance occurrence or if there are important functional relationships between these genes and the class I and II genes. Because this chapter focuses on the HLA class I and II genes and molecules, no further discussion of class III genes is presented.

Data from Bodmer et al.[13]

Class I and II Genes

Class I and II genes, with minor exceptions, have similar structures (Fig. 134-2). They are split genes containing six to eight exons coding sequences that correspond to functional regions of the gene product. The exons code a leader sequence, two to three extracytoplasmic domains, a transmembrane sequence, and two to three intracytoplasmic sequences.[18] [19]

Only the heavy chain of the HLA class I molecule is encoded in the MHC. Genes encoding HLA-A, -B, and -C alleles each contain three extracytoplasmic exons coding for; $_1$, $_2$, and $_3$ domains of the heavy chain, a transmembrane, and three cytoplasmic tail exons. The associated class I light chain, $_2$ -microglobulin, is encoded on chromosome 15.[20] By contrast, both and protein chains of HLA class II molecules are encoded within the MHC. -Chain genes usually contain four exons coding for a leader sequence, $_1$ and $_2$ domains, and a combined transmembrane-cytoplasmic tail. -Chain genes, in addition to leader, $_1$, and $_2$ exons, have a separate transmembrane and two distinct cytoplasmic tail exons.

Each class II molecule contains an - and a -chain. All DR molecules use DRA for -chains but can use alleles coded by DRB1 (the classical DR specificities), DRB3 (DR52 molecules), DRB4 (DR53), or DRB5 (DR51). DP molecules are the product of DPA1 and DPB1 alleles; DQ molecules are the product of DQA1 and DQB1 alleles; DM molecules are the product of DMA and DMB alleles; and DO molecules are the product of DNA and DOB alleles. Several class I and II genes, as noted in Table 134-1 , are pseudogenes. Other class II genes are potentially functional but are not known to be expressed in adults (DQA2, DQB2, DQB3). [13] (The structures of the various HLA gene products are discussed later in more detail under the Physical Structure of HLA Gene Products.) Important functional roles for two additional HLA class II gene products, HLA-DM and HLA-DO, have been identified during the past 5 years. [21] [22] DM is not expressed on the cell membrane but is found primarily in endosomal compartments. The DM molecule physically associates with classical class II molecules during their transit to the endosomal compartments. DM appears to stabilize class II molecules during the time period that the invariant chain-derived peptide has dissociated until another stable peptide is firmly bound. DO and DM have similar distributions because they associate together in the endocytoplasmic reticulum and endosomal compartments. Preliminary evidence suggests that DO may negatively regulate the function of DM.

Expression of HLA Molecules

HLA molecules are expressed constitutively on the cell membranes of many different cell types. HLA class I molecules are found on most nucleated cells. [23] They also occur on platelets, in plasma, and, to a limited extent, on reticulocytes. [24] Constitutive expression of class II molecules, by contrast, is restricted to relatively few cells, principally B cells, tissue dendritic cells, Langerhans cells, and some endothelial cells. [25]

Expression of class I and II chains can also be up-regulated in most cells by the action of cytokines or through direct cell-cell contacts. [26] The expression of class II molecules in certain physiologic and pathologic conditions contributes significantly to the pathogenesis of the allograft rejection process and in certain types of autoimmune disease. Induction is controlled by regulatory elements found in the 5-flanking regions and intron regions contiguous to exon 1. [27] [28] Major advances have been made in defining the regulatory elements that govern MHC expression. (For reviews of these elements and key trans-acting DNA-binding proteins, refer to references[29] [30] [31]) The major cytokine that initiates the sequence of nuclear events leading to increased expression of HLA molecules in differentiated cells is interferon- (IFN-).[32] [33] [34]

The existence of additional MHC class I genes in mice has

Figure 134-1 Physical map of the HLA genetic complex, illustrating the clusters of genes according to the class of encoded gene products. The symbol represents four DRB pseudogenes, designated DRB6, 7, 8, and 9. Other pseudogenes are shown in gray.

been known for several years. These molecules are called class Ib to distinguish them from the classical class Ia genes.

More than 17 class Ib genes have been identified in humans. These sequences are found on either side of the HLA-A locus. Although a majority of the sequences are pseudogenes, at least six are potentially capable of generating expressed gene products. Orr and colleagues characterized three class I genes contained within Hind III restriction enzyme fragments encompassing the HLA-A region, HLA-E, -F, and -G. [35] The genes transcribe mRNA for class I-like heavy chains that associate with $_2$ -microglobulin. HLA-G codes for a transmembrane class I molecule of limited polymorphism that is expressed on cytotrophoblasts and is ubiquitously expressed in low levels on other cells, including lymphocytes, cells of dendritic lineage, and mononuclear phagocytes. [36] HLA-G serves as a ligand that can inhibit the cytotoxic response of many natural killer (NK) cells. [37] [38] Expression at the fetomaternal interface thus may protect the trophoblast from NK-mediated fetal rejection during pregnancy. Transfection experiments demonstrate that HLA-E and -F genes produce class I-like heavy chains that associate with $_2$ -microglobulin within the cytoplasm, but the molecules do not insert into the cell membrane. [39] The functions of these gene products are currently not clear. Four additional class I pseudogenes, HLA-H, -J, -K, and -L, flank HLA-A. [14]

To summarize, most of the human MHC has been mapped and sequenced. In addition to class I, II, and III genes of known function, there are many other potentially functional genes. Some of the novel class I molecules appear to be analogous to the murine Qa molecules. If the observed MHC-linked mating preference [40] extends to humans, some of the class I-like genes could mediate chemosensory recognition between members of the same species.

Inheritance and Linkage Disequilibrium

Because of their close physical linkage, HLA genes are normally inherited en bloc from the parents, unless a recombination event has occurred. Thus, despite the complexity of the gene clusters, there are normally only four genotypes transmitted to offspring, and the probability of genotypic HLA identity of two siblings is 25%. Recombinant HLA haplotypes (the portion of a single chromosome carrying one set of the HLA genes) are observed in 23% of offspring, a frequency that would be expected based on the length of the genetic complex. HLA genes are expressed codominantly, and while null or amorphic class I or class II alleles are observed, they are uncommon. On some chromosomes, specific functional HLA-DR loci are commonly deleted on different HLA haplotypes. The DRB1 locus, which codes for the -chain of classical DR molecules, is found on all HLA haplotypes. Some DR1 haplotypes carry only the DRB5 locus, while other DR1 haplotypes do not bear DRB3, 4, or 5 loci. DR2 haplotypes carry only DRB5. DR3, 5, and 6 haplotypes carry only DRB3. DR4, 7, and 9 haplotypes carry only DRB4. Finally, DR8 and DR10 haplotypes carry only DRB1.[13] Null alleles are common in the C4 and C2 class III genes. [41]

Certain combinations of genes occur in HLA haplotypes within the population far more frequently than expected on the basis of gene frequencies. This phenomenon, referred to as linkage disequilibrium, is quite common in the HLA system and has important biologic and clinical implications. In large, randomly mating populations, such as humans, gene frequencies rapidly achieve equilibrium within the population after one or two generations, unless some positive or negative selection pressure is acting on the gene (Hardy-Weinberg principle). When equilibrium exists, the occurrence of any two HLA genes on a particular haplotype should be an independent event governed only

Figure 134-3 Three-dimensional configuration of HLA-A2, modeled from x-ray crystallographic studies. *(From Bjorkman et al.,[45] with permission.)*

by the gene frequencies in the population. For example, if HLA-A1 and HLA-B8 gene frequencies are respectively 0.16 and 0.1 in a population, the expected occurrence of an HLA haplotype bearing both A1 and B8 should be 0.16 × 0.1 × 100 = 1.6%. In certain white populations with origins in Northern Europe, the actual occurrence of this haplotype in the population may be as high as 8%. Linkage disequilibrium effects often can be seen throughout an entire haplotype, involving class III as well as class I and II MHC encoded genes.[42] The possible causes and significance of linkage disequilibrium are discussed in more detail later in the section titled Evolution and Functions of HLA Gene Products.

PHYSICAL STRUCTURE OF HLA GENE PRODUCTS

Class I and II molecules are heterodimeric glycoproteins. Although the peptide chains are different for each class of molecules, the overall three-dimensional configurations of the molecules are probably very similar (Fig. 134-3). The protein chains of each class of molecule, the class I heavy chain, $_2$ -microglobulin, and the class II - and -chains, belong to the immunoglobulin gene superfamily. [43] Each protein contains one of the immunoglobulin-like domain structures typical of this family, and these domains show sequence homologies with domains of other members of that family.

Class I Molecules

HLA class I molecules contain a heavy protein chain, of approximately 45 kd mass, that is noncovalently associated with $_2$ -microglobulin, a nonpolymorphic protein of 12 kd mass. The heavy chain structure correlates closely with the exonic arrangement of the gene. Beginning with the N-terminal amino acid, there are three extracytoplasmic domains ($_1$, $_2$, and $_3$), followed by a hydrophobic transmembrane stretch of amino acids and terminating in a cytoplasmic tail. $_2$ -Microglobulin, together with the heavy chain domain, constitutes the membrane-proximal portion of the molecule. The amino acid sequences of 4050 class I molecules, deduced from class I nucleotide sequences, [44] demonstrate that amino acid sequences of the $_3$ domain are highly conserved. $_2$ -Microglobulin in humans is essentially monomorphic. All class I polymorphism detected by serologic and cellular techniques resides in the $_1$ and $_2$ domains. Like immunoglobulins, most class I polymorphism occurs in specific sites referred to as hypervariable regions. Comparisons of the various class I amino acid sequences to HLA-A2 indicate that virtually all hypervariable sites occur within or in close proximity to the peptide groove. [45]

Early structural models of class I molecules indicated that both the $_1$ and $_2$ domains contained stretches of amino acid sequences in an -helical configuration. The significance of this observation was not appreciated until further landmark studies of Bjorkman and colleagues [45] [46] identified the three-dimensional structure of HLA-A2 (Fig. 134-4). The $_1$ and $_2$ domains form a platform of eight antiparallel strands overlain by the two helices (Fig. 134-5). This configuration forms a groove that is about 25 A long, 10 A wide, and 11 A deep. This site, referred to as the peptide groove, accommodates processed peptides for presentation to T-cell receptors (see the section titled Evolution and Functions of the HLA Gene Products). The ends of the class I peptide groove are relatively closed, restricting the size of

Figure 134-4 Comparative configurations of HLA-A2 (class I) and of HLA-DRI (class II). *(From Hammer and Sinigaglia,[207] with permission from Hogrefe & Huber Publishers, Seattle, Toronto, Bern, Göttingen.)*

peptides that can be accommodated. The size range of class I peptides is 711, with a modal length of 9. Peptide grooves of both class I and II molecules contain recesses (pockets) that favor certain types of amino acid side chains. [46] These anchor residues largely determine if a particular peptide will bind with high affinity to a specific HLA molecule. Clusters of HLA molecules share similar pockets that favor the binding of like peptides. Peptides bearing the appropriate amino acid anchor residues that favor binding to a cluster of HLA molecules are referred to as a supermotif. [47] This observation has important implications for the production of peptide-based vaccines.

Class II Molecules

HLA class II molecules contain two noncovalently associated protein chains, , of approximately 33 kd mass, and , of approximately 29 kd mass. Each chain is a transmembrane protein that consists of a cytoplasmic tail, a hydrophobic transmembrane segment, and two membrane-distal domains. An HLA class II molecule has been crystallized and its structure deduced (Fig. 134-4). The peptide-binding site structure, previously projected to be similar to class I, was documented. In contrast to class I molecules, the peptide groove of class II molecules is open-ended, and a broader array of peptides, up to 18 amino acids in length, can be accommodated. Pockets that favor the binding of specific anchor residues are also characteristic of class II peptide grooves.

ORIGIN OF MHC-ASSOCIATED PEPTIDES

Peptides presented by MHC molecules are derived from two distinct sources. Exogenously derived antigens enter cells by endocytotic processes and bind primarily to class II MHC.[48] The peptide-class II complex serves as the ligand for $CD4^+$ helper T lymphocytes. This is the classical pathway utilized by antigen-presenting cells (APCs) to capture, process, and present exogenous antigens for subsequent induction of delayed-type hypersensitivity reactions or the production of antibodies. Endogenous antigens originate in the cytosolic environment of the cell. [49] Endogenous peptides, which may include peptides from self antigens or may be derived from early viral proteins produced in a virus-infected cell, are presented primarily by class I MHC molecules and are recognized by $CD8^+$ cytotoxic T lymphocytes (CTL). The routes through which the peptides and the class II or I molecules pass are referred to respectively as the exogenous and endogenous pathways, according to the origin of the peptides.

Exogenous Pathway

With appropriate route of administration, foreign antigen derived from the external environment is taken up by APCs via random or receptor-mediated endocytosis. The antigen undergoes limited proteolysis within membrane-bound acidic endosomal compartments, which are now referred to as MHC class II peptide-loading compartments (MIICs). Concurrently, MHC class II molecules are assembled in the endoplasmic reticulum. Early class II molecules contain a third chain, in addition to the and , called the invariant chain (Ii). The chain serves several important functions in the exogenous pathway. It occupies the peptide-binding groove and prevents most endogenously derived peptides from binding to the newly assembled class II molecules. It functions to stabilize class II molecules, and it also contains an amino acid sequence that targets the molecular complex to MIICs. Upon entry into MIICs, most of the invariant chain is degraded, leaving only the small portion that is bound in the peptide groove (called class II-associated Ii chain, or CLIP). The nonclassical class II molecule HLA-DM facilitates the process of loading specific endogenous peptide into classical HLA class II molecules. HLA-DM and Ii expression are co-regulated with the classical class II genes. DM is largely absent from the cell membrane, but accumulates in MIICs. DM molecules do not bind peptides within their own peptide grooves. The role of DM in peptide loading is to function as a chaperone for class II molecules that are empty, or loaded with low-stability peptides. Class II molecules are susceptible to denaturation during this period, and DM molecules prevent this until a high-stability peptide is loaded. The DM molecule then dissociates from the stable peptide-MHC trimer, which is then transported to the plasma membrane and is re-expressed on its surface.

Endogenous Pathway

Peptides presented by class I MHC molecules have their origins mainly from proteins found in the cytosol. Most are derived from self proteins under normal circumstances. Endogenous peptides are also derived from viral proteins when these proteins are actively synthesized by a virus-infected cell. [50] Peptides from phagocytosed microbial antigens and other endocytosed material also can gain access to newly synthesized class I molecules via leakage into the cytosol. This may constitute a minor component of the endogenous pathway. It appears that evolution provided the endogenous pathway and class I MHC molecules as a mechanism to survey the internal environment of the cell for antigens from replicating organs and from mutated self proteins that would otherwise escape recognition by antibody or other extracellular immune mechanisms.

In contrast to class II molecules, whose structure is temporarily stabilized by invariant chain, then by HLA-DM prior to peptide binding in MIIC compartments, class I molecules must bind peptides within the endoplasmic reticulum. Otherwise, the physical association of the class I heavy chain with $_2$ -microglobulin is unstable.[49] [51] [52] Until the time that peptides are loaded into their peptide grooves, class I molecules are stabilized by a complex series of cofactors that include two calcium-dependent chaperones and the protein, tapasin. [53] The newly formed HLA heavy chain first associates with calnexin. When $_2$ -microglobulin

associates with the heavy chain, calnexin dissociates and calreticulin binds. During this time period, tapasin also associates with the class I-calreticulin complex. The complex then binds to MHC-encoded transporter associated with antigen processing molecules (TAP1/TAP2 heterodimer) via the class I molecule. TAP molecules insert through the endoplasmic reticulum membrane. Endogenous peptides that will be transported through TAP molecules are derived from proteins that are degraded into a series of peptides through the action of cytosolic proteasomes. Two proteins, LMP2 and LMP7, that are involved in this process are encoded in the class II region of HLA.[54] Since proteasomes contain multiple protease enzymes, a variety of different peptides may be obtained from the same protein. The class I molecules ultimately select the appropriate peptides based on anchor residues and affinity. If no peptides meet the criteria for binding after a period of time, the class I molecules are released and ultimately degraded in the cytosol by proteasomes. This process produces class I-derived peptides that can be loaded and presented by other HLA molecules, a process that has clinical relevance in allotransplantation. Peptides transported into the endoplasmic reticulum insert into the peptide groove of the docked class I molecules. Stable trimeric complexes are transported to the plasma membrane and re-expressed on the membrane surface.

To summarize, the high degree of polymorphism found in both class I and class II molecules is restricted to specific, hypervariable regions of the membrane distal domains that form the peptide groove. The remaining portions of the molecules are relatively conserved, reflecting structural constraints imposed by the functions of the molecules in antigen presentation and cellular interactions. Indeed, studies of the types of amino acid substitutions found in the hypervariable regions compared to those in conserved regions indicate that both positive and negative selection pressures may be exerted on the molecules: positive selection in the hypervariable regions that favors conformational or charge change and negative selection that favors no conformational or charge change.

ANTIGENIC STRUCTURE OF HLA MOLECULES

HLA molecules contain multiple alloepitopes that can induce humoral and cellular responses during alloimmunization. Serologically defined HLA alloepitopes are defined with well-characterized, operationally monospecific alloantibodies. T-cell epitopes are characterized using cloned T lymphocytes. The availability of HLA structure and amino acid sequence data, together with monoclonal antibodies and the technology of site-directed mutagenesis, now makes mapping of alloepitopes on the HLA molecules technically feasible. [55] As expected, serologically definable epitopes are located on and adjacent to the peptide groove. Epitopes recognized by T cells are distinct from the serologically defined epitopes. [56] [57] This was anticipated, since T and B cells recognize epitopes through different mechanisms (see the section titled Evolution and Functions of the HLA Gene Products).

Two general types of alloepitopes, based on their distribution pattern, have been defined serologically. [58] Certain epitopes (private epitopes) occur only on a single gene product or its allelic molecular variants, (for example, HLA-A2). Serologic reagents that recognize private epitopes have been important for HLA antigen typing. Other alloepitopes, termed public epitopes, differentially occur on more than one distinct HLA gene product. Many public epitopes are widely distributed among HLA molecules. Antibodies to public epitopes have been used to categorize HLA gene products into major cross-reactive groups (CREGs). The current significance of public epitopes, however, is their clinical relevance for patients awaiting transplants or requiring repetitive platelet transfusions. A single alloantibody directed against a high-frequency public epitope can have devastating consequences for potential transplant recipients or patients who need repetitive platelet transfusions (see the section titled HLA Testing for Transplantation and Transfusion). The HLA-Bw4 and -Bw6 specificities are prototypic examples of public epitopes. These two specificities were originally thought to define a diallelic locus closely linked to, but distinct from, HLA. All individuals studied were either Bw4, Bw6, or both. Sequential immunoprecipitation studies subsequently demonstrated that Bw4 and Bw6 are alternative specificities present on virtually all HLA-B molecules and a few HLA-A molecules. Parham and colleagues[59] identified $_1$ -domain amino acid patterns in positions 7983 that correlate with Bw4, Bw6, or the absence of Bw4 or Bw6 (most A-locus alleles). Table 134-2 lists the currently recognized HLA specificities. [13] Table 134-3 is a summary of the major public epitopes and their approximate distribution among HLA molecules.

TABLE 134-3 -- Population Frequencies of Major Cross-Reactive or Determinants Present on HLA-A and HLA-B Gene Products

HLA ALLOIMMUNIZATION

Alloimmunization to HLA antigens occurs through pregnancy, transfusion of blood products, or prior transplantation. HLA molecules traditionally have been considered strong immunogens because of their influence on allograft rejection and the development of graft-versus-host disease (GvHD). Surprisingly, only about one-third of individuals who are alloimmunized develop HLA alloantibodies, [60] suggesting to some that these molecules may be relatively poor immunogens. Since cell-mediated immunity is a principal mechanism of graft rejection in nonimmune recipients, it also is possible that HLA molecules preferentially induce T-cell-mediated responses. T-cell responses, however, are difficult to measure in vitro because the frequency of precursor T cells activated in vitro to an HLA molecule may be an order of magnitude greater than the frequency of precursor T cells activated to strong antigens, such as tetanus toxoid. [61] [62] Generally, there is no consistent difference in CTL or proliferative cell precursor frequency between nonimmune and alloimmunized individuals. [63]

An alternative to poor immunogenicity as an explanation for the relatively low percentage of antibody responses to alloimmunization is that the molecules are strong immunogens, but immune effector responses are modified by concurrent immune responses that down-regulate effector products such as antibodies or CTL. Evidence suggests that regulatory immune responses do occur.[64] [65] Suciu-Foca and others[66] [67] [68] have described the occurrence of autoanti-idiotypic-like antibodies (AB2) in the serum of many alloimmunized individuals who do not make HLA alloantibodies. AB2 appear to have specificity for cross-reactive idiotypes present on HLA-specific alloantibodies, as shown by the capacity of AB2 to inhibit binding of the HLA alloantibodies to relevant HLA targets. Reed et al. [69] reported that the presence of AB2 inhibiting one or more HLA antibodies to incompatible HLA antigens on donor grafts is associated with excellent graft outcome, whereas the absence of AB2 predicts early graft loss. Although there is no direct evidence that these autoantibodies are important components in early activation of immune regulation, their occurrence suggests that alloimmunization with specific HLA incompatibilities will modify subsequent immune responses to the incompatibilities, either positively or negatively.

Immune regulation of effector responses may also be mediated through differential cytokine production by T cells. Helper T cells with distinctive patterns of cytokine secretion occur in mice[70] and in humans.[71] [72] One T-cell phenotype, Th1, which secretes predominantly IL-2, TNF-, and IFN-, mediates classical delayed-type hypersensitivity reactions. The second type, Th2, secretes predominantly IL-4, IL-5, and IL-10, and is largely responsible for B-cell activation and differentiation into antibody-secreting cells.[73] Once differentiated, these two helper T-cell types are mutually regulatory: IL-4 and INF- each reciprocally inhibit synthesis of the other cytokine. Thus, preferential activation of one Th type subsequently inhibits activation of the other type. Predominant Th2 cytokine profiles in an allograft is associated with decreased acute cellular rejection because cellular immune effector mechanisms are suppressed. However, it can be associated with humoral and chronic rejection processes.[74]

Two types of HLA allorecognition, direct and indirect, are recognized based on the mode of peptide presentation. Direct allorecognition occurs only in the context of HLA alloimmunization because of the unique role MHC molecules play in antigen presentation. T cells responding to donor-derived, allogeneic APCs can be activated directly by HLA molecules present on the APCs. Besides antigenic differences in the HLA molecules themselves, they contain a large array of peptides that are potentially antigenic. The cumulative number of different antigens in this setting activates large numbers of T cells. Direct allorecognition is a vigorous and early HLA immunization event that is largely responsible for the acute cellular rejection response observed in organ transplantation, and for acute GvHD. Indirect allorecognition is the classical antigen presentation pathway, in which an exogenous antigen, in this case donor-derived HLA antigens, is taken up by endocytosis into the responders own APCs. The antigen is then processed and the peptides presented on self-HLA molecules. Indirect antigen presentation may play a prominent role in chronic rejection of solid organ allografts, and possibly in chronic GvHD. [75] [76]

LABORATORY DETECTION OF HLA ANTIGENS AND ANTIBODIES

Historically, HLA antigens and antibodies have been defined by serologic techniques, using complement-dependent lymphocytotoxicity (CDC) techniques. Although serology remains a keystone for clinical HLA testing, newer procedures are available that supplement or may gradually replace CDC. These include DNA-based typing procedures, flow cytometry for crossmatching and HLA antibody screening, and solid phase immunoassays for HLA antibody detection. Oligonucleotide primers, probes, and direct sequencing, used in conjunction with the polymerase chain reaction (PCR) or other process that amplifies copies of the relevant gene, are emerging as the principal adjunct procedure for class II typing. Many centers no longer type class II antigens using serologic techniques because DNA typing, which provides more information, can be performed for the same charge and with comparable turnaround time. Commercial kits for antigen-level HLA class I typing are now available. Molecular genetic typing techniques will most likely replace serology as the primary form of HLA testing as probes become available and the procedures become cost- and time-effective. With the availability of allele-level HLA class II molecular typing, the unidirectional mixed leukocyte reaction (MLR), once a common clinical procedure used to identify composite HLA-D region compatibility between donor and recipient, now is rarely used for compatibility testing. [77]

Microlymphocytotoxicity Procedure

The standard procedure[78] for HLA testing is a complement-dependent microlymphocytotoxicity test (CDC). The test is miniaturized, requiring 1 l and 2,000 cells per well, on microplates containing up to 96 wells. Because of extensive polymorphism of the HLA system, multiple antisera (or cells) must be used for complete testing. It is not uncommon to employ 120140 antisera to determine the HLA phenotype of an individual or to test against 60 cells when screening patients sera for HLA antibodies. The general procedure, summarized in Figure 134-6 , involves an initial incubation of antiserum and lymphocytes, followed by the addition of rabbit serum as a source of complement. If specific binding of antibody to relevant HLA molecules has efficiently activated the complement cascade, cell membrane injury occurs and is visualized microscopically by the addition of a vital dye such as eosin Y, trypan blue, or ethidium bromide.

Class I HLA molecules are present on both T and B lymphocytes. Class II molecules, however, are normally present only on the B-cell population. To perform class II typing, relatively purified B-cell lymphocytes must be used as targets (nylon wool adherence or antibody-specific capture to a solid phase) or B cells must be tagged so that they can be distinguished from T cells (tagged with fluorochrome-labeled, B-cell-specific antibody). [79]

CDC is used for HLA typing (unknown cell tested against panels of HLA antisera), HLA serum analysis (unknown serum tested against panels of HLA typed cells), or crossmatches between

Figure 134-6 Summary of the complement-dependent lymphocytotoxicity (CDC) procedure, showing the optional antiglobulin augmentation step.

potential recipients and donor pairs (recipient serum tested against donor cells). A limitation of CDC in antibody detection is that not all HLA antibodies efficiently activate the complement system and certain HLA specificities are not detected. Thus, antibody reactivity can be greatly underestimated in some patients. Failure to detect certain antibodies with CDC is referred to as the cytotoxicity negative but adsorption positive (CYNAP) phenomenon. [80] CYNAP can be minimized by the addition of anti-human light chain-specific or $(Fab)_2$ -specific antiglobulin reagent. [81] [82] This modified test is termed the antiglobulin-augmented microlymphocytotoxicity (AHG-CDC) test. The mechanism of augmentation is that more efficient complement activation occurs with the provision of additional heavy chain complement-binding sites in proximity to bound HLA antibodies. CYNAP commonly occurs with antibodies directed against public or CREG specificities. Consequently, standard CDC defines only partial specificity of the antibody. An example of the CYNAP phenomenon is given in Table 134-4 . The serum, directed against the 2C public epitope, shows no reactivity with the HLA-A9 (A23, A24) epitopes until tested by AHG-CDC.

Indirect immunofluorescence using flow cytometry is more sensitive than AHG-CDC for the detection of HLA antibodies and is gradually replacing CDC or AHG-CDC as the final crossmatch procedure used for organ transplantation. [83] Limited HLA specificity analysis of selected sera by flow cytometry also is performed in some centers, and its use may increase as better reagents become available to increase throughput. Solid phase immunoassays that use solubilized HLA molecules as targets now are commercially available for HLA antibody screening. They are formatted either as ELISA trays or as coated microparticles for use in flow cytometry. As solid phase immunoassays that employ purified single HLA molecular species per well or particle continue to improve, they will replace CDC procedures as the standard HLA antibody screening technique.

Molecular Typing

HLA class II DR and DQ typing by molecular techniques is routinely performed in many clinical laboratories that support transplantation programs. Two general procedures are employed, depending on the level of resolution desired to discriminate between variant alleles. One procedure, referred to as sequence-specific primer typing (PCR-SSP), utilizes DNA primers that are specific for individual or similar groups of class II alleles. The primers are used in conjunction with PCR to amplify the relevant genomic DNA. The amplified products for each primer pair are subjected to gel electrophoresis and visualized by staining. [84] Amplification occurs only when the appropriate sequence is present, and a product of known base pair size is generated. This technique is especially useful for typing individual patients but loses efficiency when larger numbers of patients (>50 per week) are typed, owing to the need for larger numbers of electrophoresis units. Additional labeled probes are not necessary to routinely define the amplified DNA, and the test can be performed within 2 hours using nonradioactive techniques. The procedure is often used for antigen-level class II typing (comparable to or better than serologically defined typing), but can be used for allele-level typing by performing further amplifications with additional primers.

A second common procedure, PCR-SSO, uses locus-specific or group-specific primers to amplify the desired genomic DNA, followed by the application of a labeled oligonucleotide probe that binds to an allele-specific sequence. For dot blotting, amplified DNA is usually applied to a membrane as multiple dots, and labeled probes are added to each DNA dot for hybridization and subsequent visualization. [85] In reverse dot blotting, nonlabeled probes are attached to a membrane through linking molecules and stored. Amplified, labeled DNA is then added at the time of testing. A number of sensitive, nonradioactive labels are now available. Reverse dot blotting is often used for allele-level typing of individual patients, whereas dot blotting is used when large numbers of samples can be tested at one time.

All of the molecular typing procedures are evolving rapidly. Typing for HLA class I is more complex because the number of variant alleles is greater and two, rather than one, exons are polymorphic. Finally, the HLA complex contains a number of HLA class I pseudogenes that could be inappropriately amplified with a poorly designed primer or probe. The technology for semi-automated, radioisotope-free, direct nucleotide sequencing is also developing rapidly and could become the

principal molecular typing method in the near future. [86]

EVOLUTION AND FUNCTIONS OF HLA GENE PRODUCTS

MHC molecules are crucial to the general process by which an organism discriminates, at a molecular, cellular, and perhaps species member level, between relevant self and non-self elements. This function is most clearly demonstrated in the immune system, which functions mainly to eliminate foreign or altered self-products from the internal environment. The selection of a T-cell receptor repertoire during thymus maturation of T cells, for example, is determined by the type of MHC-peptide configuration present in the thymic cortex and medulla.[7] [87] Differentiating thymocyte receptors with T-cell receptors having any affinity for self MHC molecules are positively selected for clonal expansion. Next, there is an elimination or suppression of high-affinity self-reactive receptors that could result in lethal autoimmunity. The final repertoire of cells contains receptors that recognize alterations of self MHC caused by physical association of foreign peptides, but generally lacks high-affinity receptors that recognize autologous peptides bound to self MHC molecules.

A second major function of MHC molecules is antigen presentation to T cells. After the three-dimensional structure of HLA-A2 was determined, the molecular basis of the MHC restriction became apparent. The ligand of a T-cell receptor is a complex that consists of a peptide bound within the peptide groove of an MHC molecule. The configuration imparted by this combination determines the affinity of this complex for a set of T-cell receptors and subsequent activation of the T cell. The estimated length of peptides that can be accommodated in the MHC peptide groove is 717 amino acids, depending on the class of HLA molecule. [88] [89] The peptide groove of class II molecules, which appears to be open at both ends, can accommodate peptides 1317 amino acids in length. Class I peptide grooves are closed at one end and will only carry peptides of 711 amino acids in length. Most peptides presented to T-cell receptors by MHC molecules are derived from larger protein chains through limited proteolysis within cells. Although the MHC-peptide complex is essential for antigen-specific T-cell activation, it is not sufficient. APCs must provide additional signals, either cytokines or other expressed membrane receptors, [90] [91] to allow T-cell activation to occur. Finally, a variety of accessory molecules that enhance contact between APCs and T cells promote T-cell activation.[90] Two T-cell accessory molecules, CD8 and CD4, respectively interact directly with class I and II MHC molecules to enhance T cell-APC contact and T-cell activation. [92] [93]

Class I and II molecules have related but distinct roles in the antigen presentation process. The class I-peptide complex interacts primarily with T-cell receptors of $CD8^+$ T cells. This effector arm of the immune response is particularly important for endogenously derived peptides. [94] Thus, viral proteins produced very early during the initial replication cycle can be processed and presented before significant viral replication occurred. Similarly, presentation of peptides derived from abnormal self-proteins may permit recognition of mutant cells, such as chronic myelocytic leukemia cells. [95]

The predominant function of class II molecules is presentation of peptides from exogenously derived proteins to $CD4^+$ T cells. This heterogeneous population includes helper T-cell subsets, Th1 and Th2, [70] [71] [72] [73] that secrete distinct cytokine profiles and are associated with classical delayed-type hypersensitivity and B-cell helper activity, respectively. A subset of $CD4^+$ T cells also facilitates induction of $CD8^+$ T cells with suppressor activity.[96] [97]

HLA molecules also have a significant biologic role in innate immunity, serving as ligands for inhibitory receptors present on different subsets of NK cells. [98] [99] [100] Absence of MHC class I expression on mutant cells has been known to confer resistance to killing by NK cells. Some NK cells are inhibited by certain HLA-C locus alleles and by the class I public epitope, Bw4. Selective inhibition of NK killing is mediated through a complex series of NK cell inhibitory receptors (KIRs). Through these pathways, MHC molecules coordinate reciprocal functional activities of NK and T cells.

Biologic Basis of Alloreactivity

The estimated precursor frequency of T cells from immunized donors that will proliferate in vitro to tetanus toxoid or other strong immunogens is about 1 in 5,00020,000. By contrast, the precursor frequency of T cells from nonimmune donors to an allogeneic MHC molecule is 1 in 5002,000. [61] [62] Similar differences are observed when CTL precursor frequencies are estimated. This large discrepancy has puzzled investigators for a number of years, particularly since exposure to allogeneic molecules is not known to occur in nature except during pregnancy. Recognition of allogeneic MHC molecules and self MHC-foreign peptide complexes may not involve distinct sets of receptors, since cloned T cells that can react with both are described. This evidence suggested that MHC alloreactivity is actually a form of cross-reactivity with altered self. That is, a given allogeneic MHC molecule and its bound peptide may have a configuration that is similar to that recognized by a set of T cells that react with self MHC complexed with a foreign peptide. [101] [102] In the absence of processed foreign peptides, peptide grooves of MHC molecules are normally occupied by self peptides. Thus, exposure to an apparently homogeneous allogeneic MHC molecule by serologic testing is actually, at the T-cell level, exposure to MHC molecules already complexed with a large array of potentially foreign peptides. [103] Consequently, a proportionally broader set of T cells is activated.

Evolutionary Basis of MHC Polymorphism

Every individual who is heterozygous for each known MHC gene product has six class I molecules (two each of HLA-A, -B, and -C gene products) and eight class II molecules (two each of DR, DP, DQ, and DRw51, w52, and w53). Within the human species, however, there are at least 500 discrete class I and II gene products. Two general theories, selectionist and neutralist, are proposed to explain the level of polymorphism. [104] [105] Both theories propose that a high level of polymorphism has been established and maintained because of heterozygous advantage. However, the theories differ in proposed reason and mechanism. Selectionist theories propose that new MHC molecules are selected and maintained in the species because they confer some form of survival advantage. Neutralist theories propose that positive selection does not occur but that neutral random mutations are accumulated to favor outbreeding and heterozygosity. The conclusion that the mutations favor genetic heterozygosity is based partly on the observation that H-2 linked mating preference in mice promotes MHC-incompatible matings. [40]

Recent observations that positive selection appears to influence amino acid substitutions in the MHC hypervariable region favor a selectionist theory. [44] Such theories propose that the major evolutionary pressure for developing polymorphism was a need to select an optimal number of alternative antigen presenting molecules within the species to attain parity with constantly mutating environmental pathogens. The limited number of gene products carried by a single individual must be used to present all foreign peptides encountered by the individual. An MHC molecule can present many but not all different peptides. A single amino acid substitution in the peptide groove of an MHC can abrogate the molecules capacity to carry a specific peptide. [106] Therefore, the capacity of one MHC molecule to accommodate different foreign peptides is broad but not limitless. It is possible that some peptides cannot be effectively presented

to or recognized by T cells in a given individual. Some Ir gene phenomena in inbred animals are a reflection of these physiologic blind spots.

A final question concerns the mechanisms through which MHC polymorphism is generated. Initially, genetic hotspots of hypermutability that favored a higher than normal mutation rate in MHC molecules were thought to exist. This mechanism would tend to produce an ever-changing set of MHC molecules of relatively recent origin. Comparative amino acid sequence data in different animal strains, however, indicate that most of the observed MHC polymorphism in rodents and primates actually predates speciation and has been retained as long as 5 to 10 million years. Gene conversion, originally suggested as a major source of class I polymorphism

in inbred mice,[106] was not as apparent in highly outbred human populations. However, sequencing of HLA class I alleles in Amerindian populations with limited HLA gene pools serologically reveals highly diverse alleleic microvariants that developed through gene conversion events. Thus, gene conversion may play a prominent role in sustaining HLA heterogeneity within relatively inbred populations. [16] [17]

HLA TESTING FOR TRANSPLANTATION AND TRANSFUSION

Three general procedures are used for clinical HLA testing: HLA typing to identify HLA specificities, serum analysis to detect HLA alloantibodies, and crossmatch procedures to determine compatibility between a specific donor-recipient pair. Transfusion of blood products and pregnancy conceptually are allografts. As such, they induce similar immunologic responses. The responses, however, are modified according to differences such as the physical structure of the graft, the manner in which it is introduced into the host, and the duration of time in the host. Transfused leukocytes, for example, persist for relatively short periods in individuals with normal immune function compared to fetal allografts or vascularized organ allografts. Immune responses differ even among solid organs. Liver allografts, which shed large amounts of HLA antigen as well as passenger leukocytes, have a large capacity to clear preformed donor-specific antibodies and evoke different types of immunity tolerance. Organs, because they express different levels of HLA molecules and have different patterns of vascularization, also are affected differently by immune effector responses. Because of these differences, it is not possible to make categorical statements concerning HLA that apply to all transplant situations. In the following sections renal transplantation data will be used for most of the discussion of transplantation principles, with a brief indication of cases in which the principles do not apply to other organ transplants.

Renal Transplantation

When an allogeneic organ is transplanted, incompatible alloantigens present in the tissues are recognized appropriately as foreign. This recognition initiates a complex sequence of immunologic events that leads to the production of immune effector as well as immune regulatory responses. In a nonimmunosuppressed recipient, effector responses usually dominate early in the course of the immune response, leading to rejection of the tissue. Although primary rejection is mediated by cellular mechanisms in the nonimmune recipient,[107] preformed donor-specific alloantibodies directed against alloantigens in the endothelium (ABH blood group antigens, HLA antigens, and possibly endothelial-specific alloantigens) can cause the rapid loss of a vascularized graft.

Three clinical strategies have been employed to increase the probability of graft acceptance: (1) use of immunosuppressive agents to blunt immune effector mechanisms, (2) histocompatibility matching to reduce graft foreignness, and (3) pretransplantation alloimmunization to initiate the early phases of donor-specific hyporesponsiveness to alloantigens present in the graft.[108]

Immunosuppressive agents are a keystone of transplantation. Without some form of immunosuppression, all but grafts from monozygotic twins will be rejected. The first successful combination of drugs for organ transplantation was azathioprine and prednisone.[109] This drug therapy has been replaced by or supplemented with more effective immunosuppressive drugs, Cyclosporin A and tacrolimus (FK506). A principal mode of action of these agents as an immunosuppressive agent is the inhibition of factors that activate IL-2 and IL-2 receptor genes of T cells. IL-2 production plays a central role in the early amplification of cellular responses to the allograft.[110] Immunosuppression in transplant recipients, however, is a two-edged sword. Sufficient immunosuppression must be given to sustain engraftment while allowing the patient to respond adequately to environmental pathogens. There are no effective in vitro assays to quantify immunosuppression, so it is difficult to define adequate immunosuppression in the organ transplant recipient. In comparison to bone marrow transplantation, in which the immune system must be ablated with lethal doses of x-irradiation or drugs, the degree of immunosuppression used in organ transplantation is modest, yet the majority of grafts survive. As noted below, the role of immunosuppressive drugs in organ transplantation may be partly indirect, by facilitating immunologically mediated donor-specific acquired tolerance, as well as directly suppressing immune effector responses. The success of Cyclosporin A and tacrolimus in improving graft survival, particularly for nonrenal organ transplants, continues to spur searches for additional immunosuppressive agents, and a number of promising drugs are currently being tested. One drug, mycophenolate mefotil, is now approved for clinical use for supplemental immunosuppression in conjunction with Cyclosporin A or tacrolimus.[111] [112]

The two major transplantation antigen systems in human organ transplantation are the ABO and HLA systems. ABH substances are present in endothelial cell membranes. Naturally occurring isohemagglutinins can bind to the endothelium and cause hyperacute rejection of kidney and heart allografts. ABO matching of organs is therefore performed according to the same principles used for red cell transfusion. The second major transplantation antigen system is HLA. In humans, the most compelling evidence that HLA is the MHC is the superior graft survival rate of organs obtained from genotypic HLA-identical siblings when compared with graft survival from any other donors.[113] [114] Patients receiving these grafts have fewer rejection episodes and require lower doses of immunosuppressive drugs. Renal graft survival rates in this group exceed 90% at 2 years.

The importance in improving graft survival rates of HLA-A, -B, and -DR matching of kidney donors derived from cadaveric sources is well documented,[115] [116] but it has been difficult to establish significant improvement with lesser degrees of HLA matching. This is especially true if graft survival rates are evaluated only during the 2-year immediate post-transplantation period. However, a statistically significant improvement in graft survival rates can be demonstrated in major registries that monitor renal transplant results submitted by multiple centers.[113] [115] [116] Terasaki and colleagues[117] presented evidence that the beneficial effect of HLA matching is most apparent when long-term graft outcome (1520 years) is considered. Because graft loss after the first year following transplantation is linear, graft biologic half-lives can be estimated for grafts in different risk categories. The half-life of a genotypic HLA-identical graft, for example, is 25 years, and it is 13 years for parental one-haplotype matched grafts. By contrast, calculated half-lives for cadaveric grafts matched or mismatched for HLA-A, -B, and -DR are 17 and 8 years, respectively. This means that after 10 years,

60% of mismatched cadaveric grafts are lost. Thus, the chances of long-term graft survival are improved if HLA-compatible matches are provided, an increasingly important consideration in an era of donor organ shortages and limited health care funds.

Prior alloimmunization, through blood transfusion, pregnancy, or prior allografts, poses an additional risk for potential recipients. The presence of donor-specific HLA antibodies, especially antibodies directed against donor HLA class I antigens, in a patients serum is associated with a high incidence of early graft failure.[118] [119] These antibodies, detected by crossmatching procedures, preclude the use of that donor. Serum of potential recipients is regularly monitored for HLA antibodies against panels of HLA typed cells. Antibody reactivity to the panel, expressed as percent reactive antibody (PRA), is an indication of the likelihood that a compatible donor will be found. Alloimmunized patients serum may react against as many as 80100% of panel cells. In such patients, defining the specificity of the HLA antibodies becomes an important factor in predicting which donors will be compatible. Interestingly, the high PRA in the highly sensitized patients is not due to multiple HLA antibodies. Rather, it is almost always due to the presence of a few HLA antibodies with specificity to the high-frequency public or CREG epitopes (see the section titled HLA Alloimmunization).

Although prior alloimmunization may be detrimental to potential transplant recipients who make HLA antibodies, it paradoxically promotes graft acceptance in crossmatch-negative transplants.[60] [120] [121] Opelz et al.[120] noted that renal cadaveric graft survival rates in crossmatch-negative recipients who received no blood transfusions prior to transplantation were 60% lower than in comparable patients who had received blood. The beneficial effect of blood transfusion was most striking in patients who had received repetitive donor-specific blood transfusions before receiving kidneys from living-related donors.[60] [121] Following these observations, most

centers established a policy of deliberate pretransplantation blood transfusion. Although the mechanisms responsible for the blood transfusion effect have not been established, evidence suggests that pretransplantation alloimmunization may promote establishment of donor-specific hyporesponsiveness (DSH). (This concept is discussed in the section titled Concept of Allograft Acceptance.) Interestingly, the beneficial effect of blood transfusion of graft survival has not been so apparent in the cyclosporine era.[122] The apparent loss of this effect is attributed to the general use of Cyclosporin A and to improved procedures for management of early rejection episodes. Most centers now do not perform deliberate blood transfusion. However, the concept of pretransplantation exposure to donor-specific antigens as a means to promote DSH has re-emerged in different formats, driven by the need to improve long-term graft survival by reducing the incidence of chronic rejection.

Other Organ Transplantation

Heart, liver, pancreas, and lung transplantation are now established forms of therapy for end-stage organ failure. A beneficial effect of HLA matching is also observed in heart, pancreas, and more recently lung transplants.[114] [123] No beneficial effect of HLA matching has been observed in patients receiving primary liver transplants.

Concept of Allograft Acceptance

During the first two decades of organ transplantation, most investigations focused on mechanisms that lead to allograft rejection. An important by-product of the observed beneficial effect of blood transfusion was raised awareness that graft acceptance might be an active immunologic process. This concept suggests that a primary role of immunosuppressive drugs in successful allograft acceptance is to facilitate the emergence of DSH. Long-term graft survival would thus depend on how effectively this process is achieved. Multiple mechanisms of active immune regulation have been identified in experimental transplant models. Donor-specific T-suppressor cells, adoptively transferred from an engrafted animal to a nonimmune animal, support acceptance of a similar graft in that animal.[124] [125] [126] Early graft acceptance also may be promoted through the induction of anti-idiotypic antibodies,[66] [69] although the relationships between the early and late regulatory events have not been formulated. Recent studies of cytokine profiles locally secreted by graft-infiltrating cells may reflect the state of immunologic balance in the allograft. Acute rejection is associated with elevations in IL-2, IFN-, and CTL-derived enzymes granzyme B and perforin. IL-2 and IFN- are secreted by the Th1 type of helper T cell. Cytokine patterns characteristic of Th2-type cells, IL-4 and IL-10, are reported more frequently during graft acceptance.[127] [128] Finally, donor graft-derived passenger leukocytes have been observed to persist in the peripheral lymphoid tissues of some animals and patients with long-term allograft acceptance.[129] [130] Persistence of mononuclear leukocyte microchimerism has been proposed, through unknown mechanisms, to induce or sustain a state of donor-specific unresponsiveness.[128] However, this theory remains controversial. Other investigators, noting that microchimerism can also be detected in patients with failed grafts, suggest that is an epiphenomenon associated with effective general immunosuppression.

Techniques and reagents for DSH induction during the pre- or peritransplantion period are actively sought. A variety of reagents, including monoclonal anti-CD4, a recombinant molecule, CTLA-Ig, and others, have been used to study DSH induction experimentally.[131] [132] Anti-CD4 and CTLA-Ig are in Phase I clinical trials. The general events that seem to favor DSH induction are the production of generalized immunosuppression in the recipient during graft or donor antigen placement, while concurrently giving a reagent that effectively prevents a primary immune response to specific donor antigens. In many models, DSH persists after the period of general immunosuppression has abated. Implementation of effective DSH induction will clearly provide a major new treatment modality for organ transplantation. There is no current evidence that the new protocols result in true acquired tolerance, but they do appear to shift the balance in favor of graft acceptance.

To summarize, alloimmunization initiates two opposing immune responses that are in dynamic balance: strong effector immune responses that cause allograft rejection, and relatively weaker regulatory immune responses that potentially suppress graft rejection responses that are waning or have been actively blunted through immunosuppression. The intensity of effector immune responses is less when allografts are well matched for histocompatibility antigens. When effector responses predominate, graft rejection occurs. When regulatory mechanisms predominate, the rejection process is down-regulated and a state of graft acceptance ensues.

HLA Alloimmunization in Platelet Transfusion

HLA class I molecules, expressed on platelets, are a major cause of immunologic refractoriness in the alloimmunized thrombocytopenic patient.[133] [134] [135] Although it would be useful to provide HLA-identical platelet products to patients who need repetitive platelet transfusions, extensive HLA polymorphism precludes this as a routine practice. Further, additional factors contribute to the refractory state, especially in patients who are treated intensively with chemotherapeutic agents that damage vascular endothelium.[136] Platelet-specific antigens, such as HPA-1a ($P1^{A1}$), are uncommon causes of refractoriness because each diallelic system contains a high-frequency allele.[137] In about one-third of transfusion events, the cause of apparent immunologic refractoriness cannot be identified. Thus, most patients receive either random pooled platelets or ABO-compatible random

single-donor platelets until signs of immunologic refractoriness develop; then efforts are made to provide HLA-compatible single-donor platelet products.

The optimal clinical approach to this problem is to prevent HLA alloimmunization. Two methods that prevent or forestall the development of the refractory state, leukocyte depletion of platelet products[138] [139] and ultraviolet (UV) irradiation of platelet products,[140] [141] can reduce HLA alloimmunization by 50%, presumably by eliminating APCs.[142] Class II molecules are important during the cognitive phase of primary alloimmunization. Experimental models of alloimmunization indicate that recognition of class I alloantigens may not occur in the absence of metabolically functional class II-bearing APCs.[143] Platelets bear only class I HLA antigens. Both clinical methods remove the class II-bearing APCs (monocytes, dendritic cells) either physically (through leukodepletion) or functionally (through UV irradiation).

Although the number of thrombocytopenic patients alloimmunized by repetitive transfusion of blood products may be dramatically reduced with these procedures, alloimmunization is not eliminated. Patients at risk for the development of refractoriness to platelet transfusions can be alloimmunized from prior transplantation, pregnancies, and transfusions in which depleted products are not used. In these cases, HLA-matched platelets may be required. At least 1,5003,000 HLA-typed apheresis donors are needed for a reasonable chance of procuring several compatible platelet products for the average patient.[144] [145] When compatible donors are not found, subsequent selection of donors having one or more mismatched antigens is often random. However, it is possible to increase the likelihood of providing mismatches to which the patient is not yet alloimmunized through an understanding of the types of HLA antibodies induced by alloimmunization.

Concepts of HLA Matching and Permissible Mismatching

Table 134-5 summarizes a hierarchical strategy used in our laboratory for the selection of HLA-typed single-donor platelet

TABLE 134-5 -- Search Strategy for Potential HLA-Typed Platelet Donors That Includes Analyses of Public Epitopes and Antibodies to Public Epitopes

Data needed for search
Recipient phenotype (based on private epitopes): A1, 3, B8, 27
Recipient phenotype (based on public epitopes); 1C, , 7C, 8C, 4C, 6C (see Table 134-3)
Recipient serum analysis: anti-2C (A2, 28, 9, B17) HLA antibodies detected
Prioritized donor search
HLA match
HLA compatible[a]
HLA public match[b]
Permissible mismatch[c]
Random crossmatching
Acceptable donor phenotype(s) for:
HLA match: A1, 3, B8, 27

HLA compatible: Any donor with one or two blanks in the phenotype (e.g., A1, , B8,)
HLA public match: Any donor with no public epitope incompatibilities
Permissible mismatch: Any donor lacking the 2C public epitope
Random crossmatching: Any crossmatch-negative donor[d]

From Rodey and Fuller,[5ε] with permission.

[a] Platelet donor has blanks in phenotype due to either homozygosity or rare HLA alleles.
[b] Donor phenotype usually contains mismatched private epitopes, previously referred to as cross-reactive mismatching.
[c] Selection requires careful analysis of recipient serum for HLA alloantibodies.
[d] No evidence of donor-specific HLA or platelet antibodies in recipient serum.

products.[5ε] HLA match (also referred to as A match) requires full HLA-A and -B phenotypes in both recipient and donor and matching of all four alleles. HLA-compatible means that no mismatches exist. This occurs when the donor phenotype contains blanks in the phenotype (fewer than four HLA-A and -B alleles identified). Incomplete phenotyping is usually due to homozygosity or, less commonly, to a rare allele for which the laboratory has no reagents. When it is due to homozygosity, the products are actually matched. HLA public match is also referred to as cross-reactive matching. This is an important partial matching strategy, because antibodies directed against the public epitopes are the most frequent cause of the highly alloimmunized state. Selection of donors matched for public epitopes thus increases the odds that the patient will not have antibodies directed against the platelet product.

Most centers that provide HLA-typed single-donor platelets already select products for refractory patients on the basis of the criteria summarized previously. When donors cannot be found in these groups, the next step traditionally has been to select donors with one or more arbitrarily mismatched antigens. The process can be greatly improved if the specificity of HLA antibodies can be ascertained in advance. When HLA antibody specifications are known, mismatched antigens to which the patient has developed antibodies can be avoided. This strategy is referred to as selective or permissible mismatching. Because the highly HLA sensitized state is caused by relatively few antibodies directed against high-frequency public specificities rather than many antibodies against low-frequency specificities, determination of antibody specificity is usually feasible, even in patients with reactivity against >75% of donor cells. [146] [147]

Finally, selection of HLA-compatible donors by crossmatching is effective if sufficiently sensitive procedures are used to detect anti-HLA antibodies. Crossmatching does not need to be random, and the probability of selecting crossmatch-negative products from available single-donor products is significantly improved by selecting products that are public epitope- or CREG-compatible and do not contain HLA specificities to which the patient has known HLA antibodies.

SUMMARY

HLA molecules were originally defined serologically as transplantation antigens. Clinically, the most common application of histocompatibility testing is still the selection of donors for recipients who require organ and tissue transplantation or compatible single-donor platelet products. The biologic significance of HLA molecules, however, extends far beyond their applications in transplantation, and the greatest potential clinical applications of HLA in transplantation and in the treatment or prevention of other diseases have not been realized. As the crucial role of HLA molecules in immunologic reactivity is further defined and understood, additional therapeutic applications will undoubtedly emerge.

NEUTROPHIL ANTIGENS AND IMMUNE NEUTROPENIAS

The development of antileukocyte antibodies after blood transfusion was first reported by Doan in 1926. [148] Later, the presence of leukoagglutinins was described in association with agranulocytosis. [149] [150] The demonstration of leukocyte antibodies in sera of multiparous women [151] [152] subsequently led to the discovery of the HLA antigens. Concurrent with this event, neonatal neutropenia due to fetomaternal incompatibility was described, [153] and investigation of the involved antibodies demonstrated the existence of several alloantigens expressed only on neutrophils. [154] [155] [156] Further studies of these antigens established their polymorphism and their role in autoimmune neutropenia, [157] [158] febrile and pulmonary transfusion reactions, [159] [160] [161] [162] quinine-induced

neutropenia, [163] and in some neutropenias following bone marrow transplantation. [164]

In addition to neutrophil-specific antigens, other clinically important antigens, not restricted to neutrophils, have been identified by serologic methods. Also, the use of monoclonal antibodies has led to recognition on neutrophils of functionally important structures such as adhesion molecules and receptors. In this section, the emphasis will be on neutrophil antigens defined by alloantibodies.

NEUTROPHIL ANTIGEN CLASSIFICATION

The classification in Table 134-6 is based on differences in distribution patterns, serology and relationships with known functional structures. Neutrophil alloantigens are divided into those expressed only on neutrophils, those shared with other leukocytes, and those with wide tissue distribution. Phenotype and gene frequencies of the antigens commonly associated with neutrophils are described in Table 134-7 .

Neutrophil-Specific Antigens (N Series)

The letter N used in the nomenclature of neutrophil-specific antigens indicates their restriction to neutrophilic leukocytes; genetic loci and individual alleles are identified alphabetically and numerically, respectively. The antigens thus far identified in this group (Table 134-6) all have been involved in the development of alloimmune neonatal neutropenia and represent epitopes on the low-affinity Fc receptor on human neutrophils (FcRIIIb, CD16). Another common property is their absence from myeloid precursors and their appearance after metamyelocyte differentiation. Biochemically, the NA antigens are sialoglycoproteins varying in molecular weight between 50 and 80 kd, depending on the degree of N-glycosylation. Anti-NA antibodies bind to a 2328 kd Mr protein backbone. Neutrophils usually express two types of low-affinity IgG receptors known as FcRII (CD32) and FcRIII (CD16). A third receptor, the high-affinity FcRI (CD64), appears only on neutrophils produced after administration of growth factors (granulocyte colony-stimulating factor, G-CSF). Characterization of the Fc receptors on human leukocytes began with their discovery by Messner and Jelinek in 1970,[165] followed by recognition of their high- and low-affinity forms[166] and further characterization of the low-affinity forms with the use of monoclonal antibodies.[167] [168] In 1985 Werner et al.[169] discovered the localization of the NA antigens on the neutrophils Fc receptor. Subsequently, the low-affinity receptors on neutrophils were found to differ from

Figure 134-7 Comparison of amino acid sequence differences in CD16 molecules as FcRIIIb expressed on neutrophils (NA1, NA2, SH) and FcRIIIa on NK cells.

those expressed on other cells (NK cells, large granular lymphocytes, T_s , and monocytes),[170] the receptor on NK cells having a 610 kd larger molecular mass with transmembrane and cytoplasmic domains. The receptor on neutrophils was found to be susceptible to dissociation by phosphatidylinositol (PI)-specific phospholipase C, and thus it was established to be anchored to the outer leaflet of the membrane lipid bilayer through a PI-anchoring mechanism (Fig. 134-7). The genes controlling these two forms of receptors (FcRIIIA on NK cells and B on neutrophils) are linked and mapped on chromosome 1q22. In the FcRIIIA gene, a single codon difference converts an in-frame UGA termination codon to CGA (Arg), thereby extending the reading frame for the transmembrane and cytoplasmic domains. The two FcRIII molecules also differ in their amino acid sequences,[171] as shown in Figure 134-7 . Whereas no polymorphism is recognized for FcRIIIA, several point mutations have been identified in FcRIIIB that relate to NA1, NA2,[172] and SH[173] alleles. The amplified cDNAs encoding FcRIII differ in NA1 and NA2 at five nucleotides, predicting four amino acid substitutions. As a result, NA1 has four and NA2 has six glycosylation sites, which accounts for higher molecular weight of NA2. Also, one point mutation, 266 C A (A1a Asp), accounts for the difference between NA2 and SH. In addition to a mutation, the SH phenotype has been recently shown to be the result of a gene duplication.[174] Similar to SH, NC1 is associated with NA2. The gene frequencies of NA1 and NA2 have been extensively studied in different populations.[175] [176] [177] NA2 has been found to be the most frequent allelomorph among whites, whereas NA1 constitutes the more frequent gene among Asians.[175] LAN[178] and SAR,[179] causing alloimmune neonatal neutropenia, are high-frequency antigens. Several cases of alloimmune neonatal neutropenia have been described in which the maternal neutrophils

TABLE 134-7 -- Phenotype and Gene Frequencies of Neutrophil Antigens

	NA1	NA2	NC1	NB1	NB2	5^a	5^b
Phenotype (%)	46	88	91	97	32	29	96

did not react with either anti-NA1 or anti-NA2 antibodies.[180] [181] [182] Because neutrophils from these individuals do not react with monoclonal anti-CD16, they are considered to be NA^{null} . Foremont et al.[183] found four NA^{null} individuals among 3,377 randomly tested French donors. Several other antigens (ND1, NE1, and HGA-3) have been described that appear to belong to the NA series. Unfortunately, the unavailability of antisera has prohibited their further characterization.

Extensive studies on FcRIII biology have clarified the functions of the NA antigens. They serve as a binding site for dimeric, complex and aggregated IgG, and participate in phagocytosis of antibody-coated particles. Neutrophils with NA1 phenotypes have been reported to be more efficient than NA2 in the phagocytosis of IgG1 opsonized bacteria, and in forming rosettes with erythrocytes coated with IgG3 anti-Rh antibodies.[184] Clinically, in addition to their high immunogenicity, which leads to alloimmunization and autoimmune disorders, their PI-linked property provides a convenient tool for the diagnosis of paroxysmal nocturnal hemoglobinuria, in which a defective anchoring mechanism results in their reduced expression on the affected neutrophils. The absence of an NA gene does not seem to lead to clinically discernible neutrophil dysfunction. In our laboratory, several members of a family were identified to be NA^{null} and all have remained in perfect health over two decades of observation. It has also been shown that the neutrophil activation results in the release of the NA antigens into plasma.[185] These soluble forms have been considered to influence Ig synthesis by B cells and in HIV infection, and a progressive reduction in their plasma concentration has been suggested to have a prognostic value.[186]

NB System

These highly immunogeneic antigens share many properties with the NA group, even though they segregate independently.[155] [187] The NB antigens are neutrophil specific, appear after differentiation to metamyelocytes, are PI-linked,[188] and their antibodies cause alloimmune neonatal neutropenia and transfusion reactions. In a family with multiple members having the NA^{null} phenotype, we observed absence of NB antigens together with NA. Further clarification of the NB system awaits their study by new molecular methods.

The neutrophil antigens, defined by human antibodies, are not detected on nonprimate neutrophils. In primates, NA2 and NBI (and 5^b) were demonstrated on chimpanzee neutrophils and NBI was detected in baboons.

Antigens (Ond and Mart) Shared by Neutrophils and Other Leukocytes

Antibodies to two high-frequency antigens, Ond^a and $Mart^a$, were found in sera of a multitransfused and a multiparous donor, respectively.[189] [190] Using

antigen-immobilization and immunoprecipitation methods, Simsek et al.[191] have identified Ond^a on $_L$ (CD11a) and Mart^a on $_m$ (CD11b) subunits of $_2$ -integrins, respectively. Molecular characterization has determined that substitutions in $_L$ (Arg 766 Thr) and in $_m$ (Arg 61 His) account for the antigenic differences. It has been speculated that monoclonal antibodies with properties similar to Ond and Mart may have clinical applications in the control of GvHD.

Antigens with Wide Tissue Distribution

ABH

Early reports on the expression of ABH antigens on human neutrophils have not been confirmed. ABO incompatibility does not alter the in vivo survival of [111]In-labeled granulocytes or their ability to localize at the sites of infection.[192] Nevertheless, in granulocyte transfusion, ABO compatibility is required because of the high red cell content of the cell preparation.

HLA Antigens on Neutrophils

A general feature of HLA antigens is their reduced expression or loss concurrent with cell maturation and differentiation. In general, HLA antigens, particularly class II, cannot be detected on cells that do not proliferate. Accordingly, class II molecules are not demonstrable on neutrophils, even with the use of monoclonal antibodies. Class I antigens are detected but at a level much lower than the level at which they are found on lymphocytes.

Group 5

Antigens 5^a and 5^b , the two alleles known in group 5,[187] are expressed on all blood and solid tissue cells except erythrocytes.[193] Antibodies to 5^b cause febrile and pulmonary transfusion reactions,[161] [194] but not alloimmune neonatal neutropenia.

Leukocyte Antigens Defined by Cold-Reactive Antibodies

Anti-I and anti-i antibodies cause reversible cold agglutination of neutrophils similar to red cell hemagglutination.[195] These antigens also have been demonstrated on lymphocytes by cytotoxicity assays. Other types of cold-reactive leukocyte antigens have also been described that react with a cold leukoagglutinin present in low titers in 25% of normal donors. A high-titer cold leukoagglutinin was observed in the serum of a severely neutropenic patient,[196] presumably representing a disorder equivalent of cold agglutinin-associated hemolytic anemia.

METHODS FOR DETECTION OF NEUTROPHIL ANTIGEN/ANTIBODY REACTIONS

The agglutination technique is the method of choice for detection of antibodies against the N series and group 5. These antibodies are not usually cytotoxic. Unlike hemagglutination, neutrophil agglutination is not mediated by the formation of immunologic bridges. Rather, the reaction is a temperature-dependent activity that requires viable cells. Neutrophils, activated by the effects of antibodies, form pseudopods and need hours of incubation to move toward each other and form aggregates. Thus, many reactions will be missed if the incubation period is inadequate. The immunofluorescence assays, [159] including flow cytometry, are also suitable methods. NB2 (9^a) and 5^b, however, do not react in the immunofluorescence tests, indicating the need to use multiple techniques for neutrophil antibody screening. Also, the immunofluorescence test employed for detection of neutrophil-bound IgG may produce misleading results because of nonspecific positive reactions found on neutrophils of patients who receive G-CSF. Subsequent studies in our and other laboratories [197] [198] revealed that G-CSF treatment induces expression on neutrophils of the high-affinity receptor for IgG (FcR1, CD64), which binds IgG from serum. A proper interpretation of a positive immunofluorescence reaction, therefore, must consider conditions likely to lead to expression of FcR1 on the test neutrophils. For monoclonal antibodies, flow cytometry remains the method of choice. Monoclonal antibody-specific immobilization of granulocyte antigen assay (MAIGA) [191] is a promising new method that allows the simultaneous detection of alloantibodies and determination of their position on any cell membrane structure to which a specific monoclonal antibody is available. In this assay, neutrophils are incubated with the test sera and with the desired monoclonal antibody. The cells are washed and then solubilized by detergents to release the alloantibody-Ag-monoclonal antibody

complex. A goat anti-mouse antibody, attached to a solid surface, is used to capture monoclonal antibody, and the presence of human Ig on the captured complex is detected by ELISA. In another method called luminoimmunoprecipitation, [191] neutrophils are biotinylated, incubated with the antibody source, washed, and solubilized, and the complexes are captured by agarose beads coated with staphylococcus protein A. The captured complexes are then subjected to SDS-PAGE, trans-blotted, and then visualized with enzyme-conjugated streptavidin and quantified. With the advent of molecular biology, neutrophil genotyping also has become practical, using well-defined primers to obtain NA1, NA2, and SH PCR products. Other methods used for detection of leukocyte antibodies are reviewed elsewhere. [192]

CLINICAL DISORDERS RELATED TO NEUTROPHIL ANTIGENS AND ANTIBODIES

Immunologically Induced Neutropenias During Infancy

Four types of immunologically induced neutropenia during infancy are recognized: alloimmune neonatal neutropenia, transient neutropenia secondary to maternal autoimmune neutropenia, autoimmune neutropenia of infancy, and autoimmune neutropenia associated with hemolytic anemia or thrombocytopenia.

Alloimmune Neonatal Neutropenia

Alloimmune neonatal neutropenia is a disorder analogous to erythroblastosis that is caused by transplacental transfer of maternal neutrophil-specific alloantibodies into the fetal circulation. [153] [154] [155] [156]

Etiology and Pathophysiology

Maternal alloimmunization can occur any time after the first trimester of pregnancy when the hematopoietic cells are developed. The incidence of pregnancy-induced neutrophil alloimmunization has been estimated to be 0.10.2%, [199] [200] in contrast to 20% for the HLA antigens. The target for antineutrophil antibodies in the fetus and neonates is a small mass confined to mature neutrophils. This results in selective destruction of the mature cells, but the precursors as well as the monocytes and eosinophils are spared. These effects are distinct from those anticipated for the HLA-type antibodies, which must overcome the placental barrier where some cells express HLA. The transferred HLA antibodies are then likely to be neutralized by the antigens in circulation and on the surface of various tissue cells, reducing the antibody levels to the extent that adverse effects can occur only if the antibody concentration is overwhelming.

Infants affected by alloimmune neonatal neutropenia are, as a rule, neutropenic at birth. In some cases, however, neutropenia does not occur at birth but is recognized after a delay of 13 days. The immaturity of the macrophages involved in neutrophil destruction may be one explanation for this delay.

Among various neutrophil specificities, NA1 is involved in 34%, NB1 in 13%, and NA2 in 12% of cases of alloimmune neonatal neutropenia. In one-third of cases other specificities, many not yet defined, have been involved, and in 4% of cases no antibodies are detected. An unexplained high incidence of spontaneous abortion, stillbirth, prematurity, and twin pregnancy has been reported in the affected families.

Pathogenesis

Complement-dependent cell lysis does not seem to occur, because the antibodies do not fix complement. Phagocytosis of the opsonized neutrophils by macrophages has been shown in vitro and in the bone marrow of some of the patients with autoimmune neutropenia of infancy. [201] Antibody-dependent neutrophil agglutination may also prove to be a factor. Such aggregates, produced by activated C5, or experimentally produced by phorbol myristate acetate, become trapped in the lung capillaries. Entrapment of neutrophils may similarly occur in the splenic sinusoids and liver capillaries.

Clinical Presentation and Laboratory Evaluation

Alloimmune neonatal neutropenia is often asymptomatic, and the absence of neutrophils is discovered only if a routine blood examination is performed at birth. In symptomatic cases, fever, respiratory, urinary, or skin infections, mostly caused by staphylococci, -hemolytic *Streptococcus*, and *Escherichia coli*, develop within 1 or 2 weeks. Neutropenia may last from 2 weeks to 6 months. We have recorded only four deaths due to sepsis, all occurring before the disease was recognized.

The total leukocyte count is usually normal, and the diagnosis requires manual differential counts. The blood smear reveals paucity or complete absence of the mature neutrophils, often with eosinophilia and monocytosis (commonly reported as atypical lymphocytes). Band forms or more immature myeloid cells may also be seen. Red blood cells and platelets are normal unless there is an associated neonatal thrombocytopenia. In a retrospective study of sera from 33 affected families, we detected antineutrophil and platelet antibodies in 10. The bone marrow shows myeloid hyperplasia with a characteristic left shift often described as maturation arrest at either myelocyte, metamyelocyte, or band stage. Occasionally, the segmented neutrophils are found in the marrow in near-normal numbers.

Once neutropenia is recognized, the alloimmune nature of the disorder must be established by demonstrating neutrophil-specific alloantibodies in the maternal sera. Neutrophil specificity of the antibodies can be established by absorption of the maternal plasma with paternal platelets to remove non-neutrophilic antibodies.

Transient Congenital Neutropenia

Mothers with autoimmune neutropenia may give birth to infants who develop transient neutropenia. [202] In one of our patients, the mother had a persistent leukopenia, mild Crohns disease, and a palpable spleen. The fourth child, a premature infant, was born with a normal leukocyte count but on day 5 had only 1% neutrophils. The neutropenia lasted 6 weeks. Four years later the mother gave birth to her fifth child, who also developed a transient but severe neutropenia lasting 2 weeks. In the second family, the mother had had chronic neutropenia and a slightly enlarged spleen for at least 3 years when she gave birth to her first infant. On the second day of life, the infant had an absolute neutrophil count of 500, which returned to normal within 4 months. The following year, a second child was born and found to be neutropenic after 1 week, recovering within 4 weeks. The autoimmune nature of the mothers neutropenia was established by positive serologic tests.

Autoimmune Neutropenia of Infancy

Chronic benign neutropenia of infancy and early childhood has long been recognized. The autoimmune nature of this disorder was established when autoantibodies with specificity for neutrophils were demonstrated. [157] Autoimmune neutropenia of infancy is the most common form of chronic neutropenia in infants. [158] Severe neutropenia is usually recognized when the child is 47 months old. The diagnosis of neutropenia is made either by a routine blood test or during evaluation of an infection. The chronicity becomes apparent when the blood tests, repeated after recovery from infection, remain abnormal. The clinical course of autoimmune neutropenia of infancy is relatively mild, with occasional stomatitis, otitis, diarrhea, and respiratory infection. The incidence of these complications diminishes as the child grows older. Occasionally, chronic otitis results in

hearing loss, and persistent gingivitis in older children leads to tooth loss. Neutropenia is self-limited, and complete recovery within 16 years is the rule. Recurrence of

the autoimmunity has not thus far been observed on long-term follow-up. The cause of and the reason for the spontaneous loss of the autoantibodies have not been clarified.

Autoimmune Neutropenias Associated with Hemolytic Anemia and Thrombocytopenia

Autoimmune neutropenia may occur in combination with autoimmune hemolytic anemia and thrombocytopenia during the perinatal period. This disorder is distinct from autoimmune neutropenia of infancy, the clinical course often being much more severe.

Management of Immune Neutropenias in Infancy

These types of neutropenias are usually self-limited and compatible with normal growth and development. Affected infants, however, should receive protective mouth and skin care and kept from exposure to potential sources of infection. Hospitalization and vigorous antibiotic therapy are required only for severe infections. Recombinant G-CSF has temporarily corrected neutropenia in both alloimmune neonatal neutropenia and autoimmune neutropenia of infancy. The dose required varies from 1 to 5 g/kg and can be administered subcutaneously one to three times per week after a few initial daily doses. This treatment should be used only in symptomatic cases, and prophylactically when patients need surgery. Long-term treatment should be avoided. Intravenous administration of large doses of -globulin also reverses the neutropenia in autoimmune neutropenia of infancy. [203] In alloimmune neonatal neutropenia, the demonstration of neutrophil antibodies in the maternal sera indicates potential occurrence in future pregnancies. Preventive treatment with IV IgG during the last trimester, as recommended for alloimmune neonatal thrombocytopenia, is not warranted because of the benign nature of the disorder. But mothers with neutrophil alloantibodies should be warned about the possibility of febrile reactions if they receive blood transfusions. They should also be advised that transfusion of their blood, or even their packed red blood cells, into normal recipients might cause a severe and potentially fatal pulmonary transfusion reaction.

Differential Diagnosis of Neutropenias in Infants

The prognosis of neutropenias in infancy varies according to cause. Therefore, once neutropenia is recognized, every effort should be made to determine its cause. Immunologically induced neutropenias, except those associated with hemolytic anemia and thrombocytopenia, have a benign course. The nonimmune congenital forms, by contrast, last for life and may be complicated by repeated life-threatening infections. In alloimmune neonatal neutropenia, alloantibodies are demonstrated in the maternal sera. In autoimmune neutropenia of infancy, documentation of a normal neutrophil count before the apparent onset of the disease is most valuable. The diagnosis of autoimmune neutropenia of infancy is established by demonstrating antibodies in the affected children rather than in the maternal sera. A positive diagnosis of the transient congenital form is made by documenting an autoimmune neutropenia in the mother. The differential diagnosis includes disorders of neutrophil production, stem cell abnormalities, and neutropenias associated with infection.

Neutropenia Associated with Infections

The relative neutrophil reserve (the total number of neutrophils, bands, and metamyelocytes) in the bone marrow in newborn infants is small compared to adults. The bone marrow reserve in newborn rats has been estimated to be $2 \pm 0.1 \times 10^6$ /g, compared to $4.5 \pm 0.2 \times 10^6$ /g in adult rats.[204] Moreover, newborn rats, unlike adults, cannot increase the rate of stem cell proliferation in response to bacterial inoculation, presumably because their myeloid cells are already maximally stimulated. Similar limitations may contribute to the neutropenia associated with viral and bacterial infections in infants. In all these cases, other diagnoses should be suspected if the neutropenia persists after the acute inflammation has subsided.

Primary Autoimmune Neutropenias in Adolescents and Adults

The hematologic profile is that of an absence or reduction in the number of neutrophils, with or without a reduction in other granulocytes and lymphocytes. Monocytosis is commonly present. The bone marrow typically reveals an absence of mature cells with an increased number of myeloid precursors. Splenomegaly is not a consistent finding, and clinical manifestations vary. The serologic diagnosis is made by demonstrating neutrophil antibodies, and in some cases with specificity for the known antigens. In rare instances, neutropenia may be caused by cold-reactive antibodies.

Secondary Immune Neutropenias in Adults

Autoimmune neutropenias may be associated with systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, Grave disease, and lymphoproliferative disorders (e.g., T-cell or hairy cell leukemia). A combination with hemolytic anemia or thrombocytopenia, in a characteristic sequence, has been designated alternating autoimmune hemocytopenia. In this form, the disease is initially limited to only one of the cell types. Remissions occur with or without treatment, but relapses may involve other cell types. Alternation between neutropenia, thrombocytopenia, and hemolytic anemia continues until pancytopenia, often resistant to treatment, prevails. Neutropenia may also occur in infectious mononucleosis or *Mycoplasma* pneumonia. In these cases, cold-reactive antibodies have been considered to be a contributory factor.

Febrile Transfusion Reactions

The association between leukoagglutinins and febrile transfusion reaction has long been established. Anti-HLA, 5^b, and antibodies against neutrophil-specific antigens have been implicated. Because these antibodies do not occur naturally, the reaction occurs only in previously alloimmunized patients. More recently, nonhemolytic transfusion reactions have been attributed to the presence of cytokines such as IL-I and IL-6 in the donors plasma. [205] These cytokines are probably generated during storage of non-leuko-reduced blood products. In either case, transfusion of leuko-reduced products will minimize the reaction.

Pulmonary Transfusion Reaction

This serious complication is a noncardiogenic pulmonary edema attributed to the presence of leukocyte antibodies in the donors plasma and should be suspected in all patients who experience unexplained acute respiratory distress syndrome following transfusion of blood or blood products. The radiologic appearance of bilateral pulmonary infiltrates, without cardiomegaly or pulmonary vascular congestion, is diagnostic.

FUTURE DIRECTIONS

The development of new methods such as MAIGA and the more frequent use of techniques of molecular biology should

further facilitate characterization of the ever-increasing number of neutrophil antigens, especially those that represent polymorphism of adhesion molecules and their receptors. Significant progress has already been made in elucidating the functions of the FcRIII molecule. It is now known that collaboration between this receptor and FcRIIa is involved in the phagocytosis of opsonized bacteria, and that the binding of soluble CD16 molecules to its receptor, the CR3 on monocytes, induces production of IL-6 and IL-8. [206]

In autoimmune neutropenia, a disorder far more common than is generally appreciated, often neutrophils are the only affected cells. This model of autoimmunity, in which the target can be defined at its amino acid sequence (i.e., NA antigens), offers an opportunity for research on the pathophysiology of the immune system. Examples of autoimmune leukopenia in which neutrophils and other leukocytes are affected together may now be explained by the discovery of new target antigens that are shared by neutrophils and other leukocytes, like those representing adhesion molecules and their receptors. Moreover, understanding of the relationships between the target antigens and functional structures may reveal why some neutropenic patients remain asymptomatic whereas others, even with higher leukocyte counts, develop serious symptoms.

A promising new approach in the treatment of autoimmune neutropenia is the administration of G-CSF. Treatment with low doses of G-CSF leads to elevated neutrophil counts and elimination of symptoms. In these patients, treatment with G-CSF probably converts an uncompensated disorder to a compensated form, analogous to compensated forms of autoimmune hemolytic anemia in which the patient maintains a normal hematocrit. High doses and long-term administration of G-CSF, however, invariably result in thrombocytopenia, a complication that should be avoided but is correctable by reducing the dose. The effects of G-CSF on immunologically induced neutropenias may prove to be more profound. In this model, the autoimmune disease is controlled not by immunosuppression but by increasing the mass of the target organ, a feat not achievable in other tissues. The impact of this challenge to the immune system needs to be evaluated. The increase in the target mass may drive the affected immune system either to exhaustion, leading to a full recovery, or perhaps to further aggression.

With the introduction of G-CSF, there will be a reduction in the use of intravenous immunoglobulins. IV IgG, however, may be needed in cases of leukopenia in which cells other than neutrophils are destroyed. The future will determine whether growth factors with broader hematopoietic activities would be beneficial in these forms of leukopenia.

Chapter 135 - Principles of Red Blood Cell Transfusion

Paul M. Ness
Kate Rothko

INTRODUCTION

Approximately 12 million units of blood were transfused in the United States in 1992. This figure is striking if one remembers that the era of blood transfusion began only about a century ago, with the discovery of the ABO system by Landsteiner.[1] Actually, it was not until about four decades later, with the description of the Rh system by Levine, Stetson, Landsteiner, Wiener, and Peters[2] [3] [4] and, perhaps even more critically, with the introduction of a safe and effective anticoagulant-preservative solution suggested by Loutit and Mollison,[5] that the clinical practice of transfusion as we know it began. Another important landmark at about the same time was the development of the antiglobulin test by Coombs,[6] which permitted the detection of antibodies in recipient plasma that did not produce direct agglutination in the test tube but might be capable of causing in vivo red cell destruction.

After these initial breakthroughs, the next several decades of development in transfusion practice focused on improvements in the preservation of red cells and on expansion of knowledge of red cell antigens and their clinical significance. However, it was not until the mid-1960s, with the introduction of plastic blood packs by Walter and Murphy,[7] that a new phase, the era of component therapy, began. This innovation, combined with the ability to store blood for extended periods, again revolutionized transfusion practice.

The next two decades saw major advances in transplantation and open heart surgery and in therapy for many malignancies, supported by the ready availability of blood component support. During this period, although some adverse effects of transfusion, such as transmission of hepatitis, became well established, the new-found benefits of transfusion seemed to outweigh any risks.

Since the recognition in late 1982 that the human immunodeficiency virus is transmissible by blood transfusion, the risks of transfusion are weighed more heavily against the benefits. Donor blood is subjected to an ever-growing battery of tests to detect potentially transmissible infectious agents, and the era in which ABO compatibility was the major hurdle seems eons away.

RED BLOOD CELL PRESERVATION AND STORAGE

The first key to storage of blood for later transfusion is a stable, minimally toxic anticoagulant with preservative properties. During the early 1900s it was recognized that citrate met these criteria.[8] [9] [10] Although slightly more toxic than heparin, if given rapidly and in large amounts, citrate has preservative action that heparin lacks. Citrate has the added advantage of not causing systemic anticoagulation in the recipient.

The other factor essential for long-term storage is a mechanism to maintain cell viability and function. Fresh transfused red cells have a good survival rate in the recipients circulation, with a destruction rate approximately equal to that of the recipients own cells: 1%/day. [11] The arbitrary standard used for stored red cells requires 70% to remain in the circulation for 24 hours.

Adenosine Triphosphate Levels

Adenosine triphosphate (ATP) levels appear to be a major determinant of red cell viability. [12] [13] [14] The drop in cellular ATP levels during storage has been correlated with the change from a disk to a sphere configuration, with increased cell rigidity, and with loss of membrane lipid leading to decreased critical hemolytic volume. [15] For this reason, most efforts to extend the period of red cell storage have focused on ways to maintain intracellular ATP levels. First, dextrose was introduced into the citrate solution (citrate-phosphate-dextrose [CPD]: 21 days), to which adenine was added (CPDA-1: 35 days). Recently, two additive solutions containing additional dextrose and adenine (Nutricell, or AS-3) or dextrose and adenine plus mannitol (Adsol, or AS-1) have been licensed, extending the maximum storage time to 42 days (Table 135-1). Unfortunately, ATP is not the sole determinant of red blood cell viability. [16] It appears that when intracellular ATP is maintained at >1.5 mol/g hemoglobin (Hb), other factors also predict viability. Because these factors remain undefined, no in vitro test is available to predict the in vivo survival rate of stored red cells.

2,3-Diphosphoglycerate Levels

Stored red cells must also maintain their capacity to deliver oxygen. It was not until 1967 that the central role of 2,3-diphosphoglycerate (2,3-DPG) in releasing oxygen from oxyhemoglobin was recognized.[17] [18] Interestingly, it had already been observed that the oxygen dissociation curve of stored red cells was shifted to the left. [19] Attention was then focused on ways to maintain

TABLE 135-1 -- Biochemical Changes in Stored Red Cells

Variable	CPDA-1		Adsol
	Fresh	35 Days	35 Days
In vivo survival (at 24 hours) (%)	100	<71.0	<88.0
pH	<7.5	< 6.7	< 6.7
ATP (% initial)	100	<45.0	<76.0
2,3-DPG (% initial)	100	<10.0	<10.0
Plasma K^+ (mEq/L)	5.1	<78.5	<49.0

Data from Fenwal Laboratories, [117] Zuck et al.,[118] and Moore et al.[119]

high levels of 2,3-DPG in stored cells. The first anticoagulant introduced on a large scale, acid citrate-dextrose, was ineffective because of its low initial pH, so that the new CPD, with its higher initial pH and slower fall in pH, was superior. CPDA-1, Adsol, and Nutricell have not further improved 2,3-DPG maintenance. Although 2,3-DPG depletion of stored red cells is known to decrease their oxygen delivery, the clinical significance of these findings is unclear. 2,3-DPG levels in stored cells are rapidly regenerated in vivo, rising to 50% of normal within several hours and to normal within 24 hours. [20] Although a patient with normal cardiac status should be able to compensate by increasing cardiac output to maintain normal oxygen delivery until 2,3-DPG levels are regenerated, an improvement in 2,3-DPG preservation in stored red cells is still desirable. New additive systems containing ascorbate, ascorbate-2-phosphate, or other materials that maintain pH and 2,3-DPG levels are under study but have not yet been licensed for clinical use. [21] [22]

By-products of Red Cell Storage with Potentially Adverse Effects

Infusion of large volumes of blood with citrate anticoagulant over a short period may cause plasma citrate levels to reach the toxic range. The primary concern is the cardiovascular effects of hypocalcemia caused by chelation of calcium by citrate. The risk of citrate toxicity is exacerbated in the setting of liver dysfunction or liver immaturity, so that the situations of greatest risk appear to be exchange transfusion of premature infants and massive transfusion. Despite these theoretical considerations, there is little documented evidence of clinical citrate toxicity, and the problem can usually be prevented by slower infusion. [23] If large amounts of blood have to be infused over a very short period, administration of calcium gluconate can be considered, but whether the benefits justify the risk is controversial. [24]

Another issue with prolonged storage is the question of excess potassium in the red cell supernatant that could cause cardiac problems. At a storage temperature of 4°C the red cell sodium-potassium pump is essentially nonfunctional, and intra- and extracellular levels gradually equilibrate. In addition, the hemolysis that occurs during the storage period results in increased potassium in the supernatant. However, because the total volume of plasma in red cell concentrates is low (70 ml), the total potassium burden is only 5.5 mEq at product expiration. Practically speaking, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure. In this situation, fresher units of red cells or washed red cells may be used.

Microaggregates consisting of platelets, leukocytes, and fibrin form during blood storage. Although several studies have shown that pulmonary dysfunction after massive transfusion may be significantly diminished by the use of a microaggregate filter of pore size 2040 m, [25] [26] other studies have not confirmed microaggregates as the cause of hypoxia.[27] [28] Since microaggregate filters have been found to slow the infusion rate, their use is not uniformly recommended in cases of trauma. Some authorities suggest their application in cardiopulmonary bypass and when more than 5 units of blood are to be given. [29]

Since their introduction in the 1960s, plastic blood bags used for storing red cells have been made from polyvinylchloride containing the plasticizer di(2-ethyl)phthalate (DEHP), which confers pliability. Nevertheless, questions have been raised for many years about the safety of DEHP, which is known to be lipophilic, to leach from the bag and to be present at levels of 5070 mg/L in stored red cells. [30] Numerous studies in animal models have addressed the toxicity of the substance and are summarized in a comprehensive review.[31] The DEHP effects found in animals range from a shock lung-like picture, to loss of fertility, to

hepatocarcinogenicity, to teratogenicity. Although

none of these adverse effects has been documented in humans, the question of potential toxicity has obviously been raised, initiating a search for alternative materials.[32] The situation is complicated by DEHP having been shown to have a significant stabilizing effect on the red blood cell membrane, and red cells stored in various containers lacking DEHP have shown unacceptable recovery at the end of the storage period. This decreased recovery has been shown to be due to increased hemolysis and increased osmotic fragility. [33] Recently, however, Baxter-Fenwal has introduced a new plastic, PL 2209, a polyvinylchloride plasticized with butyryl-*n*-trihexyl-citrate (BTHC) in place of DEHP. BTHC undergoes less leaching from the bag than does DEHP and has passed numerous safety tests. In addition, the 24-hour post-transfusion recovery of red cells held in these bags to the end of the permitted storage period is excellent (83%), and hemolysis is minimal. [34]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

RED BLOOD CELL COMPONENTS

Modern transfusion medicine assumes that it is preferable to give the patient the specific portion of the blood required rather than whole blood: red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for microvascular bleeding. The component therapy approach allows for optimal use of a limited community resource (Table 135-2). Methods for extended storage of red cells do not result in optimal preservation of other blood elements.

Today the clinician wishing to increase the patients oxygen-carrying capacity is more likely to be using a red cell concentrate than whole blood, although there may still be situations in which whole blood, if available, is appropriate. Several modifications can be made to red cell products to render them leukocyte or plasma depleted that have particular clinical applications. Red cells can also be frozen for long-term storage.

Whole Blood

A unit of whole blood is collected in CPDA-1 anticoagulant, giving it a shelf-life of 35 days and a volume of approximately

TABLE 135-2 -- Red Cell Components: Characteristics and Indications

Component	Characteristics	Indications
Whole blood	High volume; good flow	Combined red cell/volume deficit (massive hemorrhage; exchange transfusion)
Red blood cells	Lower volume	Red cell deficit
	Higher hematocrit	
	Good flow in AS-1	
Leukocyte-reduced red blood cells	$<10^8$ leukocytes	Prevention of febrile reactions
	$<10^8$ leukocytes	Reduction of alloimmunization
Washed red cells	Plasma depletion	Prevention of severe allergic reactions
	Must use within 24 hr	Prevention of anaphylaxis in IgA deficiency
Frozen red cells	Long-term storage	Rare donor unit storage
	Plasma and leukocyte depletion	Autologous storage for postponed surgery
	Must use within 24 hr of thawing	

510 ml (450 ml of blood plus 63 ml of CPDA-1). Within 24 hours of collection, the platelets in the unit, [35] as well as the granulocytes, are dysfunctional, and several plasma coagulation factors have fallen to suboptimal levels. [36]

Whole blood has the single advantage of correcting simultaneous deficits in oxygen-carrying capacity and blood volume. Therefore, whole blood is indicated in the management of trauma or in surgical cases involving extensive blood loss. In this setting, whole blood has two distinct advantages: (1) it provides colloid osmotic pressure and some coagulation factors not supplied by crystalloid solutions, and (2) it does not expose the recipient to red cells and plasma from different donors.

However, the goal of using whole blood for all cases of concomitant red cell and volume deficit is a very difficult one to achieve in practice. Not only is it difficult to balance the overall community need for production of other blood components, but it may be difficult for the hospital to predict inventory needs. Most cases requiring massive transfusion involve either trauma victims or emergency cardiovascular surgery. Although various studies of this issue maintain that 2050% of red cell transfusions should be met with whole blood, [37] [38] [39] some trauma centers manage patients exclusively with red cell concentrates. [40]

In the absence of whole blood, the simultaneous need for volume and oxygen-carrying capacity can be met by combining red cell concentrates with one of several volume expanders. If blood loss is mild to moderate, volume can generally be replaced with crystalloid (e.g., normal saline), which has the dual advantages of sterility and economy. In the setting of massive transfusion, there may be a need to replace intravascular proteins. Colloid solutions (albumin and plasma protein fraction) are expensive but are preferred to plasma because they carry no risk of disease transmission. In fact, plasma is rarely indicated, even in the setting of massive transfusion, unless there is a well-documented coagulopathy, as in the setting of liver failure. [41] [42] In addition, in some cases of trauma and cardiovascular surgery platelet transfusion may be indicated to combat microvascular bleeding from dilutional thrombocytopenia or bypass-associated platelet dysfunction. The transfusion of an average adult dose of platelets usually supplies the equivalent of several units of relatively fresh plasma, so that there is no reason for further donor exposure by the administration of frozen plasma.

Whole blood that is <5 days old is indicated for exchange transfusion in infants to provide the proper hematocrit and coagulation factors while limiting donor exposure. For elective surgery commonly associated with massive transfusion, particularly liver transplantation, in which large amounts of plasma are transfused, whole blood would certainly be advantageous if it could be made available.

Red Cell Concentrates

Red cell concentrates are obtained from whole blood after removal of most of the plasma for the production of frozen plasma or platelets, or both. At most blood centers, the red cells are then mixed with 100 ml of an additive nutrient solution that extends the storage period to 42 days [43] and results in flow properties similar to those of whole blood. [44] Alternatively, red cells can be produced from CPDA-1-anticoagulated blood and stored for 35 days.

Red cell concentrates are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in chronic anemia. These concentrates have a particular advantage over whole blood in patients with cardiovascular compromise, who might be unable to deal with the volume of whole blood.

Another setting in which packed cells rather than whole blood must be used is the emergency transfusion of patients of unknown ABO type. Concentrated type O red cells are transfused after the plasma containing isohemagglutinins is

removed to prevent potential hemolysis of the recipients red cells.

Leukocyte-Reduced Red Cells

Leukocyte-reduced red cells (LRRCs) can be prepared by a variety of methods, resulting in differing degrees of white cell removal. The minimum standard, set by the American Association of Blood Banks (AABB), is a leukocyte number in the final component of $<5 \times 10^8$.[45] Early techniques of preparation involved centrifugation or washing with saline, whereby the buffy coat was repeatedly removed. Subsequently, a second-generation technique known as the spin-cool-filter method was introduced. This required use of 1-week-old red cells, which were centrifuged and then cooled for 4 hours to enhance microaggregate formation before passage through a microaggregate filter. Currently the most widely used method of leuko-reduction is filtration, which can be performed either in the laboratory or at the bedside. The various filters on the market result in >99% leukocyte reduction while depleting <10% of the red cells. [46] Most recently, blood bags with in-line filters, which allow prestorage leuko-reduction, have become available.

The major indication for the use of LRRCs has been the prevention of the nonhemolytic febrile transfusion reaction, which is the most common adverse effect of transfusion, particularly in multiply transfused patients or multiparous females. [47] Traditionally these reactions have been felt to be mediated by antibodies directed against leukocyte antigens,[48] but whether lymphocyte HLA antigens or granulocyte-specific antigens are the major targets has remained a subject of controversy. [49] Depletion of leukocytes to $<5 \times 10^8$ has been shown to prevent, or at least ameliorate, such reactions in most patients. [50] [51] Increasing evidence has accumulated suggesting that cytokines play a role in causing these reactions. [52] [53] Because cytokines may be released from leukocytes during storage, it has been suggested that prestorage leuko-depletion may be more helpful. At present, however, the practice is relatively limited, and it remains unclear whether this method will prove cost-effective in preventing such reactions. [53]

A second important indication for LRRCs is the prevention of alloimmunization to HLA antigens that can adversely affect post-transfusion platelet increments, such as in cancer patients undergoing chemotherapy. [54] [55] This approach will be effective only if platelets for transfusion can also be white cell depleted. According to current AABB standards,[45] the total leukocyte number must be $<5 \times 10^6$ when intended for this purpose. With the introduction of third-generation leuko-reduction filters for both red cells and platelets, this goal is achievable. However, there is little consensus on the degree of leukocyte depletion necessary to significantly diminish or eliminate alloimmunization.[56] [57] A recent multicenter study known as TRAP addressed this issue. The recently published data showed that the use of leuko-reduction filters significantly decreased the rate of alloimmunization but did not totally eliminate the problem. [58]

Leuko-reduction has also been studied for its ability to prevent transfusion-mediated immunosuppression, which is of particular concern in the postoperative period. (See further discussion under Appropriate Transfusion Practice in Various Clinical SettingsPerioperative Period.) Data collected to date suggest that this practice may be of value.[59] Indeed, even simple removal of the buffy coat from red cells (which is a routine procedure during component preparation in Europe) may provide a sufficient degree of leuko-reduction. [60] Because component preparation in the United States does not include a buffy coat removal step and because soluble white cell fragments may be capable of mediating immunosuppression, a prestorage leuko-reduction method might be required to abrogate this adverse effect in transfusion recipients in the United States. However, despite numerous studies in this area, the data remain contradictory. Therefore, at the present time, leuko-depletion for the sole purpose of preventing immunosuppression does not appear to be justified.

Washed Red Cells

Red cells are washed, using isotonic saline solutions, by either automated or manual techniques. Automated techniques are more efficient, but there is always some degree of red cell loss with each wash cycle. Because the washing is performed in an open system, the resulting product must be transfused within 24 hours.

The primary aim of washing is to remove plasma proteins, although some leukocytes and platelets are removed simultaneously. The major indication for washed red cells is the prevention of severe allergic transfusion reactions, thought to be mediated by recipient antibodies (most likely IgE) to donor plasma proteins. Washing is recommended when reactions are recurrent and severe, even in the face of antihistamine administration. In IgA-deficient patients who have preformed antibody to IgA, IgA-containing plasma can actually cause anaphylaxis (see Chap. 141). [61] Multiple cell washes may be required to remove the contaminating plasma protein. [62] [63]

Another setting in which washed cells may be indicated is paroxysmal nocturnal hemoglobinuria. [64] However, one study has suggested that these patients do not require washed cells.[65] In theory, washing removes complement components that could cause lysis of the patients complement-sensitive red cells.

Frozen Red Cells

Red cells can be frozen (with glycerol used as a cryoprotective agent) and stored in liquid nitrogen or mechanical freezers. The required concentration of glycerol depends on the rate and the temperature of freezing.[66] [67] [68] The freezing process destroys other blood constituents, except for a small percentage of immunocompetent lymphocytes.[69] Red cells are prepared for transfusion by thawing and washing away the glycerol using a series of progressively less hypertonic saline solutions, allowing glycerol to diffuse gradually from the cells to prevent hemolysis. The cells are resuspended in isotonic saline solution containing glucose. The extensive washing removes 99.9% of the plasma[70] as well as cellular debris.

Red cells can be stored in the frozen state for 10 years by regulation [45] and for considerably longer periods, with good viability. [71] After thawing and washing, storage is limited to 24 hours because of the open system. The 24-hour post-transfusion survival rate is 8590%. [68]

Frozen cells have been shown to maintain prefreezing ATP and 2,3-DPG levels. The standard is to freeze within 6 days of collection, while these factors are still present in high levels. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine has provided excellent results.[72]

The major indication for frozen red cells is the maintenance of a collection of rare donor units for transfusion to patients with unusual red cell phenotypes who have developed alloantibodies. Sometimes patients with such rare phenotypes can make autologous donations that can be frozen for later use. Cells from autologous donors can be frozen if more units are required than can be collected in the 42-day liquid storage period or if surgery is postponed. One other legitimate use for frozen red cells deserves mention. In patients with severe aplastic anemia awaiting bone marrow transplantation and in whom transfusion cannot be avoided, frozen cells have the least adverse effect on subsequent graft survival. [73] [74]

Because of the high cost and cumbersome nature of freeze-thaw procedures, other uses of frozen red cells are somewhat

difficult to justify. Occasionally, frozen red cells are effective in preventing severe febrile transfusion reactions when LRRCs in conjunction with medications have failed.

APPROPRIATE TRANSFUSION PRACTICE IN VARIOUS CLINICAL SETTINGS

The response to red cell transfusion varies from patient to patient. In the absence of increased red cell destruction or sequestration, 1 unit of red cells can be expected to increase the Hb level by 1 g/dl or the hematocrit by approximately 3%. This rise is usually not measurable until 24 hours after transfusion, when the plasma volume has had time to return to normal. On the basis of a half-life of about 57.7 days for donor red cells, Mollison et al. [11] calculated that an average-sized adult requires 24 ml red cells/day to maintain a given hematocrit, assuming no red cell production. Petz and Tomasulo [75] estimated this requirement to be 2 units of red cells every 2 weeks.

Several factors can adversely affect the survival of transfused red cells. Hemolysis caused by either immune red cell damage or mechanical trauma shortens the survival of transfused cells, much as it shortens the survival of the patients own cells. Hypersplenism can lead to initial sequestration as well as increased destruction of red cells. Continued blood loss is another obvious cause of suboptimal response to transfusion. It should also be emphasized that transfusion suppresses erythropoiesis, so that the net result of transfusion may be less than expected. [76]

Chronic Anemia

As a rule, signs and symptoms attributable to anemia are unlikely to develop at an Hb level of >78 g/dl. [75] When the anemia is of gradual onset, the bodys compensatory mechanisms for maintaining oxygen delivery to the tissues come into play. Cardiac output is increased and intracellular 2,3-DPG is increased; thus, oxygen unloads at a lower oxygen saturation of Hb. When chronic anemia is due to red cell destruction, the healthy bone marrow can respond by increasing production by up to sixfold.

Red cell transfusion is always symptomatic and supportive rather than definitive therapy for anemia. Transfusion should be used only when there is no definitive treatment for the underlying cause, or when the severity of the anemia and the clinical manifestations in the patient make it impossible to wait for the effects of the treatment to be realized.

Generalizations about whether or when to transfuse red cells, and how many, are difficult to make and are usually inappropriate. The clinical impact of anemia varies, depending on its pathogenesis, rate of onset, the presence or absence of accompanying hypovolemia, and, most important, the individual patient. The Hb level at which a given individual manifests the signs and symptoms of anemia relates, in part, to underlying health status, cardiorespiratory reserve, and activity level.

Perioperative Period

Many generalizations have been made about the appropriate transfusion management of acute blood loss, often with very little hard data to support the arguments. One rule of thumb is that blood losses of 10% of total blood volume require no replacement therapy at all, losses of up to 20% can be replaced exclusively with crystalloid solutions, while losses of >25% generally require red cell transfusion to restore oxygen-carrying capacity, along with crystalloid and sometimes colloid solutions to restore intravascular volume and maintain perfusion. For years the figure of 10 g/dl of Hb has been used as the gold standard for the red cell transfusion trigger during the perioperative period. [77]

In the acquired immunodeficiency syndrome era, however, this approach is no longer justified. Each case must be evaluated individually on the basis of clinical signs and symptoms, rather than on the basis of laboratory values. If the cardiovascular system is healthy and the degree of hypoperfusion is not significant, good tissue oxygenation can be maintained at much lower Hb levels. A recent National Institutes of Health consensus conference suggested that many surgical patients do not need transfusion unless the Hb level falls to <7 g/dl. [77] Recent re-examination of these issues has laid to rest the long-held belief that these lower Hb levels interfere with wound healing[78] or automatically make general anesthesia a risk. [79]

Given that red blood cell transfusion should be tailored to individual needs, the question arises, is there any readily available, objective measurement that can be used to determine how low the Hb level can safely be allowed to fall before red cell transfusion is initiated? Several recent studies of acute normovolemic anemia in rats,[80] dogs,[81] and baboons[82] [83] have focused on the whole body oxygen extraction ratio (ER) as an indicator of when to transfuse. These studies make the seemingly valid assumption that the heart is the major organ at risk. With progressive hemodilution, healthy animals with normal coronary trees were able to maintain normal levels of oxygen consumption through a moderate increase in cardiac output, an increase in coronary blood flow, and a linear increase in the ER up to a ratio of 50%. As the hematocrit fell to <10%, however, oxygen consumption began to fall off, and the animals were no longer able to increase the ER enough to compensate for the low oxygen blood tension. An ER of 50% was found to represent the critical point at which the myocardium converted from aerobic to anaerobic metabolism, reflected in net lactate production. At this point, metabolic acidosis set in, resulting in hemodynamic instability. Most recently, experimenters compared the response to acute normovolemic anemia in healthy dogs to the response in dogs with critical coronary stenosis and found that both groups converted to anaerobic metabolism and went into congestive heart failure at an ER of >50%, but that an ER of >50% occurred at a hematocrit of 17.0% in the dogs with critical stenosis, compared to a hematocrit of 8.6% in the healthy group.[84] On the basis of these studies, it seems reasonable to extrapolate to humans and to suggest that the ER, which is a variable readily obtainable from standard hemodynamic monitoring devices, can be used to help assess transfusion need and that an ER of 50% can be used as a red cell transfusion trigger, since it appears to be a valid indicator of marginal myocardial oxygen reserve in both healthy persons and individuals with coronary artery disease.

Because the potential immunomodulatory effects of transfusion have been studied mainly in surgical patients, this topic is appropriately addressed here. The possibility of immunomodulation by allogeneic transfusions in humans was first suggested about 25 years ago when improved renal allograft survival was reported in pretransplant transfusion recipients. [85] A potential link between allogeneic transfusion and an increased rate of cancer recurrence and postoperative infection was first raised in the 1980s, [86] [87] [88] and numerous retrospective and prospective observational studies supporting these contentions have been reported in the literature since that time. These studies, as well as reports from investigations with opposing data, have been analyzed in two recent reviews on the topic. [89] [90] Studies in experimental animals have also yielded contradictory results. Research using animal models and human subjects on the specific immunomodulatory effects of transfusion has consistently pointed to depression of cell-mediated immunity, although the specific defects seen have varied. [91] [92] The mediators of these immunomodulatory effects appear to be leukocytes present in cellular blood components, including whole blood and red blood cells. [89] However, the fact that plasma transfusions have also been associated with immunosuppression suggests that soluble leukocyte fragments may also be capable of mediating the

adverse effect.[93] [94] Several well-designed, prospective, randomized controlled trials have been conducted comparing transfusion with leuko-reduced blood components or autologous blood to transfusion with unmodified allogeneic blood components. Based on previous reports and the apparent pathogenesis of the immunosuppression, it was predicted that the recipients of leuko-reduced blood or autologous blood would have a significantly lower risk of immunosuppression.

However, the results of these studies do not fully support the findings of the earlier observational studies, and controversy continues to rage. [60] [89] [90]

Red Cell Transfusion in Neonates

In neonates, as is often the case with adult patients, it is convenient to consider periodic, small-volume transfusion separately from massive transfusion situations. Not only are the trigger for transfusion and the optimal type of component very different in the two settings, but, particularly in infants, the potential adverse effects may be quite distinct.

Low-volume red cell transfusion is rarely indicated in full-term infants unless some acute blood loss has occurred at birth or an intrauterine situation has led to prenatal anemia. In contrast, premature infants are frequent recipients of these transfusions. In the intensive care setting, the premature infant is subjected to frequent blood sampling, and iatrogenic anemia may necessitate transfusion. Anemia of prematurity is also a well-recognized entity, with premature infants having a slightly lower Hb value at birth and with the postnatal decline in Hb occurring earlier and being more pronounced than in full-term infants. [95] The mechanism for this anemia of prematurity appears to involve relatively lower output of erythropoietin (EPO) in response to a given degree of anemia in premature infants. [96] [97] This may be due in part to the fact that the liver, rather than the kidney, is the major site of EPO production in these infants. [98] Although some have considered this degree of anemia to be physiologic, whether it is truly benign remains an area of controversy.

Another debate among neonatologists concerns what clinical signs and symptoms are valid reflections of poor tissue oxygenation and so should be used as triggers for red cell transfusion. Congestive heart failure and severe pulmonary disease are generally accepted indications for transfusion; however, recurrent apnea, tachypnea, tachycardia, and failure to thrive as transfusion triggers are more controversial. [95] [99] [100] Recently, the AABB has published very general guidelines for neonatal transfusion, and similar documents have been developed in Britain and Canada, but none of the three addresses the critical issue of how to define symptomatic anemia in this patient population.[101] Although this controversy has continued, the rate of transfusion and the donor exposure rate of premature infants have consistently declined. These changes, rather than being attributable to changes in the transfusion trigger, reflect improvements in patient care (e.g., microtesting methods resulting in less iatrogenic blood loss; the use of surfactant resulting in decreases in respiratory distress) as well as the use of a single unit to supply one infant over a longer period. The latter has become possible with the advent of the sterile docking technology, which preserves the full shelf-life of the unit of red cells, combined with accumulating solid evidence that fresh blood is not necessary for low-volume transfusions in neonates, because supernatant potassium and decreased pH are not of concern in this setting. [95] [100] Finally, several recent trials of EPO therapy in premature infants have been undertaken and are summarized in a recent review.[102] Although administration of relatively high-dose EPO has been shown to raise Hb levels and reticulocyte counts in healthy premature infants, the effect in sicker neonates is unclear. Although transfusion exposure was decreased, the significance of this is diminished, given the promise of the new strategies for limiting transfusions and donor exposure outlined above. Therefore, the high cost of EPO treatment may not be justified in this patient population. [103]

In the case of massive transfusion, the situation differs, with marked increases in transfusion in recent years in full-term as well as premature infants. With the advent of highly sophisticated techniques of open heart surgery in neonates and the introduction of extracorporeal membrane oxygenation (ECMO) as a means of temporarily sustaining life in neonates with severe but reversible cardiorespiratory disease, massive transfusion is no longer confined to those infants requiring exchange transfusion.

Despite the decline in Rh hemolytic disease of the newborn, this disease remains the main indication for exchange transfusion. The two triggers for exchange are (1) rapidly rising levels of unconjugated bilirubin that may lead to kernicterus and permanent central nervous system damage, and (2) congestive heart failure secondary to severe anemia. Exchange transfusion is especially beneficial in hemolytic disease of the newborn because it clears the bilirubin and the offending antibody from the circulation and removes antibody-coated red cells before lysis, while at the same time providing a source of red cells that cannot be attacked by the antibody. A two-blood-volume exchange is commonly performed by using a fresh unit of blood concentrated to a final hematocrit of about 50%. [104] In hyperbilirubinemia resulting from other causes (e.g., that associated with liver immaturity in premature infants), phototherapy is the treatment of choice because its effects are usually more sustained, and exchange transfusion is only used for marked elevations. [105] ECMO and open heart surgery are two other situations in which the neonate is exposed to large volumes of allogeneic red cells. The ECMO circuit requires a prime with 2 units of red cells, as do many of the types of extracorporeal circuits in use for cardiopulmonary bypass. Transfusion support for these two types of procedures was the subject of a very complete, recent review. [105]

Although accumulating evidence supports the safety of using red cell units of any age and with any preservative solution for low-volume transfusions in neonates, the same transfusion policies may not apply to massive transfusion. Newborn physiology is unique in several ways that may have implications for massive transfusion therapy. The newborn does not handle metabolites in a mature fashion. Renal immaturity may lead to problems in clearing potassium or acid from stored red cells, and the immature liver may not catabolize citrate efficiently. These problems are accentuated and protracted in the premature infant. To address the concern about potassium load, fresh (<5 days old) or washed red cells are often used, although the necessity of this practice is actively debated. [106] [107] Fresh blood may also be preferred because of its higher 2,3-DPG levels and better red cell integrity. [105] The citrate problem is probably best handled by using slow infusion rates, [23] since the use of bicarbonate or calcium replacement to counteract the acid load or calcium-chelating effects of citrate is controversial. [24] Finally, the use of red cells stored in the newer preservative solutions (CPDA-1, Adsol, Nutricell) is rejected by some authorities because of the risk of renal damage and renal stones due to adenine metabolites.[108] In addition, the potential toxicity of the various additives is of concern, as is a significant depletion of plasma proteins associated with transfusion of Adsol or Nutricell units.[109] [110] If CPD red cells are not available, the additive solution can be removed and the cells washed. Red cells preserved in Adsol or Nutricell also have a lower hematocrit, which must be taken into account in making calculations for exchange transfusion. [105]

The humoral and cellular immune systems of the neonate are also immature; again, the problem is accentuated in the premature infant. This has two implications for transfusion therapy. There is a small but real risk of transfusion-induced

graft-versus-host disease in premature infants receiving red cell transfusions [111] [112] and in the fetus undergoing intrauterine transfusion. [113] Irradiation of red cells is performed in these two settings. Another risk of transfusion in low birth weight (<1,500 g), premature infants is the development of clinical cytomegalovirus (CMV) infection in infants of CMV-seronegative mothers. [114] CMV-seronegative blood is now routinely used in these neonates. However, it appears that leuko-reduction by filtration may offer an alternative to CMV screening [115] [116] and is currently being used by some institutions when the supply of CMV-seronegative blood is inadequate.

Chapter 136 - Principles of Platelet Transfusion Therapy

Thomas S. Kickler

INTRODUCTION

In 1910 a Johns Hopkins physician, W.W. Duke, demonstrated the relation of blood platelets to hemorrhagic disease, described a method for determining the bleeding time, and for the first time showed that hemorrhagic disease caused by thrombocytopenia could be relieved by transfusion. However, reliable methods for platelet preparation were not developed until 1950. [1] Even in 1970, platelet transfusion therapy was readily available only in specialized medical centers. Before 1960, two-thirds of patients with acute leukemia died of hemorrhage. [2] The development of potentially curable chemotherapeutic regimens, which led to severe myelosuppression, necessitated intensive research

into the biology of platelets, methods and devices for their procurement and storage, and platelet transfusion practices. This research allowed the widespread availability of platelet transfusions for the treatment of benign and malignant medical disorders, trauma cases, and complicated surgical procedures. Unlike the surgery patient to whom platelet transfusions are given during the perioperative period, medical patients frequently receive longer courses of platelet transfusions. Consequently, platelet alloimmunization and refractoriness to platelet transfusions occur. This is especially true in patients undergoing myelosuppressive therapy resulting in amegakaryocytic thrombocytopenia and in aplastic anemia. These groups of patients represent the largest recipients of platelet transfusions.

Alloimmunization is the single most important factor limiting the therapeutic effectiveness of platelet transfusion therapy. [3] The purpose of this chapter is to describe the effective use of platelet transfusions in medical patients and the immune and nonimmune reactions to platelet transfusions. Because refractoriness to platelet transfusions is a serious problem, methods to circumvent or prevent it are also described.

PLATELET PREPARATIONS

Platelet Concentrates and Apheresis Platelets

Platelet transfusions are available as platelet concentrates or as apheresis units. [4] The former are prepared from units of whole blood by centrifugation and the latter are collected by pheresis devices. Various arguments have been proposed for the superiority of apheresis platelets, including reduced rates of alloimmunization and transfusion reactions.[5] [6] However, the only compelling argument seems to be the reduced risk of infection with apheresis platelets.

In the United States, platelet concentrates are separated from whole blood by first preparing platelet-rich plasma and then centrifuging the platelets with a second centrifugation.[4] Although the contents of the platelet concentrates are highly variable, depending on the preparation technique, the 50-ml platelet concentrate usually has at least 5.5×10^{10} platelets. In Europe the buffy coat method is the most common method of platelet preparation.[7] [8] This method involves centrifugation to prepare a buffy coat, from which platelets are separated by an additional centrifugation. The white cell contamination is approximately 10^{8} WBCs per bag when the platelet-rich plasma method of concentration is used and 10^{6} WBCs per bag for platelets prepared by the buffy coat method. The relatively lower WBC content in platelets prepared by the buffy coat method may be advantageous in reducing alloimmunization and febrile transfusion reactions.

Pheresis platelets are collected from donors by continuous centrifugation using a large intravenous catheter that allows processing of a large volume of blood and the removal of platelets by means of an automated system. Since a conventional transfusion dose for an adult patient is approximately 6 units of pooled platelets, collection parameters have been used to collect this number of platelets from a donor. Modern pheresis devices are equipped to predict the yield from the donors size, platelet count, and hematocrit. The leukocyte content of a pheresis platelet depends on the technology used, but most devices yield a WBC contamination of less than 10^{6} per bag. Platelets from single donors pose less infectious risk to the recipient than do pooled platelets simply because there are fewer donor exposures. Much has been written about the benefits of pheresis platelets in reducing the risk of alloimmunization. Data from a recently completed multicenter trial to reduce alloimmunization to platelets, however, have shown that leukocyte-reduced pheresis platelets provide no additional reduction in alloimmunization over that afforded by leukocyte-reduced platelet concentrates. [9]

Platelet blood components are licensed for a storage time of 5 days at room temperature. Clinical studies indicate that there is little loss of platelet function and viability with 5-day-old platelets. [10] Maintenance of the function and viability of liquid stored platelets is limited to a relatively short period of time because of the storage lesion that develops. There is considerable interest in improving the storage condition for platelets to reduce the functional abnormalities that occur during storage. When platelets are removed from the human circulation and exposed to the foreign conditions of even the most carefully designed collection and storage system, a variety of changes collectively referred to as platelet activation begin. [11] [12] [13] A number of variables may produce minimal changes that perpetuate the process as more platelets are recruited into the activated state. These activation changes may be reflected in platelet shape change, adhesion, or aggregation, the secretion of platelet granular contents, and the expression of activation antigens. The challenge of preparing platelets for transfusion has been to minimize the damaging effects of preparation and storage.

A major advance in improving stored platelets was the elucidation of the metabolic factors that lead to a deleterious fall in the pH. [10] Early in the development of platelet storage techniques, it was recognized that a drop in the pH to <6 was associated with a marked reduction in platelet viability. The drop in pH was caused by an accumulation of lactic acid through glycolysis and was promoted by the relatively hypoxic storage conditions found in the older generation of platelet storage bags. With improved transmission of oxygen through gas-permeable storage bags (second-generation containers), metabolism by oxidative phosphorylation was facilitated, thereby largely circumventing the fall in pH and allowing improved platelet viability.

Because of the possible deleterious effects caused by plasma factors, such as thrombin and complement, on platelets, there has been an increased interest in developing different storage solutions for platelets. A variety of crystalloid solutions are under development that allow for improved platelet metabolism while reducing the amount of plasma to low limits. If these new media ultimately are shown to improve platelet function, other benefits of plasma removal from platelet concentrates are foreseeable.[14] First, the unneeded plasma could be used in plasma fractionation. Second, transfusion practices may be improved. By removing plasma, there would be less concern about administering ABO-incompatible plasma, which would minimize the risk of hemolysis in susceptible transfusion recipients. If viral inactivation of platelets by photosensitive dyes should become feasible, the absence of plasma in platelets would be an advantage. A problem with viral photoinactivation of blood products is the competition between serum proteins and viral particles for viricidal dyes. [15]

Cryopreserved Platelets

Cryopreserved platelets have been developed for long-term platelet storage using dimethylsulfoxide (DMSO) or glycerol. The average post-transfusion recovery of cryopreserved platelets is 50%. Hemostasis seems to be maintained with DMSOpreserved platelets. Despite early promising results with glycerol-preserved platelets, this technique has not been successfully adapted for clinical practice. Cryopreserved platelets were especially developed for patients who become alloimmunized during induction chemotherapy for acute leukemia and later needed additional marrow suppressive therapy. Platelets could be collected during remission, frozen, and subsequently used when necessary. Because using frozen platelets is accompanied by some logistical considerations, they are not widely used. [16]

Lyophilized Platelets

The lyophilization of platelets is an alternative that circumvents the logistical concerns inherent to the use of frozen stored platelets. In 1995 Read and co-workers reported that lyophilized platelets may support hemostasis in an animal model. [17] They reported that they could correct the bleeding time in thrombocytopenic animals, and also that transfused reconstituted lyophilized platelets participated in carotid arterial thrombus formation in a canine model. This form of platelet is currently undergoing human clinical trials and is not yet approved for routine use. Although these studies are provocative, additional studies are needed to substantiate the usefulness and safety of lyophilized platelets and to investigate other potential forms of platelet substitutes.

CLINICAL APPLICATIONS OF PLATELET TRANSFUSIONS

The Thrombocytopenic Patient

Platelet transfusions are given prophylactically or therapeutically to thrombocytopenic patients and to patients undergoing invasive procedures. There has been considerable interest in defining the lowest safe platelet concentration at which bleeding is unlikely, so that fewer prophylactic transfusions would be needed. This interest was initially stimulated by the hypothesis that if fewer platelets were given, alloimmunization rates would be lower. This hypothesis, however, does not appear to hold true in patients with acute leukemia. There does not appear to be a dose-response relationship between the number of platelet concentrates given and the rate of alloimmunization.[18] Certainly, by lowering the level at which one transfuses platelets, the expense of platelet transfusions may be decreased. Currently >3 million units of platelets are transfused annually in the United States. The majority of these units are transfused in tertiary care hospitals to manage hematologic malignancies. In a recent review of practices at the University of Minnesota Hospital and Clinics, 86% of platelet transfusions were used in patients with hematologic malignancies. Sixty-eight percent of transfusions were given prophylactically to prevent bleeding, and some 32% were given therapeutically during episodes of bleeding.[19]

Clinicians have been generally aware that hemorrhage is more common during the most severe stages of thrombocytopenia. In an effort to identify a hemorrhage threshold related to the degree of thrombocytopenia, Gaydos et al. reviewed hemorrhagic episodes in 92 consecutive patients treated for acute hemorrhage between 1956 and 1959 at the National Cancer Institute.[20] Platelet counts of <100,000/mm^3 were associated with an increased risk of bleeding. Patients with platelet counts of 5,000/mm^3 manifested gross hemorrhage on approximately one-third of days at risk. The authors could not, however, identify a distinct threshold. Rather, the risk of hemorrhage increased progressively as the platelet count fell. In examining patients with fatal hemorrhage, Gaydos et al. also noted that patients in blast crisis hemorrhaged despite having adequate platelet counts. When such patients are excluded, only eight of the 92 patients experienced fatal hemorrhage. Of these eight patients, only one had a platelet count of >5,000/mm^3 , and none had a platelet count of >10,000/mm^3 .

Based on the experience of Gaydos et al., several centers tested strategies of prophylactic platelet transfusion. Higby et al. compared prophylactic platelet transfusions and prophylactic transfusions with platelet-poor plasma.[21] Of note, both groups in this study experienced equivalent degrees of thrombocytopenia, which suggests that marrow ablation was not complete or that the quality of transfused platelets may not have been optimal. Nonetheless, an increased rate of bleeding episodes was noted in patients receiving platelet-rich plasma, and the study was terminated early. At approximately the same time, Roy et al. compared two doses of platelet transfusions given prophylactically with results in historical patients.[22] Overall, bleeding episodes were reduced from 56% in historical controls to 58% in patients receiving platelet transfusions. Rates of both minor and major bleeding episodes were decreased in the treated groups. However, there was no difference between the low dose or high dose of platelets.

Based on these studies, a prophylactic platelet transfusion strategy has been widely adopted by nearly all American oncologists. Undoubtedly, practical matters were a major factor in the adoption of this strategy. In the 1960s and 1970s, platelet concentrates were not available on an emergency basis. Various methods for storing platelets, some clearly less than optimal, were employed, resulting in platelet concentrates of variable efficacy. Further, there was a general feeling among clinicians that hemorrhagic episodes were catastrophic and irreversible. In this context, a prophylactic platelet transfusion strategy was generally accepted and a 20,000/mm^3 triggerd was adopted.

Since the adoption of this policy, the availability of platelets has changed dramatically. Today, platelets are easily available on an emergency basis. Nonetheless, American oncologists have persisted in using a platelet count of 20,000/mm^3 as a trigger for transfusion, despite the improved availability of platelet concentrates and considerable physiologic and clinical data that question the efficacy of this strategy.

In 1997 Heckman and co-workers, in a randomized study of prophylactic platelet transfusion thresholds during induction therapy in adult patients with acute leukemia, reported that giving prophylactic transfusions only when the platelet count dipped to <10,000/mm^3 decreased platelet utilization, with only a small adverse effect on bleeding and no effect on mortality.[23] It therefore appears that with amegakaryocytic thrombocytopenia, prophylactic transfusions should be given if the count falls to <5,000/mm^3 . At values between 5,000 and 10,000/mm^3 , the clinician may be able to abstain from transfusing if the patient is stable and if no other conditions make spontaneous bleeding likely. These conditions include blast crisis, anticoagulation with heparin for disseminated intravascular coagulation (DIC), the use of drugs that affect platelet function, uremia, and recent invasive procedures, including spinal taps or the placement of central venous catheters. This approach has recently been confirmed by other investigators, who showed that lowering the transfusion threshold to 10,000/mm^3 was not only safe but reduced the number of platelet transfusions by 22%.[24]

Platelet Transfusion Dose

The dose administered to a thrombocytopenic patient depends on the therapeutic goal. A clinician administering prophylactic platelet transfusions to a myelosuppressed patient may wish to give only enough platelets to prevent bleeding. In this situation the general practice is to administer sufficient platelets to maintain a sustained platelet count of >10,00020,000/mm^3 . To accomplish this, one must take into consideration different physiologic factors, including the presence of fever, active bleeding, or DIC. Approximately one-third of transfused platelets are sequestered in the splenic pool.[25] Because of this, approximately one-third more platelets need to be transfused to accomplish a target platelet count. Although normal platelet survival is 9 days, there exists a direct relationship between the platelet count and the survival of platelets in thrombocytopenic individuals. The survival of transfused platelets may be followed by frequent platelet counts to estimate the frequency of transfusion. Knowing the concentration, or average concentration, of platelets supplied by a blood center, one can calculate the volume of platelets to transfuse. FDA guidelines dictate that pheresis platelets must contain >3 × 10^{11} platelets (6 equivalent

units) or >5.5 × 10^{10} in platelet concentrates prepared from units of whole blood. In a normal-sized individual, 3 × 10^{11} platelets is considered an appropriate dose. If a patient is being managed as an outpatient, larger doses of platelets may extend the interval between transfusions. In calculating the administration dose, the physician should realize that in many instances a platelet count is not always available on the platelet bag, or if it is, the accuracy of the count may have a variability of 20%.[10]

Other Quantitative Platelet Disorders

Thrombocytopenia may develop on the basis of increased consumption or splenic sequestration of platelets. In addition, when a patient is massively transfused (one total blood volume replacement), thrombocytopenia may develop. This type of thrombocytopenia has been called dilutional, because stored red cell transfusions have

very few platelets.[26] Increased platelet destruction is seen in autoimmune thrombocytopenia, drug-induced thrombocytopenia, DIC, and thrombotic thrombocytopenia purpura (TTP). Thrombocytopenia in these conditions can be quite severe, and profound bleeding and purpura are not uncommon presenting symptoms in autoimmune or drug-induced thrombocytopenia; therefore, platelet transfusions may be considered necessary in patients who are having catastrophic bleeding.

Autoimmune Thrombocytopenia and Drug-Induced Thrombocytopenia

Autoimmune thrombocytopenia is due to antibodies directed toward antigenic targets located on platelet glycoproteins. In drug-induced thrombocytopenia, the drug may serve as a hapten to bind to platelet glycoproteins, inciting an immune response. Thus, transfused platelets are as likely to undergo immune destruction as are autologous platelets, and through the same mechanisms. Platelet transfusions are never the only means of treating autoimmune thrombocytopenia. A variety of approaches are used, as well as intravenous -globulin, that interfere with platelet destruction. In some clinical situations, such as intracranial hemorrhage, platelet transfusions are only one of multiple methods used to try to prevent life-threatening bleeding until other treatments have an effect. One combinational approach is to use both intravenous -globulin and platelet transfusions to block the effect of the autoantibody on the transfused platelets. [27] This approach may prove beneficial in patients who may need surgery or undergo invasive procedures. There is no evidence that preoperative platelet transfusions have any use when a patient is to undergo splenectomy as part of the treatment of chronic autoimmune thrombocytopenia.

Qualitative Platelet Disorders

There are a variety of acquired and congenital qualitative platelet disorders. The most common acquired qualitative platelet abnormalities are either drug-induced or caused by uremia. Other acquired platelet disorders are seen in myeloproliferative disorders, in the dysgammaglobulinemias, or consequent on the use of mechanical cardiac assist devices. Aspirin is probably the most common drug that affects platelet function. Platelet transfusions can improve the bleeding time in patients taking aspirin if the transfused platelets constitute 10% of the platelet population. This is especially important in cardiac patients who are taking aspirin prophylactically and need emergency platelet transfusions. Platelet transfusions are not usually considered first-line management in uremia-induced platelet dysfunction. Rather, hemodialysis, cryoprecipitate administration, or correction of severe anemia by transfusion or erythropoietin is tried first. [4] [10]

A variety of inherited qualitative platelet disorders exist that can be accompanied by severe bleeding, particularly following trauma. These disorders include Glanzmann thrombasthenia and Bernard-Soulier syndrome. Platelet transfusions are effective in these disorders. However, because the disorders are characterized by absence of the glycoproteins that are carried on transfused platelets, isoimmunization to these proteins can occur. When this happens, platelet transfusions are ineffective.[28]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PLATELET TRANSFUSION REFRACTORINESS

Failure to achieve an expected increment in platelet count in response to a platelet transfusion is called platelet transfusion refractoriness. Refractoriness may occur on an immune or nonimmune basis.[29] Management of refractoriness to platelet transfusion requires identifying the specific cause. Different patient populations may be at greater risk for certain types of platelet refractoriness than others. Patients with acute promyelocytic leukemia may be expected to have a higher incidence of DIC-related transfusion failures. Bone marrow transplant recipients may experience a higher rate of veno-occlusive disease. Several authors have reported multivariate analyses of platelet transfusion failures. [29]

Clinically, the response to a platelet transfusion can be assessed by measuring the increment in the platelet count over time. The post-transfusion platelet response should be calculated on the basis of the patients body surface area and corrected for the number of platelets transfused. The corrected platelet count increment is calculated using the following formula:

In general, a successful corrected count increment should be >7,500 within 160 minutes of a transfusion and >4,500 if measured 1824 hours after transfusion. It has been suggested that the corrected platelet count increment 1 hour after platelet transfusion is a useful indirect measure with which to establish alloimmunization versus nonimmune causes of platelet transfusion failure. HLA antibodies are only one of many factors that influence 1-hour platelet count increments. It should also be noted that even when platelet antibodies are present, acceptable 1-hour increments may be achieved. This latter phenomenon may be seen when platelets with weak expression of HLA-B locus antigens are given. [30]

Immunologic Basis of Platelet Transfusion Refractoriness

Immunologic destruction of transfused platelets may be the result of alloantibodies, autoantibodies, drug-induced antibodies, or immune complexes. Any of these factors may contribute to immune platelet transfusion refractoriness. The platelet membrane carries class I HLA antigens and the human platelet antigens (PLA, Bak, Br, Ko, and Pen). However, antibodies to class I HLA-A and HLA-B loci antigens account for most cases of immune-mediated platelet destruction. Antibodies to the human platelet antigens are relatively infrequent causes of platelet transfusion refractoriness. [29]

HLA Alloantigens

Soon after the introduction of prophylactic platelet transfusion, it became apparent that in many patients, serial transfusion resulted in decreasing effectiveness. Through the work of Yankee and others, it is now recognized that transfusion failure results

from the induction of alloantibodies to HLA and other antigens. [3] Yankee et al. were able to show that most cases of platelet refractoriness could be reversed by use of platelet transfusions that were phenotypically matched at the HLA-A and -B loci. It was also recognized that the development of HLA antibodies as measured by lymphocytotoxic activity correlated with the development of the immune refractory state. [31] It is now well recognized that response to HLA-A and B loci antigens is the major cause of post-transfusion alloimmune transfusion failure.

Understanding the HLA system is important so that compatible platelet transfusions may be selected for alloimmunized patients (Table 136-1). Only HLA-A and HLA-B antigens have been shown to be important in causing immune-mediated platelet transfusion refractoriness. [31] [32] [33] There are two broad types of HLA antibodies made in response to platelet transfusions. The first type recognizes epitopes unique to a particular HLA allele and referred to as antibodies to private specificities. Antibodies to A2 or B12 fall into this group. The second type of HLA antibodies recognize more than one gene product. These antibodies recognize structural similarities between gene products (cross-reactive epitopes) or identical epitopes present on different gene products of different alleles and are referred to as antibodies to public epitopes (Table 136-2). Traditionally, HLA serology has placed the greatest emphasis on classifying the private antigens. More importance has recently been placed on the clinical importance of public HLA specificities. The best-known

TABLE 136-2 -- Class I Cross-Reactive HLA Groups (associated private epitopes)

A1C (1, 3, 11, 10, W19, 9, 28)
A2C (2, 28, 9, 17, 10, 33)
B5C (5, 53, 35, 18, 15, 17, 70, 49)
B7C (7, 27, 22, 42, 48, 40, 41, 13, 47)
B8C (8, 14, 16, 22, 42, 48, 40, 41, 13, 47)
B8C (8, 14, 16, 22, 52)
B12C (12, 21, 40, 41, 13)

examples of public specificities are Bw4 and Bw6. These antigens are encoded by a diallelic system and are associated with two different groups of HLA-B class I antigens. Other public antigens carried by HLA-B class I antigens have been divided into four cross-reactive groups, B5, B7, B8, and B12. The observation that the specificity of HLA antibodies in multiply transfused individuals is generally against public epitopes suggests that matching for these public antigens is important. With improved serologic approaches to identifying specificities to class I HLA antigens, selection of platelets for transfusion may be simplified by relying on a process based on public specificities. [34] [35] [36]

Human Platelet Antigens

Human platelet antigens (HPA), previously called platelet-specific antigens, arise as the result of polymorphisms of platelet membrane glycoproteins. The nomenclature for these antigens is shown in Table 136-3 . [37] [38] [39] Since the antigen systems arise because of polymorphisms of integrins, some of the antigen systems are not specific for platelets. Because these antigens are epitopes on integrins, some platelet-specific antigens may be expressed on endothelial cells, fibroblasts, and smooth muscle cells. For example, antigens associated with glycoprotein IIIa (GPIIIa) may have this diverse tissue distribution, whereas antigens associated with GPIIb are restricted to platelets.

Antibodies to the human platelet antigens HPA-1 to HPA-5 (PLA, Bak, Ko, Br, Pen) are only rarely causes of platelet transfusion refractoriness. In a large series of patients who received platelet transfusions, only 2% of patients had detectable antibodies to the human platelet antigens. Most of these antibodies were found in patients who were also alloimmunized to class I HLA antigens. In patients in whom HLA-identical platelet transfusions fail, antibodies to the human platelet antigens should be suspected. [40]

Detection of Antibodies in Platelet Transfusion Refractoriness

Specific identification of alloimmunization can be done by measuring HLA antibodies using lymphocytotoxicity testing. [3] Serial lymphocytotoxic antibody measurements are helpful in managing alloimmunized patients. [41] Some patients may have decreases or a loss of lymphocytotoxic antibodies, either permanently or transiently, and can be successfully transfused with platelet concentrates. It should be noted that some patients may have antibodies to HLA class I antigens and yet not experience platelet transfusion failure. A new development for detection of HLA antibodies has been reported by Kao and co-workers. [42] This solid phase enzyme-linked immunoassay detects the presence of IgG anti-HLA antibodies using purified HLA antigens

prepared from platelet concentrates. The test is commercially available and is now widely used to screen for HLA antibodies in a variety of transfusion and transplantation conditions. Antibody specificity to the platelet-specific antigens can be identified using isolated platelet glycoproteins. In general, few donor centers have a donor population typed for the human platelet antigens except for those in the HPA-1 system. The recent introduction of DNA-based typing for the human platelet antigens permits accurate typing of donors and even thrombocytopenic patients because lymphocyte-derived DNA is used. [37]

Clinical Features of Alloimmune Refractoriness

The incidence of alloimmunization to class I HLA antigens in repeatedly transfused recipients may vary from 20% to 80%, depending on the population studied. [9] [40] In

general, patients with aplastic anemia have higher rates of alloimmunization than those with acute leukemia. The lower alloimmunization rates in leukemia may be due to the underlying disease or to immunosuppressive therapy. In a series of 114 patients reported by Dutcher et al., 42% of patients developed lymphocytotoxic antibody within the first 8 weeks of transfusion. [18] Approximately one-quarter of these developed it within 1 week, suggesting the presence of an amnestic response. Seventy-five percent of responders appeared to have a de novo response. Of those patients who manifested lymphocytotoxic antibody, 17 patients ultimately lost it despite further transfusion. More interestingly, of those initial patients who did not respond by developing lymphocytotoxic antibody in the first 8 weeks, 92% remained unresponsive despite continued transfusion therapy. Thus the development of an alloimmune response post transfusion seems to be an early event in transfusion therapy. Responsiveness or nonresponsiveness to HLA antigens develops in the first weeks of therapy, and this pattern is apparently maintained throughout subsequent therapy.

Anti-platelet Glycoprotein Antibodies

Besides the phenotypic differences that arise because of polymorphisms in the platelet glycoproteins, patients may form antibodies to the entire platelet glycoprotein molecule. Therefore, individuals who have the Bernard-Soulier syndrome may become immunized to GPIb, and those with Glanzmann thrombasthenia may become immunized to GPIIb/IIIa. Patients lacking these important membrane glycoproteins and needing platelet transfusions may become immunized to normal platelets. This results in transfusion refractoriness and significantly complicates the transfusion management of patients with qualitative platelet disorders. [28]

ABH Antigens

Initially it was thought that platelets could be transfused without regard to their ABH type. Studies by Duquesnoy and co-workers indicated that at most, ABH incompatibilities could account for only a 20% decrease in survival. [32] More recently Brand and co-workers described two patients who had absolute platelet refractoriness based on ABH antibodies. [43]

Nonimmune Refractoriness

Platelet transfusions may not result in an increment in the platelet count if the stored platelets are defective. This should be relatively uncommon, given the close scrutiny devoted to quality control of blood products. However, the clinician should not fail to consider freshness of a given platelet transfusion as a cause of a single platelet transfusion failure. Other causes of nonimmune-mediated platelet refractoriness are listed as follows and should be considered in the differential diagnosis of platelet transfusion refractoriness: [29]

1. *Microangiopathic platelet destruction.* Consumption of platelets in microangiopathic hemolytic anemias has been classically described in the syndromes of TTP and the hemolytic uremic syndrome. This microangiopathic process can also be observed during bone marrow transplantation. In some cases, therapy with Cyclosporin A has been incriminated as the trigger for this process. Platelet transfusions in patients with active TTP may lead to acute worsening of both renal and cerebral function.
2. *Coagulopathy.* DIC has been classically associated with nonimmune platelet refractoriness. This syndrome has been associated with bacterial sepsis, which is common in the transfused patients, as well as with acute progranulocytic leukemia. The quantitative role of DIC in the platelet refractory state has not been well characterized. Patients with active hemorrhage will have shortened platelet survival.
3. *Splenic sequestration.* Splenomegaly is a major cause of platelet transfusion failure. Approximately 30% of the platelet mass in humans is contained within the spleen. With increases in splenic size, up to 90% of circulating platelets can be sequestered in this organ. Characteristically, splenic sequestration is associated with a reduced 1-hour platelet recovery but normal survival.
4. *Fever and infection.* Studies by several groups have implicated both fever and infection as causes of decreased platelet survival. One study noted that platelet transfusion requirements were increased by 50% in febrile patients. This may be increased further in patients with major infections, particularly those with DIC.
5. *Hepatic dysfunction/VOD.* Hepatic sequestration of platelets has been reported in association with a wide spectrum of liver diseases. Recently a syndrome of veno-occlusive disease of the liver (VOD) characterized by deposition of platelets in the hepatic venules and the development of an intrahepatic thrombosis with hepatomegaly, right upper quadrant pain, and ascites has been described. This organ dysfunction has been noted after administration of a wide variety of cytotoxic agents, including total body irradiation, alkylating agents, and vinca alkaloids.
6. *Other factors.* Platelet refractoriness has been reported with a number of medications. Amphotericin in particular has been implicated in decreasing platelet recovery and survival. Similarly, vancomycin has been reported to be a major cause of platelet refractoriness, as have antithymocyte globulin, granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, and the interferons. In view of the large number of drugs cancer patients characteristically receive, it would not be surprising if a number of agents were implicated in accelerated platelet destruction.

MANAGING THE ALLOIMMUNIZED PATIENT

Transfusion Selection

Because alloimmunization to HLA antigens accounts for the majority of cases of alloimmune platelet transfusion refractoriness, the clinician should select platelets on the basis of HLA matching. Table 136-4 outlines the fundamentals of HLA matching. In early studies, it was found unnecessary to match for HLA-C and -D loci antigens.[32] [33] Based on experience with tissue matching in renal transplantation, it was recognized that using cross-reactive HLA types could circumvent the problem of finding exactly identical HLA-typed platelets. Depending on the HLA type of an individual, one may have little difficulty in locating platelets that are identical, whereas in some patients with an unusual HLA type, such as some ethnic populations, HLA matching is difficult. The practice of using either

TABLE 136-4 -- General Guidelines for HLA Matching

1. If HLA-identical platelets are unavailable, platelets from donors whose HLA types are serologically cross-reactive with the recipients may be substituted.
2. Matching for antigens of the HLA-C locus is not necessary.
3. Mismatching for some HLA-B locus antigens that are weakly expressed on platelets is acceptable for some donor-recipient pairs.
4. If cross-reactive platelets are ineffective for some patients, attention to linked HLA specificities may be important (i.e., Bw4/Bw6).
5. Although expressed on platelets, ABO matching is less critical than HLA matching.

HLA-identical platelets or HLA- matched (not identical but serologically cross-reactive, with only minor epitope differences) has given rise to a classification of HLA match grades that should be kept in mind when discussing the level of match that a patient is receiving. This classification is given in Table 136-5 .

Relying only on HLA matching may have shortcomings. In some cases it is overly restrictive, in that in some cases some HLA-B loci antigens are not located on platelets. Because of this, in addition to antigen matching, there has been a great deal of interest in adopting an approach similar to that used for testing red cell compatibility. In this paradigm, a red cell phenotype that matches the patients phenotype is selected and then a major crossmatch is done. This same approach can be used with platelets by performing a platelet crossmatch.[44] [45] [46]

Kickler and co-workers studied the effectiveness of HLA matching as the sole method of platelet selection for alloimmunized patients. Of 50 HLA-identical platelet transfusions, 20% were unsuccessful. Of the transfusions selected on the basis of cross-reactivities without regard to matching of public specificities, 41% were failures (23 of 56 transfusions). When one or two antigen-mismatched platelets were used, approximately one-third of transfusions were failures. These observations indicate that relying solely on matching platelets on the basis of HLA private antigens is frequently unreliable. Furthermore, even if patients are alloimmunized, they may receive mismatched platelets and have successful transfusions.[44] [45] [46]

For these reasons, refining the process of selecting platelets for alloimmunized patients has been the subject of much investigation. A practical approach to selecting platelets for the alloimmunized patient that takes account of the importance of HLA matching and confirming this by platelet compatibility testing is outlined in the box. Numerous investigators have evaluated the usefulness of crossmatching a recipient against potential donors. This approach can be readily accomplished, for pheresis platelets are stored for 5 days. By taking an aliquot of platelets

TABLE 136-5 -- Donor and Recipient HLA Match Grades

Grade	Definition
A	All four donor antigens are identical to the recipients
B1U	All donor antigens are identical to those of the recipient; only three antigens are detected in the donor
B2U	All donor antigens are identical to those in the recipient but only two are detected in the donor
B1X	Three donor antigens are identical to those in the recipient; the fourth is serologically cross-reactive with a recipients antigen
B2UX	Two donor antigens are identical to those in the recipient; a third is cross-reactive; only three antigens are detected in the donor
B2X	Two antigens are identical to those in the recipient; two are cross-reactive
C	One donor antigen is mismatched with antigens in the recipient
D	Two or more donor antigens are mismatched with antigens in the recipient

AUTHORS APPROACH TO SELECTION OF PLATELETS FOR ALLOIMMUNIZED PATIENTS

1. Determine HLA phenotype and ABO type.
2. Screen patients serum for lymphocytotoxic antibody.
3. Screen patients serum for antibodies to platelet-specific antigen (optional if there is a history of failing HLA-identical platelets is not available).
4. Select from the donor pool the most compatible antigens in the HLA and, if possible, ABO systems. If a platelet-specific antibody is detected, matching for this antigen is required.
5. Crossmatch the recipients serum with the selected potential donors and select the most compatible crossmatch.
6. Determine 1-hour and 18- to 24-hour post-transfusion platelet counts, not only to assess transfusion outcome but also to guide the selection of platelets for future transfusions.
7. Before deciding that platelet refractoriness exists, measure the platelet count increment on more than one occassion to ensure that a poor increment was not related to the storage time of the platelets that were transfused.

from an integrally attached tubing segment, compatible platelets can be found in the inventory of stored platelets. Compatible donors may be found even if a patient is broadly alloimmunized. A variety of techniques exist for platelet crossmatching, most involving a labeled antiglobulin technique. Many referral centers have developed their own techniques, which they have validated in their own patient populations. Recently, commercially available platelet compatibility tests have resulted in the wider use of platelet crossmatching. In general, no consensus has emerged concerning all the methodologic requirements for platelet compatibility testing. These include the importance of detecting different immunoglobulin classes, interference by immune complexes, or the effect of isoagglutinins.

Management of Platelet Transfusion Refractoriness and Bleeding

A variety of approaches have been tried when no compatible platelets can be found for a patient who is alloimmunized, is bleeding, or may be undergoing invasive procedures. Therapeutic modalities have included splenectomy, corticosteroid administration, plasmapheresis, administration of intravenous immune globulin (IVIG), and repeated platelet transfusions. Except for IVIG, there is little evidence that any of these approaches work. [47]

Kickler and co-workers performed a randomized, placebo-controlled clinical trial investigating the use of IVIG in alloimmunized thrombocytopenic patients. [47] IVIG was administered at a dose of 400 mg/kg for 5 days. An incompatible platelet transfusion from the same donor was used before and after the patient received study drug or placebo. Seven patients received IVIG and five received placebo. Although platelet recovery in 16 hours was satisfactory in five patients after IVIG treatment, 24-hour platelet survival was not improved in most of these patients. It could not be excluded that this poor 24-hour survival was unrelated to nonimmune causes of shortened platelet survival. None of the placebo group achieved satisfactory 1-hour platelet corrected count increments. By *t*-test, the post-treatment mean values 1 hour after transfusion were significantly greater than in the control group. When a regression model was used to adjust for any distributional assumptions of the study population,

the parameter estimate for IVIG treatment was positive. This indicated that IVIG may improve 1-hour platelet recovery. These studies also suggest that the kinetics of platelet survival may be affected by IVIG. It is likely that if additional platelets were administered, severe thrombocytopenia may be corrected in these patients. Furthermore, the authors suggest that this approach may permit the performance of invasive procedures.

When conventional methods fail to increase the platelet count to hemostatic levels, the only remaining alternative that has been tried is the continuous transfusion of platelets (massive transfusion). [29] [44] It has been argued that even when there is no incremental increase in the platelet count, transfused platelets still exert some effect, permitting platelet plug formation or maintenance of endothelial integrity. These arguments are based on clinical observations. In one well-established animal model of alloimmune thrombocytopenia, if the platelet count did not increase to >60,000/mm ^{3} , capillary leakage of blood still persisted. Nonetheless, given the potentially serious risk of doing nothing in a patient experiencing active bleeding, the clinician must try to support the patient while other, more definitive treatments are undertaken to stop the bleeding or ameliorate those nonimmune factors that may be contributing to platelet refractoriness. [48]

PREVENTION OF ALLOIMMUNIZATION

Reduction of Donor Exposures

Early studies suggested a relationship between the number of platelet transfusions and the rate of alloimmunization to HLA antigens. Other studies have not documented a dose-response relationship. The reasons for these contradictory conclusions are not clear. In part, clinical differences in the study populations, including multiparity of the transfusion recipients, may be the main explanation. The definition of alloimmunization may also be important. For a primary immune response, 23 weeks may be required. If sera are not collected over a sufficiently long period of time, an antibody response may not be measured. Alternatively, some patients may lose antibodies by the time of testing, contributing to negative responses. The data are also consistent with the hypothesis that the alloimmune response may have a threshold effect. Over a low range of exposure, there may be a dose-response effect. This may explain the dose effect seen by Perkins [49] and Sintnicolaas.[6] With larger numbers of exposures, further alloimmunization may not develop if tolerance has been established. [50]

Blood Product Modification

In animal studies, depletion of contaminating leukocytes from donor blood components or ultraviolet irradiation of platelets was effective in preventing an alloantibody response to MHC antigens.[51] [52] [53] With the development of efficient methods to remove leukocytes from blood products, clinical trials were instituted to test whether leukocyte reduction would reduce alloimmunization to class I HLA antigens. Some small trials suggested that if $<10^{6}$ contaminating leukocytes remained, alloimmunization could be reduced by 3050%. Other studies were not as conclusive. Because of this, a large multicenter clinical trial was done in the United States. The Trial for the Reduction of Alloimmunization to Platelets (TRAP) tested the efficacy of transfusing platelets that were modified by leukocyte reduction or ultraviolet irradiation, or of transfusing platelets from leukocyte-depleted, single-donor platelets. The results of transfusing these modified platelet products were compared with the results of transfusing platelet concentrates. All patients received leukocyte-depleted red cells. [9]

Of 530 patients with no alloantibodies at baseline, 13% of those in the control group formed HLA antibodies and their thrombocytopenia became refractory to platelet transfusions, as compared with 3% in the group receiving filtered platelet concentrates, 5% in the group receiving ultraviolet-irradiated platelet concentrates, and 4% in the group receiving filtered apheresis platelets. Results in the treatment group were significantly different from results in the control group, but not among the treatment groups. HLA antibodies were found in 45% of the controls, compared to 1721% of the treated patients. These maneuvers were effective even though 26% of the patients had previously received nontreated blood products. Of note, none of the treatment maneuvers reduced the rate (610%) of alloimmunization to the human platelet alloantigens. Thus, this large study documents the usefulness of either leukocyte removal or inactivation by ultraviolet irradiation in the chronically transfused leukemic patient who is immunosuppressed. Interestingly, the use of random donor platelet concentrates appeared to offer no increased risk of alloimmunization over the use of single-donor apheresis concentrates.

TRANSFUSION REACTIONS

Febrile and allergic platelet transfusions are two of the most common types of platelet transfusion reactions. [54] Because platelets are suspended in donor plasma, if group O platelets from six to eight donors are pooled and transfused, a substantial amount of anti-A and anti-B isoagglutinins is present in the approximately 300 to 400-ml bag of pooled platelets. If these platelets are given to a group A or group B individual, acute hemolysis may result from the passive administration of the isoagglutinins. For this reason, it is preferable to also consider plasma compatibility when transfusing platelets. This is especially important in children and in patients who are receiving multiple transfusions each day. Another problem to consider is volume overload. If a patient is anuric or receiving multiple transfusions of platelets and other blood products, it is sometimes necessary to concentrate platelets immediately before transfusion. This can usually be done without difficulty. A preferable approach to preventing volume overload is to use pheresis platelets, since these generally have a lower volume. Because platelets contain 12 ml of red cells, they have the potential for immunizing an Rh(D)-negative patient. This is only of concern in treating females of childbearing age. Because of this concern, one may wish to use only Rh(D)-negative platelets.

Systemic Reactions to Platelet Transfusions

Acute systemic reactions to platelets are seen in 2% of all transfusions. [9] Severe reactions occur with equal frequency after the transition of platelet concentrates or pheresis platelets, and even if leukocyte reduction is done at the time of transfusion. Acute symptoms include rash, wheezing, fever, chills, dyspnea, urticaria, and hypotension. [54] These symptoms were previously attributed to either antileukocyte antibodies or IgE-mediated reactions to transfused plasma proteins. However, medical understanding of the pathophysiology of platelet reactions has changed with a better characterization of cytokines present in blood products. Several investigators have identified cytokines as possibly important factors in certain transfusion reactions associated with the administration of platelet products.

Platelet transfusions are associated with a significantly higher incidence of patient reactions than red cell transfusions. [55] [56] It was generally thought for many years that antileukocyte antibodies accounted for most febrile reactions to platelets. However, clinical observations of patients suggested that this was not the complete answer. Reactions occur not uncommonly with the first transfusion in nearly one-third of cases and are independent of the total number of transfusions. Furthermore, the majority of first reactions occur during the first three transfusions. Although presensitization might account for some

of the occurrence of early reactions, this observation suggested that other factors may be involved. [57]

A variety of cytokines can be generated during the in vitro storage of platelets. [55] Heddle et al. reported that blood product age predicted transfusion reactions. [55] [56] This was one of the first pieces of evidence that some type of biomediator was present in platelets. Transfusion reactions were fivefold greater with platelets, and the older the platelet product and the higher the white cell count, the more likely that a reaction would occur on transfusion. Similar observations were reported by Muylle et al. [58] [59] [60] In a retrospective study, Muylle and Peetermans found an increased incidence and severity of reactions to platelet transfusion associated with the use of plastic bags allowing 5-day platelet storage. [59] These reactions included bronchospasm, wheezing, and dyspnea and were related to the length of the storage time and the white cell content of the platelet concentrate.

Cytokines in Platelet Transfusions

Because blood components all contain leukocytes, which produce cytokines, it is not surprising that these hormone-like substances accumulate in products such as platelet concentrates during storage. Muylle et al. investigated cytokine levels in stored platelet concentrates and the relationship between these levels and transfusion reactions. They found increasing amounts of such cytokines as tumor necrosis factor (TNF), interleukin 1 (IL-1), and IL-6 in the plasma of stored platelet concentrates. They speculated that the source of these cytokines could be damage to leukocytes in the platelet concentrate, leading to leakage of cytokines or the activation of monocytes in the platelet concentrates. [61]

Another group of investigators has also reported significant accumulations of IL-8, IL-1, IL-6 and TNF- in platelet concentrates during storage. Stack and Snyder found that leukocyte reduction by third-generation filters on day 1 of storage prevented the generation of IL-8 and IL-1 out to day 5 of storage. [62] Other investigators have also reported that leukocyte depletion of platelets after processing and prior to storage prevented the accumulation of the above substances. Whether or not prestorage leukocyte depletion will lead to reduced platelet transfusions is not known. [63]

Bacterial Contamination of Platelets

Because platelets are stored at room temperature, organisms that were introduced during phlebotomy or during transient donor bacteremia may proliferate. Bacterial contamination of platelet products can lead to transfusion-associated sepsis. Characteristic symptoms of transfusion-associated sepsis include chills, fever, hypotension, and hypoxia. Cultures of blood drawn from the patient experiencing such reactions are positive in less than half of episodes. Estimates of the incidence of bacterial contamination in platelet products range from a high of 10% of all platelet pools to more conservative estimates of 4 in every 1,000 pools. [64] [65]

If the bacteria contaminating the platelet product are gram negative, there is an added risk of the infusion of endotoxins, which can result in endotoxic shock. Clinical features associated with endotoxins include fever, chills, hypotension, respiratory failure, and gastrointestinal symptoms, to mention a few.

It is not clear what intervention can prevent or reduce the incidence of bacterial contamination in platelet products. Although shortening the storage shelf-life to 3 days has been considered, this may be of little real value, since bacteria can achieve log growth and relatively high concentrations by day 3 of storage. [64] [65]

Because platelet transfusions are frequently given to neutropenic patients, the morbidity and mortality of septic reactions are of serious concern. Because of this, it is recommended that the untransfused contents of an aborted transfusion should be cultured and Gram stained. If the contents are positive on Gram stain, the patient should be treated for a possible septic reaction.

Chapter 137 - Principles of Neutrophil (Granulocyte) Transfusions

Ronald G. Strauss

INTRODUCTION

Current cytapheresis technology permits collection of highly enriched fractions of several types of blood leukocytes from either healthy donors or patients for transfusion and transplantation or further processing (e.g., ex vivo expansion, genetic manipulation, etc.) and storage. Neutrophils (PMNs) are collected routinely and issued as a standard blood component (granulocytes, pheresis). This chapter analyzes the use of granulocyte transfusions (GTX) as an adjunct to antimicrobial drugs in the treatment and possible prevention of progressive infections.

Serious and repeated infections with bacteria, yeast, and fungi continue to be a consequence of severe neutropenia (<0.5 × 10^{9}/L blood PMNs) and disorders of PMN function. In the recent multicenter NIH Trial to Reduce Alloimmunization to Platelets (TRAP) study, [1] 7% of adult patients with acute nonlymphocytic leukemia died of infection during first remission induction therapy. Previous attempts to prevent infections in severely neutropenic patients (prophylactic GTX) achieved only modest success (i.e., rates of certain infections were partially reduced, but GTX were toxic and expensive). Similarly,

the therapeutic use of GTX has diminished strikingly over the past several years, despite many reports that have shown them to offer benefit in certain experimental and clinical settings. [2] This lack of acceptance of GTX can be explained by the development of effective antimicrobial agents to prevent and treat infections and by the availability of recombinant hematopoietic growth factors and peripheral blood hematopoietic progenitor cell transfusions to hasten marrow recovery.

Many physicians hold strong negative opinions about the value of GTX that have been reinforced by knowledge that historically, PMN concentrates collected for transfusion contained woefully inadequate numbers of PMNs. It is now possible to collect very large numbers of PMNs from granulocyte colony-stimulating factor (G-CSF)-stimulated normal donors using large-volume leukapheresis. This fact, along with the historical success of GTX in treating bacterial infections, suggests that a critical reassessment of therapeutic GTX is warranted. Further, because of the relatively rapid engraftment following the use of peripheral blood progenitor cell transfusions as a replacement for either autologous or allogeneic bone marrow transplantation, it is reasonable to explore the possibility that severe neutropenia following intense myeloablative therapy might actually be eliminated by prophylactic GTX.

THERAPEUTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS

Recently, 34 papers that reported the therapeutic use of GTX in severely neutropenic patients (<5 × 10^9 /L blood PMNs) were reviewed.[3] The data are tabulated (Table 137-1 (Table Not Available)) according to the index infection that prompted GTX therapy. Patients are counted only once (e.g., patients with septicemia were listed only in the septicemia group, even if they had another infection such as pneumonia). As an exception, all patients with invasive fungal infections are counted together because it was impossible to accurately separate sepsis, pneumonia, sinusitis, and so forth, into distinct categories. All patients given GTX for a designated type of infection are enumerated in the Treated column. Of the treated patients, those for whom the actual course and mortality of the index infection could be clearly documented are enumerated again in the Evaluable column. GTX therapy was considered successful if so stated by the author. Several of the 34 reports described uncontrolled studies of small numbers of patients with diverse underlying diseases, types of infections, antimicrobial therapies, GTX management strategies (i.e., variable dose and quality of PMNs), and varying definitions of success. Because of these confounding factors, combining data from multiple reports is of limited value in drawing conclusions, and it was done simply to document the breadth of the reported experience (Table 137-1 (Table Not Available)).

To obtain more definitive information regarding efficacy, the seven controlled studies were analyzed in more detail. [4] [5] [6] [7] [8] [9] [10] In these seven studies, the response of infected neutropenic patients
