SECTION 1 **BODY SYSTEMS**

1 Cardiovascular System 5
Cardiac Arrhythmias and EKG-Pharmacology 5
Cell Physiology 16
Cardiac Disease and Physiology 21
Angina: Cardiac-Associated Thoracic Pain 21
Angina: Non-Cardiac-Associated Thoracic Pain 29
Cardiac Diseases without Angina 30
Cardiopulmonary Physiology 35
Peripheral Vascular Disease, Function and Physiology 36
Cardiovascular Response Tests 47

2 Central Nervous System 61
Autonomic Nervous System 61
Peripheral Nervous System and Neuromuscular Function 62
Cerebral Cortex and Cerebral Hemispheres 63
Brainstem, Spinal Cord, and Peripheral Nervous System 114
Special Senses 117
Special Senses: Non-Ophthalmic 126

3 Endocrine System 129
Gastrointestinal/Pancreatic Systems 129
Hypothalamus and Pituitary: General and Miscellaneous 130
Hypothalamus, Pituitary, and Adrenal Axis 134
Hypothalamus and Pituitary: Growth Hormone 150
Hypothalamus/Pituitary Function: Reproduction 164
Hypothalamus, Pituitary, and Thyroid Axis 170
Parathyroid 176

4 Gastrointestinal System 179
Dentistry, Oral Cavity, and Salivary Glands 179
Esophageal Function and Disorders 181
Gastric Function and Disorders 183
Pancreas 190
Intestinal Absorption Breath Tests 190
Intestinal Absorption and Permeability: Non-Breath Tests 191
Absorption and Transit Time: Non-Carbohydrate-Based Agents 199
Permeability and Ulceration 203
Intestinal Inflammation 209
Motility and Transit Time of Intestinal Tract 210
Pancreas Function and Disease 212
Neoplasia of the Intestine and Colon 219

5 Hematopoietic System 221
Hematopoiesis, Hematology, and Hemostasis 221
Immune System 228
Inflammation 244
Ex Vivo Living Systems 245
Cardiovascular: *Ex Vivo* 245
Hepatic: *Ex Vivo* 246
Hematopoietic: Lymphocytes (*Ex Vivo*) 247
Hematopoietic: Macrophages and Monocytes (*Ex Vivo*) 248
Hematopoietic: Neutrophils (*Ex Vivo*) 252
Hematopoietic: Platelets (*Ex Vivo*) 256
Hematopoietic: Red Blood Cells (*Ex Vivo*) 260
Musculoskeletal: *Ex Vivo* 260
Neoplastic Disease: *Ex Vivo* 263
Respiratory: *Ex Vivo* 264

6 Hepatic System 267
Biliary and Hepatic Diagnostics 267
Biliary 267
Hepatobiliary 268
Hepatic Blood/Plasma Flow and Perfusion 269
Hepatic Excretory Function 269
Hepatocyte Phase I Metabolism Pathways 273
Hepatocyte Phase II Biochemical Metabolism Pathways 278
Hepatic Pathology and Disease States 279

Extrahepatic Disease Caused by Liver Dysfunction 281
Pharmacogenetics 281
Pharmacogenetics Concepts and Disease Examples 281
Pharmacogenetics: General Hepatic Biochemical Metabolization 289
Pharmacogenetics: Phase I Metabolizing Enzyme Systems 290
Microsomal Enzyme Metabolizing Capacity (General) 290
Microsomal Cytochrome P450 Enzyme Systems (General) 292
Microsomal Cytochrome P450 1A1 and P450 1A2 294
Microsomal Cytochromes P450 2A6, 2C9, 2C19, 2D6, and 2E1 296
Microsomal Cytochromes P450 3A 305
Hepatic Cytochrome P450 4 Microsomal Enzymes 311
Microsomal Flavin-Based Metabolizing Systems 312
Microsomal Mixed Function Oxidases 313
Phase II Metabolizing Enzyme Systems 314
Conjugation Systems 314
Extrahepatic Pharmacogenetics 322
Extrahepatic—Cardiovascular System 322
Extrahepatic—Central Nervous System 325
Extrahepatic—Renal System 329
Extrahepatic—Respiratory System 330
Extrahepatic—Musculoskeletal System 330
Pharmacogenetics of Prognosis and Therapeutic Response 332
7 Integumentary System 337

SECTION 4 **DELIVERY MODALITIES**

22 Biological and Synthetic Delivery Modalities 811
Macro-Biological Platforms 811
Cellular-Based Delivery Systems 811
Vector-Mediated Gene (Oligonucleotide) Delivery Systems 817
Macro-Synthetic Platforms 820
Liposomes 820
Microbubbles and Microspheres 845
Nanoparticles and Nanospheres 857
Molecular Platforms 869
Micro-Synthetic Agents 869
Peptides, Proteins and Immunoglobulins 883
Mechanical Platforms 904
Index 907

Preface

The composition of this text has been guided by a common need to document the wide spectrum and range of pharmaceutical and biopharmaceutical agents that have been, or potentially could be, utilized for diagnostic purposes. The sources and motivation for the development of such agents are quite varied in nature. In recent decades, an extensive body of investigative research has been devoted specifically to the design and evaluation of diagnostic pharmaceuticals. A significant portion of these efforts have been directed toward developing agents to meet the demands for enhancing the effectiveness of conventional imaging modalities and more advanced forms of diagnostic instrumentation, including contrast-enhanced helical computed tomography (CE-HCT), dynamic susceptibility contrast magnetic resonance imaging (DSC-MRI), and trans-cranial color-coded sonography (TCCS). Alternatively, the substantial amount of mechanistic-oriented research supported through federal agencies and private foundations has indirectly provided an invaluable experimental foundation for the development of a variety of biochemical, receptor, and gene-based diagnostic agents.

Written in an evidence-based format, the text is intended to serve as an information resource for identifying pharmaceutical and biopharmaceutical agents that can be applied in vivo or ex vivo in living systems relevant to both clinical medicine and investigative research. Organization of the contents has been structured on the assumption that in most instances, the specific organ system, physiological function, or disease process of interest is already known, but the identity of the appropriate molecular probe necessary to perform a specific diagnostic objective is uncertain. Given this perception, information in each chapter consists of an alphabetical listing of individual disease states or physiological processes of interest that have been entered in bold type above the text for each entry. On a secondary header line the name of the corresponding diagnostic pharmaceutical or biological agent(s) is provided in italics. In this manner, molecular probes can be located in the text based on their application or function without prior knowledge of their identity. Some entries also have additional clarifying statements contained within brackets to better indicate the contents of the descriptions provided for a particular diagnostic pharmaceutical.

Chapters in the text have been arranged or categorized into sections, including molecular agents that function as classical molecular probes, image-enhancing pharmaceutical or biopharmaceutical agents, and delivery modalities. The chapters contained within each of these major sections are themselves organized according to individual body systems. Diagnostic pharmaceuticals have also been included in chapters or subchapters that address broad topics related to endocrinology, genetic conditions, pharmacogenetics, neoplastic disease, metabolic function, inflammatory responses, infectious disease, immunity, ex vivo diagnostic models, and breath tests. Organization of the text in this fashion not only allows information about a diagnostic agent to be found in a more expedient manner, it also facilitates a more convenient grouping of pharmaceutical and biopharmaceutical agents that have similar diagnostic applications.

The majority of the information provided about diagnostic pharmaceuticals and delivery modalities can be applied to humans and other mammalian species, including laboratory animals, companion animals, domestic livestock, and wildlife, assuming some degree of preliminary optimization may be required. Although not specifically addressed, individual diagnostic pharmaceuticals and biopharmaceutical agents could also potentially be utilized for similar purposes in avian and reptilian species. Diagnostic agents could not be provided for the assessment of all known disease states or physiological processes. In part, this is because either some clinical conditions and biological functions cannot be appropriately characterized through the use of diagnostic pharmaceuticals and biological probes, or it is due to the fact that effective molecular agents still remain to be developed for such purposes. In accord with many published texts, there is a substantial amount of information that had to be excluded from this 1st edition due to various constraints. In the near future, it is hoped that an increased interest will be stimulated in the development of diagnostic pharmaceutical and biopharmaceutical agents in concert with their evaluation and application in clinical medicine and investigative research.

COMPARATIVE DIAGNOSTIC PHARMACOLOGY
Clinical and Research Applications in Living-System Models

1 BODY SYSTEMS

1 Cardiovascular System

CARDIAC ARRYTHMIAS AND EKG-PHARMACOLOGY (ELECTROPHARMACOLOGY)

Arrythmias: Differential Diagnosis
Adenosine Triphosphate (ATP)

Background Information: The agent adenosine triphosphate has been applied for decades as a major medication for the termination of supraventricular tachycardia crisis (reentry mechanism implicating the atrioventricular node).
Application: Differential diagnosis of cardiac arrythmias including narrow or wide QRS tachycardia; latent accessory pathway, intranodal duality (non-invasive); evaluation of slow pathway ablation (non-invasive); and obscure tachycardia mechanism with palpitations or tachycardia.

Atrial Flutter: Fetal/Pregestation
Adenosine

Physiological Mechanism of Action: Negative chronotropic effect on the heart.
Application: Differentiate between atrioventricular nodal reentrant supraventricular tachyarrhythmia and atrial flutter.
Route of Administration: Cordocentesis (fetus).
Implementation: Evaluation of a cardiac arrythmia with 1:1 atrioventricular conduction applying prenatal echocardiography. Adenosine is infused via cordocentesis for the purpose of differentiating between atrioventricular nodal reentrant supraventricular tachyarrhythmia and atrial flutter.
Human Model: Fetal tachyarrhythmia with 1:1 atrioventricular conduction in a fetus at 25 weeks gestation.
Interpretation and Analysis: After infusion, transient 2:1 atrioventricular dissociation may be observed in conditions corresponding to a diagnosis of atrial flutter. Transplacental therapy with digoxin and amiodarone can then be employed for successful conversion.

Fetal tachyarrhythmia with 1:1 atrioventricular conduction. Adenosine infusion in the umbilical vein as a diagnostic test. Leiria TL, Lima GG, Dillenburg RF, Zielinsky P. Arq Bras Cardiol 2000 Jul; 75 (1), pp. 65–8.

Atrioventricular (A-V) Accessory Conduction Pathway/(Wolff-Parkinson-White Syndrome)
Flecainide

Cellular/Molecular Mechanism of Action: Flecainide inhibits membrane sodium fast channels.
Application: Flecainide is utilized as a Class Ic antiarrhythmic agent.
Route of Administration: Flecainide (intravenous). Flecainide can also be given orally since it is not as extensively removed from the portal circulation as the other pharmaceutical agents in this class of antiarrhythmic agents.
Dosage: Flecainide (2 mg/kg over 5-minute period).
Implementation: Conversion of accessory A-V conduction pathway arrythmias. Cases of accessory A-V conduction pathway can present in various classification types (e.g., total n = 21; apparent n = 16/21; latent = 1/21; concealed/blocked in the anterograde direction = 4/21) and clinical presentations (e.g., spontaneous and inducible n = 17/21; supraventricular tachycardias due to orthodromic reentry including the accessory A-V pathway n = 13/21; and atrial arrhythmias n = 4/21).
Interpretation and Analysis: Intravenous flecainide can successfully terminate supraventricular tachycardia over a time span averaging 3 minutes (e.g., n = 13/13). Such effects are achieved through depression and then blocking of retrograde conduction within the accessory pathway. Similary, approximately 75% (e.g. n = 3 of 4) of cases with atrial arrhythmia can be converted. Conduction in the accessory pathway is blocked in the anterograde direction in 75% of affected cases and depressed in the rest; it is blocked in the retrograde direction in about half the cases and depressed in the remaining cases. Intravenous flecainide completely prevents the induction of arrhythmias in approximately 76% of affected cases (e.g. n = 13/17). Oral flecainide blocks the accessory pathway in the anterograde and retrograde direction in 68.7% and 62% of these cases respectively, while preventing arrhythmias during provocative testing in approximately 82% of cases (n = 14/17). With an average follow-up of 20.7 ± 2.6 months for oral doses adapted to body weight and to the response to flecainide IV, the observed rate of recurrence for atrial fibrillation is very low (e.g., n = 1/21). Conversely, a high level of prevention for spontaneous supraventricular can be appreciated (e.g., 100%), as well as a high level of prevention for all arrhythmias (e.g., n = 16/17 or 94%). The predictive value for the response to oral therapy of the tests of regularization of SVT by IV flecainide and of the tests of non-provocation of SVT with oral or IV flecainide is excellent (100%), and cardiac tolerance is very good. A moderate percentage of cases will experience general intolerance to oral therapy in a manner that is not dose related and very few of these cases actually require interruption of therapy.

Effects of oral and injectable flecainide in patients with an accessory atrioventricular pathway. Fauchier JP, Cosnay P, Rouesnel P, Moquet B, Bonnet P, Scala PJ, Demeyer JF. Arch Mal Coeur Vaiss 1985 Oct; 78 Spec No:81–90.

Atrioventricular (A-V) Block/Intermittent High-Degree A-V Block
Procainamide

Application: Characterization of atrioventricular block.
Route of Administration: Intravenous.
Dosage: Procainamide, ≤ 10 mg/kg.
Implementation: Evaluation of cases with resting 1:1 A-V conduction but have bifascicular block and a history of syncope, with high-degree A-V block not diagnostically documented prior to performing the procainamide challenge test.

Before procainamide administration, the HV interval can be greater than 60 msec in a relative large number of cases (n = 17/42

or 41%). Results can be compared to negative reference controls (e.g., n = 3).

Human Model: Cases of suspected atrioventricular block (n = 42). Note: Absence of the development of infra-Hisian block with fixed rate atrial pacing or following programmed atrial extrastimuli in cases with > 60 msec HV intervals.

Interpretation and Analysis: Procainamide administration lengthens the mean HV interval by 11.9 msec, and in approximately 14% of cases (e.g., n = 7/42) the HV increment can be marked (e.g., between 15 and 75 msec change). Some cases may develop second or third degree infra-Hisian block (e.g., n = 4/42 or 9.5%), while a subpopulation of these cases (e.g., n = 2/4), their HV prior to procainamide administration is normal or only mildly prolonged (less than 60 msec). Among cases with bifascicular block with previously documented transient A-V block but 1:1 A-V conduction at the time of study (e.g., n = 4 cases), a relatively large percent may develop high-degree A-V block following procainamide (e.g., n = 3/4 or 75%). In conditions of bifascicular block but without syncope or documented high-degree A-V block (e.g., n = 5 cases), the mean HV interval may lengthen by 18.8 msec or more (e.g., n = 3/5 HV increment 24–30 msec). In conditions without syncope or an intraventricular conduction defect (e.g., n = 38 cases), the mean HV interval may lengthen by 5.3 msec (e.g., n = 2/38 cases with increases of 20 to 25 msec). Cases in the latter 2 groups frequently do not experience high-degree A-V block (e.g., n = 0). During follow-up periods of up to 10 years (mean 46 months), approximately 43% of cases in which procainamide provokes high-degree A-V block will subsequently progress to fixed complete A-V block (e.g., n = 3/7 cases). Although the incidence of provocation of A-V block is relatively low, it can be concluded that in conditions with possible intermittent A-V block, administration of procainamide as a test of distal conduction has limited value but is still useful and may provide information additional to that obtained from mere assessment of the HV interval.

Procainamide administration during electrophysiology study—Utility as a provocative test for intermittent atrioventricular block. Twidale N, Heddle WF, Tonkin AM. Pacing Clin Electrophysiol 1988 Oct; 11 (10), pp. 1388–97.

Atrioventricular (A-V) Block/Intermittent High-Degree Atrioventricular (A-V) Block/ Dose Infusion Optimization
Procainamide

Cellular/Molecular Mechanism of Action: Procainamide inhibits Na^+/K^+ pump function and promotes weak parasympatholytic activity similar to quinidine (quinidine has a stronger influence on cardiac parasympathetic input).

Background Information: No previous studies have determined the pharmaco-dynamics of intravenous procainamide when administered in a dose of 15 mg/kg and at a rate of 50 mg/min, as is common practice during electropharmacologic testing.

Application: Characterization of A-V block and intermittent high-degree A-V block.

Route of Administration: Procainamide (intravenous).

Dosage: Procainamide (4 mg/min to 8 mg/min).

Implementation: Evaluation of cardiovascular conditions using procainamide during electropharmacological testing procedures. In this fashion, the right ventricular effective refractory period and the QRS duration at a ventricular pacing rate of 120/min can be determined every minute for 20 minutes. Plasma procainamide concentrations are measured at 1, 5, 10, 15, and 20 minutes following loading-dose administration.

Human Model: n = 30; n = 10 cases given no maintenance infusion; n = 10 cases @ 4 mg/min maintenance infusion; n = 10 cases @ 8 mg/min maintenance infusion; n = 10 reference control cases given no procainamide.

Interpretation and Analysis: A stable plasma procainamide concentration may not be present in cases receiving procainamide administration until 15 minutes after loading-dose infusion. The effective refractory period and QRS duration increase compared with baseline at 1 minute, decrease between 1 and 10 minutes, and then remain essentially unchanged between 10 and 20 minutes (all cases groups receiving procainamide). Concentration-effect relationships are linear in cases receiving multiple procainamide administration schedules. The plasma procainamide concentrations in cases receiving infusions at 8 mg/min are significantly greater than in cases receiving 4 mg/min infusion rates; however, the effects on refractoriness and QRS duration are similar in both groups. These findings indicate that with a procainamide dosing method commonly used during electropharmacologic testing, the plasma procainamide concentration decreases significantly during the first 15 minutes after the loading dose is administered.

Pharmacodynamics of intravenous procainamide as used during acute electropharmacologic testing. Morady F, Kou WH, Schmaltz S, Annesley T, De Buitleir M, Nelson SD, Kushner JA. Am J Cardiol 1988 Jan 1; 61 (1), pp. 93–8.

Atrioventricular Nodal Reentrant Tachycardia/ Atrioventricular Nodal Block Induction
Adenosine

Physiological Mechanism of Action: Negative chronotropic effect on cardiac function.

Background Information: Adenosine at low doses preferentially blocks fast over slow pathway conduction in conditions of dual atrioventricular (A-V) nodal physiology and typical A-V nodal reentrant tachycardia (A-VNRT). During atrial pacing, this effect is manifested as an abrupt increase in the AH interval with low doses of adenosine. The demonstration of dual A-V nodal physiology may be useful as a diagnostic tool during electrophysiologic studies in cases with supraventricular tachycardia that are not easily inducible, as clear demonstration of dual A-V nodal pathways may indicate that A-VNRT is a likely diagnosis and that further attempts at arrhythmia induction should be tailored with that objective in mind. However, to be a useful test, adenosine should not cause an abrupt increase in AH interval in conditions without dual A-V nodal physiology.

Application: Incremental adenosine infusion during electrophysiologic studies can be used as a highly specific diagnostic tool for cases with dual A-V nodal pathways.

Route of Administration: Adenosine (intravenous).

Dosage: Adenosine (incrementally larger doses administered until development of A-V nodal block).

Implementation: Baseline Wenckebach cycle length (WCL) and A-V nodal effective refractory periods are measured at atrial pacing cycle lengths of 400 and 600 msec. The atrium is then paced at WCL +50 ms, and WCL +100 ms, while incrementally larger doses of intravenous adenosine are administered until induction of A-V nodal block.

Human Model: Electrophysiology cases (n = 37 without prior history of A-VNRT).

Interpretation and Analysis: The mean (± standard deviation) doses of adenosine required to cause A-V nodal block while pacing at WCL +50 msec and WCL +100 msec is approximately 7.1 ± 3.9 and 7.4 ± 4.5 mg, respectively. In a small number of cases (e.g., n = 1/37 = 2.7%, 95% confidence interval 0–8%), an abrupt prolongation of the AH interval can be appreciated with the administration of adenosine during atrial pacing as well as during the atrial refractory period determination. In the majority of cases, no dual A-V nodal

physiology can be appreciated during the refractory period determination, and there are only gradual changes in the AH interval with atrial pacing during adenosine administration. In cases without a history suggestive of A-V nodal reentrant tachycardia, only 2.7% have clinically silent dual A-V nodal pathways using the described method. Incremental adenosine infusion during electrophysiologic study can be used as a highly specific diagnostic tool for cases with dual A-V nodal pathways.

Use of adenosine as a diagnostic tool for dual atrioventricular nodal pathways: Response of control patients to incremental doses of adenosine. Burkart TA, Scozzaro MJ, Angella FR, Jayaram KN, Gonzalez MD, Conti JB, Curtis AB. Clin Cardiol 2002 Jun; 25 (6), pp. 263–6.

Brugada Syndrome/Genetic Locus: SCN5A Gene Mutation
Flecainide

Cellular Mechanism of Action: Flecainide suppresses fast sodium channels resulting in declines in Vmax and action potential overshoot within the atria, ventricles, and Purkinje fibers.
Physiological Mechanism of Action: Flecainide and the other agents in this class of local anesthetics including encainide and lorcainide exert cellular membrane electrophysiological responses that are distinctly different from those created by lidocaine. A slowing of conduction is most prominent within the His-Purkinje system, but there is minimal effect on action potential repolarization duration. On EKG tracings a noticeable widening of the QRS complex can be appreciated.
Background Information: The flecainide test is widely used to evaluate conditions of Brugada syndrome. However, its reproducibility and safety remain ill-defined.
Route of Administration: Flecainide test (intravenous bolus).
Dosage: Flecainide test (2 mg/kg over 10 minutes).
Implementation: (i) Evaluation of the frequency of mutations in the SCN5A gene in cases of Brugada syndrome that are candidates for flecainide response testing; (ii) determination of the degree of correlation that exists between SCN5A expression and results from flecainide response testing; (iii) determination of the repeatability of flecainide test response. The flecainide response is performed at baseline (e.g., n = 21/22 cases) and a second time within 2 months.

Human Model: Cases of Brugada syndrome (n = 22; n = 18 men; age = 34 years; n = 2 cases of aborted sudden cardiac death; n = 8 cases with syncope/presyncope; n = 12 asymptomatic cases).
Interpretation and Analysis: Mutations in the SCN5A gene can be appreciated in a relatively large percentage of cases of Brugada syndrome (e.g., n = 8/22). Analyses of ECG tracing may be (i) diagnostic in 86% (e.g. n = 19/22); and (ii) suggestive in 14% (e.g. n = 3/22). The flecainide test can be performed by infusion of a 2 mg/kg IV bolus over 10 minutes (e.g. n = 21/22 test subjects). In a very high percentage of cases the flecainide test is diagnostic or amplifies the typical ECG pattern (e.g., n = 21/21 or 100%). At the end of drug infusion, sustained VT that lasts 7–10 minutes may ultimately develop (e.g., n = 2/21 cases).

A second flecainide test performed within 2 months may be diagnostic in a high percentage of cases (e.g., n = 20/20 or 100%; note n = 2 cases with prior development of ventricular arrythmias; n = 1/2 with sustained VT; n = 1/2 recurrent VF). The reproducibility of the flecainide test is relatively high (e.g. 100%). Approximately 18% of cases (e.g., n = 4/22) develop ventricular arrythmias documented after the end of flecainide infusion. Ventricular arrythmias occur in 43% (e.g. n = 3/7) of cases with SCN5A gene mutation compared to 7% (e.g. n = 1/15) without an SCN5A gene mutation ($p < 0.05$). Diagnostic ECG changes or arrhythmias are usually not appreciated in reference controls (e.g., n = 25). The reproducibility of the flecainide response test is very high for supporting a diagnosis of Brugada syndrome. However, the occurrence of major VA, (significantly higher in cases with documented SCN5A gene mutation, including in asymptomatic conditions) mandates performance of the procedures under appropriate medical supervision. Whether a slower rate of drug infusion can lower the risk of VA induction while maintaining the sensitivity of the test needs to be explored.

Flecainide test in Brugada syndrome: A reproducible but risky tool. Gasparini M, Priori SG, Mantica M, Napolitano C, Galimberti P, Ceriotti C, Simonini S. Pacing Clin Electrophysiol 2003 Jan; 26 (1 Pt 2), pp. 338–41.

Brugada Syndrome/Genetic Locus: Distinct from SCN5A (Low Procainamide Sensitivity)
Procainamide

Background Information: Brugada syndrome is a form of idiopathic ventricular fibrillation characterized by a right bundle-branch block pattern and S-T segment elevation (S-TE) in the right ECG precordial leads. Sodium channel blockers increase S-TE. Mutations of the cardiac sodium channel SCN5A cause the disorder, and an implantable cardioverter-defibrillator is often recommended for the management of such conditions. Mutations in other genes have not been identified, and it is not known if the efficacy of drug testing or the malignancy of arrhythmias correlates closely with the frequency of the genetic defect.
Application: Procainamide infusions do not identify additional affected cases of Brugada syndrome beyond those already identified through the interpretation of other clinically-relevant parameters.
Implementation: Collective evaluation of histories, physical examinations, ECGs, and drug testing in cases with Brugada syndrome. Samples of DNA isolated from blood samples, polymorphic genomic markers, and polymorphisms within sodium channels can be used for a genome-wide screen, fine mapping, and linkage analysis.

Human Model: Families with multigenerations with Brugada syndrome.
Interpretation and Analysis: Some affected cases (n = 12 right bundle-branch block, ≥ 1 mm S-TE) with an autosomal dominant inheritance profile display patterns of incomplete penetrance that appears to be dependent on age and gender. Some cases (e.g. n = 4/12) also display signs of syncope, while others (e.g., n = 2/12) have documented evidence of ventricular arrhythmias. In some scenarios, there is minimal sudden death in the family history. Procainamide infusions do not identify additional affected individuals. Linkage is present to an approximately equal 15 cM region on chromosome 3p22-25 (maximum LOD score = 4.00). The sodium channel genes SCN5A, SCN10A, and SCN12A on chromosome 3 have been excluded as candidates (LOD scores ≤ −2). A Brugada syndrome locus distinct from SCN5A is associated with progressive conduction disease, a low sensitivity to procainamide testing, and a relatively good prognosis in a single large pedigree.

Clinical and molecular heterogeneity in the Brugada syndrome: A novel gene locus on chromosome 3. Weiss R, Barmada MM, Nguyen T, Seibel JS, Cavlovich D, Kornblit CA, Angelilli A, Villanueva F, McNamara DM, London B. Circulation 2002 Feb 12; 105 (6), pp. 707–13.

Brugada Syndrome and Long Q-T Interval Syndromes
Flecainide

Cellular Mechanism of Action: Flecainide suppresses fast sodium channels resulting in declines in Vmax and action potential overshoot within the atria, ventricles, and Purkinje fibers.

Physiological Mechanism of Action: In this context, flecainide and the other agents in this class of local anesthetics including encainide and lorcainide exert cellular membrane electrophysiological responses that are distinctly different than those produced by lidocaine. A slowing of conduction is most prominent within the His-Purkinje system, but there is minimal effect on action potential repolarization duration. On EKG tracings a noticeable widening of the QRS complex can be appreciated.
Application: Evaluation of SCN5A gene-related cardiac sodium channel disfunction associated with both [i]long Q-T syndrome (Q-T interval prolongation) with S-T segment elevations (leads V1 through V3); and [ii] Brugada syndrome. Intravenous flecainide is the standard provocative test used to unmask Brugada syndrome in individuals with concealed forms of the disease, and oral flecainide has been proposed as a treatment option for LQ-T3 patients because it may shorten their Q-T interval.
Route of Administration: Intravenous.
Dosage: Brugada syndrome protocol.
Considerations: The typical manifestations of Q-T syndrome (Q-T interval prolongation) and Brugada syndrome (S-T segment elevation in leads V1 through V3) may coexist in the same patients, which raises questions about the actual differences between these 2 conditions. Theoretically, differentiation between them can be achieved with the intravenous administration of flecainide based on the hypothesis that it might not only shorten the Q-T interval but may also produce elevations of the S-T segment in cases of long Q-T syndrome (Q-T interval prolongation) with S-T segment elevations (leads V1 through V3).
Interpretation and Analysis: Administration of intravenous flecainide according to Brugada syndrome protocols in conditions of long Q-T syndrome (Q-T interval prolongation) with S-T segment elevations (leads V1 through V3) can produce (i) shortening of the Q-T, Q-Tc, JT, and JTc intervals in a high percentage of cases (e.g., n = 12/13 or 92%); and (ii) S-T segment elevation in leads V1 through V3 ($\geq$ 2 mm) may also sometimes be appreciated (e.g., n = 6/13 or 46%). In this context, flecainide may induce S-T segment elevation in conditions of long Q-T syndrome (Q-T interval prolongation) accompanied by S-T segment elevations (leads V1 through V3), thereby raising concerns about the safety of flecainide therapy and demonstrates the intriguing consideration that an overlap may exist between this condition and Brugada syndrome.

The elusive link between LQ-T3 and Brugada syndrome: The role of flecainide challenge. Priori SG, Napolitano C, Schwartz PJ, Bloise R, Crotti L, Ronchetti E. Circulation 2000 Aug 29; 102 (9), pp. 945–7.

Brugada Syndrome/Tachyarrythmias: Long Q-T Syndrome
Catecholamine/Isoproterenol

Route of Administration: Isoproterenol (intravenous infusion).
Dosage: Isoproterenol.
Considerations: Catecholamines have long been used as a provocative test in some forms of tachyarrhythmias including long Q-T syndrome. In addition, catecholamines are also reported to decrease S-T segment elevation in leads V1-V3 in some conditions of Brugada syndrome.
Implementation: Differential effects of catecholamines on Q-T interval, action potential duration, transmural dispersion of repolarization, and torsade de pointes between LQ-T1, LQ-T2, and LQ-T3 forms of long Q-T syndrome can be evaluated in experimental models utilizing (i) arterially-perfused wedge preparations; and (ii) cases with congenital long Q-T syndrome, including children.
Interpretation and Analysis: Preliminary results in adult and prejuvenile forms of Brugada syndrome receiving isoproterenol infusion reveals that it is effective in decreasing the S-T segment elevation in leads V1-V2 and in suppressing the electrical storm of ventricular fibrillation.

Catecholamines in children with congenital long Q-T syndrome and Brugada syndrome. Shimizu W, Kamakura S. J Electrocardiol 2001; 34 Suppl, pp. 173–5.

Brugada Syndrome/Vagal Stimulation Sensitivity/ Angina: Atypical Thoracic Pain (Coronary Vasospastic)/Ischemic-Related Sudden Death Risk
Acetylcholine (ACh)/Ergonovine Maleate (EM)

Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such findings imply that some form of abnormality in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Background Information: Experimental studies suggest that a prominent transient outward current (I_{to})-mediated action potential notch and a subsequent loss of the action potential dome in the epicardium, but not in the endocardium, give rise to S-T segment elevation and subsequent ventricular fibrillation (VF).
Application: Characterization of the sensitivity of Brugada syndrome to vagal stimulation and possible prediction of the risk of developing ischemic-related sudden death.
Route of Administration: Acetylcholine (ACh).
Implementation: Evaluation of the frequency of coronary spasm, augmentation ($\geq$ 0.1 mV) of S-T segment elevation in leads V1 to V3, and induction of VF by intracoronary injection of ACh and/or EM.

Human Model: Cases of symptomatic Brugada syndrome (n = 27 with n = 30 control).
Interpretation and Analysis: Coronary spasm can be induced in a relatively small percentage of cases affected by Brugada syndrome (e.g., n = 3/27 or 11%) compared to approximately 43% of healthy/normal subjects (e.g., n = 13/30). S-T segment elevation is augmented in approximately 33% (e.g., n = 11/33) of right coronary injections (e.g., ACh: n = 6/11 or 55%; EM: n = 5/22 or 23%), without coronary spasm, but in essentially no or a very low percentage of left coronary injections in cases with Brugada syndrome (e.g., n = 0 or 0%). Ventricular fibrillation can be induced in approximately 9% of right coronary injections (e.g., n = 3/33; ACh: 2/11 or 18%; EM: 1/22 or 5%), but in no or only a very low percentage of left coronary injections (e.g., n = 0 or 0%). In contrast, neither S-T segment elevation nor VF can be commonly observed in control subjects (e.g., n = 0 or 0%). Such observations support the hypothesis that mild ischemia and vagal influences act additively or synergistically with the substrate responsible for Brugada syndrome elevated

S-T segments and precipitation of VF. These observations suggest that Brugada conditions may be at a higher risk for ischemia-related sudden death.

S-T segment elevation and ventricular fibrillation without coronary spasm by intracoronary injection of acetylcholine and/or ergonovine maleate in patients with Brugada syndrome. Noda T, Shimizu W, Taguchi A, Satomi K, Suyama K, Kurita T, Aihara N, Kamakura S. J Am Coll Cardiol 2002 Nov 20; 40 (10), pp. 1841–7.

Brugada Syndrome: Unmasking Silent ECG Pattern/ [Syncope of Unknown Origin]
Ajmaline/Pro-Arrhythmic Effect

Cellular/Molecular Mechanism of Action: Ajmaline is a a blocking agent for sodium channels.
Background Information: The diagnostic ECG pattern in Brugada syndrome (BS) can transiently normalize and may be unmasked by sodium channel blockers. Proarrhythmic effects of the drug have been well documented in the literature. A detailed protocol for the ajmaline challenge in Brugada syndrome has not been thoroughly described.
Application: Standardized ajmaline test for unmasking ECG evidence of Brugada syndrome.
Route of Administration: Ajmaline (intravenous).
Dosage: Ajmaline (10 mg fractions every 2 minutes up to a target dose of 1 mg/kg).
Implementation: Evaluation of ajmaline as a "test" agent during ECG evaluation of Brugada syndrome.

Human Model: n = 158 cases subjected to a ajmaline test over a 60-month period.
Interpretation and Analysis: In approximately one-fourth of all cases of Brugada syndrome, the typical coved-type ECG pattern of the condition is unmasked with ajmaline administration (e.g., n = 37/158 or 23%). During test evaluations, symptomatic VT can occasionally be recognized (e.g., n = 2/158 or 1.3%). In other cases of Brugada syndrome, ajmaline challenge does not induce VT if the target dose; QRS prolongation > 30%, presence/appearance of the typical ECG; or the occurrence of premature ventricular ectopy are considered as criteria end points. A positive response to a ajmaline can be induced in a small number of cases (e.g., n = 2/94 or 2%) that have a normal baseline ECG but are subjected to evaluation solely for syncope of unknown origin.

The ajmaline challenge using a fractionated drug administration protocol is a safe method to diagnose BS. Because of the potential induction of VT, it should be performed under continuous medical surveillance with advanced life-support facilities. Due to the prognostic importance all cases with aborted sudden death or unexplained syncope without demonstrable structural heart disease and family members of affected individuals should presently undergo drug testing for unmasking Brugada syndrome.

The ajmaline challenge in Brugada syndrome: Diagnostic impact, safety, and recommended protocol. Rolf S, Bruns HJ, Wichter T, Kirchhof P, Ribbing M, Wasmer K, Paul M, Breithardt G, Haverkamp W, Eckardt L. Eur Heart J 2003 Jun; 24 (12), pp. 1104–12.

Brugada Syndrome (Case Report)/Vasospastic Angina: Associated Syncope
Acetylcholine/Class I Antiarrhythmic Agents/Procainamide/[Diltiazam]/[Flicanide]

Cellular/Molecular Mechanism of Action: Acetylcholine promotes vascular smooth muscle contraction by acting as a neurotransmitter for the parasympathetic segment of the autonomic nervous system. Procainamide is a Class I antiarrhythmic sodium channel blocker.
Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such findings imply that some form of abnormality in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Procainamide exerts both a direct effect on the heart and an indirect effect mediated through the autonomic nervous system. The overall effect of procainamide on cardiac automaticity, excitability, responsiveness and conduction are virtually identical to that reported for quinidine.
Application: Administered as a provocative test for inducing spasms of coronary arteries applied in combination with electrocardiography monitoring.
Route of Administration: Acetylcholine (selective intracoronary injection).
Dosage: Acetylcholine.
Implementation: Evaluation of conditions associated with coronary artery spasm.

Human Model: Cases of coronary artery spasm accompanied by syncopal attacks and chest pain (e.g. n = 1/68-year-old male)with evidence of Brugada syndrome on electrocardiogram tracings. Ventricular fibrillation (VF) can be induced by programmed electrical stimulation.
Interpretation and Analysis: S-T segment elevations can be exaggerated by procainamide, which may not prevent the induction of VF. Coronary angiography may reveal no stenotic lesions, while spasm in the left coronary artery can be induced by intracoronary administration of acetylcholine resulting in the creation of similar chest pain similar to previous natural experiences. Under treatment with diltiazem and flecainide, which can suppress the induction of VF, patients may experience no recurrence of symptoms despite persistent S-T segment elevations. No previous reports have described coronary spasm associated with Brugada-type ECG abnormalities, and patients with syncope should be evaluated carefully.

Related reports have described conditions of vasospastic angina and Brugada-type ECG abnormalities. Cases may present with signs of chest pain and evidence of transient S-T segment elevations on ECG profiles. Coronary angiogram shows no organic stenosis. Syncopal episodes may follow anginal chest pain, and the same symptoms can often be created by intracoronary acetylcholine-induced vasospasm. The ECG profile at rest in many cases shows S-T segment elevation in leads V1 and V2 and a right bundle branch block pattern, which can be accentuated by a Class I antiarrhythmic drug. Ventricular fibrillation also can be induced by programmed electrical stimulation. Susceptibility to ventricular fibrillation can be modulated by the interaction of coronary vasospasm with Brugada syndrome or vice versa; therefore, it is important to study the clinical implications of the coexistence of the 2 diseases in such conditions.

Vasospastic angina accompanied by Brugada-type electrocardiographic abnormalities. Chinushi M, Kuroe Y, Ito E, Tagawa M, Aizawa Y. J Cardiovasc Electrophysiol 2001 Jan; 12 (1), pp. 108–11.

Long Q-T Syndrome: Genetic *Implications*

Background Information: The molecular genetic background of inherited cardiac arrhythmias has only recently been delineated. Delays in establishing comparisons to other inherited cardiac disorders has partly been due to the high mortality and early disease onset of these arrhythmias resulting in mostly small nucleus families. Thus, traditional genetic linkage studies, which are based on the genetic information obtained from large multigeneration families, have been difficult to conduct. Inherited arrhythmogenic disorders can be divided into primary electrical disorders (e.g., long Q-T [LQ-T] syndrome), in which evidence of organic heart disease can not be detected, and inherited diseases affecting myocardial structures (e.g., hypertrophic cardiomyopathies), in which arrhythmias occur combined with structural (functional anatomical) alterations. To date, all inherited arrhythmogenic disorders in which the causative genes have been identified can be classified as channelopathies, since the genes encode channel subunits that regulate important ion currents that "tune" the cardiac action potential. The discovery of the genetic bases of the LQ-T syndrome became a new methodologic paradigm because with the use of "classical" genetic linkage strategies (named [positional] candidate strategies), not only the causative genes have been found, but moreover, functional components with a previously unknown but fundamental role for a normal repolarization process have been discovered. Disease mutations have been determined to be not only a family-specific event with a distinct phenotype and the potential of an additional diagnostic tool, but also, when expressed in heterologous expression systems, characterize the defective ion channel in a topological way and lead to a more specific understanding of ion channel function. Most, if not all, primary electrical cardiac disorders show a high level of genetic diversity. For the LQ-T syndromes, sixth disease loci and the responsible gene have been recently discovered (so-called locus or genetic heterogeneity). Within all disease genes, the mutations are spread over the entire gene (allelic heterogeneity); in addition, more than 1 disease mutation may be present. This complexity requires, at the least, complete mutation analysis of all LQ-T genes before medical advice should be given. In addition, genotype-phenotype correlations in large families have been used to evaluate intergene, interfamilial, and intrafamilial differences in the clinical phenotype, reflecting gene specific, gene-site specific, and individual consequences of a given mutation. A widespread phenotypic heterogeneity even within mutation carriers in the same family illustrates the importance of modifying factors and genes that are mostly unknown to date. The reduced penetrance and variable expressivity associated with the LQ-T mutations remains unexplained. First insights into the complex actions of mutations are being extracted from expression data; these preliminary results may lead to potential implications for a specific (gene-site directed) therapy. The referenced paper discusses data relevant to molecular genetics and genotype-phenotype correlations in LQ-T syndrome and related disorders and the potential implications for diagnosis and treatment.

Molecular genetics of arrhythmias—A new paradigm. Schulze-Bahr E, Haverkamp W, Borggrefe M, Wedekind H, Mönnig G, Mergenthaler J, Assmann G, Funke H, Breithardt G. Z Kardiol 2000; 89 Suppl 4, pp. IV12–22.

Long Q-T Syndrome (LQ-TS) *Dobutamine*

Cellular/Molecular Mechanism of Action: Directly binds to and activates β_1 adrenergic receptor complexes.
Physiological Mechanism of Action: Dobutamine, to a lesser degree than isoproterenol, increases sinus node automaticity. Conduction velocity through the A-V node is accelerated. Atrial and ventricular impulse conductions are not influenced by dobutamine. Dobutamine has a greater effect on myocardial contraction and exerts relatively less pronounced chronotropic properties. In conditions of prolonged Q-T intervals (Q-T syndrome), dobutamine shortens the Q-T interval on EKG tracings.
Application: Low-dose dobutamine along with isoproterenol has been applied for the diagnosis and evaluation of prolonged Q-T intervals (Q-T syndrome or LQ-TS) associated with syncope and abnormal TU complexes. Diagnostically, dobutamine can be helpful in determining if syncope is due to a prolongation in Q-T intervals or if episodes are precipitated by non-cardiac related abnormalities.
Route of Administration: Continuous intravenous infusion can be implemented due to a brief plasma half-life of approximately $T_{1/2} = 2$ minutes. Dobutamine cannot be effectively administered orally.
Dosage: Dobutamine (low dose 10 μg/kg/min). In domestic animals, dobutamine administration rates between 2.5 to 15 μg/kg/min elevate myocardial contractility and cardiac output. In instances where the administration rate exceeds 20 μg/kg/min, increases in heart rate become much more pronounced.
Considerations: Dobutamine is rapidly metabolized by the liver to an inactive glucuronic conjugate. In contrast to dopamine, dobutamine does not promote renal vasculature vasodilation.
Interpretation and Analysis: When dobutamine is infused at a rate of 10 μg/kg/min, the Q-T interval corrected for heart rate (Q-Tc) is prolonged from 460 msec to 620 msec with the abnormal development of TU complexes and torsades de pointes profiles. In contrast, the Q-Tc does not appreciably change in normal unaffected patients ($n = 5$) during low-dose dobutamine infusion. Low-dose dobutamine, in addition to isoproterenol, may be useful for evaluating Q-T interval prolongation and abnormal TU complexes when LQ-TS is a consideration.

Diagnostically, dobutamine can be helpful in determining if syncope in affected cases is due to a prolongation in Q-T intervals or if episodes originate from non-cardiac related abnormalities.
Toxicity: Essentially the same as observed with isoproterenol including arrythmias and should be avoided or used with care in conditions of atrial fibrillation.

Induction of torsades de pointes by dobutamine infusion in a patient with idiopathic long Q-T syndrome. Fujikawa H, Sato Y, Arakawa H, Mitsuhashi T, Minezaki K, Kuroki S, Sekiguchi H, Nakayama T, Ikeda U, Shimada K. Intern Med 1998 Feb; 37 (2), pp. 149–52.

Norepinephrine, Epinephrine, and the Sympathomimetic Smines. Weiner N (Chapter 8: pp. 145–80). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

Long Q-T Syndrome (LQ-T1): Congenital/Silent LQ-T1 Mutation Carriers *Epinephrine*

Cellular/Molecular Mechanism of Action: Epinephrine is an endenous neurotransmitter that functions as a positive adrenergic agonist/sympathomimetic agent at α-adrenergic and β-adrenergic postsynaptic receptor complexes.

Background Information: The LQ-T1 form of congenital long Q-T syndrome is associated with a high vulnerability to sympathetic stimulation and clinically presents with incomplete penetrance.
Application: Detection of silent LQ-T1 mutation carriers.
Route of Administration: Epinephrine (infusion).
Dosage: Epinephrine (0.1 μg/kg/min).
Implementation: Evaluation of the LQ-T1 form of congenital long Q-T syndrome using epinephrine infusion. Electrocardiographic (12-lead) parameters are recorded before and after epinephrine infusion.

Human Model: Congenital LQ-T1 (n = 19 mutation carriers with a baseline corrected Q-T interval (Q-Tc) of ≥ 460 msec (Group I); n = 15 mutation carriers with a Q-Tc of < 460 msec (Group II); n = 12 non-mutation carriers (Group III), and 15 controls (Group IV).
Interpretation and Analysis: The mean corrected Q-Tend (Q-Tce), Q-Tpeak (Q-Tcp), and Tpeak-end (Tcp-e) intervals among 12-leads prior to epinephrine are significantly larger in Group I cases than in other cases groups. Epinephrine significantly increases the mean Q-Tce, Q-Tcp, and Tcp-e and the dispersion of Q-Tcp in Groups I and II, but not in Groups III and IV. Sensitivity and specificity of Q-Tce measurements to identify mutation carriers is approximately 59% (e.g. n = 20/34) and 100% (e.g. n = 27/27), respectively, before epinephrine, and the sensitivity is substantially improved to 91% (e.g. n = 31/34) without the expense of specificity (100%, or n = 27/27) after epinephrine. The mean Q-Tce, Q-Tcp, and Tcp-e before and after epinephrine is significantly larger in symptomatic (e.g., n = 15) than in asymptomatic (e.g. n = 19) mutation carriers in case Groups I and II, and the prolongation of the mean Q-Tce with epinephrine is significantly larger in symptomatic cases. Epinephrine challenge can function as a powerful test to establish electrocardiographic diagnosis in silent LQ-T1 mutation carriers, thus allowing implementation of prophylactic measures aimed at reducing sudden cardiac death.

Epinephrine unmasks latent mutation carriers with LQ-T1 form of congenital long Q-T syndrome. J Am Coll Cardiol 2003 Feb 19; 41 (4), pp. 633–42.

Long Q-T Syndrome/Ventricular Tachycardias/ Wolff-Parkinson-White Syndrome
Therapeutic Response/[Encainide]/[Flecainide]/ [Lidocaine]/[Lorcainide]

Cellular/Molecular Mechanism of Action: Flecainide suppresses fast sodium channels resulting in declines in Vmax and action potential overshoot within the atria, ventricles, and Purkinje fibers.
Physiological Mechanism of Action: Flecainide and the other agents in this class of local anesthetics, including encainide and lorcainide, exert cellular membrane electrophysiological responses that are distinctly different from those associated with lidocaine. A slowing of conduction is most prominent within the His-Purkinje system but there is minimal effect on action potential repolarization duration. On EKG tracings a noticeable widening of the QRS complex can be appreciated.
Application: The local anesthetics encainide, flecainide, and lorcainide as a group possess advantages in inhibiting premature ventricular contractions and potentially lethal ventricular tachycardias. Encainide and flecainide have been applied in the conversion of Wolff-Parkinson-White syndrome.
Dosage: The estimated half-life of flecainide has not been extensively studied, but in the few reports that have described these values in humans reveal a $T_{1/2}$ between 7 and 24 hours.
Considerations: Similar to many local anesthetics (e.g., lidocaine, encainide, lorcainide), flecainide is absorbed following oral administration. Flecainide differs from most of these agents by the fact that it is removed from the peripheral intravascular compartment to a much lesser degree on first pass through the hepatic circulation.

Antiarrythmic Drugs. Bigger JT, Hoffman BF (Chapter 31: pp. 748–83). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

Purkinje Fiber Action Potential Duration/ (Bladder Contractions)
Potassium ATP Channel Opener/[^{125}I]A-312110

Cellular/Molecular Mechanism of Action: [^{125}I]A-312110 or [(9R)-9-(4-fluoro-3-^{125}iodophenyl)-2,3,5,9-tetrahydro-4H-pyrano[3,4-b]thieno[2,3-e]pyridin-8(7H)-one-1,1-dioxide] functions as a potassium ATP (KATP) channel opener in cardiac tissues.
Physiological Mechanism of Action: In the *in vivo* application of [^{125}I]A-312110 or [(9R)-9-(4-fluoro-3-^{125}iodophenyl)-2,3,5,9-tetrahydro-4H-pyrano[3,4-b]thieno[2,3-e]pyridin-8(7H)-one-1,1-dioxide], can either suppress action potential duration (APD) in Purkinje fibers and can relax electrical field-stimulated bladder contractions.
Application: [^{125}I]A-312110 or [(9R)-9-(4-fluoro-3-125iodophenyl)-2,3,5,9-tetrahydro-4H-pyrano[3,4-b]thieno[2,3-e]pyridin-8(7H)-one-1,1-dioxide] can be applied for detecting and characterizing potassium ATP channels in addition to functioning as a potential imaging agent for delineating the distribution and expression density of potassium ATP channels. In this context, [^{125}I]A-312110 can be used to delineate the molecular and functional properties of the KATP channel complex and the identification of new channel blockers and openers that interact with cardiac/smooth muscle-type KATP channels.
Route of Administration: [^{125}I]A-312110 (intravenous).
Considerations: Although ATP-sensitive K+ channels continue to be explored for their therapeutic potential, developments in high-affinity radioligands to investigate native and recombinant KATP channels have been less forthcoming.
Interpretation and Analysis: The agent [^{125}I]A-312110 binds with high affinity to a single class of binding sites in guinea pig cardiac membranes (KD = 5.8 nM) and urinary bladder membranes (KD = 4.9 nM) in a saturable manner. Displacement of [^{125}I]A-312110 by structurally diverse potassium channel openers (KCOs) indicates a similar rank order of potency in both guinea pig cardiac and bladder membranes (Ki, heart): A-312110 (4.3 nM) > N-cyano-N′-(1,1-dimethylpropyl)-N′′-3-pyridylguanidine (P1075) > (-)-N-(2-ethoxyphenyl)-N′-(1,2,3-trimethylpropyl)-2-nitroethene-1,1-diamine (Bay X 9228) > pinacidil > (-)-cromakalim > N-(4-benzoyl phenyl)-3,3,3-trifluro-2-hydroxy-2-methylpropionamine (ZD6169) > 9-(3-cyanophenyl)-3,4,6,7,9,10-hexahydro-1,8-(2H,5H)-acridinedione (ZM244085) >> diazoxide (16.7 μM). Displacement by KATP channel blockers, the sulfonylurea glyburide, and the cyanoguanidine N-[1-(3-chlorophenyl)cyclobutyl]-N′-cyano-N′′-3-pyridinyl-guanidine (PNU-99963) are biphasic in the heart but monophasic in the bladder with about a 100- to 500-fold difference in Ki values between high- and low-affinity sites. Good correlations exist between cardiac or bladder-binding affinities of potassium channel openers with functional activation as assessed by their

respective potencies to either suppress APD in Purkinje fibers or to relax electrical field-stimulated bladder contractions. Collectively, these results demonstrate that [^{125}I]A-312110 binds with high affinity and has an improved activity profile compared with other radiolabeled potassium channel opener agents. [^{125}I]A-312110 is a useful tool for investigating the molecular and functional properties of the KATP channel complex and for the identification, in a high throughput manner, of both novel channel blockers and openers that interact with cardiac/smooth muscle-type KATP channels.

[^{125}I]A-312110, a novel high-affinity 1,4-dihydropyridine ATP-sensitive K+ channel opener: Characterization and pharmacology of binding. Mol Pharmacol 2003 Jul; 64 (1), pp. 143–53.

Sick Sinus Syndrome: Sinus Node and S-A Node Function

Atropine/Neostigmine/Isoprenaline (Isoproterenol)

Cellular/Molecular Mechanism of Action:

Atropine: Binds to muscarinic cholinertic receptor complexes in a manner that competitively inhibits the biological activity of acetylcholine.

Neostigmine (Quaterinary Amine): Reversibly binds to and biochemically inactivates acetylcholine esterase in a manner that promotes the postsynaptic accumulation of acetylcholine neurotransmitter. The carbamyl ester configuation of neostigmine is hydrolyzed by acetylcholine esterase. Under physiological conditions, neostigmine becomes highly cationic in character and this feature encourages its direct interaction with the biochemically active site of acetylcholine esterase. In this manner, neostigmine functions as a competitive substrate resulting in disruption of the hydroxyl serine group of acetylcholine and covalent bonding of neostigmine through the formation of a reversible carbamate bond structure.

Isoproterenol: Binds to and positively activates both β_1 and β_2 adrenergic receptor complexes.

Physiological Mechanism of Action:

Atropine: Suppresses the function of exocrine gland secretion, smooth muscle, and cardiac muscle. Postganglionic cholinergic stimulation is also depressed in function. The primary influence of atropine on the heart is a transient negative chronotropic effect with mid-range doses presumably due to increased central vagal tone just before the occurance of peripheral muscarinic cholinergic blockage. Changes in heart rate are usually minor and not accompanied by changes in peripheral blood pressure or cardiac output. Incremental increases in dose subsequently produce proportional increases in heart rate achieved through inhibition of vagal tone influences on the S-A node pacemaker. Maximal heart rate during strenuous exercise is not altered. Neonates and geriatric patients can often be refractory to the effect of atropine on heart rate. Although atropine can cause cardiac arrythmias (e.g., atrial arrhythmias and ventricular dissociation), it often does so without causing cardiovascular symptoms.

The vascular effects of atropine when administered alone are not profound, which is in part due to the belief that vascular beds are not extensively innervated by cholinergic axons. Furthermore, cholinergic sympathetic vasodilatory axons synapsing on vessels with skeletal muscle tissues seem not to be important in maintaining normal vascular tone.

Neostigmine: Interaction of neostigmine with the biochemically active site of acetylcholine esterase competitively inhibits the ability of this enzyme to hydrolyze acetylcholine neurotransmitter. As a result, acetylcholine begins to accumulate, resulting in excessive stimulation of postsynaptic membrane acetylcholine receptor complexes. The impact of acetylcholine esterase inhibition includes activation of muscarinic receptors expressed by autonomic responsive tissues; activation of autonomic ganglia; activation of nicotinic skeletal muscle; and stimulation of cholinergic receptors within the central nervous system (CNS) if they are able to pass across the blood-brain barrier. Both autonomic ganglia and skeletal muscle receptors can become over-stimulated to the point of paralysis or depressed function.

Neostigmine impact on cardiac function involves ganglionic and postganglionic interactions. Elevations in peripheral acetylcholine concentrations primarily have the effect of slowing the heart rate, in contrast to blood pressure changes that only become altered at relatively higher dosages since this is due to greater CNS penetration of neostigmine. The cardiac refractive period becomes shorter due to neostigmine's influence, resulting in a lengthening of the refractory period and prolonged conduction.

At the level of the vasculature, neostigmine promotes vasodilation. Interesingly, the opposite vasoactive response is observed in coronary and pulmonary vascular structures. Hypotension is not a profound feature, though, because ganglionic acetylcholine first activates but then exerts a suppressive effect at higher dosages. The stimulatory effect on parasympathetic ganglia enhances decreases in cardiac output, in contrast to the influence of elevated acetylcholine levels on sympathetic ganglia and cardiac output. The influence of acetylecholine on medullary vasomotor and cardiac brainstem centers is initially excitatory and subsequently diminished stimulation. Furthermore, increases in secondary sympathetic tone are complemented by acetylcholine-mediated adrenal medulla epinephrine release. An appreciation of these concepts is therefore responsible for the wide spectrum of cardiovascular responses observed in response to neostigmine administration and related anticholinesterase pharmaceuticals.

Since neostigmine is a quaterinary ammonium compound, it is poorly absorbed from the gastrointestinal tract and almost none of the compound penetrates across the CNS blood-brain barrier. Consequently, neostigmine is active primarily at skeletal muscle neuromuscular junctions and functions both as an anticholinergic agent and as a direct acting agonist. Other important sites of action include the eye and gastrointestinal tract when administered at clinically relevant dosages.

Isoprenaline (Isoproterenol): Due to relatively minimal influence on α-adrenergic receptor complexes, changes in cardiac function, bronchial smooth muscle, skeletal muscle vasculature, and the gastrointestinal tract are the primary organ systems influenced by the physiological properties exerted by isoproterenol. . . . Cardiovascular influences of isoproterenol include diminished peripheral vascular resistance, especially within vascular networks perfusing musculoskeletal structures. The increases in heart rate and contractility induced by isoproterenol promote declines in diastolic pressure and elevations in cardiac output sufficient to maintain or elevate systolic pressures (mean blood pressure is lowered).

Application: Characterization of sick sinus syndrome.

Route of Administration: Isoprenaline, atropine, *and* neostigmine can be injected intravenously. Neostigmine is poorly absorbed from the gastrointestinal tract since it is a quaterinary ammonium compound.

Considerations: Atropine can be applied in the conversion of parasympathetic (cholinergic) mediated atrial block arrythmias.

Implementation: Evaluation of sick sinus syndrome conditions using various physical (postural reflex tests, Valsalva maneuver, carotid sinus massage), pharmacological challenges (intravenous iso-

prenaline, atropine, neostigmine, and total autonomic blockade), and electrophysiological tests in order to identify simple non-invasive markers of intrinsic sick sinus syndrome.

Human Model: Cases of sick sinus syndrome (n = 13).

Interpretation and Analysis: Following autonomic blockade, nearly 50% of cases may develop a normal heart rate (e.g., n = 6/13), while slightly greater than 50% (e.g., n = 7/13) may have an abnormal intrinsic heart rate. Electrophysiological testing can reveal abnormal sinus node parameters in approximately two-thirds of cases in the basal state (e.g., n = 8/13), and 85% (e.g., n = 11/13) after autonomic blockade. Carotid sinus massage is abnormal in most cases with an abnormal intrinsic heart rate (e.g., n = 13/13, 100%), compared to 33% of cases with a normal intrinsic heart rate (e.g., n = 2/6 and $p < 0.05$). The heart rate response to isoprenaline (isoproterenol) is abnormal in approximately 83% of cases (e.g., n = 5/6) with normal as compared to only about 14% (e.g., n = 1/7) with abnormal intrinsic heart rate. Isoprenaline (isoproterenol) yields a significantly ($p < 0.05$) higher increase in heart rate in conditions with abnormal as compared to those with normal intrinsic heart rate. Other physical and drug tests appear not to be helpful for the purpose of differentiating between intrinsic and extrinsic mechanisms. Thus, carotid sinus massage and, to some extent, isoprenaline (isoproterenol) administration appear to be simple bedside tests that may be helpful in identifying the underlying mechanism of sick sinus syndrome.

Instrumentation: Electrocardiogram diagnostic system (EKG).

Sinus Node Disease: Case Report
Flecainide Acetate

Cellular/Molecular Mechanism of Action: Flecainide exerts a suppressive effect on fast sodium channels.

Physiological Mechanism of Action: Flecainide promotes a decrease in the Vmax and and "overshoot" of the action potentials within the atrial, ventricles, and Purkinje fibers, thereby slowing conduction velocities within these cardiac structures.

Application: Flecaininde is used as a Class IC antiarrhythmic agent.

Route of Administration: Flecainide (intravascular injection).

Interpretation and Analysis: There can be dramatic increases in sinus node recovery times and in sinoatrial conduction times, and the magnitude of the response can only be witnessed because of the emergence of a subsidiary junctional pacemaker without retrograde conduction to the atria.

Response of an abnormal sinus node to intravenous flecainide acetate. Hellestrand KJ, Nathan AW, Bexton RS, Camm AJ. Pacing Clin Electrophysiol 1984 May; 7 (3 Pt 1), pp. 436–9.

T Wave Alternans/Coronary Artery Disease/ Ventricular Arrhythmias: Life-Threatening Risk Stratification
Esmolol

Physiological Mechanism of Action: Esmolol promotes sympathetic blockade, while atropine exerts parasympathetic blockade.

Background Information: T wave alternans (TWA) is an important non-invasive measure of ventricular arrhythmia vulnerability.

Implementation: Evaluation of the influence of the autonomc nervous system on T wave alternans (TWA) measurements in high-risk conditions of coronary artery disease, left ventricular dysfunction, and inducible sustained ventricular tachycardia during electrophysiological studies. Parameters for TWA are measured at baseline with atrial pacing at 100 bpm (600 msec), 109 bpm (550 msec), and 120 bpm (500 msec). After a 10-minute recovery period, TWA is measured again after sympathetic blockade (esmolol, n = 20), parasympathetic blockade (atropine, n = 20), or no intervention (control subjects, n = 20).

Human Model: Coronary artery disease (n = 60 cases).

Interpretation and Analysis: The prevalence of significant TWA is unchanged compared with baseline profiles after atropine infusion and in controls. Conversely, the amplitude of TWA in the vector magnitude lead is significantly reduced after esmolol infusion ($p < 0.001$), and the number of positive TWA tests is reduced by 50% (70 vs 35%, $p < 0.05$). Such observations have important implications for the administration of TWA to risk-stratify cases for life-threatening ventricular arrhythmias and provide a new potential mechanism for the reduction in sudden cardiac death conferred by beta-blockers among cases with coronary artery disease and congestive heart failure.

Effects of selective autonomic blockade on T wave alternans in humans. Rashba EJ, Cooklin M, MacMurdy K, Kavesh N, Kirk M, Sarang S, Peters RW, Shorofsky SR, Gold MR. Circulation 2002 Feb 19; 105 (7), pp. 837–42.

T Wave Lability (Non-Alternating)/Genotype LQ-T1, LQ-T2, and LQ-T3
Phenylephrine/Dobutamine

Cellular/Molecular Mechanism of Action: Phenylephrine and dobutamine function as catecholamine neurotransmitter agonists.

Application: Electropharmacology challenge tests with phenylephrine and dobutamine for identifying alterations in repolarization lability in conditions with genotyped long Q-T syndrome (LQ-TS). Quantification of such phenomenon may assist in identifying LQ-TS cases with an increased risk of sudden cardiac death.

Route of Administration: Intravenous injection.

Implementation: Determination of the effects of phenylephrine and dobutamine on repolarization lability in cases with genotyped long Q-T syndrome (LQ-TS). Electrocardiographic stress testing involving aperiodic repolarization lability can be quantified from digitized electrocardiograms recorded during catecholamine challenge with phenylephrine and dobutamine. T wave lability is quantified as a root-mean-square of the differences between corresponding signal values of subsequent beats. The magnitude of aperiodic T wave lability is quantified by using a newly derived T wave lability index (TWLI).

Human Model: Cases with the genotyped LQ-TS (n = 23 total; n = 13 LQ-T1; n = 7 LQ-T2; n = 3 LQ-T3; n = 16 reference controls).

Interpretation and Analysis: The TWLI is significantly greater in LQ-TS genotypes relative to controls (0.0945 ± 0.0517 vs 0.0445 ± 0.0123; $p < 0.003$). Marked T wave lability (TWLI ≥ 0.095) may be detected in all 3 LQ-TS genotypes (e.g. n = 10/23) but not in reference controls ($p < 0.003$). There is no correlation between TWLI and baseline corrected Q-T interval. High-risk cases that have either a history of out-of-hospital cardiac arrest or syncope almost invariably have a TWLI of 0.095 or greater. Beat-to-beat non-alternating T wave lability occurs in conditions of LQ-T1, LQ-T2, and LQ-T3 during catecholamine provocation and is associated with a history of prior cardiac events. Quantification of this novel phenomenon may assist in identifying LQ-TS cases with an increased risk of sudden cardiac death.

Instrumentation: Electrocardiography system.

Catecholamine-induced T wave lability in congenital long Q-T syndrome: A novel phenomenon associated with syncope and cardiac arrest. Nemec J, Hejlik JB, Shen WK, Ackerman MJ. Mayo Clin Proc 2003 Jan; 78 (1), pp. 40–50.

Tachycardia: Inappropriate Sinus Tachycardia (IST)
Adenosine

Physiological Mechanism of Action: Adenosine exerts a negative chronotropic effect on the heart.

Background Information: Adenosine is an endogenous nucleoside that has an important role in the diagnosis and treatment of several cardiac arrhythmias. However, its effects on IST have not been well established.

Application: Potential diagnostic agent for detecting and characterizing IST.

Dosage: Adenosine (0.1 to 0.15 mg/kg).

Implementation: Determine the response to intravenous adenosine (0.1 to 0.15 mg/kg) and evaluate its direct effect during pharmacologic β-adrenergic and cholinergic blockade. Atrial cycle length (ACL) is measured before adenosine injection, at the time of the greatest cycle length prolongation, and during the maximum rebound acceleration of heart rate.

Human Model: Cases (n = 18, age 46 ± 15 years) given adenosine alone, compared to cases (n = 5) to determine the direct effects of adenosine during pharmacologic β-adrenergic and cholinergic blockade. Reference controls (n = 18, age 46 ± 11 years) with normal sinus rhythm undergoing clinically indicated electrophysiologic study.

Interpretation and Analysis: Adenosine does not terminate IST in the vast majority of cases. The maximum dose of adenosine prolongs the sinus interval significantly, from 780 ± 128 msec to 985 ± 225 msec ($p < 0.001$) in the control subjects. Conversely, adenosine causes no significant lengthening of atrial cycle length (527 ± 69 msec vs 590 ± 148 msec; p = ns) in the patients with IST. Similar differences in the response to adenosine can be appreciated during the pharmacologic autonomic blockade. Reflex increase of the sinus rate (rebound effect) is greater in control subjects than in IST cases (21.2% ± 9.7 vs 8.5% ± 8.8%; $p < 0.001$). The usual negative chronotropic effect of adenosine is impaired in IST cases. This may have important diagnostic implications and provide new insight into the mechanism(s) of IST.

Impaired negative chronotropic response to adenosine in patients with inappropriate sinus tachycardia. Still AM, Huikuri HV, Airaksinen KE, Koistinen MJ, Kettunen R, Hartikainen J, Mitrani RD, Castellanos A, Myerburg RJ, Raatikainen MJ. J Cardiovasc Electrophysiol 2002 Jun; 13 (6), pp. 557–62.

Tachycardia: Regular Broad Complex Type/ Atrioventricular Function in Wolff-Parkinson-White Syndrome (Accessory Atrioventricular Connections)
Adenosine/Adinosine Triphosphate/Propanolol (IV) Reversal

Cellular/Molecular Mechanism of Action:

Adenosine: Shortens antegrade refractoriness of accessory A-V connections, and in some patients this action is mediated by β-adrenergic stimulation. Adenosine may cause acceleration of pre-excited atrial arrhythmias, but these effects are transient and should not discourage the use of adenosine as a diagnostic agent in broad complex, regular tachycardias of uncertain origin.

Propanolol: Binds to and blocks sympathetic/β-adrenergic receptor complexes.

Physiological Mechanism of Action:

Adenosine: shortens antegrade refractoriness of accessory A-V connections, and in some cases this action is mediated by β-adrenergic stimulation. Adenosine may cause acceleration of pre-excited atrial arrhythmias, but these effects are transient and should not discourage the use of adenosine as a diagnostic agent in broad complex, regular tachycardias of uncertain origin.

Propanolol: In the atria, propanolol inhibits spontaneous frequency, maximal driving frequency, and contractility but increases the electrical threshold and A-V conduction time. Spontaneous depolarization rate of ectopic pacemakers is decreased but resting potentials and repolarization are minimally altered since propanolol reduces intracellular sodium currents, resulting in decreases in the height and rate of action potential elevations.

In the normal heart at rest, propanolol has less of an effect in contrast to a heart subjected to elevations in adrenergic tone as occurs in certain heart conditions and exercise. The most obvious effect of β-adrenergic blockade on cardiac physiology is a negative chronotropic effect, declines in cardiac output, increased duration of systole, and subtle declines in blood pressure at rest. Sodium secretion influences β-adrenergic blockade properties exerted by propanolol; in this context, in situations where there are elevations in sodium retention and extracellular fluid volume, especially in conditions of cardiac dysfunction.

Route of Administration: Adenosine and propanolol (intravenous).

Dosage: Adenosine (12 mg, rapid bolus) and propranolol (0.2 mg/kg).

Considerations: Several groups of clinicians have suggested the use of intravenous adenosine or adenosine triphosphate for the diagnosis of regular broad complex tachycardias. However, the short half-life of these agents has precluded assessment of their effects on refractoriness of accessory connections, and their safety in pre-excited arrhythmias has not been demonstrated.

Implementation: Evaluation of the effects of intravenous adenosine on accessory atrioventricular (A-V) connections in Wolff-Parkinson-White syndrome.

Human Model: Cases of accessory atrioventricular (A-V) connections in Wolff-Parkinson-White syndrome (n = 30).

Interpretation and Analysis: Adenosine administration (n = 14) during continuous atrial pacing at a cycle length 20 msec below that required to cause 2:1 conduction block in the accessory connection (mean pacing cycle length 261 ± 41 msec) creates a transient 1:1 conduction (n = 12/14) via the accessory connection (shortening

of antegrade refractoriness). Such effects can be abolished (n = 3/7 of affected subjects) following intravenous propranolol (0.2 mg/kg). Adenosine administration in conditions of Wolff-Parkinson-White syndrome (n = 19 during induced, pre-excited atrial arrhythmias) results in observed minimum RR interval during pre-excited atrial fibrillation that subsequently transiently decreases (252 ± 44 msec to 224 ± 35 msec, $p < 0.01$) after adenosine, but no change in average RR interval can be observed (360 ± 59 msec to 357 ± 60 msec, ns). The pre-excited ventricular response to atrial flutter is transiently accelerated (n = 5/8: 415 ± 21 msec to 360 ± 49 msec, $p < 0.05$) due to shortening of flutter cycle length (207 ± 10 msec to 180 ± 24 msec, $p < 0.05$). However, 2:1 accessory connection conduction is maintained (n = 8/8). All effects are short lived, with the decrease in RR interval during atrial fibrillation ocurring for a maximum of 2 RR intervals only. Ventricular arrhythmias or hemodynamic deterioration are usually not appreciated.

Toxicity: Increased sodium retention in conditions of pre-existing severe cardiac disease.

Effects of intravenous adenosine on antegrade refractoriness of accessory atrioventricular connections. Garratt CJ, Griffith MJ, O'Nunain S, Ward DE, Camm AJ. Circulation 1991 Nov; 84 (5), pp. 1962–8.

Tachycardia: Regular Narrow Complex (Unknown Origin)/Sinus Node Reentrant Tachycardia
Adenosine

Cellular/Molecular Mechanism of Action: A minimum of 2 adenosine receptors exist based on their response to adenosine analogs and whether activation increases or decreases cAMP production.

Physiological Mechanism of Action: Adenosine shortens antegrade refractoriness of accessory A-V connections, and in some cases this action is mediated by β-adrenergic stimulation. Adenosine may cause acceleration of pre-excited atrial arrhythmias, but these effects are transient and should not discourage the use of adenosine as a diagnostic agent in broad complex, regular tachycardias of uncertain origin.

Application: Sinus node reentrant tachycardia.

Route of Administration: Intravenous bolus of 0.1 mg/kg and 0.15 mg/kg.

Dosage: Adenosine (0.1 mg/kg and 0.15 mg/kg).

Considerations: Its effects are usually transient owing to its extremely short plasma half-life and, as a consequence, it is thought to be safer than other drugs used in the acute treatment of such arrhythmias. However, adenosine may created a proarrhythmic effect when administered in attempts to confirm a diagnosis of atrial flutter.

Interpretation and Analysis: For narrow complexes, as expected, a transient increase in atrioventricular block can be seen, but this is followed by a doubling of the ventricular rate and hemodynamic compromise requiring immediate DC cardioversion. It is postulated that the secondary catecholamine-mediated effects of adenosine are responsible for this phenomenon.

Adenosine may slow the atrial rate and actually terminate tachycardia profiles. These effects of adenosine on sinus node reentrant tachycardia suggest that sinus nodal tissue (as opposed to perinodal atrial tissue) is involved in the tachycardia circuit and that these effects should be considered when adenosine is used as a diagnostic agent in narrow complex tachycardia.

Instrumentation: Electrocardiogram.

The effects of adenosine on sinus node reentrant tachycardia. Griffith MJ, Garratt CJ, Ward DE, Camm AJ. Clin Cardiol 1989 Jul; 12 (7), pp. 409–11.

Tachycardia: Ventricular Dysrhythmias/ Differentiation
Therapeutic Response: [Adenosine]/[Magnesium Sulfate]/[Lidocaine]/[Procainamide]

Physiological Mechanism of Action: Adenosine shortens antegrade refractoriness of accessory A-V connections, and in some conditions this action is mediated by β-adrenergic stimulation. Adenosine may cause acceleration of pre-excited atrial arrhythmias, but these effects are transient and should not discourage the use of adenosine as a diagnostic agent in broad complex, regular tachycardias of uncertain origin.

Background Information: Wide complex tachycardias present diagnostic challenges for emergency physicians. The history, physical examination, and ECG provide information required to arrive at a correct diagnosis. When a previous history of heart disease exists, VT should be suspected; however, no single clinical feature is sufficiently reliable for distinguishing VT from SVT.

Application: Conditions of ventricular tachycardia (dysrhythmia differentiation).

Considerations: Reports of complications with the use of adenosine as a diagnostic agent have not yet been recognized, but may occur after sufficient numbers of cases have accumulated. Magnesium sulfate may be useful in refractory cases of VT and torsades de pointes. Chronic treatment of patients prone to VT may include complex pharmacotherapy and AICDs.

Implementation: Cases with VT may tolerate their dysrhythmias for several hours and maintain hemodynamic stability. ECG analysis is the most useful process in differentiating SVT and VT. Characteristics suggestive of VT include evidence of A-V dissociation, QRS duration of longer than 0.16 seconds, and QRS axis between −90 degrees ± 180 degrees. Predictive QRS morphologic criteria also have been established for VT. A 4-step approach to ECG analysis has been reported to accurately identify cases with VT, but prospective validation in an ED setting is lacking. The initial approach to treating patients with wide QRS tachycardias depends on hemodynamic stability. Until the identity of a dysrhythmia is certain, consider all cases to be suffering from VT. Unstable conditions require immediate cardioversion. Acute treatment of stable cases includes lidocaine or procainamide. Adenosine is appropriate when wide QRS SVT is the diagnosis, and it also has been used as a diagnostic aid to identify dysrhythmias.

Interpretation and Analysis: Development of new class III agents and enhancement of AICD technology may result in improved patient outcomes and the availability of more choices for emergent therapy of wide QRS tachycardias.

Instrumentation: Electrocardiogram.

Wide complex tachycardia. Delbridge TR, Yealy DM. Emerg Med Clin North Am 1995 Nov; 13 (4), pp. 903–24.

Torsade de Pointes (TdP)/U Wave to T Wave Amplitude (UTA) Ratio Identification Electrocardiographic Index for Predicting Torsade de Pointes
Calmodulin Inhibitor (W7)

Cellular/Molecular Mechanism of Action: The agent W7 inhibits the biological function of calmodulin.

Application: Selective suppression of TdP inducibility by W7, without shortening the duration of cardiac repolarization, allows identification of the UTA ratio, an electrocardiographic index for predicting TdP onset.

Implementation: Analysis of ECGs acquired from a well-characterized animal model of TdP to identify more reliable predictors of life-threatening ventricular arrhythmia.

Animal Model: Rabbit (n = 14; n = 12 TdP induced with methoxamine and clofilium pretreated with vehicle control).

Interpretation and Analysis: Methoxamine and clofilium can induce TdP in rabbits pretreated with vehicle control (n = 12/14). Pretreatment with W7 (50 μM/kg), an inhibitor of the intracellular Ca^{2+}-binding protein calmodulin, significantly suppresses TdP induction (n = 1/11 with TdP, $p < 0.001$). W7 does not affect heart rate, increases in Q-T intervals, or dispersion compared with measurements in vehicle-treated controls. However, a progressive and significant increase in the ratio of UTA occurs before TdP onset in control animals, and this can be prevented by W7.

The calmodulin inhibitor W7 suppresses TdP without shortening the Q-T interval, which is consistent with other findings that Q-T prolongation, per se, is insufficient to generate TdP. Selective suppression of TdP inducibility by W7, without shortening the duration of cardiac repolarization, allows identification of the UTA ratio as a new electrocardiographic index for predicting TdP onset. These findings are consistent with the idea that prolonged repolarization is not the proximate cause of arrhythmia initiation, and they suggest that an increased UTA ratio reflects activation of intracellular Ca^{2+}/calmodulin-dependent processes that are required for triggering TdP in this model.

Calmodulin inhibitor W7 unmasks a novel electrocardiographic parameter that predicts initiation of torsade de pointes. Gbadebo TD, Trimble RW, Khoo MS, Temple J, Roden DM, Anderson ME. Circulation 2002 Feb 12; 105 (6), pp. 770–4.

Ventricular Arrythmias
Lidocaine

Cellular/Molecular Mechanism of Action: Inhibits membrane-associated Na^+/K^+ pump activity. Cells within the ventricular Purkinje system are relatively more sensitive to the inhibition of membrane-associated Na^+/K^+ pump activity compared to cells within the epicardium and myocardium. Influence of lidocaine on atrial membrane action potentials is minimal to non-existent.

Diagnostic Application: Lidocaine is utilized for the correction of arrythmias originating from biochemical and/or organic lesions residing within the ventricular myocardium. Examples include premature ventricular contractions, ventricular fibrillation, and ventricular tachycardia.

Route of Administration and Dosage: Intravenous infusion is the only preferred administration route for lidocaine when applied for the purpose of correcting ventricular arrhythmias. Lidocaine must be administered by continuous infusion due to the very high rate of "first-pass" extraction following perfusion through the hepatic sinousoid network.

Considerations: Lidocaine is ineffective for the correction of arrythmias originating from within the atrial myocardium.

Interpretation and Analysis: Correction (cardioconversion) of the ventricular arrhythmia based upon interpretation of ECG analysis. Although constant lidocaine infusion may correct a ventricular arrhythmia, this effect may be temporary and the abnormality may subsequently return in the absence of the pharmaceutical. Such occurrences are common in situations where a permanent organic lesion resides within the ventricular myocardium that is responsible for generation of the arrhythmia condition.

CELL PHYSIOLOGY

Endothelial Adhesion/Platelet Interactions/[Retinal Microvascular Pathology]
Platelets (Fluorescent Labeled)/Carboxyfluorescein Diacetate Succinimidyl Ester

Cellular/Molecular Mechanism of Action: Carboxyfluorescein diacetate succinimidyl ester interacts with light and functions as a fluorescent marker molecule suitable for "tracing" the *in vivo* migration of different cell types.

Application: Visualization of *in vivo* platelet behavior within the retinal microcirculation. The methodology allows for quantitative evaluation of platelet dynamics and platelet-endothelial interactions in pathologic conditions affecting the retina.

Route of Administration: Intravascular.

Considerations: Represents the development of a new method for evaluating the *in vivo* dynamics of platelets within the retinal microcirculation and the quantitative investigation of platelet-endothelial interactions.

Implementation: Isolated platelet samples are labeled with carboxyfluorescein diacetate succinimidyl ester. After intravenous administration, platelet behavior in the retinal microcirculation can be evaluated with a scanning laser ophthalmoscope. Images are recorded on S-VHS videotape and analyzed with a computer-assisted image analysis system. Platelet-endothelial interactions in the retinal microcirculation can also be investigated employing lipopolysaccharide-stimulated endothelium or platelets activated with thrombin.

Animal Model: Rat (retina).

Interpretation and Analysis: Fluorescent platelets are recognized as distinct dots within the retinal microcirculation that can be traced frame by frame. The velocity of platelets in the retinal arteries, capillaries, and veins is approximately 26.1 ± 6.4, 1.6 ± 0.4, and 19.9 ± 8.2 mm/sec, respectively. In control rats, even activated platelets show minimal interaction with retinal endothelial cells. Conversely, stimulated retinal endothelium show active platelet-endothelial interactions, with many platelets observed rolling and adhering along the major retinal veins. The interactions between platelets and stimulated endothelial cells are substantially inhibited with the injection of P-selectin monoclonal antibody.

In vivo evaluation of platelet-endothelial interactions in retinal microcirculation of rats. Tsujikawa A, Kiryu J, Nonaka A, Yamashiro K, Nishiwaki H, Tojo SJ, Ogura Y, Honda Y. Invest Ophthalmol Vis Sci 1999 Nov; 40 (12), pp. 2918–24.

Endothelial Adhesion/Cellular Interactions: Colon Carcinoma/Intravital Observation of Cancer Cell/Microcirculation Interactions
CalceinAM

Background Information: Organ-specific tumor cell adhesion within the microcirculation of host organs is an important step within the metastatic cascade. Circulating tumor cells have to adhere within the microcirculatory vessels, quickly stabilize their adhesion to endothelial surfaces, and then probably need to leave the circulation to avoid the toxic effects of hydrodynamic shear forces of circulating blood.

Application: Intravital observation of colon carcinoma cell adhesion within the hepatic microcirculation.

Implementation: CalceinAM can be used to label colon carcinoma cell populations (e.g., HT-29 [human] and CC531 [rat]) that are then injected intra-arterially as single-cell suspensions. Intravital fluorescence microscopy is then applied to detect adhesive interactions between circulating tumor cells and endothelial surfaces within the hepatic microcirculation. These interactions are then analyzed regarding their time course and site localization within the vascular tree.

Animal Model: Rats (Sprague-Dawley).

Interpretation and Analysis: Autofluorescence of liver parenchyma is sufficient to facilitate distinction of hepatic sinusoids. Intravital microscopy is capable of differentiating early events in adhesion formation within hepatic sinusoids, adhesion stabilization, and extravasation of the tumor cells into the liver parenchyma. Tumor cell adhesion occurs almost exclusively within sinusoidal capillaries; however, the diameter of these vessels is usually larger than that of the tumor cells leaving remaining perfused lumen of the capillaries. Colon carcinoma cells rapidly migrated into the liver parenchyma after successful adhesion within the sinusoids. In contrast to common endpoint assays of the metastatic cascade, this *in vivo* model allows the investigation of metastatic colon carcinoma cell adhesion within the liver microcirculation as specific steps during the formation of hematogenous metastasis and their underlying mechanisms.

Instrumentation: Intravital fluorescence microscopy.

An intravital model to monitor steps of metastatic tumor cell adhesion within the hepatic microcirculation. Haier J, Korb T, Hotz B, Spiegel HU, Senninger N. J Gastrointest Surg 2003 May–Jun; 7 (4), pp. 507–14; discussion 514–5.

Endothelial Integrity/Endothelial Injury and Viability
Evans Blue Dye Staining

Cellular/Molecular Mechanism of Action: Evans blue dye is a pigment-based reagent that becomes differentially associated with viable vs compromised cell populations (e.g., vascular endothelium).

Physiological Mechanism of Action: Tumor necrosis factor-alpha (TNF-α) soluble receptor (TNFsr) has been shown *in vitro* and *in vivo* to neutralize TNF-mediated biological activity.

Background Information: Tumor necrosis factor-α is expressed locally in arteries at sites of balloon injury. In vitro studies have shown that TNF inhibits cell cycle progression and induces apoptosis in endothelial cells. Accordingly, we performed a series of experiments to test the hypothesis that inhibiting TNF could accelerate endothelial recovery after angioplasty.

Application: Evans blue dye staining can be applied to evaluate viable *ex vivo* preparations of vascular structures for the purpose of establishing the integrity of endothelial surfaces.

Implementation: Evaluation of vascular endothelial integrity using Evans Blue dye as a indicator of cellular injury. In this context, Evans Blue dye can be used to evaluate the efficacy of agents designed to enhance the integrity of vascular endothelial structure.

A relevant application example includes the evaluation of TNFsr vs control IgG administered by intraperitoneal injection following De-endothelializing created by balloon injury. The resulting endothelial lesions created can then be assessed at 1 week post-injury for evidence of reendothelialization (Evans blue dye staining); and then again after 2 weeks in order to evaluate reendothelialization and endothelial function.

Animal Model: Rat (Sprague-Dawling strain).

Interpretation and Analysis: At both time points, blockade of TNF biological activity with TNFsr results in increased reendothelialization measured as absolute area and percent area reendothelialized. TNFsr also accelerates functional endothelial recovery that manifests as an increase in nitric oxide production. Neointimal thickening can also be appreciated as being inhibited. Blockade of TNF *in vivo* accelerates functional endothelial recovery after barotraumatic de-endothelializing injury. Locally expressed TNF therefore acts to inhibit functional endothelial recovery after angioplasty and transient blockade of TNF may improve the long-term success of angioplasty.

Evans Blue Staining: The reagent facilitates detection of a demarcation between viable endothelial cell populations and subendothelial collagen.

In vivo blockade of tumor necrosis factor-alpha accelerates functional endothelial recovery after balloon angioplasty. Krasinski K, Spyridopoulos I, Kearney M, Losordo DW. Circulation 2001 Oct 9; 104 (15), pp. 1754–6.

Endothelial Integrity/Vascular Permeability/ Extravasation
Evans Blue Dye

Cellular/Molecular Mechanism of Action: Evans blue dye is a pigment-based reagent that can be detected visually within the visible light range.

Background Information: Oxidative stress appears to be relevant to asthma pathogenesis.

Application: Evans blue dye is a pigment-based reagent that can be used as a visual marker or indicator molecule and has the advantage of being compatible with biological systems. In this context, it is often applied as a dilution marker system within the intravascular compartment for measuring total intravascular compartment size and extravasation of plasma proteins and hematologial cell types into the extravascular tissue space.

Implementation: Applicaton of Evans blue dye to evaluate extravasation into bronchoalveolar lavage fluid following antigen-induced pulmonary responses in sensitized *in vivo* models and the effectiveness of the antioxidant N-acetylcysteine (oral, 1 mmol/kg per day for 7 days before challenge).

Animal Model: Rat (Brown Norway strain).

Interpretation and Analysis: N-acetylcysteine does not reduce the immediate bronchospasm that follows aerosol antigen exposure but does prevent airway hyperreactivity to 5-hydroxytryptamine at 24 hours after antigen challenge, and reduces eosinophil numbers (from 0.178 ± 0.038 in the absence to $0.064 \pm 0.020 \times 10^6$ cells/ml in the presence of N-acetylcysteine; $p < 0.05$), and Evans blue dye extravasation into bronchoalveolar lavage fluid. Taurine levels in bronchoalveolar lavage fluid from antigen-challenged *in vivo* models are higher than control values but treatment with N-acetylcysteine fails to further increase these augmented levels. N-acetylcysteine appears to have a beneficial effects *in vivo* in models of experimental asthma and serves to validate related findings pertaining to other models of lung injury.

Effectiveness of oral N-acetylcysteine in a rat experimental model of asthma. Blesa S, Cortijo J, Martinez-Losa M, Mata M, Seda E, Santangelo F, Morcillo EJ. Pharmacol Res 2002 Feb; 45 (2), pp. 135–40.

Endothelial Integrity (Retinal)/Minimally-Invasive Diagnostic Strategy [Diabetes]
Sodium Fluorescein

Background Information: Diabetic retinopathy is the leading cause of blindness in working-age individuals in the United States. Breakdown of the blood-retinal barrier is one of the earliest events in the progression of diabetic retinopathy. Ideally, therapeutic measures would be directed at this early stage, but there are few sensitive, quantitative methods to assess the retinal vascular barrier *in vivo*.
Application: Quantitative assessment of vascular barrier such as those associated with the retina.
Implementation: Utilization of 2 fluorescent tracers in combination with fluorescence microangiography to quantitatively assess retinal vascular barrier integrity (± infusion of a hyperosmolar solution of 1.6 M mannitol for 5 minutes).
Animal Model: Rat (Long-Evans strain).
Interpretation and Analysis: Permeability × surface area/flow (PS/F) describing the retinal vasculature is 0.086 ± 0.031 (n = 13, avg. ± SD). Based on estimates of flow and surface area, estimated permeability of sodium fluorescein is approximately 1.2 x 10^{-5} cm/s. Infusion of a hyperosmolar mannitol solution significantly increases PS/F within individual veins and significantly increases flow-weighted PS/F from 0.073 ± 0.028 to 0.16 ± 0.034 (n = 3). Quantitative *in vivo* assessment of retinal vasculature can be delineated applying an adapted indicator dilution technique. Dual-tracer fluorescence angiography appears to be a sensitive indicator for detecting increases in the blood-retinal barrier produced by hyperosmolar mannitol. The methodology may be a promising new minimally-invasive strategy that can be adapted to quantitatively track retinal vascular permeability.
Instrumentation: Fluorescence microangiography.

Retinal vascular permeability determined by dual-tracer fluorescence angiography. Russ PK, Gaylord GM, Haselton FR. Ann Biomed Eng 2001 Aug; 29 (8), pp. 638–47.

Gene Expression/ Imaging the Location, Magnitude, and Time Course of Gene Expression
Adenovirus-Expressing Firefly Luciferase/D-Luciferin

Cellular/Molecular Mechanism of Action: D-luciferin is a fluorescent substrate for firefly luciferase enzyme fractions.
Background Information: Studies of cardiac gene transfer rely on postmortem analysis using histologic staining or enzyme assays. Non-invasive imaging of the temporal and spatial characteristics of cardiac gene expression in the same subject offers significant advantages.
Application: Fluorescent marker system for validating the positive detection of gene-specific transcription processes.
Route of Administration: D-luciferin can be injected intraperitoneally following adenovirus-facilitated firefly luciferase gene expression.
Implementation: Direct myocardial injection via left thoracotomy with adenovirus-expressing firefly luciferase (Ad-CMV-Fluc; n = 30). The reporter substrate D-luciferin can be injected intraperitoneally. Serial images are acquired by use of a cooled charge-coupled detector (CCD) camera. Results are expressed as relative light unit per minute (RLU/min). To assess the detection sensitivity, serially diluted titers of Ad-CMV-Fluc can be injected: 1×10^9 (195, 393 ± 14,896), 1×10^8 (33,777 ± 18,179), 1×10^7 (417 ± 91), 1×10^6 (185 ± 64), 1×1^5 (53 ± 1), and control (54 ± 1) ($p < 0.05$ for 1×10^9, 1×10^8, and 1×10^7 plaque-forming units vs control adenovirus-expressing mutant thymidine kinase [Ad-CMV-HSV1-sr39tk]; n = 3).
Animal Model: Rat.
Interpretation and Analysis: Rats transduced with 1×10^9 plaque-forming units show decremental cardiac luciferase activity over time: 152,070 ± 21,170 (day 2), 195,806 ± 62,630 (day 5), 7250 ± 2941 (day 8), and 2040 ± 971 RLU/min (day 14). Rats are sacrificed, and *in vitro* luciferase activity correlated with *in vivo* CCD signals ($r^2 = 0.92$). Such observations demonstrate the feasibility of imaging the location, magnitude, and time course of cardiac reporter gene expression in living (*in vivo*) systems. Cardiac gene therapy studies could be aided with wider application of this approach.

Optical imaging of cardiac reporter gene expression in living rats. Wu JC, Inubushi M, Sundaresan G, Schelbert HR, Gambhir SS. Circulation 2002 Apr 9; 105 (14), pp. 1631–4.

Glucose Metabolization: Myocardial
$H_2[^{15}O]$/1-[^{11}C]-Glucose/Phenylephrine/[Positron Emission Tomography]

Cellular/Molecular Mechanism of Action: The agent $H_2[^{15}O]$ is an analog that mimics the behaviors of natural water molecules within biological systems. Similarly, 1-[^{11}C]-glucose is transported across cellular membranes and perceived biochemically/metabolically in a manner analogous to natural/native glucose molecules. Procainamide inhibits Na^+/K^+ pump function and promotes weak parasympatholytic activity similar to quinidine (quinidine has a stronger influence on cardiac parasympathetic input).
Background Information: Measurements of the rate of myocardial glucose utilization (rMGU) play a key role in the assessment of alterations in myocardial substrate metabolism in normal and abnormal cardiac states. In this context, rMGU can be quantified *in vivo* using 1-[^{11}C]glucose in combination with positron emission tomography (PET) imaging analysis.
Application: 1-[^{11}C]Glucose can function as a probe for assessing alterations in myocardial glucose metabolism in both normal and abnormal myocardium.
Implementation: Measurements of myocardial blood flow and rMGU applying PET methodologies facilitated by the use of $H_2[^{15}O]$ and 1-[^{11}C]-glucose, respectively. Arterial-coronary sinus sampling is performed to measure rMGU according to the Fick method.
Animal Model: Canine (n = 20; n = 5 fasting; n = 6 hyperinsulinemia-euglycemic clamp at rest; n = 5 clamp and phenylephrine; n = 4 clamp and dobutamine).
Interpretation and Analysis: Values for rMGU range from 50 to 2436 nmol/g/min. Myocardial 1-[^{11}C]-glucose images of high quality can be obtained. There is a close and direct correlation between values for rMGU measured by PET and those measured directly ($y = 0.86x + 112$, $r = 0.98$, $p < 0.0001$). The coefficient of variation for the regional estimates of rMGU ranges from between 11.3% ± 7.4% during clamp at rest to 16.3% ± 8.4% during clamp with phenylephrine.

It now appears possible to quantify myocardial glucose utilization by PET with 1-[^{11}C]-glucose.

Quantification of myocardial glucose utilization by PET and 1-carbon-11-glucose. Herrero P, Weinheimer CJ, Dence C, Oellerich WF, Gropler RJ. J Nucl Cardiol 2002 Jan-Feb; 9 (1), pp. 5–14.

Ischemia: Myocardial
Dipyridamole/Leukocyte Chemotaxis

Cellular/Molecular Mechanism of Action: Dipyridamole influences the activity of phosphodiesterase in a manner that promotes elevations in intracellular (platelet) cAMP concentrations and potentiates the vasoactive and antiplatelet aggregatory properties mediated by PGI_2. Dipyridamole is classified as a adenosine nucleotide trasport blocker whereby it prevents adenosine influx into myocardial cells.
Application: Detection parameter for identifying conditions of myocardial ischemia.
Implementation: Evaluation of myocardial ischemia conditions as a function of neutrophil chemotactic responses with and without the administration of dipyridamole.
Interpretation and Analysis: Chemotaxis of control PMNs toward plasma isolated from cases without signs of myocardial ischemia 7 minutes after dipyridamole administration is significantly diminished compared to baseline values ($p = 0.003$). Plasma obtained 7 minutes after dipyridamole infusion from patients manifesting signs of myocardial ischemia by single photon emission computed tomography (SPECT) attract control PMNs more intensively compared to plasma isolated at time = 0 (significant at $p = 0.0005$).
Interpretation and Analysis: Transient myocardial ischemia induced by dipyridamole challenge leads to the generation of chemotactic factors detectable within peripheral blood plasma.
Instrumentation: Boyden chemotactic chamber.

Plasma chemotactic activity during dipyridamole-induced myocardial ischemia. Wysocki H, Kazmierczak M, Wykretowicz A, Szczepanik A, Minczykowski A. Int J Cardiol 1998 Jan 5; 63 (1), pp. 15–9.

Reactive Oxygen Species Production/Myocardial
Dihydroethidium

Background Information: Protein kinase C (PKC) and reactive oxygen species (ROS) are known to have a role in anesthetic preconditioning (APC). Cardiac preconditioning by triggers other than volatile anesthetics, such as opioids or brief ischemia, is known to be isoform selective, but the isoform required for APC is not known.
Application: Detection and characterization of intracellular reactive oxygen species production. Examples include the identification of PKC isoform involved in APC and elucidation of the relative positions of PKC activation and ROS formation within the APC signaling cascade.
Implementation: Evaluation of the influence of sevoflurane APC in heart tissue prior to the initiation of ischemic reperfusion injury in the absence or presence of a non-specific PKC inhibitor(chelerythrine), a PKC-delta inhibitor (PP101), or a PKC-epsilon inhibitor (PP149). Spectrofluorometry and the fluorescent probe dihydroethidium is used to measure intracellular ROS, while assay of effluent dityrosine is used to measure extracellular ROS release.
Animal Model: Isolated guinea pig hearts subjected to 30 minutes of ischemia and 120 minutes of reperfusion.
Interpretation and Analysis: Previous sevoflurane exposure protects heart tissues against ischemia-reperfusion injury. Chelerythrine or PP149 abolishes such protection, but PP101 does not. Reactive oxygen species formation can be observed during sevoflurane exposure but it is not altered by any of the PKC inhibitors. Anesthetic preconditioning is mediated by PKC-epsilon but not by PKC-delta. Furthermore, PKC activation probably occurs downstream of ROS generation in the APC signaling cascade.

Reactive oxygen species precede the epsilon isoform of protein kinase C in the anesthetic preconditioning signaling cascade. Novalija E, Kevin LG, Camara AK, Bosnjak ZJ, Kampine JP, Stowe DF. Anesthesiology 2003 Aug; 99 (2), pp. 421–8.

Permeation Properties: Myocardial Cells
Ethidium Bromide (EB)

Cellular/Molecular Mechanism of Action: Ethidium bromide selectively binds to nucleic acids and can also function as a passive biological marker molecule. Ethidium bromide also possesses fluorescent properties when exposed to ultraviolet light energy.
Background Information: Strong electric pulses produce reversible or irreversible membrane breakdown (electroporation).
Application: Detection of alteration in membrane pore size.
Implementation: Analyze the permeation properties of minute pores caused by hyperpolarization or lysophosphatidylcholine (LPC) by comparing the amount of charge carried by irregular inward currents (I^{hi}) with changes in EB fluorescence in isolated rabbit ventricular myocytes.
Technique: Forty-second negative pulses from a holding potential of -20 mV induces I^{hi} whose conductance increases with hyperpolarization.
Interpretation and Analysis: Mean conductance (G^{hi}) is 63.6 ± 9.9 pS/pF (mean ± S.E.M., n = 9) at −160 mV. Ethidium bromide fluorescence increases during voltage pulses in parallel with the time integral of I^{hi} (Q^{hi}), with the magnitude of increases in nuclear EB fluorescence being 5.3 times greater than in the cytoplasm at −160 mV. Similar hyperpolarization-induced parallel increases in I^{hi} and EB fluorescence is also obtained in Na^+-free, N-methyl-D-glucamine (NMDG) solution. LPC (10 μM) induced large (101.2 ± 21.2 pS/pF, n = 16), rapid (rise times, 1–10 msec) I^{hi} with slow relaxation rates at −80 mV that reflect increases in G^{hi} to 94.3 ± 24.8 pS/pF (n = 8) at 6 minutes. Plots of ethidium bromide fluorescence vs Q^{hi} can be well fitted by a common Hill's equation with a Hill coefficient of 0.97. Taken together, such findings indicate that hyperpolarization and LPC produce pores that have the same filter properties for the permeation of small ions, including ethidium(+), and that I^{hi} (carried in part by Ca^{2+} generated by membrane breakdown) is capable of supplying sufficient ions to evoke abnormal excitation and contraction in cardiac myocytes.

Hyperpolarization and lysophosphatidylcholine induce inward currents and ethidium fluorescence in rabbit ventricular myocytes. Song YM, Ochi R. J Physiol 2002 Dec 1; 545 (Pt 2), pp. 463–73.

Platelet Function in Arterial Disease/Peripheral Arterial Disease (PAD) of the Lower Limb/Carotid Artery Disease/Abdominal Aorta Aneurysm (AAA)
Adenosine Diphosphate/Collagen

Cellular/Molecular Mechanism of Action: Adenosine diphosphate is released by platelets during activation phenomenon which in turn promotes activation/aggregation of nearby platelets. Soluble collagen binds membrane-associated receptors expressed by platelets and promotes aggregatory responses.
Background Information: Conditions of PAD have a 3-fold increase in cardiovascular mortality. Standard antiplatelet treatment

may not confer uniform benefit in different patient groups. Studies have described the comparison of platelet function in cases of lower limb PAD, carotid disease, and AAA with age- and sex-matched healthy controls.

Application: Detection and chacterization of arterial disease related to alterations in platelet function.

Implementation: Evaluation of PAD as a function of spontaneous platelet aggregatory (SPA) properties can be assessed in whole-blood samples applying adenosine diphosphate (ADP) and collagen to induce aggregation responses. Flow cytometry analyses can also be used to detect platelet P-selectin and the PAC-1 antigen as markers of platelet activation and aggregation.

Human Model: Cases of PAD of the lower limbs (n = 20 PAD); carotid artery disease (n = 40); abdominal aortic aneurysm (n = 13 AAA); and age-/sex-matched healthy controls (n = 20).

Interpretation and Analysis: Conditions of lower limb PAD or AAA have higher baseline SPA compared to normal controls ($p < 0.01$). There is significantly higher collagen-induced aggregation in IC patients compared to normal controls ($p < 0.01$). However, there is no difference in ADP-induced aggregation between lower limb PAD and reference controls. There is no difference in PAC-1 binding between control patients and the patients with lower limb PAD, carotid disease, or AAA. Conditions of carotid artery disease express higher levels of P-selectin compared to normal controls ($p < 0.05$).

Therefore, evidence exists that suggests platelet hyperactivity is present in conditions of PAD despite the use of antiplatelet therapy. Further antiplatelet strategies may be indicated for the therapeutic management of such disease states.

Instrumentation: Flow cytometry instrumentation.

Increased platelet aggregation and activation in peripheral arterial disease. Robless PA, Okonko D, Lintott P, Mansfield AO, Mikhailidis DP, Stansby GP. Eur J Vasc Endovasc Surg 2003 Jan; 25 (1), pp. 16–22.

Reperfusion Injury/Leukocyte Rolling Phenomenon Following Ischemic Insult

Acridine Orange

Cellular/Molecular Mechanism of Action: Acridine orange emits a fluorescent color when exposed to certain wavelengths of light energy.

Background Information: Recent reports have shown that ischemic preconditioning induces substantial protection against retinal damage by subsequent prolonged ischemia and that this protection is mediated by mechanisms involving the adenosine A1 receptor.

Application: Evaluate quantitatively the effects of ischemic preconditioning on leukocyte-mediated reperfusion injury after transient retinal ischemia and to define the role of the adenosine A1 receptor in these effects.

Implementation: The adenosine A1 receptor antagonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) is administered intramuscularly immediately after ischemic preconditioning. Leukocyte behavior in the retina after 60 minutes of ischemia is evaluated *in vivo* with acridine orange digital fluorography.

Animal Model: Rats/male (transient retinal ischemia is induced by temporary ligation of the optic nerve. Ischemic preconditioning [5 minutes of ischemia] is induced 24 hours before 60 minutes of ischemia).

Interpretation and Analysis: Ischemic preconditioning inhibits leukocyte rolling. The maximum number of rolling leukocytes is reduced to 3% at 12 hours after reperfusion ($p < 0.01$). Subsequent leukocyte accumulation is also decreased with ischemic preconditioning. The maximum number of accumulated leukocytes is reduced to 22.6% at 24 hours after reperfusion ($p < 0.01$). These inhibitory effects are suppressed by the administration of DPCPX ($p < 0.0001$). The numbers of rolling leukocytes at 12 hours after reperfusion and accumulated leukocytes at 24 hours after reperfusion are approximately 102.7% (ns) and 83.4% ($p < 0.01$), respectively, compared with numbers without ischemic preconditioning. Ischemic preconditioning, therefore, has an inhibitory effect on leukocyte rolling and subsequent leukocyte accumulation during retinal ischemia-reperfusion injury. Furthermore, the adenosine A1 receptor may play an important role in these inhibitory effects.

Instrumentation: Digital fluorography.

Inhibitory effect of ischemic preconditioning on leukocyte participation in retinal ischemia-reperfusion injury. Nonaka A, Kiryu J, Tsujikawa A, Yamashiro K, Nishijima K, Miyamoto K, Nishiwaki H, Honda Y, Ogura Y. Invest Ophthalmol Vis Sci 2001 Sep; 42 (10), pp. 2380–5.

Stem Cells: Mesenchymal/Retention, Engraftment, and Migration

Iron Fluorophore Particle (IFP)/Mesenchymal Stem Cells

Cellular/Molecular Mechanism of Action: Stem cells have the potential to differentiate into a multitude of different cell types within tissue/organ environments.

Background Information: Delivery and tracking of endomyocardial stem cells is limited by the inability to image transplanted cells noninvasively in the beating heart.

Application: Mesenchymal stem cells (MSCs) can be labeled with iron fluorophore particle (IFP) to provide MRI contrast for *in vivo* assessment of immediate and long-term localization in order to establish parameters pertaining to retention, engraftment, and migration within tissues/organs.

Route of Administration: Mesenchymal stem cells (variable including percutaneous).

Implementation: Short-term incubation of mesenchymal stem cells with IFP results in efficient dose-dependent labeling. Postlabeling, cells remain viable for multiple passages and retain *in vitro* proliferation and differentiation capacity. Labeled mesenchymal stem cells (10^4 to 10^6 cells/150 μL) are then injected percutaneously into normal and freshly infarcted myocardial tissues. Serial cardiac MRI (1.5 T) are then performed at 4 (e.g. n = 1 *in vivo* preparations), 8 (e.g. n = 3 *in vivo* preparations), and 21 days (e.g. n = 1 *in vivo* preparation). MRI contrast properties are then measured both *in vivo* and *in vitro* for cells embedded in agar. Injection sites containing as few as 10^5 MSCs can be detected and contain intact IFP-bearing mesenchymal stem cells on histology.

Animal Model: Swine (mesenchymal stem cells and porcine myocardium [normal & infracted]).

Interpretation and Analysis: IFP labeling of mesenchymal stem cells imparts useful MRI contrast, enabling ready detection in the beating heart on a conventional cardiac MR scanner after transplantation into normal and infarcted myocardium. The dual-labeled MSCs can be identified at locations corresponding to injection sites, both *ex vivo* using fluorescence microscopy and *in vivo* using susceptibility contrast on MRI. This technology may permit effective *in vivo* study of stem cell retention, engraftment, and migration.

Serial cardiac magnetic resonance imaging of injected mesenchymal stem cells. Hill JM, Dick AJ, Raman VK, Thompson RB, Yu ZX, Hinds KA, Pessanha BS, Guttman MA, Varney TR, Martin BJ, Dunbar CE, McVeigh ER, Lederman RJ. Circulation. 2003 Aug 26; 108 (8), pp. 1009–14. Epub 2003 Aug 11.

CARDIAC DISEASE AND PHYSIOLOGY

ANGINA: CARDIAC-ASSOCIATED THORACIC PAIN

Angina Pectoris/Atherosclerosis: Coronary Artery/ Hydroxyapatite Deposition/Musculoskeletal: Osteoblastic Activity/Neoplastic Disease: Osteosarcoma
Near-Infrared Light Emitting Probes/Fluorescent Bisphosphonate Derivatives/[Near-Infrared]

Background Information: In vertebrates, the development and integrity of the skeleton requires hydroxyapatite (HA) deposition by osteoblasts. Sites of osteoblastic activity have most commonly been imaged *in vivo* using gamma-emitting radioisotopes. The scan times required are long, and the resultant radioscintigraphic images suffer from relatively low resolution.
Application: Hydroxyapatite deposition is a marker of, or a participant in, processes as diverse as cancer and atherosclerosis.
Semi-Synthetic Methods: Production of a near-infrared (NIR) fluorescent bisphosphonate derivative.
Implementation: Evaluation of the ability for NIR fluorescent bisphosphonate derivatives to physically bind to hydroxyapatite deposits.
Interpretation and Analysis: Near-infrared light-based probes like fluorescent bisphosphonate derivatives possess an ability to bind to hydroxyapatite under *in vitro* conditions, in addition to recognizing osteoblastic activity in living animals. Such biotechnology can be applied to study skeletal development, osteoblastic metastasis, coronary atherosclerosis, and other disease states.

In vivo near-infrared fluorescence imaging of osteoblastic activity. Zaheer A, Lenkinski RE, Mahmood A, Jones AG, Cantley LC, Frangioni JV. Nat Biotechnol 2001 Dec; 19 (12), pp. 1148–54.

Angina Pectoris/Coronary Artery Spasms/ Vasospastic Disease
Acetylcholine

Cellular/Molecular Mechanism of Action: Acetylcholine binds to and activates both nicotinic and muscarinic acetylcholine receptor complexes.
Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Application: Determine the sensitivity and specificity of coronary artery spasm induced by intracoronary artery injection of acetylcholine in conditions of vasospastic angina.
Considerations: Intracoronary injection of acetylcholine is a sensitive and reliable method for the induction of coronary spasm in patients with vasospastic angina as well as in those with variant angina.
Route of Administration: Direct intracoronary artery injection.
Dosage: Incremental doses of acetylcholine (20, 30, and 50 μg).
Dosage: Evaluation of coronary artery function/response to incremental doses of intracoronary artery injected acetylcholine.
Human Model: Cases with variant angina (Group A; n = 21); cases with other types of vasospastic angina (Group B; n = 28), and cases without any significant coronary artery disease (Group C; n = 20).
Interpretation and Analysis: Coronary artery spasm is defined as severe vasoconstriction (greater than or equal to 90% of reduction in luminal diameter) with chest pain and/or ischemic changes appreciated on electrocardiogram tracings. Intracoronary injection of acetylcholine induces spasm of at least 1 coronary artery in 95% of Group A cases (e.g. n = 20/21), in 96% of Group B cases (e.g. n = 27/28); and in only a relatively low percentage of Group C cases (e.g. n = 2/20 or 10%).Low-dose acetylcholine regimens (20 μg) induces coronary spasm more frequently in Group A cases (81%) than in Group B patients (43%) ($p < 0.05$). S-T segment elevations associated with anginal attacks are significantly ($p < 0.05$) more frequent in Group A (71%) than in Group B (39%) cases. When acetylcholine is injected separately into the left and right coronary arteries, spasm of both coronary arteries can be observed in approximately 50% of Group A type individuals (e.g. n = 7/14); in 36% of Group B type individuals (e.g. n = 8/22), and in a very low percentage of 20 Group C type individuals (e.g. n = 0/20 or 0%).

Usefulness of intracoronary injection of acetylcholine as a provocative test for coronary artery spasm in patients with vasospastic angina. Miwa K, Fujita M, Ejiri M, Sasayama S. Heart Vessels 1991; 6 (2), pp. 96–101.

Angina Pectoris: Coronary Artery Spasm
Acetylcholine/Ergonovine/[Electrocardiography]

Cellular/Molecular Mechanism of Action: Acetylcholine binds directly to and positively activates acetylcholine receptor complexes located on the surface of postsynaptic membranes. Ergonovine directly binds to and positively (submaximally) activates tryptaminergic and α-adrenergic receptor complexes to a degree that is less potent than ergotamine. At dopaminergic receptor complexes, ergonovine functions as a weak antagonist. At both tryptaminergic and dopaminergic sites, ergonovine can exert both partial agonist and antagonist properties within certain regions of the central nervous system (CNS). In various smooth muscle tissues, the compound exerts antagonist properties.
Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations.

Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Application: Acetylcholine and ergonovine can be used to identify (detect) and characterize cases suffering from spasms of the coronary artery. Speculation suggests that there may be some potential applications related to other vascular disorders including patent ductus arteriosus and extrahepatic portosystemic shunts.

Implementation: Delineation of mechanisms involved in the pathogenesis of coronary artery spasms can be facilitated by comparing the action of acetylcholine with that of ergonovine. Coronary arteriography is performed immediately after intracoronary injections of titrated incremental doses of acetylcholine or ergonovine.

Human Model: Cases of vasospastic angina (n = 11 Group 1), and chest pain cases (n = 15 Group 2).

Interpretation and Analysis: Occlusive or near-occlusive (99% luminal narrowing) coronary spasm associated with angina and ischemic electrocardiographic S-T changes can be appreciated in a large percentage of Group 1 type cases (e.g., n = 9/11 with acetylcholine and n = 11/11 patients with ergonovine). The region and degree of the most severe coronary spasm on coronary arteriograms evoked by the 2 agents are the same in majority of Group 1 type cases (e.g., n = 9/11). In the remaining Group 1 type cases (e.g., n = 2/11), spontaneous focal coronary spastic stenosis in the baseline coronary arteriogram can be relieved by the intracoronary injection of acetylcholine, and a focal coronary occlusive spasm in the same region can be induced repeatedly by the subsequent intracoronary injection of ergonovine (paradoxic phenomenon). Conversely, occlusive or near-occlusive coronary spasm cannot be induced by either agent in the vast majority of Group 1 type cases (e.g., n = 0/15). Such findings suggest that the 2 provocative tests for coronary spasm employing acetylcholine and ergonovine are clinically useful in the diagnosis of vasospastic angina, but testing with intracoronary ergonovine is needed when a spontaneous focal coronary spasm is relieved by intracoronary injection of acetylcholine. The results also indicate that in many conditions with vasospastic angina, non-specific hypersensitivity to acetylcholine or ergonovine in a definite region of the coronary arteries generally plays an important role in the induction of coronary spasm.

Induction of coronary artery spasm by intracoronary acetylcholine: Comparison with intracoronary ergonovine. Suzuki Y, Tokunaga S, Ikeguchi S, Miki S, Iwase T, Tomita T, Murakami T, Kawai C. Am Heart J 1992 Jul; 124 (1), pp. 39–47.

Angina Pectoris: Differential Diagnosis with Esophogeal Spasm
Ergonovine Maleate

Application: Differential diagnosis of chest pain symptoms. Intravenous ergonovine may be useful in identifying esophageal spasm in selected cases with chest pain who have normal coronary arteries or in whom coronary artery disease is insufficient to explain the severity of symptoms.

Implementation: Evaluation of cases of chest pain resembling angina pectoris employing intravenous administration of ergonovine maleate.

Interpretation and Analysis: Administration of intravenous ergonovine maleate in cases of chest pain resembling angina pectoris (e.g., n = 14) can induce the typical signs of discomfort previously experienced by affected cases (e.g., n = 5/14) while manometric signs of esophageal spasm may also develop. A certain percentage of affected cases (e.g., n = 9/14) and negative reference control subjects will not experience signs of chest pain. However, the vast majority of affected cases will experience some form of symptomatic response to ergonovine, including chest warmth or heaviness, headache, mild choking sensation, facial numbness, flushing, or nausea. Manometric signs of esophageal spasm after ergonovine can be detected in some patients that experience no signs of chest pain (e.g., n = 2/9) on a level similar to negative reference controls. In this context, the potential risks of ergonovine do not justify its routine use as a provocative agent for esophageal spasm.

Use of ergonovine to identify esophageal spasm in patients with chest pain. Eastwood GL, Weiner BH, Dickerson WJ 2nd, White EM, Ockene IS, Haffajee CI, Alpert JS. Ann Intern Med 1981 Jun; 94 (6), pp. 768–71.

Angina Pectoris/Coronary Artery Spasm/ Vasospastic Disease/S-T Segment Depression
Ergonovine/Angiography

Cellular/Molecular Mechanism of Action: Directly binds and positively, but submaximally activates tryptaminergic and α-adrenergic receptor complexes at a level that is less than produced by ergotamine. At dopaminergic receptor complexes, ergonovine functions as a weak antagonist. At both tryptaminergic and dopaminergic sites, ergonovine can exert both partial agonist and antagonist properties at certain sites within the central nervous system. In various smooth muscle tissues, the compound exerts antagonist properties.

Physiological Mechanism of Action: Promotes vasoconstrictive responses within both venous and arterial structures through direct stimulation of vascular smooth muscle. Systemic administration can produce elevations in blood pressure due to peripheral vasoconstriction. Ergonovine can produce coronary artery vascular responses that are detected as ischemic patterns on EKG tracings and development of angina pain in cases with coronary artery disease. Bradycardia is often induced by ergot alkaloids even when no elevations in blood pressure are evident, due in part to increased vagal activity, and to a lesser extent, by diminished CND sympathetic tone and direct-acting myocardial depression.

Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the vascular endothelial cell layer is intact by releasing nitric oxide (NO). Vascular responses of this nature can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such findings imply that some form of abnormality in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin.

In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Application: Induction and characterization of coronary artery vasocontrictive responses.

Route of Administration: Intravascular.

Implementation: Evaluation of conditions of angina pectoris suspected of originating from spasms of the coronary artery.

Interpretation and Analysis: Reoccurrence of angina pectoris upon selective infusion of ergonovine suggests that natural episodes of angina pectoris are due to vasoactive episodes affecting the coronary artery and may reflect the presence of coronary artery disease.

Oxytocin, Prostaglandin, Ergot Alkaloids, and Tocolytic Agents. Rall TW, Schleifer LS (Chapter 39: pp. 926–45). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW,

Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

Angina Pectoris/Coronary Artery Spasm/ Vasospastic Disease/Inhibition of Spasm Activity
Molsidomine

Application: Molsidomine has been applied as an anticoronary artery spasm agent following alkaline buffer infusion.
Route of Administration: Molsidomine (intravascular); alkaline buffer (intravascular).
Dosage: The rapid infusion of an alkaline buffer followed by maximal hyperventilation and molsidomine (4 mg) in cases of angina pectoris.
Considerations: Evaluation of the appearance of anginal pain and developmet of significant, transient ischemic changes in the S-T segment resulting from alkalosis-induced coronary spasm.
Interpretation and Analysis: Reversal of pro-coronary artery spasm effect induced by alkaline buffer infusion utilizing molsidomine. A 2nd provocative test can be performed under the same conditions, 24 hours later, after the administration of 4 mg of molsidomine. Molsidomine prevents the development of coronary artery spasm in a high percentage of cases (approximately 80%). These preliminary results justify further clinical evaluation of molsidomine in the characterization and treatment of vasospastic angina.

Angina Pectoris: Vasospastic Coronary Artery
Systemic Alkalosis/Nitroglycerin Reversal

Physiological Mechanism of Action: Induced systemic alkalosis promotes vasoconstriction or spasms of the coronary artery.
Application: Detection of coronary spasms by creating systemic alkalosis in cases with infrequent, angina-compatible chest pain.
Considerations: Previous reports have applied the provocative test without a previous coronary arteriography procedure but only in cases with negative submaximal exercise test responses.

Hyperventilation appears to be a safe and specific diagnostic procedure in a subset of cases in whom the probability of coronary artery disease may not be judged sufficient to warrant coronary arteriography as a primary diagnostic procedure.
Interpretation and Analysis: Rapid infusion of alkaline solution followed by maximal hyperventilation raises arterial pH above the 7.65 value necessary for diagnostic significance in approximately 83% of cases (e.g., n = 196). In approximately 12% of cases, (e.g., n = 24), the provocative test induces significant ischemic S-T segment changes. In all cases with a positive response, coronary artery disease that is predominantly vasospastic (e.g., n = 19 cases) or atheromatous with a vasospastic contribution (e.g., n = 5 cases) can be demonstrated by coronary arteriography followed, if necessary, by diagnostic injection of a ergot derivative.

Chest pain and ECG changes can essentially always be reversed within 5 minutes by intravenous nitroglycerin. In instances where coronary arteriography is not performed in cases with a negative response, the sensitivity of the procedure cannot be accurately assessed. However, in cases with a negative response to hyperventilation that undergo coronary arteriography, approximately 92% (e.g., n = 33) have normal arteriograms and a negative response to ergot derivatives.

Systemic alkalosis as a provocative test for coronary artery spasm in patients with infrequent resting chest pain. Weber S, Cabanes L, Simon JC, Letrait M, Fouchard J, Guerin F, Degeorges M. Am Heart J 1988 Jan; 115 (1 Pt 1), pp. 54–9.

Angina Pectoris/Coronary Artery Spasm/ Vascular Response Testing/Intractable Coronary Artery Spasm: Prinzmental's Variant Angina
Ergonovine Maleate/Nifedipine

Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such findings imply that some form of abnormality in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Application: Detection and characterization of angina pectoris conditions.
Implementation: Evaluation of the management of cases suffering from intractable coronary arterial spasms that have Prinzmetal's variant angina, normal or mildly abnormal coronary arteriograms, and a positive ergonovine maleate provocative test. Characterization angina pectoris conditions can involve delineation of functional responses to ergonovine maleate and nifedipine reversal.

Human Model: Cases with anginal attacks occurring at least 3 times a week during isosorbide dinitrate therapeutic regimens.
Interpretation and Analysis: Majority of affected cases demonstrate a decrease in the frequency of ischemic attacks with nifedipine. Holter monitor evaluation can serve to confirm the absence of ischemic changes in response to nifedipine (e.g., n = 7 cases). When nifedipine dosage is decreased or therapy is discontinued, a very large percentage of cases will demonstrate a recurrence of anginal attacks (e.g., n = 6/6). Some cases will experience minor side effects that require a decrease in nifedipine dosage (e.g., n = 2). Nifedipine in general is well tolerated, and no major complications are usually appreciated. Nifedipine appears to be effective in the management of cases with symptomatic coronary arterial spasm and normal or mildly abnormal coronary arteriograms. Investigations conducted to date imply that further investigation of nifedipine for the characterization and treatment of such patients is justified.

Nifedipine therapy for refractory coronary arterial spasm. Heupler FA Jr, Proudfit WL. Am J Cardiol 1979 Oct 22; 44 (5), pp. 798–803.

Angina Pectoris/Coronary Artery Spasm/ Vasospastic Disease/Angiography Classification/ Coronary Artery Diameter/M-Mode Characterization of Coronary Artery Flow Dynamics/Vascular Response Testing: Differentiation of Variants/Vasospastic Angina without Coronary Stenosis/Vasospastic Angina with Coronary Stenosis/Coronary Stenosis without Vasospastic Angina
Ergonovine/Acetylcholine/Nitroglycerin Reversal

Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact

by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Background Information: The definite diagnosis of vasospastic angina can be established by performing a coronary spasm provocative test using ergonovine maleate or acetylcholine facilitated by selective cardiac catheterization. Current non-invasive, non-pharmacologic diagnostic methods are not sensitive enough for the diagnosis of vasospastic angina.

Application: Diagnosis of angina associated with cardiovascular function (ergonovine).

Route of Administration: Nitroglycerin (sublingual).

Dosage: Nitroglycerin (0.3 mg).

Considerations: Induced episodes of cardiovascular angina are reversible through the administration of nitroglycerin.

Implementation: Evaluation of normal left main coronary artery branch applying angiography imaging procedures for the purpose of classification into 4 groups based on the presence or absence of more than 50% stenosis in the coronary arteries except for the left main trunk and results observed with acetylcholine or ergonovine provocative testing. The left main trunk diameter can be measured by M-mode echocardiography before and after sublingual administration of nitroglycerin (0.3 mg), and alterations in dilation calculated to assess coronary artery tone.

Human Model: Cases with angiographically normal left main trunk (n = 38).

Interpretation and Analysis: The percent dilation of the left main trunk diameter induced by sublingual nitroglycerin at 7 A.M. and at noon is 22.4 ± 4.7% (mean ± SD) and 18.1 ± 4% in conditions of vasospastic angina and without coronary stenosis (e.g., n = 11); 14.9 ± 7.1% and 11.2 ± 6.9% in conditions of vasospastic angina and coronary stenosis (e.g., n = 9); 6.1 ± 3.5% and 7.0 ± 5.1% in conditions without vasospastic angina but with coronary stenosis (e.g., n = 8); and 8.1 ± 5.6% and 7.8 ± 5.7% in normal reference controls (e.g., n = 10). The percent dilation at 7 A.M. is significantly greater in conditions with vasospastic angina without coronary stenosis than in conditions of vasospastic angina and coronary stenosis or coronary stenosis without vasospastic angina. In case groups with vasospastic angina, the percent dilation at 7 A.M. is significantly greater than values observed at noon. Establishing a 7 A.M. percent dilation exceeding 15% as being defined as positive for the diagnosis of vasospastic angina, the sensitivity and specificity of the procedure can be improved to 80% and 94%, respectively. Therefore, it appears that basal tone of the left main trunk is elevated in the early morning in vasospastic angina. Dilation of the left main trunk diameter exceeding 15% induced by sublingual nitroglycerin in the early morning as measured by M-mode echocardiography is a highly sensitive and specific criterion for the diagnosis of vasospastic angina.

Instrumentation: M-mode echocardiogram capabilities (left main coronary artery trunk).

A new noninvasive method of diagnosing vasospastic angina based on dilation response of the left main coronary artery to nitroglycerin as measured by echocardiography. Morita H, Ohmori K, Matsuyama T, Mizushige K, Matsuo H. J Am Coll Cardiol 1996 May; 27 (6), pp. 1450–7.

Angina Pectoris: Prinzmetal's Variant Angina *Ergonovine/Hyperventilation*

Physiological Mechanism of Action: Ergonvine promotes vasoconstriction of both venous and arterial structures through direct stimulation of vascular smooth muscle. Systemic administration in this manner can produce elevations in blood pressure due to peripheral vasoconstriction. Ergonovine can produce coronary artery vascular responses that can be detected as ischemic patterns on EKG tracings and angina pain in patients with coronary artery disease. Bradycardia is often induced by ergot alkaloids even when no elevations in blood pressure are evident, due in part to increased vagal activity, and to a lesser extent, diminished CND sympathetic tone and direct-acting myocardial depression.

Coronary spasm is induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact, and is promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. In general, all ergot alkaloid exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptors. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentration. The contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Background Information: Prinzmetal's variant angina is a classification for a subtype of angina pectoris cases in which attacks are experienced at rest, while exercise capacity is well preserved and attacks are associated with electrocardiographic evidence of S-T segment elevations.

Application: Detection and characterization of spontaneous variant angina response.

Route of Administration: Ergonovine (intravenous).

Considerations: The incidence of chest pain and ventricular arrhythmias is similar during both the hyperventilation and ergonovine tests. However, spontaneous remission of ischemia is more frequent after hyperventilation than following ergonovine administration (48 vs 14%).

Interpretation and Analysis: Hyperventilation produces a positive response in a high percentage of cases (n = 25/30 or 83%) and ergonovine (n = 28/30 or 93%). Hyperventilation can also induce S-T segment elevation (n = 22/25 or 88%), S-T segment depression (n = 2/25 or 8%), or T wave pseudonormalization (n = 1/25 or 4%). Similarly, ergonovine can promote S-T segment elevation (n = 23/25 or 92%), S-T segment depression (n = 4/25), or T wave pseudonormalization (n = 1/25). In the vast majority of cases, the electrocardiographic changes occur in the same leads as during episodes of spontaneous attacks.

Acute ischemia develops at a mean of 218 ± 112 seconds after the end of hyperventilation in majority of positive tests (e.g., n = 19/25); and at that time the double product is not significantly different from basal values. The sensitivity of hyperventilation is similar to ergonovine in cases with greater than or equal to 1 daily attack (95% -vs- 100%), while in those with less than 1 daily attack the sensitivity of hyperventilation decreased to 55% compared to 77% for ergonovine.

In conditions of variant angina the sensitivity of both the hyperventilation and ergonovine tests closely correlate with disease activ-

ity. Hyperventilation is a safe provocative test with a level of sensitivity similar to ergonovine in conditions of active disease; however, in patients with sporadic attacks hyperventilation has a lower sensitivity than ergonovine and therefore a limited diagnostic value.

Hyperventilation and ergonovine tests in Prinzmetal's variant angina pectoris in men. Previtali M, Ardissino D, Barberis P, Panciroli C, Chimienti M, Salerno JA. Am J Cardiol 1989 Jan 1; 63 (1), pp. 17–20.

Oxytocin, Prostaglandin, Ergot Alkaloids, and Tocolytic Agents. Rall TW, Schleifer LS (Chapter 39: pp. 926–45). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

Angina Pectoris: Prinzmetal's Variant Angina
Nifedipine

Cellular/Molecular Mechanism of Action: Nifedipine functions as a calcium-blocking agent.
Application: Characterization of the cause of thoracic pain (e.g., angina) and the responsiveness of coronary vessels to vasodilatory intervention.
Background Information: Prinzmetal's variant angina is a classification for a subtype of angina pectoris characterized by the onset of attacks during periods of rest, while exercise capacity is well preserved and attacks are associated with electrocardiographic evidence of S-T segment elevations.
Implementation: Evaluation of angina pectoris conditions using responses to nifedipine administration as a diagnostic parameter.

Human Model: Cases with variant angina pectoris (e.g., n = 12; 44 to 67 years of age [e.g. n = 5/12 with vasospasm of the left anterior descending coronary artery; n = 7/12 with spasm of a dominant right coronary artery). The frequency of anginal attacks per 24 hours can vary stubstantially (e.g., n = 1 to 12/24 hrs) with ventricular tachycardia episodes being accompanied by (i) ischemic episodes (e.g., n = 7/12 cases) and (ii) high grade atrioventricular block (e.g., n = 2/12 cases).
Interpretation and Analysis: Nifedipine administration results in a high percentage of cases demonstrating profound improvement and relief of clinical signs (e.g., n = 11/12 patients), many of which experience a long-term benefit (e.g., n = 7/11). Withdrawal of nifedipine frequently leads to recurrence of angina (e.g., n = 6 episodes per 4 cases).

Provocative testing with the aid of cardiac catheterization procedures in concert with the cold pressor test or ergonovine maleate before and after nifedipine administration demonstrates that this agent is capable of blocking both α-adrenergic and ergonovine-induced vasospasms. Nifedipine may have a significant role in the diagnosis and therapy of angina caused by coronary spasm.

Nifedipine in the treatment of Prinzmetal's (variant) angina. Goldberg S, Reichek N, Wilson J, Hirshfeld JW Jr, Muller J, Kastor JA. Am J Cardiol 1979 Oct 22; 44 (5), pp. 804–10.

Angina Pectoris: Prinzmetal's Variant Angina (PVA)
Ergonovine Maleate

Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Application: Ergonovine maleate (IV) is sometimes used as a diagnostic aid for detecting/characterizing PVA conditions. The cold pressor test is also used in a similar diagnostic manner.
Background Information: Prinzmetal's variant angina is a classification scheme for a subtype of angina pectoris in which attacks are experienced at rest, while exercise capacity is well preserved and attacks are associated with electrocardiographic evidence of S-T segment elevations.
Considerations: Prinzmetal's variant angina is a form of angina caused by coronary-artery vasospasm (CAS) that is not associated with exertion. Nitrates, adrenergic-blocking agents, and calcium-channel blocking agents can be used in the treatment of PVA conditions. Nitroglycerin and isosorbide dinitrate effectively relieve CAS. However, long-term prospective studies on the use of these drugs for PVA are lacking in the literature. Studies on treating PVA with adrenergic-blocking agents have been equivocal, with some studies reporting improvement and some reporting worsening. Calcium-channel blocking agents are promising drugs for PVA. Nifedipine is generally considered the prototype of this class for antianginal activity. It is effective when administered orally in PVA conditions. Side effects are mild and do not usually require termination of therapy. Verapamil hydrochloride, the prototype calcium-channel blocking agent for arrhythmias, is effective for PVA, but only 10–20% of an orally administered dose reaches systemic circulation because of the hepatic first-pass effect. Other calcium-channel blockers, including perhexilene maleate, diltiazem hydrochloride, prenylamine, and lidoflazine, have been tested in a few CAS cases with some success; adverse effects and toxicities limit the use of some of these agents, especially perhexilene. Therapy, using combinations of nitrates, adrenergic-blocking agents, and calcium-channel blocking agents, is needed in some patients. Dosing guidelines for all drugs have been described (see citation). Treatment of PVA should begin with oral nitrates. Calcium-channel blocking agents are indicated in cases that fail to respond or that are intolerant to maximum doses of nitrates given in various forms.
Interpretation and Analysis: Prinzmetal's variant angina is diagnosed by history, electrocardiogram, or coronary-artery angiography.

Angina Pectoris: Prinzmetal's Variant Angina (PVA)/ Vascular Response Testing
Methylergonovine Maleate/Nifedipine

Cellular/Molecular Mechanism of Action: Methylergonovine maleate (methergine) directly binds and positively activates at a submaximal level tryptaminergic, and α-adrenergic receptor complexes but to a lesser extent than does ergotamine. At dopaminergic receptor complexes, ergonovine functions as a weak antagonist. At both tryptaminergic and dopaminergic sites, ergonovine

can exert both partial agonist and antagonist properties at certain CNS sites. In various smooth muscle tissues, the compound exerts antagonist properties. Nifedipine functions as a calcium inhibitor.

Physiological Mechanism of Action: Promotes vasoconstriction of both venous and arterial structures through direct vascular smooth muscle stimulation. Systemic administration can produce elevations in blood pressure due to peripheral vasoconstriction. Ergonovine produces coronary artery vascular responses that can be detected as ischemic patterns on EKG tracings and angina pain in cases with coronary artery disease. Bradycardia is often induced by ergot alkaloids even when no elevations in blood pressure are evident, due in part to increased vagal activity, and to a lesser extent, diminished CND sympathetic tone and direct-acting myocardial depression.

Coronary spasm is induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when vascular endothelial cell layers are intact. The response can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. In general, all ergot alkaloid exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptors. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentration. The contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Application: Detection of PVA cases applying 3 challenge schedules.

Route of Administration: Intravascularly infused (injected) directly into the coronary artery.

Dosage: Nifedipine (0.2 mg).

Considerations: Coronary spasm, frequently recognized during coronary arteriography procedures in cases with PVA, can be treated with intravenous or intracoronary injections of nitroglycerin or nifedipine.

Implementation: Evaluation of vascular spasm responses and the capacity of nifedipine administration to suppress vasoconstrictive responses.

Interpretation and Analysis: Nifedipine (0.2 mg) injected directly into the involved artery suppresses vascular spasms in approximately 75% (e.g., n = 9/12 cases). In the residual 25% of cases (e.g., n = 3/12) nifedipine increases coronary sinus flow that had been decreased by spasm responses in 1 of the branches of the left coronary artery. Patients with PVA that have spasm superimposed on atherosclerotic lesions can benefit from coronary arterial bypass grafting combined with partial denervation of the heart. This combination yields acceptable results (83.4% favorable outcome); recurrence of attacks occurs in only 6.7% of cases of this profile type. In those forms of angina in which spasm occurs in angiographically-normal coronary arteries, medical rather than surgical intervention is preferred for therapeutic management. In conditions treated with oral nifedipine (30–40 mg/day), suppression of attacks can be achieved in a relatively large percentage of cases (e.g., n = 11/13). During periods of treatment, the methergine provocative test, which is consistently positive prior to treatment subsequently converts to negative (e.g. n = 12/12 cases). Transient withdrawal of nifedipine may cause recurrence of pain in some cases (e.g. n = 2).

Myocardial Infarction
[Antimyosin]-PEG/Liposomes/PEG and Selective Antibody Content/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Liposomes function as a physical barrier to dilution of pharmaceutical agents into biological fluids, prevent accelerated excretion or metabolism, and serve as a potential modality for selective delivery at "high" concentrations.

Background Information: Experimental myocardial infarction in rabbits can be detected as a function of their biodistribution patterns and relative size of infarct accumulations utilizing different liposome preparations.

Application: Liposomes formulated with optimized concentrations of poly(ethylene glycol) (PEG) and antimyosin immunoglobulin can function as a delivery format for the detection and characterization of experimental lesions of myocardial infarction.

Route of Administration: Intravenous.

Implementation: Delineation of the influence of parameters such as liposome size and presence or absence of PEG and infarct-specific antimyosin antibody (AM) on *in vivo* liposome biodistribution.

Interpretation and Analysis: The variables of liposome size, PEG content, and infarct-specific antimyosin antibody all affect patterns of liposome biodistribution. Liposome size is the least significant variable. Statistical analysis reveals that of all variables, PEG coating expresses the strongest influence on liposome blood clearance, significantly ($p = 0.0001$) increasing the mean level of blood radioactivity in all conditions. Infarct accumulation depends upon the presence of both PEG ($p = 0.0013$) and antimyosin monoclonal antibody content ($p = 0.005$). The infarct-to-normal accumulation ratio is affected by the presence of antimyosin monoclonal antibody ($p = 0.0002$), but the extent of the effect depends also on the presence of PEG ($p = 0.01$). The 2 different mechanisms of slow accumulation via the impaired filtration (accumulation of PEG-liposomes), and specific binding of immunoliposomes with the exposed antigen (AM-liposomes), collectively contribute to the development of relatively high target-to-background ratios. Both mechanisms are supplementary (complementary) in scenarios of liposomes carrying PEG and AM simultaneously. Multiple strategies exist for futher optimizing PEC/AM liposome preparations as a selective delivery modality.

Poly(ethylene glycol)-coated anticardiac myosin immunoliposomes: Factors influencing targeted accumulation in the infarcted myocardium. Torchilin VP, Narula J, Halpern E, Khaw BA. Biochim Biophys Acta 1996 Feb 21; 1279 (1), pp. 75–83.

Myocardial Infarction
Antimyosin Monoclonal Antibody/[Nuclear Scintigraphy]

Application: Non-invasive *in vivo* detection of acute myocardial infarction.

Route of Administration: Antimyosin monoclonal antibody (intravenous).

Design and Validation: Antimyosin antibody preparations have been development as a diagnostic imaging platform for the *in vivo* detection of acute myocardial infarction. Through its application in this capacity, it has subsequently became apparent that antimyosin antibody can detect the presence of an assortment of other disease states affecting the heart where the hallmark of the pathogenesis of the condition includes myocyte necrosis. Consistent with

this concept, antimyosin antibody has been used as a non-invasive imaging agent for the diagnosis of acute myocarditis, heart transplant rejection, drug-induced cardiotoxicity, and other cardiomyopathies.

Clinical experience gained with first-generation antimyosin monoclonal antibody preparations has served as a foundation for the design of second-generation monoclonal antibodies such as antifibrin and antiplatelet immunoglobulins used in the *in vivo* diagnosis of deep venous thrombosis of the upper limbs, pulmonary embolism, and antiatherosclerotic lesion-specific antibody for diagnosis of metabolically active lesions. Potential candidates for the class of third-generation monoclonal antibodies includes ultrasmall antigen-binding immunoglobulin fragments or synthetic peptides and negative charge-modified antibodies.

Interpretation and Analysis: Positive accumulation of antimyosin monoclonal antibody within a region of the myocardium is an indication of the presence of some type of cellular injury within the heart (e.g., ischemia/ischemic necrosis). Antimyosin preparations have also been used clinically for non-invasive diagnosis of acute myocarditis, heart transplant rejection, drug-induced cardiotoxicity, and other cardiomyopathies.

Antibody imaging in the evaluation of cardiovascular diseases. Khaw BA, Narula J. J Nucl Cardiol 1994 Sep-Oct; 1 (5 Pt 1), pp. 457–76.

Myocardial Infarction (MI)/Innervation: Heterogeneous Cardiac Sympathetic Innervation *[^{131}I]-Meta-Iodobenzylguanidine (MIBG)/[^{125}I]-Iodocyanopindolol (ICYP)/[Nuclear Scintigraphy]*

Cellular/Molecular Mechanism of Action: Meta-iodobenzylguanidine is a norepinephrine analog. Iodocyanopindolol is a β-adrenoreceptor ligand.

Application: Detection and characterization of MI lesions.

Route of Administration: [^{131}I]-meta-iodobenzylguanidine (MIBG) and [^{125}I]-iodocyanopindolol (ICYP) are both administered intravenously.

Implementation: Evaluation of cardiac neuronal function and beta-receptor expression with a dual-tracer method utilizing [^{131}I]-meta-iodobenzylguanidine (MIBG) and [^{125}I]-iodocyanopindolol (ICYP) in rat heart failure after MI.

Animal Model: Rat (MI).

Interpretation and Analysis: In rats with MI, left ventricular (LV) systolic function is decreased, and LV dimension and right ventricular (RV) mass increase gradually. Accumulations of [^{131}I]-meta-iodobenzylguanidine (MIBG) within non-infarcted LV (remote region) and RV are decreased by 15% at 1 week compared with sham-operated *in vivo* models. These same accumulations are restored by 71% and 56%, respectively, at 24 weeks compared with age-matched sham *in vivo* models despite sustained depletion of myocardial norepinephrine contents within these anatomical regions. Accumulations of [^{125}I]-iodocyanopindolol (ICYP) in the remote region and in the RV do not decrease during any stage. Myocardial MIBG distribution is heterogeneous at 1 week and lower in the peri-infarcted region than in the remote region, associated with reduced ICYP accumulation in the peri-infarcted region. At week 12, the heterogeneous distribution of both isotopes disappears. Thus cardiac sympathetic neuronal alteration appears to be coupled with a down-regulation of beta-receptors in heart failure after myocardial infarction. The abnormal adrenergic signaling occurs heterogeneously in terms of ventricular distribution and time course after myocardial infarction.

Heterogeneous cardiac sympathetic innervation in heart failure after myocardial infarction of rats. Igawa A, Nozawa T, Yoshida N, Fujii N, Inoue M, Tazawa S, Asanoi H, Inoue H. Am J Physiol Heart Circ Physiol 2000 Apr; 278 (4), pp. H1134–41.

Myocardial Infarction: Myocardial Potassium (K^+) *Glibenclaminde/Pinacidil/Bumetanide/Triphenyl Tetrazolium Chloride/Evans Blue Dye/[^{87}Rb]/[Nuclear Scintrigraphy]*

Cellular/Molecular Mechanism of Action: (i) Rubidium ion (Rb^+) is a K^+ tracer element; (ii) glibenclamide is a blocker of ATP-sensitive K^+ channels; (iii) pinacidil is a K^+(ATP) opener; (iv) bumetanide is a $K^+/Na^+/2Cl^-$ co-transporter inhibitor.

Application: [^{87}Rb] can be applied in MRI procedures to identify and characterize myocardial infarcts. Evans blue and triphenyl tetrazolium chloride staining can be applied to delineate areas at risk (AAR) and areas of necrosis, respectively.

Dosage: Glibenclamide (3 μM); pinacidil (10 μM); bumetanide (10 μM).

Implementation: Delineation of the effect of drugs that can modulate passive permeability of K^+ into cardiomyocytes in normal and reperfusion-damaged cardiac muscle. Rubidium ion (Rb^+) is used as a K^+ tracer and [^{87}Rb] MRI as a detection method. Preparations are incubated in buffer containing either (i) glibenclamide, (ii) pinacidil, (iii) bumetanide, or (iv) no drug (control). Upon reperfusion, 3-dimensional [^{87}Rb] MR images are acquired to obtain kinetics profiles of [Rb^+] uptake and its distribution. Areas at risk and areas of necrosis are determined by Evans blue dye and triphenyl tetrazolium chloride staining techniques, respectively.

Animal Model: Swine (left anterior descending artery [LAD] of isolated pig hearts perfused with Krebs-Henseleit buffer [KHB] occluded for 2 hours and subsequently reperfused for 2 hours with KHB containing 4.7 mM RbCl instead of KCl).

Interpretation and Analysis: The kinetics remain monoexponential in the affected anterior wall and the uptake rates are approximately 32%, 36%, 37%, and 21% of that in the posterior wall in the control, glib, pin, and bum groups, respectively. Infarct sizes determined histologically as a percentage of total ventricular (left + right) mass (14%–22%) correspond to the size of areas with 20% to 40% of maximal Rb image intensity [I_{Rb}^{Max} 15%–22%], except for values observed with pinacidil (12.5% vs 21%). The sizes of areas with 20% to 50% of I_{Rb}^{Max} (30%–36%) closely correlate with those of AAR determined histologically (31–33%). Lactate dehydrogenase release does not differ between any of the preparations. Therefore, (i) reperfusion damage quickly inhibits [Rb^+]uptake; (ii) [Rb^+] uptake in normal and reperfused tissue does not significantly depend on K^+(ATP) or the $K^+/Na^+/2Cl^-$ co-transporter; and (iii) areas with 20%–40% of maximal image intensity correspond to areas of infarct lesions.

The effects of drugs modulating K(+) transport on Rb(+) uptake and distribution in pig hearts following regional ischemia: (87)Rb MRI study. Kupriyanov VV, Xiang B, Sun J, Jilkina O. NMR Biomed 2002 Aug; 15 (5), pp. 348–55.

Myocardial Infarction (Acute)/Prognosis: Mortality Prediction *Streptokinase (SK) Response*

Cellular/Molecular Mechanism of Action: Streptokinase promotes fibrinolytic activity.

Application: Promotion of biochemical fibrinolysis activity in conditions of acute stroke or myocardial infarction.
Route of Administration: Streptokinase (intravascular).
Implementation: Determination of the relationship between response to SK and troponinT (TnT) concentrations in cases of acute myocardial infarction.

Human Model: Acute myocardial infarction (AMI) (e.g., n = 76 AMI cases) assessed follow hospital admission.
Interpretation and Analysis: Approximately 37% of TnT positive cases display a response to SK (e.g., n = 10/27) as determined by non-invasive criterion for reperfusion. Conversely, approximately 49% of TnT negative cases respond to SK (n = 24/49). There appears to be a trend toward a better response to SK in TnT cases. The mean time interval between the onset of symptoms and thrombolytic treatment among TnT positive "non-responders" is significantly ($p < 0.005$) higher than with TnT negative "non-responders" (5.23 + 3.42 hours vs 2.38 ± 1.37 hours). During reevaluations at 18 months, a higher mortality rate (33%) can be appreciated with TnT positive cases compared to TnT negative cases (10%). Mortality among TnT positive "non-responders" is significantly higher ($p = 0.0494$) than mortality among TnT negative "non-responders" (43 vs 9%), indicating that TnT positive cases , non-responsive to SK, are at a greater risk of cardiac death. Such findings suggest that TnT levels at admission can be of value in risk stratification of AMI conditions.

Admission troponin T as a prognostic marker and its relationship to streptokinase treatment patients with acute myocardial infarction. Kazmi KA, Iqbal MP, Rahbar A, Mehboobali N. Trop Doct 2003 Jan; 33 (1), pp. 18–22.

Myocardial Infarction (MI)/Salvage of Myocardium as a Function of Infarct Location/Anterior Wall -vs- Posterior Wall MI Size Reduction
AMP579/[^{99m}Tc]-SestaMIBI/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: AMP579 is a mixed adenosine agonist with both A1 and A2 effects.
Background Information: Evidence suggests that myocardial ischemic preconditioning and reperfusion injury may be mediated by adenosine A1 and A2 receptors. In animal models of acute MI, AMP579 reduces infarct size at serum levels of 15 to 24 ng/mL.
Application: Establishing predictive indicators for myocardial salvage as a function of infarct location.
Route of Administration: AMP579 (6-hour continuous infusion).
Dosage: AMP579 (multiple including 60 μg/kg).
Considerations: Placebo-controlled studies can be employed.
Implementation: Evaluation of the influence of 3 different AMP579 doses infused continuously over a 6-hour period. The primary end point is final MI size measured by technetium [^{99m}Tc]-sestaMIBI scanning at 120 to 216 hours following percutaneous transluminal coronary angioplasty (PTCA). Secondary end points include (i) myocardial salvage and salvage index at the same time interval (case subset subjected to baseline technetium [^{99m}Tc]-sestaMIBI scan); (ii) left ventricular ejection fraction and heart failure at 4 to 6 weeks; (iii) duration of hospitalization, and (iv) cardiac events at 4 weeks and 6 months.

Human Model: Cases undergoing primary PTCA after acute S-T segment elevation myocardial infarction (n = 311).
Interpretation and Analysis: Final infarct size does not differ among case groups receiving either AMP579 or placebo pertaining to either anterior myocardial infarction or non-anterior myocardial infarction. For cases with anterior myocardial infarction, median myocardial salvage is increasingly higher in groups receiving ascending dosages of AMP579 plus PTCA. Serum levels approaching levels shown to reduce infarct size in animal models can be achieved only with 60 μg/kg dose levels. AMP579 is safe at the doses tested, but it does not reduce infarct size. There is a trend toward greater myocardial salvage in treated patients with anterior MI.

A randomized, double blinded, placebo-controlled, dose-ranging study measuring the effect of an adenosine agonist on infarct size reduction in patients undergoing primary percutaneous transluminal coronary angioplasty: The ADMIRE (AmP579 Delivery for Myocardial Infarction REduction) study. Kopecky SL, Aviles RJ, Bell MR, Lobl JK, Tipping D, Frommell G, Ramsey K, Holland AE, Midei M, Jain A, Kellett M, Gibbons RJ. Am Heart J 2003 Jul; 146 (1), pp. 146–52.

Myocardial Infarction/Superoxide Anion Production/Mitochondrial [K^+/ATP] Channels
Fluorescent Probe/[K^+/ATP] Channel Blocker/Vitality Stain/Triphenyltetrazolium (Myocardial Infarct)/Dihydroethidium (Fluorescent Probe)/5-Hydroxydecanoate (5-HD = K^+/ATP Channel Blocker)

Cellular/Molecular Mechanism of Action: Dihydroethidium emits fluorescent color when exposed to certain wavelengths of light energy. 5-Hydroxydecanoate inhibits the cellular function of membrane-associated K^+/ATP channels.
Background Information: It is unknown if the opening of mitochondrial adenosine triphosphate-regulated potassium (K^+/ATP) channels is a trigger or an end effector of anesthetic-induced preconditioning.
Application: Assess superoxide anion production.
Implementation: Determination if opening of mitochondrial K^+/ATP channels *in vivo* triggers isoflurane-induced preconditioning by generating reactive oxygen species (ROS). To achieve this purpose, the fluorescent probe dihydroethidium can be used to assess superoxide anion production during the administration of 5-HD or the ROS scavengers N-acetylcysteine or N-2-mercaptopropionyl glycine (2-MPG) in the presence or absence of 1.0 MAC isoflurane. Myocardial infarct size and superoxide anion production can be measured using triphenyltetrazolium staining and confocal fluorescence microscopy, respectively.

Animal Model: Rabbit (pentobarbital anesthetized) subjected to a 30-minute coronary artery occlusion followed by a 3-hour period of reperfusion. Rabbits can be randomly assigned to receive a vehicle (0.9% saline) or the selective mitochondrial K^+/ATP channel blocker, 5-hydroxydecanoate (5-HD) alone 10 minutes before or immediately after a 30-minute exposure to 1.0 minimum alveolar concentration (MAC) isoflurane.
Interpretation and Analysis: Isoflurane ($p < 0.05$) decreases infarct size to 19 ± 3% (mean ± SEM) of the left ventricular area at risk as compared to the control (38 ± 4%). 5-HD administered before but not after isoflurane abolishes this beneficial effect (37 ± 4% as compared to 24 ± 3%). 5-HD alone has no effect on infarct size (42 ± 3%). Isoflurane increases fluorescence intensity. Pretreatment with N-acetylcysteine, 2-MPG, or 5-HD before isoflurane abolishes increases fluorescence, but administration of 5-HD after isoflurane only partially attenuates increases in fluorescence produced by volatile anesthetic agents (e.g., isoflurane). Therefore, mitochondrial K^+/ATP channel opening acts as a trigger for isoflurane-induced preconditioning by generating ROS *in vivo*.
Instrumentation: Confocal fluorescence microscopy.

Mitochondrial adenosine triphosphate-regulated potassium channel opening acts as a trigger for isoflurane-induced preconditioning by generating reactive oxygen species. Tanaka K, Weihrauch D, Ludwig LM, Kersten JR, Pagel PS, Warltier DC. Anesthesiology 2003 Apr; 98 (4), pp. 935–43.

ANGINA: NON-CARDIAC-ASSOCIATED THORACIC PAIN

Angina: Thoracic Pain of Non-Cardiac Origin
Atropine

Cellular/Molecular Mechanism of Action: Atropine blocks muscarinic parasympathetic (cholinergic) receptor complexes.
Physiological Mechanism of Action: Parasympatholytic effect.
Background Information: Intraesophageal balloon distension has been introduced recently as a provocative test for the assessment of non-cardiac chest pain.
Application: Differentiation between angina of cardiovascular origin and non-cardiovascular associated chest pain.
Route of Administration: Atropine (intravenous)
Dosage: Atropine (10 μg/kg)
Implementation: Evaluation of the effect of balloon location and muscarinic blockade on distension-induced pain in, asymptomatic normal controls studied on 2 separate days using a low-compliance perfused manometry system incorporating a silicone rubber balloon. Five-second-duration balloon distensions using balloon volumes of 2.5, 5, 7.5, and 10 ml of air are performed with the balloon located both 16 cm (proximal site) and 6 cm (distal site) above the lower esophageal sphincter (LES) before and after administration of atropine or placebo in a randomized double blind fashion. A standardized scoring system can be used to assess balloon distension-induced pain.

Human Model: Cases classified as asymptomatic male volunteers (e.g. n = 10).
Interpretation and Analysis: Pain scores vary directly with balloon volume but are consistently higher with the balloon located at the proximal site vs the distal site. This is usually not associated with any differences in intraballoon pressures between the 2 sites; however, contraction amplitude orad to the balloon is greater with balloon distension at the proximal site. Atropine significantly decreases pain sensation scores with the balloon located distally but not proximally. Such attenuation is not associated with significant changes in intraballoon pressures; however, contractions orad to the balloon are markedly inhibited by atropine with distal but not with proximal distension. Such findings indicate that balloon distension-induced pain varies depending on the location of distension. This difference can not be explained by differences in esophageal wall tension at the site of distension.

Effect of intraesophageal location and muscarinic blockade on balloon distension-induced chest pain. Paterson WG, Selucky M, Hynna-Liepert TT. Dig Dis Sci 1991 Mar; 36 (3), pp. 282–8.

Angina Pectoris: Thoracic Pain of Non-Cardiac Origin
Edrophonium Chloride

Cellular/Molecular Mechanism of Action: Edrophonium binds to and directly inactivates the biochemical activity of acetylcholine esterase. As a consequence of acetylcholine esterase inhibition, acetylcholine neurotransmitter concentrations accumulate within the synaptic cleft, thereby increasing the (over) stimulation of cholinergic receptor complexes.
Physiological Mechanism of Action: Promotes increases in parasympathetic tone (parasympathomimetic).
Application: Assessment of non-cardiac chest pain (NCCP).
Route of Administration: Intravenous.
Dosage: Alternating doses of edrophonium (80 μg/kg bolus compared to a 10 mg bolus).
Implementation: Distal esophageal pressures can be measured before and after pharmaceutical injection in response to 10 5 cc wet swallows.

Human Model: Study of 150 consecutive NCCP patients and 50 age-matched controls that alternatively receive either 80 μg/kg or 10 mg intravenous bolus doses of edrophonium preceded by saline placebo injections.
Interpretation and Analysis: Side effects are similar between doses, but there is a significant ($p = 0.02$) linear relationship between intensity of side effects and the edrophonium dose per kilogram of body weight. Edrophonium (10 mg) produces chest pain sensations (e.g., 33% of cases) and control subjects (e.g., 4%) while 29% of cases and no controls receiving an 80 μg/kg dose experience chest pain sensations. Amplitude changes after either dose are not significantly different for all comparisons, but the duration of response does distinguish the 2 doses in cases with chest pain. A significantly greater ($p = 0.01$) increase in distal contraction duration occurs after 10 mg (74 ± 12% SE) compared to 80 μg/kg doses (43 ± 6%). However, individual response to the 2 doses overlaps considerably. If a positive test is redefined to include both chest pain and manometric changes that are significantly different from controls, the positivity rate changes drastically: 33% to 9% in the 10 mg group and 30% to 3% in the 80 μg/kg group.

Anticholinesterase Agents. Taylor P (Chapter 6: pp. 113–29). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

Angina Pectoris/Thoracic Pain of Non-Cardiac Origin/Esophogeal Motor Activity Differential Diagnosis
Ergonovine Maleate

Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Implementation: Evaluation of angina pectoris–like chest pain cases that have been excluded from having significant coronary heart disease by cardiac catheterization procedures utilizing ergonovine maleate (EM) to determine if esophageal motor activity is the cause of clinical signs.

Human Model: Angina pectoris–like chest pain cases that have been excluded from having significant coronary heart disease by cardiac catheterization procedures (e.g., n = 18),

Interpretation and Analysis: Over half of such cases (e.g., n = 12/18 or 66%) can demonstrate abnormal baseline levels of esophageal motility. Following the injection of EM, a number of cases will experience a typical form of chest pain (e.g., n = 10/18) at the onset of repetitive contractions. Such provocative tests aid in delineating a direct association between chest pain and esophageal dysfunction. Compared with saline injection, only the repetitive contractions are significantly increased after AM in such cases ($p \leq 0.01$). Amplitude and duration of contractions are increased after EM, but not significantly. Due to potentially serious adverse effects, however, EM cannot be recommended as a routine provocative agent for establishing a differential diagnosis of angina pectoris–like chest pain.

Ergonovine-induced esophageal spasm in patients with chest pain resembling angina pectoris. Koch KL, Curry RC, Feldman RL, Pepine CJ, Long A, Mathias JR. Dig Dis Sci 1982 Dec; 27 (12), pp. 1073–80.

Angina Pectoris/Thoracic Pain of Non-Cardiac Origin/Esophagitis/Gastroesophogeal Reflux Disease (GERD)/MIBI Negative NCCP
High-Dose Omeprazole/[^{99m}Tc-SestaMIBI]

Cellular/Molecular Mechanism of Action: Omeprazole inhibits H^+/K^+-ATPase that exchanges hydrogen ion for potassium ion within parietal cell populations. In this fashion, less hydrochloric acid is available for secretion into the gastric lumen. [^{123}I]-meta-iodobenzylguanidine functions as an analog of norepinephrine.
Background Information: Non-cardiac chest pain (NCCP) presents as a frequent diagnostic challenge, with affected cases tending to use a disproportionate level of health care resources. Gastroesophageal reflux disease is the most frequent cause of NCCP.
Application: Detection of NCCP etiologies due to esophagitis and gastric esophageal reflux disease in order to avoid nuclear scintigraphy evaluation of cardiac function/physiology.
Route of Administration: Omeprazole (oral).
Dosage: Omeprazole (40 mg twice daily).
Considerations: Gastroesophageal reflux disease is the most frequent cause of NCCP rest/stress perfusion.
Implementation: Evaluation of recurrent chest pain conditions utilizing a prospective, double blinded, placebo-controlled, crossover trial using high-dose omeprazole. Findings are then compared with those of endoscopy, manometry, and ambulatory 24-hour 2-channel esophageal pH monitoring. Initial diagnostic upper endoscopy, esophageal manometry, and 24-hour pH monitoring can also applied to establish evaluation parameters. Cases are then randomly assigned to either placebo or omeprazole for 14 days, washed out for 21 days, and then crossed over. Clinical symptoms are determined using a Visual Analogue Scale to measure the severity of chest pain before and after each period.

Human Model: Cases (n = 18 men; n = 24 women; age 22–77 years) with recurrent complaints of chest pain of a non-cardiac etiology, as determined by rest/stress perfusion imaging with technetium [^{99m}Tc]-sestaMIBI.
Interpretation and Analysis: Improvement in perceived chest pain can be detected in approximately 71% of cases receiving omeprazole compared to only 18% for placebo reference controls. Abnormal results on manometry (20%), 24-hour pH monitoring (42%), or endoscopy with visual evidence of esophagitis (26%) can be appreciated less frequently. Combination of the 3 tests does not significantly increase their usefulness. In NCCP patients with GERD, as defined by positive results on a 24-hour pH test or presence of esophagitis on endoscopy, omeprazole treatment results in a response in 95% of cases, whereas 90% of GERD-positive patients treated with placebo do not respond. Of NCCP patients determined to be GERD negative, approximately 39% will respond to omeprazole. Therefore, omeprazole as a first diagnostic tool in the evaluation of MIBI-negative NCCP is sensitive and specific for determining the cause of NCCP. Endoscopy, manometry, and 24-hour pH monitoring are not only less sensitive in diagnosing NCCP, but they were significantly more expensive.

Short course of omeprazole: A better first diagnostic approach to non-cardiac chest pain than endoscopy, manometry, or 24-hour esophageal pH monitoring. Pandak WM, Arezo S, Everett S, Jesse R, DeCosta G, Crofts T, Gennings C, Siuta M, Zfass A. J Clin Gastroenterol 2002 Oct; 35 (4), pp. 307–14.

Angina Pectoris/Thoracic Pain of Non-Cardiac Origin/Gastric Reflux -vs- Cardiac-Associated Pain
Lansoprazole

Physiological Mechanism of Action: Lansoprazole reduces gastric acid production.
Application: Potential detection of gastric function/acid production as a cause for non-cardiac chest pain. The agent could possibly be used as a screening diagnostic agent prior to performing cardiac angiography and possibly gastric endoscopy studies.
Route of Administration: Lansoprazole (oral).
Dosage: Lansoprazole (30 mg).
Implementation: Evaluation of the influence of lansoprazole on non-cardiac thoracic pain applying 24-hour ambulatory esophageal pH monitoring (daily for 4 weeks duration). Chest pain symptoms are then recorded before and 1 month after treatment validated by the use of a questionnaire. The symptom score is calculated by multiplying the severity and frequency of the symptom and symptom improvement defined as > 50% reduction in the symptom score.

Human Model: Cases suffering from chest pain that have normal angiography imaging profiles and are without gastric or esophageal lesions (n = 68; n = 36 lansoprazole, n = 32 placebo).
Interpretation and Analysis: Symptom scores are reduced significantly in both groups ($p < 0.001$). In cases receiving lansoprazole, more individuals with vs without abnormal reflux show symptomatic improvement (92 vs 33%; odds ratio = 22; 95% confidence interval, 2.3–201.8; $chi^2 = 10.9$; $p = 0.001$), giving a sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of 92%, 67%, 58%, 94%, and 75%, respectively. Alternatively, cases receiving a placebo display rates of symptom improvement that are similar between those with and without abnormal reflux (33 vs 35%, p = ns). Treatment with lansoprazole is a useful test in diagnosing endoscopy-negative gastroesophageal reflux disease in cases with non-cardiac chest pain.

Symptomatic response to lansoprazole predicts abnormal acid reflux in endoscopy-negative patients with non-cardiac chest pain. Xia HH, Lai KC, Lam SK, Hu WH, Wong NY, Hui WM, Lau CP, Chen WH, Chan CK, Wong WM, Wong BC. Aliment Pharmacol Ther 2003 Feb; 17 (3), pp. 369–77.

CARDIAC DISEASE WITHOUT ANGINA

Aortic Valve/Left Ventricular Systolic Dysfunction and Aortic Stenosis/Low Output and Low Mean Gradient/Surgical Candidate Identification
Dobutamine

Background Information: Although aortic valve replacement can be performed at an acceptable risk level in selected cases with left ventricular systolic dysfunction and low-output low-gradient

aortic stenosis, not all cases presenting with these hemodynamics will benefit from surgical intervention. Some cases may have only mild aortic stenosis, despite a small calculated valve area. Some reports have described the clinical utility of diagnostic dobutamine stimulation during cardiac catheterization in these diagnostically challenging conditions.

Application: In cases with left ventricular systolic dysfunction and aortic stenosis with a low output and a low mean gradient, dobutamine challenge may aid in selecting those who would benefit from an aortic valve operation.

Route of Administration: Intravascular.

Implementation: Evaluation of the influence of dobutamine infusion in cases of low-output, low-gradient aortic stenosis

Human Model: Cases of low-output, low-gradient aortic stenosis and an ejection fraction $< 40\%$ ($n = 32$).

Interpretation and Analysis: On the basis of the results of the dobutamine test, approximately 66% of cases may meet the criteria necessary to justify performing aortic valve replacement (e.g. $n = 21/32$). A high percentage of cases with a final aortic valve area ≤ 1.2 cm^2 at peak dobutamine infusion and a mean gradient of > 30 mm Hg have severe calcific aortic stenosis that can be appreciated the time of surgical intervention (e.g., 100% in 1 study). In cases with contractile reserve identified during dobutamine challenge based on observed increases in stroke volume ($> 20\%$), complications that can occur include perioperative death ($n = 1/15$ or 7%); but the majority are still alive ($n = 12/15$ New York Heart Association class I or II status) at the time of case follow-up.

Low-output, low-gradient aortic stenosis in patients with depressed left ventricular systolic function: The clinical utility of the dobutamine challenge in the catheterization laboratory. Nishimura RA, Grantham JA, Connolly HM, Schaff HV, Higano ST, Holmes DR Jr. Circulation 2002 Aug 13; 106 (7), pp. 809–13.

Aortic Valve/Subaortic Stenosis: Aortic Valve/ Idiopathic Hypertrophic
Phentolamine

Cellular/Molecular Mechanism of Action: Competitive α-adrenergic blockade (transient) and vasodilation is due to a direct action on vascular smooth muscle.

Physiological Mechanism of Action: Inhibition of responses to 5-HT, gastrointestinal tract stimulation (blocked by atropine), vasodilation, decreased blood pressure, and cardiac stimulation.

Considerations: The clinical use of phentolamine has increased since its introduction as an antihypertensive agent. The vasodilatory action of phentolamine, as well as its positive inotropic effect has led to its use in the treatment of congestive heart failure. Recently, phentolamine has been used by several clinical groups to improve left ventricular function in acute myocardial infarction. There appears to be great promise for the use of phentolamine in such clinical settings. The drug given intravenously or orally can suppress ventricular premature beats and supraventricular premature beats. However, experience with phentolamine as an antiarrhythmic agent is still limited. Similarly, the relief of angina pectoris by phentolamine requires confirmation by additional clinical studies.

Interpretation and Analysis: Phentolamine can be used as a provocative test for characterizing idiopathic hypertrophic subaortic stenosis. Since it does not produce cardiac arrhythmias, it may be safer than isoproterenol for such purposes. The comparative (relative) effectiveness of phentolamine and isoproterenol in diagnosing idiopathic hypertrophic subaortic stenosis is unknown. Phentolamine has been advocated for several years as an effective agent for the treatment of shock. The experience is still limited to a few groups that have reported favorable results. Phentolamine has also been used as a bronchodilator and a pulmonary artery dilator. Preliminary results suggest that phenotolamine is effective for this purpose but further investigation is necessary to validate these early impressions. A sensitive measurement of the blood levels of phentolamine is not available. When this is accomplished, further insight into the metabolism of this drug will be forthcoming.

Phentolamine. Gould L, Reddy CV. Am Heart J 1976 Sep; 92 (3), pp. 397–402.

Left Ventricular Aortic Outflow Obstruction
Phentolamine/(Isoproterenol Inhalation Alternative)/(Amyl Nitrite Alternative)/Valsalva's Maneuver Alternative

Cellular/Molecular Mechanism of Action: Phentolamine transiently binds directly to α-adrenergic receptor complexes in a manner that competitively inhibits the biological activity of adrenergic neurotransmitter agents. Interestingly, the biological activity of 5-HT is also inhibited, and its vasodilatory effect is due to a direct effect of phentolamine on vascular smooth muscle.

Physiological Mechanism of Action: Cardiac and smooth muscle structures are the most prominent tissues that have their function altered by phentolamine. Effects include or result in cardiac stimulation, increased gastrointestinal motility and secretion, and peripheral vascular vasodilation accompanied by declines in blood pressure. In effect, decreases in peripheral/pulmonary vascular resistance and increases in venous compacitance are produced. The influence of phentolamine on peripheral vascular resistance is not solely responsible for its effect on cardiac function.

Application: Enhances myocardial contractility and decreased afterload with induction of only slight tachycardia. Beneficial in the diagnosis of cases suffering from idiopathic hypertrophic subaortic stenosis and valvular dysfunction.

Route of Administration: Phentolamine (intravenous).

Dosage: Phentolamine (5 mg).

Considerations: Intravenous injection of phentolamine potentially offers a better provocative test for aortic left ventricular outflow tract obstruction than does the Valsalva's maneuver, or the inhalation of either isoproterenol or amyl nitrite.

Interpretation and Analysis: Applying echocardiographic and phonocardiographic recordings, systolic pressures can fall an average of 20 mm Hg while remaining above 90 mm Hg and accompanied by no notable increases in heart rate. Phentolamine appears to be a safe, simple, and specific diagnostic agent for eliciting dynamic obstruction in IHSS.

Basis for Characterizing Alternative: In typical idiopathic hypertrophic subaortic stenosis, amyl nitrite increases the obstructive index (39.6 ± 12 to 51 ± 18.9: $p < 0.05$) compared to phentolamine (increased obstructive index 69.8 ± 25.6: $p < 0.015$). After a 2-week course of oral administration of 80 mg of propranolol daily, and then either inhalation of amyl nitrite or injection of phentolamine, there is usually no change from the mean resting obstructive index. Phentolamine is more potent than amyl nitrite in eliciting dynamic obstruction in IHSS; phentolamine and amyl nitrite do not affect the obstructive index in conditions with beta blockade.

Toxicity: Creation of cardiac arrythmias (tachycardias), hyperperistaltic-induced diarrhea with abdominal discomfort.

Evaluation of phentolamine as a provocative test for idiopathic hypertrophic subaortic stenosis. Kerin NZ, Mori I, Edelstein J, Blonder R, Rubenfire M. Am Heart J 1979 Feb; 97 (2), pp. 204–10.

Phentolamine. Gould L, Reddy CV. Am Heart J 1976 Sep; 92 (3), pp. 397–402.

Left Ventricular Hypertrophy (LVH)/Functional Response: Dynamic
Acetylcholine/Adenosine/Sodium Nitroprusside

Physiological Mechanism of Action: Acetylcholine (parasympathetic cholinergic agonist); adenosine (negative chronotropic response); sodium nitroprusside (lowers systemic blood pressure).
Application: Dectection and characterization of alterations in cardiovascular function.
Implementation: Evaluation of changes in coronary morphology and hemodynamic function during Q regression in established conditions of LVH following surgical unloading. Alterations delineated can include degree of LVH, coronary hemodynamic function, and contemporaneous vessel morphology 42 days postoperation. Parameter can then be reassessed in an identically treated *in vivo* models debanded and the same parameters measured after 1, 3, and 6 weeks to assess hemodynamic and morphological changes that occur with hypertrophy regression.

Animal Model: Guinea pig (induced LVH created by aortic banding while sham operated animals serve as controls).
Interpretation and Analysis: Banding results in an aortic pressure gradient of 41 $\pm$ 9 mm Hg and increases in heart/body weight ratio (46%), myocyte size (26%), and a doubling of arteriolar wall thickness (e.g. all at $p < 0.01$). These changes are accompanied by a reduction in coronary reserve (38%) and significant ($p < 0.01$) decreases in maximal response to acetylcholine (70%), sodium nitroprusside (87%), adenosine (70%), and reactive hyperemia (52%). Surgical debanding normalizes the systemic hemodynamics and removes the aortic gradient after 7 days. There is some limited improvement in coronary structure and, to a lesser extent, function despite continued presence of significant LVH. Such developments completely regress to normal levels 23 days after debanding and are accompanied by a normalization of coronary structure and function, although systolic impedance to flow remains significantly increased. After 44 days, debanding results in complete cardiac morphological and functional recovery. Left ventricular hemodynamic unloading can result in complete normalization of LVH, coronary morphology, and hemodynamic function. Although morphological and functional recovery is closely correlated, recovery of coronary morphology and function slightly precedes that of the myocardium in this aortic banded/debanded model.

Recovery of coronary function and morphology during regression of left ventricular hypertrophy. Kingsbury M, Mahnke A, Turner M, Sheridan D. Cardiovasc Res 2002 Jul; 55 (1), pp. 83–96.

Murmurs: Cardiac Murmurs
Isobutyl Nitrite (ISBN)/(Analytical Assay)

Application: Delineation of cardiac murmurs and for the therapeutic management of angina pectoris.
Considerations: Compounds are highly volatile vasodilators and sometimes abused as inhalant agents.
Interpretation and Analysis: A mean recovery of ISBN from the blood is approximately 86% over a concentration range of 1.0 to 400 ng/ml (rat). The interday coefficient of variation is below 15% at the lowest quantifiable blood concentration of 1 ng/ml ISBN (rat). Applying the newly developed gas chromatography assay, new pharmacokinetic information about ISBN has been acquired. Results discovered with the new analysis method have shown that rats inhaling 900 ppm ISBN for 45 minutes produce steady-state blood concentrations of about 290 ng/ml and a rapid elimination half-life of 1.4 minutes.
Instrumentation: A gas chromatographic assay has been developed using electron capture detection for the analysis of the representative nitrite inhalant, ISBN, in rat and human whole blood. Unconventional sampling and processing techniques are required because of the high volatility and chemical instability of nitrites in biological fluids.

Analysis of isobutyl nitrite inhalant in rat and human blood: Application for pharmacokinetic investigations. Kielbasa WB, Bauer JA, Fung HL. J Chromatogr B Biomed Sci Appl 1999 Oct 29; 734 (1), pp. 83–9.

Syncope Differentiation Diagnosis
ATP/Isoproterenol (Tilt Test)

Cellular/Molecular Mechanism of Action: Isoproterenol is a non-selective β-adrenergic receptor agonist.
Background Information: In patients with vasovagal syndrome, head-up tilt testing may reproduce symptoms generally associated with vasodepression. Recent research suggests ATP testing can identify cases with abnormal vagal cardiac inhibition.
Application: The tilt and ATP tests individually and jointly can be utilized to determine the underlying mechanisms of vasovagal symptoms in most cases of syncope.
Route of Administration: ATP (20 mg).
Dosage: ATP (intravenous).
Implementation: Evaluation of isoproterenol and ATP provocative tests performed in random order during 1 session and outside of predominant sympathetic periods in cases related to syncope. In passive and isoproterenol-provocative tilt testing by standard protocol, reproduction of symptoms is defined as a positive test. The ATP test consists of administering injectable ATP (at bedside) while continuously monitoring ECG and blood pressure with a vagal cardiac pause > 10 seconds defined a positive test result. For most cases (64%), a ≥ 1 test will be positive.

Human Model: Cases suffering from syncope ($n = 56$); cases of presyncope ($n = 56$) for whom no cardiac or extracardiac etiologies can be identified.
Interpretation and Analysis: In 57% of cases (e.g., $n = 41/72$) with a positive tilt test (either passive or provoked by isoproterenol), approximately 32% have cardiac disease, while a very low percentage have significant bradycardia (e.g., $n = 0$; < 50 bpm). In cases with positive ATP test findings (e.g., $n = 8$ or 11%), approximately two-thirds or 62% have cardiac disease. The probability of a positive result increases with age ($p = 0.015$). Both tests are positive in a small number of cases (e.g., $n = 3$) while a relatively larger number have a negative responses to both evaluation procedures (e.g., $n = 26$). Results from tilt and ATP test procedures appear to be uncorrelated ($p = 0.28$). Therefore, tilt and ATP tests individually and jointly can assist in determining the mechanism of vasovagal symptoms in most cases of syncope. Vagal cardiac inhibition appears to increase with age.

Contribution of head-up tilt testing and ATP testing in assessing the mechanisms of vasovagal syndrome: Preliminary results and potential therapeutic implications. Flammang D, Erickson M, McCarville S, Church T, Hamani D, Donal E. Circulation 1999 May 11; 99 (18), pp. 2427–33.

Syncope/Hypoxia (Sudden)/Bradycardia (Sudden)/ Vasovagal Syncope (Unexplained)/ [Vascular Graft Patency] *Nitroglycerin/Isoproterenol*

Cellular/Molecular Mechanism of Action: Isoproterenol recognizes, physically binds to, and activates sympathetic/adrenergic receptor complexes.

Physiological Mechanism of Action: Nitroglycerin induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and patients with coronary artery disease when nitroglycerin is given by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce a significant hypotensive episode.

Application: Diagnosis of vasovagal syncope and can be utilized in combination with quantitative angiography for the evaluation of vascular blood flow integrity (vasodilation vs vasoconstriction) and patency of vascular grafts. Injectable nitroglycerin (TNG) is employed during cardiac catheterizations primarily in cases undergoing provocative tests for coronary spasm with ergonovine maleate where it has demonstrated considerable efficacy.

Route of Administration: Nitroglycerin (intravascular).

Dosage: Nitroglycerin given at progressively increasing infusion rates (increments of 0.86 μg/kg/hr at each stage).

Implementation: Evaluation of unexplained syncope conditions through analysis of provoked changes in coronary artery vascular blood flow. A maximum of 5 successive stages consisting of 5 minutes in the supine position are performed plus 10 minutes of 80-degree upright tilt at progressively increasing infusion rates (increments of 0.86 μg/kg/hr every stage).

Human Model: Cases of unexplained syncope (n = 40; n = 23/40 women, mean age 47 years; n = 25 asymptomatic controls with negative baseline head-up tilt undergoing 2 other tilting tests, 1 during nitroglycerin infusion and 1 during isoproterenol infusion).

Interpretation and Analysis: During the nitroglycerin test a positive response (syncope in association with sudden hypotension and bradycardia) can occur in approximately 53% of cases (e.g., n = 21/40) with unexplained syncope; an exaggerated response (minor symptoms in association with slowly increasing hypotension alone) occurs in about 25% (e.g., n = 10/40); a negative response in 22% of cases (e.g., n = 9/40); and drug intolerance in a very small percentage (e.g., n = 0 or 0%). During the isoproterenol test these percentages are 25%, 25%, 32%, and 18%, respectively. Only a small percentage of controls have a positive response to the nitroglycerin test and to the isoproterenol test (e.g., n = 2 or 8% for each test). Thus the nitroglycerin test seems to be a useful alternative tool for diagnosis of vasovagal syncope; it is equally specific but more sensitive and feasible than the isoproterenol test.

Nitroglycerin infusion during upright tilt: a new test for the diagnosis of vasovagal syncope. Raviele A; Gasparini G; Di Pede F; Menozzi C; Brignole M; Dinelli M; Alboni P; Piccolo E. Am Heart J] 1994 Jan; Vol. 127 (1), pp. 103–11.

Syncope: Neurocardiogenic *Isosorbide Dinitrate/Isoproterenol*

Cellular/Molecular Mechanism of Action: Isosorbide dinitrate (active metabolite: isosorbide-2-mononitrate; isosorbide-5-mononitrate) is believed to activate guanylate cyclase and increase the synthesis of guanosine 3′,5′ monophophate (cGMP) in smooth muscle and other tissues. Formation of reactive free radical nitric oxide (NO) occurs, which interacts with and activates guanylate cyclase. Isoproterenol binds to and potently activates β-adrenergic receptor complexes (β-adrenergic receptor agonist).

Physiological Mechanism of Action: Isosorbide dinitrate is an arterial and venous dilating agent. The (sympathomimetic) effect of isoproterenol is mainly directed at the heart and smooth muscle tissues of the bronchioles, skeletal muscle vasculature, and alimentary tract. Physiologically isoproterenol promotes declines in peripheral vascular resistance primarily at the level of the skeletal muscle vasculature.

Application: Isosorbide dinitrate and isoproterenol can be applied to identify and characterize cases of suspected cardiogenic syncope.

Route of Administration: Isosorbide dinitrate (sublingual), isoproterenol (intravenous).

Dosage: Isosorbide dinitrate (5 mg), isoproterenol (4 μg/min).

Implementation: In cases of suspected neurocardiogenic syncope (e.g., n = 120; 15–77 years), the response to a head-up tilt test (HUT) can be divided into subjects that either do or do not develop syncope/presyncope during a passive HUT test for 30 minutes. Cases that do not develop symptoms are subjected to repeated HUT tests with isoproterenol influsions (4 μg/min; 10 minutes) and then tilted after a sublingual administration of isosorbide dinitrate (another 12 minutes). The HUT/isosorbide dinitrate test is usually performed after the HUT/isoproterenol test.

Interpretation and Analysis: Sensitivity and specificity of passive HUT is 41% (95% C.I. 32.9% to 51%) and 100%, respectively. Sensitivity of isoproterenol HUT is 51.4% (95% C.I. 39.2% to 63.6%) and specificity 70% (95% C.I. 55.4% to 82.1%), and for isosorbide dinitrate HUT is 70% (95% C.I. 57.9% to 80.4%) and 88% (95% C.I. 75.7% to 95.5%), respectively. The accuracy of the isosorbide HUT is significantly higher than the accuracy of the isoproterenol HUT 77.5% (95% C.I. 68.9% to 84.6%). Sublingual isosorbide dinitrate is at least as sensitive as isoproterenol for the assessment of suspected cases of neurocardiogenic syncope that display a negative tilt test without provocation. The low rate of side effects and the higher accuracy of the idosrobide dinitrate HUT, along with the simplicity of this challenge compared to the isoproterenol HUT test, suggest that sublingual isosorbide dinitrate should be preferred as a provocative agent to evaluate neurocardiogenic syncope after a negative passive tilt test.

Tilt testing in neurocardiogenic syncope: Isosorbide vs isoproterenol. Hermosillo AG, Marquez MF, Jauregui-Renaud K, Falcon JC, Casanova JM, Guevara M, Cardenas M. Acta Cardiol 2000 Dec; 55 (6), pp. 351–5.

Syncope: Neurocardiogenic *Glyceryl Trinitrate (Nitroglycerin)/Isoprenaline (Isoproterenol)*

Cellular/Molecular Mechanism of Action: Glyceryl trinitrate (nitroglycerin) activates guanylate cyclase and increases the synthesis of guanosine 3′,5′ monophophate (cGMP) in smooth muscle and other tissues. Formation of reactive free radical nitric oxide (NO) occurs, which interacts with and activates guanylate cyclase.

Isoprenaline (isoproterenol) binds to and potently activates β-adrenergic receptor complexes (β-adrenergic receptor agonist).

Physiological Mechanism of Action: Glyceryl trinitrate (nitroglyerin) is an arterial and venous dilating agent. Isoprenaline (isoproterenol: sympathomimetic) exerts effects mainly directed at the heart and smooth muscle tissues of the bronchioles, skeletal muscle vasculature, and alimentary tract. Physiologically isoprenaline (isoproterenol) promotes declines in peripheral vascular resistance primarily at the level of the skeletal muscle vasculature.

Application: Glyceryl trinitrate (nitroglycerin) and isoprenaline (isoproterenol) can be used to detect and characterize conditions of neurocardiogenic syncope.

Implementation: In unexplained cases of syncope with a negative passive head-up tilt at 70 degrees (40 minutes), the glyceryl trinitrate head-up tilt and isoprenaline head-up tilt tests can be of diagnostic value (performed 1 week apart). Diagnostic criteria include induced symptoms (syncope, presyncope) in concert with the development of hypotension.

Interpretation and Analysis: In cases with negative passive head-up tilt, the sensitivity of glyceryl trinitrate in diagnosing vasovagal syncope is approximately 48% with a 71% level of specificity. Isoprenaline sensitivity is 21% with a 64% level of specificity. There is a rather drastic difference in the incidence of undesirable side effects observed with glyceryl trinitrate compared to isoprenaline. Glyceryl trinitrate is well tolerated. In contrast, a large percentage of cases (68%) display side effects with isoprenaline that are severe enough to require termination of testing procedures. The most common adverse effects are the development of hypertension or tachycardia and intolerable "flushing" or nausea. Based on comparison evaluations, glyceryl trinitrate (nitroglycerin) head-up tilt is as effective as isoprenaline (isoproterenol) head-up tilt as a provocative agent for vasovagal syncope and has a lower incidence of adverse events.

Comparison of provocative tests for unexplained syncope: Isoprenaline and glyceryl trinitrate for diagnosing vasovagal syncope. Graham LA, Gray JC, Kenny RA. Eur Heart J 2001 Mar; 22 (6), pp. 497–503.

Syncope: Vasovagal
Edrophonium

Cellular/Molecular Mechanism of Action: Edrophonium functions as an inhibitor of acetylcholinesterase biochemical activity.

Physiological Mechanism of Action: Edrophonium through the inhibition of acetycholine esterase promotes accumulation of acetylecholine neurotransmitter at cholinergic receptor complexes associated with postsynaptic membranes.

Background Information: Vasovagal syncope after head-up tilting is thought to be secondary to a complex, neurally-mediated reflex with both vasodepressor and cardioinhibitory efferent components.

Application: Edrophonium has been utilized as a provocative agent for triggering syncope during head-up tilt testing protocols of benefit in detecting cases of vasovagal mediated syncope. The edrophonium/head-up tilt test (i) is currently considered to significantly increase the sensitivity of detecting cases of vasovagal syncope; (ii) may be particularly useful when provocation with isoproterenol is undesirable; and (iii) may be an effective method to help differentiate cases with a significant reflex cardioinhibitory component from those with a predominantly reflex vasodepressor component.

Route of Administration: Edrophonium (intravenous).

Dosage: Edrophonium (10 mg).

Implementation: Evaluation of the efficacy of edrophonium as a provocative diagnostic agent for the purpose of "triggering" syncope during head-up tilt testing procedures. In cases suffering from recurrent unexplained syncope, edrophonium is administered after 30 minutes of 60 degrees head-up tilting alone.

Human Model: Cases suffering from recurrent unexplained syncope (e.g., n = 45 affected and n = 20 negative reference controls).

Interpretation and Analysis: Syncope can be induced in a little less than 50% of cases (e.g., n = 19/45), with some cases (e.g. n = 9/19) observed to develope syncope with head-up tilt with the predominant hemodynamic alteration recognized during such episodes being marked vasodepression. Conversely, other cases will develop syncope only after head-up tilting in combination with edrophonium (e.g., n = 10/19), with the predominant hemodynamic findings being marked vasodepression and bradycardia. Syncope can occasionally be induced in normal reference controls (e.g., n = 1/20) following head-up tilting and edrophonium. There are no long-term complications associated with edrophonium in diagnostic procedures.

Evaluation of edrophonium as a provocative agent for vasovagal syncope during head-up tilt-table testing. Lurie KG, Dutton J, Mangat R, Newman D, Eisenberg S, Scheinman M. Am J Cardiol 1993 Dec 1; 72 (17), pp. 1286–90.

Syncope: Vasovagal
Nitroglycerin/[Tilt-Table Test]

Cellular/Molecular Mechanism of Action: Nitroglycerin has a direct action on vascular smooth muscle and its effects are not directly mediated through modifications of the autonomic nervous system.

Physiological Mechanism of Action: Induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are the changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and patients with coronary artery disease when nitroglycerin is given by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce significant episodes of hypotension.

Background Information: Vasovagal syncope can occur in any individual, given sufficient provocation, and probably half the population suffers at least 1 episode during life. Often it occurs in youth and may occur in clusters. Usually there is a history of a previous episode. Prodromal symptoms include nausea, sweatiness, and a sensation of warmth.

Diagnostic Application: Patients suffering from syncope of unknown origin that may be due to vasovagal syncope.

Considerations: A classical history and a positive tilt test obviate the need for further investigation in clinical practice, but in the context of aviation (pilots), it is wise to determine if there is a small possibility of intermittent rhythm and/or conduction disturbance as an alternative explanation for the episode.

Implementation: Diagnostic detection of vasovagal syncope can be achieved by obtaining a careful history and performing a tilt test in concert with nitroglycerin administration. In instances where intermittent rhythm and/or conduction disturbance are thought to be important as an alternative explanation for episodes, it then becomes reasonable to carry out a Holter recording and exercise electrocardiogram, perhaps also echocardiography.

Interpretation and Analysis: Patients suffering from syncope of unknown origin display a 53% rate of positive response (hypotension and bradycardia) when subjected to a tilt-table test and nitroglycerin administration. An exaggerated response (hypotension only) is observed in 20% of cases presented for diagnosis (suffering from vasovagal syncope). Other reports have described a 1.3% false positive rate for passive tilt test, and the true positive rate being about 70% when a nitroglycerin challenge is included. No treatment is of much benefit, although many agents, including beta-blocking drugs, have been used. Some cases have undergone permanent dual chamber pacing with some favorable results. Explanation and reassurance is important. From a licensing point of view (e.g. pilots), following investigation after an attack, consideration may be given to providing restricted certification with regular follow-up examinations. Case review with diagnostic investigations after an event-free interval, (arbitrarily set for 2 years), may permit full certification. Malignant vasovagal syncope with no warning of impending attack should warrant disbarment.

Syncope of Unknown Origin
Isoproterenol/[Tilt-Table Test]

Cellular/Molecular Mechanism of Action: Isoproterenol binds to and positively activates both β_1 and β_2 adrenergic membrane-associated receptor complexes.

Due to a relatively minimal influence on α-adrenergic receptor complexes, cardiac function, bronchial smooth muscle, skeletal muscle vasculature, and the gastrointestinal tract are the primary organ systems influenced by the physiological properties exerted by isoproterenol administration. Cardiovascular influences of isoproterenol include diminished peripheral vascular resistance, especially within the vascular networks that perfuse musculoskeletal structures. The increases in heart rate and contractility induced by isoproterenol promote declines in diastolic pressure and elevations in cardiac output sufficient to maintain or elevate systolic pressures (mean blood pressure is lowered).

Background Information: Isoproterenol is widely used as a provocative medium for vasovagal responses during tilt test procedures.

Diagnostic Application: Multi-state isoproterenol tilt-table (MSITT) test.

Route of Administration: Intravenous.

Dosage: Isoproterenol given as constant infusion (3 μg/min). Dose of isoproterenol infusion is generally titrated empirically based on increases in resting heart rate before tilt up test. Administration can involved the use of a 2-stage isoproterenol-tilt protocol, with doses of 0.01 and 0.02 μg/kg per minute for 10 minutes each, or 1-stage isoproterenol-tilt protocol, with a dose of 1 or 2 μg/min for 10 minutes.

Implementation: Evaluation of the optimal increase in resting heart rate with isoproterenol for tilt-induced vasovagal responses. After the end of a negative baseline tilt (80 degrees for 30 minutes), the isoproterenol tilt is performed using 1 of 2 protocols: 2-stage isoproterenol-tilt protocol, or 1-stage isoproterenol-tilt protocol. Resting heart rate increases are defined as a percentage increase in the resting heart rate after isoproterenol infusion, compared to baseline heart rates before initiation of the tilt test.

Human Model: Cases of unexplained syncope (n = 97 consecutive patients).

Interpretation and Analysis: Combining the use of a tilt-table and isoproterenol diagnostic challenge increases the sensitivity of detecting cases suffering from vasovagal mediated syncope (95% by 5 minutes). Conversely, the application of the MSITT alone without the use of isoproterenol results in an 80% positive response rate. Cases that are suffering from bradycardia show a lower rate of positive response rate compared to the MSITT test (10%).

Ninety-three percent (93%) of positive tilt-table procedures (e.g., n = 28/30) occur with a resting heart rate increases of ≥ 21%. With a resting heart rate increase of 60% and 100%, 18 (60%) and 27 (90%) positive responses can be observed, respectively. In conclusion, a minimum resting heart rate increase of ≥ 21% is required to provoke a vasovagal response during a subsequent isoproterenol tilt (80 degrees for 10 minutes). Preferably, heart rate should be increased to 60–100% by isoproterenol titration before tilting.

Norepinephrine, Epinephrine, and the Sympathomimetic Amines. Weiner N (Chapter 8: pp. 145–80). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

What is the optimal increase in resting heart rate with low-dose isoproterenol infusion for tilt-induced vasovagal response? Sumiyoshi M, Abe H, Mineda Y, Tokano T, Yasuda M, Nakazato K, Nakazato Y, Nakata Y, Daida H. J Cardiovasc Pharmacol 2003 Dec; 42 Suppl 1, pp. S19–22.

CARDIOPULMONARY PHYSIOLOGY

Cardiac Filling and Output/Intravascular Dynamics/ Cardiography
Lithium Dilution Cardiac Output (LiDCO)

Cellular/Molecular Mechanism of Action: Lithium ion can be applied as a passive elemental tracer/indicator agent.

Background Information: Lithium dilution cardiac output has primarily been developed as a simple calibration technique for establishing continuous arterial waveform analysis (PulseCO trademark, LiDCO, London, UK).

Application: Minimally invasive passive indicator dilution analysis technique for the measurement of cardiac output.

Route of Administration: Lithium chloride (intravenous).

Dosage: Lithium chloride.

Implementation: Evaluation of cardiac output employing a small dose of lithium chloride injected as an intravenous bolus. Cardiac output is derived from the dilution curve generated by the measurement of lithium using a lithium-sensitive electrode attached to an arterial line.

Interpretation and Analysis: The technique is quick, simple, and requires only an arterial line and central or peripheral venous access. Studies in humans and animals have shown good agreement compared with results obtained with other techniques, and the efficacy in pediatric cases has also been established. Compared with thermodilution, lithium dilution shows closer agreement in clinical studies with electromagnetic flow measurement. The PulseCO trademark is a beat-to-beat cardiac output monitor that calculates stroke volume from the arterial pressure waveform using an autocorrelation algorithm. The algorithm is not dependent on waveform morphology; rather, it calculates nominal stroke volume from a pressure-volume transform of the entire waveform. The nominal stroke volume is converted to actual stroke volume by calibration of the algorithm with lithium tracer agents. Initial studies indicate good fidelity, and results

from centers in the United States and the United Kingdom have validated the effectiveness of the methodology. The PulseCO trademark monitor incorporates software for interpretation of the hemodynamic data generated and provides real-time analysis of arterial pressure variations (i.e., stroke volume variation, pulse pressure variation, and systolic pressure variation) as theoretical guides to intravascular and cardiac filling.

Instrumentation: Lithium-sensitive electrode attached to the arterial line.

Lithium dilution measurement of cardiac output and arterial pulse waveform analysis: An indicator dilution calibrated beat-by-beat system for continuous estimation of cardiac output. Jonas MM, Tanser SJ. Curr Opin Crit Care 2002 Jun; 8 (3), pp. 257–61.

Cardiopulmonary Function/Influence of Altitude
Propanolol/Glycopyrolate

Physiological Mechanism of Action: Propanolol functions as a β-adrenergic antagonist (sympatholytic agent), while glycopyrrolate functions as a muscarinic/parasympatholytic agent.

Background Information: After acclimatization to high altitude, maximal exercise cardiac output (Q-T) is reduced. Possible contributing factors include (i) blood volume depletion, (ii) increased blood viscosity, (iii) myocardial hypoxia, (iv) altered autonomic nervous system (ANS) function affecting maximal heart rate (HR), and (v) reduced flow demand from reduced muscle work capability.

Application: Potential agents for characterizing cardiopulmonary parameters associated with alterations in elevation/altitude and physical conditioning.

Route of Administration: Propranolol (intravenous), glycopyrrolate (intravenous).

Dosage: Propanolol (8.0 mg), glycopyrrolate (0.8 mg).

Implementation: Evaluation of the role of ANS-mediated reductions of HR in have in the phenomenon of altitude acclamation. One approach to addressing this objective can entail separate pharmacological "blocking" of the sympathetic and parasympathetic arms of the ANS during maximal exercise following a 2-week period of acclimatization at 3,800 m in concert with maximal HR measurment. Examples of pharmaceutical agents that can be employed for such purposes include propranolol and glycopyrrolate.

Human Model: Normal healthy subjects (n = 5)

Interpretation and Analysis: At altitude, peak HR is approximately 170 ± 6 beats/min and is reduced from 186 ± 3 beats/min ($p = 0.012$) at sea level. Propranolol further reduces peak HR to 139 ± 2 beats/min ($p = 0.001$), whereas glycopyrrolate increases peak HR to sea level values, 184 ± 3 beats/min, confirming adequate dosing with each drug. Conversely, peak O_2 consumption, work rate, and Q-T are similar at altitude under all drug treatments (peak Q-T = 16.2 ± 1.2 [control], 15.5 ± 1.3 [propranolol], and 16.2 ± 1.1 l/min [glycopyrrolate]). All Q-T results at altitude are lower than those at sea level (20.0 ± 1.8 l/min in air). Such findings suggest that, whereas the ANS may affect HR at altitude, peak Q-T is unaffected by ANS blockade. The effect of altered ANS function on HR is not the cause of the reduced maximal Q-T at altitude.

Role of the autonomic nervous system in the reduced maximal cardiac output at altitude. Bogaard HJ, Hopkins SR, Yamaya Y, Niizeki K, Ziegler MG, Wagner PD. J Appl Physiol 2002 Jul; 93 (1), pp. 271–9.

Left Ventricular Volume
Saline/Trans-Cardiac Conductance (TCC)

Background Information: The TCC method provides on-line left ventricular (LV) volume signals by determining the electrical conductance of blood in the LV by means of central venous and epithoracic electrodes. Conductive structures outside the LV blood pool cause a "parallel conductance" offset term (Vp) that can be determined by bolus injections of hypertonic saline in the pulmonary artery (Vp_{saline}), which cause a transient increase in blood conductivity.

Application: Measurement of left ventricular volume. The saline method can be applied to determine Vp for TCC. IA-V is substantial, so that Vp must be determined in each individual *in vivo* subject, but within individual subject variability is relatively small.

Implementation: Evaluation of the accuracy of the saline calibration method and intersubject variabilities of Vp; variations in hemodynamic conditions and during the cardiac cycle. The conventional intracardiac conductance catheter method is used to obtain independent estimates of Vp by the zero-volume method ($Vp_{zero\ volume}$).

Animal Model: Sheep (anesthetized).

Interpretation and Analysis: Mean baseline Vp_{saline} and $Vp_{zero\ volume}$ are 104 ± 6 ml and 106 ± 6 ml, respectively. Bland-Altman analysis reveals a small non-significant bias (-2.5 ml) and narrow limits of agreement (4.6 ml). Vp are not significantly different between hemodynamic conditions (baseline, dobutamine, volume load, propranolol), but have a substantial interanimal variability (IA-V) (38%). Average variations during the cardiac cycle are < 10% of mean Vp.

The trans-cardiac conductance method for on-line measurement of left ventricular volume: Assessment of parallel conductance offset volume. Staal EM, Steendijk P, Baan J. IEEE Trans Biomed Eng 2003 Feb; 50 (2), pp. 234–40.

PERIPHERAL VASCULAR DISEASE, FUNCTION AND PHYSIOLOGY

Angiogenesis: Neoplastic Disease/Tumor Dimethylarginine Dimethylaminohydrolase Overexpression
NC100150/Hoechst 33342/[Fluorescent Imaging]

Cellular/Molecular Mechanism of Action: The orientation of NC100150 becomes altered within a magnetic field. Alternatively, Hoechst 33342 emits fluorescent light energy.

Background Information: Intracellular factors that regulate nitric oxide (NO) synthesis represent important targets in tumor progression. Overexpression of dimethylarginine dimethylaminohydrolase (DDAH), which metabolizes the endogenous inhibitors of NO synthesis asymmetric dimethylarginine and N-monomethyl-L-arginine, results in C6 gliomas that display enhanced growth rates compared with wild type.

Application: NC100150 can be utilized as an intravascular blood pool contrast agent that is detectable by magnetic resonance imaging (MRI) methodologies. Hoechst 33342 can be used as a fluorescent perfusion-marker dye that can be measured by flourescent detection systems.

Route of Administration: Utilization of NC100150 and Hoechst 33342 for neoplastic lesion angiogenesis requires that these be delivered intravascularly.

Implementation: Delineate the effects of DDAH on tumor vascular morphogenesis *in vivo*, through the measurement of the transverse relaxation rates R_2* and R_2 in (i) clone D27 gliomas overexpressing DDAH; and (ii) C6 wild-type gliomas utilizing susceptibility contrast-enhanced MRI aided by the use of NC100150 (intravascular blood pool contrast agent). As a point of reference, findings can be compared with results from fluorescence microscopy for assessing tumor uptake of the perfusion marker Hoechst 33342,

and/or intrinsic susceptibility MRI, sensitive to changes in endogenous [deoxyhemoglobin].

Interpretation and Analysis: The baseline R_2* is significantly faster in D27 tumors, consistent with greater vascular development ($p < 0.02$, ANOVA). There is no significant difference between the response of the 2 tumor types to hypercapnia (5% CO_2/95% air), used as a probe for vascular maturation, or hyperoxia (5% CO_2/95% O_2), used as a probe for vascular function. NC100150 increases the R_2* and R_2 rates of both tumor types and demonstrates a significantly larger blood volume in the D27 tumors ($p < 0.02$, ANOVA). This correlates with a significantly greater uptake of Hoechst 33342 in D27 tumors compared to C6 wild-type tumors ($p < 0.02$, ANOVA). Despite increased tumor blood volume, the Delta R_2*/Delta R_2 ratio, an index of microvessel size, shows that the capillaries in the 2 tumor types are of a similar caliber. Such observations demonstrate the potential of susceptibility MRI-derived quantitative end points to non-invasively assess tumor angiogenesis. Application of intravascular blood pool contrast agents such as NC100150 for such purposes appears very promising. Overexpression of DDAH results in increased *in vivo* neovascularization of C6 gliomas. The lack of significant difference in hypercapnic/hyperoxic response between the C6 and D27 tumors and the similar vessel caliber are also consistent with a role for DDAH in the initial stages of vasculogenesis.

Instrumentation: MRI and fluorescence microscopy instrumentation.

Effects of overexpression of dimethylarginine dimethylaminohydrolase on tumor angiogenesis assessed by susceptibility magnetic resonance imaging. Kostourou V, Robinson SP, Whitley GS, Griffiths JR. Cancer Res 2003 Aug 15; 63 (16), pp. 4960–6.

Angiogenesis/Vascular Perfusion Density Changes/(Prostatic Carcinoma: PC-3m)/Evaluation of Angiogenesis Inhibitory Agents
Protamine/Contrast-Enhanced Doppler Ultrasound

Cellular/Molecular Mechanism of Action: Contrast media is can be utilized to enhance Doppler ultrasound image quality and sensitivity based on the interaction of ultrasound energy with the physical properties of media preparations (echogenic properties).

Application: Detection of altrations in tumor vascularity.

Route of Administration: Intravenous.

Implementation: Evaluation of vascularity and blood flow in neoplastic lesions. Contrast agent is administered and color flow signal-pixel rate (SPR) of images calculated using the number of pixels showing color Doppler signals as a ratio of the total number of pixels covering the lesion.

Animal Model: Murine. (BALB/C nude mice; $n = 48$) first received subcutaneous transplants of human prostate carcinoma PC-3m tumor followed by protamine injections (SQ) as an angiogenesis inhibitor. Subjects are randomly divided into 3 groups according to protamine dose.

Interpretation and Analysis: The SPR of the high- and low-dose groups is significantly lower than that of control groups ($p < 0.01$). Mean SPR $\pm$ SD is 0.09 ± 0.05, 0.11 ± 0.05, and 0.22 ± 0.10 for different treatment groups, respectively. The SPR parameters correlate significantly with the density of microvessel structures ($r = 0.86$ to 0.94, $p < 0.01$). Therefore, contrast-agent enhanced Doppler ultrasound imaging can effectively reveal changes in vascularity in neoplastic lesions (e.g., $\pm$ protamine). In addition to microvessel density, contrast-agent enhanced Doppler ultrasound imaging may become one of several independent prognostic indexes of angiogenesis inhibitor therapy.

Evaluation of the effect of protamine on human prostate carcinoma PC-3m using contrast enhanced Doppler ultrasound. Tang J, Li S, Li J, Zhang Y, Li X, Dong B, Shi H, Zhang G. J Urol 2003 Aug; 170 (2 Pt 1), pp. 611–4.

Biomarker Selective Targeting/Vascular Endothelium/Inflammation/Ischemia/Neoplastic Disease
Polymerized Nanoparticle

Background Information: In order to be successful in personalizing treatment protocols, methods for effective case selection as well as development of good surrogate biomarkers for monitoring the effects of treatment in concert with the development of an efficacious targeted therapy is required.

Application: Selective detection and targeting of disease-specific biomarker systems.

Route of Administration: Intravascular.

Implementation: Development of a polymerized nanoparticle platform technology that will allow the application of different targeting moieties on the surface of the particles in addition to loading particles with different contrast and therapeutic agents.

Interpretation and Analysis: Nanoparticles can be targeted to endothelial receptors and different payloads of contrast and therapeutic agents can be delivered to target cells with high target-to-background ratios. Using this combined vascular targeting approach for imaging and therapy, it is highly possible that personalize/individualize treatment regimens can be developed for different disease processes such as cancer, inflammatory responses, and ischemia.

Combined vascular targeted imaging and therapy: A paradigm for personalized treatment. Li KC, Guccione S, Bednarski MD. J Cell Biochem Suppl 2002; 39, pp. 65–71.

Capillary Bed Blood Flow/Multiphoton In Vivo Imaging
Semiconductor Nanocrystal Fluorescent Markers/Cadmium Selenide-Zinc Sulfide Quantum Dots/[Fluorescent Imaging]

Cellular/Molecular Mechanism of Action: Cadmium selenide-zinc sulfide quantum dot modalities emit fluorescent light energy.

Application: Cadmium selenide-zinc sulfide quantum dots can be applied as a fluorescent tracer modality for the evaluation of various physiological parameters.

Fluorescent labels for multiphoton microscopy that enable multicolor imaging in demanding biological environments such as living tissue.

Implementation: Semiconductor nanocrystals (quantum dots) can be applied as fluorescent tracer agents for *in vivo* multiphoton microscopy, enabling the acquisition of multicolor image analyses. In this context, water-soluble cadmium selenide-zinc sulfide quantum dots can be used for multiphoton *in vivo* imaging. The fluorescent probes have 2-photon action cross sections as high as 47,000 Goeppert-Mayer units, by far the largest of any label used in multiphoton microscopy.

Animal Model: Mouse.

Interpretation and Analysis: It is possible to visualize quantum dots dynamically through the skin of living mice, within capillaries hundreds of micrometers deep. Evidence of blinking (fluorescence intermittency) cannot be appreciated in solution on nanosecond to millisecond time scales.

Instrumentation: Multiphoton microscopy.

Water-soluble quantum dots for multiphoton fluorescence imaging *in vivo*. Larson DR, Zipfel WR, Williams RM, Clark SW, Bruchez MP, Wise FW, Webb WW. Science 2003 May 30; 300 (5624), pp. 1434–6.

Capillary Bed Tolerance of Small Particle or Liquid Plastic Occlusion
Lidocaine

Cellular/Molecular Mechanism of Action: Lidocaine creates alterations in Na^+/K^+ pump function resulting in increased K^+ ion conductance.
Physiological Mechanism of Action: Promotes vasodilation.
Physiological Mechanism of Action: Exerts a direct effect on the heart independent of any influences imposed by the autonomic system. Declines in the pacemaker current and increases in time-independent outward current are induced by lidocaine which can be recognized as decreases in the slope of the normal Purkinje phase-4 depolarization phase. Depolarized Purkinje fibers under tension display depressed levels of automaticity, and the diastolic threshold in cardiac Purkinje fibers is increased (increased K^+ conductance). Parameters for Vm or threshold voltage are not affected. In the Purkinje system and ventricles, the chronological duration of action potentials is lengthened slightly (disruption of small Na^+ current flow during action potential plateau), but non-specialized or atrial tissues are not affected. Minimal changes are usually appreciated on EKG tracings except for a shortening of the Q-T interval. Refractoriness of the A-V node is most often unaffected. One of the most important influences of lidocaine is its ability to promote pronounced decreases in the refractory period of the His-Purkinje system.
Application: Evaluation of capillary bed tolerance for small particle or liquid plastic occlusion.
Route of Administration: Intra-arterial (affected arterial structures).
Considerations: Endovascular obliteration of hypervascular lesions of the head and neck has become clinically accepted, but it may cause stroke and peripheral cranial nerve palsy. By using a flow-controlled technique to deliver the materials and by knowing the vascular anatomy of the cranial nerves, these problems are less likely to occur. Occasionally, though, vascular anatomy is distorted by the lesion or is anomalous in its distribution.
Implementation: Evaluation of various branches of the external carotid arteries utilizing a lidocaine challenge protocol.

Human Model: Cases with vascular abnormalities (e.g. n = 26)
Interpretation and Analysis: Case may developed transient palsies (e.g. n = 3), thereby requiring modification of treatment regimens. Cases usually do not develop complications of embolization (e.g. n = 0/26).

Lidocaine injection into external carotid branches: Provocative test to preserve cranial nerve function in therapeutic embolization. Horton JA, Kerber CW. AJNR Am J Neuroradiol 1986 Jan–Feb; 7 (1), pp. 105–8.

Extracellular Tissue Space/Volume Estimation
$TmDOTP^{-5}$ and $CoEDTA^-$

Application: Extracellular tissue space volume estimation.
Dosage: $TmDOTP^{-5}$ (0.16 mmol/rat in washout studies).
Implementation: Evaluation and comparison of the distribution of $TmDOTP^{-5}$ and $CoEDTA^-$ (anionic complex previously used as a marker system for establishing extracellular space). Heart, liver, muscle, blood, and urine are collected after infusion of either complex and quantitatively analyzed by atomic absorption spectroscopy. Experiments can also be performed to evaluate the washout kinetics of $TmDOTP^{-5}$ washout kinetics.

Animal Model: Rat (anesthetized in washout studies).
Interpretation and Analysis: Although total $TmDOTP^{-5}$ in blood and tissue is consistently lower (0.88 ± 0.04; n = 6) than $CoEDTA^-$ after an identical infusion protocol (presumably because of some association of the phosphonate complex with bone), a comparison of blood and tissue contents indicates that the 2 anionic complexes distribute into identical extracellular spaces. Relative extracellular space in the liver (evaluated *in vivo*), as determined by $TmDOTP^{-5}$ and $CoEDTA^-$, is 0.18 ± 0.02 and 0.15 ± 0.01, respectively. The corresponding relative *in vivo* extracellular space values for the heart calculated using the 2 agents are identical (0.11 ± 0.02). In washout kinetic studies with $TmDOTP^{-5}$ (0.16 mmol total dose), 81% appears in urine by 180 minutes, and $< 2\%$ is found in all remaining soft tissue, leaving approximately 18% undetected. The rate of Tm appearance in urine can be fitted to a standard pharmacokinetic model that includes 4 tissue compartments: plasma, 1 fast equilibrating space, 1 slow equilibrating space, and 1 very slow equilibrating space (presumably bone). The best fit result suggests that the highly charged $TmDOTP^{-5}$ complex is cleared from plasma more rapidly than are the typical lower charged Gd-based contrast agents and that release from bone is slow compared with renal clearance.

Distribution of $TmDOTP^{-5}$ in rat tissues: $TmDOTP^{-5}$ vs $CoEDTA^-$ as markers of extracellular tissue space. Makos JD, Malloy CR, Sherry AD. J Appl Physiol 1998 Nov; 85 (5), pp. 1800–5.

Extracellular Fluid Space Distribution Parameters/ Interstitial Fluid Compartment/Water Diffusion Coefficients
Gallamine/Inulin

Cellular/Molecular Mechanism of Action: Gallamine and inulin per se do not exert any biochemical or physiological mechanism of action. Instead they function as diagnostic tracer agents based in part due to their molecular weight which directly influences their relative permeability across capillary membranes and facilitate their detection in biological fluids.
Application: Gallamine and inulin can be detected in diluted form within biological fluids where they can function as passive marker/indicator molecules.
Route of Administration: Gallamine and inulin (simultaneous intravenous injection).
Implementation: Simultaneous evaluation of the kinetics of inulin and gallamine. The distribution of both compounds in extracellular fluid space can be characterized by a 3-compartment model in which the mean central compartment blood volume of 1.37 liters is identical with expected values.

Animal Model: Canine (anesthetized).
Interpretation and Analysis: The 2 peripheral compartments of the model appear to represent rapid and slow equilibrating interstitial fluid compartments. A mammillary model structure can be selected in which intercompartmental clearance corresponds to transcapillary exchange. Previous studies indicate that inulin and smaller hydrophyllic molecules diffuse across capillary walls at rates proportional to their respective free water diffusion coefficients. For the ratio of the transcapillary permeability coefficients of inulin and gallamine to equal their free water diffusion coefficient ratio of 5.34 ± 0.02 ($\pm$ SD), it appears that the sum of blood flow to the fast and slow interstitial fluid compartments is less than cardiac output. When this assumption is made, blood flow to fast equilibrating interstitial

fluid is estimated to be 39% of cardiac output, in agreement with previous measurements of splanchnic blood flow. This supports the hypothesis that the fast equilibrating interstitial fluid space is supplied by porous splanchnic capillaries that lack a continuous investment of basement membrane.

Heterogeneity of interstitial fluid space demonstrated by simultaneous kinetic analysis of the distribution and elimination of inulin and gallamine. Henthorn TK, Avram MJ, Frederiksen MC, Atkinson AJ Jr. J Pharmacol Exp Ther 1982 Aug; 222 (2), pp. 389–94.

Hemorrhage: Intracranial
Hirudin

Cellular/Molecular Mechanism of Action: Hirudin has a relatively strong binding avidity for thrombin and functions as an inhibitor of most of the biological properties associated with this enzyme fraction.

Background Information: In humans, intracerebral hemorrhage (ICH) causes marked perihematomal edema formation and neurological deficits. A rat ICH model, involving infusion of autologous blood into the caudate, has been used extensively to study mechanisms of edema formation. However, examination of the behavioral outcome would improve its preclinical utility and provide a more rigorous assessment of the pathological cascade of events that occur over time. Batteries of sensorimotor function tests have been applied (e.g. rat) to examine the neurological effects of ICH and to examine which components of the hematoma are involved in generating those effects.

Application: Detection and characterization of central nervous system hemorrhagic conditions.

Route of Administration: Intravenous.

Implementation: Evaluation neurologic function from day 1 to day 28 postinjection of (i) autologous whole blood; (ii) injection of blood plus hirudin (thrombin inhibitor); (iii) packed red blood cells; (iv) thrombin; (v) saline; (vi) or needle placement only.

Animal Model: Rat (behavioral tests employing forelimb placing, preference for forelimb use for weight shifts during vertical exploration of a cylindrical enclosure, and a corner turn test).

Interpretation and Analysis: Radioisotope-labeled hirudin accumulates at sites of intravascular thrombosis. Behavioral reaction tests detect the presence of marked neurological deficits by day 1 after ICH, with progressive recovery of function over 4 weeks. The forelimb placing score parallels changes in edema. Injection of thrombin causes (promotes), while injected hirudin reduces, ICH-induced neurological deficits. Injection of packed red blood cells (promotes delayed edema formation) induces delayed neurological deficits. Such tests allow continuous monitoring of neurological deficits after rat ICH and assessment of therapeutic interventions. The time course of the neurological deficit closely matches the time course of cerebral edema for both ICH and injection of blood components. There is marked recovery of function after ICH, which may be amenable to therapeutic manipulation.

Behavioral tests after intracerebral hemorrhage in the rat. Hua Y, Schallert T, Keep RF, Wu J, Hoff JT, Xi G. Stroke 2002 Oct; 33 (10), pp. 2478–84.

Intravascular Blood Volume Estimation/ Extravascular Volume
Indocyanine Green (COLD System)/Methylene Blue/Dual Thermal-Dye Double Indicator Technique

Cellular/Molecular Mechanism of Action: Indocyanine green and methylene blue can function as indicator/tracer molecules that passively diffuse throughout the intravascular and potentially other body fluid compartments.

Physiological Mechanism of Action: Methylene blue can induce acute vasoconstrictive and positive inotropic effects during episodes of septic shock.

Application: Indocyanine green and methylene blue can be used as detectable molecular markers in biological systems.

Route of Administration: Methylene blue (intravenous).

Dosage: Bolus dose of methylene blue (3 mg/kg over 10 minutes).

Implementation: Assess the effects of inhibiting guanylate cyclase, an enzyme involved in sepsis-related vascular and myocardial dysfunctions, on hemodynamic variables including blood volume and pulmonary vascular permeability during conditions of septic shock.

A fiber-optic catheter is inserted to determine blood and extravascular volumes applying the thermal-dye double indicator technique, using indocyanine green (COLD system) in combination with methylene blue. COLD-derived variables are recorded before methylene blue and 20 minutes, 1 hour, and 2 hours after the end of methylene blue infusion.

Human Model: Septic shock associated with persisting hypotension despite conventional treatment including fluid loading, vasopressors, and inotropes ($n = 15$ cases). Standard hemodynamic and oxygen-derived variables; total, intrathoracic, systolic, and diastolic cardiac blood volumes; extravascular lung water; plasma osmolarity; and lactate and protein concentrations are recorded.

Interpretation and Analysis: Mean arterial and pulmonary artery pressures, systemic and pulmonary vascular resistances, and left ventricular stroke work index increase, and blood lactate transiently decreases after methylene blue ($p < 0.05$). Other variables recorded are unchanged during a 2-hour period following methylene blue infusion. Such findings demonstrate the acute vasoconstrictive and positive inotropic effects of methylene blue during septic shock. These effects are not associated with changes in blood volume, myocardial diastolic function, or pulmonary vascular permeability assessed by extravascular lung water.

Does methylene blue administration to septic shock patients affect vascular permeability and blood volume? Donati A, Conti G, Loggi S, Münch C, Coltrinari R, Pelaia P, Pietropaoli P, Preiser JC. Crit Care Med 2002 Oct; 30 (10), pp. 2271–7.

Intravascular Compartment Volume Estimation
Labeled Albumin (Non-Radioactive)

Cellular/Molecular Mechanism of Action: Functions as a detectable biological "marker" system that is largely incapable of simple diffusion across biological membranes. The relatively large molecular weight of albumin fractions compared to pharmaceutical agents is the foundation for the application of this particular protein fraction for such purposes.

Diagnostic Application: Non-radioactive labeled albumin has been applied to estimate systemic intravascular fluid volume and detect extravascular hemorrhage or transcapillary "weeping." It has been of particular benefit in the estimation of intravascular fluid volume in the field of exercise physiology.

Route of Administration and Dosage: Intravenous injection only.

Considerations: Disease abnormalities such as protein-losing enteropathy or nephropathy will promote an underestimation of the intravascular fluid volume. Usually the blood sample utilized to estimate the degree of dilution of labeled albumin within the intravascular compartment is collected within a brief period of time following

intravenous injection. This makes underestimation of intravascular fluid volume in the presence of disease conditions less probable.

Interpretation and Analysis: Labeled albumin concentrations within blood (serum) samples are measured and values are ultimately utilized to estimate approximate intravascular fluid volume based upon the known total dose administered.

Instrumentation: Spectrophotometric assay techniques can be applied for the detection and measurement of certain non-radioactive "marker" systems. Examples include *p*-nitroanalide (pNA), fluorescent covalent cross-linking reagents, and biotin:strepavidin-HRPO detection systems.

Intravascular Compartment Volume Estimation
Evans Blue Dye

Cellular/Molecular Mechanism of Action: Functions as a detectable biological dye marker system that can be quantitated in biological fluid samples (whole blood).

Clinical Application: Utilized for calculating the approximate systemic intravascular fluid volume. This is calculated based upon the known initial amount (total dose) of Evans blue dye initially administered and its final concentration following complete dispersal within the intravascular compartment.

Route of Administration: Evans blue (intravenous).

Dosage: Evans blue (1 mg/kg single intravenous bolus).

Considerations: In instances of lowered systemic pH levels (running excercise, metabolic acidosis), the Evans blue dye/albumin complex may dissociate to some degree. As a result, excessively high estimates of intravascular compartment volume may be observed (calculated) since the lower pH level displaces the Evans blue dye from its protein binding site. Ultimately, the increased amount of "free" Evans Blue dye (displaced from albumin by hydrogen ion) is eliminated from the intravascular compartment at a more accelerated rate than is the protein-bound Evans Blue dye. Although Evans blue dye has a different binding constant, this phenomenon is analogous to hydrogen ion displacement of penicillins and non-steroidal anti-inflammatory drugs (NSAIDS) from their respective protein binding sites on albumin.

Interpretation and Analysis: Blood concentration is approximately 0.027 mg/ml. Estimated intravascular volume is calculated using the mathematical formula 1000/0.027 = 37 L (total intravascular blood volume).

Laboratory Instrumentation: Measurement of spectrophotometric absorbance at 570 nm.

Intravascular Compartment Volume Estimation/ Intravascular Compartment
Fluorescein Isothiocyanate Labeled Hydroxyethyl Starch/Radiolabeled Red Blood Cells/Radiolabeled Serum Albumin

Cellular/Molecular Mechanism of Action: Labeled albumin, labeled red blood cells, and labeled hydroxyethyl starch can be applied to measure approximate intravascular blood volume.

Application: Estimation of approximate blood volume.

Route of Administration: Intravascular, usually by intravenous injection

Semi-Synthetic Methods: A proprietary brand of hydroxyethyl starch (Elohaes) covalently labeled with fluorescein isothiocyanate.

Implementation: Evaluation of blood volume measurements in suspected cases of polycythemia utilizing labeled albumin, red blood cells, and hydroxyethyl starch (Elohaes). Dilution of labeled hydroxyethyl starch (Elohaes) *in vivo* can be used to calculate approximate measurements of blood volume. Reference methodologies can employ the use of radiolabeled albumin and radiolabeled red cells.

Human Model: Cases of suspected polycythemia (e.g., n = 17; n = 8 undergoing major surgery and/or receiving intensive postoperative care).

Interpretation and Analysis: Elimination of the labeled starch occurs in a manner essentially the same as the "parent" unlabeled compound. Such findings indicate that *in vivo*, the fluorescent tag is stable and does not significantly alter the molecular characteristics of the carrier molecule. The volume of distribution for labeled starch is 2.5 mL/kg lower than that for labeled albumin ($p = 0.05$). Blood volume, measured from the dilution of fluorescent starch, is lower (4.9 mL/kg) than that measured with albumin ($p = 0.048$) but higher (6.61 mL/kg) than that measured with red blood cells ($p = 0.0007$). The latter difference may be even smaller at marginally higher doses of the fluorescent starch. Hydroxyethyl starch appears to provide a valid alternative to labeled red cells as a means of calculating blood volume. Labeling of starch with a fluorescent marker makes the assay procedure more sensitive and infinitely easier to perform. The dose required is not high enough to affect hemodynamic parameters.

Measuring blood volume with fluorescent-labeled hydroxyethyl starch. Thomas E, Jones G, de Souza P, Wardrop C, Wusteman F. Crit Care Med 2000 Mar; 28 (3), pp. 627–31.

Thrombosis: Intravascular
Platelet-Specific Monoclonal Antibody (P256)/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Radiolabeled platelet-specific monoclonal antibody (P256) selectively detects antigens expressed on the surface membrane of aggregated platelets.

Application: Detection of vascular thrombosis through diagnostic nuclear imaging.

Experimental Interpretation: Intact (whole) immunoglobulin promotes platelet aggregation at concentration ranging between 10^{-9} to 10^{-7} M with a maximum of 70% aggregation. The F(ab′)2 fragment is less potent in promoting platelet aggregation and displays a maximum response of only 45%. In contrast, monovalent Fab′ fragment causes no aggregation at concentrations up to 10^{-7} M. Binding studies with [^{111}In]-labelled monovalent Fab′ fragment demonstrate saturable displaceable binding ($Kd = 9.1 \times 10^{-9}$ M). Note: aggregation induced by the divalent forms of the antibody is partially dependent upon the addition of fibrinogen.

Interpretation and Analysis: Monovalent Fab′ fragment of P256 may be used in platelet-labelling studies without risk of inducing aggregation irrespective of concentration. The whole antibody, or its divalent F(ab′)2 fragment, may also be used provided their concentrations are kept below 10^{-9} M.

Instrumentation: Computer-integrated nuclear medicine scintigraphy camera.

In vitro studies with an antiplatelet monoclonal antibody; P256. Stuttle AW, Ritter JM, Peters AM, Lavender JP. Nucl Med Commun 1988 Oct; 9 (10), pp. 813–5.

Vascular Blood Flow and Patency/Ultrasound Contrast-Enhancing Agents
C_3F_8 Microbubbles/N_2 Microbubbles/SF_6 Microbubbles/[Ultrasonography]

Cellular/Molecular Mechanism of Action: Use of fluorocarbon vapor extends (prolongs) the *in vivo* persistence of microbubbles from seconds to minutes, thereby facilitating the application of contrast ultrasonography in clinical medicine.

Application: Imaging techniques and reagents that selectively suppress the intensity of signal from tissue structures, but not injected microbubbles, serve to further enhance image contrast. Approved products consist of C_3F_8 or SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14}. These agents allow the detection and characterization of cardiovascular abnormalities and solid organ lesions, such as tumors. By providing higher quality images, they improve the accuracy and confidence of disease diagnosis and can play a decisive role in clinical decision making. Future development objectives include the design of agents that target specific cells for the molecular imaging of disease, and drug and gene delivery, including ultrasound-triggered delivery.
Route of Administration: Preparations of C_3F_8 microbubbles, SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14} are administered intravenously.
Dosage: C_3F_8 microbubbles, SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14} are administered at dosages commensurate with the diagnostic procedure being performed.
Considerations: Ultrasonography has, until recently, lacked effective contrast-enhancing agents. Micrometer-sized gas bubbles that resonate at diagnostic frequencies are ideal reflectors for ultrasound. However, simple air bubbles, when injected into the blood stream, disappear within seconds through the combined effects of Laplace pressure, blood pressure, and exposure to ultrasound energy.
Interpretation and Analysis: These agents allow the detection and characterization of cardiovascular abnormalities and solid organ lesions, such as tumors. By providing higher quality images, they improve the accuracy and confidence for diagnosing disease conditions and can play a decisive role in clinical decision making. New objectives include the design of agents that target specific cells for the molecular imaging of disease, and drug and gene delivery, including ultrasound-triggered delivery.

Injectable microbubbles as contrast agents for diagnostic ultrasound imaging: The key role of perfluorochemicals. Schutt EG, Klein DH, Mattrey RM, Riess JG. Angew Chem Int Ed Engl 2003 Jul 21; 42 (28), pp. 3218–35.

Vascular Blood Flow and Perfusion/Capillary Circulation/Perfusion
Fluorescein Isothiocyanate-Labeled Dextran

Cellular/Molecular Mechanism of Action: Fluorescein isothiocyanate can be used as a light-emitting molecular marker system.
Application: Fluorescein isothiocyanate can be used as a light-emitting tracer/marker molecule in biological systems. Dextran labeled with fluorescein isothiocyanate can be utilized as an *in vivo* molecular tracer system for evaluating the acute microhemodynamic effects of various stimuli (e.g., static and alternating magnetic fields delivered at threshold levels in muscle capillary mirocirculation beds).
Route of Administration: FITC-dextran solution (intravascular: e.g., vena cava).
Implementation: The skin in a tibialis anterior is circularly removed with 1.5 mm diameter sufficient to faciliate intravital-microscopic recording of capillary blood velocity in the tibialis anterior muscle. Fluorescein isothiocyanate (FITC)-labeled dextran (MW 150 kDa) can be used as an *in vivo* fluorescent plasma marker system applicable for evaluating muscle capillaries. Following a bolus injection of FITC-dextran solution into the caudal vein, the peak blood velocity in the muscle capillaries is measured prior to, during, and following exposure to static magnetic fields (SMF) or 50 Hz electromagnetic fields (EMF). The whole body of each experimental animal is then placed on an observation stage of a fluorescence microscope and exposed to static magnetic fields (SMF = 0.3, 1, and 10 mT) or 50 Hz EMF (0.3 and 1 mT) for 10 minutes with the electromagnet not energized during sham exposures.
Animal Model: Mice anesthetized with pentobarbital and exposed to static and alternating magnetic fields (threshold levels).
Interpretation and Analysis: During periods of exposure and postexposure to SMF of 10 mT, the peak blood velocity significantly increases compared to sham exposure preparations. After the withdrawal of SMF and 50 Hz EMF of 1 mT, significant similar effects on the blood velocity can be recognized (e.g. equivalent or enhanced/greater responses). Such findings suggest that field intensity of 1 mT might be considered as a threshold level for enhancing muscle microcirculation under pentobarbital-induced hypnosis.
Instrumentation: Utilization of an (i) electromagnet specifically designed to deliver static magnetic fields (SMF = 0.3, 1, and 10 mT); (ii) 50 Hz EMF (0.3 and 1 mT) instrumentation (fluorescence epi-illumination system); and (iii) a fluorescence microscope.

Acute effects of whole-body exposure to static magnetic fields and 50 Hz electromagnetic fields on muscle microcirculation in anesthetized mice. Xu S, Okano H, Ohkubo C. Bioelectrochemistry 2001 Jan; 53 (1), pp. 127–35.

Vascular Blood Flow Characteristics
Fluorescent-Labeled Red Blood Cells

Application: Evluation of blood flow characteristics.
Considerations: Whole organ studies in cat skeletal muscle have shown that increases in venous resistance associated with reduced arterial pressures are nearly abolished when muscle is perfused with a non-aggregated red blood cell suspension.
Implementation: Delineation of the influence red blood cell aggregation has on *in vivo* vascular flow patterns and determination of whether it leads to blunted red blood cell velocity profiles at reduced shear rates. In this context, fluorescent-labeled red blood cells can be applied in tracer quantities to obtain velocity profiles in venous microvessels.
Interpretation and Analysis: Velocity profiles in venous microvessels (45–75 μm) of rat spinotrapezius muscle have centerline velocities between 0.3 and 14 mm/sec (pseudoshear rates 3-120 mm/sec under normal (non-aggregating) conditions, and following induction of red blood cell aggregation with Dextran 500. Profiles are nearly parabolic (Poiseuille flow) over this flow rate range in the absence of aggregation. When aggregation is present, profiles are parabolic at high shear rates and become significantly blunted at pseudoshear rates of 40 mm/sec and below. These results indicate a possible mechanism for increased venous resistance at reduced flows.
Instrumentation: Video system equipped with a gated image intensifier.

Effect of erythrocyte aggregation on velocity profiles in venules. Bishop JJ, Nance PR, Popel AS, Intaglietta M, Johnson PC. Am J Physiol Heart Circ Physiol 2001 Jan; 280 (1), pp. H222–36.

Vascular Blood Flow Characterization/Aorta/Renal Artery and Vein/Portal Vein/Vena Cava
Indocyanine Green/SH U 508 A Microbubbles (Levovist)/[Doppler Ultrasound]

Cellular/Molecular Mechanism of Action: Indocyanine green and microbubbles can be infused into the intravascular compartment where they passively disperse throughout the blood volume whereby they function as a tracer agents.

Application: Indocyanine green and microbubbles can be applied to characterize blood flow through vascular structures.
Route of Administration: Indocyanine green and microbubbles are both administered intravascularly.
Dosage: Indocyanine green (1.25 mg/mL at 0.1 mL/kg); SH U 508 A (300 mg/mL at 0.1 mL/kg).
Considerations: SH U 508 A microbubbles (Levovist) can be detected by Doppler ultrasound.
Implementation: Evaluation of blood flow within the vena cava, aorta, renal artery, renal vein, and portal vein. The kinetics of indocyanine green can be evaluated by measuring absorbance values using a photodiode, while SH U 508 A microbubbles (Levovist) are detectable using Doppler ultrasound.
Animal Model: Rabbit (n = 5).
Interpretation and Analysis: Peak signal intensity is observed immediately after injection of SH U 508 A, followed by a biphasic decay pattern. The rates of biphasic decay are similar in all vessels. A second peak of the signal that represents microbubble recirculation is observed within the vena cava. The circulation and recirculation times of the microbubbles after injection of SH U 508 A are similar to that of indocyanine green. These findings suggest that majority of the SH U 508 A microbubbles circulate through the body in a manner similarly to blood flow and without retention in microvasculature structures.

In vivo kinetics of microbubbles of SH U 508 A (Levovist): Comparison with indocyanine green in rabbits. Uchimoto R, Niwa K, Eguchi H, Kamiyama N, Mine Y, Miyazawa T, Brautigam M. Ultrasound Med Biol 1999 Nov; 25 (9), pp. 1365–70.

Vascular Malformation (Cardiac): Patent Ductus Arteriosus
Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

Cellular/Molecular Mechanism of Action: Permanently inhibits cyclooxygenase biochemical activity through direct acetylation of the enzyme, thereby preventing the conversion of arachidonic acid (generated by phospholipase A_2) to the prostaglandin intermediates, PGG and PGH.
Diagnostic Application: In cases of systolic murmurs in neonatal infants, NSAIDs can be applied to diagnose and therapeutically manage congenital patent ductus arteriosus disorders. If it has already been established through auscultation and echocardiography that a neonatal case has a patent ductus arteriosus, then NSAIDs can assist in determining if the PDA is physiological or functional. The proposed mechanism behind the response to NSAIDs in physiological PDA is that the endothelium within the PDA persistently synthesizes elevated concentrations of PGI_2, which is one of the most potent vasodilators identified to date. Indomethocin is an example of one non-steroidal agent used in human neonatal internal medicine that can facilitate the closure of physiological PDA through inhibition of PDA endothelial PGI_2 synthesis.
Route of Administration and Dosage: Intravenous or oral administration.
Considerations: Prolonged administration promotes development of several types of pathological lesions including gastric/intestinal ulceration and renal papillary necrosis. Such responses have been theorized as being associated with vasoconstriction due to decreases in the synthesis of vasodilatory prostacyclin (PGI_2).
Laboratory Instrumentation: Inhibition of platelet PGI_2 synthesis by NSAIDs can be detected by direct RIA or ELISA based assay methodologies. Alternatively, inhibition of platelet PGI_2 synthesis can be indirectly detected by measurement of malondialdehyde production, applying thiobarbituric acid in a low pH buffer environment. The chemical reaction is very sensitive but its specificity, even with improvement of preanalytical (sampling, preservatives) and analytical stages (fluorescence, HPLC), is still a matter of debate. At present, the concept of "thiobarbituric acid reactive substances" (TBARS) has merged and progressively replaced the initial malondialdehyde assay.

Vascular Malformation (Central Nervous System): Arteriovenous
Methohexital/[Angiography]

Physiological Mechanism of Action: Methohexital is a barbiturate that acts as a central nervous system depressant.
Application: Existing reports suggest that methohexital is a safe provocative agent for use prior to embolotherapy for brain arteriovenous malformations. However, the full effects of methohexital within the cerebral circulation remain to be elucidated.
Route of Administration: Methohexital (intra-arterial).
Dosage: Methohexital (1% concentration with individual doses of 1–6 mg/injection).
Interpretation and Analysis: Arterovenous malformation can initially be characterized with the aid of digital vascular imaging methods performed just prior to and just after intra-arterial methohexital injection.
Human Model: Cases without angiographic or clinically detectable evidence of vasospasms (e.g. n = 66 vascular pedicle injections in n = 30 cases).
Interpretation and Analysis: Perfusion of functional tissue with methohexital can often immediately precipitate evidence of altered neurologic status that fortunately almost invariably resolves within 2 minutes of the initial onset. No signs of either prolongation of the induced clinical symptoms or seizures are evident to suggest any adverse effects related to either methohexital crystallization or the effects of injecting an alkaline solution into the cerebral vascular circulation.

Though the full effects of methohexital in the cerebral circulation remain to be elucidated, existing reports suggest it is a safe provocative agent for use prior to embolotherapy for brain arteriovenous malformations.

Intra-arterial use of sodium methohexital for provocative testing during brain embolotherapy. Peters KR, Quisling RG, Gilmore R, Mickle P, Kuperus JH. AJNR Am J Neuroradiol 1993 Jan–Feb; 14 (1), pp. 171–4.

Vascular Malformation (Central Nervous System)/ Arteriovenous Embolism (Cerebral)/Vascular Blood Flow
Sodium Amobarbital/N-butyl Cyanoacrylate Glue/[Angiography]

Application: Determine whether a method of targeted neurologic and cognitive testing procedures performed as a guide during arteriovenous malformation (AVM) embolization techniques can reduce the incidence of focal cognitive and other neurologic deficits associated with performing such procedure.
Route of Administration: In each feeder-vessel initially being considered for embolization procedures, sodium amobarbital is superselectively delivered applying a microcatheter system. N-butyl cyanoacrylate glue is sequentially delivered by the same route of administration if the proposed site of embolization is deemed to be without undesirable side effects.
Dosage: Sodium amobarbital (50 mg); N-butyl cyanoacrylate glue (dose appropriate for the diameter of the cerebral AVM).

Considerations: Transarterial embolization of cerebral AVMs has been associated with postprocedural neurologic complications in 7 to 39% of affected cases.
Implementation: Prior to AVM embolization, cases are subjected to cognitive neurologic examinations (n = 12 cases) involving a battery of tests tailored for their specific ability using stimuli selected from standard and experimental cognitive tests to probe specific regions of the brain directly related to the location of the cerebral arteriovenous malformations. Immediately following the administration of sodium amobarbital into each feeder vessel to be embolized, neurologic and cognitive testing is initiated utilizing a tailored battery of stimuli and then the position of the microcatheter tip validated by fluoroscopy. If the provocative test results were negative, the evaluated feeder vessel is then embolized with an injection of N-butyl cyanoacrylate glue.
Interpretation and Analysis: Provocative amobarbital injections often produce negative results (27/29), which implies that subsequent embolization of cerebral AVMs will not produce an undesirable neurologic deficit. A small percentage of cases (e.g. n = 2/29) will experience cognitive deficits during tailored provocative testing with amobarbital injections with the evoked deficits that subsequently resolve when the pharmaceutical dissipates. In such instances, the feeder vessels are usually not embolized. Neurologic and cognitive evaluations are performed after permanent embolization with N-butyl cyanoacrylate glue.

Tailored cognitive testing with provocative amobarbital injection preceding A-VM embolization. Moo LR, Murphy KJ, Gailloud P, Tesoro M, Hart J. AJNR Am J Neuroradiol 2002 Mar; 23 (3), pp. 416–21.

Vascular Malformation (Central Nervous System)/Autonomic Nervous System Dynamic Time-Frequency Analysis
Sodium Amobarbitol/Wada Test

Background Information: Recently, time-frequency analysis has become very popular for examining non-stationary time series and for researching fast-changing phenomena.
Application: Utilization in Wada test techniques involving the injection of sodium amobarbitol into the internal carotid artery, resulting in the inactivation of cerebral structures supplied by the ipsilateral anterior and middle cerebral arteries. The intracarotid instillation of amobarbital can be combined with electrocardiographic analyses to monitor regions and extent of localized CNS anesthesia (electrocardiopharmacology test).
Route of Administration: Amobarbitol (catheter instillation into the internal carotid artery).
Implementation: Utilization of a smoothed-pseudo Wigner-Ville distribution to model the underlying dynamic autonomic nervous system changes induced during intracarotid sodium amobarbital administration (ISA Wada test). Electrocardiogram (EKG) tracing are recorded during the entire procedure and 10 minutes prior to each injection to establish baseline values for a given hemisphere. Interbeat-interval time series are created from such data and then further analyzed (smoothed-pseudo Wigner-Ville distribution to model).

Human Model: Case affected by a vascular malformation within the central nervous system (e.g. n = 1 that is 13-years of age).
Interpretation and Analysis: Review of data generated in the fashion described reveals that an injection of sodium amobarbitol into either side (e.g. cerebral hemisphere) produces decreased power in the vagally mediated high-frequency band (0.14–0.40 Hz). Importantly, the decrease is greater when the right hemisphere is inactivated in contrast to the left side. Such results are consistent with the known lateralized innervation of the heart such that right-sided autonomic input has a greater influence on cardiac chronotropy. Very rapid changes in autonomic control occur that characterize the inactivation and subsequent recovery of the cerebral hemispheres and serve to confirm the utility of time-frequency analysis in the investigation of cardiac time series.

Time frequency analysis of the cardiovascular response during the intracarotid amobarbital test. Sollers JJ 3rd, Ahern GL, Merritt MM, Thayer JF. Biomed Sci Instrum 2002; 38, pp. 267–71.

Vascular Malformation: Hepatic Portosystemic Shunt/Non-Invasive Detection of Portosystemic Shunt Patency/Postoperative Shunt Anastomois Occlusion
D-Xylose/[Urinary Excretion]

Physiological Mechanism of Action: D-xylose is normally assimilated by hepatocytes. In circumstances where the plasma concentration of D-xylose exceeds the renal threshold, significant amounts are excreted into the urinary filtrate.
Application: The D-xylose excretion test appears to be a useful method of monitoring shunt patency after a portasystemic venous anastomsis for portal hypertension.
Implementation: Evaluation of cases of hepatic portosystemic shunt using a D-xylose 0.5-hour urinary excretion test.

Human Model: Cases of hepatic portosystemic shunt.
Interpretation and Analysis: A 5-hour D-xylose urinary excretion test yielding a total estimate greater than 6 grams appears to be an acceptable indicator that a shunt is patent. A second criterion for patency is an increase of 4 grams or more over results observed during preoperative tests. If the excretion rate falls in the postoperative period or remains less than 4–2 grams/5 hours, the anastomosis may be assumed to be occluded.

Assessment of portasystemic shunt patency by estimation of D-xylose excretion. Smith RC, Macpherson AI. Br J Surg 1976 Jun; 63 (6), pp. 435–7.

Vascular Malformation/Recirculation
Glucose

Application: Vascular access recirculation is an important cause of diminished dialysis efficiency. A screening test has been developed based on glucose infusion as a tracer for assessing recirculation.
Implementation: The glucose infusion test (GIT) protocol involves collection of a basal blood sample (A) from the arterial port, followed by injection of a 5 mL bolus of 20% glucose into the venous chamber (time 0). A second sample (B) is collected in 4 seconds (from 13 to 17 s with QB 300 mL/min) from the same port. Blood glucose levels can be determined at the bedside with a reflectance photometer (CV 1.8%).

Human Model: Cases subjected to hemodialysis (e.g. n = 39).
Interpretation and Analysis: Interpretation of the test is straightforward: If B = A, there is no recirculation, whereas if B > A, recirculation can be calculated from the regression equation, $0.046 \times (B - A) + 0.07$, obtained from *in vitro* tests reproducing artificial recirculation at 0, 5, and 10%. To validate the method *in vivo*, comparisons can be made between GIT and the urea test in cases managed by hemodialysis. The degree of correlation is relatively high (r = 0.93). The 2 tests are considered positive (presence of recirculation) when the lower 95% confidence intervals are more than 0. Cases can be divided into 2 groups: those with evidence of recirculation (e.g. n = 22/39 with 11.8% mean recirculation) or

without evidence of recirculation (e.g. n = 17/39; mean 0.06%). The urea test does not recognize approximately 30% of cases (e.g., n = 7/22) because they have a small degree of recirculation below the urea test limit of detection. GIT is more sensitive (detection limit 0.3%), simpler, and immediate in the generation of meaningful results compared to the urea test. It is an accurate and low-cost technique for screening and the follow-up of vascular access in a dialysis unit.

Glucose infusion test: A new screening test for vascular access recirculation. Magnasco A, Alloatti S, Bonfant G, Copello F, Solari P. Kidney Int 2000 May; 57 (5), pp. 2123–8.

Vascular Patency (Vascular Grafts)/Endothelium Response and Dysfunction/Epicardial Response/Coronary Endothelial Function/Microvascular Flow
Acetylcholine/Nitroglycerin

Cellular/Molecular Mechanism of Action: Acetylcholine is a neutrotransmitter that binds to and stimulates parasympathetic (cholinergic) receptor complexes.
Physiological Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such findings imply that some form of abnormality in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Background Information: Coronary endothelial dysfunction may be an early marker for cardiac allograft vasculopathy (CAV) in orthotopic heart transplant recipients. Using serial studies with intravascular ultrasound and Doppler flow-wire measurements, it has been demonstrated that annual decrements in coronary endothelial function are associated with progressive intimal thickening.
Application: Assessment of epicardial response, microvascular response, and endothelium-dependent responses that can provide valuable information about the integrity and function of vascular graft transplants.
Route of Administration: Adenosine, acetylcholine, and nitroglycerin infused into the left anterior descending coronary artery.
Dosage: Adenosine (32 μg bolus), acetylcholine (54 μg over 2 minutes), and nitroglycerin (200 μg).
Implementation: Evaluation of endothelial dysfunction as a potential parameter capable of predicting subsequent clinical events, including cardiac death and development of CAV conditions.

Clincial cases can be characterized on a yearly basis initially beginning at the time of transplantation procedures until reaching a prespecified end point determined as angiographic evidence of CAV (> 50% stenosis) or cardiac death (graft failure or sudden death). During each study, coronary endothelial function is measured with the aid of intracoronary infusions of adenosine (32 μg bolus), acetylcholine (54 μg over 2 minutes), and nitroglycerin (200 μg) into the left anterior descending coronary artery; intravascular ultrasound images and Doppler velocities are simultaneously recorded during and after diagnostic challenges.

Human Model: Cases of vascular transplant (n = 73).
Interpretation and Analysis: A modest percentage of cases will reach an end point during the evaluation process (e.g., n = 14; n = 6 CAV; n = 4 deaths including n = 4 known CAV; n = 1 graft failure, and n = 3 sudden death). Case group types with an end point will display decreased epicardial acetylcholine responses (constriction of 11.1 ± 2.9% vs dilation of 1.7 ± 2.2%, p = 0.01) and microvascular acetylcholine responses (flow increase of 75 ± 20% vs 149 ± 16%, p = 0.03), as well as endothelium-dependent responses to acetylcholine compared with cases that do not reach an end point. Responses to adenosine and nitroglycerin do not differ significantly. Endothelial dysfunction detected as an abnormal responses to acetylcholine, precedes the development of clinical end points. These data implicate endothelial dysfunction in the development of clinically significant vasculopathy and suggest that serial studies evaluating endothelial function have clinical utility.

Coronary endothelial dysfunction after heart transplantation predicts allograft vasculopathy and cardiac death. Hollenberg SM, Klein LW, Parrillo JE, Scherer M, Burns D, Tamburro P, Oberoi M, Johnson MR, Costanzo MR. Circulation 2001 Dec 18; 104 (25), pp. 3091–6.

Vascular Perfusion: Coronary Microcirculation/Regulation: Vasodilatory and Perfusion Reserve
Adenosine Phosphate/Colored Microspheres

Cellular/Molecular Mechanism of Action: Colored microspheres variably impede/absorb/reflect ultrasound wave energy forms.
Physiological Mechanism of Action: Adenosine phosphate promotes relaxation of vascular smooth muscle.
Application: Evaluation of microvascular perfusion parameters.
Route of Administration: Adenosine phosphate (intravenous/rat), colored microspheres (intravenous).
Dosage: Adenosine phosphage (3 mg/kg/min).
Implementation: Measurement of perfusion parameters based on perfusion-sensitive T1 relaxation after magnetic spin labeling of water protons. Regional blood volume (RBV) is determined from steady-state measurements of T1 before and after administration of an intravascular contrast agent. A colored microsphere technique can be used as a reference method for establishing perfusion measurements. Regional blood volume and perfusion maps are obtained at rest and during administration.

Animal Model: Rat.
Interpretation and Analysis: At MR imaging, perfusion during resting conditions is 3.5 mL/g/min ± 0.1 (SEM), while RBV is 11.6% ± 0.6 (SEM). Adenosine phosphate significantly increases perfusion to 4.5 mL/g/min ± 0.3 (SEM) and decreases mean arterial pressure from 120 mm Hg to 65 mm Hg, which implies a reduction of coronary resistance to 40% of baseline. Regional blood volume increases consistently to 23.8% ± 0.6 (SEM). Quantitative mapping of perfusion and RBV can therefore be performed noninvasively *in vivo* by means of MR imaging. The presented method allows determination of vasodilation and perfusion reserve, which reflects the *in vivo* regulation of coronary microcirculation for a given stimulus.

Myocardial perfusion and intracapillary blood volume in rats at rest and with coronary dilatation: MR imaging *in vivo* with use of a spin-labeling technique. Waller C, Kahler E, Hiller KH, Hu K, Nahrendorf M, Voll S, Haase A, Ertl G, Bauer WR. Radiology 2000 Apr; 215 (1), pp. 189–97.

Vascular Perfusion: Dermal Microvasculature/ Delineation of Perfused to Total Capillary Ratio
Sodium Fluorescein

Application: Delination of the nature of temporal variation in capillary numbers and determination of the proportion of perfused to total nutritional capillaries within normal skin tissues.
Implementation: Using *in vivo* microscopy, the temporal behavior of the number of visible capillaries in the skin of the dorsum of the foot can be observed over periods of time varying from 5 minutes to 55 days. Capillary perfusion is then studied by comparing capillary numbers before and after intravenous injection of sodium fluorescein.

Human Model: Healthy subjects.
Interpretation and Analysis: The mean percent difference in the number of visible capillaries over a mean period of 25.3 days is 5.5%. The percentage ratio of perfused to total capillaries is 54.2%. There appears to be little quantitative change in capillary numbers over periods of up to 50 days, and under physiological conditions, about half of the nutritional capillaries of the skin are not perfused.

Study of temporal and perfusion physiology of skin capillaries in the dorsum of the foot. Lamah M, Mortimer PS, Dormandy JA. J Vasc Res 2001 Jan-Feb; 38 (1), pp. 59–63.

Vascular Perfusion: Dermal Microvascular (Diabetic Foot Ulcers)
Fluorescein

Background Information: Fluorescein dermofluorometry can be used to relate the uptake of fluorescein in the skin to blood flow.
Application: The dye wash-in time constant parameters are inversely proportional to local dermal blood flow.
Implementation: Evaluation of fluorescein dermofluorometry for the detection and characterization of dermal ulcers. The outcomes of foot ulcers have been documented in cases over a 4–14 month period of time. Following intravenous injection of sodium fluorescein, the change in the fluorescein signal with time is continuously measured at the plantar surface of the foot. Both the initial slope of the signal and the wash-in time constant are then calculated.

Human Model: Cases of cutaneous diabetic foot ulcers (n = 4 groups: non-diabetic control patients, diabetic control patients, diabetic patients with chronic foot ulcers, and diabetic patients with acute foot ulcers).
Interpretation and Analysis: Significant differences in the wash-in time constant can be appreciated between diabetic and non-diabetic conditions and between diabetic subjects with and without foot ulcers. In cases with foot ulcers, a relatively large percent may not display an early washout in the dermofluorometer signal and later require amputation (e.g., n = 2/8 or 25%). The fluorescein wash-in time constant demonstrates better correlation with the presence of diabetic microvascular disease than does the initial slope of the signal. Differences in the wash-in time constants of non-diabetic and diabetic subjects support the hemodynamic hypothesis for the development of microvascular disease. The indication of early washout of the fluorescein signal may also be useful in the prediction of ulcer healing.

Fluorescein dermofluorometry for the assessment of diabetic microvascular disease. Oh DK, Jones RN, Marshall W, Magin RL. Skin Res Technol 2001 May; 7 (2), pp. 105–11.

Vascular Perfusion: Dermal Microvasculature (Diabetic Foot Ulcers)/Ulcers: Dermal Vasomotor Responses in Diabetes Associated Foot Lesions
Sodium Fluorescein

Background Information: A loss of sympathetic function could lead to changes in capillary fluid filtration in diabetic conditions.
Application: Delineation of the association between abnormal capillary leakage with decreases in sympathetically mediated dermal vasomotion responses in diabetic conditions.
Implementation: Evaluation of sensory and motor nerve function of the distal extremities assessed utilizing standard neurography and expressed as a sensory-motor nerve function score. Sympathetic vasomotion of the skin microcirculation is assessed by determining the power of blood flow variability in the low-frequency (0.02–0.14 Hz) band by spectral analysis of laser Doppler flowmetry at the median ankle. Skin capillary leakage is evaluated by sodium fluorescein videodensitometry at the same site over the foot.

Human Model: Cases of diabetic cutaneous foot ulcers (n = 3 matched groups; n = 18 diabetic cases with documented peripheral neuropathy [DN], n = 18 diabetic cases without peripheral neuropathy [D], n = 18 healthy control subjects [C]).
Interpretation and Analysis: Sympathetically mediated vasomotion of foot skin microcirculation is lower in diabetic conditions with documented peripheral neuropathy compared with diabetic conditions without peripheral neuropathy and control subjects ($p < 0.001$). Capillary sodium fluorescein leakage is greater in diabetic cases with documented peripheral neuropathy (n = 18) than in diabetic cases without peripheral neuropathy ($p < 0.02$) and C ($p < 0.005$). Multiple regression analysis reveals that reduced sympathetically mediated vasomotion, together with a lower sensory-motor nerve function score, independently contributes to variances in sodium fluorescein leakage [30% ($p < 0.001$); and 17% ($p < 0.01$), respectively]. A loss of sympathetic tone, apart from sensory-motor nerve dysfunction, seems to be a major determinant of increased capillary permeability in diabetic cases with neuropathy.

Sympathetic mediated vasomotion and skin capillary permeability in diabetic patients with peripheral neuropathy. Lefrandt JD, Bosma E, Oomen PH, Hoeven JH, Roon AM, Smit AJ, Hoogenberg K. Diabetologia 2003 Jan; 46 (1), pp. 40–7.

Vascular Permeability: Capillary/Blood Flow and Arterial Input Function
Indocyanine Green (ICG)/Methylene Blue (MB)/[MRI]

Cellular/Molecular Mechanism of Action: Indocyanine green and MB are pigment-based dyes.
Application: Indocyanine green and MB can be utilized as aqueous soluble molecular marker/indicator systems for the evaluation of various physiological processes.
Implementation: Following administration of indocyanine green and methylene blue, measurements are acquired with a combined frequency-domain and steady-state optical technique that facilitates rapid measurement of tissue absorption in the 650–1000 nm spectral range. Tumors can also be imaged by using contrast-enhanced magnetic resonance imaging and coregistered with the location of the optical probe. The absolute concentrations of contrast agent, oxyhemoglobin, deoxyhemoglobin, and water are measured simultaneously each second for a period of approximately 10 minutes.

Animal Model: Rat (adenocarcinoma).
Interpretation and Analysis: The differing tissue uptake kinetics of ICG and MB in late-stage tumors arise from differences in their effective molecular weights. ICG, because of its binding to plasma proteins, behaves as a macromolecular contrast agent with a lower degree of vascular permeability. A compartmental model describing ICG dynamics is used to quantify physiologic parameters related to capillary permeability. In contrast, MB behaves as a small-molecular-weight contrast agent that leaks rapidly from the vasculature into the extravascular, extracellular space and is sensitive to blood flow and the arterial input function.

In vivo quantification of optical contrast agent dynamics in rat tumors by use of diffuse optical spectroscopy with magnetic resonance imaging coregistration. Cuccia DJ, Bevilacqua F, Durkin AJ, Merritt S, Tromberg BJ, Gulsen G, Yu H, Wang J, Nalcioglu O. Appl Opt 2003 Jun 1; 42 (16), pp. 2940–50.

Vascular Permeability (Endothelial Integrity)/ Endothelial Injury and Viability
Evans Blue Dye Staining

Cellular/Molecular Mechanism of Action: Evans blue dye is a pigment-based reagent that becomes differentially associated with viable vs compromised cell populations (e.g., vascular endothelium).
Physiological Mechanism of Action: Tumor necrosis factor-alpha (TNF-α) soluble receptor (TNFsr) has been shown *in vitro* and *in vivo* to neutralize TNF-mediated biological activity.
Background Information: Tumor necrosis factor-α is expressed locally in arteries at sites of balloon injury. *In vitro* studies have shown that TNF inhibits cell cycle progression and induces apoptosis in endothelial cells.
Application: Evans blue dye staining can be applied to evaluate viable *ex vivo* preparations of vascular structures to determine the integrity of endothelial surfaces.
Implementation: Evaluation of the hypothesis that inhibiting TNF could accelerate endothelial recovery after angioplasty. Preparations of TNFsr vs control IgG can be administered by intraperitoneal injection. De-endothelializing balloon injury can then be created, and the resulting induced lesions evaluated 1 week later for evidence of reendothelialization (Evans Blue dye staining); and then after 2 weeks evaluated for reendothelialization and endothelial function.

Animal Model: Rat (Sprague-Dawling strain).
Interpretation and Analysis: At both time points, blockade of TNF biological activity with TNFsr results in increased reendothelialization, as measured as absolute area and percent area reendothelialized. TNFsr also accelerates functional endothelial recovery that manifests as an increase in nitric oxide (NO) production. Neointimal thickening can also be appreciated as being inhibited. Blockade of TNF *in vivo* accelerates functional endothelial recovery after barotraumatic de-endothelializing injury. Locally expressed TNF therefore acts to inhibit functional endothelial recovery after angioplasty and transient blockade of TNF may improve the long-term success of angioplasty.

Evans Blue Staining: The reagent facilitates detection of a demarcation between viable endothelial cell populations and subendothelial collagen.

In vivo blockade of tumor necrosis factor-alpha accelerates functional endothelial recovery after balloon angioplasty. Krasinski K, Spyridopoulos I, Kearney M, Losordo DW. Circulation 2001 Oct 9; 104 (15), pp. 1754–6.

Vascular Permeability/Extravasation Processes
Evans Blue Dye

Cellular/Molecular Mechanism of Action: Evans Blue dye is a pigment-based reagent that can be detected visually within the visible light range.
Background Information: Oxidative stress appears to be relevant to asthma pathogenesis.
Application: Evans blue dye is a pigment-based reagent that can be used as a visual marker or indicator molecule that is compatible with biological systems. In this context, it is often applied as a dilution marker system within the intravascular compartment for measuring total intravascular compartment size and extravasation of plasma proteins and hematologial cell types into the extravascular tissue space.
Implementation: Application of Evans Blue dye to evaluate extravasation into bronchoalveolar lavage fluid following antigen-induced pulmonary responses and the effectiveness of the antioxidant N-acetylcysteine (oral, 1 mmol/kg/day for 7 days before challenge).

Animal Model: Rat (Brown Norway strain that are antigen pre-sensitized).
Interpretation and Analysis: N-acetylcysteine does not reduce the immediate bronchospasm that follows aerosol antigen exposure but does prevent airway hyperreactivity to 5-hydroxytryptamine at 24 hours after antigen challenge. In the absences of N-acetylcysteine, eosinophil numbers are higher (0.178 ± 0.038) than with the administration of N-acetylcysteine ($0.064 \pm 0.020 \times 10^6$ cells/ml) which is significant ($p < 0.05$) and directly corresponds with concentrations of Evans blue dye extravasated into bronchoalveolar lavage fluid. Taurine levels in bronchoalveolar lavage fluid from antigen-challenged *in vivo* models are higher than control values but treatment with N-acetylcysteine fails to further increase these augmented levels. N-acetylcysteine appears to have beneficial effects in *in vivo* models of experimental asthma and serves to validate related findings pertaining to other models of lung injury.

Effectiveness of oral N-acetylcysteine in a rat experimental model of asthma. Blesa S, Cortijo J, Martinez-Losa M, Mata M, Seda E, Santangelo F, Morcillo EJ. Pharmacol Res 2002 Feb; 45 (2), pp. 135–40.

Vascular Permeability: Retinal/Minimally-Invasive Diagnostic Strategy [Diabetes]
Sodium Fluorescein

Background Information: Diabetic retinopathy is the leading cause of blindness in working-age individuals in the United States. Breakdown of the blood-retinal barrier is one of the earliest events in the progression of diabetic retinopathy. Ideally, therapeutic measures should be directed at this early stage of such conditions, but there are few sensitive, quantitative methods to assess the retinal vascular barrier *in vivo*.
Application: Quantitative assessment of the retinal vascular barrier.
Implementation: Utilization of two fluorescent tracers in combination with fluorescence microangiography to quantitatively assess retinal vascular barrier (± infusion of a hyperosmolar solution of 1.6 M mannitol for 5 minutes).

Animal Model: Rat (Long-Evans strain).
Interpretation and Analysis: Permeability × surface area/flow (PS/F) describing the retinal vasculature is 0.086 ± 0.031 ($n = 13$,

avg. ± SD). Based on estimates of flow and surface area, estimated permeability of sodium fluorescein is approximately 1.2 x 10^{-5} cm/sec. Infusion of a hyperosmolar mannitol solution significantly increases PS/F within individual veins and significantly increases flow-weighted PS/F from 0.073 ± 0.028 to 0.16 ± 0.034 (n = 3). Quantitative *in vivo* assessment of retinal vasculature can be delineated applying an adapted indicator dilution technique. Dual-tracer fluorescence angiography appears to be a sensitive indicator for detecting increases in the blood-retinal barrier produced by hyperosmolar mannitol. The methodology may be a promising new minimally-invasive strategy that may be adapted to quantitatively track retinal vascular permeability.

Instrumentation: Fluorescence microangiography.

Retinal vascular permeability determined by dual-tracer fluorescence angiography. Russ PK, Gaylord GM, Haselton FR. Ann Biomed Eng 2001 Aug; 29 (8), pp. 638–47.

Vasodilation Response Capacity: Echocardiography
Nitroglycerin

Cellular/Molecular Mechanism of Action: Activates guanylate cyclase, thereby increasing the synthesis of guanosine 3′,5′ monophosphate (cGMP) within smooth muscle tissues. In part this is mediated by increasing nitric oxide (NO) production that in turn increases cGMP levels. Ultimately light chain myosin is dephosphorylated, which functions in the contractile process. Analogs of cGMP also relax vascular and bronchial smooth muscles.

Physiological Mechanism of Action: Nitroglycerin promotes primarily venodilation properties at lower dosages compared to its effect on arteriole structures.

Application: Echocardiography/pharmaceutical provocative test procedures.

Route of Administration: Nitroglycerin (multiple/variable).

Implementation: Evaluate the effects of non-ECG-triggered imaging. During ultrasound studies of endothelial function, brachial artery diameters can be measured throughout the cardiac cycle at rest, during reactive hyperemia, and after nitroglycerin administration. R-wave-triggered imaging can be performed using a 7.5 MHz ultrasound transducer with data acquisition every 41.7–66.7 ms. Cardiac cycle-related variation is computed as the maximum percent change from the end-diastolic diameter. The range of possible errors in flow-mediated dilation (FMD) and nitroglycerin-mediated vasodilation that may result from ignoring cyclic variations in diameter are determined for each condition.

Human Model: n = 24 subjects.

Interpretation and Analysis: True FMD, true nitroglycerin-mediated vasodilation, and the maximum and minimum values that can be erroneously calculated for FMD if timing is ignored all differ dramatically ($p < 0.05$). The range of apparent FMD values that can be measured is nearly 3 times the true FMD value. Ignoring temporal position within the cardiac cycle artifactually increases calculated FMD into the normal range, despite truly impaired FMD. Peak arterial dilation occurs before end-systole and greater baseline vessel compliance is associated with greater FMD. Brachial arterial diameters vary significantly throughout the cardiac cycle. The magnitude of this variation is similar to the arterial dilation induced by reactive hyperemia and nitroglycerin, making ECG-triggered imaging mandatory for accurate and reproducible measurements of artery diameters and FMD. Measurement of diameters at end-diastole may be preferred to other time points in the cardiac cycle.

Instrumentation: 7.5 MHz ultrasound transducer.

Effect of cardiac cycle on ultrasound assessment of endothelial function. Chuang ML, Douglas PS, Bisinov EA, Stein JH. Vasc Med 2002 May; 7 (2), pp. 103–8.

CARDIOVASCULAR RESPONSE TESTS

Angina
Dipyridamole/[^{201}Thallium]/Stress Test/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Influences the metabolism and transport of adenosine and adenosine nucleotides. In this context, dipyridamole, a nucleotide transport blocker, suppresses the intracellular infux of adenosine, which is released from myocardial tissues that have been deprived of adequate oxygen.

Physiological Mechanism of Action: Dipyridamole promotes diminished coronary artery vascular resistance, coronary artery vasodilation, elevates coronary artery blood flow, and increases coronary artery oxygen delivery. One of the most prominent influences of dipyridamole in this regard is its effect on the smaller diameter vascular bed supplied by the coronary artery, but it has minimal effect in regions of ischemia since these same vessels tend to already be maximally dilated.

Application: Characterization of coronary artery function.

Implementation: Evaluation of conditions associated with effort angina using a series of tests including the ECG stress test, stress [^{201}Tl] scintigraphy, coronary arteriography; [^{201}Tl] scintigraphy, coronary arteriography, hemodynamic echo 2-D, and ecographic monitoring performed during a dipyridamole-induced vasodilation test (D).

Human Model: Cases of cardiac-associated angina. Based on coronary arteriography results with the condition categorized in groups classified as Type-A cases (n = 10 patients with significant stenosis ≥ 50%) or Type-B cases (n = 9 subjects with no significant stenosis).

Interpretation and Analysis: Type-A disease states can present with positive stress ECG and scintigraphy images (e.g., n = 9 cases). The dipyridamole test can induce angor and ecographic changes (e.g., n = 5 cases) and left ventricle wall motion disorders (e.g., n = 4 cases). Usually, [^{201}Tl] scans are positive in the vast majority of Type-A cases (e.g., n = 9/9). Type-B disease states are associated with ecographic changes in only a relatively small number of cases (e.g., n = 2/9), but approximately two-thirds will demonstrate positive [^{201}Tl] scan results (e.g., n = 6/9). In Type-B cases, dipyridamole can produce angor (e.g., n = 2/9); ecographic changes (e.g., n = 1/9); left ventricle wall motion disorders (e.g., n = 1); and similar [^{201}Tl] defects as previously detected. In both case group types, identical coronary arteriography findings can be observed immediately before and during dipyridamole infusion. In this context, dipyridamole confirms provocative tests for ischemia. The same ischemic pattern observed at stress and with dipyridamole scintigraphy in cases with no significant coronary stenosis suggests as pathogenetic mechanism involving a regional lack of dilatory reserve.

Instrumentation: Coronary arteriography; [^{201}Tl] scan, coronary arteriography, hemodynamic, echo 2-D, ecographic monitoring.

Angina Pectoris
Dipyridamole/Stress Test/(^{201}Thallium)/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Influences the metabolism and transport of adenosine and adenosine nucleotides. In this context, dipyridamole, a nucleotide transport blocker, suppresses the intracellular influx of adenosine released from myocardial tissues that have been deprived of adequate oxygen.
Physiological Mechanism of Action: Dipyridamole promotes diminished coronary artery vascular resistance, coronary artery vasodilation, elevated coronary artery blood flow, and increases coronary artery oxygen delivery. One of the most prominent influences of dipyridamole in this regard is its effect on the smaller diameter vascular beds supplied by the coronary artery; but it has minimal effect in regions of ischemia since these same vessels tend to already be maximally dilated.
Application: Detection and characterization of alterations in vascular blood flow (e.g. coronary artery)
Implementation: Evaluation of effort-induced angina conditions using a spectrum of challenge or stress test procedures including; (i) ECG stress test, (ii) stress [^{201}Tl] scan, (iii) coronary arteriography; (iv) [^{201}Tl] scan; (v) coronary arteriography; (vi) hemodynamic echo 2-D, (vii) ecographic monitoring during the dipyridamole test (D).
Considerations: Based on coronary arteriography results, cases can be divided into groups. In Group A (10 patients with significant stenoses $\geq$ 50%), stress ecg and scintigraphy are positive in a large percentage of cases (e.g. n = 9/10); while the dipyridamole test induces angor and ecographic changes in many cases (e.g. n = 5 cases) and in left ventricle wall motion disorders (e.g. n = 4). In [^{201}Tl] scan results are usually positive in the vast majority of cases affected by these two conditions (e.g. n = 9/9 cases).

In Group B type cases (n = 9 with no significant stenosis), ecographic changes can be observed in a small percentage of cases (e.g n = 2/9) while [^{201}Tl] scans are positive in a larger percentage of cases (e.g. n = 6/9). Dipyridamol can induce angor (e.g. n = 2 cases), ecographic changes (e.g. n = 1), left ventricle wall motion disorders (e.g. n = 1), and the same [^{201}Tl] defects in previously individualized patients (e.g. n = 6).
Interpretation and Analysis: Identical findings have been observed in both case group types administered dipyridamole during coronary arteriography when results are compared to preinjection images. Some clinicians feel confident that dipyridamole has been confirmed as an effective provocative test for ischemia. Markedly similar ischemic patterns observed with stress and dipyridamole scintigraphy in cases with no significant coronary stenosis suggest a lack of regional dilatory reserve as a pathogenic mechanism.
Instrumentation: Coronary arteriography; [^{201}Tl] scan, coronary arteriography, hemodynamic, echo 2-D, ecographic monitoring.

Dipyridamole test and myocardial scintigraphy with Tl-201 in the diagnosis of myocardial ischemic pathology. Caputo V, De Nardo D, Antolini M, Caiazza F, Pitucco G. Radiol Med (Torino) 1987 May; 73 (5), pp. 390–3.

Angina Pectoris/Flow Velocity: Coronary Artery Left Anterior Descending Branch/Coronary Flow Reserve and Vascular Flow Velocity/Transthoracic Echocardiography Assessement
Dipyridamole/[Adenosine]/Echocardiography

Background Information: There is an increasing need for new, functional, and more quantitative parameters to assess coronary arterial function for the purposes of evidence-based medicine. Coronary arterial function has been widely studied using pharmacological stimulation induced by dipyridamole or adenosine. Coronary flow reserve (CFR), defined as the ratio of pharmacologically-induced hyperemic flow divided by basal flow, has been found to be an important functional index in both the clinical and subclinical stages of cardiovascular diseases.
Application: Assessment of coronary blood flow and flow velocity determined through the combined use of dipyridamole and transthoracic echocardiography (TTE). Such methodologies can also be utilized to evaluate the patency of vascular graft sites.
Route of Administration: Dipyridamole (intravascular infusion).
Implementation: Evaluation and comparison of transthoracic Doppler echocardiography and MRI for measuring left anterior descending coronary artery (LAD) flow velocity and CFR. Additional parameters that can be measured include the time-response curve of dipyridamole infusion using transthoracic echocardiography (TTE).

Human Model: Cases without known abnormalities (n = 10 along with n = 5 normal controls for dipyridamole infusion time response curve measurements).
Interpretation and Analysis: Assessment of blood flow velocity, measured as MDV, PDV, and VTI, generates Pearson's correlation coefficients of 0.88, 0.85, and 0.70, respectively, between flow velocity measurements performed using TTE and MRI. The results indicate that, despite minor differences in LAD diastolic velocities measured by TTE and MRI, the correlation of the LAD diastolic velocities measured using both methods is good and both methods are feasible for measuring CFR. Moreover, TTE has the unique capability of acquiring continuous measurements of LAD flow velocity, which allows assessment of the time-response curve for dipyridamole-induced increase in LAD flow velocity. Such findings indicate that the TTE method may be used in sequential or on-line monitoring of LAD blood flow velocity and therefore can be applied to evaluate the time- or dose-response effects of infused drugs in the coronary circulation of humans.

Correlation of transthoracic Doppler echocardiography and magnetic resonance imaging in measuring left anterior descending artery flow velocity and time-course of dipyridamole-induced coronary flow increase. Koskenvuo JW, Saraste M, Niemi P, Knuuti J, Sakuma H, Toikka JO, Komu M, Järvisalo MJ, Hartiala JJ. Scand J Clin Lab Invest 2003; 63 (1), pp. 65–72.

Angina Pectoris: Ischemic Heart Disease/Neurologic Deficits Secondary to Ischemic Heart Disease
Dipyridamole (DPD)/[Acetazolamide]/[Single Photon Emission Computed Tomography (SPECT)]

Background Information: The diagnosis of transient ischemic attack (TIA) is mainly based on the profile of clinical symptoms. Nuclear medicine techniques have been successful in detecting TIA SPECT instrumentation. Improved sensitivity of the examination using a stress test protocol (e.g., acetazolamide) has been well described in the literature.
Application: Dipyridamole has been used to evaluate various aspects of vascular function and response to specific stimuli.
Implementation: Evaluation of the relationship between transient neurological symptoms provoked by the dipyridamole stress test performed in conditions of ischemic heart disease, and changes in regional cerebral blood flow indicated by brain SPECT imaging.

Human Model: Cases of ischemic heart disease evaluated for evidence of secondary alterations in cerebral vascular perfusion (e.g. n = 100).

Interpretation and Analysis: Intravenous dipyridamole injection can create various forms of transient neurological deficits in 23% of ischemic heart disease cases with a considerably higher incidence than previously reported in the literature (1.22/10,000). The so-called "TIA positive" cases can subsequently be examined further using the combination of dipyridamole stress test and brain SPECT imaging.

Dipyridamole test in the early detection of cerebrovascular disorders? Molnár T, Zámbó K, Schmidt E, Tekeres M. Orv Hetil 2000 Dec 10; 141 (50), pp. 2717–22.

Angina Pectoris: Vasodilatory Response Evaluation/ Arterial Graft Vasodilatory Function/Post-Operative Angina

Acetylcholine/Nitroglycerin/[Angiography Adjunct Diagnostic Pharmaceutical]

Cellular/Molecular Mechanism of Action: Acetylcholine binds to and activates its respective postsynaptic membrane receptor complexes. As a neurotransmitter, it is released from postganglionic parasympathetic axons, preganglionic axons, somatic motor axons, and specific CNS synapses.

Acetylcholine: Serves as a neutrotransmitter that influences the function or activation of tissues and organs innervated by the parasympathetic autonomic nervous system in addition to autonomic ganglionic cells (parasympathetic and sympathetic) and cells in the adrenal medulla. Acetylcholine primarily promotes peripheral and pulmonary vasodilation (muscarinic receptors), decreases in heart rate, and suppresses contractile forces (primarily atrial effect). Increased vasodilation causes declines in blood pressure and, therefore, a reflex tachycardia, but acetylcholine is believed to exert a minimal effect at the level of the coronary artery. Bradycardia is observed at the higher range of the Ach dose spectrum.

At the level of the heart, acetylcholine binds to and activates postsynaptic receptor complexes associated with parasympathetic cholinergic synapses found at high densities within the S-A node, A-V node, and atrial tissues. Acetylcholine decreases the heart rate by promoting a hyperpolarization effect, thereby suppressing the frequency of spontaneous S-A node depolarization during diastole (delays action potential reaching threshold potential). Acetylcholine decreases the intensity of atrial contraction and shortens atrial action potential duration in a manner that accentuates atrial flutter and atrial fibrillation induced by increased vagal tone. Alternatively, acetylcholine slows conduction and increases the duration of the refractory period within the A-V node and, to a lesser degree, the Purkinje system. The increase in the duration of the refractory period produced by acetylecholine can decrease the initiation of aberrant atrial impulses transmitted to the ventricles. The negative influence that acetylcholine has on ventricular heart rate is much less that its effect on atrial function, but it does diminish Purkinje system automaticity. In this regard, acetylcholine can diminish or inhibit adrenergic-mediated cardiac stimulation. The latter effect is due to a direct suppression of myocardium adrenergic responsiveness and diminished release of norepinephrine from presynaptic membranes of the autonomic nervous system.

Nitroglycerin: Induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are observed changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and cases with coronary artery disease when nitroglycerin is given by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce a significant hypotensive episode.

Background Information: Cigarette smoking is known to promote endothelial dysfunction, thus it can be responsible for an impaired "late" endothelium-dependent vasomotility in arterial grafts after coronary surgery.

Application: Evaluation of endothelial function in the left internal thoracic artery after coronary artery bypass surgery and the identification of predictors or indicators that detect or reflect early dysfunction. Other uses include provocative testing in cases that have undergone routine postoperative coronary angiography.

Route of Administration: Acetylcholine and nitroglycerin (selective intravascular infusion).

Dosage: Acetylcholine (10^{-6} mmol/ml) and nitroglycerin (500 μg).

Considerations: Acetylcholine is rapidly degraded enzymatically by acetylecholineesterase (AchE) and butyrylcholinesterase within the intravascular compartment. Since acetylcholine is a quarternary ammonium compound that is rapidly metabolized within the plasma, very little of this neurotransmitter penetrates the CNS at physiologically significant concentrations. At excessively high doses, acetylcholine can promote a positive effect on cardiac contractility mediated through the release of catecholamine.

Implementation: Evaluation of vascular grafts utilizing vasoactive agents in concert with performing quantitative angiography procedures (long-term follow-up mean time 2.5 years). To assess both endothelium-dependent and independent vasomotility, angiograms can be acquired before and after selective infusions of acetylcholine and nitroglycerin. The predictive value of risk factors, including previous and continued smoking, for impairment of endothelium-dependent vasomotility can also be assessed.

Human Model: Cases previously having undergone coronary bypass surgery utilizing the internal thoracic artery ($n = 20$ with mean age = 64.5 years).

Interpretation and Analysis: The thoracic artery shows a 6.8% ($p < 0.001$) and 9% ($p < 0.001$) increase in mean diameter after acetylcholine and nitroglycerin administration, respectively. Vasodilation responses to acetylcholine and nitroglycerin administration strongly correlate with one another (R: 0.88; $p < 0.001$). Only the common risk factor of age is associated with impairment in the vasodilation response of the arterial graft ($p = 0.001$), and acetylcholine-induced vasodilation is inversely correlated with age (R: 0.69; $p < 0.001$).

Angina following a coronary intervention may be due to vasospasm rather than restenosis. Some cases experience angina following a previously successful recanalization (e.g., $n = 2$ cases). Usually, vasospasm can be documented as the cause of angina (e.g., $n = 2/2$). Validation of this concept can be determined through the use of an ergonovine provocative test or the evaluation of lesion response to nitroglycerin. Rather than another intervention, vasodilator treatment is sometimes instituted, accompanied by effective symptom amelioration.

The digitalis cardiac glycosides promotes increased vagal tone on the function of the heart.

Angina Pectoris: Vasospastic/Presynaptic Myocardial Sympathetic Abnormality

Ergonovine/[^{123}I]Iodine-Labelled Metaiodobenzylguanidine (MIBG)/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Ergonovine promotes arterial wall smooth muscle contraction. [^{123}I] Iodine-labelled metaiodobenzylguanidine (MIBG) functions as an analog of norepinephrine.

Application: Assess the presence and location of presynaptic myocardial sympathetic abnormalities in conditions of vasospastic angina.

Route of Administration: [^{123}I]-labelled metaiodobenzylguanidine (MIBG) given IV. Ergonovine is administered by intracoronary infusion (ICA).

Dosage: ^{123}Iodine-labelled metaiodobenzylguanidine (MIBG; 111 mBq).

Implementation: Evaluation of conditions of suspected vasospastic angina utilizing single photon emission computed tomography (SPECT) facilitated by the use of MIBG (image agent) and ergonovine provocative challenge. Such diagnostic strategies permit the non-invasive detection and evaluation of suspected vasospastic angina events.

Human Model: Cases of suspected vasospastic angina pectoris (e.g. n = 50) previously evaluated by coronary artery angiography following intracoronary artery ergonovine infusion, with a 99–100% obstructive spasm defined as a positive response.

Interpretation and Analysis: Images aquired 20 minutes and 3 hours following the administration of 111 mBq [^{123}I]-MIBG SPECT can reveal mild reductions in tissue uptake (e.g. n = 5/25). In the majority of the suspect cases, images at 3 hours often demonstrate [^{123}I]-MIBG SPECT abnormalities (e.g. n = 20/25). The location of [^{123}I]-MIBG abnormalities can be completely or partially consistent with the spastic coronary territory (e.g. n = 18/25). Alternatively, reduced [^{123}I]-MIBG uptake may be noted in cases with a negative ergonovine provocative test (e.g. n = 4/25). Accordingly, positive and negative predictive values of MIBG SPECT for the provocative test have been estimated to be 83% (e.g. n = 20/24) and 81% (e.g. n = 21/26), respectively.

Instrumentation: Single photon emission computed tomography.

Value of iodine-123 metaiodobenzylguanidine scintigraphy in patients with vasospastic angina. Taki J, Yasuhara S, Takamatsu T, Nakajima K, Tatami R, Ishise S, Matsunari I, Takayama T, Tonami N. Eur J Nucl Med 1998 Mar; 25 (3), pp. 229–34.

Angina Pectoris: Vasospastic (Coronary Artery Tone)

Acetylcholine/Ergonovine/Nitroglycerin/[Echocardiography]

Cellular/Molecular Mechanism of Action:

Acetylcholine: Binds directly to and positively activates acetylcholine receptor complexes located on the surface of postsynaptic membranes.

Ergonovine: Directly binds and positively but not maximally activates tryptaminergic and a-adrenergic receptor complexes but to a lesser extent than ergotamine. At dopaminergic receptor complexes, ergonovine functions as a weak antagonist. At both tryptaminergic and dopaminergic receptor sites, ergonovine can exert both partial agonist and antagonist properties within certain regions of the central nervous system (CNS). In various smooth muscle tissues, the compound exerts antagonist properties.

Physiological Mechanism of Action:

Nitroglycerin: Induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are the changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and cases with coronary artery disease when given nitroglycerin by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce a significant hypotensive episode.

Ergonovine: Vasoconstriction can be induced affecting both venous and arterial vascular structures through direct stimulation of vascular smooth muscle. Systemic administration produces elevations in blood pressure due to peripheral vasoconstriction. Ergonovine can produce coronary artery vascular responses that are detectable as ischemic patterns on EKG tracings and angina pain in cases with coronary artery disease. Bradycardia is often induced by ergot alkaloids even when no elevations in blood pressure are evident, due in part to increased vagal activity and, to a lesser extent, diminished CND sympathetic tone and direct-acting myocardial depression.

Application: Detection and characterization of vasospastic angina. Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser extent by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.

Dosage: Nitroglycerin (0.3 mg sublingual)

Considerations: Basal tone of the left main trunk is elevated in the early morning in vasospastic angina. The definite diagnosis of vasospastic angina is done by a coronary spasm provocative test using ergonovine maleate or acetylcholine during cardiac catheterization. Current non-invasive, non-pharmacologic diagnostic methods are not sensitive enough for the diagnosis of vasospastic angina.

Implementation: Evaluation of the capacity for nitroglycerin to detect and characterize conditions of vasospastic angina pectoris conditions.

One effective approach has been the characterization of the condition at 7 A.M. and at noon on the same day involving measurement of the left main coronary artery trunk diameter by M-mode echocardiography before and after sublingual nitroglycerin administration. Parameters that are calculated include the extent of dilation as a reflection of the degree of coronary artery tone present.

Human Model: Cases with an angiographically normal left main trunk (n = 38). Cases can be classified into 4 groups based on the presence or absence of more than 50% stenosis in the coronary arteries except for the left main trunk and responses the acetylcholine or ergonovine provocative tests.

Interpretation and Analysis: The percent dilation of the left main trunk diameter induced by sublingual nitroglycerin at 7 A.M. and at noon is 22.4 ± 4.7% (mean ± SD) and 18.1 ± 4% in cases with vasospastic angina and without coronary stenosis (e.g. n = 11), 14.9 ± 7.1% and 11.2 ± 6.9% in cases with vasospastic angina and coronary stenosis (e.g. n = 9), 6.1 ± 3.5% and 7.0 ± 5.1% in cases without vasospastic angina but with coronary stenosis (e.g. n = 8), and 8.1 ± 5.6% and 7.8 ± 5.7% in control subjects (e.g. n = 10). The percent dilation at 7 A.M. is significantly greater in case groups with vasospastic angina without coronary stenosis than in the remaining 3 case group types, and in the vasospastic angina groups, the percent dilation at 7 A.M. is significantly greater than that at noon. When percent dilation at 7 A.M. exceeding 15% is defined as positive for the diagnosis of vasospastic angina, the sensitivity is 80% and the specificity 94%.

A new noninvasive method of diagnosing vasospastic angina based on dilation response of the left main coronary artery to nitroglycerin as measured by echocardiography. Morita H, Ohmori K, Matsuyama T, Mizushige K, Matsuo H. J Am Coll Cardiol 1996 May; 27 (6), pp. 1450–7.

Aortic Stenosis: Left Ventricular Contractile Reserve/Cardiac Index/Operative Mortality Rate: Prediction Parameters/Long-Term Survival Predictive Markers
Dobutamine/[Doppler Ultrasound]

Background Information: The prognostic value of dobutamine stress hemodynamic data in the setting of low-gradient aortic stenosis has been addressed in small, single-center studies. Larger studies are needed to define the criteria for selecting the patients who will benefit from valve replacement.

Application: Dobutamine stress Doppler hemodynamics may be factored into the risk-benefit analysis for cases of aortic stenosis.

Implementation: Evaluation of aortic stenosis conditions using dobutamine stress test protocols in combination with Doppler imaging analysis.

Human Model: Aortic stenosis (n = 136 cases; n = 96 males [median age = 72 years; range 65–77 years]; median aortic valve = 0.7 cm^2 [range = 0.6 to 0.8]; mean transaortic gradient = 29 mm Hg [range = 23–34 mm Hg]; cardiac index = 2.11 L × min^{-1} × m^{-2} [range, 1.75 to 2.55 L × min^{-1} × m^{-2}]).

Interpretation and Analysis: Left ventricular contractile reserve on the dobutamine stress Doppler study can be detected in a large number of cases (e.g., n = 92/136; and absent in n = 44/136). Operative mortality is relatively low (e.g., n = 3/64 or 5%) in cases with left ventricular contractile reserve. Alternatively, the operative mortality rate is significantly higher in cases without evidence of left ventricular contractile reserve (e.g., n = 10/31 or 32%; p = 0.0002). Predictors for operative mortality include a lack of contractile reserve (odds ratio, 10.9; 95% confidence interval [CI], 2.6 to 43.4; p = 0.001) and a mean transaortic gradient ≤ 20 mm Hg (odds ratio, 4.7; 95% CI, 1.1 to 21.0; p = 0.04). Predictors for long-term survival are valve replacement (hazard ratio, 0.30; 95% CI, 0.17 to 0.53; p = 0.001) and left ventricular contractile reserve (hazard ratio, 0.40; 95% CI, 0.23 to 0.69; p = 0.001). In the setting of low-gradient aortic stenosis, surgery seems beneficial for most cases with left ventricular contractile reserve.

Low-gradient aortic stenosis: Operative risk stratification and predictors for long-term outcome: A multicenter study using dobutamine stress hemodynamics. Monin JL, Quéré JP, Monchi M, Petit H, Baleynaud S, Chauvel C, Pop C, Ohlmann P, Lelguen C, Dehant P, Tribouilloy C, Guéret P. Circulation 2003 Jul 22; 108 (3), pp. 319–24.

Aortic Stenosis: Aortic Valve Replacement/Coronary Flow Reserve
Dipyridamole/[Angiography]

Physiological Mechanism of Action: Dipyridamole induces vasodilatory responses.

Background Information: In cases with aortic stenosis and a normal coronary angiogram, coronary flow reserve (CFR) is impaired.

Application: Examine the effect of aortic valve replacement (AVR) on CFR after a long-term follow-up

Route of Administration: Dipyridamole (intravascular).

Dosage: Dipyridamole (0.56 mg/kg for 4 minutes).

Implementation: Evaluation of CFR measurements 123 ± 137 days before and 497 ± 167 days after AVR (e.g., n = 21 cases). Coronary flow reserve measurements are performed according to a standardized protocol, with a vasodilator stimulus (e.g. dipyridamole) and peak diastolic velocity measurements recorded at 6 minutes.

Human Model: Cases of aortic stenosis with normal coronary angiogram images (n = 30).

Interpretation and Analysis: The initial average peak gradient of aortic stenosis is 89.5 ± 22.4 mm Hg. After AVR, it decreases to 26.2 ± 9 mm Hg. Left ventricular mass is significantly lower after AVR: 354.9 ± 107.9 g vs 223.8 ± 73.6 g (p < 0.001). The average baseline diastolic velocity measured by pulsed Doppler in the left anterior descending coronary artery amounts to 62.2 ± 25.5 cm/s before and 40.1 ± 13.6 cm/s after AVR. The difference is statistically significant (p < 0.01). The average diastolic velocity at maximum stress equals 117 ± 42.8 cm/s preoperatively, and 91.5 ± 34 cm/s postoperatively (p < 0.005). Calculated CFR before AVR is 1.96 ± 0.5 and increases to 2.37 ± 0.8 postoperatively. The difference is statistically significant (p < 0.05). Prosthetic AVR is of considerable benefit concerning the CFR in cases with a normal coronary angiogram after a long-term follow-up evaluation.

The effect of aortic valve replacement on coronary flow reserve in patients with a normal coronary angiogram. Nemes A, Forster T, Kovács Z, Thury A, Ungi I, Csanády M. Herz 2002 Dec; 27 (8), pp. 780–4.

Atherosclerotic Plaque Deformation: Ultrasound Visualization
Acetylcholine/Isosorbide Dinitrate (Vasodilation)/[Ultrasound]

Cellular/Molecular Mechanism of Action: Acetylcholine functions as a parasympathetic/cholinergic neurotransmitter by physically binding to its corresponding post-synaptic membrane receptor complex.

Physiological Mechanism of Action: Isosorbide dinitrate (vasodilation).

Application: Visualize ultrasonically deformations of atherosclerotic plaques in human coronary arteries during vasoconstriction and vasodilation responses.
Route of Administration: Acetylcholine (selective intravascular); isosorbide dinitrate (intracoronary injection).
Considerations: The cross-sectional area of the atherosclerotic plaque appeared to be constant during vasomotion of human coronary arteries.
Implementation: Evaluation of the "pliability" of atherosclerotic plaque following vasoactive responses induced by acethylcholine and isosorbide dinitrate injection.
Interpretation and Analysis: Intravascular ultrasound can detect occult atherosclerosis in angiographically normal coronary arteries in instances of chest pain at rest (n = 8). During the acetylcholine provocative tests, intravascular ultrasound can be used to monitor deformations of the atherosclerotic plaques. During the last phase of the test, vasodilation can be promoted with intracoronary injection of isosorbide dinitrate. Under control, acetylcholine-treated, and isosorbide dinitrate-treated conditions, the cross-sectional areas of sonolucent circle and vessel lumen can be measured in order to establish the area of atherosclerotic plaques. In the process of vasoconstriction and vasodilation, the plaque area does not change significantly.

Intravascular ultrasonic evidence by constant cross-sectional area of atherosclerotic plaques during coronary vasomotion in humans. Matsu-ura Y, Kijima Y, Hashimura K, Kato Y, Ueda T, Yasuda T, Mori I, Hoshida S, Hori M. Eur Heart J 1997 Jun; 18 (6), pp. 949–53.

Cardiac Failure: Chronic/Inotropic Activity/Cardiac Output/Pressor Effect/Inotropic Agent Selection
Dobutamine/Carvedilol/Metoprolol/ [Echocardiography]

Cellular/Molecular Mechanism of Action: Dobutamine functions as a positive adrenergic (sympathomimetic) agent. Metoprolol is a selective β_1 adrenoreceptor antagonist (blocker), while carvedilol is a non-selective β-adrenoreceptor blocker.
Physiological Mechanism of Action: Dobutamine promotes positive cardiac inotropic responses and can also promote increases in cardiac output and elevations in systemic blood pressure.
Application: Adjunct form of diagnostic intervention during stress echocardiography procedures thereby functioning as a guide when choosing a (therapeutic) inotropic agent.
Route of Administration: Dobutamine (intravenous).
Dosage: Carvedilol and metoprolol CR/XL (target dose 50 mg twice daily and 200 mg once daily, respectively) for 8 weeks. Dobutamine (5 μg/kg/min and high-dose 15 μg/kg/min).
Implementation: Evaluation of carvedilol and metoprolol CR/XL as potential adjunct forms of intervention during dobutamine-stress echocardiography procedures performed at the end of each maintenance period. Parameters evaluated include determining if conditions of congestive heart failure display different hemodynamic responses during dobutamine challenge in the presence of beta adrenoreceptor blocking agents.

Model: Cases with stable chronic congestive heart failure (ejection fraction < 40%) on chronic treatment with metoprolol CR/XL (e.g. n = 10). Single center, single blind, randomized, 2-period crossover study comparing carvedilol with metoprolol CR/XL.
Interpretation and Analysis: No significant hemodynamic differences can be seen at rest after 2 treatments. There is a more pronounced increase in heart rate and cardiac output during dobutamine infusion when cases are given metoprolol in contrast to carvedilol. Mean arterial pressure increases significantly with carvedilol. Cardiac output increases during low-dose dobutamine, without further changes being appreciated with high-dose dobutamine administration. During infusions of dobutamine, there is no significant difference in ejection fraction between carvedilol and metoprolol treatment. Therefore, differences in response to the inotropic drug dobutamine can be appreciated in conditions of congestive heart failure managed with a non-selective β-adenoreceptor blocker compared to β-selective blocker administration. Selective β_1 blockade with metoprolol can be counteracted by dobutamine, whereas with carvedilol a low dose of dobutamine increases cardiac output and a higher dose of dobutamine cause a pressor effect. Such findings may be clinically relevant when choosing an inotropic pharmaceutical agent.

Different responses to dobutamine in the presence of carvedilol or metoprolol in patients with chronic heart failure. Bollano E, Täng MS, Hjalmarson A, Waagstein F, Andersson B. Heart 2003 Jun; 89 (6), pp. 621–4.

Cardiomyopathy: Dilated Cardiomyopathy (DCM) and Coronary Vasospasm/Response Prediction: Antispasmatic Agents/Atrial Fibrillation as an Indicator for DCM
Ergonovine/[Echocardiography]

Cellular/Molecular Mechanism of Action: Coronary artery spasm can be induced by acetylcholine, serotonin, ergonovine, or histamine, all of which cause vasodilation when the endothelium is intact by releasing nitric oxide (NO). In conditions of coronary artery spasm, acetylcholine induces a spasmodic response that can be promptly relieved by nitroglycerin, which promotes vasodilation through a direct action on vascular smooth muscle. Such finding imply that some form of abnormally in endothelial integrity exists in conditions of coronary spasm that can be accentuated by acetylcholine and histamine, and to a lesser by ergonovine and serotonin. In general, all ergot alkaloids exert their biological effect as partial agonists or antagonists at adrenergic, dopaminergic, and tryptaminergic receptor complexes. Effects of full agonists like norepinephrine are usually augmented by low ergot alkaloid concentrations. Similarly, the contractile response to agents like acetylcholine can sometimes be augmented by low ergot alkaloid concentrations.
Background Information: The pathogenesis of dilated cardiomyopathy (DCM) is unknown, but clinical evidence suggests that coronary vasospasm is associated with the development of DCM in some cases.
Application: Detection and characterization of alterations in vascular function.
Route of Administration: Ergonovine (cardiac catheterization).
Implementation: Evaluate and profile the [i] prevalence of coronary vasospasm in DCM conditions; [ii] characteristics of cases with DCM and coronary vasospasm; and [iii] effects of antivasospastic agents on cases with DCM and coronary vasospasm utilizing the ergonovine provocation testing

Human Model: Dilated cardiomyopathy cases (n = 18). Approximately one-third of cases experience coronary vasospasm, thereby requiring secondary administration of antivasospastic agents following cardiac catheterization.
Interpretation and Analysis: A diagnoses of coronary vasospasm can be suspected if ergonovine induces coronary vasoconstriction (≥ 75% diameter narrowing) compared to the diameter after nitroglycerin administration. The prevalence of atrial fibrillation in cases with DCM and coronary vasospasm is greater than that in DCM without coronary vasospasm (67 vs 8% [$p < 0.05$]). The left

ventricular end-diastolic dimension decreases from 61 mm (range 56 to 64) to 55 mm (range 53 to 56) (median, 25th/75th percentile, $p < 0.05$) and the left ventricular ejection fraction increases from 36% (range 32 to 40) to 47% (range 46 to 48) (median, 25th/75th percentile, $p < 0.05$) after the administration of antivasospastic agents ($n = 4/6$ cases improve symptomatically). Ergonovine provocation testing is useful in identifying conditions of DCM and coronary vasospasm, in whom cardiac performance is expected to be improved with antivasospastic agent therapy. DCM patients with atrial fibrillation may be a clue for identifying patients with coronary vasospasm.

Effects of antivasospastic agents in Japanese patients with dilated cardiomyopathy and coronary vasospasm. Nishi I, Ilda K, Kawano S, Masumi T, Fumikura Y, Ohtsuka S, Watanabe S, Yamaguchi I. Jpn Heart J 2002 Jul; 43 (4), pp. 333–42.

Cardiomyopathy: Dilated Cardiomyopathy (DCM)/Left Ventricular Ejection Fraction (LVEF)/Predict Improved Cardiac Sympathetic Nerve Activity/Predict Improved Cardiac Function/Predict Improved Symptoms Posttreatment for Dilated Cardiomyopathy
Dobutamine/[^{123}I]-Meta-Iodobenzylguanidine/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: [^{123}I]-meta-iodobenzylguanidine functions as an analog of norepinephrine.
Physiological Mechanism of Action: Dobutamine exerts adrenergic/sympathomimetic properties.
Route of Administration: Dobutamine (intravascular).
Dosage: Dobutamine (5, 10, and 15 μg/kg/min).
Implementation: Evaluation of dilated cardiomyopathy conditions by measuring left ventricular ejection fraction (LVEF) at rest and in response to gradient dose increases in dobutamine. Infusions of dopamine can be performed before initiation of therapy in conditions of DCM according to protocols for dobutamine gated blood pool scintigraphy (DOB-GBP). Examinations are performed before and after 1 year of therapeutic intervention. The heart/mediastinum count (H/M) ratio and total defect score (TDS) are determined for [^{123}I]-meta-iodobenzylguanidine images from anterior planar image and single photon emission computed tomography (SPECT) images. Left ventricular ejection fraction and left ventricular end-diastolic dimension (LVDd) are determined by echocardiography.

Human Model: Cases of dilated cardiomyopathy ($n = 22$).
Interpretation and Analysis: After 1 year of treatment, echocardiographic LVEF improves $> 5\%$ (e.g., $n = 11/22$ cases). Before treatment, TDS, H/M, LVEF, and LVDd are similar in both groups. However, there is a greater increase in the LVEF during dobutamine infusion in cases displaying improvement compared to those that do not improve ($21 \pm 8\%$ vs $9 \pm 3\%$, $p < 0.001$). If a critical value of 15% for the DeltaLVEF is used to predict the improvement in LVEF after treatment, sensitivity is 91% and specificity is 82%. The TDS, H/M ratio, LVDd, and New York Heart Association functional class improves in cases demonstrating a post 1–year response that is greater than comparable values for cases that do not demonstrate a response. Dobutamine gated blood pool scintigraphy therefore can be used to predict improved cardiac sympathetic nerve activity, cardiac function, and symptoms after treatment in DCM conditions.

Dobutamine gated blood pool scintigraphy predicts the improvement of cardiac sympathetic nerve activity, cardiac function, and symptoms after treatment in patients with dilated cardiomyopathy. Kasama S, Toyama T, Hoshizaki H, Oshima S, Taniguchi K, Suzuki T, Kurabayashi M. Chest 2002 Aug; 122 (2), pp. 542–8.

Cardiomyopathy: Idiopathic Dilated Cardiomyopathy (IDCM)/Prognostic Parameters for Mortality and Survival
Dobutamine/Low-Dose Dobutamine Echocardiography/[Echocardiography]

Physiological Mechanism of Action: Dobutamine exerts adrenergic agonist properties.
Background Information: Dobutamine echocardiography is widely used to detect and measure myocardial contractile reserve.
Application: Determine the response of the left ventricle to low-dose dobutamine infusion, which adds clinically valuable prognostic information for the evaluation of IDCM.
Dosage: Dobutamine (10 μg/kg/min for 5 minutes).
Implementation: Evaluation of cardiomyopathy conditions as a function of measurements of 2-dimensional and Doppler echocardiographic variables before and after the infusion of dobutamine.

Human Model: Cases suffering from cardiovascular disease (e.g., $n = 77$ IDCM cases; age $= 49 \pm 9$ years; men $= 82\%$) with left ventricular (LV) ejection fractions of $< 40\%$. Study population: $n = 30/77$ died; $n = 5/77$ successful heart transplant over a 63 ± 7-month follow-up period (range, 49 to 75 months).
Interpretation and Analysis: Using multivariate regression analysis, the only significant factors related to fatal outcome or the need for cardiac transplantation were the following: (i) LV end-systolic volume of > 150 mL after low-dose dobutamine infusion (odds ratio [OR], 2.2; confidence interval [CI], 1.2 to 4.1; $p = 0.011$); (ii) no decrease of LV end-diastolic volume after dobutamine infusion (OR, 1.9; CI, 1.1 to 3.4; $p = 0.031$); (iii) atrial fibrillation (OR, 2.7; CI, 1.4 to 5.3; $p = 0.003$); and (iv) male gender (OR, 2.6; CI, 1.2 to 5.5; $p = 0.017$). A scoring system has been proposed with 1 point assigned for each of the above-mentioned factors. The mortality rates for total scores of 0, 1, 2, 3, and 4 were 0%, 19%, 48%, 83%, and 100%, respectively. The response of the LV to low-dose dobutamine infusion adds clinically valuable prognostic information to the evaluation of the patient with IDCM.

Prognostic value of low-dose dobutamine echocardiography in patients with idiopathic dilated cardiomyopathy. Drozdz J, Krzemińska-Pakula M, Plewka M, Ciesielczyk M, Kasprzak JD. Chest 2002 Apr; 121 (4), pp. 1216–22.

Cardiomyopathy: Idopathic Dilated Cardiomyopathy (IDCM)/Contractile Reserve (CR)/ Cyclic Variation/Prognostic Indicator
Dobutamine/[Echocardiography]

Cellular/Molecular Mechanism of Action: Dobutamine possesses adrenergic agonist properties.
Background Information: Conventional resting echocardiography is not able to predict the CR of cases with IDCM.
Application: Dobutamine has been utilized in combination with ultrasonic myocardial texture analysis in IDCM for the purpose of discriminating cases with and without preserved CR and cases with an unfavorable prognosis.
Route of Administration: Dobutamine infusion (intravenous).
Dosage: Dobutamine infusion (10 μg/kg/min).
Implementation: Myocardial texture analysis can be performed on echocardiographic digitized images in conditions of IDCM through a calibrated 256 gray level digitization system. Cyclic variation (CV) index of myocardial mean gray level (MGL) is calculated

according to the formula ($MGL_{diast} - MGL_{syst}$)/ $MGL_{diast} \times 100$. Contractile reserve is defined as the %-change of ejection fraction by 10 μg/kg/min dobutamine infusion. A clinical follow-up is also performed for all cases for an average of 8 ± 3 months.

Human Model: Idiopathic dilated cardiomyopathy (IDCM n = 27 cases).

Interpretation and Analysis: Contractile reserve ranges between −1.8% and 50.3%. Cyclic variation index of both septum and posterior wall (PW) is the parameters that most significantly correlates with CR ($r = 0.69$ and $r = 0.77$, respectively, $p < 0.0001$ for both). The mean resting CV index of septum and PW are significantly lower in cases with CR < 17% median value of all subjects (5.7 ± 5.6 vs 16.9 ± 7.9 and 5.4 ± 5.9 vs 16.1 ± 6.4, respectively, $p < 0.0001$ for both). A CV index of 10% for both septum and PW yields a sensitivity of 77% and 84%, and a specificity of 84% and 84% for predicting diminished CR, respectively. The event-free survival rate is significantly lower in patients with CR less than 17% (61.5 vs 92.8%, $p < 0.05$). The CV index of both septum and PW are also significantly lower in cases with cardiac events (13.6 ± 8 vs 4.3 ± 6, $p < 0.05$ and 14.7 ± 7 vs 4.1 ± 7, $p < 0.01$, respectively). Ultrasonic myocardial texture analysis in IDCM has a good ability to discriminate between cases with and without preserved CR, and cases with unfavorable outcome as well.

Instrumentation: Videodensitometric myocardial texture analysis.

Myocardial texture analysis in idiopathic dilated cardiomyopathy: Prediction of contractile reserve on dobutamine echocardiography. Dagdeviren B, Akdemir O, Bolca O, Eren M, Gürlertop Y, Tezel T. J Am Soc Echocardiogr 2002 Jan; 15 (1), pp. 36–42.

Cardiomyopathy: Ischemic/Low-Dose Wall Motion Scores: Risk Stratification/Prediction of Benefit from Revascularization
Dobutamine/[Echocardiography]

Physiological Mechanism of Action: Dobutamine exerts adrenergic/sympathetic agonist properties.

Application: Evaluation of dobutamine low-dose wall motion scores for estimating risk stratification of cases with ischemic cardiomyopathy and identifying those who do and do not benefit from revascularization.

Route of Administration: Dobutamine (intravascular).

Dosage: Dobutamine (low-dose = 10 μg/kg/min and high-dose/maximal dose 50 μg/kg/min) infusion.

Implementation: Delineation of the value of wall motion scores at rest and with low- and high-dose dobutamine infusion for predicting the outcome and benefit from revascularization in cases with ischemic cardiomyopathy. Complementary follow-up evaluation of ischemic cardiomyopathy cases can entailechocardiography image acquision at rest and during low-dose and high-dose/maximum dobutamine infusion.

Human Model: Cases of ischemic cardiomyopathy (n = 139).

Interpretation and Analysis: Both rest and low-dose wall motion scores are multivariate predictors of cardiac death, but ischemia and peak dose scores are not predictors. Cases can be classified into resting case scores that have been risk stratified into 3 groups: (i) score (1.00 to 1.99) with 11% cardiac death; (ii) score (2.00 to 2.49) with 30% death; and (iii) score ≥ 2.50 with 47% death. One-third of cases with rest scores ≥ 2.50 have improvement in scores to < 2.50 with low-dose dobutamine. Their frequency of cardiac death is reduced to 23% compared with 60% ($p = 0.04$) in those that remain with low-dose scores ≥ 2.50. Low-dose scores also can identify those cases that will benefit from revascularization. In cases with low-dose scores (1.00 to 1.99), the frequency of cardiac death is marginally lower in revascularized than non-revascularized cases (10 vs 21%, $p = 0.28$). In cases with scores (2.00 to 2.49), revascularized subjects have a significantly lower frequency of cardiac death than non-revascularized cases (15 vs 41%, $p < 0.05$). The frequency of death in those with low-dose scores ≥ 2.50 is very high in both revascularized (75%) and non-revascularized (56%, $p = 0.42$) cases.

Usefulness of rest and low-dose dobutamine wall motion scores in predicting survival and benefit from revascularization in patients with ischemic cardiomyopathy. Sawada SG, Lewis SJ, Foltz J, Ando A, Khouri S, Kaser S, Gradus-Pizlo I, Gill W, Fineberg N, Segar D, Feigenbaum H. Am J Cardiol 2002 Apr 1; 89 (7), pp. 811–6.

Functional Reserve: Cardiovascular/Global Ventricular Function/Tei Index
Dobutamine Stress Echocardiography

Cellular/Molecular Mechanism of Action: Dobutamine exerts adrenergic/sympathomimetic properties.

Background Information: Dobutamine stress echocardiography has become accepted as an evaluation modality for assessing cardiac functional reserve. Although the Doppler-derived index of combined systolic/diastolic myocardial performance (Tei index) has been reported to be easily obtainable and useful for predicting left ventricular performance, the effect of dobutamine on the Tei index has not been thoroughly established in children.

Application: Dobutamine can be applied in combination with diagnostic ultrasound to characterize various aspects of cardiac physiology (e.g., ventricular function).

Route of Administration: Dobutamine (infusion).

Dosage: Dobutamine (5 μg/kg/min).

Implementation: Assess the effect of dobutamine on the Tei index in cases of postoperative ventricular septal defect and Kawasaki disease. Echocardiographic recordings are obtained before and after dobutamine infusion. Variables measured include transmitral flow velocities (E, A, E/A), rate-corrected mean velocity of circumferential fiber shortening (rate-corrected Vcf), and IMP. Isovolumic contraction time (ICT), isovolumic relaxation time (IRT), and ejection time (ET) are measured and then applied to calculate the Tei index using the following formula: Tei index = (ICT + IRT)/ET.

Human Model: Postoperative ventricular septal defect (n = 8 cases); and cases of Kawasaki disease (n = 7).

Interpretation and Analysis: Dobutamine infusion increases rate-corrected Vcf (29%, $p < 0.01$), peak E (7%, $p < 0.05$), and peak A (13%, $p < 0.05$). E/A ratios do not change during dobutamine infusion. Ejection time, ICT, and IRT decrease during dobutamine infusion. The magnitude of the change in ICT (−21%, $p < 0.01$) is greater than those in IRT (−12%, $p < 0.01$) and ET (−8%, $p < 0.05$). The decrease in Tei index (−16%, $p < 0.01$) results in a decrease in ICT/ET (−21%, $p < 0.01$) and a slight decrease in IRT/ET (−12%, $p < 0.05$). The Tei index has the potential of functioning as a sensitive indicator of the effects of inotropic stimulation on global left ventricular function.

Effect of dobutamine on a Doppler echocardiographic index of combined systolic and diastolic performance. Harada K, Tamura M, Toyono M, Yasuoka K. Pediatr Cardiol 2002 Nov-Dec; 23 (6), pp. 613–7.

Hemodynamic Responses: Heart Rate and Systolic Blood Pressure/Cardiac Death: Independent Predictive Parameters
Adenosine/[Single Photon Emission Computed Tomography (SPECT)]

Physiological Mechanism of Action: Adenosine phosphate promotes relaxation of vascular smooth muscle and a negative chronotropic effect on cardiac function.
Application: Detection of hemodynamic responses to adenosine that add incremental prognostic value to myocardial perfusion single photon emission computed tomography imaging procedures.
Implementation: Evaluation of outcome in cases subjected to adenosine stress myocardial perfusion SPECT (without additional exercise). Multivariable Cox proportional hazards analysis can be used to assess the prognostic value of hemodynamic variables in predicting cardiac death (CD).

Human Model: Postevaluation cases of adenosine stress myocardial perfusion studies (MPS; n = 3444 cases; women = 53.5%; mean age 74 ± 8.4 years) during a 2 ± 0.8 year follow-up (monitoring) period.
Interpretation and Analysis: During an extended monitoring period of 2 ± 0.8 years, a relatively small percentage of cardiac deaths may be appreciated (e.g., n = 224/3444 or 6.5%). Review of multivariable analysis of various parameters reveals a higher resting heart rate (HR) and to a lesser extent lower peak HR as viable markers of impending CD. In addition, peak/rest HR ratio is an independent predictor of CD when added to the multivariable model in place of peak and rest heart rate. Peak/rest HR ratios can also be used to risk stratify cases within each MPS category. A significant interaction can be appreciated between gender and peak systolic blood pressure (SBP), in which there is an increased risk associated with a low peak systolic blood pressure (SBP < 90 mm Hg at end of adenosine infusion) in men but not in women. Cases undergoing adenosine stress MPS with high rest HR and low peak/rest HR ratio have an increased risk of CD, as do male cases with a low peak SBP measurement. Detection of the hemodynamic response to adenosine adds incremental prognostic value to MPS results and enhances identification of cases at risk for CD.

Prognostic impact of hemodynamic response to adenosine in patients older than age 55 years undergoing vasodilator stress myocardial perfusion study. Abidov A, Hachamovitch R, Hayes SW, Ng CK, Cohen I, Friedman JD, Germano G, Berman DS. Circulation 2003 Jun 17; 107 (23), pp. 2894–9.

Myocardial Dysfunction: Left Ventricular (Chronic)/ Ventricular Wall Motion Score Index (WMSI)
Glucose-Insulin-Potassium/Dobutamine/ [Echocardiography]

Background Information: Glucose-insulin-potassium (GIK) infusion improves cardiac function and outcome during acute ischemia.
Application: To determine whether GIK infusion benefits conditions of chronic ischemic left ventricular dysfunction, and if so whether this is related to qualitative and quantitative parameters pertaining to viable myocardium.
Route of Administration: Dobutamine (intravenous) and G-I-K (4-hour intravenous infusion).
Implementation: Dobutamine echocardiography combined with a 4-hour infusion of GIK. Segmental responses are quantified by improvement in WMSI and peak systolic velocity using tissue Doppler. Global responses are assessed by left ventricular volume and ejection fraction, measured using a 3-dimensional reconstruction. Myocardial perfusion is also determined using contrast echocardiography.

Human Model: Chronic ischemic left ventricular dysfunction (n = 30 cases).
Interpretation and Analysis: Ventricular WMSI (mean ± SD) improves with dobutamine (from 1.8 ± 0.4 to 1.6 ± 0.4, $p < 0.001$) and with GIK (from 1.8 ± 0.4 to 1.7 ± 0.4, $p < 0.001$); there is a similar increment for both. Improvement in wall motion score with GIK is observed in 55% of the 62 segments classed as viable by dobutamine echocardiography, and in 5% of 162 segments classed as non-viable. There is an increment in peak systolic velocity after both dobutamine echocardiography (from 2.5 ± 1.8 to 3.2 ± 2.2 cm/s, $p < 0.01$) and GIK (from 3.0 ± 1.6 to 3.5 ± 1.7 cm/s, $p < 0.001$). The GIK effects are not mediated by changes in pulse, mean arterial pressure, lactate, or catecholamines, nor do they correlate with myocardial perfusion. End systolic volume improves after GIK ($p = 0.03$), but only in cases that have a viable myocardium appreciated by dobutamine echocardiography. Therefore, for cases with viable myocardium and chronic left ventricular dysfunction, GIK improves wall motion score, myocardial velocity, and end systolic volume, independent of effects on hemodynamics or catecholamines. The response to GIK is observed in areas of normal and abnormal perfusion assessed by contrast echocardiography.

Effects of glucose-insulin-potassium infusion on chronic ischemic left ventricular dysfunction. Khoury VK, Haluska B, Prins J, Marwick TH. Heart 2003 Jan; 89 (1), pp. 61–5.

Myocardial Dysfunction: Left Ventricular (Doxorubicin)/Screening Test
Dobutamine (Low Dose)/[Echocardiography]

Cellular/Molecular Mechanism of Action: Dobutamine possesses adrenergic agonist/sympathomimetic properties.
Background Information: Late cardiotoxicity after anthracycline chemotherapy administered for childhood cancer is a well recognized sequelae. Many long-term survivors may have subclinical cardiac dysfunction undetectable at a baseline evaluation. Various tests have been utilized for the diagnosis of left ventricular impairment. Recently, low-dose dobutamine stress echocardiography has been proposed as a more sensitive screening test.
Application: Detections of alterations in myocardial dysfunction precipitated by doxorubicin-mediated injury.
Route of Administration: Dobutamine (intravenous).
Dosage: Dobutamine (5–10 μg/kg/min).
Implementation: Evaluation of low-dose dobutamine stress echocardiography in asymptomatic survivors.

Human Model: Cases treated with doxorubicin (e.g., n = 36; n = 20 male; n = 16 female aged 14.6 ± 4.7 years) administered a cumulative dose of 226 ± 106 mg/m^2 of doxorubicin. Note: Median follow-up 5 years. Reference control group (20 sex- and age-matched volunteers (n = 12 male; n = 8 female age = 12.6 ± 4.9 years).
Interpretation and Analysis: Significant differences can be appreciated in mean velocity of circumferential fiber shortening, myocardial performance index (Tei index), left ventricular posterior wall thickening, and end-systolic wall stress at a baseline. The stress response is significantly blunted only with regard to the following parameters: end-systolic wall stress, isovolumic relaxation time, and

myocardial performance index. The threshold response is abnormal (0–5% improvement of a variable only) in 45% of reference controls subjects for only 1 or 2 parameters. In contrast, 63% of subjects from case groups respond in a pathological manner (variable worsening) pertaining to 1 or more parameters. A correlation between risk factors of late cardiotoxicity and stress changes of left ventricular function parameters have not been appreciated. Low-dose dobutamine stress echocardiography therefore appears to be a safe and feasible diagnostic tool in children and adolescents. Dobutamine significantly increases the differences in cardiac variables between healthy populations and asymptomatic survivors for childhood cancer. Relative to control subjects, most asymptomatic patients reveal subclinical myocardial damage. The predictive value for the development of clinical symptoms and cardiac complications needs to be assessed in a large prospective study.

The evaluation of left ventricular function in childhood cancer survivors by pharmacological stress echocardiography. Elbl L, Hrstkova H, Chaloupka V, Novotny J, Michalek J. Neoplasma 2003; 50 (3), pp. 191–7.

Myocardial Infarction (Uncomplicated)/Prediction of Favorable Outcome and Risk Stratification/High Negative Predictive Value Assessment
Dobutamine/Electropharmacology/ [Echocardiography]

Cellular/Molecular Mechanism of Action: Dobutamine is an adrenergic agonist/sympathomimetic agent.
Background Information: Risk stratification after uncomplicated myocardial infarction is a major clinical problem. In particular, the prognostic value of residual inducible ischemia is still controversial.
Application: Exercise ECG and dobutamine stress echocardiography procedures can be utilized to prognostically evaluate uncomplicated myocardial infarction during the early postinfarction period.
Route of Administration: Dobutamine (intravenous).
Implementation: Evaluation of maximal exercise ECG tracings and dobutamine stress echocardiography within 10 days of an uncomplicated myocardial infarction in the absence of therapeutic intervention in concert with prospective monitoring over an 8.8 month period. The variables of age, sex, diabetes, smoking habit, hypertension, dyslipidaemia, infarct location, thrombolysis, and resting wall motion score index are taken into account as relevant clinical variables. Prognostic correlations are made versus spontaneous events (cardiac death, non-fatal reinfarction, and unstable angina requiring hospitalization) while cases undergo revascularization procedures (e.g. percutaneous transluminal coronary angioplasty or coronary artery bypass surgery).

Human Model: Cases of an uncomplicated myocardial infarction (off therapy) and prospectively monitored for 8.8 months ($n = 406$ with $n = 53$ females; aged 57 ± 9 years).
Interpretation and Analysis: A relatively high number of events usually occur during the monitoring period (e.g., $n = 127$; $n = 41$ or 10% spontaneous [5 deaths; 12 reinfarctions; 24 unstable angina]; $n = 86$ procedural related [27 angioplasty; 59 bypass surgery]). Spontaneous events cannot be predicted by any clinical, exercise ECG, or dobutamine stress echocardiography variable. However, the negative predictive value of both tests is excellent (91% and 90%, respectively). With multivariate Cox analysis, male gender, positive low-workload (< 100 W) exercise ECG ($p < 0.0001$), positive low-dose dobutamine stress echocardiography ($p < 0.0001$), and rest-stress wall motion score index variation ($p < 0.001$) are capable of predicting cumulative cardiac events with an independent and additive value.

Model: Dobutamine stress echocardiography is significantly more sensitive (p , 0.05) and less specific (p , 0.01) in predicting the outcome of cases with anterior infarction, while exercise ECG is significantly more sensitive (p , 0.05) in cases with non-Q wave infarction. The most valuable concepts related to these observations include (i) spontaneous events are poorly predicted by provocative tests in low-risk cases after uncomplicated myocardial infarction; (ii) however, both exercise ECG and dobutamine stress echocardiography can predict a favorable outcome with a very high negative predictive value; (iii) dobutamine stress echocardiography should be considered a secondary option in cases where the exercise ECG is equivocal or when the location of ischemia is a relevant issue; and (iv) the possibility that the 2 tests have a differential utility depending on the infarct location and type (Q wave vs non-Q wave) may be clinically relevant and deserves further evaluation.

Prognostic value of residual ischemia assessed by exercise electrocardiography and dobutamine stress echocardiography in low-risk patients following acute myocardial infarction. Bigi R, Galati A, Curti G, Coletta C, Barlera S, Partesana N, Bordi L, Ceci V, Occhi G, Fiorentini C. Eur Heart J 1997 Dec; 18 (12), pp. 1873–81.

Myocardial Ishchemia: Functional Markers/ Hypokinesia, Akinesia, or Dyskinesia
Dobutamine/[Magnetic Resonance Imaging (MRI)]

Cellular/Molecular Mechanism of Action: Dobutamine is an adrenergic agonist/sympathomimetic pharmaceutical agent.
Application: Detection or exclusion of myocardial ischemia and viability in cases with suspected coronary artery disease.
Dosage: Dobutamine (increasing doses of 10, 20, 30, and 40 μg/kg/min).
Implementation: Assessment of the clinical applicability of DS-MRI for the detection of myocardial ischemia and myocardial viability. Three left ventricular short-axis planes are examined for occurrence of disorders in wall movement during infusion of increasing larger doses of dobutamine (10, 20, 30, and 40 μg/kg/min). Temporary recovery of wall thickening in a previously diminished or non-contracting segment under 5 μg/kg/min of dobutamine is considered proof of viability. Development of hypokinesia, akinesia, or dyskinesia at higher doses of dobutamine serves as an indicator of ischemia. If the DS-MRI test is positive for ischemia, then coronary angiography is performed. Such evaluations, if indicated, are subsequently subjected to revascularization. If DS-MRI does not reveal ischemia, then cases may be monitored on an outpatient basis.

Human Model: Cases of suspected coronary artery disease subjected to breath-hold DS-MRI (1 Tesla) 4 days after cessation of anti-ischemic medication that can not be studied by means of conventional bicycle ergometry.

Human Model: Cases of suspected coronary artery disease ($n = 100$; $n = 62$ men; $n = 38$ female; mean age $= 62$ years $\pm$ 12). All cases with non-ischemic DS-MRI scans (e.g., $n = 53$) are followed up for 11 to 23 months (mean 17 months). One case expired suddenly 2 weeks after the MRI test. Other cases may not experience any coronary events or sudden cardiac death (e.g., $n = 52/100$).
Interpretation and Analysis: A high percentage of cases subjected to DS-MRI will yield diagnostic information ($n = 95/100$ or 95%). In cases with DS-MRI scans considered positive for ischemia and in which coronary angiography is subsequently performed, essentially all affected individuals have coronary abnormalities that

suggest revascularization is necessary (n = 41/42; n = 1 false positive). The predictive value of a positive DS-MRI scan for ischemia is 98% and the predictive value of a negative DS-MRI scan is also 98%. DS-MRI is a safe diagnostic method for the detection or exclusion of myocardial ischemia and viability in cases with suspected coronary artery disease.

Dobutamine stress magnetic resonance imaging (DS-MRI), a valuable tool for the diagnosis of ischemic heart disease. van Dijkman PR, Kuijpers TJ, Blom BM, van Herpen G. Ned Tijdschr Geneeskd 2002 Jul 13; 146 (28), pp. 1327–32.

Myocardial Ischemia: Cardiomyopathy (Ischemic)/ Diabetes Mellitus
Acipimox/[^{18}F]-FDG Single Photon Emission Computed Tomography (SPECT)

Cellular/Molecular Mechanism of Action: The agent [^{18}F]-FDG functions as an analog of glucose. Acipimox is a nicotinic acid derivative.
Application: Evaluation of differences in glucose metabolism using [^{18}F]-FDG. Acipimox utilized in combination with [^{18}F]-FDG SPECT metabolic imaging can be used to assess conditions of ischemic cardiomyopathy even in cases suffering from diabetes mellitus.
Implementation: Evaluation of ischemic cardiomyopathy cases applying [^{18}F]-FDG SPECT imaging analysis in combination with acipimox to assess myocardial viability. Complementary image analysis involves performing resting 2-dimensional echocardiography in an effort to identify dysfunctional myocardial tissues. Image quality is then scored visually and quantitatively, while the myocardium-to-background ratio is determined by region-of-interest analysis. The plasma concentrations of glucose and free fatty acids are determined to evaluate metabolic status before and during [^{18}F]-FDG imaging.

Human Model: Ischemic cardiomyopathy (n = 70; n = 34/70 diabetes mellitus; n = 12/34 insulin-dependent diabetes mellitus; n = 22/34 non-insulin-dependent diabetes mellitus; n = 36/70 non-diabetic).
Interpretation and Analysis: Acipimox significantly lowers plasma levels of free fatty acids in both categories of case type. Approximately 50% of diabetic cases (e.g., n = 15/34) have plasma glucose levels of > 9 mmol/L, which is lowered successfully in essentially all cases when administered additional insulin. Visual evaluation of [^{18}F]-FDG images reveals variable quality in cases with either diabetes (good n = 27/34; moderate n = 5/34; poor n = 2/34; p = ns) or individuals without diabetes (non-diabetic: good n 32/34; moderate n = 4/34; poor n = 0/34; p = ns). The myocardium-to-background ratio of [^{18}F]-FDG SPECT images is comparable in cases with and without diabetes mellitus (3.1 ± 1 vs 3.5 ± 0.9; p = ns). The type of diabetes has no influence on [^{18}F]-FDG image quality. Note: Severe side effects usually are not appreciated with [^{18}F]-FDG SPECT procedures. [^{18}F]-FDG SPECT metabolic imaging after acipimox appears to be safe and practical for routine assessment of viability in cases with ischemic cardiomyopathy. Image quality is good, even in patients with diabetes, although additional insulin is sometimes needed.

Effect of diabetes mellitus on myocardial 18F-FDG SPECT using acipimox for the assessment of myocardial viability. Schinkel AF, Bax JJ, Valkema R, Elhendy A, van Domburg RT, Vourvouri EC, Bountioukos MA, Krenning EP, Roelandt JR, Poldermans D. J Nucl Med 2003 Jun; 44 (6), pp. 877–83.

Myocardial Ischemia
Dipyridamole/[^{99m}Tc]-SestaMIBI/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Dipyridamole influences the metabolism and transport of adenosine and adenosine nucleotides. In this context, dipyridamole, a nucleotide transport blocker, suppresses the intracellular infux of adenosine released from myocardial tissues that have been deprived of adequate oxygen. Dipyridamole also induces the release of hydrogen peroxide and chemotactic factors from peripheral blood leukocyte populations.
Physiological Mechanism of Action: Dipyridamole promotes diminished coronary artery vascular resistance, increased coronary artery vasodilation, elevated coronary artery blood flow, and increased coronary artery oxygen delivery. One of the most prominent influences of dipyridamole in this regard is its effect on small-diameter vascular beds supplied by the coronary artery. However, it has a minimal effect in regions of ischemia since these same vessels tend to already be maximally dilated.
Application: Dipyridamole can be applied to characterize conditions of angina pectoris either in stress tests or during the course of performing advanced forms of imaging analysis.
Considerations: Radionuclide myocardial perfusion imaging has been shown to have favorable diagnostic and prognostic value in this setting. Early sensitivity is excellent for the detection of acute myocardial infarction not achieved by other diagnostic/testing modalities.
Route of Administration: Intravenous.
Interpretation and Analysis: Elevation in plasma leukocyte chemotactic factors correspond with positive imaging results obtained with the application of [^{99m}Tc]-sestaMIBI. Sensitivity for detecting early acute myocardial infarction (MI) has been superior to findings achieved with other testing modalities based on the validation of findings applying [^{99m}Tc]-sestaMIBI scintigraphy.
Instrumentation: Boyden leukocyte chemotactic chamber and nuclear medicine scintigraphy imaging instrumentation.
Toxicity: Relatively low but includes peripheral vascular hypotension, nausea, vomiting, diarrhea.

Myocardial Perfusion Assessment
Dipyridamole/[^{201}Thallium] Single Photon Emission Computed Tomography (SPECT)/[Nuclear Scintigraphy]

Cellular/Molecular Mechanism of Action: Dipyridamole is classified as a adenosine nucleotide trasport blocker whereby it prevents adenosine influx into myocardial cells.
Application: Detection and characterization of myocardial ischemia.
Route of Administration: Dipyridamole (slow IV).
Dosage: Dipyridamole.
Considerations: A dipyridamole stress test might be considered appropriate as a provocative test when physical exercise cannot be carried out.
Implementation: Evaluate the diagnostic capability of SPECT to detect diseased coronary vessels utilizing dipyridamole in concert with [^{201}thallium]/SPECT imaging.

Assessment of myocardial infusion (+ maximal ergometric exercise) can be facilitated by infusion of dipyridamole in concert with myocardial imaging techniques employing [^{201}thallium]/SPECT. To evaluate the diagnostic capability of SPECT in the detection of

diseased coronary vessels, the left ventricular myocardium can be subdivided into 6 segments related to the 3 major coronary arteries. Images using SPECT are acquired after dipyridamole infusion (Methodology Type 1 with n = 41 cases) or after tracer injections at maximal ergometric exercise (Methodology Type 2 with n = 162 cases). Based on findings from [^{201}Tl] and dipyridamole evaluations, cases are then subdivided into 2 groups for diagnostic coronary angiography.

Human Model: Cases suffering from cardiovascular disease involving the coronary artery(n = 203).

Interpretation and Analysis: Sensitivity for characterizing the left anterior descending artery is 77% with Methodology Type 1 and 79% for Methodology Type II; while specificity is 80% and 96%, respectively. Sensitivity for the right coronary artery is 91% with Method 1 and 85% with Method 2; while specificity is 81% and 73%. For the left circumflex artery sensitivity is 65% with Method 1 and 67% for Method 2, while specificity is 89% and 88%, respectively. Myocardial SPECT results after ergometric exercise and dipyridamole infusion turned out to be almost superimposable (identical).

Diagnostic accuracy of single photon emission computed tomography with thallium-201 for the identification of diseased coronary arteries. Comparison between dipyridamole infusion and exercise stress test. Dondi M, Monetti N, Levorato M, Corbelli C, Zagni P, Tartagni F, Maiello L, Fallani F, Ortolani P. J Nucl Med Allied Sci 1990 Jan-Mar; 34 (1), pp. 19–23.

Myocardial Perfusion/Microvascular Permeability/ Renal Hypertension/Hypercholesterolemia Model *Dobutamine/Adenosine/[Computed Tomography]*

Cellular/Molecular Mechanism of Action: Explanations have been provided for review in a previous citation entry for the molecular and physiological mechanisms of actions for adenosine and dobutamine (adrenoreceptor agonist/sympathomimetic agent).

Physiological Mechanism of Action: Adenosine phosphate promotes relaxation of vascular smooth muscle and exerts a negative chronotropic effect on the heart.

Background Information: Hypercholesterolemia (HC) and hypertension (HT) are both major risk factors for the development and progression of atherosclerotic heart disease. Simultaneous occurrence of both conditions has been associated with an increased incidence of cardiac events in clinical studies. Hypercholesterolemia and HT are individually associated with abnormal myocardial vascular function, but whether HT exacerbates HC-induced myocardial vascular dysfunction remains uncertain.

Application: Evaluation of myocardial perfusion and microvascular permeability.

Route of Administration: Adenosine (intravenous) and dobutamine (intravenous).

Implementation: Evaluation of myocardial perfusion and microvascular permeability *in vivo* applying electron-beam computed tomography in response to cardiac challenge with adenosine and dobutamine administration. The involvement of systemic and myocardial tissue oxidative stress *in vitro* is assessed by oxidizability of LDL, levels of endogenous antioxidants, and tissue activity levels of radical-scavenger systems.

Animal Model: Swine (dietary hypercholesterolemia and renovascular hypertension).

Interpretation and Analysis: While in normal control *in vivo* models myocardial perfusion increases in response to adenosine (+36 ± 13%, $p < 0.05$), in HC and HT alone the increase is blunted. In HC + HT myocardial perfusion response is further attenuated and significantly lower than normal, while myocardial vascular resistance fails to decrease (+7.6 ± 8.8 vs −21 ± 5.8%, p = 0.02 vs normal). HC + HT also show a blunted response to dobutamine, and augmented *in vivo* increases in microvascular permeability. These functional abnormalities are associated with increases in systemic and myocardial tissue oxidative stress compared to HC or HT alone, and synergistic decreases in endogenous antioxidant defenses in myocardial tissue. Furthermore, chronic antioxidant vitamin supplementation in combined HC and HT improves myocardial vascular responses. Hypertension amplifies hypercholesterolemia-induced myocardial microvascular dysfunction hypercholesterolemia *in vivo* and increases oxidative stress *in vitro*. These alterations may potentially play a role in the increased incidence of cardiac events observed when HC and HT co-exist.

Hypertension exacerbates the effect of hypercholesterolemia on the myocardial microvasculature. Rodriguez-Porcel M, Lerman A, Herrmann J, Schwartz RS, Sawamura T, Condorelli M, Napoli C, Lerman LO. Cardiovasc Res 2003 Apr 1; 58 (1), pp. 213–21.

Myocardial Perfusion: Kawasaki Disease (KD)/ Regional Hypoperfusion *Dipyridamole/[^{99m}Tc]-Tetrofosmin/[Nuclear Scintigraphy]*

Cellular/Molecular Mechanism of Action: Dipyridamole is classified as a adenosine nucleotide transport blocker whereby it prevents adenosine influx into myocardial cells.

Physiological Mechanism of Action: Dipyridamole promotes vasodilator activity.

Background Information: The coronary artery abnormalities in KD often cause myocardial ischemia. The radionuclide [^{201}thallium] has been applied for the purpose of imaging myocardial perfusion in order to determine the extent of ischemia in KD cases. The technetium perfusion agents offer better resolution and may offer additional information about ventricular function in KD conditions.

Application: Tetrofosmin myocardial perfusion imaging can detect regional areas of myocardial hypoperfusion (e.g., Kawasaki disease of children).

Dosage: Dipyridamole (high-dose = 0.70 mg/kg); [^{99m}technetium]-tetrofosmin (first dose = 74 to 370 MBq; second dose = 148 to 740 MBq).

Implementation: Evaluation of myocardial perfusion in cases of KD applying [^{99m}technetium]-tetrofosmin (TF) in conjunction with performing a dipyridamole vasodilator stress test. Significant coronary artery stenosis is classified as being ≥ a 75% reduction in lumen diameter. After the administration of high-dose dipyridamole by infusion, [^{99m}Tc]-tetrofosmin is injected followed by as second [^{99m}Tc]-tetrofosmin injection at rest 4 hours later. Single photon emission computed tomography (SPECT) images are then obtained more than 30 minutes after TF injection.

Human Model: Kawasaki disease (n = 86 cases 11.5 ± 6.4 years; n = 20 age-matched controls without heart disease).

Interpretation and Analysis: Significant coronary artery stenosis, coronary aneurysm without stenosis, and an absence of coronary lesions can be appreciated in a moderate number of cases (e.g., n = 20/86, n = 37/86, and n = 29/86, respectively). Regional myocardial hypoperfusion can be observed in a number of cases that have coronary artery stenosis of 75% or greater (n = 18/86; sensitivity, 90%, and specificity, 100%). A small percentage of cases do not demonstrate ischemic changes in the presence of coronary artery stenosis (n = 2) and some of these cases have good collateral flow (n = 1 of 2).

Myocardial ischemia in Kawasaki disease: Evaluation with dipyridamole stress technetium 99m tetrofosmin scintigraphy. Fukuda T, Ishibashi M, Yokoyama T, Otaki M, Shinohara T, Nakamura Y, Miyake T, Kudoh T, Oku H. J Nucl Cardiol 2002 Nov-Dec; 9 (6), pp. 632–7.

Ventricular (Myocardial) Function *Dobutamine/Nitroglycerin/[Echocardiography]*

Cellular/Molecular Mechanism of Action: Dobutamine is an adrenergic agonist/sympathomimetic agent.
Physiological Mechanism of Action: Nitroglycerin exerts vasodilatory properties.
Background Information: Dobutamine-inducible left ventricular obstruction lacks sound clinical meaning. The phenomenon may be related to an abnormal response of the heart to sympathetic stimulation. Head-up tilt can elicit intraventricular obstruction in cases known to develop such responses during dobutamine administration, through the synergistic effects of reduced preload, hypercontractility, and reflex increases in cardiac sympathetic tone.
Application: Dobutamine echocardiography analyses for the evaluation of ventricular function.
Route of Administration: Dobutamine (infusion), and nitroglycerin (infusion).
Dosage: Dobutamine and nitroglycerin (0.3 mcg/kg/min).
Implementation: Evaluation of dobutamine stress echocardiography and 60-degrees head-up tilt on echocardiographic and electrocardiographic monitoring in drug-free and during nitroglycerin infusion (0.3 mcg/kg/min) protocols. Doppler echocardiographic measurements of left ventricular diameters, function, and outflow tract flow velocity are acquired in addition to assessment of power heart rate variability analyzed on short electrocardiographic recordings (low-/high-frequency ratio). In addition, plasma catecholamines can be determined at baseline and during tilt maneuvers.

Human Model: Normal coronaries (n = 21; of which n = 12 cases with left ventricular obstruction during dobutamine stress echocardiography [n = 7/12 males, aged 61 ± 7 years]; n = 9 failed to develop complications [n = 3 males, aged 60 ± 9 years]).
Interpretation and Analysis: Intraventricular obstruction does not develop in group 1 type cases. Baseline differences can be appreciated in ventricular dimensions and mitral early-to-late velocity ratios between case group types 1 and 2 in contrast to hemodynamic patterns during either tilt maneuver which appear to be very similar Low/high frequency ratios, that are similar at baseline and similarly increased with the head-up tilt test, conversely increase significantly less in nitroglycerin-tilt tests for group 1 type cases. Differences in plasma catecholamine concentrations can usually not be appreciated. In summary, reflex cardiovascular adaptive responses such as those elicited by passive tilt are not involved in dynamic intraventricular obstruction in cases with dobutamine-inducible obstruction, and data indicates that left ventricular geometry and hypercontractility are not sufficient pathophysiological determinants.

Dobutamine-inducible left ventricular obstruction: Head-up tilt and autonomic balance. Barletta G. Int J Cardiol 2003 Feb; 87 (2–3), pp. 245–52.

Ventricular Wall Motion: Post–Heart Transplant/ Myocardial Contractile Response *Dipyridamole/[Echocardiography]*

Background Information: Coronary allograft vasculopathy (CAV) remains a major factor limiting long-term survival after heart transplantation. The diagnosis of CAV is still based on serial coronary angiography imaging.
Application: Evaluation of CAV applied in combination with echocardiography image analysis. Dipyridamole echocardiography is a simple, non-invasive test that after heart transplantation may identify cases with altered wall motion that require stricter surveillance.
Dosage: Dipyridamole (high-dose).
Implementation: Evaluation of the prognostic value of high-dose dipyridamole echocardiography in heart transplant cases. Coronary allograft vasculopathy is defined as CAV 1 (focal or diffuse stenosis $< 50\%$) or CAV 2 (focal or diffuse stenosis $\geq 50\%$). Wall motion score index (WMSI) is evaluated at rest and after dipyridamole challenge.

Human Model: Cases 48 hours prior to scheduled annual coronary angiography (n = 68 cases).
Interpretation and Analysis: Results of coronary angiography imaging are normal in a large number of cases (n = 43/68 or 63%), approximately 16% show CAV 1 (n = 11/68), and CAV 2 can be appreciated in about 21% of cases (e.g., n = 14/68). Similary, resting wall motion is normal in a large percentage of cases (n = 39/68 normal; n = 29/68 abnormal). Following dipyridamole administration, wall motion remains unchanged in normal cases (e.g., n = 39/39; Group 1, no CAV in n = 34, and CAV 1 in n = 5). In cases with resting wall motion abnormalities (e.g., n = 29), dipyridamole creates no changes or worsening in most instances (e.g., n = 21/29; Group 3, CAV 2 in n = 14, and no CAV or CAV 1 in n = 7), but can reverse conditions to normal in a modest number of cases (n = 8/29; Group 2, no CAV in n = 7 and CAV 1 in n = 1). During a 6-year (± 3 years) monitoring period, a large number of cases will experience a major cardiac event (n = 15; n = 11 Group 3; n = 4 Groups 1 and 2). Wall motion at rest and after dipyridamole administration and CAV are independent predictors for cardiac events; only dipyridamole WMSI > 1 remains significant ($p < 0.0001$) when evaluated using multivariate analysis.

Prognostic value of contractile response during high-dose dipyridamole echocardiography test in heart transplant recipients. Ciliberto GR, Parodi O, Cataldo G, Mangiavacchi M, Alberti A, Parolini M, Frigerio M. J Heart Lung Transplant 2003 May; 22 (5), pp. 526–32.

Vasodilation Response: Pharmaceutical-Mediated *Nitroglycerin/[Ultrasound]*

Physiological Mechanism of Action: Nitroglycerin promotes vasodilatory/venodilation properties with venodilation most predominant at lower dosages.
Application: Provocative pharmaceutical challenge for enhancing the diagnostic accuracy of echocardiography procedures.
Route of Administration: Nitroglycerin (multiple).
Dosage: Nitroglycerin.
Implementation: Investigate the effects of non-ECG-triggered imaging during ultrasound studies assessing endothelial function. Brachial artery diameters are measured throughout the cardiac cycle at rest, during reactive hyperemia, and after nitroglycerin administration. R wave-triggered imaging using a 7.5 MHz ultrasound transducer can be utilize with image acquisition every 41.7–66.7 ms. Cardiac cycle-related variation is computed as the maximum percent change from the end-diastolic diameter. The range of possible errors in flow-mediated dilation (FMD) and nitroglycerin-mediated vasodilation that may result from ignoring cyclic variations in diameter are then determined for each condition.

Human Model: n = 24 subjects.
Interpretation and Analysis: True FMD, true nitroglycerin-mediated vasodilation, and the maximum and minimum values that

can be erroneously calculated for FMD if timing is ignored all differ dramatically ($p < 0.05$). The range of apparent FMD values that can be measured is nearly 3 times the true FMD value. Ignoring temporal position within the cardiac cycle artifactually increases calculated FMD into the normal range, despite the presence of truly impaired FMD. Peak arterial dilation occurs before end-systole and greater baseline vessel compliance is associated with greater FMD. Brachial artery diameters vary significantly throughout the cardiac cycle. The magnitude of this variation is similar to the arterial dilation induced by reactive hyperemia and nitroglycerin, making ECG-triggered imaging mandatory for acquiring accurate and reproducible clinical and research measurements of artery diameters and FMD. Measurement of diameters at end-diastole may be preferred to other time points in the cardiac cycle.

Instrumentation: 7.5 MHz ultrasound transducer.

Effect of cardiac cycle on ultrasound assessment of endothelial function. Chuang ML, Douglas PS, Bisinov EA, Stein JH. Vasc Med 2002 May; 7 (2), pp. 103–8.

2 Central Nervous System

AUTONOMIC NERVOUS SYSTEM

Dynamic Time-Frequency Analysis of the Autonomic Nervous System
Sodium Amobarbitol/Wada Test

Background Information: Recently, time-frequency analysis has become very popular for examining non-stationary time series and for researching fast-changing phenomena.
Application: Utilized in performing the Wada test which involves the (selective) injection of sodium amobarbitol into the internal carotid artery resulting in the inactivation of cerebral structures supplied by the ipsilateral anterior and middle cerebral arteries. The intra-carotid instillation of amobarbital can be combined with electrocardiographic analyses (electrocardiopharmacology test).
Route of Administration: Amobarbitol (catheter instillation into the internal carotid artery).
Implementation: Utilization of a smoothed-pseudo Wigner-Ville distribution to model the underlying dynamic autonomic nervous system changes that occur during the intracarotid sodium amobarbital (ISA Wada test). Electrocardiogram (EKG) data are recorded during the entire procedure and 10 minutes prior to each injection which are used as baseline values for that hemisphere. Interbeat-interval time series are created from such data for further analyses (smoothed-pseudo Wigner-Ville distribution to model).
Human Model: 13-year-old patient.
Interpretation and Analysis: Evaluations of data generated in the fashion described reveals that sodium amobarbitol injection to either side of the brain produces decreased power in the vagally mediated high frequency band (.14-.40 Hz). Importantly, the decrease is greater when the right hemisphere is inactivated compared to the left side. Such results are consistent with the known lateralized innervation of the heart such that right-sided autonomic inputs have greater influence on cardiac chronotropy. Very rapid changes in autonomic control occur that characterize the inactivation and subsequent recovery of the cerebral hemispheres and serve to confirm the utility of time-frequency analysis in the investigation of cardiac time series.

Time frequency analysis of the cardiovascular response during the intracarotid amobarbital test. Sollers JJ 3rd, Ahern GL, Merritt MM, Thayer JF. Biomed Sci Instrum 2002; 38, pp. 267–71.

Ileus: Postoperative/Myasthenia Gravis
Neostigmine

Cellular/Molecular Mechanism of Action: Inhibits the biochemical activity of acetylecholine esterase, resulting in accumulation of acetylcholine neutrotransmitter. As a result, there is an elevated level of parasympathetic activity within the autonomic nervous system.
Diagnostic Application: (i) verification of the presence of normal gastrointestinal function in conditions of postoperative and pain-induced ileus. (ii) diagnostic detection of myasthenia gravis conditions.
Route of Administration and Dosage: Subcutaneous injection usually preferred.
Considerations: Rapid intravenous injection can promote spastic (painful) contractions of gastrointestinal smooth muscle. Administration in cases suffering from myasthenia gravis can exacerbate the severity of the condition through depletion of axonal acetylcholine stores.
Interpretation and Analysis: Alleviation of gastrointestinal ileus based upon detection of auscultatable borborygmi, palpable contractions, and visualization of fecal production. Myasthenia gravis cases will temporarily demonstrate an improvement in generalized motor function and a reduction in the severity of apparent paresis.

Ileus: Reversible (Postoperative):
Adenosine Receptor Antagonist Ligands
FK352/DPCPX

Cellular/Molecular Mechanism of Action: (R)-1-[(E)-3-(2-phenylpyrazolo[1,5-a]pyridin-3-yl) acryloyl]-piperidin-2-yl acetic acid (FK352) and 8-cyclopentyl-1, 3-dipropylxanthine (DPCPX) function as adenosine A_1 receptor antagonists.
Physiological Mechanism of Action: Reversal of declines in large intestine motility.
Application: Diagnostic interpretation of postoperative ileus or hypomotility related to pain.
Implemenation: Evaluation of colonic propulsive motility as a function of dye migration following injection into the lumen of the colon. Relevant experimental stimuli include pentobarbital anesthesia or surgical trauma (partial gastrectomy, cecectomy, or gentle touching of the colon with fingers).
Animal Model: Rat (unrestrained).
Interpretation and Analysis: Propulsive motility significantly decreases after anesthesia or partial gastrectomy. Intravenous administration of either (R)-1-[(E)-3-(2-phenylpyrazolo[1,5-a]pyridin-3-yl) acryloyl]-piperidin-2-yl acetic acid (FK352) or 8-cyclopentyl-1, 3-dipropylxanthine (DPCPX) function as adenosine A_1 receptor antagonists and reverse the slowing of colonic propulsion activity in experimental ileus models. Blockade of adenosine A_1 receptors therefore has both diagnostic benefits for assessing the integrity of parasympathetic regulation of gastrointestinal motility, and intestinal smooth muscle function relevant to conditions including post-operative ileus. Adenosine A_1 receptor blockade also has several potential therapeutic applications.

Adenosine A1 receptor blockade reverses experimental postoperative ileus in rat colon. Kadowaki M, Nagakura Y, Tokita K, Hanaoka K, Tomoi M. Eur J Pharmacol 2003 Jan 1; 458 (1–2), pp. 197–200.

Sympathetic Nervous System/Reflex Sympathetic Dystrophy: Cocaine-Induced Reflex
Phentolamine

Cellular/Molecular Mechanism of Action: Phentolamine (α-adrenergic blocker).
Physiological Mechanism of Action: Cocaine (vasoconstrictor activity); phentolamine (vasodilator activity).
Background Information: Reflex sympathetic dystrophy (RSD) usually follows traumatic injuries or neurologic disorders.

Human Model: Rare cases of RSD following intra-arterial administration of cocaine in the presence of a history of intravenous drug abuse. An example of a representative case includes cocaine self-administered inadvertently into the femoral artery rather than into the femoral vein.
Interpretation and Analysis: Despite the intense pain, swelling, and dermatologic changes that can accompany intra-arterial carotid cocaine injection, a diagnosis of RSD should be validated by scintigraphic imaging. A combination of normal radiographic finding, a normal leukocyte study, and abnormal bone scan lesions in the region of tenderness and swelling serve to exclude other possibilities and suggest a diagnosis of RSD. In some conditions of RSD, the disorder is likely caused by an ischemic autonomic injury induced by the vasoconstrictor activity of cocaine. Clinical follow-up and relief using phentolamine, an α-adrenergic blocker and vasodilator, make the diagnosis of RSD most likely.

Cocaine-induced reflex sympathetic dystrophy. Gay D, Singh A. Clin Nucl Med 2000 Nov; 25 (11), pp. 863–5.

PERIPHERAL NERVOUS SYSTEM AND NEUROMUSCULAR FUNCTION

Neurologic vs Musculoskeletal Differentiation
Lidocaine/Mepivicaine/Bupivicaine

Cellular/Molecular Mechanism of Action: Inhibits axonal membrane-associated Na^+/K^+ pump activity, thereby diminishing the rate or completely preventing transmission of neurologic impulses.
Diagnostic Application: Localization of sites of musculoskeletal pain associated with bone and joint structures. In instances where the origin of pain is uncertain (e.g. veterinary medicine), then injections of local anesthetic are initially injected at the most distal regions of a limb with progressively more proximal injections made until the painful foci is desensitized. Local peripheral nerve blocks can also be applied to differentiate musculoskeletal pain from neurologic deficit/disorders.

Localization of pain to specific anatomical foci or regions improves the accuracy of detecting pathological lesions and facilitates more efficient if not accurate radiographic examinations. The procedure is of particular applicability in lameness examinations performed in veterinary medicine (e.g., equine gait abnormalities).
Route of Administration and Dosage: Local injection either intra-articular or in a juxta-position along peripheral nerves.
Considerations: Lidocaine has an onset of action of approximately 5 minutes with a duration of action that approaches 30 to 45 minutes. Mepivicaine (Carbocaine) has a slightly longer onset of action and a duration of activity lasting approximately 45 to 60 minutes. Bupivicaine (Marcaine) has the longest onset of action and the longest duration of activity; on average it can last between 3 and 4 hours.

Onset of action and duration of activity are inversely related and are dependent upon the individual diffusion characteristics of each local anesthetic agent across axonal membrane structures. Duration of activity can be enhanced with preparations containing epinephrine that promote vasoconstriction which inhibits diffusion away from the site of local injection. Dextrose has also been included in preparations of local anesthetic agents to increase their osmotic characteristics and promote accumulation of tissue fluid at the site of injection, thereby inhibiting diffusion of local anesthetic agent away from the site of injection.
Implementation: Injection of a local anesthetic agent in joint structures or in a juxta-position along peripheral nerves that directly correspond to anatomical regions suspected of being a source of pain.

Clinical Example: Evaluation of confirmed cases of osteoarthrosis (osteoarthritis, OA) of the hip and spine with concomitant lower extremity pain below the knee that is coxalgic or neuropathic. One approach to determining if leg symptoms are coxalgic or neuropathic can involve the administration of Bupivicaine by intra-articular injection into the hip as a provocative test.

Human Model: Cases with roentgenographically proven osteoarthrosis (osteoarthritis, OA) of the hip and spine (e.g. n = 18 consecutive patients).

Interpretation: Alleviation of pain or signs of abnormal locomotion or gait which directly corresponds to the anatomical site of anesthetic agent injection (e.g., intra-articular or peripheral nerve branch). In the clinical example provided pertaining to osteoarthritis lesions affecting the hip and spine, such tests allow correct identification of the source of the pain with a sensitivity of 87%, a specificity of 100%, and an efficiency of 88%. A provocative test of this nature provides significant savings in terms of diagnostic tests and patient discomfort.

The value of bupivicaine hip injection in the differentiation of coxarthrosis from lower extremity neuropathy. Kleiner JB; Thorne RP; Curd JG. J Rheumatol] 1991 Mar; Vol. 18 (3), pp. 422-7.

Neuromuscular Disorder: Botulinum Neurotoxins: Type A/[Botulinum Neurotoxins B and E]/[Tetanus Toxin]/[Myasthenia Gravis]
3,4-Diaminopyridine/4-Aminopyridine

Cellular/Molecular Mechanism of Action: Both 3,4-diaminopyridine (3,4-DAP) and 4-aminopyridine function as A-type K^+ channel blockers.
Diagnostic Application: Partial or substantial response appreciated in cases of botulism intoxication caused by *Clostridium botulinum* exotoxin.
Application: Detection, characterization, and differentiation of neuromuscular disorders due to botulinum neurotoxin types A, B, and E, in addition to tetanus toxin.
Implementation: Evaluation of the potential for 4-aminopyridine and 3,4-diaminopyridine to delay the onset of paralysis due to botulinum neurotoxin types A, B, and E. Complementary investigations can involve evaluation of the potential for 3,4-diaminopyridine to reverse paralysis due to botulinum toxin using phrenic nerve-hemidiaphragm *ex vivo* preparations previously poisoned *in vivo*. Analogous types of experiments can be done using tetanus toxin.

Animal Model: Murine (mouse excised phrenic nerve-hemidiaphragm preparations).
Interpretation and Analysis: At a concentration that produces enhancement of muscle twitch amplitude, 4-aminopyridine and 3,4-diaminopyridine delay the onset of paralysis due to botulinum toxin type A. Under the same conditions, the drugs do little to protect tissues against botulinum toxin types B and E. The agent 3,4-diaminopyridine produces transient increases in neuromuscular transmission, with the

"reversal" effect being greater for botulinum neurotoxin type A than for botulinum neurotoxin types B and E. Results with 3,4-diaminopyridine show that tetanus toxin resembles botulinum toxins type B and E. Such findings clarify the role of aminopyridines as potential diagnostic/therapeutic agents in the treatment of botulism. They also provide insights into the mechanism of action of clostridial neurotoxins.

A preclinical evaluation of aminopyridines as putative therapeutic agents in the treatment of botulism. Simpson LL. Infect Immun 1986 Jun; 52 (3), pp. 858–62.

Neuromuscular Disorders/Lambert-Eaton Myasthenic Syndrome/Botulism
4-Aminopyridine/Neostigmine/[d-Tubocurarine]

Cellular/Molecular Mechanism of Action: Neostigmine inhibits the biochemical activity of acetylecholine esterase. D-tubocurarine competitively inhibits binding of acetylcholine to its corresponding receptor complex.
Application: Classification and characterization of presynaptic disorders, including Lambert-Eaton myasthenic syndrome and botulism.
Implementation: Evaluation of pre- and postsynaptic events at the neuromuscular junction in muscle tissue exposed to clinically significant concentrations of 4-aminopyridine (4-AP), neostigmine, or combinations of the 2 drugs.
Animal Model: Rat (skeletal muscle tissue).
Interpretation and Analysis: Simultaneous application of 4-AP and neostigmine produces increases in the amplitudes of nerve-evoked end plate potentials that are significantly greater than the summed effects of the drugs applied individually. Such synergism is present at junctions where transmission is blocked either postsynaptically by d-tubocurarine or presynaptically by low $[Ca^{2+}]0$ and high $[Mg^{2+}]0$. Quantal content analysis of the latter preparation indicates that the evoked release of acetylcholine is potentiated significantly more than the amplitude of spontaneous miniature end plate potentials, suggesting that the site of synergism is predominantly presynaptic. For symptomatic relief and long-term management of the neuromuscular junction disorders, it has been proposed that when applied in combination, aminopyridine and anticholinesterase agents should be applied at reduced dosages, thereby minimizing adverse effects. Such combinations should be particularly effective in presynaptic disorders, including Lambert-Eaton myasthenic syndrome and botulism.

Synergistic interaction of 4-aminopyridine with neostigmine at the neuromuscular junction. Tierney PC, Kim YI, Johns TR. Eur J Pharmacol 1985 Sep 24; 115 (2–3), pp. 241–7.

The value of bupivicaine hip injection in the differentiation of coxarthrosis from lower extremity neuropathy. Kleiner JB; Thorne RP; Curd JG. J Rheumatol] 1991 Mar; Vol. 18 (3), pp. 422-7.

Peripheral Nerve Function Post–Crush Injury/ Sensorimotor Recovery/Temporary -vs- Permanent Nerve Injury
$ACTH_{1\text{-}24}$/$ACTH_{1\text{-}16}NH_2$ / $ACTH_{4\text{-}10}$/[Met(O_2) 4,D-Lys_8,Phe_9]$ACTH_{4\text{-}9}$ (Org. 2766)

Cellular/Molecular Mechanism of Action: The most well known mechanism of adrenalcorticotropin hormone (ACTH) pertains to its ability to promote the release of cortisol from the adrenal cortex. Other physiological properties of ACTH extend beyond this most prominent function (e.g., "crossover" melanocyte maturation).
Application: Discovery of the potential for peripheral nerve crush injury to regain sensorimotor function.
Implementation: Evaluation of sensorimotor function recovery using the "foot-flick" response test after crushing of the sciatic nerve. Every other day, $ACTH_{1\text{-}24}$ is administered by subcutaneous injection immediately after the foot-flick test.
Animal Model: Rat (foot-flick response test following mechanical crushing of the sciatic nerve).
Interpretation and Analysis: Administration of $ACTH_{1\text{-}24}$ promotes a faster recovery of sensorimotor function compared to reference controls. Such beneficial effects are dose-dependent. In contrast, no effect on toe-spreading can be detected. To investigate what part of the peptide molecule contains the active site and is devoid of steroid properties, smaller sequences of $ACTH_{1\text{-}24}$ without corticotrophic activity are then tested. Treatment with $ACTH_{1\text{-}16}NH_2$, $ACTH_{4\text{-}10}$, or [Met(O_2)4_4,D-Lys_8,Phe_9] $ACTH_{4\text{-}9}$ (Org. 2766) mimic the effects of $ACTH_{1\text{-}24}$, whereas treatment with $ACTH_{1\text{-}24}$ does not affect the return of sensorimotor function. The stimulatory effects of corticotrophin$_{1\text{-}24}$ and congeners on recovery of sensorimotor function have been described in terms of the direct effect of these peptides on nervous tissue, probably through enhanced brain and spinal cord protein synthesis.

Effects of corticotrophin (ACTH) on recovery of sensorimotor function in the rat: Structure-activity study. Bijlsma WA, Jennekens FG, Schotman P, Gispen WH. Eur J Pharmacol 1981 Nov 19; 76 (1), pp. 73–9.

CEREBRAL CORTEX AND CEREBRAL HEMISPHERES

Acetylcholine Receptor Complexes: Nicotinic Ligands
Bis-Nicotinium, Bis-Pyridinium/Bis-Picolinium, Bis-Quinolinium

Cellular/Molecular Mechanism of Action: Recognize and bind to nicotinic acetylcholine receptor complexes (nAChRs).
Physiological Mechanism of Action: Nicotinic acetylcholine receptor antagonist (parasympatholytic) and could potentially be applied as an indicator/marker molecule in non-imaging diagnostic procedures, or as a carrier imaging agent in nuclear medicine oriented investigations.
Application: Nictotinic acetylcholine receptor antagonist activity. Variation of N-n-alkyl chain length together with structural modification of the azaaromatic quaternary ammonium moiety affords selective antagonist activity for the $\alpha_4\beta_2$* nAChR subtype, as well as the formation of ligands with selectivity at α_7* nAChRs. The experimental findings provide a foundation for investigations devoted to the molecular design of nicotinic acetylcholine receptor ligands.
Implementation: Evaluation of a series of bis-nicotinium, bis-pyridinium, bis-picolinium, bis-quinolinium and bis-isoquinolinium compounds for their binding affinity at nAChRs expressed in neurologic tissues.
Ex-Vivo Model: Preparations of rat brain membranes.
Interpretation and Analysis: N,N′-Decane-1,12-diyl-bis-nicotinium diiodide (bNDI) exhibits the highest affinity for [^{3}H]-nicotine binding sites (K_i = 330 nM), but does not inhibit [^{3}H]-methyllycaconitine binding (K_i > 100 μM), indicative of an interaction with $\alpha_4\beta_2$*, but not α_7* receptor subtypes, respectively. In addition, bNDI inhibits (IC_{50} = 3.76 microM) nicotine-evoked [$^{86}Rb^+$] efflux from thalamic synaptosomes, indicating antagonist activity at $\alpha_4\beta_2$* nAChRs. N,N′-Dodecane-1,12-diyl-bis-quinolinium dibromide (bQDDB) exhibits the highest affinity for [^{3}H]-methyllycaconitine binding sites (K_i = 1.61 μM), but does not inhibit [^{3}H]-nicotine binding (K_i > 100 μM), demonstrating an interaction with α_7* but not $\alpha_4\beta_2$* nAChRs.

Bis-Azaaromatic quaternary ammonium analogues: Ligands for $\alpha4\beta_2$* and α_7* subtypes of neuronal nicotinic receptors. Ayers JT, Dwoskin LP, Deaciuc AG, Grinevich VP, Zhu J, Crooks PA. Bioorg Med Chem Lett 2002 Nov 4; 12 (21), pp. 3067–71.

Acetylcholine Receptors/Neurodegenerative Disease States: Acethylcholine Nictotinic $\alpha_4\beta_2$ Receptors/Tobacco Dependency
(S)-5-[^{123}I]Iodo-3-(2-Azetidinylmethoxy)Pyridine

Cellular/Molecular Mechanism of Action: (S)-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine selectively binds to $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes.
Application: The iodinated analog (S)-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine of A-85380 can be used for the specific detection and characterization of $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes in neurodegenerative disease states including conditions of tobacco dependence.
Route of Administration: (S)-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine (intravenous).
Implementation: Accurate measurement of (S)-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine plasma concentrations in order to determine its capacity to function as an "tracer" molecule for *in vivo* quantification of $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes.
Human Model: Non-human and human primates.
Interpretation and Analysis: In human/non-human primate whole blood as well as in plasma, the parent compound is only stable for approximately 5 minutes, after which it decomposes. In contrast, the radioligand is stable in the injection solution and in protein-free (> 30-kDa M.W.) plasma ultrafiltrate for at least 18 hours. To preserve the parent compound in plasma the radioactive plasma must be mixed with equal volumes of acetonitrile within 5 minutes of collection or, alternatively, radioactive blood should be collected and mixed with sodium azide (3 mg/ml blood). The *in vivo* metabolism of [^{123}I]5-IA generates 2 distinct components including (i) a radiometabolite that is less lipophilic than the parent compound; and (ii) a polar radiometabolite that is not free radioiodide because of the absence of accumulated radioactivity within the thyroid.

Measurement of plasma metabolites of (S)-5-[123I]iodo-3-(2-azetidinylmethoxy)pyridine (5-IA-85380), a nicotinic acetylcholine receptor imaging agent, in nonhuman primates. Zoghbi SS, Tamagnan G, Baldwin MF, Al-Tikriti MS, Amici L, Seibyl JP, Innis RB. Nucl Med Biol 2001 Jan; 28 (1), pp. 91–6.

Acetylcholine Receptors: Nicotinic Ligands
5-(3-Pyridinyl)-4-Azahomoadamantane 2a

Cellular/Molecular Mechanism of Action: Recognizes and has binding avidity for α_7 nicotinic acetylcholine receptor complexes.
Physiological Mechanism of Action: Competitive antagonist of acetylecholine at nicotinic receptor complexes (parasympatholytic).
Application: Potential carrier molecule for imaging the distribution and expression density of nicotinic-class acetylcholine receptor complexes.
Semi-Synthetic Methods: Applying a general synthetic route, nicotinic ligands can be produced that bear a variety of bulky azaring groups and yield 5-(3-pyridinyl)- and 5-(3-quinolinyl)-4 azahomoadamantanes 2a, 3a and 2b, 3b.
Interpretation and Analysis: The parent compound, 5-(3-pyridinyl)-4-azahomoadamantane 2a (K_i = 5.0 μM) binds with about a 100 times lower affinity than (+)-epibatidine 1 (K_i = 0.045 μM) to α_7 nicotinic acetylcholine receptors (nAChRs). N-methyl substitution of 2a gives rise to compound 3a, which has about 9 times lower binding affinity. The replacement of pyridinyl with a quinolinyl ring (compounds 2b, 3b) results in a dramatic reduction in potency (Ki > 1000 μM).

Synthesis and binding affinities of 5-(3-pyridinyl)- and 5-(3-quinolinyl)-4-azahomoadamantanes to α_7 nicotinic acetylcholine receptors. Tataridis D, Kolocouris A, Fytas G, Kolocouris N, Foscolos GB, Poulas K, Tzartos SJ. Farmaco. 2002 Dec; 57 (12), pp. 979–84.

Alcoholism: Genetic-Associated Sensitivity/Central Nervous System EEG Patterns
Ethanol/Electroencephalogram Analysis/ (Electropharmacogenetics)

Cellular/Molecular Mechanism of Action: Ethanol functions as a central nervous system depressant.
Background Information: Electroencephalogram (EEG) analysis offers several advantages for performing pharmacogentic-related studies since it simultaneously evaluates both genetic traits and challenge characteristics.
Application: Delineation of alterations in electroencephalogram tracings induced by ethanol that are associated with specific genetic characteristics that may be related to a predisposition of alcoholism.
Route of Administration: Ethanol is administered orally to effect.
Implementation: Pharmacogenetic studies employing electroencephalogram analysis have been applied to characterize the influence of acute ethanol dosing on brain function. Performance of such investigations in twin individuals facilitates the discovery of certain ethanol-induced alterations in brain wave profiles that are directly associated with genetic-related characteristics.
Interpretation and Analysis: Pharmacogenetic studies employing electroencephalogram analysis combined with acute ethanol dosing in twin individuals reveals that certain alterations in EEG tracings profiles induced by this depressant are genetic regulated in nature. Among the various genetically determined variants of EEG tracings, the poorly synchronized alpha EEG exhibits the most pronounced response. Examination of a series of alcoholics of both sexes as well as their 1st-degree relatives reveals that in females the poorly synchronized alpha EEG may be a predictive indicator reflecting a predisposition to alcoholism. Such observations support the perception that the disposition to alcoholism is under genetic influence not only at the metabolic but also at the pharmacodynamic level.

Pharmacogenetics of alcohol's CNS effect: Implications for the etiology of alcoholism. Propping P. Pharmacol Biochem Behav 1983;18 Suppl 1, pp. 549–53.

Alcoholism: Genetic-Associated Sensitivity/ Cholinergic Function
Ethanol/[^{3}H]-Quinuclidinyl Benzilate

Cellular/Molecular Mechanism of Action: Ethanol functions as a central nervous system depressant.
Application: Characterization of pharmacogentic properties associated with vulnerability or resistance to the development of alcoholism pertaining to different aspects of cholinergic function within the autonomic nervous system.
Route of Administration: Ethanol is traditionally administered orally (per os).
Dosage: Ethanol (4.6 g/kg).
Implementation: Evaluation of alterations in choline acetyltransferase (ChAT), acetylcholinesterase (AChE), aand [^{3}H]-quinu-

clidinyl benzilate (QNB) binding within different regions of the brain following ethanol administration.

Animal Model: Murine (C57BL/6 and BABLB/c inbred strains of mice)

Interpretation and Analysis: Choline acetyltransferase in the striatum and septum of C57BL/6 *in vivo* models exhibit greater sensitivity to ethanol compared to BALB/c *in vivo* models. The limbic system and related structures of BALB/c *in vivo* models show greater sensitivity to ethanol compared to C57BL/6 *in vivo* models. Acute ethanol administration in C57BL/6 *in vivo* models increases striatal ChAT activity (up to 22% with 60-minute latency). Induction of ethanol-induced augmentation of ChAT activity in this manner is associated with non-synchronous decreases in kinetic characteristics of stratum QNB binding. In contrast, no such changes are seen in BALB/c *in vivo* models, except the observation of an increase in K_d up to 90 min after acute ethanol treatment. Similar significant increases in ChAT activity can also be observed in the septum of C57BL/6 *in vivo* models 165 minutes after ethanol administration. However, the septum in BALB/c *in vivo* models does not exhibit comparable changes. Ethanol increases ChAT activity in several brain areas of both C57BL/6 and BALB/c *in vivo* models. Regions of the CNS that are affected include the hippocampus, temporal limbic cortex, and piriform cortex or paleocortex. Interestingly, the latencies to increased ChAT activity in these areas are much shorter in BALB/c than in C57 *in vivo* models. The kinetic characteristics of QNB binding sites (B_{max} and K_d) and AChE activity are unchanged in all regions of the brain and do not differ between strains (except where previously indicated). Genetic differences in ethanol preference and sensitivity in these strains therefore are accompanied by differential sensitivity of ChAT to acute ethanol. Genotypic variations in dopaminergic-cholinergic interactions in striatum and hippocampus, septum, and temporal limbic and piriform cortex could contribute to genetic differences in cholinergic sensitivity to ethanol. In addition, different blood-brain barrier and membrane properties may also contribute to genetic differences in the sensitivity of cholinergic function to ethanol. The differential effects on ChAT activity could possibly be responsible for genetic differences in memory disorders (limbic system and related structures) and motor incoordination (basal ganglia) following high-dose alcohol administration.

Genetically-determined responses of central cholinergic markers: The effects of ethanol on inbred strains of mice. Hashemzadeh-Gargari H, Mandel P. Neurotoxicology. 1989 Fall; 10 (3), pp. 555–68.

Alcoholism: Neuroendocrinology
Ethanol Challenge/[Angiotensin II]

Application: Detection of variations in responses to ethanol intoxication for the purpose of detecting and characterizing conditions of alcoholism.

Route of Administration: Ethanol (oral).

Implementation: Simultaneous evaluation of multiple circulating neurohormones, osmolality, thirst, and fluid balance following oral ethanol challenge for the purpose of identifying [i] aberrant hormonal responses related to Ang II and AVP.; and [ii] diagnostic parameters that can potentially be utilized to detect and characterize conditions of chronic alcoholism. Parameters and blood samples are collected prior to and 12 hours after ethanol challenge.

Human Model: Cases of alcoholism (e.g. n = 8 actively drinking, alcoholic males) and n = 7 controls.

Interpretation and Analysis: Basal levels of serum osmolality and thirst are significantly higher in alcoholics compared to controls, yet actively drinking alcoholics have normal vasopressin levels, plasma angiotensin II (Ang II), plasma renin activity, plasma aldosterone, and plasma catecholamines. In response to ethanol, serum osmolalities increases are significantly higher, while plasma vasopressin levels are significantly suppressed in alcoholics. After ethanol stimulus, plasma angiotensin II levels of alcoholics are significantly higher than those of controls at 11 A.M. (12.15 ± 4.49 vs 1.83 ± 0.6 pg/ml; $p < 0.02$) and noon (14.93 ± 6.81 vs 1.37 ± 0.17 pg/ml, $p < 0.04$). Neither plasma renin activity nor aldosterone change in accordance with the elevated plasma angiotensin II in alcoholics. Diuresis in alcoholics (assessed by the sum of urine output following the challenge dose) is significantly less than that of controls. Thirst scores and fluid intakes after the ethanol challenge do not differ between alcoholics and controls. The lack of an angiotensin II mediated increase in plasma aldosterone or thirst response suggests that ethanol may have a specific blunting effect on angiotensin II receptors.

Neuroendocrine, fluid balance, and thirst responses to alcohol in alcoholics. Collins GB, Brosnihan KB, Zuti RA, Messina M, Gupta MK. Alcohol Clin Exp Res 1992 Apr; 16 (2), pp. 228–33.

Alcohoism/Seizures/Recurrent Alcoholic Detoxification Episodes
Chlordiazepoxide/Pharmaco-Electroencephalography

Application: Delineation of recurrent alcoholic detoxification seizures.

Route of Administration: Per os (oral) during detoxification events (associated with the elimination of withdrawal seizures).

Implementation: Evaluation of the potential increased risk of seizure activity during conditions of recurrent alcohol detoxifications. Structural brain damage, focal neurologic deficits, epileptogenic findings on electroencephalograms, and provocative drug use are considered pertinent variables for seizure risk.

Human Model: Review of detoxification and seizure histories (n = 256 men; n = 45 women voluntarily admitted to a 5-day inpatient detoxification program).

Interpretation and Analysis: Administration of chlordiazepoxide is usually associated with the elimination of withdrawal seizures. Some cases have a history of seizures (e.g., n = 64/301) while others have significantly abnormal electroencephalograms during detoxification (e.g., n = 42/301), or have focal slowing on the electroencephalogram (e.g., n = 30/301). No correlation exists between the duration of alcohol abuse or lifetime consumption of alcohol and seizure activity. There is, however, a significant correlation between the number of inpatient alcohol detoxifications and the prevalence of seizure disorders. This correlation holds true even when provocative drug use is taken into consideration.

Seizure risk with recurrent alcohol detoxification. Lechtenberg R, Worner TM. Arch Neurol 1990 May; 47 (5), pp. 535–8.

Alcoholism/Sensitivity to Ethanol
Ethanol/Calcium Chloride/A23187 (Calcium Ionophor)

Cellular/Molecular Mechanism of Action: Ethanol functions as a central nervous system depressant.

Application: Characterization of differences in central nervous system ethanol metabolism.

Route of Administration: Ethanol is administered orally (per os).

Implementation: Sensitivity to ethanol is measured as a function of the blood ethanol concentration at the point where the righting reflex is lost.

Animal Model: Murine (SS and LS mice)

Interpretation and Analysis: Sensitivity to ethanol is increased significantly in SS but not LS mice following intracerebroventricular (ICV) administration of calcium chloride or a calcium ionophore (e.g. A23187). Magnesium chloride or lanthanum chloride, ICV, does not alter sensitivity to ethanol in either SS or LS mice, further indicating a specificity for calcium cation. Calcium does not affect sensitivity to halothane narcosis in LS or SS mice. Endogenous brain calcium content is similar in these mouse lines, and ethanol administration either *in vivo* or *in vitro* does not alter brain calcium concentration. Differences in brain sensitivity to ethanol are therefore mediated, in part, by genetic differences in calcium-related processes and support the hypothesis that ethanol-induced narcosis may be due to alterations in calcium metabolism in the CNS.

Calcium influence on neuronal sensitivity to ethanol in selectively bred mouse lines. Morrow EL, Erwin VG. Pharmacol Biochem Behav 1986 Apr; 24 (4), pp. 949–54.

Alcoholism/Salsolinol: Striatal Production/Alcohol Dehydrogenase/Aldehyde Dehydrogenase
Cyanamide/4-Methylpyrazole/Ethanol

Cellular/Molecular Mechanism of Action: Cyanamide (CY) is a potent inhibitor of aldehyde dehydrogenase. 4-methylpyrazole (4-MP) is a strong inhibitor of alcohol dehydrogenase.
Application: The *in-vivo* formation of salsolinol (1-methyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquionoline), an endogeneous condensation product of dopamine (DA) with acetaldehyde (AcH), can be characterized following the administration of cyanamide (CY) plus ethanol (EtOH) using microdialysis-high-performance liquid chromatography with electrochemical detection.
Route of Administration: Cyanamide (50 mg/kg); 4-MP (82 mg/kg); EtOH (1 g/kg).
Implementation: Evaluation of the capacity for [i] CY to inhibit aldehyde dehydrogenase; [ii] 4-MP to inhibit alcohol dehydrogenase; and [iii] the combined effect of CY + 4-MP administration. One hour latter, EtOH, CY and 4-HP is administered (only by intraperitoneal administration).
Animal Model: Rat (microdialysis probe inserted into the striatum).
Interpretation and Analysis: Administration of CY + EtOH promotes elevation in the amount of salsolinol detected in striatal (CNS) dialysates, and high AcH concentrations are found in the blood. The time course of changes in salsolinol concentrations correlates with blood AcH concentrations. Alternatively, salsolinol in the dialysates and high AcH concentrations in the blood are not detected with other treatment challenges. Such metabolite profiles indicate that (i) high AcH concentrations induce the formation of salsolinol in the striatum; and (ii) there is no effect of EtOH or AcH on striatal dialysate concentrations of DA and 5-hydroxytryptamine.

In vivo formation of salsolinol induced by high acetaldehyde concentration in rat striatum employing microdialysis. Jamal M, Ameno K, Kubota T, Ameno S, Zhang X, Kumihashi M, Ijiri I. Alcohol 2003 May–Jun; 38 (3), pp. 197–201.

Alzheimer's Disease (AD): Acethylcholine Receptors (Muscarinic)/Muscarinic-Cholinergic Investigative Probe
RS 86/2-Ethyl-8-Methyl-2,8-Diazaspiro-[4,5]-Decan-1,3-Dion Hydrobromide/Oxotremorine/Arecoline/Pilocarpine /Aceclidine

Cellular/Molecular Mechanism of Action: The agent 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) recognizes and physically binds to cholinergic muscarinic receptor complexes as a component of the parasympathetic autonomic nervous system. In this context, it functions as a potent, centrally acting, selective muscarinic receptor agonist.
Application: The agent 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) appears to be an adequate probe for the clinical examination of the cholinergic hypothesis for the molecular pathogenesis of AD.
Implementation: Evaluate and compare the effects of the compound 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) to those of classical muscarinic receptor agonists utilizing *in vitro* and *in vivo* test systems for muscarinic cholinergic activity.
Animal Model: Guinea pig (*ex vitro* ileum preparations).
Animal Model: Rat (superior cervical ganglion).
Animal Model: Murine.
Interpretation and Analysis: In radioligand binding assays RS 86 displays high nanomolar apparent affinity only for sites labeled by [^{3}H]-muscarinic receptor agonists while its apparent affinity for sites labeled by [^{3}H]-muscarinic receptor antagonists including [^{3}H]QNB, [^{3}H]NMS, and [^{3}H]pirenzepine is in the micromolar range. RS 86 has no or only low affinity (IC_{50} greater than 10 μM) for other neurotransmitter or drug receptor sites. The compound induces scopolamine-sensitive contractions of isolated guinea pig ileum showing a pD2 of 6 in this model. In the isolated rat superior cervical ganglion RS 86 also functions as an agonist with a pD2 of 6.7. When given to mice or rats by different routes RS 86 induces central and peripheral effects typical of a muscarinic receptor agonist, such as hypothermia, tremor, mydriasis, salivation, lacrimation, diarrhea, and modification of behavior as observed in an "open-field" environment. In several of these tests RS 86 is about 10 times less potent than oxotremorine but more potent than arecoline, pilocarpine, aceclidine, or the compound (cis) AF-30. The ED_{50} values for some central effects, including the induction of hypothermia and alert non-mobile behavior, are lower than those for tremor and peripheral effects. Some of the effects last for up to 6 hours depending on dose. Finally, RS 86 administration results in modifications of brain acetylcholine turnover and high affinity choline uptake typical of a central muscarinic receptor agonist. Taken together these results demonstrate clearly that RS 86 is a potent, centrally acting, selective muscarinic receptor agonist. RS 86 appears to be an adequate tool for the clinical examination of the cholinergic hypothesis of Alzheimer's disease.

The pharmacological assessment of RS 86 (2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide). A potent, specific muscarinic acetylcholine receptor agonist. Palacios JM, Bolliger G, Closse A, Enz A, Gmelin G, Malanowski J. Eur J Pharmacol 1986 Jun 5; 125 (1), pp. 45–62.

Alzheimer's Disease (AD): Amyloid (A-beta) Fibrils/Senile Plaques and Neurofibrillary Tangles
Methoxy-X04/Derivative of Congo Red and Chrysamine-G

Cellular/Molecular Mechanism of Action: Similar to Congo red, methoxy-X04 is a fluorescent dye that possesses binding avidity for molecular amyloid beta fibrils.
Background Information: The identification of amyloid deposits in living AD cases is important for both early diagnosis of the condition and for monitoring the efficacy of newly developed antiamyloid therapies.
Application: Visual fluorescent detection and characterization of amyloid beta fibrils deposits contained within plaques, tangles, and cerebrovascular amyloid deposits.

Route of Administration: Methoxy-X04 (IV = 5 to 10 mg/kg; IP = 10 mg/kg in mice).
Dosage: Methoxy-X04 (intravenous, intraperitoneal in mice).
Semi-Synthetic Methods: Methoxy-X04 is a derivative of Congo red and chrysamine-G that contains no acid groups and is therefore smaller and much more lipophilic than Congo red or chrysamine-G.
Implementation: Evaluation of the *in vivo* ability of methoxy-X04 to selectively "associate" with individual plaques in a manner that can facilitate non-invasive detection applying multiphoton microscopy.
Animal Model: Mouse (PSI/APP).
Interpretation and Analysis: Methoxy-X04 retains *in vitro* binding affinity for amyloid beta (a-beta) fibrils (K_i = 26.8 nM) very similar to that of chrysamine-G (K_i = 25.3 nM). The fluorescent properties of methoxy-X04 stained plaques, tangles, and cerebrovascular amyloid in postmortem sections of AD brain reveals good levels of specificity. In an *in vivo* environment (mice), multiphoton microscopy can be applied to obtain high-resolution (1 μm) fluorescent images of the brain. Under such conditions, it is possible to detect individual plaques that can be recognized within 30 to 60 minutes after a single intravenous injection (e.g. PSI/APP mouse brain). A single intraperitoneal methoxy-X04 injection at 10 mg/kg also produces high contrast images of plaques and cerebrovascular amyloid (e.g. PSI/APP mouse brain). Quantitative studies using tracer doses of [^{11}C]labeled methoxy-X04 show that it enters rat brain in amounts that suggest it is a viable candidate as a positron emission tomography (PET) amyloid-imaging agent for *in vivo* human diagnostic studies.
Instrumentation: Multiphoton microscopy.

Imaging a-beta plaques in living transgenic mice with multiphoton microscopy and methoxy-X04, a systemically administered Congo red derivative. Klunk WE, Bacskai BJ, Mathis CA, Kajdasz ST, McLellan ME, Frosch MP, Debnath ML, Holt DP, Wang Y, Hyman BT. J Neuropathol Exp Neurol 2002 Sep; 61 (9), pp. 797–805.

Alzheimer's Disease (AD): Amyloid Beta/Dense Plaque Oxidative Properties
Oxidation-Activated Fluorogenic Probes/N-Tert-Butyl-Alpha-Phenylnitrone

Cellular/Molecular Mechanism of Action: N-tert-butyl-alpha-phenylnitrone functions as a free radical spin trap.
Background Information: Amyloid beta, the primary constituent of senile plaques in AD, is hypothesized to cause neuronal damage and cognitive failure, but the mechanisms that mediate such alterations remain largely unknown.
Application: Fluorogenic compounds can be used *in vivo* to determine the degree of association between amyloid beta deposits and free radical production. The compound N-tert-butyl-alpha-phenylnitrone can function as a means of validating the effectiveness and accuracy of tracers and probes designed to detect anatomical regions of elevated oxidation potential.
Implementation: Utilization of compounds that actively fluoresce following exposure to tissues/anatomical regions that have elevated oxidative potential thereby facilitating their detection utilizing infrared laser imaging techniques. As a validation procedure, N-tert-butyl-alpha-phenylnitrone (a free radical spin trap) can be systemically administered to determine the accuracy of oxidation-activated fluorogenic probes. Collectively, these agents can be applied to delineate if a direct association exists between amyloid-beta deposits and free radical production.
Animal Model: Mouse (*in vivo* transgenic AD).
Human Model: Brain tissue from cases of AD (*ex vivo*).
Interpretation and Analysis: Fluorescence can be appreciated in dense core plaques, but not diffuse plaques, as determined by subsequent addition of thioflavine S and immunohistochemistry analysis for amyloid beta. Systemic administration of N-tert-butyl-alpha-phenylnitrone greatly reduces the detection of probes activated by tissue oxidative processes. It is therefore believed that a subset of amyloid plaques produce free radical species in living Alzheimer's models and in human Alzheimer tissue sections. Antioxidant therapy neutralizes these highly reactive molecules and may therefore be of both diagnostic and therapeutic value in AD.
Instrumentation: Multiphoton imaging.

In vivo imaging of reactive oxygen species specifically associated with thioflavine S-positive amyloid plaques by multiphoton microscopy. McLellan ME, Kajdasz ST, Hyman BT, Bacskai BJ. J Neurosci 2003 Mar 15; 23 (6), pp. 2212–7.

Alzheimer's Disease (AD): Amyloid/A-beta$_{1\text{-}40}$ Fibrils/Senile Plaques and Neurofibrillary Tangles
[^{18}F]FDDNP

Cellular/Molecular Mechanism of Action: The agent 2-(1-(6-[(2-[^{18}F]fluoroethyl)-(methyl)amino]-2-naphthyl)ethylidene) malononitrile ([^{18}F]FDDNP) is a hydrophobic dual-function semi-synthetic compound that emits fluorescent light and possess binding avidity for certain types of molecular amyloid.
Background Information: Senile plaques (SPs) and neurofibrillary tangles (NFTs) are hallmark pathologies that accompany the neurodegeneration associated with AD. Beta-amyloid (a-beta) peptide is a major constituent of SPs.
Application: Hydrophobic, fluorescent molecular-imaging probe [^{18}F]FDDNP, crosses the blood-brain barrier and determines the localization and load of SPs and NFTs *in vivo* in cases of AD.
Route of Administration: Intravascular.
Implementation: Determination of the binding avidity of FDDNP and its analog, 1-(6-[(2-[^{18}F]fluoroethyl)(methyl) amino] naphthalen-2-yl)ethanone ([^{18}F]FENE), to synthetic fibrils of a-beta$_{1\text{-}40}$ applying fluorimetric and radioactive binding assays.
Interpretation and Analysis: Both FDDNP and FENE bind to kinetically distinguishable binding sites (n = 2 sites) on a-beta$_{1\text{-}40}$ fibrils. Fluorescence titrations yield apparent K_d values of 0.12 and 0.16 nm associated with high-affinity binding sites for FDDNP and FENE, respectively, and apparent K_d values of 1.86 and 71.2 nm for low-affinity binding sites. The traditional radioactive binding assays also produce apparent K_d values in the low nanomolar range. The presence of 2 kinetically distinguishable binding sites for FDDNP and FENE suggests multiple binding sites for SPs and identifies the parameters that allow for the structural optimization of this family of probes for *in vivo* use. The high-affinity binding of the probes to multiple binding sites on fibrils is consistent with results obtained with digital autoradiography, immunohistochemistry, and confocal fluorescence microscopy using human brain specimens of AD cases.

Binding characteristics of radiofluorinated 6-dialkylamino-2-naphthylethylidene derivatives as positron emission tomography imaging probes for beta-amyloid plaques in Alzheimer's disease. Agdeppa ED, Kepe V, Liu J, Flores-Torres S, Satyamurthy N, Petric A, Cole GM, Small GW, Huang SC, Barrio JR. J Neurosci 2001 Dec 15; 21 (24), pp. RC189.

Alzheimer's Disease (AD): Amyloid Beta-Sheet Proteins/Amyloid Plaques: A-beta Peptide/ Neurofibrillary Tangles: Tau Protein
Thioflavin Derivatives

Cellular/Molecular Mechanism of Action: Thioflavin-T (ThT) derivatives possess binding avidity for beta-sheet proteins deposited in amyloid plaques (a-beta peptide) and neurofibrillary tangles (tau protein).

Background Information: Assessment of the beta-sheet proteins deposited *in vivo* in amyloid plaques (a-beta peptide) or neurofibrillary tangles (tau protein) represents a target for the development of biological markers for AD.

Application: Detection and characterization of beta-sheet proteins deposited in amyloid plaques (a-beta peptide) and neurofibrillary tangles (tau protein) similar to those associated with the pathogenesis of AD.

Route of Administration: [Intravenous] if eventually applied in a clinical environment.

Semi-Synthetic Methods: Production of thioflavin-T (ThT) derivatives and the carbon-11-labeled compound [N-methyl-^{11}C]6-Me-BTA-1.

Implementation: Evaluate and characterize the ability for [N-methyl-^{11}C]6-Me-BTA-1 to enter into and be cleared from the brain.

Animal Model: Mouse (Swiss-Webster).

Interpretation and Analysis: These compounds lack the positively charged quaternary heterocyclic nitrogen of ThT and are therefore uncharged at physiological pH. They are 600-fold more lipophilic than ThT. Derivatives of ThT bind to a-beta$_{1\text{-}40}$ fibrils with higher affinity (K_i = 20.2 nM) than ThT (K_i = 890 nM). The uncharged ThT derivatives stain both plaques and neurofibrillary tangles in postmortem AD brain, showing some preference for plaque staining.

The compound [N-methyl-^{11}C]6-Me-BTA-1 enters the brain at levels comparable to commonly used neuroreceptor imaging agents (0.223 %ID-kg/g or 7.61 %ID/g at 2 minutes postinjection) and shows good clearance of free and non-specifically bound radioactivity in normal rodent brain tissue (brain clearance $T_{1/2}$ = 20 minutes). The combination of relatively high affinity for amyloid, specificity for staining plaques and neurofibrillary tangles in postmortem AD brain, and good brain entry and clearance makes [N-methyl-^{11}C]6-Me-BTA-1 a promising candidate as an *in vivo* positron emission tomography beta-sheet imaging agent.

Uncharged thioflavin-T derivatives bind to amyloid-beta protein with high affinity and readily enter the brain. Klunk WE, Wang Y, Huang GF, Debnath ML, Holt DP, Mathis CA. Life Sci 2001 Aug 17; 69 (13), pp. 1471–84.

Alzheimer's Disease (AD): Amyloid/Extracellular Amyloid-Beta Protein/Abnormal Tau Protein/ Abnormal Synuclein Proteins/[Alzheimer's Disease]
[Trans/Trans]-1-Bromo-2,5-bis-(3-Hydroxycarbonyl-4-Hydroxy)Styrylbenzene/Thioflavin S

Cellular/Molecular Mechanism of Action: Congo red-derived fluorescent probe [trans/trans]-1-bromo-2,5-bis-(3-hydroxycarbonyl-4-hydroxy)styrylbenzene (BSB) binds to molecular amyloid.

Background Information: The novel Congo red-derived fluorescent probe BSB binds to amyloid plaques of postmortem Alzheimer's disease brains and *in vivo* in the brains of transgenic mice.

Application: Prototype imaging agent for detecting and characterizing amyloid deposits/plaques (e.g. AD).

Implementation: Evaluation of postmortem tissues from cases with various neurodegenerative diseases possessing diagnostic lesions using BSB as a probe. Additionally, BSB can be assessed for its ability to characterize fibrillar intra- or extracellular lesions and compare its properties with standard histochemical dyes such as thioflavin S and immunohistochemical stains specific for the same lesion type.

Interpretation and Analysis: Laboratory results reveals that BSB binds not only to extracellular amyloid beta protein but also to many intracellular lesions composed of abnormal tau and synuclein proteins which suggests that radioiodinated BSB derivatives or related ligands may be useful *in vivo* imaging agents for detecting and monitoring diverse types of amyloid.

The fluorescent Congo red derivative, (trans, trans)-1-bromo-2,5-bis-(3-hydroxycarbonyl-4-hydroxy)styrylbenzene (BSB), labels diverse beta-pleated sheet structures in postmortem human neurodegenerative disease brains. Schmidt ML, Schuck T, Sheridan S, Kung MP, Kung H, Zhuang ZP, Bergeron C, Lamarche JS, Skovronsky D, Giasson BI, Lee VM, Trojanowski JQ. Am J Pathol 2001 Sep; 159 (3), pp. 937–43.

Alzheimer's Disease (AD): Amyloid Plaques (A-beta)
Stilbene Derivatives/N-[^{11}C]Methylamino-4′-Hydroxystilbene

Cellular/Molecular Mechanism of Action: Stilbene derivatives recognize and physically bind to amyloid plaques analogous to those associated with AD.

Application: N-[^{11}C]methylamino-4′-hydroxystilbene, or [^{11}C]4 may be useful as a positron emission tomography (PET) imaging agent for mapping a-beta plaques in the brain of cases with AD.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Synthesis of a series of stilbene derivative can be successfully achieved by performing a simple Wadsworth-Emmons reaction between diethyl (4-nitrobenzyl)phosphonate and 4-methoxybenzaldehyde. The [^{11}C] labeled 4-N-methylamino-4′-hydroxystilbene, [^{11}C] 4, is prepared by [^{11}C] methylation of 4-amino-4′-hydroxystilbene.

Analysis and Interpretation: 4-N,N-dimethylamino-4′-methyoxy and the corresponding 4-N-monomethylamino-, 4′-hydroxy stilbenes show good binding affinities toward a-beta aggregates *in vitro* (K_i < 10 nM). The [^{11}C]4 displays a moderate lipophilicity (log p = 2.36) and shows very good brain penetration and washout from normal rat brain following intravenous injection. *In vitro* autoradiography of transgenic AD mouse brain sections shows a high specific labeling of beta-amyloid plaques, whereas control sections show no binding.

11C-labeled stilbene derivatives as A-beta-aggregate-specific PET imaging agents for Alzheimer's disease. Ono M, Wilson A, Nobrega J, Westaway D, Verhoeff P, Zhuang ZP, Kung MP, Kung HF. Nucl Med Biol 2003 Aug; 30 (6), pp. 565–71.

Alzheimer's Disease (AD): Amyloid Deposits (Related Conditions)/Differential Stain Recognition: Non-Fibrillar vs Fibrillar Amyloid/Transthyretin: Amyloidic Protein
X-34/Congo Red/Thioflavin S

Cellular/Molecular Mechanism of Action: The agents Congo red, thioflavin S, and X-34 all possess binding avidity for molecular amyloid.

Background Information: Transgenic *Caenorhabditis elegans* animals can be engineered to express high levels of human beta amyloid peptide (a-beta). Histochemistry of fixed tissue reveals deposits reactive with the amyloid-specific dyes Congo red and thioflavin S.
Implementation: Discovery of the potential for X-34 to bind to amyloid deposits in *Caenorhabditis elegans* applying immunoelectron microscopy as a validation methodology.
Interpretation and Analysis: Immunoelectron microscopy can detect intracellular immunoreactive deposits with classic amyloid fibrillar ultrastructure. These deposits can be visualized in living animals using the newly developed, intensively fluorescent, amyloid-specific dye X-34. *In vivo* staining allows monitoring of amyloid deposition over time. The specificity of X-34 staining is demonstrated by examining transgenic models expressing high levels of a non-fibrillar beta peptide variant, the beta single-chain dimer. These animals have deposits immunoreactive with antibeta antibodies but do not have X-34 positive-staining deposits or deposits with a fibrillar ultrastructure. Visualization of putative amyloid deposits resulting from accumulation of human transthyretin, another amyloidic protein, can also be achieved *in vivo* using X-34 dye reagent. *In vivo* amyloid staining with X-34 may be a useful tool for monitoring anti-amyloidic treatments in real time or screening for genetic alterations that affect amyloid formation.

Visualization of fibrillar amyloid deposits in living, transgenic Caenorhabditis elegans animals using the sensitive amyloid dye, X-34. Link CD, Johnson CJ, Fonte V, Paupard M, Hall DH, Styren S, Mathis CA, Klunk WE. Neurobiol Aging 2001 Mar–Apr; 22 (2), pp. 217–26.

Alzheimer's (Dementia Type): Cerebral Cortical Function/Mini-Mental State Examination/ Prediction Classification: Stable/Improvement vs Deterioration
Pharmaco-EEG/Tetrahydroaminoacridine

Cellular/Molecular Mechanism of Action: Tetrahydroaminoacridine (THA) is a reversible cholinesterase inhibitor.
Physiological Mechanism of Action: Tetrahydroaminoacridine (THA) can function as an antidementia agent that is capable of reversing the decreases in acetylcholine release, and improve the spatial memory deficits associated with the administration of Delta9-tetrahydrocannabinol, a major psychoactive component of marijuana.
Background Information: Previous investigations have indicated that a single-dose pharmaco-EEG may predict the outcome of 4 to 7 weeks of THA treatment in Alzheimer's type of dementia (DAT).
Application: Characterization of alterations in cerebral cortical function in DAT conditions. The pharmaceutical has been used in the treatment of Alzheimer's disease.
Route of Administration: Tetrahydroaminoacridine (oral).
Dosage: Tetrahydroaminoacridine (30 mg).
Implementation: Evaluate the influence of THA on cerebral cortex function in conditions of DAT applying quantitative EEG analyses. Tracings are recorded 2 hours after an intial oral dose and then again after 12 weeks of THA.

Human Model: Probable cases of DAT (n = 24). Investigations can be designed in the format of an open trial study.
Interpretation and Analysis: The EEG in conditions of DAT that exhibit stable or improved scores on Mini-Mental State Examinations (MMSE) at 12 weeks display a significantly faster baseline mean alpha frequency as well as significant reductions in relative theta power following a single THA dose compared to conditions displaying evidence of deterioration. Discriminant analysis using test dose response EEG variables can correctly classify 75–79% of these 2 patient group types, suggesting that the procedure may be a useful approach for optimizing the individual selection for anti-dementia treatments.

Pharmaco-EEG test dose response predicts cholinesterase inhibitor treatment outcome in Alzheimer's disease. Knott V, Mohr E, Mahoney C, Ilivitsky V. Methods Find Exp Clin Pharmacol 2000 Mar; 22 (2), pp. 115–22.

Alzheimer's Disease (AD): Histamine H_3 Receptors
A-304121/A-317920/Thioperamide, Ciproxifan, and GT-2331

Cellular/Molecular Mechanism of Action: Physically bind to and functionally antagonize H_3 receptor sites.
Physiological Mechanism of Action: Pharmacological blockade of central histamine H_3 receptors (H3Rs) enhances cognition in rodents.
Application: Potentially beneficial for the clinical diagnosis (imaging) and treatment of certain neurological disorders (Alzheimer's-like conditions).
Route of Administration: [(4-(3-(4-((2R)-2-aminopropanoyl)-1-piperazinyl)-propoxy)-phenyl)-cyclopropylmethanone] and A-317920 [N-((1R)-2-(4-(3-(4-(cyclopropylcarbonyl)-phenoxy)-propyl)-1-piperazinyl)-1-methyl-2-oxo-ethyl)-2-furamide].
Dosage: Agent #1—[(4-(3-(4-((2R)-2-aminopropanoyl)-1-piperazinyl)-propoxy)-phenyl)-cyclopropylmethanone] (A-304121: dipsogenia (1 mg/kg); rat-pup avoidance (10 mg/kg)]. Agent #2—[N-((1R)-2-(4-(3-(4-(cyclopropylcarbonyl)-phenoxy)-propyl)-1-piperazinyl)-1-methyl-2-oxo-ethyl)-2-furamide] [A-317920: dipsogenia (0.45 mg/kg); rat-pup avoidance 3 mg/kg)].
Considerations: Several previously characterized H_3R antagonists are either not selective for H_3Rs or have potentially significant tolerability issues.
Interpretation and Analysis: Both A-304121 [(4-(3-(4-((2R)-2-aminopropanoyl)-1-piperazinyl)propoxy)-phenyl)-cyclopropylmethanone] and A-317920 [N-((1R)-2-(4-(3-(4-(cyclopropylcarbonyl)-phenoxy)-propyl)-1-piperazinyl)-1-methyl-2-oxo-ethyl)-2-furamide] evoke functional blockade of central H_3 receptors based on their ability to significantly attenuate acute dipsogenia responses mediated by the selective H_3R agonist (R)-alpha-methylhistamine [(R)-alpha-MeHA].

Behavioral and neurophysiological research (*in vivo*) has demonstrated that cognitive performance is improved in 5-trial rat-pup avoidance tests following the administration of A-304121 (10 mg/kg) or A-317920 (3 mg/kg), with efficacy levels comparable with previously published observations for the reference H_3R antagonists thioperamide (10 mg/kg), ciproxifan (3 mg/kg), and GT-2331 [(1R,2R)-4-(2-(5,5-dimethylhex-1-ynyl)cyclopropyl)imidazole] (1 mg/kg). Social memory is also significantly enhanced in the adult rat with A-304121 (3, 10 mg/kg) and A-317920 (1, 3 mg/kg) at doses that produce no significant change in electroencephalogram slow-wave amplitude activity. Relative therapeutic indices (TIs) of 30 and 42 have been estimated for A-304121 and A-317920, respectively, by comparing doses producing adverse effects in general observation studies with potency in inhibitory avoidance, which are superior to TIs of 8, 10, and 18 observed for the reference antagonists thioperamide, ciproxifan, and GT-2331, respectively. The compounds A-304121 and A-317920 represent a series of novel, H_3R-selective piperazine amides that enhance cognition *in vivo*, which could offer advantages over existing H_3R antagonists or cognition-enhancing agents.

Two novel and selective nonimidazole H3 receptor antagonists A-304121 and A-317920: II. *In vivo* behavioral and neurophysiological characterization. Fox GB, Pan JB, Radek RJ, Lewis AM, Bitner RS, Esbenshade TA, Faghih R, Bennani YL, Williams M, Yao BB, Decker MW, Hancock AA. J Pharmacol Exp Ther 2003 Jun; 305 (3), pp. 897–908. Epub 2003 Feb 20.

Antidepressant Profiling Influences on Cortex Function
Pharmaco-Electroencephalography Psychometric Tests/S-Adenosyl-L-Methionine (SAMe)/L-Methionine (SAMe)/Ademetionine

Physiological Mechanism of Action: S-adenosyl-L-methionine promotes EEG patterns similar to the thymoleptic-type properties associated with imipramine and amitriptyline.
Application: S-adenosyl-L-methionine, L-methionine (SAMe), or ademetionine.
Route of Administration: S-adenosyl-L-methionine (infusion over 30 minutes for 7 days with a washout period of 3 weeks enforced between serial EEG recordings).
Dosage: S-adenosyl-L-methionine (800 mg).
Implementation: Evaluation of the influence of SAMe, L-methionine (SAMe), and ademetionine on brain function and behavior utilizing EEG mapping and psychometry analyses. S-adenosyl-L-methionine is administered with an enforced washout period of 3 weeks in between serial analyses. EEG recordings and psychometric analyses are performed 0, 1, 3, and 6 hours after drug administration on days 1 and 7.

Human Model: Cases of normal healthy elderly volunteers (n = 10; n = 5 males; n = 5 females; age = 56–71 years, mean: = 59.3 years). Investigation design: Double blind, placebo-controlled crossover study.
Interpretation and Analysis: Multivariate analysis based on MANOVA/Hotelling T_2 tests demonstrate significant central effects of SAMe compared to placebo after acute, subacute, and superimposed drug administration. Acute SAMe induces changes that are characterized by a decrease in total power, an increase in absolute delta, and a decrease in absolute alpha power; further by an increase in relative delta and a decrease in relative alpha power; and a slowing of the delta/theta centroid as well as a slowing of the centroid of the total power spectrum. These changes are typical of classical antidepressants of the thymoleptic type (e.g. imipramine and amitriptyline). After 1 week of daily infusions there are marked increases in total power, reminiscent of nootropic drug effects. One additional superimposed dosage mitigates these effects in the direction of an antidepressant profile, with the inter-drug differences waning in the 6^{th} hour. Pharmaco-EEG findings therefore reveal that both inhibitory and excitatory drug effects underlying the antidepressant properties of SAMe are well documented in clinical trials. Psychometric tests concerning noopsychic and thymopsychic measures as well as critical flicker frequency generally demonstrate a lack of differences between SAMe and placebo in a manner that reflects the good tolerability of the agent in elderly subjects.

Pharmacodynamic studies on the central mode of action of S-adenosyl-L-methionine (SAMe) infusions in elderly subjects, utilizing EEG mapping and psychometry. Saletu B, Anderer P, Linzmayer L, Semlitsch HV, Lindeck-Pozza E, Assandri A, di Padova C, Saletu-Zyhlarz GM. Ther Drug Monit 2002 Aug; 24 (4), pp. 532–6.

Arteriovenous Malformations: Central Nervous System (CNS)
Methohexital

Physiological Mechanism of Action: Methohexital is a barbiturate that acts as a central nervous system depressant.
Application: Existing reports suggest that methohexital is a safe provocative agent for use prior to embolotherapy for brain arteriovenous malformations. However, the full effects of methohexital within the cerebral circulation remain to be elucidated.
Route of Administration: Methohexital (intra-arterial).
Dosage: Methohexital (1% concentration with individual doses of 1–6 mg/injection).
Interpretation and Analysis: Arterovenous malformation can initially be characterized with the aid of digital vascular imaging methods performed just prior to and just after intra-arterial methohexital injection.

Human Model: Cases without angiographic or clinically detectable evidence of vasospasms (e.g. n = 66 vascular pedicle injections in n = 30 cases).
Interpretation and Analysis: Perfusion of functional tissue with methohexital can often immediately precipitate evidence of altered neurologic status that fortunately almost invariably resolves within 2 minutes of the initial onset. No signs of either prolongation of the induced clinical symptoms or seizures are evident to suggest any adverse effects related to either methohexital crystallization or the effects of injecting an alkaline solution into the cerebral vascular circulation.

Though the full effects of methohexital in the cerebral circulation remain to be elucidated, existing reports suggest it is a safe provocative agent for use prior to embolotherapy for brain arteriovenous malformations.

Intra-arterial use of sodium methohexital for provocative testing during brain embolotherapy. Peters KR, Quisling RG, Gilmore R, Mickle P, Kuperus JH. AJNR Am J Neuroradiol 1993 Jan–Feb; 14 (1), pp. 171–4.

Autism (Infantile): Hypothalamic Dysfunction/ Parkinson's Disease
L-dopa

Cellular/Molecular Mechanism of Action: Systemically, L-dopa is converted to dopamine, which is responsible for the primary physiological properties of L-dopa preparations.
Application: Delineation of hypothalamic dysfunction and possible relationship to dopaminergic abnormalities in cases of infantile autism fulfilling the DSM-III criteria for this disorder.
Considerations: Following oral administration, approximately 95% of the L-dopa ingested is decarboxylated to dopamine (poorly penetrates the blood-brain barrier). In order to achieve changes in neurological function through the accumulation of L-dopa in the CNS, relatively large doses have to be administered. Over time, a tolerance to L-dopa begins to develop. The conversion of L-dopa to dopamine, however, can be inhibited by the co-administration of inhibitors of hepatic dopa decarboxylase (L-amino acid decarboxylase inhibitors: carbidopa [USA] benserazide [Europe]).

One side effect of L-dopa is an inhibition of prolactin secretion presumably through a direct effect on the adenohypophysis and possibly the release of prolactin inhibitor factor. Other side effects are

rather common when L-dopa is applied as a therapeutic modality (vomiting, nausea).

Drug interactions may occur with pyridoxine since L-dopa is decarboxylated by the pyridoxine-dependent enzyme L-amino acid decarboxylase. Excess amounts of pyridoxine enhance extracerebral metabolism of L-dopa, thereby neutralizing its biological/physiological effect (e.g., pyridoxine in vitamin supplements). Reserpine depletes intracellular dopamine stores.

Implementation: Evaluation of suspected cases of autism and Parkinson's disease.

Interpretation and Analysis: Results indicate a high incidence (at least 30%) of blunted plasma growth hormone responses following oral L-doap administration. These data suggest an alteration of hypothalamic dopamine receptor sensitivity in cases with blunted responses. Thus, a subgroup of autistic cases within a descriptively homogeneous diagnostic category shows evidence of hypothalamic dysregulation and dopaminergic abnormalities.

In conditions of Parkinson's disease, approximately 75% of the cases respond favoriably to L-dopa administration and may appear essentially symptom free. To some degree, all of the clinical signs of Parkinson's disease respond to L-dopa administration except episodes of dementia.

Plasma growth hormone response to oral L-dopa in infantile autism. Deutsch SI, Campbell M, Sachar EJ, Green WH, David R. J Autism Dev Disord 1985 Jun; 15 (2), pp. 205–12.

Autonomic Nervous System Dynamic Time-Frequency Analysis
Sodium Amobarbitol/Wada Test

Background Information: Recently, time-frequency analysis has become very popular for examining non-stationary time series and for researching fast-changing phenomena.

Application: Utilized in performing the Wada test which involves the (selective) injection of sodium amobarbitol into the internal carotid artery resulting in the inactivation of cerebral structures supplied by the ipsilateral anterior and middle cerebral arteries. The intra-carotid instillation of amobarbital can be combined with electrocardiographic analyses (electrocardiopharmacology test).

Route of Administration: Amobarbitol (catheter instillation into the internal carotid artery).

Implementation: Utilization of a smoothed-pseudo Wigner-Ville distribution to model the underlying dynamic autonomic nervous system changes that occur during the intracarotid sodium amobarbital (ISA Wada test). Electrocardiogram (EKG) data are recorded during the entire procedure and 10 minutes prior to each injection which are used as baseline values for that hemisphere. Interbeat-interval time series are created from such data for further analyses (smoothed-pseudo Wigner-Ville distribution to model).

Human Model: 13-year-old patient.

Interpretation and Analysis: Evaluations of data generated in the fashion described reveals that sodium amobarbitol injection to either side of the brain produces decreased power in the vagally mediated high frequency band (.14-.40 Hz). Importantly, the decrease is greater when the right hemisphere is inactivated compared to the left side. Such results are consistent with the known lateralized innervation of the heart such that right-sided autonomic inputs have greater influence on cardiac chronotropy. Very rapid changes in autonomic control occur that characterize the inactivation and subsequent recovery of the cerebral hemispheres and serve to confirm the utility of time-frequency analysis in the investigation of cardiac time series.

Time frequency analysis of the cardiovascular response during the intracarotid amobarbital test. Sollers JJ 3rd, Ahern GL, Merritt MM, Thayer JF. Biomed Sci Instrum 2002; 38, pp. 267–71.

Behavior: Depression/REM Latency Disturbances
Pharmaco-Electroencephalography/Growth Hormone/DST

Application: Provocative stimulation tests that promote increased growth hormone secretion can be applied to detect and characterize certain types of behavioral depression.

Implementation: Evaluate the influence of provocative neuroendocrine stimulation tests with DST and growth hormone (GH) on cerebral cortical function during sleep analyzed by EEG recordings.

Human Model: Cases of prepubueral monozygotic twins (n = 2 males) with Major Depressive Disorder. Results are compared with results from a normal puberal control boy (e.g., n = 1), and an adolescent female (e.g., n = 1) suffering from major depression.

Interpretation and Analysis: The REM latency is reduced in the adolescent depressed girl but not in the puberal depressed twins when compared to normal controls (e.g., n = 1). Sleep continuity and sleep architecture are, however, disturbed in examples of puberal and adolescent depression and a function of or directly related to the severity of the original depressive state. The results of the DST reveal abnormal cortisol values in severely depressed individuals (e.g., most severely depressed twin and in the depressed adolescent). Growth hormone secretion after DMI shows a clear GH response in the less depressed twin and in normal subjects (e.g., n = 1) while in the depressed adolescent (e.g., n = 1), the GH response is blunted. Therefore, REM latency disturbances in at least some cases of depression do not appear before adolescence, while neuroendocrine dysfunction can already be present in puberal depression.

Electroencephalogram and neuroendocrine parameters in pubertal and adolescent depressed children. A case report study. Mendlewicz J, Hoffmann G, Kerkhofs M, Linkowski P. J Affect Disord 1984 Jun; 6 (3–4), pp. 265–72.

Behavior: Depression
L-5-Hydroxytryptophan (L-5HTP)

Background Information: Phenylalanine, tyrosine, L-dopa, L-tryptophan, and L-5-hydroxytryptophan (L-5HTP) have been found to induce differential behavioral and biochemical effects in both healthy subjects and endogenous depressed individuals. Indoleamine precursors predominantly cause mood changes. However, the efficacy of these amino acids as antidepressants has been neither clearly established nor refuted, probably due to insufficient consideration of the following criteria: lack of adequately high plasma levels to facilitate passive transport of enough agent into the brain; lack of effective serotoninergic system stimulation; and selective increase of serotonin turnover with minimal interaction with other neurotransmitters.

Application: Characterization of depressive behavior patterns.
Route of Administration: L-5HTP (intravenous).
Implementation: Evaluation of strategies for systemic loading with precursor amino acids of the monoamines that are postulated to be involved in the molecular pathogenesis of mental disorders. One approach towards achieving this objective involves delineating the concentration profile for intravenous L-5HTP utilized as a provocative test for cases of depression, administered in concert with the concomitant measurement of neuroendocrinological and psychometric parameters.

Theoretical and therapeutic potential of indolamine precursors in affective disorders. Wirz-Justice A. Neuropsychobiology 1977; 3 (4), pp. 199–233.

Behavior: Depression
Sulpiride/(Prolactin Response)

Cellular/Molecular Mechanism of Action: Sulpiride is a dopamine D2 receptor antagonist.
Background Information: Multiple lines of investigation have implicated the role of the dopaminergic system in disorders of depression.
Application: Detection and characterization of the molecular basis for depression behavior (e.g. cerebral hemisphere disfunction).
Implementation: Characterization of dopamine D_2 receptor sensitivity status in depressed vs negative control cases by means of a neuroendocrine challenge test involving the measurement of prolactin response to sulpiride challenge. Cases are diagnosed as positive according to DSM-IV criteria, in concert with the application of the Montgomery Asberg and Zung scales.

Human Model: Cases of behavioral central nervous system depression (n = 10 with n = 10 age-matched male volunteer controls). No significant difference in baseline levels of prolactin can be appreciated between the depressed and control case groups.
Interpretation and Analysis: Significantly higher prolactin levels after sulpiride challenge can be appreciated in cases suffering from depression in contrast to unaffected controls at all time points following sulpiride administration. Such a neuroendocrine challenge paradigm suggests that the prolactin response to sulpiride is enhanced in depression, and suggests that this receptor might be supersensitive in depression disorders compared to controls. Observations of this nature add to the data implicating the dopaminergic system in the pathophysiology of depression and suggest that dopaminergic mechanisms might be a target of diagnostic and therapeutic interest.

The prolactin response to sulpiride in major depression: The role of the D2 receptor in depression. Verbeeck WJ, Berk M, Paiker J, Jersky B. Eur Neuropsychopharmacol 2001 Jun; 11 (3), pp. 215–20.

Behavior: Depression
Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: One of the biological effects of hypothalamic thyrotropin-releasing hormone (TRH, rifathyroin) is induced production/release of pituitary thyroid stimulating hormone.
Physiological Mechanism of Action: Possesses a peculiar spectrum of stimulating action bringing it nearer to such psychotropic agents as psychostimulants and antidepressants.
Application: Thyrotropin-releasing hormone (TRH, rifathyroin) can be applied to characterize conditions of mental depression.
Considerations: In animals, TRH increases locomotivity without induction of aggression, stereotypia, or epileptic disorders; while it enhances the effects of amphetamine, apomorphine, and L-dopa; and reduces the action of reserpine, haloperidol, and clonidine.
Experimental Interpretation: Thyrotropin-releasing hormone facilitates the teaching of rats in a T-form labyrinth causing rotating behavior of rats during selective administration to the head of the caudate nucleus. In this context, experimental data has revealed that TRH possess adreno- and dopamine-stimulating properties in TRH.
Clinical Interpretation: Euphoristic and stimulating effects have been noted with the clinical application of TRH as a diagnostic agent in cases with depressive disturbances (e.g. n = 42).

Behavior: Depression: Cerebral Hemisphere Function/Pharmaco-EEG Profile/Delta and Alpha Power/Delta/Theta Centroid/Centroid of the Total Power Spectrum/Noopsychic and Thymopsychic Measures/Critical Flicker Frequency
S-adenosyl-L-Methionine/Ademetionine/[Imipramine]/[Amitriptyline]

Physiological Mechanism of Action: S-adenosyl-L-methionine promotes EEG patterns similar to the thymoleptic-type properties associated with imipramine and amitriptyline.
Application: S-adenosyl-L-methionine, L-methionine (SAMe), or ademetionine.
Route of Administration: S-adenosyl-L-methionine (infusion over 30 minutes for 7 days with a washout period of 3 weeks enforced between serial EEG recordings).
Dosage: S-adenosyl-L-methionine (800 mg).
Implementation: Evaluation of the influence of SAMe, L-methionine (SAMe), and ademetionine on brain function and behavior utilizing EEG mapping and psychometry analyses. S-adenosyl-L-methionine is administered with an enforced washout period of 3 weeks in between serial analyses. EEG recordings and psychometric analyses are performed 0, 1, 3, and 6 hours after drug administration on days 1 and 7.

Human Model: Cases of normal healthy elderly volunteers (n = 10; n = 5 males; n = 5 females; age = 56–71 years, mean: = 59.3 years). Investigation design: Double blind, placebo-controlled crossover study.
Interpretation and Analysis: Multivariate analysis based on MANOVA/Hotelling T_2 tests demonstrate significant central effects of SAMe compared to placebo after acute, subacute, and superimposed drug administration. Acute SAMe induces changes that are characterized by a decrease in total power, an increase in absolute delta, and a decrease in absolute alpha power; an increase in relative delta and a decrease in relative alpha power; and a slowing of the delta/theta centroid as well as a slowing of the centroid of the total power spectrum. These changes are typical of classical antidepressants of the thymoleptic type (e.g. imipramine and amitriptyline). After 1 week of daily infusions there are marked increases in total power, reminiscent of nootropic drug effects. One additional superimposed dosage mitigates these effects in the direction of an antidepressant profile, with the inter-drug differences waning in the 6^{th} hour. Pharmaco-EEG findings therefore reveal that both inhibitory and excitatory drug effects underlying the antidepressant properties of SAMe are well documented in clinical trials. Psychometric tests concerning noopsychic and thymopsychic measures as well as critical flicker frequency generally demonstrate a lack of differences between SAMe and placebo in a manner that reflects the good tolerability of the agent in elderly subjects.

Pozza E, Assandri A, di Padova C, Saletu-Zyhlarz GM. Ther Drug Monit 2002 Aug; 24 (4), pp. 532–6.

Behavior: Depression
L-dopa/TRH/[Propanolol]

Cellular/Molecular Mechanism of Action: Induces growth hormone (GH) release/secretion
Background Information: Suboptimal concentrations of GH can be found in serum following the administration of L-dopa/propanolol.
Application: Detection of deficiencies in systemic GH production.
Implementation: Evaluation of endocrine factors in conditions of mental depression using the dexamethasone suppression test (DST), thyroid-stimulating hormone test (TSH), prolactin (PRL) responses to thyrotropin-releasing hormone (TRH), in addition to GH responses to L-dopa challenge. Provocative tests are performed before commencement of antidepressant treatment and after recognition of a clinical response to determine if; (i) a functional relationship exists between the hypothalamic-pituitary-adrenal (HPA) axis, the hypothalamic-pituitary-thyroid (HPT) axis, and the dopaminergic system in disorders of depression, in addition to determining if (ii) alterations in these hormonal functions occur during treatment with antidepressants.

Human Model: Cases of mental depression (n = 19).
Interpretation and Analysis: Thyroid-stimulating hormone responses to TRH show a tendency to increase from pre- to post-treatment periods, while TRH-induced PRL and L-dopa-induced GH responses do not change during treatment for depression in cases that noticeably respond favorably to intervention. Females show significantly higher TSH and PRL responses to TRH compared to males. No interconnections can be appreciated between responses in DST, TRH stimulation test, and L-dopa-induced GH test. Therefore, there appears to be no support that an interrelationship exists between the abnormalities in the HPT and HPA axes and central dopaminergic activity in depression.

Effects of antidepressant treatment on thyrotropin-releasing hormone stimulation, growth hormone response to L-dopa, and dexamethasone suppression tests in major depressive cases. Esel E, Kartalci S, Tutus A, Turan T, Sofuoglu S. Prog Neuropsychopharmacol Biol Psychiatry 2004 Mar; 28 (2), pp. 303–9.

Behavior Modification
Naloxone

Cellular/Molecular Mechanism of Action: Competitively blocks binding of endogenous endorphins to membrane-associated opiod receptor sites.
Diagnostic Application: Management of endorphin-reinforced "self-reward" behavior. Examples include horses displaying "cribbing," "weaving," and self-mutilation behaviors (e.g. equine species); and excessive licking, tail-chasing, and biting/chewing in dogs and cats.
Route of Administration and Dosage: Parenteral/systemic ideally administered using a slow "timed-release" type of delivery modality. An example of such a preparation is an impregnated resin pellet.
Interpretation and Analysis: A positive response is detected by a reversal or prevention of behavior abnormalities (pharmacological behavior modification). Naloxone has a relatively short duration of action which complicates the practicality of administering the agent for the purpose of behavior modification. Slow timed-release forms appear to be one alternative approach to avoiding the disadvantages of short duration of action.

Behavior: Neuropsychological Testing/Cholinergic Receptor Complexes: Muscarinic
Scopolamine/Physostigmine/Methylphenidate

Cellular/Molecular Mechanism of Action: Scopolamine binds to muscarinic cholinergic receptor complexes in a manner that competitively inhibits the biological activity of acetylcholine as a neurotransmitter, thereby functioning as anticholinergic/parasympatholytic agent. Physostigmine binds to and inactivates the biochemical activity of acetylcholine esterase in a manner that promotes accumulation of acetylchline neurotransmitter (anticholinesterase properties). Methylphenidate, like other amphetamines, promotes the release of biogenic amines from storage granules located within presynaptic membranes.
Physiological Mechanism of Action: Scopolamine (anticholinergic), scopolamine plus physostigmine (anticholinesterase), scopolamine plus methylphenidate (adrenergic: mild CNS stimulant and produces convulsions at higher dosage levels). Methylphenidate promotes locomotor stimulation that is generally associated with norepinephrine release in contrast to the release of dopamine from dopaminergic nerve terminals within the CNS (e.g., neostiatum). Higher doses of methylphenidate are believed to cause the release of 5-hydroxytryptamine (5-HT or serotonin) from tryptaminergic presynaptic membranes (mesolimbic system) in a manner that promotes psychotic behavioral changes.
Application: Neurophysiological testing utilized in combination with evoked potential analyses to evaluate various types of dysfunction, including age-related cognitive impairment and Alzheimer's like dementia conditions (DAL) that are linked to alterations in the cholinergic system.
Examples of Clinical Implementation: Scopolamine prolongs the P3 latency and reduces the spectral power of long latency evoked potentials without significantly altering earlier components. Physostigmine partially reverses these effects, but methylphenidate does not. Motor speed is slowed by scopolamine but not by scopolamine/methylphenidate combinations. The cholinergic systems appear to be involved in the generation or modulation of the P3 potential, possibly secondary to the cholinergic role in selective attention. Similar techniques and pharmaceutical agents may be useful as *in vivo* probes of central cholinergic function and thus as research and diagnostic aids in aging and disease.

In vivo probe of central cholinergic systems. Meador KJ, Loring DW, Lee GP, Taylor HS, Hughes DR, Feldman DS. J Gerontol 1988 Nov; 43 (6), pp. M158–62.

Behavior/Opioid Abstinence (Acute Morphine Withdrawl)
Naloxone/Nalorphine

Cellular/Molecular Mechanism of Action: Morphine, naloxone, and nalorphine bind to opioid receptor complexes residing within the central nervous system.
Implementation: Evaluation of the effects of morphine, naloxone, and nalorphine on "responses" when *in vivo* models are maintained under variable-interval schedules for food presentation.

Observations are assessed before and after successive periods of daily morphine maintenance (15 mg/kg/day SC). Withdrawal from morphine dependence is performed gradually following 2 initial maintenance periods and abruptly following a third period. Schedule-controlled "response" is disrupted when morphine maintenance is abruptly discontinued but not when the maintenance dosage is gradually reduced to zero.

Animal Model: Primate (rhesus monkeys).

Interpretation and Analysis: Tolerance to the acute effects of morphine (IV) on "responses" develop during morphine maintenance and dissipate when daily injections are discontinued. Effects of naloxone and nalorphine following each period of morphine maintenance are generally similar to their effects in initial periods of evaluation. Such observations indicate that tolerance-producing regimens of repeated daily injections with morphine do not necessarily produce enduring changes in the effects of opiate antagonists on schedule-controlled behavior. Additionally, gradual withdrawal from morphine maintenance can minimize the behavioral disruptions that attend abrupt abstinence.

Behavioral effects of naloxone and nalorphine preceding and following morphine maintenance in the rhesus monkey. Bergman J, Schuster CR. Psychopharmacology (Berl)] 1985; 86 (3), pp. 324–7.

Behavior/Panic Disorder/Cerebral Cortex Function
Sodium Lactate/Carbon Dioxide/Caffeine/Yohimbine/Isoprenaline/Cholecystokinin

Background Information: The pharmacological challenge strategy involves giving a provoking agent according to controlled protocols to clarify some aspect of behavioral or biological function.

Implementation: Various agents such as sodium lactate, carbon dioxide, caffeine, yohimbine, isoprenaline, and cholecystokinin have been used as agents to provoke panic disorder in healthy volunteers as well as in panic cases.

Interpretation and Analysis: Results obtained in this field of study have been updated, with emphasis on the potential mechanisms of action. It has been concluded that there may be a final pathway between carbon dioxide, sodium lactate, and cholecystokinin inducing panic attacks.

Provocative agents in panic disorder. Bourin M, Malinge M, Guitton B. Therapie 1995 Jul–Aug; 50 (4), pp. 301–6.

Behavior/Pharmaco-Electroencephalogram Mapping
Diazepam

Cellular/Molecular Mechanism of Action: Diazepam inhibits central nervous system gamma aminobutyrate (GABA), which functions as a neurotransmitter. Suppression is associated with the known ability of diazepam to bind to membrane-associated GABA receptor complexes.

Application: Diazepam (central nervous system depressant).

Dosage: Diazepam (10 mg).

Implementation: Evaluate the influence of diazepam on brain (cerebral cortex) function applying EET topographical mapping techniques (recordings applied from 4 different reference sites). Four referential derivations including ipsilateral earlobe (A1A2), average reference (AV), source derivation (SD), and balanced noncephalic electrode (BNE) can be used. One-minute vigilance-controlled EEGs before drug administration and 2 hours after drug administration are analyzed using Fourier transformation followed by the calculation of absolute power and relative power for 4 frequency bands.

Human Model: Cases of normal healthy volunteers (n = 10 right-handed males; 21–25 years of age). Double blind crossover trials with a single oral dose of 10 mg diazepam or placebo control administered in random sequence at intervals of 1 week.

Interpretation and Analysis: Diazepam causes a widespread increase of beta-frequency relative power, and a widespread decrease of theta-frequency absolute power when A1A2 and SD are taken as references. From the comparison of different reference electrodes, the selection of the reference and of spectral parameters (absolute power or relative power) play an important role in pharmaco-EEG studies.

Pharmaco-EEG mapping of diazepam effects using different references and absolute and relative power. Yamadera H, Kato M, Ueno T, Tsukahara Y, Okuma T. Pharmacopsychiatry 1993 Nov; 26 (6), pp. 254–8.

Behavior/Psychotropic (Central) Side Effects
Pharmaco-Electroencephalogram/Loderix (Setastine)/Terfenadine (Teldane)/Chloropyramine HCl (Suprastin)

Physiological Mechanism of Action: The pharmaceutical agents, terfenadine, Teldane, chloropyramine HCl, and Suprastin possess sedative effects of very different degrees.

Application: Manipulation of cerebral cortex function and evaluation of pharmaceutical intervention in neurological disorders.

Implementation: Evaluate the influence of Loderix (setastine), in addition to a "vehicle" and with 2 reference pharmaceuticals (terfenadine, Teldane; and chloropyramine HCl, Suprastin) on cerebral cortex function applying EEG analysis as a means of monitoring efficacy.

Human Model: Cases of normal healthy male volunteers (n = 10) in a double blind, placebo-controlled, crossover arrangement.

Interpretation and Analysis: The different effects of the drugs on the central nervous system (CNS) are precisely indicated by the posterior alpha/theta ratio in the EEG. This marker parameter is affected by Loderix in the same direction as by Teldane and in the opposite direction relative to Suprastin. In addition, Loderix increases the beta frequency range in the median areas of both hemispheres; moreover, it increases the total EEG power. The latter changes raise the question about the possibility that Loderix has an "own" action on EEG analyses. (The observed "own" effect could not even be brought into connection with a decrease of the vigilance level). Observations made to date strengthen the view that the action of Loderix on the EEG is similar to that induced by Teldane, a drug very favorable with respect to sedative side effects. Moreover, the drug does not affect the EEG power spectra in a direction that corresponded to a sedative action. The spectral parameters in the "pharmaco" EEG recordings seem to be useful in the objective definition of the central (psychotropic) side effects of drugs.

Assessing the sedative (adverse) effects of antiallergic drugs by quantitative electroencephalography: Effects of setastine, a non-sedating antihistaminic drug. Rajna P, Veres J. Ther Hung 1994; 42 (1), pp. 14–20.

Behavior: Schizophrenia/Pellegra
Niacin Challenge

Application: Clinical and biochemical evidence for alterations in phospholipid function in schizophrenia conditions. Used in cases with frank psychoses that may also simultaneously be suffering from pellagra-associated neurological abnormalities.

Dosage: Relatively large doses of niacin are required to induce neurologic signs, particularly when the psychosis is associated with conditions of encephalopathy.

Interpretation and Analysis: In human cases of pellagra with neurological signs of confusion, inappetence, nausea, and vomiting, the administration of nicotinic acid results in an abalation of signs within a period of 12 hours (approximately). Pellegra may be accompanied by conditions of peripheral neuritis precipitated by a thiamine deficiency.

The niacin challenge test: Clinical manifestation of altered transmembrane signal transduction in schizophrenia? Hudson CJ, Lin A, Cogan S, Cashman F, Warsh JJ. Biol Psychiatry 1997 Mar 1; 41 (5), pp. 507–13.

Behavior: Schizophrenia
Niacin (Skin Flush Response)/Niacin Challenge

Cellular/Molecular Mechanism of Action: Niacin selectively mediates the release of vasodilatory prostaglandins in the skin, creating a "flush" type response or sensation.

Application: Detection and characterization of schizophrenia conditions.

Implementation: Detection and characterization of schizophrenia cases.

Interpretation and Analysis: A normal skin flush response to niacin is attenuated in many individuals with schizophrenia (SCZ). Such findings suggest abnormal prostaglandin signaling in SCZ. Since prostaglandins are derived from arachidonic acid (AA), the finding of an abnormal skin flush response is consistent with biochemical data suggesting relative depletion of AA, and other essential fatty acids (EFAs), in a substantial portion of people with SCZ. Reports have described the mechanism of the skin flush response to niacin and why it is abnormal in SCZ conditions. The disease state is not related to psychotropic medications, and it may be a marker of EFA deficiency, which has been documented to be present in many SCZ cases.

Relationship between the niacin skin flush response and essential fatty acids in schizophrenia. Messamore E. Prostaglandins Leukot Essent Fatty Acids 2003 Dec; 69 (6), pp. 413–9.

Behavior: Schizophrenia (Familial Clusters of Disease)
Lithium

Background Information: Selecting a drug according to the treatment response in a blood relative has been widely accepted advice in the management of mood disorders. However, this recommendation has not been adequately substantiated in the literature. Minimal information is known about to what extent the response to long-term lithium treatment is a familial trait.

Implementation: Evalation and comparison of the response to long-term lithium treatment in bipolar blood relatives of bipolar lithium responders and bipolar controls. Validation of a diagnosis for bipolar disorder can be determined using the Schedule for Affective Disorders and Schizophrenia-Lifetime Version (SADS-L) and Research Diagnostic Criteria (RDC). Lithium response is evaluated on a rating scale reflecting the quality and quantity of available data.

Human Model: Relatives of cases with bipolar disorders (n = 24) identified in families of 106 cases with lithium-response disorder; and lithium-treated bipolar cases serving as a comparison control group (e.g. n = 40).

Interpretation and Analysis: Relatives with bipolar disorder identified in families with lithium-responsive bipolar disorder, compared to lithium-treated bipolar cases (comparison controls) reveals a prevalence of unequivocal response among the relatives of 67%, compared to a response rate of 35% in the comparison group (chi^2 = 6.04, df = 1, p = 0.014). The highly significant difference in observed response between relatives and reference control groups supports the perspective that lithium prophylaxis clusters exist within families and the general population.

Is response to prophylactic lithium a familial trait? Grof P, Duffy A, Cavazzoni P, Grof E, Garnham J, MacDougall M, O'Donovan C, Alda M. J Clin Psychiatry 2002 Oct; 63 (10), pp. 942–7.

Behavior: Tourette's Syndrome (Tic Disorders)
Amphetamine/Dextroamphetamine/Haloperidol/ Levamfetamine Succinate/Apomorphine/Piribedil/ [^{11}C]-Raclopride

Cellular/Molecular Mechanism of Action: Apomorphine is postulated to interact with presynaptic dopamine receptors. Dopamine functions as a inhibitory neurotransmitter.

Background Information: Dopaminergic abnormalities in frontal-subcortical circuits have been hypothesized as the underlying pathophysiologic mechanism in Tourette's syndrome.

Application: Administration is based on the hypothesis that presynaptic dopamine/catecholamine release from anatomical structures like the striatum is abnormal in adults with Tourette's syndrome.

Implementation: Evaluation of Tourette's syndrome conditions utilizing 2 positron emission tomography (PET) scans with high specific activity [^{11}C]-raclopride. The 1st scan is performed after an intravenous injection of saline, while the 2nd scan is made after intravenous amphetamine injection. Relative dopamine release is estimated as the percentage difference in binding potential between the post-saline and post-amphetamine scans.

Interpretation and Analysis:

Nuclear Medicine Studies: Binding potential determined after initial [^{11}C]-raclopride scans do not significantly differ between Tourette's syndrome cases and control subjects. After amphetamine challenge, the mean value of intrasynaptic dopamine in the putamen (as determined by true equilibrium bolus estimation) increases by 21% in subjects with Tourette's syndrome but does not change in control subjects; the mean values increase by 16.9% and decrease by 1.8%, respectively (constrained method of measurement). Dopamine release in the caudate region is not significantly different with Tourette's syndrome and comparison subjects. Greater putamen dopamine release is seen in adults with Tourette's syndrome than in comparison subjects after a pharmacologic challenge with amphetamine. These results suggest that the underlying pathobiology in Tourette's syndrome is a phasic dysfunction of dopamine transmission.

Behavioral Studies: Both dextroamphetamine and levamfetamine increase the severity of the symptoms; dextroamphetamine is more potent. Haloperidol controls the symptoms and also antagonizes the effect of dextroamphetamine. Apomorphine injections reduce the severity of symptoms, even in the presence of dextroamphetamine. Therefore, dopamine rather than norepinephrine is the principal catecholamine responsible for observed symptoms. The effect of apomorphine may be understood through its action on postulated presynaptic inhibitory dopamine receptors or other presynaptic mechanisms of action.

Effects of dopamine agonists and antagonists in Tourette's disease. Feinberg M, Carroll BJ. Arch Gen Psychiatry 1979 Aug; 36 (9), pp. 979–85.

Benzodiazepine/Receptor Ligands
2, 9-Disubstituted Quinolino[2′, 3′-5, 4](3-Pyrazolino)Pyrimidin-2-Ones/2, 9-Disubstituted Quinolino[2′, 3′-5, 4](3-Pyrazolino)Purin-4-Ones

Cellular/Molecular Mechanism of Action: The compounds 2, 9-disubstituted quinolino[2′, 3′-5, 4](3-pyrazolino)pyrimidin-2-ones and purin-4-ones recognize and bind to benzodiazepine receptor complexes (GABA).
Physiological Mechanism of Action: The compounds 2, 9-disubstituted quinolino[2′, 3′-5, 4](3-pyrazolino)pyrimidin-2-ones and purin-4-ones displace [^{3}H]R015-1788 from its specific binding site in bovine brain membranes.
Interpretation and Analysis: Compound 5c causes 83% (± 8%) inhibition of [^{3}H]R015-1788 specific benzodiazepine receptor binding followed by compounds 5f, 5h, and 5i, in decreasing order of binding avidity. Other analogs are inactive at 10 μM.

Synthesis and benzodiazepine receptor binding activity of 2, 9-disubstituted quinolino[2′, 3′-5, 4](3-pyrazolino)[3, 2-b]purin-4-ones. El-Sayed OA, Habib NS, Aboul-Enein HY, Costa B, Lucacchini A, Martini C. Arch Pharm (Weinheim) 2002 May; 335 (5), pp. 207–12.

Bladder Function/Over-Active Bladder Conditions/ Serotonin (5-HT) Production in the Central Nervous System/Physiological Processes Mediated by Alterations in Serotonin Production
Clomipramine/Fluoxetine

Cellular/Molecular Mechanism of Action: Clomipramine modifies (reduces) concentrations of serotonin (5-HT) within the central nervous system (CNS). Fluoxetine is a selective CNS serotonin uptake inhibitor.
Physiological Mechanism of Action: Clomipramine promotes endogenous CNS depression while fluoxetine can reverse these CNS properties induced by clomipramine.
Background Information: Serotonin (5-HT) in the CNS may inhibit bladder activity. Based on this consideration, it has been postulated that CNS depression associated with altered 5-HT production may be associated with or be the cause of conditions such as overactive bladder (OAB) activity.
Application: Detection and evaluation of physiological functions or conditions (e.g., OAB) that may be associated with alterations in serotonin (5-HT) production within the CNS.
Dosage: Clomipramine hydrochloride (22.5 mg/kg body weight) compared to an equal volume of sterile physiological saline administered by injection to negative reference controls. Fluoxetine (20 mg/kg daily).
Implementation: Evaluation of the influence of clomipramine hydrochloride on urinary voiding frequency at 10 and 15 weeks. Behavioral correlates of depression are assessed using a forced-swim challenge. At age 15 weeks cystometry (CMG) analysis is performed. Fluoxetine is then co-administered with clomipramine or saline followed by the measurement of void frequency (VF) and reevaluation of CMG analyses.

Animal Model: Rat (Wistar pups, postnatal days 8 to 21) endogenous model for depression promoted by lowering serotonin (5-HT) concentrations.
Interpretation and Analysis: Clomipramine increases immobility when combined with forced-swim challenge testing (indication of depression). Clomipramine promotes more frequent voiding compared to negative saline controls at 10 and 15 weeks. Interestingly, the difference is significant only in females. Cystometry of clomipramine/females reveals decreased bladder capacity, micturition volume, and inter-micturition contractions compared with negative saline reference controls. Fluoxetine reverses these changes (comprable to saline negative reference controls). Such observations support the hypothesis that OAB may be associated with altered 5-HT function and may explain previous descriptions of an association between depression and OAB.

Alterations in voiding frequency and cystometry in the clomipramine induced model of endogenous depression and reversal with fluoxetine. Lee KS, Na YG, Dean-McKinney T, Klausner AP, Tuttle JB, Steers WD. J Urol 2003 Nov; 170 (5), pp. 2067–71.

Blood-Brain Cerebrospinal Fluid (CSF) Barrier/ Carrier Mediated Efflux Transport System
[^{3}H]-Oestrone-3-Sulfate

Cellular/Molecular Mechanism of Action: Oestrone-3-sulfate is a steroid hormone.
Application: Evaluation and characterization of blood-brain barrier transport mechanisms.
Implementation: Evaluation of the efflux transport of oestrone-3-sulfate, a steroid hormone sulfate, across the blood-cerebrospinal fluid barrier has been examined following its intracerebroventricular administration. To characterize the oestrone-3-sulfate transport process, an *in vitro* uptake experiment can be performed using isolated rat choroid plexus.

Animal Model: Rat (*in vivo* and applying isolated rat *ex vivo* choroid plexus preparation).
Interpretation and Analysis: [^{3}H]oestrone-3-sulfate is eliminated from CSF with an apparent efflux clearance of 205 μL min^{-1}. Approximately 25% of unmetabolized [^{3}H]oestrone-3-sulfate is in the plasma 5 minutes after intracerebroventricular administration, indicating that at least a fraction of [^{3}H]oestrone-3-sulfate is transported from the CSF, across the CSF-blood barrier and into the circulating blood (intravascular compartment). This efflux transport is inhibited by the co-administration of excess oestrone-3-sulfate (25 mM 10 μL = 0.25 μmol) into the cerebral ventricle.

Oestrone-3-sulfate uptake by isolated choroid plexus (*ex vivo* preparation) is a saturable process with a Michaelis-Menten constant (K_m) of 18.1 ± 6.3 μM, and a maximum uptake rate (V_{max}) of 48.0 ± 15.1 pmol/min/μL of tissue. The oestrone-3-sulfate transport process is temperature dependent and inhibited by metabolic inhibitors such as 2,4-dinitrophenol and rotenone, suggesting that the process is energy dependent. Such uptake events are also inhibited by steroid hormone sulfates (1 mM dehydroepiandrosterone sulfate at 1 mM; and oestrone sulfate at 1 mM), bile acids (taurocholic acid at 1 mM; and cholic acid at 1 mM), and organic anions (sulphobromophthalein at 1 mM; and phenolsulphonphthalein at 1 mM), whereas *p*-aminohippuric acid at 1 mM, *p*-nitrophenol sulfate at 1 mM, methotrexate at 0.1 mM, and the cardiac glycoside digoxin at 2.5 μM have little effect. Therefore, oestrone-3-sulfate appears to be transported from the CSF into the circulating blood across the blood-CSF barrier via a carrier-mediated efflux transport system.

In vivo and *in vitro* evidence of a carrier-mediated efflux transport system for oestrone-3-sulfate across the blood-cerebrospinal fluid barrier. Kitazawa T, Hosoya K, Takahashi T, Sugiyama Y, Terasaki T. J Pharm Pharmacol 2000 Mar; 52 (3), pp. 281–8.

Caffeine/Cerebral Cortex Function/Environmental Psychostimulant Interference
Caffeine/Topographic Quantitative EEG

Cellular/Molecular Mechanism of Action: Caffeine is classified as a xanthine analog that promotes stimulation of the central nervous system.
Physiological Mechanism of Action: Caffeine (psychostimulants and stimulate the medullary respiratory centers).
Background Information: Despite the widespread use of caffeine as a central nervous stimulant, the central pharmacodynamic properties of the drug have not yet been conclusively evaluated in humans.
Application: Evaluation of the interference of environmental psychostimulant on topographic quantitative electroencephalography analyses.
Route of Administration: Caffeine (oral powder in water).
Dosage: Caffeine (200 mg equivalent to 2 cups of coffee).
Implementation: Evaluate the influence of caffeine on cerebral cortex function by topographically measuring quantitative electroencephalogram (EEG) profiles. Oral caffeine is administered under randomized, double blind crossover conditions on 2 different occasions. Before administration and 30 minutes afterward, a 17-channel quantitative EEG is recorded during relaxation with eyes open and closed (15 minutes each).
Human Subjects: Cases of normal cerebral cortex function (n = 10 healthy subjects; mean age = 25 and SD ± 4 years).
Interpretation and Analysis: Caffeine causes a significant reduction of total EEG power at fronto-parieto-occipital and central electrode positions of both hemispheres when the eyes are kept open. Absolute power of the slow and fast alpha and slow beta activities are diminished in various regions of the brain ($p < 0.05$). The effect is more pronounced when the eyes are kept open than when the eyes are kept closed. Quantitative EEG appears to be a sensitive method for assessing the effects of psychostimulants on the human brain. Therefore, in pharmaco-EEG studies, environmental factors such as caffeine have to be excluded.

Effects of caffeine on topographic quantitative EEG. Siepmann M, Kirch W. Neuropsychobiology 2002; 45 (3), pp. 161–6.

Cerebrospinal Fluid (CSF)Rhinorrhea: Cranial Trauma
Fluorescein Dye

Background Information: Cerebrospinal fluid rhinorrhea typically results from trauma to the base of the skull, producing leaks through either the cribiform plate region or the sphenoid bone. Traditional approaches to the repair of such leaks include a frontal craniotomy or external ethmoidectomy. An endoscopic approach through the nose has also proven to be successful.
Implementation: Evaluation of traumatic CSF rhinorrhea and development of a meningocele in the region of the cribiform plate using fluorescein dye to demonstrate the site of CSF leakage.
Interpretation and Analysis: Visualization of the defect with fluorescein dye can fasciliate repair of the defect via a transnasal endoscopic approach. Given such a scenario, a variety of complementary diagnostic procedures (radiographic assessment) and approaches for repair and postoperative care can subsequently be employed.

Endoscopic repair of traumatic CSF rhinorrhea in a pediatric patient. Wetmore RF, Duhaime AC, Klausner RD. Int J Pediatr Otorhinolaryngol 1996 Jul; 36 (2), pp. 109–15.

Reconstruction of the lacrimal drainage system. Holt JE, Holt GR. Arch Otolaryngol 1984 Apr; 110 (4), pp. 211–20.

Chorea-Acanthocytosis (Familial)/Hypothalamic Disorder/Dopaminergic System
Levodopa/Thyroid-Stimulating Hormone (TSH)/ Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: Levodopa promotes the release of growth hormone releasing hormone.
Application: Assessment of hypothalamic/pituitary function (acromegaly, gigantism, anterior secretion, somatropin secretion). L-dopa can be used to assess growth hormone releasing hormone synthesis/release. Thyroid-stimulating hormone can be used to evaluate thyroid function, while thyrotropin releasing hormone (TRH) can be utilized to assess plasma prolactin responses (also promotes TSH release).
Dosage: Glucose (oral tolerance test 75 grams).
Implemenation: Hypothalamic/pituitary interactions and functionality can be assessed by the collective administration of L-dopa, TSH, TRH, and oral glucose tolerance test. Additionally, it is possible to evaluate endocrinology aspects of dopaminergic regulation of the hypothalamic-pituitary axis in conditions of familial chorea-acanthocytosis.
Human Model: Cases of familial chorea-acanthocytosis (n = 3 females, 38–47 years of age).
Interpretation and Analysis: Many cases of familial chorea-acanthocytosis (e.g., n = 3/3) will exhibit low basal levels of triiodothyronine (T3), in addition to slightly elevated baseline plasma prolactin levels (e.g., n = 2/3). Cases will have delayed plasma TSH responses and plasma PRL excessive responses to TRH, and a low plasma growth hormone releasing hormone (GRF) response to L-dopa. Such TSH, PRL, and GRF responses represent a secretion pattern that is associated with a hypothalamic disorder that suggests the presence of impaired regulation of hormone secretion by the dopaminergic system, primarily in the level of the hypothalamus. In addition, an increased growth hormone (GH) secretory response following TRH (paradoxical response) can also be observed in some cases (e.g., n = 2/3), suggesting pituitary involvement. The vast majority of affected cases may display a diabetic profile when evaluated using an oral glucose tolerance test.

Disturbance of hypothalamic-pituitary hormone secretion in familial chorea-acanthocytosis. Terao S, Sobue G, Takahashi M, Miura N, Mitsuma T, Takeda A, Sakakibara T. No To Shinkei (Brain and Nerve) 1995 Jan; 47 (1), pp. 57–61.

Cough Reflex Induction: Brainstem/Internal Branches of the Superior Laryngeal Nerve/Forced Vital Capacity/Identification of Postanesthesia Complications/Resumption of Oral Feeding: Decision Criteria
Tartaric Acid (Nebulized)/Lidocaine

Physiological Mechanism of Action: Tartaric acid as applied for the activation of the cough reflex is perceived as a chemical irritant by receptors within the upper respiratory system.
Background Information: The internal branch of the superior laryngeal nerve (ibSLN) conveys impulses for the laryngeal cough reflex, which protects the laryngeal aditus and prevents the development of aspiration pneumonia.

Application: Determine the effect of bilateral anesthesia of the ibSLN on the cough reflex after inhalation of a nebulized chemoirritant solution of tartaric acid.
Route of Administration: Tartaric acid (inhaled/nebulization).
Implementation: Lidocaine (2% without epinephrine) is injected bilaterally into the paraglottic space containing internal branches of the superior laryngeal nerve (ibSLN). Tidal volume after inhalation of nebulized tartaric acid solution (20%) followed by the measurement of forced vital capacity (FVC) before and after injection. Data is analyzed using the Wilcoxon signed ranks, Mann-Whitney, and sign tests.

Human Model: Cases are normal healthy volunteers (n = 9).
Interpretation and Analysis: Complete anesthesia of the ibSLN abolishes the laryngeal cough reflex. Postinjection tidal volumes are significantly lower than preinjection volumes ($p < .01$). The decrease in tidal volume with complete bilateral anesthesia is significantly larger than decreases in tidal volume with partial anesthesia (n = 6/9 vs n = 3/9 @ $p < .05$). Force vital capacity measurements for both complete bilateral anesthesia and partial anesthesia do not significantly change from pre-injection to post-injection. Complications or adverse respiratory sequelae rarely develop. Tartaric acid–induced coughing may be useful in assessing the integrity of the laryngeal cough reflex after anesthesia or in cases with neurologic injury that are at risk of developing aspiration pneumonia. It may also be useful in making the decision whether to resume oral feeding schedules.

Anesthesia for the superior laryngeal nerves and tartaric acid-induced cough. Addington WR, Stephens RE, Goulding RE. Arch Phys Med Rehabil 1999 Dec; 80 (12), pp. 1584–6.

Dystonia (Childhood)/Encephalopathic and Neurologic Acute Crisis/Cerebral Cortex Function/ Glutaryl-CoA Dehydrogenase Deficiency/Glutaric Acidemia, Type I (GA-I)/Acute Encephalopathic/ Neurologic Crisis
Promethazine/[Diphenhydramine]

Background Information: The characteristic clinical feature of glutaric academia Type I (GA-I) is an acute encephalopathic and neurologic crisis typically occurring during a catabolic state. Despite slow improvement, many cases do not fully recover from a neurologic crisis, and residual neurologic morbidity can be significant.
Application: Promethazine may possibly be applied to characterize conditions of childhood dystonia associated with glutaric acidemia Type I (glutaryl-CoA dehydrogenase deficiency) in situations when the disease state can be detected by newborn screening with tandem mass spectrometry.

Human Model: Case of childhood dystonia (n = 1; promethazine-induced).
Interpretation and Analysis: Promethazine can induce dystonia in childhood cases while displaying a lack of a response to diphenhydramine administration. Such response profiles suggests a diagnosis of glutaric acidemia, type I (GA-I), classified as an autosomal recessive inborn error of metabolism caused by a deficiency of glutaryl-CoA dehydrogenase. Although newborn screening using tandem mass spectrometry is expected to enable presymptomatic diagnosis of GA-I, the case in the present report could not be detected by newborn screening with tandem mass spectrometry. Therefore, a high suspicion of GA-I must be maintained in the evaluation of childhood dystonia, even when newborn screening results are reportedly normal.

Glutaric acidemia, type I, missed by newborn screening in an infant with dystonia following promethazine administration. Smith WE, Millington DS, Koeberl DD, Lesser PS. Pediatrics 2001 May; 107 (5), pp. 1184–7.

Electroencephalography: Pharmacology Assisted Mapping/Behavior
Diazepam

Cellular/Molecular Mechanism of Action: Diazepam inhibits central nervous system gamma aminobutyrate (GABA), which functions as a neurotransmitter. Suppression is associated with the known ability of diazepam to bind to membrane-associated GABA receptor complexes.
Application: Diazepam (central nervous system depressant).
Dosage: Diazepam (10 mg).
Implementation: Evaluate the influence of diazepam on brain (cerebral cortex) function applying EET topographical mapping techniques (recordings applied from 4 different reference sites). Four referential derivations including ipsilateral earlobe (A1A2), average reference (AV), source derivation (SD), and balanced noncephalic electrode (BNE) can be used. One-minute vigilance-controlled EEGs before drug administration and 2 hours after drug administration are analyzed using Fourier transformation; followed by the calculation of absolute power and relative power for 4 frequency bands.

Human Model: Cases of normal healthy volunteers (n = 10 right-handed males; 21–25 years of age). Double blind crossover trials with a single oral dose of 10 mg diazepam or placebo control administered in random sequence at intervals of 1 week.
Interpretation and Analysis: Diazepam causes a widespread increase of beta-frequency relative power, and a widespread decrease of theta-frequency absolute power when A1A2 and SD are taken as references. From the comparison of different reference electrodes, the selection of the reference and of spectral parameters (absolute power or relative power) play an important role in pharmaco-EEG studies.

Pharmaco-EEG mapping of diazepam effects using different references and absolute and relative power. Yamadera H, Kato M, Ueno T, Tsukahara Y, Okuma T. Pharmacopsychiatry 1993 Nov; 26 (6), pp. 254–8.

Electroencephalography: Pharmacology Assisted/ Behavior/Depression: Antidepressants/ $GABA_A$ Receptor Complexes/ Serotonin Uptake: Cerebral Cortex Function/Hypocampal Electroencephalogram Profiles
Pharmaco-Electroencephalogram Analyses/ Serotoninertic Agents/Pentylenetetrazol/ Imipramine/Fluoxetine/Trazodone/ Desipramine/Nortriptyline

Cellular/Molecular Mechanism of Action: The antidepressants imipramine, fluoxetine, or trazodone inhibit serotonin uptake. Conversely, the antidepressants desipramine and nortriptyline inhibit norepinephrine uptake.
Application: Evaluate the influence of antidepressants with serotonergic and adrenergic effects on the function of $GABA_A$ receptor complexes.
Route of Administration: Pentylenetetrazol, imipramine, fluoxetine, or trazodone (intraperitoneal in rat *in vivo* model).
Dosage: Pentylenetetrazol (PTZ; 27.5 mg/kg) and imipramine, fluoxetine, or trazodone (7 days at 10 mg/kg given twice a day).

Implementation: Evaluate power spectrum changes induced by PTZ (chloride ionophore antagonist) in hippocampal electroencephalograms in order to better delineate the antidepressant drug effects on $GABA_A$ receptor complexes (e.g. $GABA_A$ receptor, chloride ionophore, and benzodiazepine receptor).

Animal Model: Rat (hippocampal EEG).

Interpretation and Analysis: In control recording, PTZ increases EEG power at frequencies under 12 Hz up to 5 times. After *in vivo* models are pretreated with imipramine, fluoxetine, or trazodone for 7 days (10 mg/kg i.p. twice a day), PTZ does not increase EEG power to more than 3 times the power before injection; this effect is not observed after 3 days of pretreatment. These 3 antidepressants inhibit serotonin uptake, while antidepressants that inhibit norepinephrine uptake (desipramine, nortriptyline) fail to counter the effect of PTZ. Antidepressants with serotonergic effects enhance the function of the $GABA_A$ receptor complex.

Electrophysiologic analysis of antidepressant drug effects on the $GABA_A$ receptor complex based upon antagonist-induced encephalographic power spectrum changes. Matsubara M, Suzuki S, Miura K, Terashima M, Sugita S, Kimura H, Hatsuda S, Mori T, Murakami H, Hayashi T, Ohta T, Ohara M. Neuropsychobiology 2000; 42 (3), pp. 149–57.

Electroencephalography: Pharmacology Assisted/ Behavior/Psychometry Tests
CATEEM/IBIS Psychometry

Background Information: Both psychometric tests and quantitative pharmaco-EEG are accepted as necessary tools in different fields of pharmacology. However, using these methods separately, neither is able to generate information about the behavioral performance and the central nervous demand simultaneously. The solution to this problem is a complex psychophysiological investigative design. Such complex measurement setups are a rarity. The main reason is the impossibility of EEG recordings during psychometric tests without the occurance of different artefacts.

Implementation: Utilization of a CATEEM-System in connection with the IBIS-Psychometry-system to determine the possibility of acquiring artifact-free EEG recordings during psychometric test conditions. The different mental loads at different tests produce a graduated increase in the delta and theta frequency range of the EEG of the fronto-temporal region and the occipital region of the cortex.

Interpretation and Analysis: During test evaluations a decrease of alpha activity is generally appreciated. These effects can be described quantitatively as the topographical distribution of frequency changes. The present data are in line with the knowledge about the functional and anatomical structure of the human brain.

Relation between psychometric tests and quantitative topographic EEG in pharmacology. Schober F, Dimpfel W. Int J Clin Pharmacol Ther Toxicol 1992 Nov; 30 (11), pp. 428–30.

Electroencephalography: Pharmacology Assisted/ Behavior/Psychometric Tests/ Antidepressant Profiling Influences on Cortex Function
S-Adenosyl-L-Methionine (SAMe)/L-Methionine (SAMe)/Ademetionine

Physiological Mechanism of Action: S-adenosyl-L-methionine promotes EEG patterns similar to the thymoleptic-type properties associated with imipramine and amitriptyline.

Application: S-adenosyl-L-methionine, L-methionine (SAMe), or ademetionine.

Route of Administration: S-adenosyl-L-methionine (infusion over 30 minutes for 7 days with a washout period of 3 weeks enforced between serial EEG recordings).

Dosage: S-adenosyl-L-methionine (800 mg).

Implementation: Evaluation of the influence of SAMe, L-methionine (SAMe), and ademetionine on brain function and behavior utilizing EEG mapping and psychometry analyses. S-adenosyl-L-methionine is administered with an enforced washout period of 3 weeks in between serial analyses. EEG recordings and psychometric analyses are performed 0, 1, 3, and 6 hours after drug administration on days 1 and 7.

Human Model: Cases of normal healthy elderly volunteers (n = 10; n = 5 males; n = 5 females; age = 56–71 years, mean: = 59.3 years). Investigation design: Double blind, placebo-controlled crossover study.

Interpretation and Analysis: Multivariate analysis based on MANOVA/Hotelling T_2 tests demonstrate significant central effects of SAMe compared to placebo after acute, subacute, and superimposed drug administration. Acute SAMe induces changes that are characterized by a decrease in total power, an increase in absolute delta, and a decrease in absolute alpha power; an increase in relative delta and a decrease in relative alpha power; and a slowing of the delta/theta centroid as well as a slowing of the centroid of the total power spectrum. These changes are typical of classical antidepressants of the thymoleptic type (e.g., imipramine and amitriptyline). After 1 week of daily infusions there are marked increases in total power, reminiscent of nootropic drug effects. One additional superimposed dosage mitigates these effects in the direction of an antidepressant profile, with the inter-drug differences waning in the 6^{th} hour. Pharmaco-EEG findings therefore reveal that both inhibitory and excitatory drug effects underlying the antidepressant properties of SAMe are well documented in clinical trials. Psychometric tests concerning noopsychic and thymopsychic measures as well as critical flicker frequency generally demonstrate a lack of differences between SAMe and placebo in a manner that reflects the good tolerability of the agent in elderly subjects.

Pharmacodynamic studies on the central mode of action of S-adenosyl-L-methionine (SAMe) infusions in elderly subjects, utilizing EEG mapping and psychometry. Saletu B, Anderer P, Linzmayer L, Semlitsch HV, Lindeck-Pozza E, Assandri A, di Padova C, Saletu-Zyhlarz GM. Ther Drug Monit 2002 Aug; 24 (4), pp. 532–6.

Electroencephalography: Pharmacology Assisted/ Behavior/Psychotropic (Central) Side Effects
Pharmaco-Electroencephalogram/Loderix (Setastine)/Terfenadine (Teldane)/ Chloropyramine HCl (Suprastin)

Physiological Mechanism of Action: The pharmaceutical agents, terfenadine, Teldane, chloropyramine HCl, and Suprastin possess sedative effects of very different degrees.

Application: Manipulation of cerebral cortex function and evaluation of pharmaceutical intervention in neurological disorders.

Implementation: Evaluate the influence of Loderix (setastine), in addition to a "vehicle" and with 2 reference pharmaceuticals (terfenadine, Teldane; and chloropyramine HCl, Suprastin) on cerebral cortex function applying EEG analysis as a means of monitoring efficacy.

Human Model: Cases of normal healthy male volunteers (n = 10) in a double blind, placebo-controlled, crossover arrangement.

Interpretation and Analysis: The different effects of the reference drugs on the central nervous system (CNS) are precisely indicated

by the posterior alpha/theta ratio in the EEG. This marker parameter is affected by Loderix in the same direction as by Teldane and in the opposite direction relative to Suprastin. In addition, Loderix increases the beta frequency range in the median areas of both hemispheres; moreover, it increases the total EEG power. The latter changes raise the question about the possibility that Loderix has an "own" action on EEG analyses. (The observed "own" effect could not even be brought into connection with a decrease of the vigilance level). Observations made to date strengthen the view that the action of Loderix on the EEG is similar to that induced by Teldane, a drug very favorable with respect to sedative side effects. Moreover, the drug does not affect the EEG power spectra in a direction that corresponded to a sedative action. The spectral parameters in the "pharmaco" EEG recordings seem to be useful in the objective definition of the central (psychotropic) side effects of drugs.

Assessing the sedative (adverse) effects of antiallergic drugs by quantitative electroencephalography: Effects of setastine, a non-sedating antihistaminic drug. Rajna P, Veres J. Ther Hung 1994; 42 (1), pp. 14–20.

Electroencephalography: Pharmacology Assisted/ Caffeine/Environmental Psychostimulant Interference
Caffeine/Topographic Quantitative EEG

Cellular/Molecular Mechanism of Action: Caffeine is classified as a xanthine analog that promotes stimulation of the central nervous system.
Physiological Mechanism of Action: Caffeine (psychostimulants and stimulate the medullary respiratory centers).
Background Information: Despite the widespread use of caffeine as a central nervous stimulant, the central pharmacodynamic properties of the drug have not yet been conclusively evaluated in humans.
Application: Evaluation of the interference of environmental psychostimulant on topographic quantitative electroencephalography analyses.
Route of Administration: Caffeine (oral powder in water).
Dosage: Caffeine (200 mg equivalent to 2 cups of coffee).
Implementation: Evaluate the influence of caffeine on cerebral cortex function by topographically measuring quantitative electroencephalogram (EEG) profiles. Oral caffeine is administered under randomized, double blind crossover conditions on 2 different occasions. Before administration and 30 minutes afterward, a 17-channel quantitative EEG is recorded during relaxation with eyes open and closed (15 minutes each).

Human Subjects: Cases of normal cerebral cortex function (n = 10 healthy subjects; mean age = 25 and SD ± 4 years).
Interpretation and Analysis: Caffeine causes a significant reduction of total EEG power at fronto-parieto-occipital and central electrode positions of both hemispheres when the eyes are kept open. Absolute power of the slow and fast alpha and slow beta activities are diminished in various regions of the brain ($p < 0.05$). The effect is more pronounced when the eyes are kept open than when the eyes are kept closed. Quantitative EEG appears to be a sensitive method for assessing the effects of psychostimulants on the human brain. Therefore, in pharmaco-EEG studies, environmental factors such as caffeine have to be excluded.

Effects of caffeine on topographic quantitative EEG. Siepmann M, Kirch W. Neuropsychobiology 2002; 45 (3), pp. 161–6.

Electroencephalography: Pharmacology Assisted/ Epilepsy: Uncontrollable/Pharmacokinetic and Pharmacodynamic Analyses of Antiepileptic Agents
Quantitative Pharmaco-Electroencephalography/ Clonazepam/Valproate

Cellular/Molecular Mechanism of Action: Clonazepam inhibits central nervous system gamma aminobutyrate (GABA), which functions as a neurotransmitter. In this context, diazepam is known to bind to membrane-associated GABA receptor complexes.
Route of Administration: Clonazepam (orally/per os).
Dosage: Clonazepam (CZP 0.05 mg/kg single dose).
Implementation: Evaluation of the pharmacokinetic (PK) and pharmacodynamic (PD) profiles of valproate (VPA) and clonazepam (CZP) in epileptic children in addition to its effect on cerebral cortex function applying quantitative pharmaco-EEG (QPEEG) techniques. Following a single clonazepam dose, blood samples are collected at 0, 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 8.0, 12.0, and 24.0 hours. At each blood collection time point, EEG signals (60 s) are recorded for brain electrical activity mapping, and the power percentage average (PPA) of each frequency band calculated. The relationship between drug concentrations and their corresponding PPA of each frequency band are then analyzed.

Human Model: Cases of childhood epilepsy (n = 4) suffering from uncontrolled seizures despite long-term VPA therapy.
Interpretation and Analysis: Valproate steady-state drug concentrations (Css) are within the therapeutic range and not affected by CZP. The peak concentration (C_{max}) of CZP and the time intervals from dosing to C_{max} (T_{max}) are 20.9 ng/mL to 113.8 ng/mL and 1 hour to 1.5 hours, respectively. There is no significant correlation between VPA concentrations and the PPA of any of the EEG frequency bands. Clonazepam blood concentrations show significant correlation with PPA in a high percentage of cases (e.g., n = 3/4 cases). Clonazepam may therefore affect fast wave activities in proportion to CZP blood concentrations. Quantitative pharmaco-electroencephalography appears to be a promising technique for studying the pharmacokinetics and pharmacodynamics of selected antiepileptic drugs.
Instrumentation: High-pressure liquid chromatography (clonazepam) and gas-chromatography (valproate).

Pharmacokinetic and pharmacodynamic effects of clonazepam in children with epilepsy treated with valproate: A preliminary study. Wang L, Wang XD. Ther Drug Monit 2002 Aug; 24 (4), pp. 532–6.

Electroencephalography: Pharmacology Assisted/ Epilepsy
Pharmaco-Electroencephalogram/ Carbamazepine (CBZ)

Application: Delineating the influence of CBZ on cerebral cortex function in epileptic disease states.
Dosage: Carbamazepine (300 mg, single dose).
Implementation: Evaluate the influence of CBZ on cerebral cortex function in epileptic conditions utilizing quantitative EEG (qEEG) techniques and instrumentation. Sample EEG tracings are recorded before and at regular intervals within 24 hours following pharmaceutical administration. The EEG activity is processed by power spectral analysis and the drug serum concentration assessed concomitantly.

Human Model: Cases of epilepsy (n = 10 epileptics; n = 10 healthy adult volunteers).
Interpretation and Analysis: Increases in serum CBZ concentrations correspond with the percentage of power progressively increasing in the theta band while it decreases in the alpha2 band. The percentage of theta and alpha2 power is found to reach maximum and minimum levels, respectively, when the peak values for serum concentration of CBZ are attained. The effects on qEEG in anterior scalp areas are more evident than in posterior scalp areas.

Quantitative pharmaco-EEG of carbamazepine in volunteers and epileptics. Wu X, Xiao CH. Clin Electroencephalogr 1996 Jan; 27 (1), pp. 40–5.

Electroencephalography: Pharmacology Assisted/ Epilepsy
Pharmaco-Electroencephalogram/Valproate

Application: Characterization of cerebral cortical function in epilepsy conditions.
Dosage: Valproate (single-dose administration).
Implementation: Evaluation of the influence of sustained-release valproate (SR-VPA) on cerebral cortex function in epilepsy conditions applying quantitative background electroencephalography (EEG). Complementary investigations include establishing SR-VPA serum concentrations.

Human Model: Cases of CNS epilepsy (n = 10 untreated with generalized tonic-clonic seizures).
Interpretation and Analysis: Pharmaco-electroencephalography reveals increased power of alpha2 band over occipital areas, a decrease of power of beta band (diffuse and preponderant on posterior scalp areas) with increasing serum concentrations. Both effects reach their maxima and minima, respectively, when the peak values of serum concentration are reached. A positive correlation exists between alpha2 power on the occipital areas and serum SR-VPA concentrations, and a negative correlation of serum concentration and beta power are detected over the posterior scalp areas.

Quantitative pharmaco-EEG of sustained release valproate in epileptics. Wu X, Xiao CH. Clin Electroencephalogr 1997 Apr; 28 (2), pp. 117–20.

Electroencephalography: Pharmacology Assisted/ Epilepsy/Cononical Correlation (Semilinear): Anesthesiology/Responders vs Non-Responders: Psychiatry/1st-Order Markov Model of Sleep Stage Transitions: Neurophysiology
Pharmaco-Electroencephalograpy (Pharmaco-EEG)

Background Information: In the clinical application and interpretation of pharmaco-EEG, it is important to appreciate its value in the context of other diagnostic parameters such as biomarkers, surrogate end points, clinical end points, and clinical outcomes.
Application: Detection and characterization of neurologic disorders through the combined application of specific pharmaceutical agents and measurement of their influence on central nervous function detected with EEG instrumentation.
Considerations: Much work still needs to be conducted to fully develop the potential capabilities that pharmaco-EEG together with pharmacokinetic-pharmacodynamic modeling can bring to therapeutics in neuroscience.
Interpretation and Analysis: State-of-the-art applications of pharmaco-EEG, together with pharmacokinetic-pharmacodynamic modeling in everyday clinical practice, is becoming a reality pertaining to the fields of anesthesiology (semilinear canonical correlation), psychiatry (discrimination between responders and non-responders to pharmacological treatment using the test dose), neurology (antiepileptic field), and neurophysiology (1st-order Markov model of sleep stage transitions). The combination of both procedures, although successfully used during some drug development programs (opioids or benzodiazepines), it is not widely applied in clinical conditions affecting the central nervous system.

Uses of pharmaco-EEG and pharmacokinetic-pharmacodynamic modeling in the clinical scenario. Barbanoj MJ, Valle M, Kulisevsky J, Perez V, Gambus P. Methods Find Exp Clin Pharmacol 2002; 24 Suppl D, pp. 139–44.

Electroencephalography: Pharmacology Assisted/ Epilepsy: Anticonvulsive Therapy Response/Relative Efficacy Evaluation/ Anticonvulsants for Petit mal/ Generalized Non-Convulsive Epilepsy
Pharmaco-Electroencephalography/Milacemide (CP 1552 S)/Sodium Valproate/Piracetam

Cellular/Molecular Mechanism of Action: Milacemide (CP 1552 S) is a derivative of glycine that exerts an anticonvulsant action by increasing GABA concentrations and endogenous glycine pools in the brain.
Physiological Mechanism of Action: Milacemide exerts a brain anticonvulsant action by increasing GABA concentrations.
Application: Compare and contrast the electroencephalography profiles and behavioral anticonvulsant properties of various therapeutic agents.
Route of Administration: Milacemide (oral).
Dosage: Milacemide (400 mg, 800 mg, 1600 mg). Reference compounds (placebo; sodium valproate at 600 mg; and piracetam at 1600 mg).
Implementation: Evaluation of the encephalotropic and psychotropic properties of milacemide by means of quantitative EEG and psychometric analyses. Electroencephalogram recordings and monitoring of blood pressure, heart rate, and side effects are performed at 0, 1, 2, 4, 6, and 8 hours. Psychometric tests are performed at 0, 2, 4, 6, and 8 hours.

Human Model: Cases functioning as healthy normal reference controls (n = 12). Study Design: Double blind placebo-controlled study.
Interpretation and Analysis: Computer-assisted spectral analysis of EEG profiles shows significant effects of milacemide on the central nervous system (CNS) in contrast to placebo, characterized by an attenuation of delta activity accompanied by an acceleration of the centroid of the slow activity but also of the total activity in response to all 3 dosage levels. Other alterations noted include increases in beta activity after 400 mg, an increase of alpha activity after 800 mg, as well as an increase of alpha activity but a decrease in beta activity after a 1600 mg dose. Such changes, also seen after 600 mg sodium valproate, are reminiscent of quantitative EEG changes described after antiepileptic drugs used in the treatment of petit mal or generalized non-convulsive epilepsy. Moreover, they are also indicative of improvement in "vigilance" in the sense of Head, which is also seen at the behavioral level, specifically after the lowest doses of milacemide, as psychometric tests demonstrate an improvement in attention, concentration, psychomotor activity, and after-effect (indicating CNS activation) as measured by means of the Archimedean spiral. Such a beneficial influence on performance declines with increasing dose. Evaluation of pulse, blood pressure,

and side effects demonstrate good tolerance after all administered substances.

Early clinical pharmacological trials with a new antiepileptic, milacemide, using pharmaco-EEG and psychometry. Saletu B, Grünberger J. Methods Find Exp Clin Pharmacol 1984 Jun; 6 (6), pp. 317–30.

Electroencephalography: Pharmacology Assisted/ Ethanol and Thiopental Cerebral Cortex Depression/Pharmacological Interactions *Pharmaco-Electroencephalography/ Captopril/Enalaprilat*

Cellular/Molecular Mechanism of Action: Captopril and enalaprilat function as angiotensin converting enzyme inhibitors.
Background Information: The influence of captopril and enalaprilat on the central nervous system has been investigated in laboratory animals.
Route of Administration: Captopril (intraperitoneal); enalaprilat (intraperitoneal); ethanol (intraperitoneal); and thiopental (intraperitoneal).
Dosage: Captopril (5 and 20 mg/kg); enalaprilat (5 and 20 mg/kg); ethanol (4 g/kg); and thiopental (70 mg/kg) single administration or repeated SID for 10 days.
Implementation: Evaluation of the effect captopril and enalaprilat have on the duration of ethanol- and thiopental-induced changes in sleep, body temperature, spontaneous locomotor activity, and analgesic properties (hot plate and tail-flick test, and pharmaco-EEG profiling).
Animal Model: Murine (hot plate and tail-flick test).
Animal Model: Rabbit (pharmaco-EEG profiles).
Interpretation and Analysis: Single administration of captopril (both doses) and single or prolonged administration of enalaprilat decrease the duration of ethanol- and thiopental-induced sleep. Captopril (5 mg/kg) and enalaprilat (5 and 20 mg/kg) increase pain thresholds. Both captopril and enalaprilat after single or repeated administration do not influence spontaneous locomotor activity (mice). Captopril and enalaprilat decrease body temperature in mice. Examined ACEIs produce changes in EEG recording, more profoundly exhibited after administration of enalaprilat.

An attempt to assess the central action of captopril and enalaprilat. Czarnecka E, Strzelec J, Pietrzak B. Med Sci Monit 2000 May–Jun; 6 (3), pp. 491–7.

Electroencephalography: Pharmacology Assisted/ Seizures: Alcoholic Detoxification/ Recurrent Episodes *Chlordiazepoxide/Pharmaco-Electroencephalography*

Application: Delineation of recurrent alcoholic detoxification seizures.
Route of Administration: Per os (oral) during detoxification events (associated with the elimination of withdrawal seizures).
Implementation: Evaluation of the potential increased risk of seizure activity during conditions of recurrent alcohol detoxifications. Structural brain damage, focal neurologic deficits, epileptogenic findings on electroencephalograms, and provocative drug use are considered pertinent variables for seizure risk.
Human Model: Review of detoxification and seizure histories (n = 256 men; n = 45 women voluntarily admitted to a 5-day inpatient detoxification program).
Interpretation and Analysis: Administration of chlordiazepoxide is usually associated with the elimination of withdrawal seizures. Some cases have a history of seizures (e.g., n = 64/301) while others have significantly abnormal electroencephalograms during detoxification (e.g., n = 42/301), or have focal slowing on the electroencephalogram (e.g., n = 30/301). No correlation exists between the duration of alcohol abuse or lifetime consumption of alcohol and seizure activity. There is, however, a significant correlation between the number of inpatient alcohol detoxifications and the prevalence of seizure disorders. This correlation holds true even when provocative drug use is taken into consideration.

Seizure risk with recurrent alcohol detoxification. Lechtenberg R, Worner TM. Arch Neurol 1990 May; 47 (5), pp. 535–8.

Electroencephalography: Pharmacology Assisted/ Seizures/Epilepsy Induction *Pentylenetetrazol/Pharmaco-Electroencephalography*

Mechanisms of Action: Pentylenetetrazol diminishes the influence of GABA on chloride ion conductance at concentrations that do not alter resting neuronal membrane conductance in the absence of GABA. Additional attributes of pentylenetetrazol include inhibition of picrotoxin association with binding sites, and it has the ability to block the enhancement of GABA and benzodiazepine binding promoted by hypnotic barbiturates. No direct stimulatory effect has been associated with pentylenetetrazol.
Diagnostic Application: Primarily of value in facilitating the diagnostic induction of epileptic episodes for the purpose of acquiring EEG recordings.
Route of Administration: Pentylenetetrazol (subcutaneous).
Dosage: Pentylenetetrazol (PTZ seizure dose = 65 mg/kg).
Considerations: Pentylenetetrazol induces seizure activity through CNS stimulation. Because of the potential hazards that seizure episodes might precipitate, appropriate antiseizure medications should always be readily (immediately) available for administration as a safety precaution.
Implementation: Truly simultaneous electroencephalogram (EEG) and functional magnetic resonance imaging (fMRI) are recorded following the induction of convulsions with pentylenetetrazol. Rigorous control of physiological parameters like body temperature and ventilation with control of blood gasses help avoid potential interference between systemic parameters and central PTZ-induced blood oxygenation level-dependent (BOLD) changes.
Animal Model: Rat (curarized rats).
Interpretation and Analysis: In experimental *in vivo* models, simultaneous EEG/fMRI recordings demonstrate progressive epileptiform EEG discharges with concomitant BOLD changes, with the latter gradually affecting most of the fore- and midbrain. Approximately 15 minutes after PTZ injection, the 1st BOLD contrast changes mainly occur in the neocortex, and coincide with the 1st minor EEG alterations. Most regions that display BOLD changes are areas with reportedly high $GABA_A$ receptor densities. Full-blown epileptiform discharges occur on the EEG tracing, approximately 30 minutes after PTZ injection, and coincide with bilateral positive and/or negative BOLD contrast changes in cortical and subcortical regions. Behavioral observations demonstrate that the 1st of several generalized clonic or clonic-tonic seizure episodes occur also around this same time period. Approximately 90 minutes after injection, the electrographic paroxysms gradually decrease in amplitude and duration, whereas BOLD signal changes still extended with alternating positive and negative traces and spread to subcortical regions like caudate-putamen and globus pallidus.

In humans, the induction of an epileptic seizure or analogous episodes following administration constitutes a positive diagnosis that can be more fully characterized through analysis of EEG recordings.

Laboratory Instrumentation: Electroencephalogram recording.

Simultaneous electroencephalographic recording and functional magnetic resonance imaging during pentylenetetrazol-induced seizures in rat. Van Camp N, D'Hooge R, Verhoye M, Peeters RR, De Deyn PP, Van der Linden A. NeuroImage 2003 Jul; 19 (3), pp. 627–36.

Electroelectroencephalography: Pharmacology Assisted/Sleep Quality
Pharmaco-Electroencephalogram (EEG) Mapping/ d-Fenfluramine (d-FEN)/l-Fenfluramine (l-FEN)/ Chlorpromazine (CPZ)/d-Amphetamine (AMPH)/Prolactin

Route of Administration: Single oral dose of each *d*-fenfluramine, l-fenfluramine, chlorpromazine, and *d*-amphetamine (AMPH @ 50 mg).
Dosage: Single dose of *d*-fenfluramine (d-FEN at 15 and 30 mg); l-fenfluramine (l-FEN at 30 mg); chlorpromazine (CPZ at 50 mg); and *d*-amphetamine (AMPH at 50 mg).
Implementation: Pharmaco-EEG mapping of the pharmacodynamic properties of *d*-FEN, l-FEN compared to CPZ, and AMPH as well as prolactin and safety assessments. Blood samples are collected to determine concentrations of AMPH, FEN and its main metabolite norFEN, as well as plasma prolactic levels; EEG recordings and evaluation of hemodynamics and spontaneous side effects are performed at 0, 2, 4, 6, and 8 hours after drug administration. Before and 24 hours after drug intake, morning subjective sleep quality is then also assessed.

Human Model: Cases of young healthy volunteers (n = 18) receiving pharmaceutical agents at weekly intervals.
Interpretation and Analysis: Blood concentration levels measured after d-FEN demonstrate a dose-dependent blood concentrations peaking after 2–4 hours and slowly declining thereafter. NorFEN, the main metabolite, exhibits a steady increase in plasma concentrations up to the 8th hour. After l-FEN a similar time course is observed, but the concentrations of the parent compound are higher and those of the metabolite lower in comparison with the *d*-isomer, suggesting stereoselective kinetics. *d*-FEN induces significant and dose-dependent pharmaco-EEG changes characterized by a decrease in total power and combined delta/theta activity; an increase in beta activity; and an acceleration of the centroid of the total activity with no changes in alpha power that are very different from those of the reference drugs. l-FEN produces only minimal changes (of the same type as d-FEN). CPZ (50 mg) and *d*-AMPH (20 mg) produce significant changes compared to placebo but with quite opposite effect profiles; the former exhibits a typical sedative-neuroleptic pattern while the latter is typical of psychostimulants. Dose/treatment and time-efficacy calculations based on all variables show in the V-EEG that only *d*-FEN (30 mg) and CPZ (50 mg) are different from placebo (with peak effects in the 8th and 4th hour, respectively), while in the resting condition (R-EEG) all drugs/dosages but l-FEN (30 mg) differ from placebo (with the peak effect occurring in the 4th–6th hour after *d*-FEN and l-FEN; in the 2nd hour after CPZ; and in the 4th–6th hour after AMPH). Plasma prolactin levels are only modified by CPZ (maximal increase in the 2nd hour).

Clinical-pharmacological study with the two isomers (d-, l-) of fenfluramine and its comparison with chlorpromazine and d-amphetamine: Blood levels, EEG mapping and safety evaluation. Saletu B, Barbanoj MJ, Anderer P, Sieghart W, Grünberger J. Methods Find Exp Clin Pharmacol 1993 Jun; 15 (5), pp. 291–312.

Endomorphins-2/Mu(1)-Opioid and Mu(2)-Opioid Receptors (Agonists/Antagonists)/Nociceptive Properties
D-Pro(2)-Endomorphin-2

Cellular/Molecular Mechanism of Action: Analogs of endomorphin-2 function as competitive antagonists at their corresponding membrane-associated receptor complex.
Physiological Mechanism of Action: Antinociception activity achieved through antagonism of endomorphin-2.
Application: Endomorphin analogues containing D-Pro(2) are considered able to discriminate between the antinociceptive actions of mu_1- and mu_2-opioid receptor agonists at the level of the spinal cord.
Implementation: Characterization of opioid/endorphin receptor complexes.

Animal Model: Use of the paw withdrawal response in mice to detect/evaluate endomorphin antagonism.
Interpretation and Analysis: D-Pro_2-endomorphin-1 and D-Pro_2-endomorphin-2, injected intrathecal (i.t.), have no significant effect on the nociceptive thermal threshold when administered individually. Alternatively, when D-Pro_2-endomorphin-1 (0.05–0.1 pmol) is injected simultaneously with i.t. endomorphin-1 (5.0 nmol) or endomorphin-2 (5.0 nmol), antinociception induced by endomorphin-1 is reduced significantly, whereas endomorphin-2-induced antinociception is not affected by D-Pro_2-endomorphin-1. Antinociception induced by i.t. endomorphin-2 (5.0 nmol) is reduced significantly by its analogue, D-Pro_2-endomorphin-2 (100 pmol), but not by D-Pro_2-endomorphin-1. D-Pro_2-endomorphin-1 also antagonizes the antinociceptive effect of i.t. DAMGO, a mu-opioid receptor agonist, whereas D-Pro_2-endomorphin-2 does not reduce the effect of DAMGO.

Endomorphin analogues containing D-Pro2 discriminate different mu-opioid receptor mediated antinociception in mice. Sakurada S, Watanabe H, Hayashi T, Yuhki M, Fujimura T, Murayama K, Sakurada C, Sakurada T. Br J Pharmacol 2002 Dec; 137 (8), pp. 1143–6.

Epilepsy: Cerebral Cortex Function/Early-Onset Epilepsy with Pleomorphic Seizures/ Guanidinoacetate N-Methyltransferase Deficiency/ Arginine/Glycine Amidinotransferase Deficiency/ Creatine Transporter 1 Dysfunction/Strategy for Case Selection for Proton Magnetic Resonance Spectroscopy Evaluation
Creatine Monohydrate

Cellular/Molecular Mechanism of Action: Creatine monohydrate is a biochemical pathway end product.
Background Information: Creatine metabolism disorders have so far been described at the level of 2 synthetic steps, (i) guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase, and at the (ii) creatine transporter 1 complex. Arginine/glycine amidinotransferase and creatine transporter 1 deficiencies are mainly present with mental retardation and severe language disorders. Guanidinoacetate N-methyltransferase deficiency results in the development of a severe neurologic condition (age–of–onset 3 months to 2 years) characterized by developmental arrest, neurologic deterioration, movement disorders, mental retardation, autistic-like behavior, and epilepsy. Severe early-onset epilepsy with pleomorphic seizures is a key symptom of such disorders.
Application: Creatine monohydrate can identify enzyme deficiencies in biochemical pathways for guanidinoacetate N-methyltransferase or arginine/glycine amidinotransferase, in addition to

disorders in creatine transporter 1 level dysfunction. Such biochemical pathway–based disorders precipitate early-onset epilepsy conditions characterized by pleomorphic seizure disorders. Creatine monohydrate can be utilized in strategies for selecting appropriate cases suitable to evaluation by proton magnetic resonance spectroscopy.

Implementation: Complementary diagnostic strategy for evaluating epilepsy conditions caused by dysfunction in 2 synthetic steps involved in creatinine metabolism including (i) guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase deficiencies; and (ii) creatine transporter 1 function.

Interpretation and Analysis: Guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase deficiencies respond positively to substitutive treatment with creatine monohydrate. Data suggest that in cases with guanidinoacetate N-methyltransferase deficiency, epilepsy and associated electroencephalographic abnormalities are more responsive to creatine supplementation than to conventional antiepilepsy drugs. All cases of creatine disorders reported to date have been detected by brain proton magnetic resonance spectroscopy, an expensive technique not routinely used in pediatric neurology. A potential diagnostic strategy to select cases for evaluation using proton magnetic resonance spectroscopy have been described.

Inborn errors of creatine metabolism and epilepsy: Clinical features, diagnosis, and treatment. Leuzzi V. J Child Neurol 2002 Dec; 17 Suppl 3, pp. 3S89–97; discussion 3S97.

Epilepsy: Cerebral Cortex Function (Uncontrollable)/ Pharmacokinetic and Pharmacodynamic Analyses of Antiepileptic Agents
Quantitative Pharmaco-Electroencephalography/ Clonazepam/Valproate

Cellular/Molecular Mechanism of Action: Clonazepam inhibits central nervous system gamma aminobutyrate (GABA), which functions as a neurotransmitter. In this context, diazepam is known to bind to membrane-associated GABA receptor complexes.

Route of Administration: Clonazepam (orally/per os).

Dosage: Clonazepam (CZP 0.05 mg/kg single dose).

Implementation: Evaluation of the pharmacokinetic (PK) and pharmacodynamic (PD) profiles of valproate (VPA) and clonazepam (CZP) in epileptic children in addition to its effect on cerebral cortex function applying quantitative pharmaco-EEG (QPEEG) techniques. Following a single clonazepam dose, blood samples are collected at 0, 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 8.0, 12.0, and 24.0 hours. At each blood collection time point, EEG signals (60 s) are recorded for brain electrical activity mapping, and the power percentage average (PPA) of each frequency band calculated. The relationship between drug concentrations and their corresponding PPA of each frequency band are then analyzed.

Human Model: Cases of childhood epilepsy (n = 4) suffering from uncontrolled seizures despite long-term VPA therapy.

Interpretation and Analysis: Valproate steady-state drug concentrations (Css) are within the therapeutic range and not affected by CZP. The peak concentration (C_{max}) of CZP and the time intervals from dosing to C_{max} (T_{max}) are 20.9 ng/mL to 113.8 ng/mL and 1 hour to 1.5 hours, respectively. There is no significant correlation between VPA concentrations and the PPA of any of the EEG frequency bands. Clonazepam blood concentrations show significant correlation with PPA in a high percentage of cases (e.g. n = 3/4 cases). Clonazepam may therefore affect fast wave activities in proportion to CZP blood concentrations. Quantitative pharmaco-electroencephalography appears to be a promising technique for studying the pharmacokinetics and pharmacodynamics of selected antiepileptic drugs.

Instrumentation: High-pressure liquid chromatography (clonazepam) and gas-chromatography (valproate).

Pharmacokinetic and pharmacodynamic effects of clonazepam in children with epilepsy treated with valproate: A preliminary study. Wang L, Wang XD. Ther Drug Monit 2002 Aug; 24 (4), pp. 532–6.

Epilepsy: Cerebral Cortex Function/Medial Temporal Lobe/Left-Sided Speech Dominance/ Atypical Speech Dominance/Psychic Auras: Limbic Seizure Spread/Epileptic Activity: Speech Reorganization
Amobarbital (Wada Test)

Physiological Mechanism of Action: Amobarbital is a barbiturate that generally exerts a depressant effects on the central nervous system.

Background Information: Factors influencing atypical speech lateralization have theoretical importance in understanding the organization and reorganization of higher cognitive functions, as well as having practical implications, especially in brain surgery and neurorehabilitation. Atypical (right-sided or bilateral) language representation is more frequent in focal epilepsy than in healthy people. This difference is thought to be related to early childhood brain injuries localized in regions near speech centers. The effect of epileptic activity on speech lateralization has not been investigated, although several investigations have suggested that epileptic activity may interfere with higher brain functions. Ideally, it can only be evaluated in a homogeneous human population with epilepsy having the same lesion type in the same anatomical localization.

Application: Detection and characterization of neurological function/dysfunction in conditions of medial temporal lobe epilepsy. The Wada test can also be applied to accurately localize foci within the CNS responsible for epileptic activity and for predicting the potential and severity of residual postoperative deficits.

Implementation: Evaluation of medial temporal lobe epilepsy (MTLE) due to unilateral hippocampal sclerosis (HS), but without other epileptogenic lesions using superselective delivery of amobarbital (Wada test). Comprehensive presurgical evaluations are performed as a baseline reference to guide decision making processes related to surgical intervention. In MTLE, the influence of age at the time of brain damage (e.g., initial precipitating injury or IPI) can be evaluated separately from other timing factors.

Human Model: Cases of MTLE due to unilateral HS, but without other epileptogenic lesions (n = 184; n = 100 Wada test procedures; n = 83 left-sided MTLE cases).

Interpretation and Analysis: The Wada test can reveal left-sided speech patterns in 76% of the left-sided MTLE and in 100% of the right-sided MTLE cases (n = 100 Wada test cases; $p < 0.05$).The mean age at seizure onset is approximately 10.1 ± 7.8 years (range 1–37 years); the mean age at evaluation is approximately 35.7 ± 9.8 years. Applying the Wada test, it is possible to detect cases with left-sided speech (e.g., n = 63) in addition to identifying cases of atypical speech dominance (e.g., n = 20 or 24%). Atypical speech representation in left MTLE is associated with a higher spiking frequency ($p < 0.05$) and with sensory auras representing an ictal involvement of the lateral temporal structures ($p < 0.01$). Psychic auras suggesting limbic seizure spread show a significant association with left-sided speech dominance in left MTLE ($p < 0.05$). Neither age at epilepsy onset nor age at IPI is associated with atypical speech in left MTLE. Therefore, cases with focal epilepsy, not only the known factors

(i.e., the age at which the brain injury occurred and its localization) but also the epileptic activity itself (i.e., interictal discharges and seizure spread), may influence speech reorganization. Such findings also suggest that not only structural elements but also functional factors have an effect on the language organization within the brain.

Epileptic activity influences the speech organization in medial temporal lobe epilepsy. Janszky J, Jokeit H, Heinemann D, Schulz R, Woermann FG, Ebner A. Brain 2003 Sep; 126 (Pt 9), pp. 2043–51.

Epilepsy: Cerebral Cortex Function/Presurgical Evaluation of Refractory Conditions/Arterial-Venous Malformations
Methohexital/[Wada Test]

Cellular/Molecular Mechanism of Action: Methohexital is a barbiturate and functions as a central nervous system depressant.
Application: Sodium methohexital (Brevital) can be applied as a local anesthetic agent in the Wada test for assessing language and memory in presurgical epilepsy cases.
Implementation: Evaluation of the diagnostic effectiveness of methohexital compared to the more commonly used anesthetic agent, sodium amobarbital (Amytal).
Human Model: Cases of presurgical epilepsy (n = 86; and n = 173 procedures).
Interpretation and Analysis: Despite differences between the methohexital and amobarbital test protocols, the behavioral and neurologic effects of the 2 anesthetics are similar. Because of the brief duration of methohexital, 2 successive injections are made on each side rather than 1, to lengthen the time available for testing both language and memory. Behavioral and EEG indices return to baseline more quickly and more completely with methohexital than with amobarbital, allowing several repetitions of the procedure without incremental drowsiness, and the total time taken for the procedure is less with methohexital than with amobarbital. Therefore, language and memory testing in the Wada test are equivalent for amobarbital and methohexital, except that methohexital has a briefer duration of action and is associated with less sedation.

Sodium methohexital (brevital) as an anesthetic in the Wada test. Buchtel HA, Passaro EA, Selwa LM, Deveikis J, Gomez-Hassan D. Epilepsia 2002 Sep; 43 (9), pp. 1056–61.

Epilepsy: Cerebral Cortex Function (Seizures)/ Refractory Status Epilepticus/Neurologic Outcomes and Survival Prediction
Pentobarbital (Coma)

Physiological Mechanism of Action: Pentobarbital is a barbiturate that promotes depression of the central nervous system.
Background Information: Status epilepticus is a life-threatening condition requiring emergency medical attention. Although initial therapies with antiepileptic drugs generally terminate seizures within 30 to 60 minutes, cases with refractory status epilepticus require additional intervention. High-dose pentobarbital has been the most commonly prescribed agent for the management of refractory status epilepticus in children.
Application: Management and assessment of projected neurologic outcomes and survival in cases of refractory status epilepticus.
Route of Administration: Pentobarbital (intravenous).
Implementation: Evaluate the association between the response of pentobarbital coma and neurologic outcomes in refractory status epilepticus. A pentobarbital-induced coma is induced for a period of at least 48 hours. Relevant information entered into medical records is reviewed in an effort to identify an association between different variables and to comparatively assess responses.
Human Model: Cases of refractory status epilepticus (n = 23).
Interpretation and Analysis: In cases classified as refractory status epilepticus, approximately (i) 50% can be controlled with pentobarbital (e.g., n = 12/23); (ii) 30% will not respond to pentobarbital (e.g., n = 6/23); and (iii) slightly greater than 20% relapsed after discontinuation or during tapering of pentobarbital administration (e.g., n = 5/23). The mortality rate among relapse cases and nonresponder cases combined is 90.9%, but the survival rate among the responder cases is very high (e.g., 100% at $p < 0.001$). The survival rate is greater among toddlers compared with neonates or older children. Failure of seizure control after pentobarbital coma is associated with a poor prognosis. The potential for serious complications of pentobarbital therapy among neonates highlights the need for careful dosing in this age group.

Neurologic outcomes of pediatric epileptic cases with pentobarbital coma. Kim SJ, Lee DY, Kim JS. Pediatr Neurol 2001 Sep; 25 (3), pp. 217–20.

Epilepsy: Cerebral Cortex Function/Early-Onset Epilepsy with Pleomorphic Seizures/ Guanidinoacetate N-Methyltransferase Deficiency/ Arginine-Glycine Amidinotransferase Deficiency/ Creatine Transporter 1 Dysfunction/Strategy for Case Selection for Proton Magnetic Resonance Spectroscopy Evaluation
Creatine Monohydrate

Cellular/Molecular Mechanism of Action: Creatine monohydrate is a biochemical pathway end product.
Background Information: Creatine metabolism disorders have so far been described at the level of 2 synthetic steps, (i) guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase, and at the (ii) creatine transporter 1 complex. Arginine/glycine amidinotransferase and creatine transporter 1 mainly present with mental retardation and severe language disorder. Guanidinoacetate N-methyltransferase deficiency results in the development of a severe neurologic condition (age of onset 3 months to 2 years) characterized by developmental arrest, neurologic deterioration, movement disorders, mental retardation, autistic-like behavior, and epilepsy. Severe early-onset epilepsy with pleomorphic seizures is a key symptom of such disorders.
Application: Creatine monohydrate can identify enzyme deficiencies in biochemical pathways for guanidinoacetate N-methyltransferase or arginine/glycine amidinotransferase, in addition to disorders in creatine transporter 1 level dysfunction. Such biochemical pathway–based disorders precipitate early—onset epilepsy conditions characterized by pleomorphic seizure disorders. Creatine monohydrate can be utilized in strategies for selecting appropriate cases suitable to evaluation by proton magnetic resonance spectroscopy.
Implementation: Complementary diagnostic strategy for evaluating epilepsy conditions caused by dysfunction in 2 synthetic steps involved in creatinine metabolism including (i) guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase deficiencies; and (ii) creatine transporter 1 function.
Interpretation and Analysis: Guanidinoacetate N-methyltransferase and arginine/glycine amidinotransferase deficiencies respond positively to substitutive treatment with creatine monohydrate. Data suggest that in cases with guanidinoacetate N-methyltransferase deficiency, epilepsy and associated electroencephalographic abnormalities are more responsive to creatine supplementation than to

conventional antiepilepsy drugs. All cases of creatine disorders reported to date have been detected by brain proton magnetic resonance spectroscopy, an expensive technique not routinely used in pediatric neurology. A potential diagnostic strategy to select cases for evaluation using proton magnetic resonance spectroscopy have been described.

Inborn errors of creatine metabolism and epilepsy: Clinical features, diagnosis, and treatment. Leuzzi V. J Child Neurol 2002 Dec; 17 Suppl 3, pp. 3S89–97; discussion 3S97.

Epilepsy: Cerebral Cortex Function/Intractable Childhood Epilepsy/Side-of-Seizure Onset Prediction/Memory Asymmetries/Temporal and Extra-Temporal Lobe Epilepsy Lateral Seizure Prediction

Amobarbital/Wada Test

Cellular/Molecular Mechanism of Action: Amobarbital is a barbiturate.

Physiological Mechanism of Action: Amobarbital functions as a depressant of central nervous system function.

Application: Selective localization of deficits and predicting the extent of undesirable side effects if surgical intervention is attemped to correct intractable neurologic disorders (e.g. uncontrollable epilepsy).

Background Information: Because of the capacity of intracarotid amobarbital (Wada) memory assessment to predict seizure-onset laterality in children has not been thoroughly investigated, 3 comprehensive epilepsy surgery centers have pooled their data and examined Wada memory asymmetries to predict side-of-seizure onset in children being considered for epilepsy surgery.

Route of Administration: Amobarbital (Wada test) involves the selective delivery of the barbiturate into specific arterial branches within the central nervous system facilitated by catheterization of the carotid artery.

Implementation: Evaluation of intractable epilepsy conditions utilizing Wada testing protocols. After return to neurologic baseline, recognition memory for the stimuli is assessed. Seizure onset is determined by simultaneous video-EEG recordings of multiple seizures.

Human Model: Cases of intractable epilepsy (n = 152 children) underwent Wada testing.

Interpretation and Analysis: Despite variations in the type of memory stimuli, number of memory stimuli, and methods applied, all children presented with 6 to 10 items soon after amobarbital injection. In children with unilateral temporal lobe seizures (n = 87), Wada memory asymmetries accurately predicts seizure laterality to a statistically significant degree. Wada memory asymmetries also correctly predict side-of-seizure onset in children with extra-temporal lobe seizures (n = 65). Although individual case prediction accuracy is statistically significant in temporal lobe cases, onset laterality is incorrectly predicted in approximately $\leq$ 52% of children with left temporal lobe seizure onset, depending on the methods and asymmetry criterion used. There also are significant differences between Wada prediction accuracy across the 3 epilepsy centers. Results suggest that Wada memory assessment is useful in predicting side-of-seizure onset in many children. However, Wada memory asymmetries should be interpreted more cautiously in children than in adults.

Prediction of seizure-onset laterality by using Wada memory asymmetries in pediatric epilepsy surgery candidates. Lee GP, Park YD, Hempel A, Westerveld M, Loring DW. Epilepsia 2002 Sep; 43 (9), pp. 1049–55.

Epilepsy: Cerebral Hemisphere Function/Intractable Epilepsy/Preoperative Foci Localization/Prediction of Residual Postoperative Deficits

Amobarbital (Wada Test)/[^{99m}Tc]-Hexamethylpropylene Aminoxime ([^{99m}Tc]-HMPAO)

Physiological Mechanism of Action: Amobarbital is a barbiturate that has a general depressant effect on central nervous system function.

Background Information: The IAP is used presurgically in cases with temporal lobe epilepsy to predict the effects of planned temporal lobectomy on LTM and language. This prognosis presumes that a similar pattern of perfusion will result in anesthesia of the same cerebral regions in most cases. Co-injection of [^{99m}Tc]-HMPAO with the barbiturate during the IAP has been used to ascertain whether this actually is true, with variable results. Moreover, most studies document only unilateral IAPs and do not report on behavioral performance.

Application: Amobarbital can be applied to assist in accurately localizing central nervous system lesions and predicting the probability and severity of postoperative deficits.

Route of Administration: Amobarbital (superselective intracarotid delivery to specific regions of the central nervous system).

Implementation: Evaluation of central nervous system disorders utilizing [^{99m}Tc]-HMPAO co-injected with amobarbital (e.g., n = 33 intracarotid amobarbital procedures; n = 15/18 bilateral, n = 3/18 unilateral). Important aspects of the procedure pertain to delineating the relationship between perfusion pattern and behavioral performance. Such objectives can be address applying SPECT analysis and comparison of results with angiographic evaluations obtained at the time of catheter placement. SPECT perfusion data is rated for presence/absence and intensity of perfusion to the ACA, MCA, and PCA territories and to H, i, or c to the injection site. V, STM, and LTM are graded according to a standardized protocol.

Human Model: Cases of epilepsy (n = 18).

Interpretation and Analysis: MCAi is perfused in 100% of cases, ACAi in 91%, PCAi in 21%, and Hi in only 6%. Crossover flow can be detected in a small percent of cases (e.g., n = 9) while 50% of cases in whom both sides are injected (on different days) have crossover, involving the ACAc territory in 80% of cases. As expected, injection on the non-ES is associated with a significantly worse LTM performance than on the ES (p = 0.006). There is no relationship between the perfusion pattern and the V level of cases (a potential confounding variable in memory/language evaluation) during IAP, nor between perfusion pattern and LTM. STM is significantly adversely affected by the presence of crossover perfusion. Angiography in general overestimates the extent of cerebral perfusion demonstrated by SPECT, most probably because of the markedly different injection conditions. Despite the best efforts to standardize injections, the perfusion pattern has been mostly unpredictable in cases. Moreover, it has little bearing on their behavioral performance, except for the prediction of poor STM performance (the clinical implications of this remain dubious). Marked LTM alterations after non-ES injections confirm remote hippocampal effects in the presence of only rare direct perfusion of that region. [^{99m}Tc]-HMPAO/amobarbital co-injection is unhelpful from a clinical perspective, most probably because a large part of the effects of amobarbital arise from deafferentation of regions not directly perfused by the anesthetic agent.

Absence of correlation between amobarbital distribution as assessed with SPECT brain perfusion imaging and behavioral manifestations during the intracarotid amobarbital procedure (Wada test). Soucy JP, Rouleau I, Roy D, Robidoux J, Laflamme K, Laflamme L. Prog Neuropsychopharmacol Biol Psychiatry 1999 Feb; 23 (2), pp. 259–74.

Epilepsy: Cerebral Cortex Function/Pharmaco-Electroencephalograpy
Pharmaco-Electroencephalogram/ Carbamazepine (CBZ)

Application: Delineating the influence of CBZ on cerebral cortex function in epileptic disease states.
Dosage: Carbamazepine (300 mg, single dose).
Implementation: Evaluate the influence of CBZ on cerebral cortex function in epileptic conditions utilizing quantitative EEG (qEEG) techniques and instrumentation. Sample EEG tracings are recorded before and at regular intervals within 24 hours following pharmaceutical administration. The EEG activity is processed by power spectral analysis and the drug serum concentration assessed concomitantly.

Human Model: Cases of epilepsy (n = 10 epileptics; n = 10 healthy adult volunteers).
Interpretation and Analysis: Increases in serum CBZ concentrations correspond with the percentage of power progressively increasing in the theta band while it decreases in the alpha2 band. The percentage of theta and alpha2 power is found to reach maximum and minimum levels, respectively, when the peak values of serum concentration of CBZ are attained. The effects on qEEG in anterior scalp areas are more evident than in posterior scalp areas.

Quantitative pharmaco-EEG of carbamazepine in volunteers and epileptics. Wu X, Xiao CH. Clin Electroencephalogr 1996 Jan; 27 (1), pp. 40–5.

Epilepsy: Cerebral Cortex Function/Pharmaco-Electroencephalograpy
Valproate/Pharmaco-Electroencephalography

Application: Characterization of cerebral cortical function in epilepsy conditions.
Dosage: Valproate (single-dose administration).
Implementation: Evaluation of the influence of sustained-release valproate (SR-VPA) on cerebral cortex function in epilepsy conditions applying quantitative background electroencephalography (EEG). Complementary investigations include establishing SR-VPA serum concentrations.

Human Model: Cases of CNS epilepsy (n = 10 untreated with generalized tonic-clonic seizures).
Interpretation and Analysis: Pharmaco-electroencephalography reveals increased power of alpha2 band over occipital areas, a decrease of power of beta band (diffuse and preponderant on posterior scalp areas) with increasing serum concentrations. Both effects reach their maxima and minima, respectively, when the peak values of serum concentration are reached. A positive correlation exists between alpha2 power on the occipital areas and serum SR-VPA concentrations, and a negative correlation of serum concentration and beta power are detected over the posterior scalp areas.

Quantitative pharmaco-EEG of sustained release valproate in epileptics. Wu X, Xiao CH. Clin Electroencephalogr 1997 Apr; 28 (2), pp. 117–20.

Epilepsy: Cerebral Cortex Function/Pharmaco-Electroencephalograpy/Cononical Correlation (Semilinear): Anesthesiology/Responders vs Non-Responders: Psychiatry/1st-Order Markov Model of Sleep Stage Transitions: Neurophysiology
Pharmaco-Electroencephalograpy (Pharmaco-EEG)

Background Information: In the clinical application and interpretation of pharmaco-EEG, it is important to appreciate its value in the context of other diagnostic parameters such as biomarkers, surrogate end points, clinical end points, and clinical outcomes.
Application: Detection and characterization of neurologic disorders through the combined application of specific pharmaceutical agents and measurement of their influence on central nervous function detected with EEG instrumentation.
Considerations: Much work still needs to be conducted to fully develop the potential capabilities that pharmaco-EEG together with pharmacokinetic-pharmacodynamic modeling can bring to therapeutics in neuroscience.
Interpretation and Analysis: State-of-the-art applications of pharmaco-EEG, together with pharmacokinetic-pharmacodynamic modeling in everyday clinical practice, is becoming a reality pertaining to the fields of anesthesiology (semilinear canonical correlation), psychiatry (discrimination between responders and non-responders to pharmacological treatment using the test dose), neurology (antiepileptic field), and neurophysiology (1st-order Markov model of sleep stage transitions). The combination of both procedures, although successfully used during some drug development programs (opioids or benzodiazepines), is not widely applied in clinical conditions affecting the central nervous system.

Uses of pharmaco-EEG and pharmacokinetic-pharmacodynamic modeling in the clinical scenario. Barbanoj MJ, Valle M, Kulisevsky J, Perez V, Gambus P. Methods Find Exp Clin Pharmacol 2002; 24 Suppl D, pp. 139–44.

Epilepsy (Intractable): Cerebral Cortex-Hemisphere Function/Preoperative Foci Localization/Prediction and Probability of Residual Postoperative Deficits/Hemiplegia Duration and Relationship to SPECT Hypoperfusion/Drug-Induced Delta EEG Activity/HMPAO-SPECT Assessment of Methohexital Distribution
Methohexital (Wada Test)/[^{99m}Tc]-Hexamethylpropylene Aminoxime

Physiological Mechanism of Action: Methohexital is a barbiturate that functions as a central nervous system depressant.
Application: Methohexital can be applied to accurately localize foci within regions of the CNS responsible for intractable epilepsy conditions. Methohexital can also simultaneously function as a means for predicting the probability and potential severity of postoperative deficits. [^{99m}Tc]hexamethylpropylene aminoxime (HMPAO) can be administered intravenously during the procedure to determine the intracerebral distribution of methohexital while performing the Wada test.
Route of Administration: Methohexital (superselective intracarotic delivery into specific predetermined regions of the central nervous system).
Implementation: Evaluation of epileptic conditions being considered for surgery for intractable epilepsy utilizing a preoperative

evaluation protocol employing intracarotid sodium methohexital delivery. The lipophilic brain SPECT agent, HMPAO is administered intravenously during the procedure to determine the intracerebral distribution of methohexital.

The validity of the ISM depends on consistent delivery of the anesthetizing agent to 1 hemisphere, including the mesial structures of the temporal lobe. To prevent postoperative language and memory deficits, correct interpretation of the test results supposes a reliable knowledge of which regions of the brain have been anesthetized. Results of HMPAO-SPECT are compared with clinical and EEG video-monitoring data and with results of digital subtraction angiography (DSA) performed during the test in an effort to establish criteria for determining the level and topographical extent of anesthesia.

Human Model: Case being considered for surgery for intractable epilepsy (n = 25).

Interpretation and Analysis: In the vast majority of cases, the effect of sodium methohexital (SM) is ipsilateral cerebral hypoperfusion on SPECT and crossed cerebellar diaschisis (e.g., n = 25/25). The distribution of HMPAO varies from patient to patient. The delivery of SM to mesial temporal lobe structures is not constant. Using non-parametric tests, it has been demonstrated that a statistically significant relationship exists between hypoperfusion on SPECT and duration of hemiplegia but not with the duration of aphasia. Hypoperfusion on SPECT is also related to the onset and duration of drug-induced delta activity on EEG. SPECT reveals a statistically different distribution of SM in the brain from that predicted with digital subtraction angiography (DSA). HMPAO-SPECT can be used for mapping the distribution of methohexital's effects during intracarotid sodium methohexital (ISM) Wada tests. Several investigations have confirmed that SPECT assessment may be an excellent way of determining the distribution of barbiturate during examinations. It increases confidence in interpreting results of speech and memory testing by detecting either contralateral diffusion of the drug due to crossflow between hemispheres or insufficient quantitative delivery to the homolateral hemisphere.

Monitoring sodium methohexital distribution with [99mTc]HMPAO with single photon emission computed tomography during Wada test. Coubes P, Baldy-Moulinier M, Zanca M, Boire JY, Child R, Bourbotte G, Frerebeau P. Epilepsia 1995 Oct; 36 (10), pp. 1041–9.

Epilepsy: Cerebral Cortex Function/Resistant Focal Epilepy/Accuracy of Amobarbital Target Delivery/ Temporary Neurologic Deficits/Risk Assessment of Postsurgical Motor Deficits Before Functional Hemispherectomy/Language Area Identification

Amobarbital (Sodium) Wada Test/[^{99m}Tc]-HMPAO/ Electrical Stimulation Mapping

Cellular/Molecular Mechanism of Action: Amobarbital is classified as a barbiturate agent.

Physiological Mechanism of Action: Amobarbital has a generalized suppressant effect on neurons within the central nervous system.

Application: Analyze the role of selective middle cerebral artery (MCA) Wada tests in the presurgical workup of cases with drug-resistant focal epilepsies.

Route of Administration: Amobarbital is administered selectively into arterial branches supplying specific regions of the cerebral cortex using a catheter introduced into the carotid artery.

Implementation: Evaluation of cerebral cortex function in conditions of (i) motor cortex cerebral hemisphere lesions (connatal MCA infarct; unilateral cortical dysplasia; Rasmussen encephalitis); (ii) circumscribed neoplastic or non-neoplastic lesions adjacent to the motor cortex or classical language regions; and (iii) sleep electrical status epilepticus. Sodium amobarbital and [^{99m}Tc]-HMPAO are simultaneously injected through a microcatheter system into the distal M1 segment, the inferior MCA trunk, or the middle cerebral artery branches in order to identify eloquent cortex.

Human Model: Cases of cerebral cortex dysfunction including (i) hemispheric lesions involving the motor cortex (n = 9 cases, of which n = 5/9 connatal MCA infarct; n = 3/9 unilateral cortical dysplasia; n = 1/9 Rasmussen encephalitis); (ii) circumscribed neoplastic or non-neoplastic lesions adjacent to the motor cortex or classic language areas (n = 5 cases); and (iii) purely electrophysiologic analyses for conditions of electrical status epilepticus in sleep (n = 2 cases). Total Wada test performed, n = 20.

Interpretation and Analysis: Co-registered single photon emission computed tomography (SPECT) and magnetic resonance imaging (MRI; n = 18) reveals that sodium amobarbital does not reach the target area during some procedures (e.g., n = 3/20). Temporary neurologic deficits can occur in slightly more than half of total Wada procedures performed (e.g., n = 12/20). Cases subjected to surgical intervention requires the use of several different surgical approaches, including functional hemispherectomy (n = 3); partial or extended lesionectomy (n = 4); anterior temporal lobectomy (n = 1); and multiple subpial transsections (n = 3). Seizure freedom (Engel class I) can be achieved in a modest percentage of cases (e.g., n = 5/16 cases). The MCA Wada tests can therefore contribute to risk assessment concerning postsurgical motor deficits before functional hemispherectomy. Other indications are less clear: The identification of language areas is targeted primarily by electrical-stimulation mapping after subdural grid implantations, and selective MCA Wada tests in ESES cases but they still ideally should be validated in a larger patient groups.

Selective middle cerebral artery Wada tests as a part of presurgical evaluation in cases with drug-resistant epilepsies. Urbach H, Von Oertzen J, Klemm E, Koenig R, Linke DB, Kurthen M, Schramm J, Elger CE. Epilepsia 2002 Oct; 43 (10), pp. 1217–23.

Epilepsy: Cerebral Cortex Function/Response to Anticonvulsive Therapy/Relative Efficacy Evaluation/ Anticonvulsants for Petit mal/Generalized Non-Convulsive Epilepsy

Pharmaco-Electroencephalography/Milacemide (CP 1552 S)/Sodium Valproate/Piracetam

Cellular/Molecular Mechanism of Action: Milacemide (CP 1552 S) is a derivative of glycine that exerts an anticonvulsant action by increasing GABA concentrations and endogenous glycine pools in the brain.

Physiological Mechanism of Action: Milacemide exerts a brain anticonvulsant action by increasing GABA concentrations.

Application: Compare and contrast the electroencephalography profiles and behavioral anticonvulsant properties of various therapeutic agents.

Route of Administration: Milacemide (oral).

Dosage: Milacemide (400 mg, 800 mg, 1600 mg). Reference compounds (placebo; sodium valproate at 600 mg; and piracetam at 1600 mg).

Implementation: Evaluation of the encephalotropic and psychotropic properties of milacemide by means of quantitative EEG and psychometric analyses. Electroencephalogram recordings and monitoring of blood pressure, heart rate, and side effects are per-

formed at 0, 1, 2, 4, 6, and 8 hours. Psychometric tests are performed at 0, 2, 4, 6, and 8 hours.

Human Model: Cases functioning as healthy normal reference controls (n = 12). Study Design: Double blind placebo-controlled study.

Interpretation and Analysis: Computer-assisted spectral analysis of EEG profiles shows significant effects of milacemide on the central nervous system (CNS) in contrast to placebo, characterized by an attenuation of delta activity accompanied by an acceleration of the centroid of the slow activity but also of the total activity in response to all 3 dosage levels. Other alterations noted include increases in beta activity after 400 mg, an increase of alpha activity after 800 mg, as well as an increase of alpha activity but a decrease in beta activity after a 1600 mg dose. Such changes, also seen after 600 mg sodium valproate, are reminiscent of quantitative EEG changes described after antiepileptic drugs used in the treatment of petit mal or generalized non-convulsive epilepsy. Moreover, they are also indicative of improvement in "vigilance" in the sense of Head, which is also seen at the behavioral level, specifically after the lowest doses of milacemide, as psychometric tests demonstrate an improvement in attention, concentration, psychomotor activity, and after-effect (indicating CNS activation) as measured by means of the Archimedean spiral. Such a beneficial influence on performance declines with increasing dose. Evaluation of pulse, blood pressure, and side effects demonstrate good tolerance after all administered substances.

Early clinical pharmacological trials with a new antiepileptic, milacemide, using pharmaco-EEG and psychometry. Saletu B, Grünberger J. Methods Find Exp Clin Pharmacol 1984 Jun; 6 (6), pp. 317–30.

Epilepsy: Cerebral Cortex Function/Spatiotemporal Patterns of Spontaneous Epileptiform Activity/ Cerebral Cortext Seizures
RH414 (Fluorescent Voltage-Sensitive Dye)/Bicuculline ($GABA_A$ Receptor Antagonist)

Application: RH414 functions as a fluorescent voltage-sensitive dye and the $GABA_A$ receptor antagonist bicuculline can be applied to induce acute spontaneous epileptoform discharges.

Implementation: Characterization of spatiotemporal patterns of *in vivo* spontaneous epileptiform activity in the cerebral cortex. The surface of the cerebral cortex is exposed under anesthesia and stained with a fluorescent voltage-sensitive dye, RH414, and optical recording techniques applied for the detection of transmembrane voltage changes. Acute spontaneous epileptiform discharges can be induced by the application of bicuculline ($GABA_A$ receptor antagonist). Changes in the intensity of fluorescence are recorded from the cerebral cortex using a photodiode system.

Animal Model: Rat cerebral cortex.

Interpretation and Analysis: Recordings can be acquired that detect spontaneous epileptiform discharges in a manner that can faciliate the construction of initiation-site maps. Initiation sites are neither unique nor randomly located but instead exhibit a multimodal distribution pattern. The incidence of epileptiform discharges is different between the initiation sites, and some sites show dominance in the induction of spontaneous epileptiform discharges.

Instrumentation: Optic fiber photodiode system (464-channel).

Optical analysis of acute spontaneous epileptiform discharges in the *in vivo* rat cerebral cortex. Iyakawa N, Yazawa I, Sasaki S, Momose-Sato Y, Sato K. Neuroimage. 2003 Mar; 18 (3), pp. 622–32.

Ethanol and Thiopental Cerebral Cortex Depression/ Pharmacological Interactions
Pharmaco-Electroencephalography/ Captopril/Enalaprilat

Cellular/Molecular Mechanism of Action: Captopril and enalaprilat function as angiotensin converting enzyme inhibitors.

Background Information: The influence of captopril and enalaprilat on the central nervous system has been investigated in laboratory animals.

Route of Administration: Captopril (intraperitoneal); enalaprilat (intraperitoneal); ethanol (intraperitoneal); and thiopental (intraperitoneal)

Dosage: Captopril (5 and 20 mg/kg); enalaprilat (5 and 20 mg/kg); ethanol (4 g/kg); and thiopental (70 mg/kg) single administration or repeated SID for 10 days.

Implementation: Evaluation of the effect captopril and enalaprilat have on the duration of ethanol- and thiopental-induced changes in sleep, body temperature, spontaneous locomotor activity, and analgesic properties (hot plate and tail-flick test, and pharmaco-EEG profiling).

Animal Model: Murine (hot plate and tail-flick test).

Animal Model: Rabbit (pharmaco-EEG profiles).

Interpretation and Analysis: Single administration of captopril (both doses) and single or prolonged administration of enalaprilat decrease the duration of ethanol- and thiopental-induced sleep. Captopril (5 mg/kg) and enalaprilat (5 and 20 mg/kg) increase pain threshold. Both captopril and enalaprilat after single or repeated administration do not influence spontaneous locomotor activity (mice). Captopril and enalaprilat decrease body temperature in mice. Examined ACEIs produce changes in EEG recording, more profoundly exhibited after administration of enalaprilat.

An attempt to assess the central action of captopril and enalaprilat. Czarnecka E, Strzelec J, Pietrzak B. Med Sci Monit 2000 May–Jun; 6 (3), pp. 491–7.

Headache Pain: Cluster Episodes/Cerebral Cortex
Sumatriptan/Prolactin/Adrenocorticotropic Hormone (ACTH)

Cellular/Molecular Mechanism of Action: Sumatriptan is a selective 5-HT(1B/1D) agonist that stimulates the secretion of growth hormone and inhibits the release of prolactin, ACTH, and cortisol.

Application: Assess the sensitivity of 5-HT(1D) receptors in cases with episodic cluster headache using sumatriptan as a pharmacological probe. These effects may be used to explore the function of serotonergic systems *in vivo*.

Route of Administration: Sumatriptan (subcutaneous).

Implementation: Evaluation of the influence of sumatriptan on cluster headaches.

Animal Model: Cases of headache (n = 20; n = 10 active phase; n = 10 remission period; n = 12 negative reference controls).

Interpretation and Analysis: Sumatriptan-induced increases in growth hormone concentrations are significantly ($p < 0.05$) blunted in cases with active cluster headache. Prolactin and ACTH responses to the drug are significantly ($p < 0.05$) reduced in cluster headache conditions in both the active and in the remission period. Therefore, cerebral serotonergic functions mediated by 5-HT(1D) receptors become altered in episodic cluster headache conditions.

Abnormal 5-HT1D receptor function in cluster headache: A neuroendocrine study with sumatriptan. Pinessi L, Rainero I, Valfrè W, Lo Giudice R, Ferrero M, Rivoiro C, Arvat E, Gianotti L, Del Rizzo P, Limone P. Cephalalgia 2003 Jun; 23 (5), pp. 354–60.

Hemorrhage: Intracranial/Cerebral Cortex
Hirudin

Cellular/Molecular Mechanism of Action: Hirudin has a relatively strong binding avidity for thrombin and functions as an inhibitor of most biological properties associated with this proteolytic enzyme fraction.
Background Information: In humans, intracerebral hemorrhage (ICH) causes marked perihematomal edema formation and neurological deficits. A rat ICH model, involving infusion of autologous blood into the caudate, has been used extensively to study mechanisms of edema formation, but an examination of behavioral outcome would improve its preclinical utility and provide a more rigorous assessment of the pathological cascade of events over time.
Application: Detection and characterization of hemorrhagic conditions affecting the central nervous system.
Route of Administration: Intravenous.
Implementation: Evaluate a battery of sensorimotor function tests to determine the neurological effects of ICH and to examine which components of the hematoma are involved in generating those effects. One experimental approach to delineating these features involves assessment from day 1 to day 28 postinjection the influence of (i) autologous whole blood injection; (ii) injection of blood plus hirudin (thrombin inhibitor); (iii) packed red blood cells; (iv) thrombin; (v) saline; and (vi) needle placement only.

Animal Model: Rat (behavioral tests employing forelimb placing, preference for forelimb use for weight shifts during vertical exploration of a cylindrical enclosure, and a corner turn test).
Interpretation and Analysis: Radioisotope-labeled hirudin accumulates at sites of intravascular thrombosis. Behavioral-oriented tests can detect the presence of marked neurological deficits by day 1 after ICH, with progressive recovery of function over 4 weeks. The forelimb placing scores parallel changes in edema. Injection of thrombin causes (promotes), while injected hirudin reduces, ICH-induced neurological deficits. Injection of packed red blood cells (promotes delayed edema formation) induces delayed neurological deficits. Such tests allow continuous monitoring of neurological deficits after rat ICH and assessment of therapeutic interventions. The time course of the neurological deficit closely matches the time course of cerebral edema for both ICH and injection of blood components. There is marked recovery of function after ICH, which may be amenable to therapeutic manipulation.

Behavioral tests after intracerebral hemorrhage in the rat. Hua Y, Schallert T, Keep RF, Wu J, Hoff JT, Xi G. Stroke 2002 Oct; 33 (10), pp. 2478–84.

Hepatoencephalopathy Coma
Bromocriptine

Diagnostic Application: Detection and characterization of coma associated with conditions of hepatoencephalopathy.
Dosage: Bromocryptine is rapidly absorbed from gastrointestinal tract and is extensively removed by 1st-pass hepatic perfusion. Peak plasma concentration (human) occurs approximately 3 hours following oral administration and the plasma $T_{1/2}$ is about 3 hours.
Considerations: Induces less dyskinesia than levodopa. A 1st-dose rapid-onset cardiovascular collapse event has been reported with bromocriptine, but this is not a feature associated with levodopa administration. Adverse effects from bromocriptine are usually related to dopaminergic agonist activity. Complications are usually recognized during the initial phases of administration of bromocriptine given for the first time in cases that are eventually managed with chronic therapy.
Interpretation and Analysis: Creates non-specific arousal of the CNS (similar to levodopa) that may be effective in treating comatose cases whose coma is caused by hepatoencephalopathy.

Hepatoencephalopathy: Coma/Non-Hepatoencephalopathy-Induced Neurologic Deficits
Flumazenil

Background Information: The pathogenesis of hepatic encephalopathy is unknown. It has been suggested that liver failure leads to the accumulation of substances that bind to receptor complexes within the brain, resulting in neural inhibition that may progress to coma. Several trials have assessed the effectiveness of benzodiazepine receptor antagonists for conditions of hepatic encephalopathy, but the results are conflicting.
Application: Flumazenil can function as a valuable diagnostic agent for characterizing conditions of coma but only with clear indications.
Considerations: Eligible trials have been/can be identified through the Cochrane Hepato-Biliary Group Controlled Trials Register, the Cochrane Controlled Trials Register, MEDLINE, EMBASE, reference lists of relevant articles, authors of trials, and the pharmaceutical company known to produce benzodiazepine receptor antagonists. Randomized trials comparing any benzodiazepine receptor antagonist vs placebo or no intervention for hepatic encephalopathy can be included, regardless of language or publication status. Trial inclusion and data extraction are made independently by multiple contributors (e.g. n = 2). Depending on the presence or absence of significant heterogeneity ($p < 0.1$), a random or fixed effect model can be used. Potential causes for heterogeneity should be explored by sensitivity analyses. Extraction of data on all outcomes from all trials may not be possible.
Implementation: Retrospective evaluation of the response, efficacy and safety of benzodiazepine receptor antagonists in conditions of acute or chronic hepatic encephalopathy. A secondary objective is to determine if any prognostic variables or factors can be identified.

Human Model: Cases with hepatoencephalopathy (n = 765).

Study Design: Twelve randomized trials with eight trials having a crossover design. All trials are double blind and assess flumazenil vs placebo.
Interpretation and Analysis: The vast majority of cases classified as having a favorable prognosis survive (flumazenil = 92% or n = 341/379 vs placebo = 91% or n = 325/356). Flumazenil has no significant effect on full recovery (2 trials), survival (9 trials), or on the occurrence of adverse events (5 trials). However, flumazenil is associated with a significant effect on improvement of hepatic encephalopathy compared to placebo at the end of treatment (30% or n = 103/346 versus 7% or 23/332), risk difference 0.23, 95% confidence interval 0.18 to 0.28 (n = 9 trials).

Flumazenil has no significant effect on recovery or survival from hepatic encephalopathy. However, flumazenil had a significant effect on short-term improvement of hepatic encephalopathy in some cases with chronic liver disease and a highly favorable prognosis. Considering the fluctuating nature of hepatic encephalopathy, future trials should use a parallel design and assess if flumazenil can promote sustained improvement or increased recovery and survival. Until this

has been demonstrated, flumazenil may be considered for cases with chronic liver disease and hepatic encephalopathy but cannot be recommended for routine clinical use.

Benzodiazepine receptor antagonists for acute and chronic hepatic encephalopathy. Als-Nielsen B, Kjaergard LL, Gluud C. Cochrane Database Syst Rev 2001 (4), p. CD002798.

Hepatoencephalopathy: Cerebral Cortical Function/Acute Hepatic Encephalopathy/ Encephalopathy Associated with Hemorrhage/ Potential Prognostic Indicators
Flumazenil/Pharmaco-Electroencephalography

Background Information: Randomized controlled trials testing flumazenil in hepatic encephalopathy have shown conflicting results. The aim of the tests is to compare flumazenil and placebo in hepatic encephalopathy in cases with cirrhosis.
Application: Evaluate the effects of flumazenil on hepatic encephalopathy in cases with liver cirrhosis and the potential of therapeutic response to correlate with prognosis.
Route of Administration: Flumazenil (intravenous).
Dosage: Flumazenil (2 mg).
Implementation: Evaluation of the response to flumazenil in conditions of encephalopathy associated with hepatic cirrhosis. Administration of flumazenil or placebo can be accompanied by the co-administration of conventional treatments (e.g., branched-chain amino acid, saline, glucose, and lactulose). Alterations in clinical signs are assessed over a 24-hour observation period. Clinical improvement is defined as a 3-point decrease in the Glasgow coma score at any time within 24 hours.

Human Model: Cases of encephalopathy associated with hepatic cirrhosis ($n = 54$ cases with hepatic encephalopathy grades III and IV). For each end point, heterogeneity and treatment efficacy are assessed.
Interpretation and Analysis: In double blind randomized controlled trials ($n = 6$ trials; with $n = 641$ cases; $n = 326/641$ treated with flumazenil; $n = 315/641$ placebo) the treatment duration can range between 5 minutes to 3 days. (Note: heterogeneity tests between control groups not significant.) In trials (e.g., $n = 5$) the mean percentage of clinical improved is approximately 27% with pharmaceutical challenge and about 3% with placebo reference controls (Peto methodology: odds ratio = 6.15; 95% confidence interval, 4.0–9.5; $p < 0.001$; Der Simonian methodology: mean rate difference, 29%; 95% confidence interval, 17–41; $p < 0.001$). The mean percentage of cases with electroencephalographic improvement is approximately 19% with flumazenil but 2% with placebo. The difference is significant only with the Peto method of analysis (odds ratio = 5.8; 95% confidence interval, 3.4–9.7; $p < 0.001$). Sensitivity analysis reveals similar findings. Meta-analysis of this type reveals that flumazenil induces clinical and electroencephalographic improvement of hepatic encephalopathy in cases with cirrhosis.

In related investigations, clinical improvement can be appreciated in a large percentage of affected cases (e.g., $n = 22/28$ with flumazenil; $n = 14/26$ placebo @ $p < 0.05$). Improvement is observed within the 1st 6 hours in the vast majority of cases given flumazenil (e.g., $n = 21/22$ cases vs $n = 3/14$ placebo). Unfortunately, the mortality rate is not different between case groups receiving either flumazenil challenge of placebo. However, a large percentage of non-responders subjected to flumazenil challenge died within 24 hours (e.g., $n = 6/6$ or 100%) in contrast to only slightly less than half of placebo-treated cases (e.g., $n = 5/12$ non-responders).

In conditions of postbleeding encephalopathy, over half of affected cases challenged with flumazenil improve ($n = 11/17$) compared to a very low number of placebo case (e.g., $n = 2/14$ @ $p < 0.001$). Flumazenil therefore exerts a beneficial effect in a subset of cases with acute hepatic encephalopathy; encephalopathy associated with bleeding is more likely to respond to flumazenil; and responders to the treatment usually improve within the 1st 6 hours while lack of response usually represents a bad prognostic sign.

Flumazenil in the treatment of acute hepatic encephalopathy in cirrhotic cases: A double blind randomized placebo controlled study. Laccetti M, Manes G, Uomo G, Lioniello M, Rabitti PG, Balzano A. Dig Liver Dis 2000 May; 32 (4), pp. 335–8.

Flumazenil vs placebo in hepatic encephalopathy in cases with cirrhosis: A meta-analysis. Goulenok C, Bernard B, Cadranel JF, Thabut D, Di Martino V, Opolon P, Poynard T. Aliment Pharmacol Ther 2002 Mar; 16 (3), pp. 361–72.

Hippocampus Neurotransmitter Function/ Dopamine, Norepinephrine, and Serotonin Induction
Bupropion

Cellular/Molecular Mechanism of Action: Bupropion is a dual dopamine/norepinephrine reuptake blocker.
Dosage: Bupropion (17 mg/kg).
Implementation: Evaluation of the influence of an acute dose of bupropion on extracellular neurotransmitter concentrations within the hippocampus collected *in vivo* using a microdialysis system. Peripheral hormonal concentrations are assessed using an indwelling catheter. A microdialysis probe is inserted in the hippocampus, and samples for serotonin, dopamine, and norepinephrine are collected every 20 minutes before and after injection of bupropion, for a total sampling time of 180 minutes. In a separate group of subjects, a catheter is placed in the vena femoralis, and blood samples collected before and after bupropion injection for quantification of growth hormone, prolactin, corticosterone, adrenocorticotropic hormone, and beta-endorphins.

Animal Model: Rat (free moving).
Interpretation and Analysis: All neurotransmitter levels (dopamine, norepinephrine, and serotonin) significantly increase after bupropion injection. This is accompanied by a significant decrease in prolactin concentrations, whereas the other hormones show no statistically significant variation. It can, therefore, be concluded that, although bupropion has dual reuptake properties, the observed effects both at the central and at the peripheral level seem to be ruled by the dopaminergic system.

Effect of bupropion on hippocampal neurotransmitters and on peripheral hormonal concentrations in the rat. Piacentini MF, Clinckers R, Meeusen R, Sarre S, Ebinger G, Michotte Y. J Appl Physiol 2003 Aug; 95 (2), pp. 652–6. Epub 2003 Apr 11.

Hippocampal Neurotransmitter Function/GABA Receptor Complex Expression Density
Muscimol-[Alexa Fluor 532]

Cellular/Molecular Mechanism of Action: Muscimol-[Alexa Fluor 532] functions as a fluorescent-labeled GABA receptor ligand.
Application: Detection and characterization of $GABA_A$ binding sites within hippocampal neurons (rat) using fluorescence correlation spectroscopy.
Semi-Synthetic Methods: Labeling of Muscimol with the fluorophore Alexa Fluor 532.

Animal Model: Rat.

Interpretation and Analysis: Based on binding constant parameters, the binding affinity of dye-labeled Muscimol-[Alexa Fluor 532] to $GABA_A$ receptors is highly specific with a K_D value of 3.4 ± 0.5 nM and a ligand-receptor dissociation rate constant (k_{diss}) of $(5.37 \pm 0.95) \times 10^{-2}$/sec. The ligand-receptor association rate constant (K_{ass})has been calculated to be $(1.57 \pm 0.28) \times 10^7$ L mol^{-1} /sec while observed diffusion coefficients are estimated to be $D_{Free} = 233 \pm 20$ μm^2/sec (n = 66) for free diffusing μ-Alexa; $D_{bound1} = 2.8 \pm 0.9$ μm^2/sec (n = 64) for the lateral mobility; and $D_{bound2} = 0.14 \pm 0.05$ microm^2/sec (n = 56) for hindered mobility of the $GABA_A$ receptor-ligand complex in the cell membrane. Saturation of Muscimol-Alexa binding is observed at a concentration of 50 nM while the maximum number of binding sites has been projected to be [$B_{max} = 18.4 \pm -0.4$ nM (n = 5)]. Similar K_i values of 4.5 ± 1.0 nM for non-labeled muscimol and 8.8 ± 1.8 nM for Muscimol-Alexa have been found by RRAs using [^{3}H]muscimol as a radiolabeled ligand. Concentration-dependent increases in the level of specific Muscimol-Alexa binding have been observed as demonstrated by the positive cooperative activity of co-incubated midazolam, which is selectively found in $GABA_A$ receptor-ligand complexes with hindered mobility.

Instrumentation: Fluorescence correlation spectroscopy.

Lateral mobility and specific binding to $GABA_A$ receptors on hippocampal neurons monitored by fluorescence correlation spectroscopy. Meissner O, Haberlein H. Biochemistry 2003 Feb 18; 42 (6), pp. 1667–72.

Histamine Receptor Agonist: H3 Selective Avidity
Histamine H_3 Ligand

Cellular/Molecular Mechanism of Action: Highly selective H_3 receptor agonist with virtually no H_4 subtype receptor affinity.

Application: Evaluation of histamine function and image analysis of histamine receptor sites.

Semi-Synthetic Methods: Production of a series of cyclopropane-based conformationally restricted analogs of histamine including the "folded" cis-analogs (1S,2R)-2-(aminomethyl)-1-(1H-imidazol-4-yl)cyclopropane (11), (1S,2S)-2-(2-aminoethyl)-1-(1H-imidazol-4-yl)cyclopropane (13), and their enantiomers ent-11 and ent-13, and the "extended" trans-analogsues (1R,2R)-2-(aminomethyl)-1-(1H-imidazol-4-yl)cyclopropane (12) and its enantiomer ent-12, have been designed as histamine H_3 receptor agonists. These target compounds were synthesized from the versatile chiral cyclopropane units, (1S,2R)- and (1R,2R)-2-(tert-butyldiphenylsilyloxy)methyl-1-formylcyclopropane (14 and 15, respectively) or their enantiomers ent-14 and ent-15.

Interpretation and Analysis: Among the conformationally restricted analogues, the "folded" analogue 13 (AEIC) having the *cis*-cyclopropane structure has been identified as a potent H_3 receptor agonist, which shows a significant binding affinity ($K_i = 1.31 \pm 0.16$ nM) and has an agonist effect (EC_{50}) value of 10 ± 3 nM) on receptor complexes. The compound owes its importance to being the 1st highly selective H_3 receptor agonist to have virtually no effect on the H_4 subtype receptor. Preliminary studies have therefore demonstrated that the cis-cyclopropane structure is very effective in the conformational restriction of histamine to improve the specific binding to the histamine H_3 receptor.

Cyclopropane-based conformational restriction of histamine. (1S,2S)-2-(2-aminoethyl)-1-(1H-imidazol-4-yl)cyclopropane, a highly selective agonist for the histamine H3 receptor, having a cis-cyclopropane structure. Kazuta Y, Hirano K, Natsume K, Yamada S, Kimura R, Matsumoto S, Furuichi K, Matsuda A, Shuto S. J Med Chem 2003 May 8; 46 (10), pp. 1980–8.

Huntington's Disease (HD)
Physostigmine/L-dopa

Cellular/Molecular Mechanism of Action: Physostigmine inhibits the biochemical activity of acetylcholine esterase, thereby increasing basal levels of acetylcholine neurotransmitter (substrate for acetylcholine esterase). The agent levodopa (L-dopa) is the immediate synthetic precursor to dopamine and melanine. Dopamine is a precursor in the production of norepinephrine.

Background Information: Huntington's disease is a dominantly inherited disorder that affects mental and motor systems and includes a rigid form as well as the better known choreic form. Many articles have been devoted to predicting the future onset of the disease in cases who are at risk, but none of the suggested predictors is currently considered completely reliable. Members from individual families do tend to show a similar age of onset, and similar intellectual and motor abnormalities do develop within a single family; but the presence or absence of this dominant gene of high penetrance is not usually certain until the obvious physical signs appear.

Psychological testing abnormalities are often seen abnormally early in the course of the disease in some cases of HD, particularly when motor dexterity or apraxia is tested. Family members often insist that various psychological traits enable them to predict which members are affected by the gene. Neurophysiologic tests have been described, including new data on the increased liklihood of H-reflexes in Huntington's disease. Electroencephalography at one time was advocated as a possible predictive test but, although there is frequently an association of a low voltage EEG activity with HD, such changes are too variable for certainty in prediction. Pneumoencephalography with specific measurements of caudate atrophy is of clinical interest, but a pneumoencephalogram is rarely needed for diagnosis and caudate atrophy may not actually be an early sign. Metabolic changes in HD include the biochemical effects of hypothalamic dysfunction, changes in growth hormone production/regulation, and reported change in GABA levels within the CSF or brain.

Application: Characterization of motor dexterity and apraxia parameters in suspected cases of Huntington's disease and their potential value as predictive indicators.

Considerations: Predictive tests are of importance not only to decide which person may develop the disorder, but they may also offer a clue to associated or causal features of the disease.

Implementation: Provocative tests have utilized numerous drugs in an attempt to predict the onset of the disease. Most commonly, this includes the diagnostic application of physostigmine and L-dopa.

Interpretation and Analysis: All of the tests elucidate peculiarities of the disease, and all are of ethical as well as neurological interest. Many of the provocative tests utilize quantification of known neurologic features of the disease, such as reduction in saccadic movements of the eye, increased reflexes, or patterns of movement. The ethical problems in predictive tests, especially tests intended to provoke features of the disease, have been a matter of quiet controversy.

Predictive tests in Huntington's disease. Paulson GW Res Publ Assoc Res Nerv Ment Dis] 1976; Vol. 55, pp. 317-29.

Huntington's Disease Chorea/Parkinsons Disease Dyskinesis/Striatal Medium Spiny Neurons/ Glutamate N-Methyl-D-Aspartate Receptors (NMDA)
Amantadine

Cellular/Molecular Mechanism of Action: Amantadine functions as an antagonist at glutamate N-methyl-D-aspartate (NMDA) receptor complexes. Amantadine also promotes release of dopamine from central neurons, particular from the nigrostriatal neurons.

Physiological Mechanism of Action: Compared to levodopa or anticholinergic agents, amantadine is relatively free of side effects.

Background Information: Chorea in Huntington's disease (HD) and in the levodopa-induced dyskinesias of Parkinson's disease (PD) may be clinically indistinguishable. In PD, hyperphosphorylation of NMDA receptors expressed on striatal medium spiny neurons contributes to peak-dose dyskinesias, and drugs that block these receptors can diminish the severity of chorea. Since striatal medium spiny neurons are the primary target of the neurodegenerative process in HD, sensitization of NMDA receptors on residual striatal neurons might also participate in the generation of motor dysfunction in HD.

Since amantadine is believed to promote the release of dopamine from intact dopaminergic terminals that remain in the nigrostriatium in conditions of Parkinson's disease, the therapeutic efficacy of this pharmaceutical can be enhanced by the concurrent administration of levodopa.

Application: Characterization of motor and cognitive function in HD.

Dosage: Amantadine (usually 400 mg/d).

Considerations: Some clinicians have entertained concerns regarding the ethical aspects of provocative testing for HD.

Implementation: Determination of the influence of acute NMDA receptor inhibition on motor and cognitive function in HD.

Interpretation and Analysis: Chorea scores are lower with amantadine treatment (usually 400 mg/d) than observed with placebo, with a median reduction in extremity chorea at rest of 36% ($p = 0.04$) and 56% in cases with the highest plasma drug levels. Improvement correlates with plasma amantadine concentrations ($p = 0.01$) but not CAG repeat length. Parkinsonian rating scores do not worsen and there is no consistent change in cognitive measures. The adverse event profile of amantadine is benign. Observations noted in preliminary investigations imply that NMDA receptor supersensitivity may contribute to the clinical expression of choreiform dyskinesias in HD and that selective antagonists at that site can safely confer palliative benefit.

A randomized trial of amantadine in Huntington's disease. O'Suilleabhain P, Dewey RB Jr. Arch Neurol 2003 Jul; 60 (7), pp. 996–8.

Ischemia Lesions/Parkinson's Disease Research
Stem Cells/Gadolinium Rhodamine Dextran (GRID)

Cellular/Molecular Mechanism of Action: Rhodamine emits light energy while gadolinium functions as an element that can be selectively detected by magnetic resonance imaging. Stem cells have an innate ability to migrate within the central nervous system to regions of neuronal injury or degradation (e.g. ischemica, Parkinson's disease).

Background Information: The ability to track stem cell transplants in the brain by *in vivo* neuroimaging will improve current understanding about how these cells mediate functional recovery after neural transplantation. One major challenge for the development and refinement of stem cell transplantation is to map the spatial distribution and rate of *in situ* migration.

Application: Gadolinium rhodamine dextran is a bifunctional contrast agent that can emit light energy and be detected in a magnetic field. These attributes allow it to be applied as a tracer or marker molecule for profiling the migration of transplanted stem cell populations within the central nervous system. Stem cells can be applied to target various types of lesions within the central nervous system including ischemic injury and neuronal degeneration associated with Parkinson's disease.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Conjugation of rhodamine to dextran applying cross-linking strategies. Addition of gadolinium to dextran can potentially be achieved by covalent bond formation or through the application of chelation groups.

Implementation: Assessment of stem cell migration applying *in vitro* labeling of populations with the bifunctional contrast agent GRID prior to transplantation. Detection is achieved applying both MRI and fluorescence microscopy, or with PKH26 for visualization exclusively under fluorescence microscopy. Brains can be evaluated by both histology and *ex vivo* MR imaging at different time points following engraftment.

Interpretation and Analysis: Transplanted stem cells can be identified by MRI only if prelabeled with GRID, whereas fluorescence microscopy can detect transplanted cells using either labeling reagent. Distribution of GRID-labeled stem cells established applying MRI corresponds to results using fluorescence microscopy. Stem cells and their migration can therefore be reliably identified applying GRID-enhanced MRI methodologies.

Tracking transplanted stem cell migration using bifunctional, contrast agent-enhanced, magnetic resonance imaging. Modo M, Cash D, Mellodew K, Williams SC, Fraser SE, Meade TJ, Price J, Hodges H. Neuroimage 2002 Oct; 17 (2), pp. 803–11.

Motion Sickness
Scopolamine (Transdermal)

Application: Characterization of motion sickness disorders.

Dosage: Scopolamine 1.0 mg over a period of 3 days.

Implementation: Evaluation of the response of motion sickness disorders to scopolamine. Subjects are exposed to a standardized slow-rotation-room test after 6 apparently identical treatments comprised of 4 placebos and 2 medications. Efficacy can be categorized as beneficial, inconsequential, or detrimental. None of the responses are detrimental. The difference in efficacy after 12 and 72 hours has practical and theoretical significance.

Interpretation and Analysis: In one clinical trial, the first administration of a scopolamine protocol, resulted in 4 beneficial responses after 12 hours, but no beneficial effect appreciated after 72 hours. Following the 2nd exposure regimen, there were 4 beneficial responses after 12 hours and 3 beneficial responses after 72 hours.

Great individual differences can be demonstrated in most test subject groups (e.g. n = 2 cases accounting for 6 beneficial responses; n = 2 cases accounting for only 1 beneficial response).

Multiple Sclerosis (MS)
Thyrotropin-Releasing Hormone (TRH) Stimulation/Bromocriptine/(Prolactin)

Cellular/Molecular Mechanism of Action: Thyrotropin-releasing hormone (TRH) promotes prolactin secretion in addition to the release of thyroid stimulating hormone (TSH).
Application: Multiple sclerosis cases reportedly display elevations in plasma prolactin concentrations.
Considerations: Before the onset and during experimental allergic encephalomyelitis (EAE; the animal counterpart of MS), the peripheral concentrations of prolactin can be found to be elevated and bromocriptine has been found to attenuate such attacks. Prolactin may play a role in the immunology of MS.
Implementation: Evaluation of prolactin levels in cases of multiple sclerosis as a diagnostic parameter.

Animal Model: Experimental allergic encephalomyelitis can be applied as a model for human MS.
Interpretation and Analysis: Multiple sclerosis cases have slightly but significantly higher prolactin levels at baseline (10.2 ± 1.6 vs 6.44 ± 0.57 ng/ml, p = 0.042) than do matched reference controls; however, values are within the normal range. Prolactin levels post-TRH are significantly higher in cases with MS with peak prolactin levels being higher than negative reference controls (57.08 ± 6.144 vs 32.94 ± 4.92 ng/ml, p = 0.006). The area under the curve of prolactin is also higher in cases than in controls (3421.87 ± 394.53 vs 2317.62 ± 257.22 ng/ml, p = 0.030).

Prolactin secretion is increased in cases with multiple sclerosis. Azar ST, Yamout B. Endocr Res 1999 May; 25 (2), pp. 207–14.

Multiple Sclerosis (MS)
Metoclopramide/Bromocriptine

Cellular/Molecular Mechanism of Action: Bromocriptine blunts elevations in prolactin while thyrotropin-releasing hormone (TRH) promotes the release of prolactin. Prolactin (PRL) belongs to the growth and lactogenic hormone family and has potent immunomodulating properties.
Background Information: Mild hyperprolactinemia has been found to enhance several autoimmune diseases, and increased PRL plasma levels have been described in natural and experimental models of MS models. The PRL antagonist bromocriptine suppresses the disease.
Application: Detection and characterization of cases suspected of suffering from MS.
Considerations: Prolactin concentrations are elevated in multiple sclerosis. Before the onset and during experimental allergic encephalomyelitis (EAE), the animal counterpart of MS, prolactin levels are elevated and bromocriptine attenuates the severity of attacks.
Implementation: Evaluation of the prolactin baseline values as a function of disease course and activity in a large population of MS cases. Furthermore, inhibitory (bromocriptine) and stimulatory (metoclopramide) tests are performed in a population subgroups to gain functional information.

Human Model: Cases suffering from MS (n = 132; n = 39/132 receiving alternating bromocriptine and metoclopramide).
Interpretation and Analysis: No correlation exists between baseline values and disease course or activity. Nevertheless, in the regression analysis of stimulatory test results, 14% of the variance is attributable to disease activity. In conclusion, PRL does not seem to be relevant as an activity marker in the whole MS population but may be relevant to certain MS subpopulations.

Prolactin stimulation in multiple sclerosis—An indicator of disease subtypes and activity? Heesen C, Gold SM, Bruhn M, Möxnch A, Schulz KH. Endocr Res 2002 Feb–May; 28 (1–2), pp. 9–18.

Multiple Sclerosis (MS)
Arginine Vasopressin (AVP)

Background Information: In the LEW/N rat model, a decreased hypothalamic-pituitary-adrenal (HPA) axis response to inflammatory and immune mediators confers susceptibility to the development of a variety of inflammatory and immune diseases, including experimental allergic encephalomyelitis. In humans with optic neuritis, early intervention with steroids is associated with a decrease in the number of cases who go on to develop MS.
Application: Multiple sclerosis cases demonstrate a blunted release of ACTH in response to AVP stimulation test.
Implementation: Evaluate the potential for MS conditions to show evidence of hypoactive HPA axis function before (baseline) and following provocative testing with the following: (i) ovine corticotrophin releasing hormone (CRH); (ii)] AVP; and (iii) ACTH stimulation. Results are then compared to negative reference controls.

Human Model: Cases of MS (n = 13).
Interpretation and Analysis: Compared to matched controls, MS cases have significantly higher plasma cortisol levels at baseline. Despite this hypercortisolism and in contrast to cases with depression that have similar elevations in plasma cortisol levels, cases with MS show normal, rather than blunted, plasma ACTH responses to ovine CRH, suggesting that the pathophysiology of hypercortisolism in MS is different than for depression. Cases with MS also show a blunted ACTH response to AVP stimulation and normal cortisol responses to high and low dose ACTH stimulation. Taken together, these findings are compatible with data from studies of experimental *in vivo* models exposed to chronic inflammatory stress, that show mild increased activation of the HPA axis with increased relative activity of AVP in the regulation of the pituitary-adrenal axis. These data do not support a role for hypocortisolism in MS once the disease is established.

Multiple sclerosis is associated with alterations in hypothalamic-pituitary-adrenal axis function. Michelson D, Stone L, Galliven E, Magiakou MA, Chrousos GP, Sternberg EM, Gold PW. J Clin Endocrinol Metab 1994 Sep; 79 (3), pp. 848–53.

Multiple Sclerosis (MS)/Inflammatory Medicator Profile (TNF-α; IL-2; IL-4; IL-6; IL-10; IgG)/Clinical Course and Severity
Azathioprine/Cyclosporin/Cyclophosphamide/ IFN-b 1a/Corticosteroids (CST)

Physiological Mechanism of Action: Azathioprine (AZA), cyclosporin, cyclophosphamide, interferon-beta 1a (IFN-β 1a) and/or corticosteroids (CST) each exert immunosuppressive properties through different individual mechanisms.
Implementation: Discover the relationship between various therapies and the clinical activity and course of MS on the *in vitro* production of (i) tumor necrosis factor-alpha (TNF-α); (ii) interleukin-2 (IL-2); (iii) IL-4; (iv) IL-6; (v) IL-10; and (vi) oligoclonal IgG (IgG OB). Experimental samples analyzed include whole blood stimulated with lipopolysaccharide or concanavalin A.

Human Model: Cases of relapsing-remitting, relapsing-progressive, or chronic progressive MS (n = 61) receiving no therapy, AZA, cyclosporin, cyclophosphamide, subcutaneous IFN-β 1a, and/or CST.

Interpretation and Analysis: The cinetics of cytokine y production show that (i) in the absence of treatment, TNF-α and IL-6 production drops after and during the periods surrounding relapse, while IL-4 is increasing before and IL-10 after relapse; (ii) with AZA, levels of TNF-α and IL-6 decrease before exacerbation, IL-4 is produced at high levels for prolonged periods before, while IL-10 is produced at high levels after relapse episodes; and (iii) along with IFN-β 1a, IL-10 is already increasing before relapse, and TNF-α is higher after relapse. When cytokine levels are analyzed independently from MS clinical activity, the use of AZA inhibits IgG OB and TNF-α synthesis ($p = 0.002$) but increases IL-4 ($p = 0.0024$), whereas IFN-β 1a stimulates TNF-α and inhibits IgG OB and inhibits IL-4 production. CST inhibits TNF-α, IL-6, IL-4, and IgG OB synthesis. Such findings illustrate the potential relevance of cytokine profiling in MS conditions.

In vitro cytokine profiles as indicators of relapse activity and clinical course in multiple sclerosis. Schluep M, van Melle G, Henry H, Städler C, Roth-Wicky B, Magistretti PJ. Mult Scler 1998 Jun; 4 (3), pp. 198–202.

Narcolepsy
Imipramine/Methylphenidate/[Food Intake]

Cellular/Molecular Mechanism of Action: Imipramine is classified as a tertiary amine.

Background Information: Narcolepsy afflicts more than 200,000 Americans. In most cases the 1st symptom of the disease, excessive daytime sleepiness, develops during childhood or adolescence. This initial presentation is followed by cataplexy or other auxiliary symptoms several years later. Not infrequently, many years pass before the proper diagnosis of narcolepsy is made. Narcolepsy is a chronic lifelong disease without periods of remission. Excessive daytime sleepiness, inappropriate sleep attacks, and the pathognomonic symptom of cataplexy are diagnostic of narcolepsy.

Diagnostic Application: Applied in the diagnosis and therapy of narcolepsy conditions. Response to imipramine and methylphenidate could potentially be used to differentiate narcolepsy from other neurologic/behavioral abnormalities.

Considerations (Equine Pharmacokinetics): In horses (e.g., n = 5 narcoleptics) pharmacokinetic profile studies can be performed by collecting blood samples before (time 0) and 3, 5, 10, 15, 20, 30, and 45 minutes and 1, 2, 3, 4, 6, 8, 12, and 24 hours after IV administration of imipramine hydrochloride (2 or 4 mg/kg of body weight). Imipramine concentrations are analyzed by HPLC for the estimation of serum concentration as a function of time.

Implementation: Evaluation of narcoleptic conditions based on diminished clinical signs in response to imipramine.

Interpretation and Analysis: Confirmation of the disease is made by performing a multiple sleep latency test. Although still not being used for diagnostic purposes, the association between narcolepsy and the human leukocyte group A (HLA) antigen DR2 is the strongest so far described for any disease. With the help of psychosocial support, therapeutic naps, and medications, cases with narcolepsy may be able to lead a normal life. Methylphenidate and imipramine are the 2 most widely used drugs for the treatment of daytime somnolence and cataplexy, respectively.

Administration of imipramine to normal individuals results in unsteady gait, clumsiness, tiredness or sleepiness, lightheadedness, quiet behavior, and drop in blood pressure. Such sequela are often accompanied by signs of blurry vision due to a decrease in the size of pupils, and a dry mouth (anticholinergic-like activity). In humans, individuals feel unhappy and experience an increased level of anxiety.

In horses, potentially serious adverse effects may be seen with doses of imipramine exceeding 2 mg/kg. Total body clearance of imipramine in horses is slower than that in humans; thus, the interval between subsequent doses should be longer in horses. Adverse effects (muscle fasciculations, tachycardia, hyperresponsiveness to sound, and hemolysis) are detected in most horses when serum imipramine concentrations are high, and these effects are most severe in horses receiving 4 mg of imipramine/kg. Residual adverse effects are usually not apparent. Values (mean ± SD) for area under the curve estimates are 3.9 ± 0.7 hours × μg/ml, while the volume of distribution is 584 ± 161.7 ml/kg, total body clearance is 522 ± 102 ml/kg/hour, and mean residence time is 1.8 ± 0.6 hours. Some horses may have signs of narcolepsy 6 and 12 hours after imipramine administration; and corrresponding serum imipramine concentrations are in such instances below the accepted therapeutic range.

Neoplasia/Ophthalmic Artery Dependent Vision/Preoperative Risk Evaluation Prior to Selective Ophthalmic Artery Embolization/[Arteriovenous Malformations of the Orbit/Dural Arteriovenous Fistulae]/[Orbital Meningiomas/Planum Sphenoidale Meningioma/Juvenile Nasal Angiofibroma]
Lidocaine/Amytal

Background Information: A number of anteriorly located cranial base and extracranial lesions receive their vascular supply wholly or in part from the ophthalmic artery, and embolization of the ophthalmic artery can be helpful in the management of these lesions, either as the primary treatment or as an adjunct to surgery.

Application: Determination of the dependency of visual function on patency of the ophthalmic artery.

Route of Administration: Lidocaine/amytal (intra-arterial catheterization).

Implementation: Evaluation of the degree visual function is impared by local delivery of anesthetic agents into branches of the ophthalmic artery that supply intra-occular and extra-occular lesions. Such preliminary examinations can be used to predict to what extent

visual sight will be affected if selective embolization therapy is implemented for partial or total resolution of lesions. In this context, lidocaine and amytal can be used as a provocative test prior to embolization procedures to assess the role of the ophthalmic artery in vision. In each case, a Tracker No. 18 microcatheter (Target Therapeutics, Inc. Fremont, CA) is navigated into the ophthalmic artery using a steerable guidewire and digital road mapping. Embolic agents include polyvinyl alcohol particles ranging from 350 to 1500 μm in diameter, 2 mm platinum microcoils, and n-butyl-cyanoacrylate. Examples of clinical conditions that can benefit from lidocaine/amytal diagnostic procedures include (i) arteriovenous malformations of the orbit; (ii) dural arteriovenous fistulae; (iii) orbital meningiomas; (iv) planum sphenoidale meningioma; and (v) juvenile nasal angiofibroma.

Interpretation and Analysis: In conditions where provocative testing with lidocaine and amytal indicate that the ophthalmic artery has a substantial effect on vision, then embolization procedures are not performed. Applying this protocol, proper case selection, judicious use of embolic agents, and use of provocative testing agents can result in safe embolization of lesions supplied by the ophthalmic artery.

Embolization of neurosurgical lesions involving the ophthalmic artery. Lefkowitz M, Giannotta SL, Hieshima G, Higashida R, Halbach V, Dowd C, Teitelbaum GP. Neurosurgery 1998 Dec; 43 (6), pp. 1298–303.

Neurotransmitter Dynamics/Relative Cerebral Blood Flow/Epilepsy/Drug Abuse/Schizophrenia/ Neurodegeneration

Superparamagnetic Iron Oxide/Amphetamine/Cocaine Analog 2β-Carbomethoxy-3-β-(4-Fluorophenyl) Tropane

Background Information: The use of functional magnetic resonance imaging (fMRI) techniques for evaluation of pharmacologic stimuli has great potential for understanding neurotransmitter dynamics for a number of brain disorders, such as drug abuse, schizophrenia, epilepsy, or neurodegeneration. Unfortunately, blood oxygenation level-dependent (BOLD) imaging at common fields strengths, such as 1.5 or 3 T, has very low sensitivity and contrast-to-noise ratios (CNRs).

Application: Detection and characterization of alterations in neurotransmitter dynamics and relative cerebral blood flow related to various conditions affecting the central nervous system including drug abuse, schizophrenia, epilepsy, and neurodegeneration.

Route of Administration: Intravascular.

Implementation: Evaluation of the ability for intravascular superparamagnetic iron oxide contrast agent with a long plasma half-life to detect hemodynamic changes related to dopaminergic stimuli using amphetamine or the cocaine analog 2β-carbomethoxy-3β-(4-fluorophenyl)tropane (CFT) as provocative diagnostic agents. The technique is sometimes referred to as increased relaxation with iron oxide nanoparticles (IRON).

Interpretation and Analysis: Results indicate that even at field strengths as high as 4.7 T, it is possible to obtain increases in CNR by factors of 2 to 3 over BOLD imaging. Benefits include greater than an order of magnitude increase in statistical power with greatly increased sensitivity to hemodynamic changes in brain regions difficult to observe using BOLD imaging. Furthermore, use of the intravascular contrast agent allows for a meaningful physiologic parameter to be measured (relative cerebral blood volume [rCBV]), compared to conventional BOLD imaging.

Improved mapping of pharmacologically induced neuronal activation using the IRON technique with superparamagnetic blood pool agents. Chen YC, Mandeville JB, Nguyen TV, Talele A, Cavagna F, Jenkins BG. J Magn Reson Imaging 2001 Nov; 14 (5), pp. 517–24.

Opioid Receptors/Delta-OR Receptors/Mu-Opioid Receptors

Fluo-Deltorphin/d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2/Fentanyl Citrate

Cellular/Molecular Mechanism of Action: Fluo-deltorphin is a fluorescent compound that physically binds to delta opioid receptors in a highly selective manner. Similarly, d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 selectively binds to mu-opioid receptor complexes. Fentanyl citrate also binds to mu receptors.

Physiological Mechanism of Action: Fluo-deltorphin is a highly selective delta opioid receptor agonist. d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 is a selective mu-opioid receptor antagonist, while fentanyl citrate alternatively functions as a mu receptor agonist.

Background Information: Opioid receptors are known to undergo complex regulatory changes in response to ligand exposure.

Application: Examine the effect of morphine on the *in vitro* and *in vivo* density and trafficking of delta opioid receptors (deltaORs).

Route of Administration: Intravascular (traditionally).

Implementation: Prolonged exposure of cortical neurons in culture to morphine (10 μm) for a period of 48-hours with and without the presence of d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 or fentanyl citrate. Alterations in the expression density of membrane associated deltaORs can be detected applying immunogold electron microscopy.

Interpretation and Analysis: Prolonged exposure of cortical neurons to morphine results in a profound increase in the internalization of fluo-deltorphin. Such an effect is mu-mediated because it is entirely blocked by d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 and is reproduced using the selective mu agonist fentanyl citrate. Based on results from immunogold electron microscopy analysis, marked increases in the expression density of surface membrane-associated deltaORs occur in neurons exposed to morphine and indicates that increases in fluo-deltorphin internalization are caused by elevations in receptor availability. Prolonged morphine exposure has no effect on delta opioid receptor complex levels, as assessed by immunocytochemistry and Western blot analysis, suggesting that the increase in bioavailable delta opioid receptors is caused by recruitment of reserve receptors from intracellular stores and not from receptor neosynthesis. Chronic treatment of adult rats with morphine (5–15 mg/kg, s.c. every 12 hours) similarly augments targeting of delta opioid receptors to neuronal plasma membranes in the dorsal horn of the spinal cord. Such exposure markedly potentiates intrathecal d-[Ala_2]deltorphin II-induced antinociception. Therefore, prolonged *in vitro* and *in vivo* stimulation of neurons with morphine markedly increases recruitment of intracellular delta opioid receptors to the cell membrane surface. Receptor subtype cross-mobilization of this type may widen the transduction repertoire of G-protein-coupled receptors and offer insight into the development of new diagnostic and therapeutic strategies.

Prolonged morphine treatment targets delta opioid receptors to neuronal plasma membranes and enhances delta-mediated antinociception. Cahill CM, Morinville A, Lee MC, Vincent JP, Collier B, Beaudet A. J Neurosci 2001 Oct 1; 21 (19), pp. 7598–607.

Opioid Tolerance/Mu-Opioid Tolerance and Receptor Down Regulation
$G_i\alpha 2$ Protein Antisense Oligodeoxynucleotide/ Etorphine/Morphine

Application: Characterization of morphine tolerance phenomenon.
Route of Administration: Etorphine or morphine administered by continuous subcutaneous (SC) infusion. Antisense oligonucleotides (intracerebroventricularly and spinal intrathecal space).
Dosage: Etorphine (200 μg/kg/day) or morphine (40 mg/kg/day + 25 mg pellet). Antisense oligonucleotides (30 μg/site/day) for 4 to 5 consecutive days.
Considerations: Although opioid receptors are G-protein coupled, the role that specific G-protein subunits play in the development of opioid tolerance and the regulation of opioid receptor number is not well understood.
Implementation: Evaluation of the influence of antisense ODN or a mismatch ODN directed at mRNA encoding for the $G_i\alpha 2$ subunit of G-proteins (controls = dH_2O). On day 2 of ODN treatment, etorphine (200 μg/kg/day) or morphine (40 mg/kg/day + 25 mg pellet) is administered by continuous subcutaneous (SC) infusion. On day 5 (72 hours later), pumps and pellets are removed and mouse whole brains are tested for morphine analgesia or mu-opioid receptor density. Reference controls initially receive injections of dH_2O and are implanted with inert placebo pellets.
Animal Model: Murine.
Interpretation and Analysis: Etorphine produces significant tolerance (ED_{50} shift = approximately 11-fold) and downregulates mu-opioid receptors (approximately 25%). Morphine produces significant tolerance (ED_{50} shift approximately 9-fold), but no mu-opioid receptor downregulation. Antisense treatment reduces $G_i\alpha 2$ protein levels in striatum and spinal cord by approximately 25%. $G_i\alpha 2$ antisense reduces the acute potency of morphine. $G_i\alpha 2$ antisense blocks the development of tolerance to morphine treatment and reduces the development of tolerance to etorphine treatment. Antisense does not have any effect on etorphine-induced mu-opioid receptor downregulation. In other investigations, 7-day treatment with morphine or etorphine similarly increases $G_i\alpha 2$ mRNA and protein abundance within spinal cord tissues. Such findings support the concept that $G_i\alpha 2$-protein has an important role in the acute effects of opioids and opioid tolerance. However, $G_i\alpha 2$ is not required for agonist-induced mu-opioid receptor density regulation *in vivo*.

Role of G(i)α2-protein in opioid tolerance and mu-opioid receptor downregulation *in vivo*. Yoburn BC, Gomes BA, Rajashekara V, Patel C, Patel M. Synapse 2003 Feb; 47 (2), pp. 109–16.

Organophosphate Intoxication
Atropine

Cellular/Molecular Mechanism of Action: Parasympatholytic activity mediated through blockade of muscarinic receptor sites.
Diagnostic Application: (i) Systemic and topical occular application as a means of non-specifically detecting cases suffering from organophosphate (OP) intoxication. (ii) Reverses or prevents narcoleptic episodes.
Considerations: Atropine can promote gastrointestinal ileus and possible luminal obstruction. Due to its molecular form, it is capable of traversing the blood-brain barrier.
Interpretation and Analysis: Alleviation of abnormal signs associated with organophosphate intoxication (specific and non-specific).

CNS involvement in acute organophosphate poisoning: Specific pattern of toxicity, clinical correlates and antidotal treatment. Finkelstein Y, Taitelman U, Biegon A. Ital J Neurol Sci 1988 Oct; 9 (5), pp. 437–46.

Parkinson's Disease (PD): Dopamine Transporter (DAT)/Attention Deficit Hyperactivity Disorder (ADHD)
Fluoratec/[^{99m}Tc]-Based Tropane Ligand

Cellular/Molecular Mechanism of Action: The DAT, is located presynaptically on dopaminergic neurons and is involved in the trans-membrane transport of dopamine.
Background Information: In ADHD, DAT density levels are elevated, while in PD these levels are depleted. The depletion of DAT levels also corresponds with the loss of dopamine. An additional feature of PD is a depletion of dopaminergic neurons within the substantia nigra accompanied by fibrillar Lewy bodies comprised primarily of alpha-synuclein.
Application: Characterization of the density of dopamine transporter complex expression within the central nervous system. Dopamine transporters are located presynaptically on dopamine neurons and can conceptually function as a biological marker for PD and ADHD.
Semi-Synthetic Methods: Design and synthesize a 2nd-generation [^{99m}technetium]-based tropane ligand [e.g. N-[(2-((3′-N′-propyl-(1′′R)-3′′alpha-(4-fluorophenyl)tropane-2′′beta-1-propanoyl)(2-mercaptoethyl)amino)acetyl)-2-aminoethanethiolato]technetium(V) oxide].
Implementation: Evaluation of the biology and SPECT imaging potential of [^{99m}technetium]-based tropane ligands based on their potent and selective binding to DATs.
Animal Model: Non-human primates.
Interpretation and Analysis: [^{99m}Technetium]-based tropane ligands possess improved selectivity and biological stability representing qualities that facilitate sufficient entry of the agent into the brain and label dopamine transporter complexes in a manner that can provide a quantitative measure of DAT densities (non-human primates). The agent N-[(2-((3′-N′-propyl-(1′′R)-3′′alpha-(4-fluorophenyl)tropane-2′′beta-1-propanoyl)(2-mercaptoethyl)amino) acetyl)-2-aminoethanethiolato]technetium(V) oxide, also known as FLUORATEC, functions as a DAT imaging agent that is a representative [^{99m}technetium]-based tropane ligand.

A second-generation 99m technetium single photon emission computed tomography agent that provides *in vivo* images of the dopamine transporter in primate brain. Meltzer PC, Blundell P, Zona T, Yang L, Huang H, Bonab AA, Livni E, Fischman A, Madras BK. J Med Chem 2003 Jul 31; 46 (16), pp. 3483–96.

Parkinson's Disease (PD): Dopamine Transporter (DAT)
3,6-Disubstituted Piperidine Derivatives

Application: The 3,6-disubstituted piperidine derivatives can function as novel templates for high-affinity inhibitors of the dopamine transporter molecule. Ultimately, the compounds could feasibly be utilized to characterize the distribution and expression density of dopamine transporter complexes.

Synthetic Methodologies: Applying the concepts of structure-activity relationships (SAR), a novel conformationally constrained lead *cis*-3,6-disubstituted piperidine derivative derived from (2,2-diphenylethyl)-[1-(4-fluorobenzyl)piperidine-4-ylmethyl]amine (I) can facilitate the design of a series of compounds synthesized by derivatizing the exocyclic N-atom at the 3-position of the lead compound. Related substituted phenyl and heterocyclic derivatives have been produced and evaluated for their affinity for DAT, serotonin transporter (SERT), and norepinephrine transporter (NET) in the brain by measuring their potency by assessing their ability to compete for the binding of [^{3}H]-WIN 35 428, [^{3}H]-citalopram, and [^{3}H]-nisoxetine, respectively. Analogous compounds have also been evaluated for their activity in inhibiting the uptake of [^{3}H]DA. The SAR results demonstrate that the nature of substitutions on the phenyl ring is important for evoking activity at the DAT with the presence of an electron-withdrawing group having the maximum effect on potency. Replacement of the phenyl ring in the benzyl group by heterocyclic moieties results in the development of compounds with moderate activity for the DAT. The 2 most potent racemic compounds can be separated by a diastereoisomeric separation procedure, and differential affinities can be observed for the enantiomers. Absolute configuration of the enantiomers can be obtained unambiguously by x-ray crystal structural study. One of the enantiomers, compound S,S-(-)-19a, exhibits the highest potency for the DAT (IC_{50} = 11.3 nM) among all the compounds tested and is as potent as GBR 12909 (1-[2-[bis(4-fluorophenyl)methoxy]ethyl]-4-(3-phenylpropyl)piperazine). However, the compound (-)-19a is more selective than GBR 12909 in binding to the DAT compared with binding to the SERT and NET.

Interpretation and Analysis: The newly developed 3,6-disubstituted piperidine derivatives are novel templates for high-affinity inhibitors of DAT. Structurally, these molecules are more constrained compared to earlier flexible piperidine molecules and, thus, should provide greater insight into their bioactive conformations.

Interaction of cis-(6-benzhydrylpiperidin-3-yl)benzylamine analogues with monoamine transporters: structure-activity relationship study of structurally constrained 3,6-disubstituted piperidine analogues of (2,2-diphenylethyl)-[1-(4-fluorobenzyl)piperidin-4-ylmethyl]amine. Kolhatkar RB, Ghorai SK, George C, Reith ME, Dutta AK. J Med Chem 2003 May 22; 46 (11), pp. 2205–15.

Parkinson's Disease (PD): Early vs Late Onset
Bromocriptine/Thyrotropin-Releasing Hormone (TRH)

Route of Administration: Thyrotropin-releasing hormone (intravascular) following bromocriptine pretreatment.

Implementation: Evalution of early-onset and late-onset conditions of Parkinson's disease as a function of basal plasma prolactin (PRL) concentrations in response to and their changes after TRH administration following bromocriptine (BCT) pretreatment (BCT/TRH test).

Human Model: Cases with early- and late-onset Parkinson's disease (n = 12 cases with young-onset < 40 years of age; and n = 10 cases with late-onset PD at > 40 years of age; compared to n = 10 healthy age-matched reference controls.

Interpretation and Analysis: Basal PRL levels are normal in both groups of cases. However, following BCT/TRH, significantly lower prolactin increases are induced in older-onset parkinsonians than in controls. Such a response becomes even more blunted in young-onset cases, being significantly more attenuated than in older-onset PD cases.

Function of dopamine receptors in young-onset Parkinson's disease: Prolactin response. Kostic VS, Marinkovic Z, Filipovic S, Momcilovic D. Mov Disord 1993 Apr; 8 (2), pp. 227–9.

Parkinson's Disease: Idiopathic/Type Differentiation of Parkinson's Disease/Parkinsonian Multiple System Atrophy/Parkinsonian Multiple Systemic Atrophy: Cerebellar
Clonidine/[GHRH-Arg]/L-dopa

Cellular/Molecular Mechanism of Action: Clonidine is a centrally active alpha 2-adrenoceptor agonist.

Physiological Mechanism of Action: Clonidine is a centrally active alpha 2-adrenoceptor agonist that raises concentrations of GH in serum.

Background Information: Idiopathic PD is a common neurodegenerative disease that is difficult to distinguish from other parkinsonian syndromes such as multiple-system atrophy (MSA). In MSA, autonomic dysfunction is common and is associated with either parkinsonian or cerebellar features, or both. Differentiation of idiopathic PD from MSA is important because prognosis, complications, and response to therapy vary according to disorder.

Diagnostic Application: Clonidine can be used to diagnostically differentiate between MSA and idiopathic PD.

Implementation: Evaluate the various conditions of Parkinson's disease as a function of growth hormone secretion in response to clonidine challenge.

Human Model: Cases of PD with clonidine administered to n = 14 idiopathic Parkinson's disease without autonomic deficits; in addition to n = 31 cases with MSA comprised of 3 different clinical forms [e.g. parkinsonian, cerebellar, and mixed]; n = 19 cases with pure autonomic failure; and n = 27 healthy participants. In a subgroup, n = 9 cases of parkinsonian MSA (MSA-P) are assessed for GH response to levodopa challenge.

Interpretation and Analysis: Clonidine raises serum GH concentrations in cases with idiopathic PD (median increase 8.98 [IQR 6.6–6.6] mU/L), normal participants (13.2 [7.0–18.6] mU/L), and cases with pure autonomic failure (12.5 [5.6–18.2] mU/L). In those with MSA that have central autonomic failure, GH concentrations remain unchanged (MSA-P; 0.41 [−0.30–2.09] mU/L and cerebellar MSA [MSA-C] 1.67 [0–4.49] mU/L). The GH response to clonidine in idiopathic Parkinson's disease is significantly different from that in MSA-P ($p < 0.0002$). In MSA-P, the dopamine precursor levodopa raises GH concentrations (from mean 2.7 [SE 1.0] mU/L to a mean of 18.2 [6.0] mU/L, $p < 0.05$) and GH-releasing hormone (GHRH) concentrations (from mean 20.6 [3.25] ng/L to a mean 68.0 [10.6] ng/L, $p < 0.05$), excluding dysfunction of pituitary somatotrophs or GHRH neurons as a cause for the absent GH response to clonidine in MSA.

Clonidine raises concentrations of GH in serum in healthy people and those with pure autonomic failure (with peripheral lesions), but not in Parkinson's cases with MSA (MSA with a central autonomic deficit). The GH responses to clonidine can clearly differentiate idiopathic PD from MSA-C and MSA-P. Together with the levodopa studies they indicated a specific alpha 2-adrenoceptor-hypothalamic deficit in MSA. The clonidine-GH test may provide further insight into central neurotransmitter and alpha 2-adrenoceptor-hypothalamic abnormalities in MSA.

Distinction of idiopathic Parkinson's disease from multiple-system atrophy by stimulation of growth-hormone release with clonidine. Kimber JR, Watson L, Mathias CJ. Lancet 1997 Jun 28; 349 (9069), pp. 1877–81.

Parkinson's Disease (PD)/Prediction of Sustained Long-Term L-dopa Responsiveness/Major Diagnostic Criteria
Levodopa (L-dopa)

Background Information: Establishing a diagnosis of clinical idiopathic PD requires following strict criteria. Final definitive diagnosis can only be made after pathological confirmation and, despite following clinical criteria, several cases can be misdiagnosed.
Application: Evaluation of the sensitivity and specificity of acute levodopa (L-dopa) challenge to predict sustained long-term L-dopa responsiveness as a major criterion for clinical diagnosis of PD.
Dosage: L-dopa-carbidopa (250/50 mg).
Implementation: Evaluation of the sensitivity and specificity of acute challenge with L-dopa to predict sustained long-term L-dopa responsiveness as a major criterion for clinical diagnosis of PD. Provocative testing involves acute challenge with L-dopa-carbidopa and results rated as positive or negative according to whether values reached a minimal 30% of improvement on UPDRS scores. Positive tests are considered supportive of a presumptive clinical diagnosis of Parkinson's disease. Blind to test results and according to clinical presumption, an examinter/evaluator initiates treatment with the necessary L-dopa dose or, alternatively, until reaching 1 g for 1 month in those who failed to display a positive test response. At 24-month follow-up, they are retested with 1 g for 1 month when required. At this point, clinical criteria of the U.K. Parkinson's Disease Society Brain Bank are applied and definitive clinical diagnosis of PD determined. Sensitivity, specificity, and positive predictive ratio for acute challenge are calculated.

Human Model: Cases of PD (n = 82) first evaluated at a movement disorders clinic. A second examiner, blind to the presumptive diagnosis, performs the prescribed provocative tests.
Interpretation and Analysis: Overall sensitivity and specificity of acute L-dopa challenge to predict a clinical diagnosis of PD is approximately 70.9% and 81.4%, respectively; positive predictive ratio is close to 88.6%. When cases are divided into 3 groups according to their UPDRS motor section score at initial examination, sensitivity and specificity vary: Group I ($\leq$ 10), 71.4% and 100%; Group II (11–20), 75% and 75%; and Group III ($\geq$ 21), 36.4% and 87%, respectively. Positive predictive ratios increase to 100% in Group I and to 87.5% in Group III. The positive result of initial acute L-dopa challenge predicts chronic L-dopa responsiveness as a major criterion of PD in all cases with UPDRS motor scores lower than 10.

Accuracy of acute levodopa challenge for clinical prediction of sustained long-term levodopa response as a major criterion for idiopathic Parkinson's disease diagnosis. Merello M, Nouzeilles MI, Arce GP, Leiguarda R. Mov Disord 2002 Jul; 17 (4), pp. 795–8.

Pharmaceutical Elimination (Brain): Suppression/(Capillary Endothelial rOat3 Organic Anion Transporter)
para-Aminohippuric Acid/Cimetadine/Pravastatin/Benzylpenicillin

Cellular/Molecular Mechanism of Action: Para-aminohippuric acid (PAH) and benzylpenicillin (PCG) are substrate competitive inhibitors of organic anion transporter 3 (rOAT3) complexes expressed by brain capillary endothelium. Cimetidine (H_2 histamine blocker) and pravastatin are also substrate competitive inhibitors of organic anion transporter 3 (rat rOat3).

Physiological Mechanism of Action: Para-aminohippuric acid and PCG can serve as tracer molecules to evaluate central nervous system elimination mechanisms (efflux transport) involving rOat3 organic anion transporter molecules expressed by brain capillary endothelium. In contrast, cimetidine and pravastatin delay the elimination of diagnostic pharmaceutical agents across the blood-brain barrier.
Background Information: Based on RT-PCR analysis, the organic anion transporter complexes rOat1 and rOat2 do not appear to be expressed in the brain capillary endothelial cells (BCEC) in contrast to rOat3 (moderate expression levels). The expression of rOat3 in the BCEC can be further confirmed by Western blot analysis and immunohistochemical staining reveals that rOat3 is located on the abluminal and, possibly, luminal membrane of the BCEC.
Application: Potential uses of pharmaceutical agents like cimetadine, *para*-aminohippuric acid (PAH), pravastatin, benzylpenicillin (PCG) include prolongation of the exposure of diagnostic pharmaceuticals to specific function targets or lesions within the central nervous sytem.
Interpretation and Analysis: As a reference model, the rOat3 substrates PAH and PCG can be used to evalate the functionality of this organic anion transporter protein. Applying these pharmaceutical marker systems, the Brain Efflux Index method can be used to determine the extent and time course of PAH and PCG elimination from the cerebrum and into the peripheral intravascular compartment. In this context, PAH and PCG are eliminated from the cerebrum with rate constants of 0.039 and 0.043/min, respectively, and the elimination processes become saturated at high substrate concentrations. Taking account of the dilution effect within the brain, the K_m values for the elimination of PAH and PCG is estimated to be 168 and 29 μM, respectively. Efflux of PAH and PCG across the BBB is inhibited in a dose-dependent manner by unlabeled PCG and PAH, respectively. The K_i value of PAH for the efflux of PCG is 106 μM and that of PCG for the efflux of PAH is 58 μM. These values are comparable with their K_m values, suggesting that they share the same efflux mechanism at the blood-brain barrier. Furthermore, cimetidine and pravastatin, which are also substrate competitive inhibitors of rOat3, significantly inhibited the efflux of PAH and PCG from the cerebrum. These results suggest that rOat3 is responsible for the elimination of PAH and PCG from the brain across the BBB.

Contribution of organic anion transporter 3 (Slc22a8) to the elimination of p-aminohippuric acid and benzylpenicillin across the blood-brain barrier. Kikuchi R, Kusuhara H, Sugiyama D, Sugiyama Y. J Pharmacol Exp Ther 2003 Jul; 306 (1), pp. 51–8. Epub 2003 Apr 8.

Polioencephalomalacia: Cerebral Cortical Dysfunction
Thiamine

Physiological Mechanism of Action: Certain strains of rumenal bacterial can produce thiaminase, thereby diminishing systemic and central nervous system concentrations of thiamine.
Background Information: Polioencephalomalacia (PEM) induced in sheep has been compared with the disease found in naturally occurring cases. Blood biochemical indicators include pyruvate, lactate, glucose, erythrocyte transketolase (TK), and stimulation of TK by addition of thiamine pyrophosphate (TPP effect). Feces and rumen contents can be assayed for thiaminase activity. The effect of treating affected sheep with thiamine is also noted. Amprolium treatment can induce thrombocytopenia, but once sheep become accustomed to amprolium in the diet they seem to be resistant to this

effect. In sheep receiving amprolium significant weight loss can serve as a variable that consistently precedes the onset of clinical signs. Further weight loss continues throughout the recovery period despite removal of amprolium from the diet and treatment with thiamine. Blood glucose levels are variable, and elevated only when marked clinical signs are present. Pyruvate and lactate levels show marked variation throughout trials. TK values are depressed and TPP effects increase well before the onset of clinical signs, although some naturally occurring cases have normal levels. Fecal thiaminase activity is negligible in all sheep on amprolium but most field cases have a high level. High fecal thiaminase is observed in about 5% of clinically normal animals from affected flocks. Depression of erythrocyte TK activity coupled with the presence of fecal thiaminase appears to be the most reliable diagnostic biochemical parameter for PEM.

Implementation: Detection of neurologic cases of PEM based on response to thiamine administration.

Interpretation and Analysis: Administration of thiamine to PEM affected sheep rapidly brings the biochemical status of animals back to normal. However, in conditions of advanced brain lesions and when the damage is permanent, such sheep treated with thiamine remain partially decorticate.

Schematic Description: Decreased RBC TK → thiamine → rapid correction of decreased RBC TK in PEM.

Biochemistry of natural and amprolium-induced polioencephalomalacia in sheep. Spicer EM, Horton BJ. Aust Vet J 1981 May; 57 (5), pp. 230–5.

Seizures: Alcoholic Detoxification/Recurrent Episodes
Chlordiazepoxide/Pharmaco-Electroencephalography

Application: Delineation of recurrent alcoholic detoxification seizures.

Route of Administration: Per os (oral) during detoxification events (associated with the elimination of withdrawal seizures).

Implementation: Evaluation of the potential increased risk of seizure activity during conditions of recurrent alcohol detoxifications. Structural brain damage, focal neurologic deficits, epileptogenic findings on electroencephalograms, and provocative drug use are considered pertinent variables for seizure risk.

Human Model: Review of detoxification and seizure histories (n = 256 men; n = 45 women voluntarily admitted to a 5-day inpatient detoxification program).

Interpretation and Analysis: Administration of chlordiazepoxide is usually associated with the elimination of withdrawal seizures. Some cases have a history of seizures (e.g., n = 64/301) while others have significantly abnormal electroencephalograms during detoxification (e.g., n = 42/301), or have focal slowing on the electroencephalogram (e.g., n = 30/301). No correlation exists between the duration of alcohol abuse or lifetime consumption of alcohol and seizure activity. There is, however, a significant correlation between the number of inpatient alcohol detoxifications and the prevalence of seizure disorders. This correlation holds true even when provocative drug use is taken into consideration.

Seizure risk with recurrent alcohol detoxification. Lechtenberg R, Worner TM. Arch Neurol 1990 May; 47 (5), pp. 535–8.

Seizures: Central Nervous System Activity
Pentylenetetrazol/Pharmaco-Electroencephalography

Mechanisms of Action: Pentylenetetrazol diminishes the influence of GABA on chloride ion conductance at concentrations that do not alter resting neuronal membrane conductance in the absence of GABA. Additional attributes of pentylenetetrazol include inhibition of picrotoxin association with binding sites, and it has the ability to block the enhancement of GABA and benzodiazepine binding promoted by hypnotic barbiturates. No direct stimulatory effect has been associated with pentylenetetrazol.

Diagnostic Application: Primarily of value in facilitating the diagnostic induction of epileptic episodes for the purpose of acquiring EEG recordings.

Route of Administration: Pentylenetetrazol (subcutaneous).

Dosage: Pentylenetetrazol (PTZ seizure dose = 65 mg/kg).

Considerations: Pentylenetetrazol induces seizure activity through CNS stimulation. Because of the potential hazards that seizure episodes might precipitate, appropriate antiseizure medications should always be readily (immediately) available for administration as a safety precaution.

Implementation: Truly simultaneous electroencephalogram (EEG) and functional magnetic resonance imaging (fMRI) are recorded following the induction of convulsions with pentylenetetrazol. Rigorous control of physiological parameters like body temperature and ventilation with control of blood gasses help avoid potential interference between systemic parameters and central PTZ-induced blood oxygenation level-dependent (BOLD) changes.

Animal Model: Rat (curarized rats).

Interpretation and Analysis: In experimental *in vivo* models, simultaneous EEG/fMRI recordings demonstrate progressive epileptiform EEG discharges with concomitant BOLD changes, with the latter gradually affecting most of the fore- and midbrain. Approximately 15 minutes after PTZ injection, the 1st BOLD contrast changes mainly occur in the neocortex, and coincide with the 1st minor EEG alterations. Most regions that display BOLD changes are areas with reportedly high $GABA_A$ receptor densities. Full-blown epileptiform discharges occur on the EEG tracing, approximately 30 minutes after PTZ injection, and coincide with bilateral positive and/or negative BOLD contrast changes in cortical and subcortical regions. Behavioral observations demonstrate that the 1st of several generalized clonic or clonic-tonic seizure episodes occur also around this same time period. Approximately 90 minutes after injection, the electrographic paroxysms gradually decrease in amplitude and duration, whereas BOLD signal changes still extended with alternating positive and negative traces and spread to subcortical regions like caudate-putamen and globus pallidus.

In humans, the induction of an epileptic seizure or analogous episodes following administration constitutes a positive diagnosis that can be more fully characterized through analysis of EEG recordings.

Laboratory Instrumentation: Electroencephalogram recording.

Simultaneous electroencephalographic recording and functional magnetic resonance imaging during pentylenetetrazol-induced seizures in rat. Van Camp N, D'Hooge R, Verhoye M, Peeters RR, De Deyn PP, Van der Linden A. NeuroImage 2003 Jul; 19 (3), pp. 627–36.

Seizures: Hypoglycemic-Induced
Glucose/Glucagon

Cellular/Molecular Mechanism of Action: Carbohydrates (starches, monosaccharides, disaccharides, polysaccharides) are broken down to monosaccharides by pancreatic saccahridases secreted into the gastrointestinal track. Monosaccharides are then absorbed from the small intestine into the blood stream. Once in the blood stream, monosaccharides are "pumped" across cellular membranes

and either (i) enter the tricarboxylic acid (TCA) cycle, where they generate the production of ATP, GTP, and lactic acid; or (ii) are transformed into hepatic or muscle glycogen, which is a storage form (pool) of glucose available for cellular metabolism at a later date.

Diagnostic Applications: (i) Glucose Tolerance Test can be utilized to detect conditions of diabetes mellitus or prediabetic conditions. (ii) Glucose Absorption Test has been applied to identify conditions of gastrointestinal malabsorption. (iii) Glucose Suppression Test: can serve as an approach for depressing growth hormone (GH) in cases with (feline) acromegaly.

Route of Administration: (i) Glucose Tolerance Test: Oral administration at a specific dose; (ii) Glucose Absorption Test: oral administration of a specific dose; (iii) Glucose Suppression Test: Oral or intravenous administration.

Dosage: (i) Glucose Tolerance Test: 75 g or approximately 1 g/kg body weight; (ii) Glucose Absorption Test: 1 g/kg body weight; (iii) Glucose Suppression Test: 1 g/kg body weight.

Considerations: Glucose given orally can be degraded by normal bacterial flora residing within the gastrointestinal tract. In addition, glucose can inhibit gastrointestinal emptying at concentrations above 10%, and stimulate pancreatic insulin secretion. Each of these confounding variables can contribute to the development of false negative results.

Semi-Synthetic Methods: A glucagon radioimmunoassay can be employed using antiserum specific for pancreatic glucagon. In this context, glucagon can be radioiodinated utilizing the chloramine T technique and purified on QAE-Sephadex A 25 to a specific activity of approximately 225 μCi/μg. The standard curve generated allows measurements to be acquired from 12 to 500 pg/ml with a sensitivity of 17.5 pg/ml, and a precision level of 6.3 to 14.9% (CV, within-assay) and 5.6 to 10.7% (CV, between-assay). Recovery is between 82 and 112%.

Interpretation and Analysis: (i) Glucose Tolerance Test: Excessively high blood glucose concentrations may imply the presence of diabetes mellitus. An excessive glucose rebound phenomenon may also be appreciated, which is interpreted by some physicians as a prediabetic condition. (ii) Glucose Absorption Test: Serum (blood) glucose levels should at least double within 2 hours of oral administration. Fasting plasma glucagon levels in diabetics, obese subjects, acromegalics, and cases with Cushing's syndrome are greater than in normals (22.0 ± 91 pg/ml; mean ± SD). Very low glucagon levels can be appreciated after oral glucose suppression (15.2 ± 3.1 pg/ml) in normal cases, while greatly increased values are detected after arginine in insulin-dependent diabetics (271.0 ± 132.3 pg/ml).

Laboratory Instrumentation: Standard clinical pathology methods for analysis and measurement of glucose concentrations within serum and urine samples.

Seizures/Insecticides and Nerve Agents/(Tabun, Sarin, Soman, Cyclosarin, VR, VX)/Relative Vulnerability to Seisure Termination: Sarin and VX Compared to Soman, Cyclsarin and VR

Anticholinergics: Atropine, Birperiden, Pyridostigmine, 2-PAM, Trihexyphenidyl/Benzodiazepines: Diazepam, Midazolam

Application: Detection of seizure episodes induced by nerve agents including tabun, sarin, soman, cyclosarin, VR, and VX. Results can possibly function as adjunct information to high-performance liquid chromatography (HPLC) analysis in efforts to differentiate between exposures to different types of nerve agents.

Route of Administration: Pyridostigmine bromide (intramuscular); soman (subcutaneously); atropine SO_4 (intramuscular).

Dosage: Pyridostigmine bromide (0.026 mg/kg); atropine SO_4 is implemented (2 mg/kg); 2-PAM Cl (25 mg/kg).

Implementation: Evaluation of pyridostigmine bromide pretreatment 30 minutes prior to challenge with 2 × LD_{50} dose of a given nerve agent (SQ). Complementary evaluations include challenges with 5 × LD_{50} of soman. One minute after agent challenge, exposure to atropine SO_4 is implemented admixed with 2-PAM Cl. Five minutes after the start of EEG seizures, different doses of anticholinergics (IM) or benzodiazepines (IM) are administered and observations made to detect termination of seizure episodes. The time to seizure onset, the time to seizure termination, and 24-hour lethality are recorded. The anticonvulsant ED_{50} of each drug for termination of seizures induced by each agent is calculated and compared. Brain tissue from *in vivo* models that survive 24 hours is examined for pathology.

Animal Model: Guinea pigs (implanted with cortical electrodes for EEG recording).

Interpretation and Analysis: All drugs are capable of terminating seizure activity, with midazolam and trihexyphenidyl being significantly more potent than the other pharmaceutical agents, and midazolam being more rapid in controlling seizure than atropine, trihexyphenidyl, or diazepam against each agent. Seizures induced by sarin or VX require lower doses of all the test anticonvulsants. The dose of a given drug that is an effective anticonvulsant against a 2 × LD_{50} challenge of soman is equally effective against seizures induced by a 5 × LD_{50} challenge. All of the nerve agents (tabun, sarin, soman, cyclosarin, VR, VX) are capable of producing neuropathology. Seizure control is strongly associated with protection against acute lethality and brain pathology.

Control of nerve agent-induced seizures is critical for neuroprotection and survival. Shih TM, Duniho SM, McDonough JH. Toxicol Appl Pharmacol 2003 Apr 15; 188 (2), pp. 69–80.

Seizures/Intractable (Medical): Surgical Intervention/Essential Tremors/Cerebral Resuscitation/Seisures: Partial, Complex Partial, and Secondary General

Amobarbital/Methohexital/Phenobarbital

Cellular/Molecular Mechanism of Action: The primary mechanism of action of barbiturates is to increase inhibition mediated through the gamma-aminobutyric acid (GABA) system. Anesthetic barbiturates also decrease excitation via a decrease in calcium conductance.

Application: Barbiturates have been used as adjunct injectable general anesthetics and as anticonvulsant agents. In this context, barbiturates have been used in the evaluation of medically intractable seizure disorders that may possibly be managed through surgical intervention. Barbiturates to a limited degree have also been applied in an experimental fashion, most notably related to characterization of cerebral resuscitation techniques.

Interpretation and Analysis: Phenobarbital (phenobarbitone), the primary anticonvulsant barbiturate, is effective for partial, complex partial, and secondarily generalized seizures. While no longer the drug of choice for all types of seizures, it remains an important and useful agent. Mysoline has been shown to be useful in the treatment of essential tremor and several other movement disorders and as an anticonvulsant. Barbiturates are also used for their sedative-hypnotic properties. Preparations of methohexital and amobarbital (amylobarbitone) are examples of barbiturates that have potential as diagnostic agents for certain seizure disorders.

The clinical use of barbiturates in neurological disorders. Smith MC, Riskin BJ. Drugs 1991 Sep; 42 (3), pp. 365–78.

Seizures: Neonatal/Prediction of Seizure Burden/Prediction of Treatment Regiment Efficacy
Phenobarbitone/Phenytoin/Lignocaine (Lidocaine)/Pharmaco-Electroencephalography

Cellular/Molecular Mechanism of Action: Phenytoin and lignocaine (lidocaine) block cell membrane sodium channels.
Physiological Mechanism of Action: Phenobarbitone is a barbiturate analog that has a depressant effect on central nervous system (CNS) activity.
Application: Prolonged electroencephalographic recordings in the presence of pharmaceutical agents reveal information that challenges the merit and justification of certain established treatment regimens. In this context, indications can be gained regarding the prognosis for future disability and severity of dysfunction attributable to CNS seizure activity.
Considerations: Evidence exists that suggests that seizure episodes are damaging to the neonatal brain. Neonatal seizures can permanently disrupt neuronal development, induce synaptic reorganization, alter plasticity, and "prime" the brain to increased damage from seizures later in life.
Implementation: Evaluation of seizure potential and prediction of future seizure burden.
Interpretation and Analysis: Electroencephalography remains the most useful strategy for determing diagnosis and future prognosis. Alternatively, phenobarbitone remains the mainstay of treatment and is effective in about one-third of cases; babies who respond tend to have a smaller seizure burden and a relatively normal background electroencephalogram. Their prognosis is better than in those who require 2nd-line treatment strategies. Phenytoin and lignocaine (membrane stabilizing drugs) are probably more effective than any of the benzodiazepines as 2nd line treatment strategies , but very few evaluation studies have been reported. Babies who require 2nd-line treatment strategies are more likely to have hypoxic ischemic encephalopathy, an abnormal background electroencephalogram, and a large seizure burden, and to have a worse prognosis than do those who respond to a single agent; most have significant disability at follow-up.
Instrumentation: Computer-integrated electroencephalogram instrumentation.

Neonatal seizures and their treatment. Rennie JM, Boylan GB. Curr Opin Neurol 2003 Apr; 16 (2), pp. 177–81.

Seizures: Non-Epileptic Attacks (NEAs)
Saline Infusion/[Verbal Suggestion]

Background Information: Non-epileptic attacks (NEA) pose as diagnostic and therapeutic delemmas and can be associated with a poor prognosis. Activation procedures like saline infusion have been used for diagnostic purposes.
Application: Induction of NEA episodes.
Implementation: Evaluation of NEA conditions applying EEG analyses. Attempts to induce attacks can be initiated with verbal suggestion and saline infusion. In clinical trials, cases can be monitored with a postal or telephone questionnaire 4.5 years after the EEG.
Human Model: Case with a probable diagnosis of NEA (n = 66).
Interpretation and Analysis: Saline infusion with verbal suggestion can induce an attack in a relatively large percentage of NEA cases (e.g., n = 41/66 cases). In follow-up monitoring, approximately 66% display a reduction in the number of attacks (e.g., n = 20/31 reduction, n = 12/20 attack free). More cases are attack free at follow-up after a positive (e.g., n = 7/16) in comparison to a negative (n = 5/15) test. A provocative test can be diagnostic in some cases with NEA. An early and firm diagnosis may lead to appropriate treatment and better outcome.

Saline infusion: A diagnostic and therapeutic tool in nonepileptic attacks? Wassmer E, Wassmer SR, Donati F. Epilepsy Behav 2003 Oct; 4 (5), pp. 500–6.

Seizures/Pesticide (Neurotoxic): Rotenone/(Dopaminergic System of the CNS)
1-Methyl-1,2,3,4-Tetrahydroisoquinoline (1MeTIQ)

Physiological Mechanism of Action: Counteracts the promotion of elevated concentrations of dopamine within the central nervous system induced by rotenone (neurotoxic pesticide).
Application: 1-methyl-1,2,3,4-tetrahydroisoquinoline (1MeTIQ) can function as a neuroprotective agent against exposure to rotenone (neurotoxic pesticide). In this context, 1MeTIQ could serve as a molecular targeting agent for the purpose of diagnostic imaging and/or as a diagnostic option in the differential diagnosis of acute-onset neurologic seizures.
Implementation: Evaluation of neurologic seizures associated with rotenone intoxication.
Animal Model: Rats. (Wistar strain with rats subjected to the effect of single and multiple administrations of rotenone (neurotoxic pesticide) in concert with the potentially neuroprotective compound 1-methyl-1,2,3,4-tetrahydroisoquinoline (1MeTIQ).
Interpretation and Analysis: The neurotoxic pesticide rotenone administered in a single dose (12 mg/kg s.c.) does not produce evidence of behavioral or biochemical alterations. In contrast, repeated administration of rotenone doses (12–15 mg/kg) causes abnormalities in general behavior while also producing considerable mortality and dramatic increases in dopamine metabolism that may be ascribed to increases in the oxidative pathway. Interestingly, 1MeTIQ depresses the concentration of the extracellular dopamine metabolite 3-MT. These behavioral and biochemical changes are effectively counteracted by administration of 1MeTIQ before each dose of rotenone. Based on findings from several laboratories, multiple systemic rotenone injections are highly toxic and induce alterations of cerebral dopamine metabolism. The compound 1MeTIQ may be considered as a potential diagnostic and protective agent against environmental factors affecting the function of the dopaminergic system.
Instrumentation: High-performance liquid chromatography (HPLC) and electrochemical monitoring equipment.
Laboratory Methodologies: Concentrations of dopamine and its metabolites (homovanillic acid-HVA, 3,4-dihydroxyphenylacetic acid-DOPAC, and 3-methoxytyramine-3-MT) are measured in 3 regions of the brain applying HPLC in concert with electrochemical detection/monitoring instrumentation. The rate of dopamine catabolism in the striatum along the N-oxidative and O-methylation pathways is assessed through the calculation of the ratio of dopamine metabolites to dopamine. In addition, the effect of rotenone on rat mortality and general behavior is recorded.

1-methyl-1,2,3,4-tetrahydroisoquinoline protects against rotenone-induced mortality and biochemical changes in rat brain. Antkiewicz-Michaluk L, Karolewicz B, Romanska I, Michaluk J, Bojarski AJ, Vetulani J. Eur J Pharmacol 2003 Apr 18; 466 (3), pp. 263–9.

Serotonin (5-HT) and Adrenergic Systems Evaluation/Myoclonic Twitches Evoked by L-5-Hydroxy-Tryptophan, Quipazine, and Fenfluramine.
Quipazine/L-5-Hydroxy-Tryptophan/Cyproheptadine/Cirazoline/Clonidine/Yohimbine/L-dopa/Salbutamol

Cellular/Molecular Mechanism of Action: Quipazine is a serotonin (5-HT) receptor agonist; L-5-hydroxy-tryptophan is a serotonin precursor molecule; fenfluramine is a 5-HT releasing agent; cyproheptadine is a 5-HT receptor antagonist; cirazoline is an alpha 1-adrenoceptor agonist; clonidine is an alpha 2-adrenoceptor agonist; yohimbine is an alpha 2-adrenoceptor antagonist; L-dopa recognizes and physically binds to dopamine receptor complexes (functions as an agonist); and salbutamol is a beta 2-adrenoceptor agonist.

Applications: Potential utilization as a test model for investigating the action of compounds on central 5-HT and adrenergic systems. Clinical relevance could pertain to characterizing exposure to agents that promote myoclonic activity.

Route of Administration: Quipazine (5-HT intravenous); L-5-hydroxy-tryptophan (L-5-HTP intravenous); fenfluramine (intravenous); cirazoline (intravenous); clonidine (intravenous); L-dopa (intraperitoneal); salbutamol (intravenous).

Dosage: Quipazine (intravenous); L-5-hydroxy-tryptophan (L-5-HTP, 50–100 mg/kg); cirazoline (0.3–3 mg/kg); clonidine (0.2 and 0.4 mg/kg); L-dopa (100 mg/kg); salbutamol (0.01–1 mg/kg).

Implementation: Evaluation of evoked myoclonic twitches of the anterior digastricus muscle created by L-5-hydroxy-tryptophan, quipazine, and fenfluramine.

Animal Model: Urethane-anesthetized rats (including decerebrate and artificially respired).

Interpretation and Analysis: The effect of L-5-HTP or quipazine on the frequency of twitches is inhibited by cyproheptadine. In addition, L-dopa (100 mg/kg intraperitoneal) or the alpha 1-adrenoceptor agonist cirazoline (0.3–3 mg/kg i.v.) evokes twitches of the muscle that are inhibited by the alpha 1-adrenoceptor antagonist, prazosin. In decerebrate, artificially respired *in vivo* models, neither L-5-HTP nor L-dopa evoke twitches. The frequency of twitches evoked by fenfluramine but not by L-dopa is increased by clonidine. The effect of clonidine is abolished by yohimbine. Salbutamol has no effect on fenfluramine-induced twitches. Therefore, (i) activation of 5-HT receptors or alpha 1-adrenoceptors in the brain of urethane-anesthetized rats evokes twitches of the anterior digastricus muscle, and (ii) this preparation can be utilized as a test to study the action of compounds on central 5-HT and adrenergic systems.

A novel *in vivo test* for drugs affecting central serotonergic and adrenergic systems. Rawlow A, King RG. Eur J Pharmacol 1990 Dec 4; 191 (3), pp. 263–72.

Serotonin and Dopamine Balance
Substituted Amphetamine Para-methoxyamphetamine (PMA)/3,4-methylenedioxymethamphetamine (MDMA)

Background Information: A number of deaths have occurred related to the recreational administration of PMA (substituted amphetamine). Relatively little is known about the mechanism(s) of action for PMA and its effects on physiological, behavioral, and neurochemical parameters.

Application: Potentially, substituted amphetamine PMA or related analogs may be valuable in evaluating serotonin physiology serotonin/dopamine balance within the central nervous system. Caution: Appropriate studies have not been performed to validate the use of PMA for such purposes.

Implementation: Compare the physiological properties of substituted amphetamine PMA with the well-known effects of MDMA. *In vivo* chronoamperometry can be used to measure the effects of MDMA and PMA on release, and inhibition of uptake, of serotonin (5-HT) and dopamine (DA) in the dorsal striatum.

Animal Model: Rats (anesthetized).

Interpretation and Analysis: At both 20° and 30°C, MDMA stimulates locomotor activity, whereas PMA has a modest effect and then only at high doses. Equivalent doses of substituted amphetamine PMA produce greater hypothermia than MDMA at an ambient temperature of 20°C. At 30°C, PMA continues to evoke hypothermia except at the highest dose, where hyperthermia ensues. MDMA alters body temperature only at the highest dose, where hyperthermia also results.

At the molecular level, MDMA evokes release of dopamine (DA) and inhibits uptake of both dopamine (DA) and serotonin (5-HT). By contrast, PMA is a relatively weak releasing agent and does not inhibit dopamine (DA) uptake. However, PMA potentially inhibits serotonin (5-HT) uptake. Collectively, these observations suggest that the acute adverse effects of PMA are more likely to be asso–ciated with alterations in serotonergic rather than dopaminergic neurotransmission.

Differential behavioural and neurochemical effects of para-methoxyamphetamine and 3,4-methylenedioxymethamphetamine in the rat. Daws LC, Irvine RJ, Callaghan PD, Toop NP, White JM, Bochner F. Prog Neuropsychopharmacol Biol Psychiatry 2000 Aug; 24 (6), pp. 955–77.

Serotonin (5-HT) Production: Central Nervous System/Physiological Processes Mediated by Alterations in Serotonin Production/Over-Active Bladder Conditions
Clomipramine/Fluoxetine

Cellular/Molecular Mechanism of Action: Clomipramine modifies (reduces) concentrations of serotonin (5-HT) within the central nervous system (CNS). Fluoxetine is a selective CNS serotonin uptake inhibitor.

Physiological Mechanism of Action: Clomipramine promotes endogenous CNS depression while fluoxetine can reverse these CNS properties induced by clomipramine.

Background Information: Serotonin (5-HT) in the CNS may inhibit bladder activity. Based on this consideration, it has been postulated that CNS depression associated with altered 5-HT production may be associated with or be the cause of conditions such as over-active bladder (OAB) activity.

Application: Detection and evaluation of physiological functions or conditions (e.g. OAB) that may be associated with alterations in serotonin (5-HT) production within the CNS.

Dosage: Clomipramine hydrochloride (22.5 mg/kg body weight) compared to an equal volume of sterile physiological saline administered by injection to negative reference controls. Fluoxetine (20 mg/kg daily).

Implementation: Evaluation of the influence of clomipramine hydrochloride on urinary voiding frequency at 10 and 15 weeks. Behavioral correlates of depression are assessed using a forced-swim challenge. At age 15 weeks cystometry (CMG) analysis is performed. Fluoxetine is then co-administered with clomipramine or saline followed by the measurement of void frequency (VF) and reevaluation of CMG analyses.

Animal Model: Rat (Wistar pups, postnatal days 8 to 21) endogenous model for depression promoted by lowering serotonin (5-HT) concentrations.
Interpretation and Analysis: Clomipramine increases immobility when combined with forced-swim challenge testing (indication of depression). Clomipramine promotes more frequent voiding compared to negative saline controls at 10 and 15 weeks. Interestingly, the difference is significant only in females. Cystometry of clomipramine/females reveals decreased bladder capacity, micturition volume, and inter-micturition contractions compared with negative saline reference controls. Fluoxetine reverses these changes (comprable to saline negative reference controls). Such observations support the hypothesis that OAB may be associated with altered 5-HT function and may explain previous descriptions of an association between depression and OAB.

Alterations in voiding frequency and cystometry in the clomipramine induced model of endogenous depression and reversal with fluoxetine. Lee KS, Na YG, Dean-McKinney T, Klausner AP, Tuttle JB, Steers WD. J Urol 2003 Nov; 170 (5), pp. 2067–71.

Serotonin 5-HT_2 Receptor Complexes: Spinal Cord/(Spasms: Neuromuscular)
Amitriptyline/Cyclobenzaprine/Cyproheptadine/Ketanserin

Cellular/Molecular Mechanism of Action: In the brain, 5-HT receptors exist in 2 major different classes referred to as 5-HT1 and 5-HT2. Methysergide and metergoline are non specific in their mechanism of action and function as antagonists at both 5-HT1 and 5-HT2 receptor complexes. Buspiron and 8-OH-DPAT function as 5-HT_{1A} agonists that exert antihypertensive properties, while pindolol and WAY100635 are antagonists of 5-$HT_{1A/1B}$ and 5-HT_{1A} receptor complexes respectively. Alternatively, cyclobenzaprine, amitriptyline, cyproheptadine, ketanserin (5-$HT_{2A/2C}$), N-desmethylclozapine (5-HT_{2C}), and spiperone (5-HT_{2A}) interact relatively selectively with 5-HT_2 receptor complexes within the spinal cord, where they all function as 5-HT antagonists. Interestingly, ketanserin also binds to α_1-adrenergic, histamine H_1, and to a lesser exent dopamine receptor complexes.
Physiological Mechanism of Action: Centrally acting muscle relaxant with its action mediated through inhibition of facilitatory descending serotonergic systems that regulate monosynaptic and polysynaptic reflex potentials within the spinal cord. Although 5-HT_2 receptors have relatively weak binding avidity for 5-HT, they are most often associated with functional responses.

The physiological effects evoked by ketanserin include vasodilatory responses (lowering of blood pressure), bronchial relaxation, antiplatelet aggregatory agent, and inhibition of sympathetic outflow from the brain. Cyproheptadine blocks smooth muscle contractions mediated by 5-HT and has weak anticholinergic activity.
Application: Diagnostic aid in determining cause of neuromuscular spasticity. Potential biological carrier systems for imaging spinal cord 5-HT_2 receptor complexes.

Other applications associated with this class of pharmaceutical agents (e.g., cyproheptadine) include its use in postgastrectomy dumping syndrome, and intestinal hypermotility of carcinoid syndrome, but these functions are not mediated by 5-HT concentrations.
Considerations: Interestingly, the structure of cyclobenzaprine is very similar to that of amitriptyline and cyproheptadine.
Interpretation and Analysis: Cyclobenzaprine, amitriptyline, cyproheptadine, and ketanserin significantly inhibit the facilitatory effects of 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) on flexor reflexes and mono- and polysynaptic spinal reflex potentials in spinalized *in vivo* models. In intact *in vivo* models, these drugs significantly reduce the mono- and polysynaptic reflex potentials. Depletion of 5-HT significantly prevents depression of spinal reflex potentials induced by cyclobenzaprine, amitriptyline, cyproheptadine, and ketanserin.

Tricyclic analogs cyclobenzaprine, amitriptyline and cyproheptadine inhibit the spinal reflex transmission through 5-HT_2 receptors. Honda M, Nishida T, Ono H. Eur J Pharmacol 2003 Jan 1; 458 (1–2), pp. 91–9.

Serotonin 5-HT_4-Receptor Distribution/Intestinal Motility: Colon
Mosapride Citrate/Cisapride

Cellular/Molecular Mechanism of Action: Function as 5-HT_4-receptor agonists.
Route of Administration: Mosapride and cisapride (intragastric).
Dosage: Mosapride and cisapride (3–30 mg/kg).
Considerations: The 5-HT_4 receptors in the colon of guinea pigs show a distribution similar to that found in humans.
Interpretation and Analysis: The enhancing effect of mosapride on colon motility is antagonized by atropine or 5-HT_4-receptor antagonist (GR113808), but not by methysergide (5-HT_1- and 5-HT_2-receptor antagonist); ondansetron (5-HT_3-receptor antagonist); or CP-99994 [tachykinin NK(1)-receptor antagonist]. *In vitro* receptor autoradiography has shown that mosapride and cisapride inhibit the specific binding of [^{125}I]-SB207710, a selective radioligand of 5-HT_4 receptors, in the colon of guinea pigs. Mosapride therefore enhances colonic motility through 5-HT_4-receptor activation in guinea pigs and may be useful for treating constipation in cases with colonic motility dysfunction.

Effects of mosapride citrate, a 5-HT_4 receptor agonist, on colonic motility in conscious guinea pigs. Inui A, Yoshikawa T, Nagai R, Yoshida N, Ito T. Jpn J Pharmacol 2002 Dec; 90 (4), pp. 313–20.

Serotonergic Systems/Serotonin Transporter (SERT)
Diphenyl Sulfide Derivatives/[^{11}C]-DASB

Application: Characterization of serotonin transporter expression and function (e.g. positron emission tomography imaging of serotonergic systems).
Semi-Synthetic Methods: Molecular modeling techniques have been used to design prototype serotonergic ligands. Predictions of binding affinity are based on models generated by Comparative Molecular Field Analysis (CoMFA) and Comparative Molecular Similarity Indices Analysis (CoMSIA). Applying this investigative approach, a large number of candidate compounds have been designed for screening purposes (n = 100). Diphenyl sulfide derivatives like [^{11}C]-DASB have proven to be promising PET ligands and therefore can serve as a diphenyl sulfide scaffold for rational modification strategies. The novel compounds designed through this approach have a predictably high selective affinity for serotonin transporter (SERT) complexes. Chemical groups that have proven effective include the introduction of fluoroethyl-oxycarbonyl (ester) and fluorethyl-carbonyl (ketone), as well as aldehyde and its corresponding oxime and imine. Another molecular modification that has proven effective is the replacement of the sulfur bridge with a cyanamide group and a fluoroethylamino group.
Interpretation and Analysis: The proposed candidate compounds possess features providing new possibilities for carbon-11 or fluorine-18 labeling. Synthesis, biological testing, and screening for

PET suitability are reasonable and potentially productive future areas of investigation.

Molecular modeling of potential new and selective PET radiotracers for the serotonin transporter. Wellsow J, Kovar KA, Machulla HJ. J Pharm Pharm Sci 2002 Sep–Dec; 5 (3), pp. 245–57.

Serotonin Uptake/$GABA_A$ Receptor Complexes/ Cerebral Cortex Function/Hypocampal Electroencephalogram Profiles/Antidepressants

Pharmaco-Electroencephalogram Analyses/ Serotoninertic Agents/ Pentylenetetrazol/ Imipramine/ Fluoxetine/Trazodone/Desipramine/Nortriptyline

Cellular/Molecular Mechanism of Action: The antidepressants imipramine, fluoxetine, or trazodone inhibit serotonin uptake. Conversely, the antidepressants desipramine and nortriptyline inhibit norepinephrine uptake.

Application: Evaluate the influence of antidepressants with serotonergic and adrenergic effects on the function of $GABA_A$ receptor complexes.

Route of Administration: Pentylenetetrazol, imipramine, fluoxetine, or trazodone (intraperitoneal in rat *in vivo* model).

Dosage: Pentylenetetrazol (PTZ; 27.5 mg/kg) and imipramine, fluoxetine, or trazodone (7 days at 10 mg/kg given twice a day).

Implementation: Evaluate power spectrum changes induced by PTZ (chloride ionophore antagonist) in hippocampal electroencephalograms in order to better delineate the antidepressant drug effects on $GABA_A$ receptor complexes (e.g. $GABA_A$ receptor, chloride ionophore, and benzodiazepine receptor).

Animal Model: Rat (hippocampal EEG).

Interpretation and Analysis: In control recording, PTZ increases EEG power at frequencies under 12 Hz up to 5 times. After *in vivo* models are pretreated with imipramine, fluoxetine, or trazodone for 7 days (10 mg/kg i.p. twice a day), PTZ does not increase EEG power to more than 3 times the power before injection; this effect is not observed after 3 days of pretreatment. These 3 antidepressants inhibit serotonin uptake, while antidepressants that inhibit norepinephrine uptake (desipramine, nortriptyline) fail to counter the effect of PTZ. Antidepressants with serotonergic effects enhance the function of the $GABA_A$ receptor complex.

Electrophysiologic analysis of antidepressant drug effects on the $GABA_A$ receptor complex based upon antagonist-induced encephalographic power spectrum changes. Matsubara M, Suzuki S, Miura K, Terashima M, Sugita S, Kimura H, Hatsuda S, Mori T, Murakami H, Hayashi T, Ohta T, Ohara M. Neuropsychobiology 2000; 42 (3), pp. 149–57.

Sleep Disorders: Application Potential

Melatonin/(Flumazenil)/(Benzodiazepine)/ (Picrotoxin)/Bicuculline Methiodide

Cellular/Molecular Mechanism of Action: Melatonin binds to the $GABA_A$ receptor mediated through the benzodiazepine recognition site, the picrotoxin site on the $GABA_A$ receptor, and partially to the GABA binding site on the $GABA_A$ receptor.

Physiological Mechanism of Action: Melatonin induces a significant sleep-promoting effect (*in vivo* models).

Background Information: The hypnotic activity of melatonin appears to be associated with $GABA_A$ receptors and mediated through the benzodiazepine recognition site on the $GABA_A$ receptor and partially through the GABA binding site on the $GABA_A$ receptor.

Application: Melatonin in concert with electroencephalogram monitoring could be applied in sleep research, based on its sleep-promoting properties when administered to *in vivo* models.

Route of Administration: Melatonin (intraperitoneal injection).

Dosage: Melatonin (10 mg/kg in rats); flumazenil (3.5 and 7 mg/kg); picrotoxin (2 and 4 mg/kg); bicuculline methiodide (2 and 4 mg/kg).

Implementation: Evaluation of sleeping disorders.

Animal Model: Rat.

Interpretation and Analysis: Melatonin induces a sleep-promoting effect that can be monitored through the use of electroencephalography (EEG). Flumazenil (3.5 and 7 mg/kg), a specific antagonist of the benzodiazepine (BZP) recognition site on the $GABA_A$ receptor, and picrotoxin, the ligand of the picrotoxin site on the $GABA_A$ receptor, seem to be devoid of an intrinsic influence on each sleep parameter when used alone, but they significantly antagonize the melatonin-induced increase in total sleep time (TS), slow-wave sleep time (SWS), paradoxical sleep time (PS), and the decrease in time to sleep onset (TSO) and wakefulness time (W). A significant interaction exists between melatonin and flumazenil or picrotoxin. When bicuculline methiodide, (a specific antagonist of the GABA binding site on the $GABA_A$ receptor), is used together with melatonin, then melatonin-induced increases in TS, SWS, and PS, along with decreases in W, are abolished. However, there is no apparent interaction between melatonin and bicuculline methiodide on sleep parameters except PS.

The $GABA_A$ receptor mediates the hypnotic activity of melatonin in rats. Wang F, Li J, Wu C, Yang J, Xu F, Zhao Q. Pharmacol Biochem Behav 2003 Feb; 74 (3), pp. 573–8.

Sleep Quality: Cerebral Function

Pharmaco-Electroencephalogram (EEG) Mapping/ d-Fenfluramine (d-FEN)/l-Fenfluramine (l-FEN)/ Chlorpromazine (CPZ)/d-Amphetamine (AMPH)/Prolactin

Route of Administration: Single oral dose of each d-fenfluramine, l-fenfluramine, chlorpromazine, and d-amphetamine (AMPH @ 50 mg).

Dosage: Single dose of d-fenfluramine (d-FEN at 15 and 30 mg); l-fenfluramine (l-FEN at 30 mg); chlorpromazine (CPZ at 50 mg); and d-amphetamine (AMPH at 50 mg).

Implementation: Pharmaco-EEG mapping of the pharmacodynamic properties of d-FEN, l-FEN compared to CPZ, and AMPH as well as prolactin and safety assessments. Blood samples are collected to determine concentrations of AMPH, FEN and its main metabolite norFEN, as well as plasma prolactin levels; EEG recordings and evaluation of hemodynamics and spontaneous side effects are performed at 0, 2, 4, 6, and 8 hours after drug administration. Before and 24 hours after drug intake, morning subjective sleep quality is then also assessed.

Human Model: Cases of young healthy volunteers (n = 18) receiving pharmaceutical agents at weekly intervals.

Interpretation and Analysis: Blood concentration levels measured after d-FEN demonstrate a dose-dependent blood concentrations peaking after 2–4 hours and slowly declining thereafter. NorFEN, the main metabolite, exhibits a steady increase in plasma concentrations up to the 8th hour. After l-FEN a similar time course is observed, but the concentrations of the parent compound are higher and those of the metabolite lower in comparison with the d-isomer, suggesting stereoselective kinetics. d-FEN induces significant and dose-dependent pharmaco-EEG changes characterized by a decrease in total power and combined delta/theta activity; an increase in beta activity; and an acceleration of the centroid of the total activity with no changes in alpha power that are very different from those of the

reference drugs. l-FEN produces only minimal changes (of the same type as d-FEN). CPZ (50 mg) and d-AMPH (20 mg) produce significant changes compared to placebo but with quite opposite effect profiles; the former exhibits a typical sedative-neuroleptic pattern while the latter is typical of psychostimulants. Dose/treatment and time-efficacy calculations based on all variables show in the V-EEG that only d-FEN (30 mg) and CPZ (50 mg) are different from placebo (with peak effects in the 8th and 4th hour, respectively), while in the resting condition (R-EEG) all drugs/dosages but l-FEN (30 mg) differ from placebo (with the peak effect occurring in the 4th–6th hour after d-FEN and l-FEN; in the 2nd hour after CPZ; and in the 4th–6th hour after AMPH). Plasma prolactin levels are only modified by CPZ (maximal increase in the 2nd hour).

Clinical-pharmacological study with the two isomers (d-, l-) of fenfluramine and its comparison with chlorpromazine and d-amphetamine: Blood levels, EEG mapping and safety evaluation. Saletu B, Barbanoj MJ, Anderer P, Sieghart W, Grünberger J. Methods Find Exp Clin Pharmacol 1993 Jun; 15 (5), pp. 291–312.

Sleep Disorders/Gamma-Hydroxybutyric Acid Receptors/$GABA_A$ and $GABA_B$ Receptors
Gamma-Hydroxybutyric Acid (GHB)/UMB68/UMB75

Cellular/Molecular Mechanism of Action: The exact mechanism of action of GHB remains to be delineated, but it is known to interact with specific GHB binding sites or receptors and that GHB undergoes metabolic conversion to GABA. The tertiary alcohol analog of GHB (UMB68) binds to GHB receptors. In drug discrimination studies, $GABA_B$ agonists, and to a lesser extent $GABA_A$ -positive modulators, substitute for GHB.

Physiological Mechanism of Action: Gamma-hydroxybutyric acid acts as a weak agonist at $GABA_B$ receptors. The tertiary alcohol analog of gamma-hydroxybutyric acid (UMB68) does not induce GABA receptor-mediated effects *in vivo* normally associated with gamma-hydroxybutyric acid.

Background Information: In drug discrimination studies, $GABA_B$ agonists, and to a lesser extent $GABA_A$-positive modulators, can substitute for GHB. To delineate the relative contributions of each receptor system to the profile of GHB, tertiary alcohol analogs of GHB and its homolog, 5-hydroxypentanoic acid (UMB58), referred to as UMB68 and UMB75, respectively, cannot be metabolized to GABA-active compounds but can be used as investigative probes.

Application: Gamma-hydroxybutyric acid (GHB) shows great promise as a treatment for sleeping disorders but is also increasingly being abused. The tertiary alcohol analog of gamma-hydroxybutyric acid (UMB68) could provide a novel tool for studying the pharmacology of the GHB receptor in the absence of complicating GABAergic effects.

Route of Administration: Gamma-hydroxybutyric acid.

Dosage: Gamma-hydroxybutyric acid.

Interpretation and Analysis: Binding studies against [^{3}H]NCS-382 [(2E)-(5-hydroxy-5,7,8,9-tetrahydro-6H-benzo[a][7] annulen-6-ylidene) ethanoic acid] show that the tertiary alcohol analog of GHB (UMB68) has similar affinity for GHB, with the longer chain analogs possessing lower levels of affinity. Against [^{3}H]GABA, UMB68 shows no affinity ($IC_{50} > 100$ μM) at $GABA_A$ or $GABA_B$ receptors. *In vivo* studies show that, at behaviorally active doses, *in vivo* models trained to discriminate GHB do not recognize the novel ligands as GHB. Thus, UMB68 is a selective GHB receptor ligand in binding assays, does not undergo metabolism to GABA-active compounds, and does not show the same effects as GHB *in vivo*. Such data suggests that, although UMB68 binds to the GHB receptor, it does not have the observed GABA receptor-mediated effects of GHB *in vivo* and could provide a novel tool for studying the pharmacology of the GHB receptor in the absence of complicating GABAergic effects.

A tertiary alcohol analog of gamma-hydroxybutyric acid as a specific gamma-hydroxybutyric acid receptor ligand. Wu H, Zink N, Carter LP, Mehta AK, Hernandez RJ, Ticku MK, Lamb R, France CP, Coop A. J Pharmacol Exp Ther 2003 May; 305 (2), pp. 675–9.

Syncope Differentiation
ATP/Isoproterenol (Tilt Test)

Cellular/Molecular Mechanism of Action: Isoproterenol is a non-selective β-adrenergic receptor agonist.

Background Information: In patients with vasovagal syndrome, head-up tilt testing may reproduce symptoms generally associated with vasodepression. Recent research suggests ATP testing can identify cases with abnormal vagal cardiac inhibition.

Application: The tilt and ATP tests individually and jointly can be utilized to determine the underlying mechanisms of vasovagal symptoms in most cases of syncope.

Route of Administration: ATP (20 mg).

Dosage: ATP (intravenous).

Implementation: Evaluation of isoproterenol and ATP provocative tests performed in random order during one session and outside of predominant sympathetic periods in cases related to syncope. In passive and isoproterenol-provocative tilt testing by standard protocols, reproduction of symptoms is defined as a positive test. The ATP test consists of administering injectable ATP (at bedside) while continuously monitoring ECG and blood pressure with a vagal cardiac pause > 10 seconds defined a positive test result. For most cases (64%), ≥ 1 test will be positive.

Human Model: Cases suffering from syncope ($n = 56$); cases of presyncope ($n = 56$) for whom no cardiac or extracardiac etiologies can be identified.

Interpretation and Analysis: In 57% of cases (e.g., $n = 41/72$) with a positive tilt test (either passive or provoked by isoproterenol), approximately 32% have cardiac disease, while a very low percentage have significant bradycardia (e.g., $n = 0$; < 50 bpm). In cases with positive ATP test findings (e.g., $n = 8$ or 11%), approximately two-thirds or 62% have cardiac disease. The probability of a positive result increases with age ($p = 0.015$). Both tests are positive in a small number of cases (e.g., $n = 3$) while a relatively larger number have a negative responses to both evaluation procedures (e.g., $n = 26$). Results from tilt and ATP test procedures appear to be uncorrelated ($p = 0.28$). Therefore, tilt and ATP tests individually and jointly can assist in determining the mechanism of vasovagal symptoms in most cases of syncope. Vagal cardiac inhibition appears to increase with age.

Contribution of head-up tilt testing and ATP testing in assessing the mechanisms of vasovagal syndrome: Preliminary results and potential therapeutic implications. Flammang D, Erickson M, McCarville S, Church T, Hamani D, Donal E. Circulation 1999 May 11; 99 (18), pp. 2427–33.

Syncope/Hypoxia: Sudden/Bradycardia: Sudden/Vasovagal Syncope: Unexplained/[Vascular Graft Patency]
Nitroglycerin/Isoproterenol

Cellular/Molecular Mechanism of Action: Isoproterenol recognizes, physically binds to, and activates sympathetic/adrenergic receptor complexes.

Physiological Mechanism of Action: Nitroglycerin induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are the changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and in cases with coronary artery disease when nitroglycerin is given by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce a significant hypotensive episode.

Application: Diagnosis of vasovagal syncope and it can be utilized in combination with quantitative angiography for the evaluation of vascular blood flow integrity (vasodilation vs vasoconstriction) and patency of vascular grafts. Injectable nitroglycerin (TNG) is employed during cardiac catheterizations primarily in cases undergoing provocative tests for coronary spasm with ergonovine maleate where it has demonstrated considerable efficacy.

Route of Administration: Nitroglycerin (intravascular).

Dosage: Nitroglycerin can be given at progressively increasing infusion rates (increments of 0.86 μg/kg/hr every stage).

Implementation: Evaluation of unexplained syncope conditions through analysis of provoked changes in coronary artery vascular blood flow. A maximum of 5 successive stages of 5 minutes in the supine position are performed plus 10 minutes of 80-degree upright tilt at progressively increasing infusion rates (increments of 0.86 μg/kg/hr every stage).

Human Model: Cases of unexplained syncope (n = 40; n = 23/40 women, mean age 47 years; n = 25 asymptomatic controls with negative baseline head-up tilt undergoing 2 other tilting tests, 1 during nitroglycerin infusion and 1 during isoproterenol infusion).

Interpretation and Analysis: During the nitroglycerin test a positive response (syncope in association with sudden hypotension and bradycardia) can occur [i] in approximately 53% (e.g., n = 21) of cases with unexplained syncope; [ii] as an exaggerated response (minor symptoms in association with slowly increasing hypotension alone) in about 25% (e.g., n = 10/40); [iii] as a negative response in 22% of cases (e.g. n = 9/40); and [iv] drug intolerance in a very small percentage (e.g., n = 0 or 0%). During the isoproterenol test these percentages are 25%, 25%, 32%, and 18%, respectively. Only a small percentage of controls have a positive response to the nitroglycerin test and to the isoproterenol test (e.g., n = 2 or 8% for each test). Thus the nitroglycerin test seems to be a useful alternative tool for the diagnosis of vasovagal syncope and it is equally specific but more sensitive and feasible than the isoproterenol test.

Nitroglycerin infusion during upright tilt: a new test for the diagnosis of vasovagal *syncope*. Raviele A; Gasparini G; Di Pede F; Menozzi C; Brignole M; Dinelli M; Alboni P; Piccolo E. Am Heart J] 1994 Jan; Vol. 127 (1), pp. 103-11.

Syncope: Neurocardiogenic
Isosorbide Dinitrate/Isoproterenol

Cellular/Molecular Mechanism of Action: Isosorbide dinitrate (active metabolite: isosorbide-2-mononitrate; isosorbide-5-mononitrate) is believed to activate guanylate cyclase and increase the synthesis of guanosine 3′,5′ monophophate (cGMP) in smooth muscle and other tissues. Formation of reactive free radical nitric oxide (NO) occurs, which interacts with and activates guanylate cyclase. Isoproterenol binds to and potently (positively) activates β-adrenergic receptor complexes (β-adrenergic receptor agonist).

Physiological Mechanism of Action: Isosorbide dinitrate is an arterial and venous dilating agent. Isoproterenol (sympathomimetic) effects are mainly directed at the heart and smooth muscle tissues of the bronchioles, skeletal muscle vasculature, and alimentary tract. Physiologically, isoproterenol promotes declines in peripheral vascular resistance primarily at the level of the vascular beds within skeletal muscle.

Application: Isosorbide dinitrate and isoproterenol can be applied to identify and characterize cases of suspected cardiogenic syncope.

Route of Administration: Isosorbide dinitrate (sublingual), isoproterenol (intravenous).

Dosage: Isosorbide dinitrate (5 mg), isoproterenol (4 μg/min).

Implementation: In cases of suspected neurocardiogenic syncope the response to a head-up tilt test (HUT) can be divided into subjects that either do or do not develop syncope/presyncope during a passive HUT test for 30 minutes. Cases that do not develop symptoms can be further evaluated using repeated HUT tests with isoproterenol infusions (4 μg/min; 10 minutes) and then tilted after a sublingual administration of isosorbide dinitrate (another 12 minutes). The HUT/isosorbide dinitrate test is usually performed after the HUT/isoproterenol test.

Human Model: Cases of suspected neurocardiogenic syncopy (e.g. n = 120; 15–77 years).

Interpretation and Analysis: Sensitivity and specificity of passive HUT is 41% (95% C.I. 32.9% to 51%) and 100%, respectively. Sensitivity of isoproterenol HUT is 51.4% (95% C.I. 39.2% to 63.6%) and specificity 70% (95% C.I. 55.4% to 82.1%), and for isosorbide dinitrate HUT is 70% (95% C.I. 57.9% to 80.4%) and 88% (95% C.I. 75.7% to 95.5%), respectively. The accuracy of the isosorbide HUT is significantly higher than the accuracy of the isoproterenol HUT 77.5% (95% C.I. 68.9% to 84.6%). Sublingual isosorbide dinitrate is at least as sensitive as isoproterenol for the assessment of suspected cases of neurocardiogenic syncope that display a negative tilt test without provocation. The low rate of side effects and the higher accuracy of the idosrobide dinitrate HUT, along with the simplicity of this challenge test compared to the isoproterenol HUT test, suggest that sublingual isosorbide dinitrate should be preferred as a provocative agent for evaluating neurocardiogenic syncope after a negative passive tilt test.

Tilt testing in neurocardiogenic syncope: Isosorbide vs isoproterenol. Hermosillo AG, Marquez MF, Jauregui-Renaud K, Falcon JC, Casanova JM, Guevara M, Cardenas M. Acta Cardiol 2000 Dec; 55 (6), pp. 351–5.

Syncope: Neurocardiogenic
Glyceryl Trinitrate (Nitroglycerin)/Isoprenaline (Isoproterenol)

Cellular/Molecular Mechanism of Action: Glyceryl trinitrate (nitroglycerin) activates guanylate cyclase and increases the synthesis of guanosine 3′,5′ monophophate (cGMP) in smooth muscle and other tissues. Formation of reactive free radical nitric oxide (NO) occurs, which interacts with and activates guanylate cyclase. Isoprenaline (isoproterenol) binds to and potently activates β-adrenergic receptor complexes (β-adrenergic receptor agonist).

Physiological Mechanism of Action: Glyceryl trinitrate (nitroglyerin) is an arterial and venous dilating agent. Isoprenaline (isoproterenol: sympathomimetic) exerts effects mainly directed at the heart and smooth muscle tissues of the bronchioles, skeletal muscle vasculature, and alimentary tract. Physiologically isoprenaline

(isoproterenol) promotes declines in peripheral vascular resistance primarily within the vascular network of skeletal muscle.

Application: Glyceryl trinitrate (nitroglycerin) and isoprenaline (isoproterenol) can be used to detect and characterize conditions of neurocardiogenic syncope.

Implementation: In unexplained cases of syncope with a negative passive head-up tilt at 70 degrees (40 minutes), the glyceryl trinitrate head-up tilt and isoprenaline head-up tilt tests can be of diagnostic value (performed 1 week apart). Diagnostic criteria include induced symptoms (syncope, presyncope) in concert with the development of hypotension.

Interpretation and Analysis: In cases with negative passive head-up tilt, the sensitivity of glyceryl trinitrate in diagnosing vasovagal syncope is approximately 48% with a 71% level of specificity. Isoprenaline sensitivity is 21% with a 64% level of specificity. There is a rather drastic difference in the incidence of undesirable side effects observed with glyceryl trinitrate compared to isoprenaline. Glyceryl trinitrate is well tolerated. In contrast, a large percentage of cases (68%) display side effects with isoprenaline that are severe enough to require termination of the testing procedure. Commonest adverse events are the development of hypertension or tachycardia and intolerable flushing or nausea. Based on comparison evaluations, glyceryl trinitrate (nitroglycerin) head-up tilt is as effective as isoprenaline (isoproterenol) head-up tilt as a provocative agent for vasovagal syncope and has a lower incidence of adverse events.

Comparison of provocative tests for unexplained syncope: Isoprenaline and glyceryl trinitrate for diagnosing vasovagal syncope. Graham LA, Gray JC, Kenny RA. Eur Heart J 2001 Mar; 22 (6), pp. 497–503.

Syncope: Vasovagal
Nitroglycerin/[Tilt-Table Test]

Cellular/Molecular Mechanism of Action: Nitroglycerin has a direct action on vascular smooth muscle and its effects are not directly mediated through modifications of the autonomic nervous system.

Physiological Mechanism of Action: Induces both venous and arterial vasodilation. Relatively selective venous vasodilation can be achieved at the lower dosage ranges of nitroglycerin, thereby promoting declines in end-diastolic left and right ventricular pressures. Such changes are more pronounced than are the changes in peripheral arterial pressure. Cardiac output is decreased in normal subjects and patients with coronary artery disease when nitroglycerin is given by the sublingual route of administration. High-dose nitroglycerin administered rapidly causes declines in both systolic and diastolic pressures accompanied by lower blood pressure levels, pallor, weakness, dizziness, and initiation of reflex sympathetic-mediated responses (tachycardia, arteriolar vasoconstriction). Transient increases in coronary blood flow (coronary vasodilation) and declines in arterial blood pressure contribute to decreases in cardiac output. Sublingual administration can therefore occasionally produce significant episodes of hypotension.

Background Information: Vasovagal syncope can occur in any individual, given sufficient provocation, and probably half the population suffers at least 1 episode during life. Often it occurs in youth and may occur in clusters. Usually there is a history of a previous episode. Prodromal symptoms include nausea, sweatiness, and a sensation of warmth.

Diagnostic Application: Patients suffering from syncope of unknown origin that may be due to vasovagal syncope.

Considerations: A classical history and a positive tilt test obviate the need for further investigation in clinical practice, but in the context of aviation (pilots), it is wise to determine if there is a small possibility of intermittent rhythm and/or conduction disturbance as an alternative explanation for the episode.

Implementation: Diagnostic detection of vasovagal syncope can be achieved by obtaining a careful history and performing a tilt test in concert with nitroglycerin administration. In instances where intermittent rhythm and/or conduction disturbance are thought to be important as an alternative explanation for episodes, it then becomes reasonable to carry out a Holter recording and exercise electrocardiogram, perhaps also echocardiography.

Interpretation and Analysis: Patients suffering from syncope of unknown origin display a 53% rate of positive response (hypotension and bradycardia) when subjected to a tilt-table test and nitroglycerin administration. An exaggerated response (hypotension only) is observed in 20% of cases presented for diagnosis (suffering from vasovagal syncope). Other reports have described a 1.3% false positive rate for passive tilt test, and the true positive rate being about 70% when a nitroglycerin challenge is included. No treatment is of much benefit, although many agents, including beta-blocking drugs, have been used. Some cases have undergone permanent dual chamber pacing with some favorable results. Explanation and reassurance is important. From a licensing point of view (e.g. pilots), following investigation after an attack, consideration may be given to providing restricted certification with regular follow-up examinations. Case review with diagnostic investigations after an event-free interval, (arbitrarily set for 2 years), may permit full certification. Malignant vasovagal syncope with no warning of impending attack should warrant disbarment.

Syncope: Vasovagal/Recurrent Syncopy of Unknown Cause
Edrophonium

Cellular/Molecular Mechanism of Action: Edrophonium functions as an inhibitor of acetylcholinesterase biochemical activity.

Physiological Mechanism of Action: Edrophonium through inhibition of acetycholine esterase, effectively promotes accumulation of acetylecholine neurotransmitter at postsynaptic membrane cholinergic receptor complexes.

Background Information: Vasovagal syncope after head-up tilting is thought to be secondary to a complex, neurally-mediated reflex with both vasodepressor and cardioinhibitory efferent components.

Application: Edrophonium has been utilized as a provocative agent for triggering syncope during head-up tilt testing protocols of benefit in detecting cases of vasovagal syncope. The edrophonium/head-up tilt test (i) is currently considered to significantly increase the sensitivity of detecting cases of vasovagal syncope; (ii) may be particularly useful when provocation with isoproterenol is undesirable; and (iii) may be an effective method to help differentiate cases with a significant reflex cardioinhibitory component from those with a predominantly reflex vasodepressor component.

Route of Administration: Edrophonium (intravenous).

Dosage: Edrophonium (10 mg).

Implementation: Evaluation of the efficacy of edrophonium as a provocative agent for "triggering" syncope during head-up tilt testing procedures for cases suffering from recurrent unexplained syncope episodes. Edrophonium is administered after 30 minutes of 60 degrees head-up tilting alone.

Human Model: Cases suffering from recurrent unexplained syncope (e.g., n = 45 affected; n = 20 negative reference controls).

Interpretation and Analysis: Syncope can be induced in a little less than 50% of cases (e.g., n = 19/45), with some cases (e.g. n = 9/19) developing syncope with head-up tilt along with the predominant hemodynamic finding being marked vasodepression. Conversely, other cases will develop syncope only after head-up tilting in combination with edrophonium (e.g., n = 10/19), with the predominant hemodynamic findings being marked vasodepression and bradycardia. Syncope can occasionally be induced in normal reference controls (e.g., n = 1/20) following head-up tilting and edrophonium. There is no long-term complication from using edrophonium.

Evaluation of edrophonium as a provocative agent for vasovagal syncope during head-up tilt-table testing. Lurie KG, Dutton J, Mangat R, Newman D, Eisenberg S, Scheinman M. Am J Cardiol 1993 Dec 1; 72 (17), pp. 1286–90.

Syncope of Unknown Origin
Isoproterenol/[Tilt-Table Test]

Cellular/Molecular Mechanism of Action: Isoproterenol binds to and positively activates both β_1 and β_2 adrenergic membrane-associated receptor complexes.

Due to a relatively minimal influence on α-adrenergic receptor complexes, cardiac function, bronchial smooth muscle, skeletal muscle vasculature, and the gastrointestinal tract are the primary organ systems influenced by the physiological properties exerted by isoproterenol administration. Cardiovascular influences of isoproterenol include diminished peripheral vascular resistance, especially within the vascular networks that perfuse musculoskeletal structures. The increases in heart rate and contractility induced by isoproterenol promote declines in diastolic pressure and elevations in cardiac output sufficient to maintain or elevate systolic pressures (mean blood pressure is lowered).

Background Information: Isoproterenol is widely used as a provocative medium for vasovagal responses during tilt test procedures.

Diagnostic Application: Multi-state isoproterenol tilt-table (MSITT) test.

Route of Administration: Intravenous.

Dosage: Isoproterenol given as constant infusion (3 μg/min). Dose of isoproterenol infusion is generally titrated empirically based on increases in resting heart rate before tilt up test. Administration can involved the use of a 2-stage isoproterenol-tilt protocol, with doses of 0.01 and 0.02 μg/kg per minute for 10 minutes each, or 1-stage isoproterenol-tilt protocol, with a dose of 1 or 2 μg/min for 10 minutes.

Implementation: Evaluation of the optimal increase in resting heart rate with isoproterenol for tilt-induced vasovagal responses. After the end of a negative baseline tilt (80 degrees for 30 minutes), the isoproterenol tilt is performed using 1 of 2 protocols: 2-stage isoproterenol-tilt protocol, or 1-stage isoproterenol-tilt protocol. Resting heart rate increases are defined as a percentage increase in the resting heart rate after isoproterenol infusion, compared to baseline heart rates before initiation of the tilt test.

Human Model: Cases of unexplained syncope (n = 97 consecutive patients).

Interpretation and Analysis: Combining the use of a tilt-table and isoproterenol diagnostic challenge increases the sensitivity of detecting cases suffering from vasovagal mediated syncope (95% by 5 minutes). Conversely, the application of the MSITT alone without the use of isoproterenol results in an 80% positive response rate. Cases that are suffering from bradycardia show a lower rate of positive response rate compared to the MSITT test (10%).

Ninety-three percent (93%) of positive tilt-table procedures (e.g. n = 28/30) occur with a resting heart rate increases of ≥ 21%. With a resting heart rate increase of 60% and 100%, 18 (60%) and 27 (90%) positive responses can be observed, respectively. In conclusion, a minimum resting heart rate increase of ≥ 21% is required to provoke a vasovagal response during a subsequent isoproterenol tilt (80 degrees for 10 minutes). Preferably, heart rate should be increased by 60–100% by isoproterenol titration before tilting.

Norepinephrine, Epinephrine, and the Sympathomimetic Amines. Weiner N (Chapter 8: pp. 145–80). Goodman and Gilman's The Pharmacological Basis of Therapeutics, eds Gilman AG, Goodman LS, Rall TW, Murad F. MacMillan Publishing Company, New York (7th edition: copyright 1985).

What is the optimal increase in resting heart rate with low-dose isoproterenol infusion for tilt-induced vasovagal response? Sumiyoshi M, Abe H, Mineda Y, Tokano T, Yasuda M, Nakazato K, Nakazato Y, Nakata Y, Daida H. J Cardiovasc Pharmacol 2003 Dec; 42 Suppl 1, pp. S19–22.

Thalamic Tectorotundal Pathway/Nucleus Rotundus (Cross-Tectal Projection Tracing)/Embryonic Pathway Development (Embryonic)
1,1′-Dioctadecyl-3,3,3′,3′-Tetramethylinodocarbocyanine (Carbocyanine)/Cholera Toxin B Subunit

Application: Tracing of crossed-tectal projections to the nucleus rotundus of the thalamus (tectorotundal pathways) of paraformaldehyde-fixed and living chick embryos.

Implementation: Molecular tracers are injected into the optic tectum under 3 experimental conditions (carbocyanine postfix, carbocyanine *in vivo*, and cholera toxin B subunit *in vivo*), and the anterograde transport by the nucleus rotundus monitored and compared. In the carbocyanine postfix method, small crystals of carbocyanine dye are inserted into the tectum of paraformaldehyde-fixed embryos. A 6-month postinsertion period is required to label the crossed tectorotundal pathway. In the carbocyanine *in vivo* method, a small volume of carbocyanine dye solution is injected into the tectum of living embryos. Similarly, in the cholera toxin B subunit *in vivo* method, a small volume of cholera toxin B subunit solution is injected into the tectum of living embryos.

Animal Model: Avian (paraformaldehyde-fixed and living chick embryos).

Interpretation and Analysis: Tectal neurons do not begin to innervate the ipsilateral nucleus rotundus until embryonic day 9 and the contralateral nucleus rotundus until embryonic day 17. This slow progression of labeling through the crossed-tectal projection results in significant contrast of "labeling" between the ipsilateral and contralateral nuclei rotundus. In the carbocyanine *in vivo* method, an 8- to 12-hour survival period is sufficient for *in vivo* labeling of the tectorotundal pathway. By embryonic day 8, labeled axons terminate in the ipsilateral nucleus rotundus and crossed tectorotundal projections can be first detected by embryonic day 10. Applying the cholera toxin B subunit *in vivo* method, heavily labeled axons can be found to bilaterally innervate the nucleus rotundus by embryonic day 8 after an initial 6- to 10-hour survival period. This appears to be the earliest time frame for detecting crossed-tectorotundal projection, compared with that of both the postfix and *in vivo* methods of employing carbocyanine dye. Based on the differences in the detectability of the crossed-tectorotundal projection between the

postfix and *in vivo* methods, such findings suggest that the former method is of limited benefit for labeling tectal collaterals during embryogenesis. Moreover, given the rapid transport rate and absence of photobleaching, which is often seen when using carbocyanine dye, the cholera toxin B subunit *in vivo* method appears to be the tracer of choice for investigating embryonic pathways.

Tracing developing pathways in the brain: A comparison of carbocyanine dyes and cholera toxin b subunit. Wu CC, Russell RM, Nguyen RT, Karten HJ. Neuroscience 2003; 117 (4), pp. 831–45.

Tourette's Syndrome (Tic Disorders) *Amphetamine/Dextroamphetamine/Haloperidol/Levamfetamine Succinate/Apomorphine/Piribedil/[^{11}C]-Raclopride*

Cellular/Molecular Mechanism of Action: Apomorphine is postulated to interact with presynaptic inhibitory dopamine receptors.

Background Information: Dopaminergic abnormalities in frontal-subcortical circuits have been hypothesized as the underlying pathophysiological mechanism involved in Tourette's syndrome.

Application: Administration of the agent is based on the hypothesis that presynaptic dopamine/catecholamine release (e.g. striatum) is abnormal in adults with Tourette's syndrome.

Implementation: Evaluation of conditions classified as Tourette's syndrome utilizing 2 positron emission tomography (PET) scans in combination with high specific activity [^{11}C]-raclopride. The first scan is performed after an intravenous injection of saline, while the second scan is made after intravenous amphetamine. The relative dopamine release is estimated as the percentage difference in binding potential between the postsaline and postamphetamine scans.

Interpretation and Analysis:

Nuclear Medicine Studies: Binding potential determined after initial [^{11}C]-raclopride scans do not significantly differ between Tourette's syndrome and control subjects. After amphetamine challenge, the mean value of intrasynaptic dopamine in the putamen (as determined by true equilibrium bolus estimations) increases by 21% in conditions of Tourette's syndrome and does not change in control subjects; the mean values increase by 16.9% and decrease by 1.8%, respectively (constrained method of measurement). Dopamine release in the caudate region is not significantly different with Tourette's syndrome and comparison subjects. Greater putamen dopamine release is seen in adults with Tourette's syndrome than in comparison subjects after a pharmacologic challenge with amphetamine. These results suggest that the underlying pathobiology in Tourette's syndrome is a phasic dysfunction of dopamine transmission.

Behavioral Studies: Both dextroamphetamine and levamfetamine increase the severity of the symptoms with dextroamphetamine being more potent in this regard. Haloperidol controls the symptoms and also antagonizes the effect of dextroamphetamine. Apomorphine injections reduce the severity of symptoms, even in the presence of dextroamphetamine. Therefore, dopamine rather than norepinephrine is the principal catecholamine responsible for observed symptoms. The effect of apomorphine may be understood through its action on postulated presynaptic inhibitory dopamine receptors or other presynaptic mechanisms of action.

Effects of dopamine agonists and antagonists in Tourette's disease. Feinberg M, Carroll BJ. Arch Gen Psychiatry 1979 Aug; 36 (9), pp. 979–85.

Trauma: Cell Reaction in Cerebral Cortex/ Chronological Staging of Traumatic CNS Injury *Beta-Amyloid Precursor Protein IgG/Microglia CD68 IgG*

Cellular/Molecular Mechanism of Action: Antigen-specific immunoglobulin physically binds in a selective manner to biological protein fractions they are designed to recognize.

Application: Detection and characterization of neuronal injury in conditions of brain trauma.

Route of Administration: Intravenous.

Implementation: Evaluate the potential to determine whether axonal injury (AI) induces a microglial reaction within 15 days after brain trauma. One investigative approach involves delineation of the topographical relation of AI and microglial reactions assessed using an immunohistochemical double-labeling technique for simultaneous demonstration of (i) axonal injury using beta-amyloid precursor protein (beta-APP) antibody; and (ii) microglia infiltration using CD68 antibody.

Human Model: Cases of confirmed axonal injury (n = 40).

Interpretation and Analysis: Although traumatic injury is usually followed by a moderate early and diffuse rise in the number of CD68-reactive cells in the white matter, increases in macrophages in areas of AI accumulation are only sporadic and do not occur until after 4 days. At survival intervals of 5 to 15 days a moderate microglial reaction in regions of beta-APP-positive injured axons can be detected, at maximum, in half of biological samples evaluated. During this interval AI-associated satellitosis-like clusters (described as stars in some reports) after a survival time of more than 7 weeks appear as isolated phenomenon. A prolonged microglial reaction as well as a reduction of beta-APP-positive AI during longer survival periods supports the hypothesis that AI is not primarily chemotactically attractive and that the injury to a portion of beta-APP-stained axons may be partly reversible. Most cases clearly require a prolonged interval of more than 15 days before initiation of the final scavenger reaction. For forensic purposes the increase in the number of microglial cells within the region of AI accumulation after a survival time of more than 5 days and the multiple and distinct demonstration of star-like microglial reactions within the white matter after survival times exceeding 7 weeks may provide valuable postmortem information on the timing of a traumatic event.

Is traumatic axonal injury (AI) associated with an early microglial activation? Application of a double-labeling technique for simultaneous detection of microglia and AI. Oehmichen M, Theuerkauf I, Meissner C. Acta Neuropathol (Berl) 1999 May; 97 (5), pp. 491–4.

Trauma: Cerebral Cortex Function Post Trauma/Stress Ulceration/Hypothalamic Injury *Thyrotropin-Releasing Hormone (TRH)/Gonadotropin-Releasing Hormone (GnRH)*

Background Information: In cases with severe head injury, hypothalamohypophysial impairment with subsequent hormone abnormalities has been well documented. Stress ulcers are another commonly encountered problem in such cases. However, little has been reported in the literature about the alterations of pituitary hormones in acute head-injured cases with stress ulcer.

Application: Detection and characterization of alteration in hypothalamic function secondary to cranial trauma reflected by modified responses to GnRH and TRH.

Implementation: Evaluation of basal serum levels of pituitary hormones measured before and in response to TRH and GnRH in order to measure pituitary function in conditions of cranial injury.

Human Model: Cases of cranial injury (n = 40 males). Candidate criteria for eligibility include (i) Glasgow coma scale 4 to 10; (ii) presentation within 24 hours following head injury; (iii) absence of shock or sepsis; and (iv) no past history of peptic ulcer. Stress ulcer is confirmed by endoscopic examination.

Interpretation and Analysis: Approximately two-thirds of cases show evidence of stress ulcer by endoscope examination (e.g., n = 27/40 or 67.5%). In the absence of stress ulcer, basal serum levels of thyroid-stimulating hormone (TSH), prolactin (PRL), growth hormone (GH), luetinizing hormone (LH), and follicle-stimulating hormone (FSH) are within normal range. However, the basal levels of PRL in conditions of stress ulcer are abnormally elevated and significantly higher than in the absence of stress ulcers ($p < 0.001$). Basal levels of TSH and GH are significantly lower with stress ulcer than in the absence of stress ulcers ($p < 0.001$). In conditions of stress ulcer, significant increases ($p < 0.001$) in serum TSH, PRL, LH, and FSH levels after TRH and GnRH provocation can be detected. Hypothalamohypophysial dysfunction and stress ulceration may occur in cases of severe cranial trauma. In the presence of stress ulcers, the abnormalities of pituitary hormones and provocative response of the pituitary to TRH and GnRH reveal normal pituitary function with hypothalamic insufficiency. Therefore, stress ulcers in acute head-injury cases is closely associated with hypothalamic damage.

Hypothalamic dysfunction in acute head-injured cases with stress ulcer. Hwang SL, Lieu AS, Howng SL, Hsieh JS, Huang TJ. Kaohsiung J Med Sci 1998 Sep; 14 (9), pp. 554–60.

Trauma/Intracranial Pressure Response/Cerebral Oxygen Consumption ($CMRO_2$) Response/ Arteriovenous Oxygen Difference ($AVDO_2$) Response/Neurologic Outcomes Prediction
Pentobarbital (Coma)

Physiological Mechanism of Action: Pentobarbital is a barbiturate that promotes depression of the central nervous system.

Application: Assessment and prediction of neurological outcome in cases of severe cerebral trauma.

Route of Administration: Pentobarbital (intravenous).

Implementation: Evaluate changes in cerebral hemodynamics in conditions of head-injury being managed with a barbiturate for refractory intracranial hypertension. Cerebral blood flow (CBF) and metabolism variables are measured at the following time periods: (i) before the loading dose of pentobarbital; (ii) after the loading dose of pentobarbital (average pentobarbital level 28.1 ± 8.3 μg/mL); and (iii) 3 days later, when the peak pentobarbital level averages 42.5 ± 17.2 μg/mL.

Human Model: Cases of severe head injury (n = 67).

Interpretation and Analysis: Intracranial pressure (ICP) and mean arterial blood pressure (MAP) decrease with loading doses of pentobarbital by an average of 12 and 9 mm Hg, respectively. Cerebral perfusion pressure (CPP) is usually unchanged following analysis of an entire group of cases. CBF, $CMRO_2$, and arteriovenous oxygen difference ($AVDO_2$ O_2) are significantly decreased after a loading dose of pentobarbital, by 20%, 31%, and 11%, respectively. The average cerebrovascular resistance (CVR) is increased by 20%. The change in $CMRO_2$ with loading doses of pentobarbital is closely related to pretreatment measurements ($n = 67$, $r^2 = 0.65$, $p < .001$). Slightly less than half of cases have a "good ICP response," with a reduction in ICP from 34 ± 9 to 15 ± 5 mm Hg after an initial loading dose of pentobarbital (n = 30/67 or 45%). In addition, a relatively large percentage of cases will have a "partial ICP response," with ICP decreasing but still remaining above 20 mm Hg after a loading dose of pentobarbital (n = 27/67 or 40%). Approximately 15% of cases have an ICP that does not change or even increase after pentobarbital (n = 10/67). In situations of a good ICP response, pretreatment $CMRO_2$ and $AVDO_2$ are usually greater before administration of pentobarbital, while $CMRO_2$ and $AVDO_2$ decrease more with loading doses of pentobarbital (n = 30/67 cases) than in conditions with partial or no ICP response. Outcomes are significantly better when a good or partial ICP response is observed following pentobarbital, with 21% of these cases having a good recovery or moderate disability at 3 months after injury, compared with 100% persistent vegetative state or death in cases classified as non-responders. Therefore, barbiturate coma can be a useful treatment modality for acutely reducing ICP in selected cases. Conditions with overwhelmingly severe injuries are not likely to benefit, partly because their $CMRO_2$ is already markedly reduced by injury and partly because their outcome is already predetermined by the injury. Cases with systemic hypotension are not likely to have a good response because hypotension limits the amount of barbiturates that can be given.

Cerebral hemodynamic effects of pentobarbital coma in head-injured cases. Cormio M, Gopinath SP, Valadka A, Robertson CS. J Neurotrauma 1999 Oct; 16 (10), pp. 927–36.

Trauma: Neuroemergency Procedures/Growth Hormone Response to TSH/Prolactin Response to GHRH/Prediction of Unfavorable Neurologic Outcome (Prognosis)
Hypothalamic Releasing Hormones/Thyroid-Stimulating Hormone (TSH)/Growth Hormone-Releasing Hormone (GHRH)

Application: Evaluate the effect of severe head injury on both the secretion of basal pituitary hormones and the response to exogenous synthetic hypothalamic releasing factors administration.

Route of Administration: Intravenous.

Implementation: Evaluation of daily basal concentrations of growth hormone (GH), prolactin (PRL), TSH, triiodothyronine, and thyroxine during the first week following CNS trauma and then again on days 15 and 16 posttrauma. Plasma insulin-like growth factor-I and cortisol can also be determined on days 2, 7, and 15. Administration of TRH (TRH test) can be applied to evaluate PRL, TSH, and GH responses on days 1 and 16 after a traumatic incident and a GHRH test for the evaluation of GH and PRL responses on days 2, 7, and 15 posttraumatic incident. Outcomes are evaluated at 6 months with the GOS.

Human Model: Cases of head-injury-induced coma (n = 22) all requiring intubation and mechanical ventilation in addition to invasive monitoring. Each case has no previous endocrinologic problems or substitutive therapies.

Interpretation and Analysis: Triiodothyronine shows low values, even if they are within the normal range, while thyroxine remains within the normal range. Significant increases in insulin-like growth factor-I concentrations are both observed on days 7 and 15 compared with day 2 ($p = .024$ and $p = .034$, respectively). The GH response to GHRH is significantly greater on days 7 and 15 than in the very acute phase ($p < 0.01$ comparing days 7 and 15 vs day 2). Higher GH responses to GHRH can be observed on day 7 in Case Group 1 compared to Case Group 2 (pertaining to both peak and

area-under-the-curve values, $p = .018$ and $p = .015$, respectively). No difference in GH response can be detected on days 2 and 15. A "paradoxical" response of GH to TRH can be observed on the day following head trauma (basal vs peak, $p = .002$) but not on day 16. The GH peak response to TRH is greater on day 1 in cases with an unfavorable clinical course (Group 1 vs Group 2, $p < 0.05$). The TSH response to TRH does not significantly correlate to the severity of trauma, but is significantly ($p < 0.04$) higher in Group 1 cases than in Group 2 cases. Finally, a "paradoxical" PRL response to GHRH administration is present on day 2 (basal vs peak, $p = 0.0003$), day 7 (basal vs peak, $p = .01$), and on day 15 after the trauma (basal vs. peak, $p = 0.04$). Some of the responses to provocative tests have been identified as "paradoxical" and seem to have a great importance in the definition of prognosis in severe head-injury cases, specifically the GH response to TRH and the PRL response to GHRH that are significantly correlated with outcome.

Provocative hypothalamopituitary axis tests in severe head injury: Correlations with severity and prognosis. Della Corte F, Mancini A, Valle D, Gallizzi F, Carducci P, Mignani V, De Marinis L. Crit Care Med 1998 Aug; 26 (8), pp. 1419–26.

Trophic Dependencies (Corticospinal Neuron)/ Response to Pathological Lesions and Therapeutic Agents
Fast Blue

Application: Evaluation of the response of corticospinal neurons (CSN) of the sensory motor cortex to lesions and therapeutic drugs.
Implementation: Before induction of lesions, CSN are retrograde-labeled with fast blue (FB). A stereotaxic cut lesion through the entire internal capsule (ICL) is used to axotomize the CSN. The extent of axotomy is determined by the application of a control tracer.

Animal Model: Rat and mouse (lesion model for the induction of death of analogous populations of CSN in rodent species).
Interpretation and Analysis: In both rodent species, FB-labeled CSN are localized in 3 major areas: (i) the sensory motor cortex; (ii) the supplementary motor and medial prefrontal cortex; and (iii) the somatosensory cortex. The ICL does not lead to complete axotomy of CSN of the rat and mouse somatosensory cortex. In rats, ICL results in complete axotomy of the CSN of the sensory motor cortex and incomplete axotomy of the caudal portion of the supplementary motor and medial prefrontal cortex. In mice, the area of axotomized CSN extends significantly further frontally. In both species, axotomy-induced death of CSN is observed in the center of the sensory motor cortex. This lesion model is useful for investigations on the response of CSN of the sensory motor cortex to pathological lesion and therapeutic drugs.

An axotomy model for the induction of death of rat and mouse corticospinal neurons *in vivo*. Bonatz H, Rohrig S, Mestres P, Meyer M, Giehl KM. J Neurosci Methods 2000 Jul 31; 100 (1–2), pp. 105–15.

Vascular Perfusion/Arteriovenous Malformation: Anterior Spinal Artery/Neurologic Function Evaluation: Arteriovenous Malformation Pre-Embolization/Embolization of Vessels: Ivalon and Polyvinyl Alcohol
Xylocaine

Physiological Mechanism of Action: Xylocaine functions as a local anesthetic.
Background Information: Spinal arteriovenous malformations (spinal AVMs) are now treated using microcatheters and various embolic materials. Interventional techniques of this type are thought to be the 1st choice for treatment of spinal AVMs.
Application: Xylocaine can be applied to preassess the potential development of neurological/cognitive deficits that may be created during arteriovenous malformation embolization procedures.
Route of Administration: Xylocaine (selective intravascular).
Dosage: Xylocaine (20 mg in bolus).
Implementation: Evaluation of CNS arteriovenous malformations using xylocaine and intermittent intravascular pressure monitoring within the anterior spinal artery conducted during embolization procedures of intramedullary arteriovenous malformations ($n = 5$). Intravascular pressure monitoring can be performed via a microcatheter located within the anterior spinal artery. Vascular embolization procedures may utilize Tracker vascular access systems and MAGIC catheters for intravascular treatment of spinal AVMs in order to avoid proximal occlusion. Effective embolic materials designed for this purpose include polyvinyl alcohol (PVA) particles (ivalon: 150–350 microns) and/or PVA solutions. Vital signs and neurologic functions are carefully monitored during and after the procedure.

Human Model: Cases of intramedullary arteriovenous malformations ($n = 5$ AVMs).
Interpretation and Analysis: In many cases, it is possible to totally to obliterate the nidus or markedly reduce its size while preserving the anterior spinal artery. The xylocaine test can be conducted on multiple occasions during embolization procedures (e.g., $n = 2/6$). In cases treated with ivalon and PVA solutions, the final provocation test may become positive, thereby necessitating termination of embolization procedures (e.g., $n = 2/5$ cases). In the remaining cases, a positive result may be appreciated on the first xylocaine test (e.g., $n = 3/5$), thereby allowing treatment with ivalon alone. Measurements of the intravascular systolic pressure prior to embolization are approximately 71.6 ± 14.1 mm Hg and they gradually increase during the procedure, reaching 99.6 ± 12.6 mm Hg (90% of the systemic systolic blood pressure) by the conclusion of embolization procedures. Serial xylocaine tests and intravascular pressure monitoring may be useful for the treatment of spinal AVMs fed mainly by the anterior spinal artery, and embolization with liquid embolic material should be terminated when the provocation test becomes positive and intravascular pressure increases to 90% of the systemic blood pressure.

Intravascular treatment of spinal arteriovenous malformations using a microcatheter—with special reference to serial xylocaine tests and intravascular pressure monitoring. Touho H, Karasawa J, Ohnishi H, Yamada K, Ito M, Kinoshita A. Surg Neurol 1994 Aug; 42 (2), pp. 148–56.

Vascular Perfusion: Arteriovenous Malformations (Cerebral/Spinal)/Safety Evaluation Prior to Vascular Embolization
Amobarbital

Physiological Mechanism of Action: Amobarbital is a central nervous system depressant (barbiturate agent).
Background Information: Transarterial embolization of cerebral arteriovenous malformations (AVMs) has been associated with postprocedural neurologic complications in 7 to 39% of cases.
Application: Assessement of the potential for creating premature neurological or cognitive deficits as a sequelae of selective AVM embolization.
Route of Administration: Sodium amobarbital (superselectively delivered into an intravascular microcatheter position within AVM lesions).

Dosage: Sodium amobarbital (50-mg bolus).
Implementation: Evaluation of a method for assessing the potential neurologic and cognitive deficits that may develop as a consequence of permanent AVM embolization procedures in order to reduce the incidence of undesirable side effects. In this context, the clinical profile of AVM conditions are reviewed prior to and after vascular embolization procedures. Each case is assessed applying a battery of tests individually tailored to each of their specific capabilities using stimuli selected from standard and experimental cognitive tests to probe specific brain regions related to the location of CNS AVM lesion. In each feeder vessel to be embolized, a sodium amobarbital bolus is superselectively administered through a microcatheter, followed immediately by neurologic and cognitive testing with the tailored battery of test evaluations. After testing, the position of the microcatheter tip is checked by fluoroscopy. If the provocative test results are negative, the vascular feeder branch of interest is subsequently embolized with N-butyl cyanoacrylate glue.

Human Model: Cases of AVM (n = 12).
Interpretation and Analysis: A relatively large percentage of provocative amobarbital injections may be negative (e.g., n = 27/29). During the course of some injection trials, deficits in cognitive function may be appreciated during tailored provocative testing (e.g., n = 2/29, n = 2 injections in n = 2 individuals). In the vast majority of these cases, evoked cognitive deficits resolve with dissipation of the amobarbital effect (e.g., n = 2/29), thereby negating the necessity for embolizing of the feeder vessels. In cases determined to have no cognitive deficits after superselective amobarbital delivery, there are almost invariably no major or minor neurologic or cognitive deficits after vascular embolization (e.g., n = 0/27). Therefore, provocative amobarbital testing prior to AVM embolization appears to be helpful in identifying vascular territories where embolization may lead to neurologic and cognitive deficits.

Tailored cognitive testing with provocative amobarbital injection preceding AVM embolization. Moo LR, Murphy KJ, Gailloud P, Tesoro M, Hart J. AJNR Am J Neuroradiol 2002 Mar; 23 (3), pp. 416–21.

Vascular Perfusion: Arteriovenous Malformations (Cerebral/Spinal)/Safety Evaluation Prior to Vascular Embolization
Lidocaine/Amobarbital

Cellular/Molecular Mechanism of Action: Lidocaine disrupts the Na^+/K^+ pump in a manner that inhibits membrane depolarization events.
Physiological Mechanism of Action: Lidocaine functions as a local anesthetic. Amobarbital functions as a central nervous system depressant.
Application: A modified provocative test for assessing the safety of embolization of cerebral and spinal arteriovenous malformations.
Route of Administration: Intravascular (selective catheterization for delivery).
Implementation: The modified test uses successive amobarbital and lidocaine injections to elicit any possible neurological deficit, both mixed with radiopaque material to visualize the distribution of the anesthetic within the lumen of the vascular tree.

Human Model: Cases classified as candidates for embolization of arteriovenous malformations (n = 27).
Interpretation and Analysis: The modified provocative test causes a very low rate of false negative results (e.g., n = 0/11) compared to approximately 23% false negatives when the unmodified method is applied (e.g., n = 6/27).

Improved provocative test for the embolization of arteriovenous malformations—technical note. Sadato A, Taki W, Nakahara I, Nishi S, Yamashita K, Matsumoto K, Tanaka M, Kikuchi H. Neurol Med Chir (Tokyo) 1994 Mar; 34 (3), pp. 187–90.

Vascular Perfusion (Cerebral): Carotid Stenosis (Asymptomatic)/Cerebrovascular Reserve Capacity/Hemispheric Ischemia/Vertebrobasilar Ischemia
Acetazolamide

Background Information: Regional cerebral blood flow reduction can be measured with cerebrovascular imaging (CVI) using [^{99m}Tc]-HMPAO-SPECT.
Application: Acetazolamide can be used as a provocative test agent to improve the diagnostic accuracy of cerebral vascular imaging procedures.
Dosage: Acetazolamide (1 gram).
Implementation: Evaluation of cerebral vascular blood flow abnormalities.

Human Model: Cases with suspected regional cerebral blood flow alterations (n = 84).
Interpretation and Analysis: Acetazolamide can facilitate differentiation between hemispheric (87%) and vertebrobasilar ischemia (64%) by revealing marked increases in sensitivity to provocative tests with acetazolamide. In approximately 62% of high grade but asymptomatic carotid stenoses, a hemodynamic effect can be demonstrated with acetazolamide, thereby justifying correction of vascular anomalies by surgical intervention.

Correlative assessment of hemodynamic parameters obtained with T2*-weighted perfusion MR imaging and SPECT in symptomatic carotid artery occlusion. Kim JH, Lee SJ, Shin T, Kang KH, Choi PY, Kim JH, Gong JC, Choi NC, Lim BH. AJNR Am J Neuroradiol 2000 Sep; 21 (8), pp. 1450–6.

A study of acetazolamide-induced changes in cerebral blood flow using ^{99m}Tc HMPAO SPECT in cases with cerebrovascular disease. Asenbaum S, Reinprecht A, Brücke T, Wenger S, Podreka I, Deecke L. Neuroradiology 1995 Jan; 37 (1), pp. 13–9.

Vascular Perfusion: Cerebral Cortex/Induced Left Temporal Cerebral Blood Flow/Induced Left Frontal Cortex Cerebral Blood Flow/Induced Right Hippocampus and Adjacent Cortex: Glucose Metabolic Rate
N-(4-Acetyl-1-Piperazinyl)-p-Fluorobenzamide

Cellular/Molecular Mechanism of Action: *N*-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate (FK960) selectively increases somatostatin release from the hippocampus. Some reports have also described an ability for FK960 (100nM) to increase mRNA and protein levels of glial cell line-derived neurotrophic factor (GDNF).
Physiological Mechanism of Action: *N*-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate (FK960) is a putative antidementia drug that modifies regional cerebral blood flow (rCBF) and regional cerebral metabolic rate of glucose (rCMRglc). Additional functions include an ability to augment long-term potentiation (LTP) in the CA3 area of the hippocampus.
Application: Anti-dementia agent.
Route of Administration: N-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate (FK960: intramuscular).
Dosage: N-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate (FK960: dose = 0, 0.01, 0.1, or 1 mg/kg for 7 consecutive days).

Implementation: Evaluation of the effect of N-(4-acetyl-1-piperazinyl)-*p*-fluorobenzamide monohydrate (FK960) on rCBF and rCMRglc facilitated by the use of positron emission tomography. Each subject is scanned a total of 4 times at ≥ 3-week intervals, after treatment with saline or 3 doses of FK960.

Animal Model: Rhesus macaques (n = 7 aged males; 21.6 ± 2.7 years).

Interpretation and Analysis: Significant increases in rCBF within the left temporal and left frontal cortex, and in rCMRglc within the right hippocampus with adjacent cortex, can be detected for FK960 at the dosage of 1 mg/kg, without affecting any other cardiovascular and respiratory variables. No statistically significant change in any region can be observed at doses of 0.01 or 0.1 mg/kg. These results suggest that FK960 restores rCBF and rCMRglc deficits in brain areas responsible for cognitive functioning (aged rhesus macaques).

Effect of N-(4-Acetyl-1-piperazinyl)-p-fluorobenzamide monohydrate (FK960), an antidementia drug with a novel mechanism of action, on regional cerebral blood flow and glucose metabolism in aged rhesus macaques studied with positron emission tomography. Noda A, Takamatsu H, Matsuoka N, Koyama S, Tsukada H, Nishimura S. J Pharmacol Exp Ther 2003 Jul; 306 (1), pp. 213–7. Epub 2003 Apr 3.

Vascular Perfusion/ Cerebral Cortex: Dural Arteriovenous Fistulas/ Altered Vascular Integrity/ Dural Arteriovenous Fistulas/ Preserved Vasoreactivity: Good Prognosis/SPECT/ Acetazolamide: Hypoperfusion/Venous Infarction/Persistent Symptoms
Acetazolamide

Cellular/Molecular Mechanism of Action: Acetazolamide functions as a carbonic anhydrase inhibitor.

Physiological Mechanism of Action: Acetazolamide can promote antiseizure activity and prevent absence seizures.

Background Information: Dural arteriovenous fistulas (DAVFs) with disturbed regional cerebral blood flow (rCBF) including retrograde leptomeningeal venous drainage (RLVD).

Application: Acetazolamide can be used as an adjuct diagnostic probe applied in conjuction with SPECT to charactize conditions of dural arteriovenous fistulas in a manner that can detect preservation or alterations in vasoreactivity that can correspond with either a good prognosis or evidence of venous infarction and persistence of symptoms.

Implementation: Characterization of pretreatment MRI/SPECT and posttreatment MRI/SPECT symptoms and response to therapeutic intervention in conditions of DAVFs with disturbed rCBF.

Human Model: Cases with DAVFs, disturbed rCBF, and various symptoms (n = 22). Case Group 1 = retrograde leptomeningeal venous drainage (RLVD) into more than 1 venous sinus (n = 11/22 cases); and Case Group 2 = RLVD into a single venous sinus (n = 11/22 cases).

Interpretation and Analysis: In Case Group 1, preoperative T2-weighted MR images show no hyperintense areas, and angiographic images display evidence of blood flow into more than 1 venous sinus. Case Group 2 cases display preoperative SPECT with hypoperfused areas that coincide with hyperintense areas on T2-weighted MR images. Following treatment, hyperintense areas disappear, and symptoms improve in a large number of these cases (e.g., n = 7/11 = Case Group 2a), and their preoperative SPECT studies demonstrate preservation of vasoreactivity after acetazolamide challenge. In Case Group 2b, the hyperintense areas and symptoms persist in response to acetazolamide challenge (n = 4/11 cases) and reoperative SPECT studies reveal marked disturbances of vasoreactivity. Hyperintense MR images are consistently observed in cases with drainage into a single venous sinus. Hypoperfusion on SPECT scans apparently reflects venous congestion, whereas unpreserved vasoreactivity after an acetazolamide challenge on SPECT scans reflects venous infarction. The preservation of vasoreactivity after the challenge appears to be a good prognostic indicator.

Pre- and posttreatment MR imaging and single photon emission CT in cases with dural arteriovenous fistulas and retrograde leptomeningeal venous drainage. Kai Y, Hamada J, Morioka M, Todaka T, Mizuno T, Ushio Y. AJNR Am J Neuroradiol 2003 Apr; 24 (4), pp. 619–25.

Vascular Perfusion/Cerebral Cortex/Arterial Resistance and Dilation
Adenosine

Cellular/Molecular Mechanism of Action: Intracarotid infusion of short-acting vasodilators, such as adenosine and nitroprusside, in doses that lack significant systemic side effects, may permit controlled manipulation of cerebrovascular resistance. In this experiment we assessed changes in cerebral blood flow (CBF) after intracarotid infusion of nitroprusside and adenosine.

Application: Increase arterial dilation in conditions of excessive vasoconstriction of the cerebral arteries.

Implementation: Evaluation of CBF using intra-arterial [^{133}Xe] 4 times during infusions of (i) saline (intravenous); (ii) phenylephrine (intravenous 0.2 μg/kg/min^{-1}) with the intent of increasing mean arterial pressure by 10–15 mm Hg; (iii) phenylephrine intravenous and intracarotid nitroprusside (0.5 μg/kg/min); and (iv) intracarotid adenosine (1 mg/min). Note: Hypotension during nitroprusside injection is avoided by delivery through the intracarotid route of administration (tests for autoregulatory vasoconstriction).

Animal Model: Non-human primate (n = 6 adult baboons) anesthetized under isoflurane anesthesia and controlled ventilation.

Interpretation and Analysis: Intravenous phenylephrine increases mean arterial pressure (69 ± 8 to 91 ± 9 mm Hg, $p < 0.0001$, n = 6), and concurrent infusion of intracarotid nitroprusside reverses such alterations. However, compared with baseline, CBF does not change with phenylephrine (IV) or with concurrent infusions of phenylephrine (IV) and nitroprusside (intracarotid). Intracarotid adenosine profoundly increases CBF (from 29 ± 8 to 75 ± 32 mL/100 g/min; $p < 0.0001$). In non-human primates, intracarotid adenosine increases CBF in doses that lack significant systemic side effects, whereas intracarotid nitroprusside has no effect. Intracarotid adenosine may be useful for manipulating cerebrovascular resistance and augmenting CBF during conditions of cerebral ischemia. Intra-arterial [^{133}Xe] CBF measurements suggest that intracarotid adenosine, in a dose that lacks significant systemic side effects, profoundly increases CBF, whereas nitroprusside has no effect.

In nonhuman primates intracarotid adenosine, but not sodium nitroprusside, increases cerebral blood flow. Joshi S, Duong H, Mangla S, Wang M, Libow AD, Popilskis SJ, Ostapkovich ND, Wang TS, Young WL, Pile-Spellman J. Anesth Analg 2002 Feb; 94 (2), pp. 393–9.

BRAINSTEM, SPINAL CORD, AND PERIPHERAL NERVOUS SYSTEM

Myasthenia Gravis (MG)
Edrophonium (Tensilon)

Cellular/Molecular Mechanism of Action: Exerts a direct inhibitory effect on cholinesterase activity somewhat analogous to organophosphate insecticides. As a result, concentrations of acetyl-

choline begin to accumulate within the synaptic cleft thereby enhancing the amount of the neurotransmitter binding to it's corresponding receptor complex located on the post-synaptic membrane (e.g. motor end-plate) In MG cases, increased availability of acetylcholine neurotransmitter created by inhibitors of acetylcholine esterase compensates for the competitive inhibition of acetylcholine receptor complexes by bound IgG antibodies produced by aberrant autoimmune humoral immune response.

Considerations: Since the response is highly variable, signs of weakness in addition to over-stimulation of parasympathetic muscarinic receptor sites may develop, resulting in the appreciation of clinical signs including salivation, miosis, vomiting, and diarrhea (cholinergic crisis).

Diagnostic Application: Congenital and acquired MG.

Route of Administration: Edrophonium (intravenous)

Dosage: Edrophonium (0.5 to 5.0 mg).

Implementation: Evaluation and characterization of suspected cases of congenital or acquired MG.

Interpretation and Analysis: Correction of exercise intolerance conditions that last a duration of 2 to 3 minutes supports the diagnosis of MG. Response is widely variable, which prevents recommendation of a specific dose regimen. If the capacity to perform physical activity is not restored, a higher dosage can be administered in a matter of just a few minutes.

Approach to generalized weakness and peripheral neuromuscular disease. LoVecchio F, Jacobson S. Emerg Med Clin North Am 1997 Aug; 15 (3), pp. 605–23.

Myasthenia Gravis (MG)
Edrophonium/Neostigmine/Pyridostigmine/ Vecuronium

Cellular/Molecular Mechanism of Action: Edrophonium (acetylcholinesterase inhibitor that binds selectively to the biochemically active site of the enzyme). Alternatively neostigmine (cholinesterase inhibitor) and pyridostigmine (carbamate cholinesterase inhibitor: charged quaternary compound) contain carbamyl ester linkages that are directly hydrolyzed by acetylcholine esterase. Vecuronium (congener of pancuronium), is a *bis*-quaternary ammonium steroid that is 5 times more potent than *d*-tubocurarine as a neuromuscular blocking agent but inhibits plasma butyrylcholinesterase to a lesser degree than pancuronium so that less cardiovascular side effects are produced.

Application: Detection and characterization of cases affected by MG that are hypersensitive to nondepolarizing neuromuscular blocking drugs. Vecuronium can be applied in ocular tests for the detection of cases suffering from myasthenia gravis.

Edrophonium: Edrophonium chloride 2 mg IV followed in 45 seconds by another dose of 8 mg if no improvement is observed. Excessive doses should be avoided in order to avoid weakness from generalized depolarization of motor end plates.

Oral Test: Neostigmine (7.5 mg); pyridostigmine (30 mg); or ambenonium (2.5 mg). Signs for improvement in neuromuscular strength are monitored. In an hour, the dose is then increased 1.5-fold and repeated until a desired effect is achieved. Results can be confirmed with the edrophonium test.

Intravenous Test: Neostigmine (0.125 mg) or pyridostigmine (0.5 mg) administered at intervals of several minutes. Atropine (0.4 to 0.6) is given prior to the initiation of the test to prevent muscarinic side effects. The optimal oral dose is equivalent to 30-fold the intravenous dose that achieved the desired level of effect.

Vecuronium and General Anesthesia: [10 μg/kg intravenously under general anesthesia with sevoflurane (2.5%) and nitrous oxide (60%) in oxygen]. Neuromuscular transmission is measured as twitch tension of the adductor pollicis muscle with supramaximal stimulation measurements serving as an evaluation parameter. Following the recording of baseline measurements, incremental doses of vecuronium (10 μg/kg IV) are administered sequentially until a 90% blockade is exceeded. The degree of blockade and onset time after the initial 10 μg/kg dose of vecuronium are assessed, and the dose required to exceed 90% blockade recorded. In addition, effective doses of 50% and 95% for vecuronium are calculated from a single data point.

Considerations: A diagnosis can usually be obtained from history, presenting complaint, and physical examination, but its differentiation from neurasthenic, infectious, endocrine, neoplastic, or degenerative neuromuscular disease states may be difficult. Provocative testing with an anticholinesterase pharmaceutical agent results in a drastic improvement in conditions of myasthenia gravis.

Although antibodies to the acetylcholine receptor (AChR) often are observed in MG cases, 10% to 30% of cases do not show an anti-AChR antibody.

In childhood cases of MG, the majority (e.g., 92%, n = 25/27) have localized ocular myasthenia with a median onset of symptoms appreciated at 33 months of age. Approximately 24% of cases progress to generalized myasthenia gravis. A few (8%) may present with respiratory failure that require ventilatory support with an onset of symptoms being appreciated at about 22 months. Thymectomy (n = 10/27 cases) has been used as a atherapeutic intervention strategy which is associated with approximately 70% complete, and a 26% partial remission rates when applied in combinatinon with immunosuppressant therapy (e.g. azathioprine), and a cholinesterase inhibitor (e.g. pyridostigmine). The development of a myasthenic crisis is relatively infrequent when cases are properly managed with appropriate therapy and follow-up monitoring.

Interpretation and Analysis: Agents should produce a relatively immediate (dramatic) improvement in clinical signs. Seronegative and seropositive MG cases are equally sensitive to vecuronium compared with unaffected negative reference control cases.

The effect of use of pyridostigmine and requirement of vecuronium in cases with myasthenia gravis. Tripathi M, Kaushik S, Dubey P. J Postgrad Med 2003 Oct–Dec; 49 (4), pp. 311–4; discussion 314–5.

Myasthenia Gravis (MG)
Edrophonium/[Esophogeal Function Screening Test]

Cellular/Molecular Mechanism of Action: Edrophonium is a short-acting acetylcholinesterase inhibitor.

Background Information: Myasthenia gravis is an autoimmune disease in which impairment of neuromuscular transmission results in pathological fatigability of striated muscles. Dysphagia is a common MG symptom. It is caused by a weakness of the striated muscles in the pharynx and esophagus.

Dosage: Edrophonium chloride (EC; 10 mg).

Implementation: Evaluate the role of esophageal scintigraphy in the assessment of esophageal function in MG aided by provocative testing with edrophonium. In this context, esophageal transit time is measured in concert with the use of a multiple swallow test protocol. Cases are studied first under baseline conditions, and then immediately after pharmacological stimulation with edrophonium.

Human Model: Cases of clinically proven myasthenia gravis (n = 15; n = 6/15 oculopharyngeal manifestations; n = 9/15 generalized weakness; n = 10/15 history of dysphagia.)

Interpretation and Analysis: Under baseline conditions all MG cases display impaired esophageal function (emptying = 58% ± 21; normal range > 85%). In a large percentage of cases (e.g. n =

14/15) esophageal transit improves after the administration of EC (emptying = 75% ± 18; $p < 0.01$), with measurements reaching the normal range in approximately 40% of cases (e.g. n = 6/15). Some cases may show no effect attributable to EC (e.g., n = 1/15). Esophageal transit is often compromised in MG. Functional abnormalities may also be present in cases without a history of dysphagia. Inhibition of cholinesterase positively affects striated muscles in the pharynx and upper esophagus, thus improving esophageal transit. Esophageal scintigraphy may be a simple, non-invasive method for diagnosing impairment of esophageal function in MG and to monitor changes under pharmacological stimulation.

Assessment of esophageal function in cases with myasthenia gravis. Linke R, Witt TN, Tatsch K. J Neurol 2003 May; 250 (5), pp. 601–6.

Myasthenia Gravis (MG)
Vecuronium

Cellular/Molecular Mechanism of Action: Vecuronium is an acetylcholinesterase enzyme inhibitor which promotes the accumulation of acetylcholine neurotransmitter within the synaptic cleft thereby increasing binding to and activation of acetylcholine receptor complexes.
Background Information: Conditions of MG are hypersensitive to non-depolarizing neuromuscular blocking drugs. Although antibodies to the acetylcholine receptor (AChR) often are observed in MG, 10% to 30% of affected cases do not show an anti-AChR antibody. Little is known about differences in sensitivity to non-depolarizing neuromuscular blocking drugs between MG cases with and without anti-AChR antibody.
Application: Determination if seronegative MG cases are as sensitive to vecuronium as seropositive MG cases.
Route of Administration: Vecuronium (intravenous).
Dosage: Incremental doses of vecuronium (10 μg/kg) during anesthesia with sevoflurane (2.5%) and nitrous oxide (60%) in oxygen.
Implementation: Evaluation of the potential differential effect of vercuronium between sero-positive and sero-negative MG conditions. Measurement and monitoring of neuromuscular transmission can be achieved by assessing twitch tension of the adductor pollicis muscle with supramaximal stimulation. After baseline measurements, 10 μg/kg IV dose increments of vecuronium are administered sequentially until blockade exceeds 90%. The degree of blockade and onset time after the initial 10 μg/kg of vecuronium is assessed, and doses required to exceed 90% blockade recorded. In addition, effective doses of 50% and 95% for vecuronium are calculated from a single data point.
Interpretation and Analysis: Both types of MG cases show increased sensitivity to vecuronium compared with non-MG cases. Therefore, seronegative and seropostive MG conditions are equally sensitive to vecuronium administration.

Vecuronium in the myasthenic patient. Hunter JM, Bell CF, Florence AM, Jones RS, Utting JE. Anaesthesia 1985 Sep; 40 (9), pp. 848–53.

Myasthenia Gravis/Ileus: Postoperative
Neostigmine

Cellular/Molecular Mechanism of Action: Inhibits biochemical activity of acetylecholine esterase, resulting in accumulation of acetylcholine neutrotransmitter. As a result, an elevated level of parasympathetic activity is created within the autonomic nervous system.
Diagnostic Application: (i) Verification of the presence of normal gastrointestinal function pertaining to parasympathetic innervation and smooth muscle integrity that are usually intact in conditions such as postoperative and pain-induced ileus. (ii) Diagnostic detection of myasthenia gravis conditions.
Route of Administration and Dosage: Subcutaneous injection is preferred.
Considerations: Rapid intravenous injection can promote spastic (painful) contractions of gastrointestinal smooth muscle. Administration in cases suffering from myasthenia gravis can exacerbate the severity of the condition through depletion of axonal acetylcholine stores.
Interpretation and Analysis: Alleviation of gastrointestinal ileus based upon detection of auscultatable borborygmi, palpable contractions, and visualization of fecal production. Myasthenia gravis cases will temporarily demonstrate an improvement in generalized motor function and a reduction in the severity of apparent paresis.

Respiratory Center Depression/Brain Stem Suppression vs Primary Pulmonary Dysfunction
Doxopram (Dopram)

Cellular/Molecular Mechanism of Action: Doxopram directly stimulates the central respiratory centers located in the reticular formation of the brainstem.
Diagnostic Application: Increases respiratory function (respiration) through direct stimulation of the brainstem respiratory center.
Route of Administration and Dosage: Intravenous injection.
Application: Differentiation between reversible suppression of central brainstem respiratory center function and primary respiratory (pulmonary) function or pathology as a cause for subnormal arterial blood oxygen levels (e.g., blood gas analysis of premature neonates).
Interpretation and Analysis: Subnormal blood oxygen concentrations attributed to primary pulmonary dysfunction may not be fully corrected by coxopram administration.
Laboratory Instrumentation: Evaluation of respiratory rate, in concert with measurement of arterial blood oxygen and carbon dioxide concentrations.

Spinal Cord/Characterization of Anatomical Morphology
Ipomiadol/Metrizamide/Renagrafin

Cellular/Molecular Mechanism of Action: The active moiety of radiographic contrast dyes is iodine because it strongly absorbs x-ray photons (radiodense properties).
Diagnostic Application: Radiographic contrast dyes are injected directly into the cerebral spinal fluid (CSF) space for the purpose of imaging anatomical features of the vertebral spinal cord.

Additional diagnostic applications include infiltration of chronic draining tracts in an effort to detect their extent, and/or presence, location, or position of foreign body objects.
Route of Administration and Dosage: One of the most common sites for injection is the atlanto-occipital (AO) space. The cerebral spinal needle is directed toward the lower mandible while the head and neck are flexed ventrally. Advancing the cerebral spinal needle with the head and neck held in such a position avoids or minimizes the risk of directing the spinal needle through the foramen magnum and into neural tissues of the CNS (e.g., cerebellum). To promote flow of radiographic contrast dyes distally along the spinal

cord, the head, neck, and cranial thorax can be held on a raised (flat but not horizontal) plane.

Techniques have been described for the injection of radiographic contrast dyes into the CSF at the level of the lumbosacral space, and less frequently the vertebral foramen. The latter method is technically difficult to perform in large animal species and may require careful interpretation of specialized imaging modalities (e.g. fluoroscopy, NMR, or CT-scan).

Direct infusion or catherization techniques are applied for the instillation of radiographic dyes into chronic draining tract lesions.

Considerations: Metrizamide-based contrast dye reagents can potentially induce seizure activity due to their ability to competitively inhibit glucose metabolic pathways that are CNS associated. Based upon the known mechanism of action, this complication can be avoided by preadministering intravenous glucose (dextrose 5%), in addition to maintaining the head and neck in a flat elevated plane in order to promote flow to more distal segments of the vertebral spinal cord. Newer generation radiographic contrast dye reagents such as ipomiadol are much less likely to interfere with CNS glucose metabolism compared to older generation contrast dye reagents such as metrizamide.

Interpretation and Analysis: Radiographic contrast dyes assist in detecting space-occupying lesions that may physically be impinging on the cervical, thoracic, lumbar, and sacral segments of the spinal cord. Lesions of this type are detected by appreciating a narrowing or obstruction of radiographic dye "column" within the CSF space surrounding the spinal cord.

Environmental Implications: Iodinated contrast media belong to the most frequently applied compounds in medicine. They exhibit a high polarity and are very persistent against metabolism by the organism and environmental degradation. A sensitive method for the determination of 5 iodinated contrast media in aqueous matrices has been described. Solid phase extraction utilizing isolute ENV+ material has been used for sample enrichment. The contrast media are partially separated on an RP-C18 column, and detection achieved using electrospray-tandem MS (API III plus and API 365), allowing the sensitive quantitation of these compounds down to the lower ng/L range. The recovery rates generally exceeded 70%, for spiked surface water as well as tap water. The analytes can be detected in native samples such as municipal sewage treatment plant effluent, the river Rhine, and even in tap water.

SPECIAL SENSES

Cataracts and Idiopathic Macular Hole/Circular Curvilinear Capsulorhexis/Internal Limiting Membrane Peeling
Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Indocyanine green emits fluorescent color when excited by certain wavelengths of visible light energy.

Application: Determine the elimination kinetics of ICG after intraocular operations using ICG staining and a monitoring indicator.

Implementation: Evaluation of the applicability of ICG mediated intraocular fluorescence (ICG) in concert with the use of a scanning laser ophthalmoscope (*in vivo: ICG angiographic mode*), and fluorescent microscopy (*in vitro*) to facilitate circular curvilinear capsulorhexis for cataract lesions, and internal limiting membrane (ILM) peeling for macular hole surgery.

Human Model: White cataract (n = 7 cases and n = 9 eyes) and idiopathic macular holes (n = 14 cases; n = 14 eyes).

Interpretation and Analysis: Scanning laser ophthalmoscopy can reveal fluorescence in the anterior segment in cases with cataracts on the first postoperative day, and fluorescence persists for a mean of 6.0 ± 2.2 days. Scanning laser ophthalmoscopy also reveals fluorescence in the posterior pole of cases with macular holes, and it remains detectable for a mean of 2.7 ± 1.4 months postoperatively. Fluorescence microscopy shows fluorescence of the entire tissues, suggesting that ICG stains not only the surface of membranes but also penetrates these structures. In both operations, visual outcomes are not significantly different from results obtained without ICG. Because entire tissues are stained, the differences in ICG kinetics may also be caused by factors other than differences in stainability, such as the environment surrounding tissue structures or molecular structural differences between the lens capsule and the ILM. Although complete disappearance of fluorescence and good functional recovery can be appreciated, the longer resident time of the dye after macular hole surgery may suggest a potential risk to intraocular tissues.

Instrumentation: Fluorescence microscopy (*in vitro*) and scanning laser ophthalmoscope (*in vivo*).

Kinetics of indocyanine green dye after intraocular surgeries using indocyanine green staining. Horiguchi M, Nagata S, Yamamoto N, Kojima Y, Shimada Y. Arch Ophthalmol 2003 Mar; 121 (3), pp. 327–31.

Corneal Trauma
Fluorescein Dye

Cellular/Molecular Mechanism of Action: Fluorescein dye is an agent that emits colored visible light upon exposure to white light energy.

Diagnostic Application: Detectable dye marker system that is compatible with biological systems.

Dosage: Applied in a topical fashion to the moist surface of the corneal epithelium.

Implementation: Detection of surface defects affecting the corneal epithelium.

Interpretation and Analysis: Fluorescein dye does not bind to intact surfaces of the corneal epithelium. Alternatively, fluorescein dye has a profound molecular affinity for subcorneal epithelial (stromal) collagen. Upon exposure, the fluorescent fluorescein dye reacts with visible light resulting in the emission of a fluorescent green color to facilitate localization of defects in the corneal epithelium.

Laboratory Instrumentation: Visual observation.

Cycloplegia Induction for Retinoscopy
Cyclopentolate/Tropicamide

Cellular/Molecular Mechanism of Action: Cyclopentolate and tropocamide are both synthetic tertiary amines that inhibit acetylcholine at muscarinic receptor complexes (competitive).

Physiological Mechanism of Action: Cyclopentolate and tropocamide inhibit motor and sensory nerve transmission (e.g., paralysis of intraoccular smooth muscle tissues). Note: cycloplegics cause ciliary muscle paralysis while mydriatics are agents that promote dilation of the pupil.

Application: Induction of ocular mydriasis and cycloplegia to facilitate improved diagnostic accuracy of ophthalmoscopic/retinoscopy procedures. Tropicamide has a much shorter recovery period compared to cyclopentolate.

Route of Administration: Ophthalmic (topical).

Dosage: Cycloplegia with tropicamide (1%) and cyclopentolate (1%) delivered as 2 drops of cycloplegic agent separated by a time span of 5 minutes. Retinoscopy is performed 25 to 30 minutes after the 1st drops are instilled.

Considerations: There were no serious adverse reactions with either agent, although an infant has been reported to have temporarily developed reddened cheeks after instillation of cyclopentolate. Certain iatrogenic side effects should be recognized, including the precipitation of acute angle-closure. A shallow anterior chamber is a fundamental ocular variable that should be evaluated before inducing mydriasis and/or cycloplegia. The technical procedures for the oblique illumination shadow test and the van Herick slit lamp test both provide an accurate estimation of the anterior chamber angle. The risk of precipitating an attack after reasonable circumspection by such preliminary evaluations approaches zero. However, should an attack occur, the procedures to rapidly lower the intraocular pressure and open the chamber angle are available for immediate application.
Interpretation and Analysis: Previous investigations have generated findings that suggest that tropicamide is as effective as cyclopentolate for the measurement of refractive error in most healthy, non-strabismic infants (4–7 months of age; mean = 5.71 months).

On a scale of 0 to 4.9, the median iris grade in infants is 4.0, which corresponds to a brown or darkly pigmented iris. Retinoscopy results reported for the horizontal meridian of the right eye include (i) mean refractive error using non-cycloplegic near retinoscopy is equal to +0.94 D (± 1.19 D); and (ii) mean refractive error +1.81 D (± 1.19 D) with tropicamide and +1.88 D (± 1.45 D) with cyclopentolate.

No statistically or clinically significant difference between the 2 cycloplegic measurements using different diagnostic agents can be appreciated ($t = -0.46$, $p = 0.65$). The mean difference between non-cycloplegic and cycloplegic retinoscopy has been observed to be 0.89 D (+/- 0.66 D) with tropicamide ($t = -6.57$, $p < 0.0001$) and 1.04 D (+/- 0.94 D) with cyclopentolate ($t = -5.38$, $p < 0.0001$; all 2-sided paired t tests).

Glaucoma
Pilocarpine/(Tonography Alternative)

Cellular/Molecular Mechanism of Action: Pilocarpine is a cholinomemitic agents that functions as a cholinergic/parasympathomimetic agonist that binds to and activates acetylcholine receptor complexes.
Physiological Mechanism of Action: Promotes parasympathomimetic-induced pupillary constriction.
Application: Glaucoma.
Route of Administration: Ophthalmic topical (Hollwichs' pilocarpine test).
Interpretation and Analysis: The pilocarpine test performed at the peak of the daily pressure curve gives comparable results to tonography and hence can be useful in suspected cases of glaucoma.
Instrumentation: Ophthalmascope and tonometer.

Pilocarpine as a diagnostic agent for early recognition of a tendency to glaucoma. [Comparable results between Hollwich's pilocarpine test and tonography (author's transl).] Lienert F, Busse H. Klin Monatsbl Augenheilkd 1976 Jul; 169 (1), pp. 116–8.

Glaucoma
Ibopamine

Diagnostic Application: Detection of cases with preclinical and clinical signs of glaucoma.
Implementation: Evaluation of suspected cases of glaucoma.
Interpretation and Analysis: Glaucoma cases show a substantial increase in ocular pressure following ibopamine administration compared to normal unaffected individuals (92% of the known glaucoma cases are positive for the ibopamine test). Many affected cases demonstrate a progressive increase in the ocular pressure increases induced by ibopamine as their disease state progresses in severity.

Glaucoma
Dexamethazone

Route of Administration: Ophthalmic (topical).
Dosage: Dexamethazone ophthalmic topical (0.1%).
Implementation: Evaluation of the responsiveness of glaucoma conditions to topically administered corticosteroids.
Human Model: Retrospective follow-up study (n = 134 cases; n = 84 women). Follow-up time varies from 5 to 15 years (mean 7.1 years).
Interpretation and Analysis: Approximately 25.4% of survey cases have a high response (n = 34/134; intraocular pressure (IOP) rise greater than or equal to 16 mm Hg), while 49.3% (n = 66/134) have an intermediate response (IOP rise 6–15 mm Hg); and 25.4% (n = 34/134) have a low response (IOP rise less than or equal to 5 mm Hg) to topically administered 0.1% dexamethasone eye drops. During follow-up periods, 21.6% (n = 29/134) cases develop glaucoma. Of these, 31% (n = 9/29) are high responders, while 24.0% (n = 7/29) are low responders to corticosteroids. Log-linear analysis shows no correlation between corticosteroid response and development of glaucoma in "study" eyes ($SD = 0.232$, $df = 2$, $p = 0.890$), the control eye ($SD = 1.234$, $df = 2$, $p = 0.540$), or both eyes ($SD = 0.618$, $df = 2$, $p = 0.734$). On final examination 56% (n = 75/134) have an IOP of greater than or equal to 22 mm Hg. Of these ocular hypertensive cases 37.7% (n = 28/75) are high responders, and 20% (n = 15/75) have a low response to corticosteroids. Approximately 33% of cases will have a family history of glaucoma (e.g., n = 44/134). Approximately 25.1% (n = 11/44) of these will be high responders and 31.8% (n = 14/44) will be low responders. Of the cases that develop glaucoma (n = 29) less than 30% (n = 8) have a family history of glaucoma. Of these, some will be high (n = 3/8) or low responders (n = 3/8). Such findings indicate that the dexaprovocative test yields relatively limited value in the screening of cases for glaucoma.

Glaucoma (Related)
Acepromazine and Ketamine/Water Provocative Test

Diagnostic Application: A standard water provocative test for dogs anesthetized with acepromazine-ketamine.
Route of Administration: Oral.
Dosage: Administration of 60 ml/kg of water to anesthetized dogs.
Interpretation and Analysis: Pressure levels decrease close to original levels by 60 minutes. Pressure increases in females and young dogs are greater than those observed in males and adults. An increase in intraocular pressure can be detected that reaches a maximum at 15 minutes postingestion. The exception is young dogs that attained a maximum increase at 10 mintues.

Graves' Ophthamology/Type Th2 Interleukines: IL-4 and IL-10
Methylprednisolone/Prednisone

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit general protein synthesis and stabilize cell membrane structures, in addition to inhibiting the biochemical activity of phospholi-

pase A_2 in a manner that decreases both leukotriene and prostaglandin synthesis.

Physiological Mechanism of Action: Corticosteroids exert anti-inflammatory and immunosuppressive properties.

Application: Elevated expression of serum IL-4 and IL-10 during successful treatment with corticosteroids indicates the possibility of using these cytokines as predictors of the beneficial effect of corticosteroids in Graves' ophthalmopathy.

Route of Administration: Methylprednisolone (MP; intravenous); prednisone (oral).

Dosage: Methylprednisolone (2 series, 3 g dose in each series); prednisone (60 mg per day according to a tapering dose schedule).

Implementation: Evaluation of conditions of Graves' ophthalmology related to the estimated influence of corticosteroids on Th1 and Th2 serum cytokine balance. Cytokines of particular interest include IFN-γ,, TNF-α, IL-4, and IL-10. In addition, complementary analysis involves delineation of the upregulation of Th2 immune response during successful treatment with corticosteroids to determine if there is a correlation with their beneficial effect in Graves' ophthalmopathy. Corticosteroid challenge/exposure consists of intravenous infusions of and subsequent treatment with oral prednisone in a tapering schedule. Serum samples are collected 24 hours before MP, 24 hours after MP, 14 days of treatment with prednisone, and at the end of corticosteroid therapy. Levels of IFN-γ, TNF-α, IL-4, and IL-10 in serum are determined using ELISA. Statistical significance is estimated by the Mann-Whitney U-test.

Human Model: Cases of Graves' disease without ophthalmopathy (e.g. n = 20 Gd); cases with clinical ophthalmopathy symptoms (e.g. n = 16 GO with CAS over 3 points, last consultation record for GO less than a year old); and normal healthy volunteers (e.g. n = 16).

Interpretation and Analysis: Deviations exist pertaining to systemic Th2 cytokine profile in Graves' disease. In GO cases, a significant increase in serum IL-10 concentration can be detected. In corticosteroid-responsive cases, the balance of serum cytokines IL-4/IFN-γ, IL-4/TNF-α, IL-10/IFN-γ, and IL-10/TNF-α increases and remains upregulated. In non-responders, the balance of serum cytokines studied increases after methylprednisolone but declines markedly during continuation of the therapy with prednisone. Therefore, efficient corticosteroid therapy may be related to its influence on cytokine profiles and Th2/Th1 cytokine balance. The upregulation of serum IL-4 and IL-10 during successful treatment with corticosteroids indicates the possibility of using these cytokines as predictors of the beneficial effect of corticosteroids in Graves' ophthalmopathy.

Serum Th1 and Th2 profile cytokine level changes in cases with Graves' ophthalmopathy treated with corticosteroids. Myśliwiec J, Kretowski A, Topolska J, Siewko K, Jakubczyk D, Szelachowska M, Mikita A, Kinalska I. Horm Metab Res 2001 Dec; 33 (12), pp. 739–43.

Glaucoma: Angle-Closure Glaucoma (ACG) Risk *Pilocarpine/Phenylephrine*

Cellular/Molecular Mechanism of Action: Pilocarpine is a cholinomimetic agent that functions as a cholinergic/parasympathomimetic agent (agonist) that binds to and activates acetylcholine receptor complexes. Phenylephrine is an analog of the adrenergic neurtransmitter epinephrine.

Physiological Mechanism of Action: Promotes parasympathomimetic-induced pupillary constriction. Phenylephrine promotes pupil dilation.

Application: The pilocarpine/phenylephrine provocative test (PPPT) has been considered a highly sensitive method for identifying active or "at-risk" conditions of ACG affecting the eye.

Route of Administration: Ophthalmic (topical).

Implementation: The pilocarpine/phenylephrine provocative test (PPPT) has been considered a highly sensitive method for identifying active or "at-risk" conditions of ACG affecting the eye.

Interpretation and Analysis: Over a 10-year time span, reports have described the outcomes assessment for cases of primary acute ACG and subacute ACG in which management was determined by results from the PPPT. A positive result has been interpreted as an indication for a peripheral iridectomy. Conversely, a negative response implies that conservative treatment is required. In spite of a negative PPPT the contralateral eyes of cases of acute ACG treated conservatively have a high rate (40%) of developing ACG. Similarly, in eyes with a history of subacute ACG with a negative PPPT, ACG develops at some stage during the follow-up in 60% of affected cases. Peripheral iridectomy alone results in normal intraocular pressure in 63% of eyes that have suffered an attack of acute ACG. In hypertensive eyes that present with subacute ACG, however, only 1 eye becomes normotensive following peripheral iridectomy alone. In the subacute ACG group a positive PPPT is closely related to the presence of glaucomatous optic disc damage. These results indicate that the PPPT lacks sensitivity in detecting eyes at risk of ACG, and a positive result is likely in eyes with damaged outflow that will not respond to peripheral iridectomy.

Glaucoma: Angle-Closure Glaucoma (ACG) Risk *Pilocarpine/Phenylephrine*

Cellular/Molecular Mechanism of Action: Pilocarpine binds to and activates parasympathetic muscarinic cholinergic receptor complexes thereby exerting cholinomimetic perperties pertaining to action of neurotransmitter, acetylcholine. Phenylephrine binds to powerfully activate sympathetic α1-adrenergic receptor complexes with little to no activation of β adrenergic receptor complexes.

Background Information: Mapstone introduced the term "partial angle closure" to describe how eyes with apparently open angles could be damaged by a covert angle-closing mechanism. Such abnormalities are identifiable by a positive result of the pilocarpine/phenylephrine provocative test (PPPT).

Application: Detection and characterization of ACG.

Route of Administration: Ophthalmic (topical).

Considerations: Clinical review demonstrates that eyes with narrow angles that have positive PPPT results do not benefit from peripheral iridectomy (PI) or laser iridectomy (LI), and therefore a positive PPPT is not indicative of the presence of an angle-closing mechanism.

Interpretation and Analysis: A review over a 10-year period of cases (n = 68) with narrow but open anterior chamber angles that underwent PI or LI based on a positive PPPT reveals that a large percentage with glaucoma or ocular hypertension (62%) have unchanged mean intraocular pressures (IOPs) following iridectomy. Approximately 45% of eyes that show glaucomatous optic disc damage at presentation, and 25.6% of ocular hypertensive eyes subsequently require trabeculectomy to achieve IOP control. In instances of no ocular abnormality other than a narrow angle (e.g. n = 16 cases with n = 19 affected eyes) have positive PPPTs and undergo PI. After a 10-year follow-up, only 1 of the 13 untreated fellow eyes developed ACG. As this is usually bilateral, many of the positive tests in this group of cases may therefore have actually been false positives.

Can the pilocarpine phenylephrine provocative test be used to detect covert angle closure. Wishart PK. Br J Ophthalmol 1991 Oct; Vol. 75 (10), pp. 615–8.

Glaucoma/Angle-Closure Glaucoma: Primary (PACG)
Brimonidine/Pilocarpine

Cellular/Molecular Mechanism of Action: Brimonidine is a selective alpha-2 adrenoceptor agonist. Pilocarpine is a cholinomimetic agent that functions as a cholinergic/parasympathomimetic agonist that binds to and activates acetylcholine receptor complexes.
Physiological Mechanism of Action: Brimonidine tartrate suppresses aqueous humor flow in the human eye and promotes parasympathomimetic-induced pupillary constriction.
Application: Provocative test for characterizing PACG.
Route of Administration: Ophthalmic topical.
Dosage: Brimonidine tartrate 0.2% instilled topically into each eye 2 hours prior to a 2nd dark-prone test.
Implementation: Determination of the capacity for pilocarpine to prevent intraocular pressure (IOP) elevations in the dark-prone provocative test for PACG.
Interpretation and Analysis: An IOP elevation of greater than 8 mm Hg is interpreted as a positive result. The IOP elevations in the first dark-prone test can be in the range of 11.91 $\pm$ 5.17 (5.7 to 27.3) mm Hg in contrast to the frequent increase in IOP (approximately 5.70 $\pm$ 2.96; range: 2.9–12.2 mm Hg) that occurs during a 2nd dark-prone test combined with brimonidine tartrate (0.2%) pretreatment ($p < 0.001$). Significant differences may also be noted in pretest IOP (15.59 $\pm$ 3.86 mm Hg vs 13.33 $\pm$ 3.65 mm Hg, $p = 0.008$) as well as in posttest IOP (27.62 $\pm$ 7.27 mm Hg vs 19.03 $\pm$ 3.50 mm Hg, $p < 0.001$) in two sequential dark-prone tests. A relatively high percentage of initially positive dark-prone tests (86.46%) convert to negative tests after pretreatment with brimonidine. There are often significant effects imposed by brimonidine tartrate (0.2%) in the prevention of IOP elevations in PACG conditions previously found to test positive in the dark-prone provocative test.

The efficacy of brimonidine in preventing intraocular pressure elevation in the provocative test for primary angle-closure glaucoma. Chen YF, Hung PT, Hsieh JW, Shein J, Hsiao CK. J Ocul Pharmacol Ther 2002 Apr; 18 (2), pp. 99–103.

Glaucoma: Closed-Angle Glaucoma (Postperipheral Iridectomy)
Corticosteroid

Application: Identification of closed-angle glaucoma in cases treated by peripheral iridectomy (affected eye) and prophylactic peripheral iridectomy (unaffected eye).
Route of Administration: Ophthalmic (topical).
Considerations: An acquired form of corticosteroid-induced ocular hypertension appears to exist as a clinical entity. The possible pathogenisis of the condition has been tentatively described, as has its clinical significance.
Interpretation and Analysis: In cases of unilateral closed-angle glaucoma treated by peripheral iridectomy (e.g. $n = 35$), ophthalmic corticosteroid in both eyes results in the detection of increased intraoccular pressure in 51% of the affected eyes and 11% of the unaffected eyes (positive corticosteroid pressure test). The closed-angle glaucoma eyes had their fellow eyes respond differently, as shown by frequency distribution graphs and also by differences between the corticosteroid-induced change in pressure (Wilcoxon test, $z = -4.80$, $p < 0.0001$).

Corticosteroid-induced ocular hypertension. II. An acquired form. Akinbehin AO. Br J Ophthalmol] 1982 Aug; Vol. 66 (8), pp. 541-5.

Glaucoma/Predictive Risk of Developing Ocular Hypertension and Perimetric Defects
Ibopamine

Application: Ibopamine can be applied as a provocative test due to its pharmacological property of increasing ocular pressure in eyes with outflow system impairment.
Route of Administration: Ophthalmic (topical).
Implementation: Evalution of glaucoma conditions applying the ibopamine provocative test.

Human Model: Cases suspected of having glaucoma ($n = 175$ [250 eyes] POAG; $n = 101$ [190 eyes] mild ocular hypertension; $n = 39$ [64 eyes] NTG; and $n = 163$ [326 eyes] healthy volunteers). Among cases suspected of POAG and glaucoma, some may be included that, starting with performing the ibopamine test, have at least 1 year of perimetric follow-up (e.g., $n = 49$ [92 eyes] and $n = 20$ [38 eyes], respectively).
Interpretation and Analysis: The ibopamine test is positive in approximately 92% of the glaucomatous cases, 61% of glaucoma suspect cases, 52% of NTG cases, and 0% of the healthy volunteers. Of the ibopamine-positive glaucoma suspects, about 28% show a perimetric deterioration within a 2.5-year follow-up period. Perimetric deterioration is rarely appreciated in ibopamine-negative glaucoma suspects (Fisher's exact test: $p = 0.038$). Among glaucomatous cases, 46% of those that are positive will show a progressive trend of the perimetric defect, compared to about 8% of glaucomatous test-negative cases (Fisher's exact test: $p = 0.003$). In this context, ibopamine can potentially be applied as a provocative test, especially in epidemiological screening studies to identify cases that might develop ocular hypertension or glaucoma and in the follow-up of glaucoma suspects, to identify cases that have a greater risk of developing perimetric defects.

Horner's Syndrome
Guanethidine/Pholedrine/[Hydroxyamphetamine]

Cellular/Molecular Mechanism of Action: Amphetamines function as indirectly acting sympathomimetic agents by promoting the release of biogenic amines from storage sites within nerve presynaptic terminals. (Note: Pholedrine is *n*-methyl derivative of hydroxyamphetamine.)
Physiological Mechanism of Action: Guanethidine's major effect is inhibition of responses to stimulation of sympathetic nerves and indirectly-acting sympathomimetic amines (e.g., tyramine, amphetamines). Pholedrine (4′-hydroxymethamphetamine) is a cardiovascular agent that exerts hypertensive and adrenergic effects.
Application: Diagnosis of Horner's syndrome.
Route of Administration: Ophthalmic (topical).
Dosage: Pholedrine (1%) yields a biological effect roughly equivalent to hydroxyamphetamine (0.5%).
Considerations: Hydroxyamphetamine (0.5% ophthalmic) is no longer available through commercial vendors.
Implementation: Evaluation of suspected conditions of Horner's syndrome.
Interpretation and Analysis: Pretreatment with topical guanethidine attenuates the response to pholedrine. Preganglionic

Horner's syndrome can be distinguished clearly when pholedrine is combined with guanethidine pretreatment.

Horner's Syndrome
Dextroamphetamine/Phenylephrine

Cellular/Molecular Mechanism of Action: Phenylephrine is an adrenergic neurotransmitter analog of epinephrine. Dextroamphetamine promotes the release of adrenergic neurotransmitter across the presynaptic membrane.
Application: Identification of the anatomical location of a deficit/lesion affecting adrenergic/sympathetic autonomic nervous system that provide input to smooth muscle ophthalmic structures (e.g., Horner's syndrome).
Route of Administration: Ophthalmic (topical).
Implementation: Differentiation between alterations in preganglionic and postganglionic adrenergic/sympathetic (autonomic nervous system) innervation to smooth muscle ophthalmic structures.
Interpretation and Analysis: Topical application of dextroamphetamine to the corneal surface when Horner's syndrome is caused by a lesion located above the terminal lower motor neuron of the sympathetic (adrenergic) autonomic nervous system results in a hyperactive pupillary light reflex response. Detection of a positive response suggests that the postganglionic adrenergic/sympathetic neuron is viable and entirely functional.

Such responses in the eye is neuroanatomically analogous to the detection of a hyperactive limb reflex with an upper motor neuron lesion affecting the brain or spinal cord. Topical application of phenylephrine to the corneal surface of cases with Horner's syndrome caused by a lesion affecting the terminal lower motor neutron of the sympathetic (adrenergic) segment of the autonomic nervous system that results in a hyperactive pupil response is due to chronic catecholamine neurotransmitter depravation of visceral (ocular) smooth muscle tissue.
Instrumentation: Ophthalmascope.

Microvasculature/Retina/Estimation of Microvasculature Blood Flow Velocity/Leukocyte Dynamics in the Choroidal Microcirculation
Indocyanine Green (ICG) Dye-Stained Leukocytes

Cellular/Molecular Mechanism of Action: Indocyanine green is a dye marker molecule that can be used *in vivo* as a detection or indicator molecule.
Application: Visualization of leukocytes moving through the choroidal vessels of pigmented animals. Enables the evaluation of leukocyte dynamics in the choroidal microcirculation.
Route of Administration: Intravascular.
Implementation: Leukocytes are collected following centrifugal separation of autologous blood and then stained with ICG dye. The ICG-stained leukocyte suspension is then injected intravenously, and fundus images obtained with a scanning laser ophthalmoscope. Images are recorded on videotape and analyzed with a personal computer-based image analysis system.
Animal Model: Pigmented rabbits and monkeys.
Interpretation and Analysis: In pigmented rabbits, fluorescent leukocytes moving in the choroidal circulation are clearly visible for a period of more than 1 hour. In monkeys, distinct fluorescent dots are seen moving approximately 50–200 μm in the foveal avascular zone for more than 30 minutes after injection of ICG-stained leukocyte fluid. Dim fluorescent dots can be seen moving in the fundus. Although the movement of the dim dots is difficult to trace, they seemed to be moving in the choroidal vessels. In rabbits, the mean flow velocity of leukocytes moving without plugging is 0.48 ± 0.14 mm/sec in the peripheral choriocapillaris. In monkeys, the mean flow velocity of distinct fluorescent leukocytes without plugging is 2.45 ± 0.48 mm/sec in the posterior choroid. In pigmented rabbits and monkeys, this method allows visualization of leukocytes passing through the choroidal vessels and provides a new way to investigate, non-invasively and *in vivo*, leukocyte dynamics in the choroidal microcirculation.
Instrumentation: Scanning laser ophthalmoscope.

Evaluation of leukocyte dynamics in choroidal circulation with indocyanine green-stained leukocytes. Takasu I, Shiraga F, Okanouchi T, Tsuchida Y, Ohtsuki H. Invest Ophthalmol Vis Sci 2000 Sep; 41 (10), pp. 2844–8.

Neurons: *In Vivo* Antegrade Staining/Visual Pathway Staining/Retinal Ganglion Staining/ Vitreoretinal Surgery: Intraoperative Probe
Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Indocyanine green emits fluorescent color when excited by certain wavelengths of light energy.
Background Information: It has been shown that the application of ICG over the retinal surface is followed by a prolonged staining of the optic disc.
Application: Indocyanine green can function as a bidirectional axonal tracer for *in vivo* (research) to stain the visual pathway and retinal ganglion.
Implementation: Evaluate the diffusion of ICG in the optic tract. More specifically ICG can be characterized for it's ability to undergo; (i) anterograde diffusion after injection into the vitreous; and (ii) retrograde diffusion after microinjection into the lateral geniculate nucleus.
Animal Model: Rabbit (vitreous ICG injection) and rats (lateral geniculate nucleus injection).
Interpretation and Analysis: Anterograde and retrograde diffusion occurs along axons at a rate of about 2 mm per hour following ICG injection. Anterograde staining of the visual pathway persists for several weeks. After injection into the lateral geniculate nucleus, fluorescent retinal ganglion cells can be visualized for at least 7 days in conscious rats. Microscopic examination reveals evidence of retrograde-labeled retinas and the detection of ICG vesicles inside the axons, cytoplasm, and dendrites of retinal ganglion cells. Evidence of toxic effects are usually not observed when applying optical microscopy. Injection of ICG into normal vitreous results in long-term staining of the visual pathway. *In vivo* counting of ICG-labeled retinal ganglion cells in rats can be performed for several days after injection. Indocyanine green is therefore potentially of interest for use in experimental neurophysiological studies. It is speculated that in humans, the epiretinal application of ICG results in prolonged staining of the visual pathway. Additional studies of long-term toxic effects of ICG on neural cells are warranted before recommending its use in humans as an intraoperative tool for vitreoretinal surgery.
Instrumentation: Conventional infrared photography.

Axon-tracing properties of indocyanine green. Paques M, Genevois O, Regnier A, Tadayoni R, Sercombe R, Gaudric A, Vicaut E. Arch Ophthalmol 2003 Mar; 121 (3), pp. 367–70.

Ophthalmic Artery Dependent Vision/ Pre-Evaluation Prior to Ophthalmic Artery Embolization/[Arteriovenous Malformations of the Orbit/Dural Arteriovenous Fistulae]/ [Orbital Meningiomas/Planum Sphenoidale Meningioma/Juvenile Nasal Angiofibroma] *Lidocaine/Amytal*

Background Information: A number of anteriorly located cranial base and extracranial lesions receive their vascular supply wholly or in part from the ophthalmic artery. Embolization of the ophthalmic artery or its branches can be helpful in the management of these lesions, either as the primary treatment or as an adjunct to surgery.
Application: Determination of the dependency of visual function on patency of the ophthalmic artery.
Route of Administration: Lidocaine/amytal (intra-arterial catheterization).
Dosage: Lidocaine/amytal.
Implementation: Evaluation of the degree visual function is impared by local delivery of anesthetic agents into branches of the ophthalmic artery that supply intra-occular and extra-occular lesions. Such preliminary examinations can be used to predict to what extent visual sight will be affected if selective embolization therapy is implemented for partial or total resolution of lesions. In this context, lidocaine and amytal can be used as a provocative test prior to embolization procedures to assess the role of the ophthalmic artery in vision. In each case, a Tracker No. 18 microcatheter (Target Therapeutics, Inc. Fremont, CA) is navigated into the ophthalmic artery using a steerable guidewire and digital road mapping. Embolic agents include polyvinyl alcohol particles ranging from 350 to 1500 μm in diameter, 2 mm platinum microcoils, and n-butyl-cyanoacrylate. Examples of clinical conditions that can benefit from lidocaine/amytal diagnostic procedures include (i) arteriovenous malformations of the orbit; (ii) dural arteriovenous fistulae; (iii) orbital meningioma; (iv) planum sphenoidale meningioma; and (v) juvenile nasal angiofibroma.
Interpretation and Analysis: In conditions where provocative testing with lidocaine and amytal indicate that the ophthalmic artery has a substantial effect on vision, then embolization procedures are not performed. Applying this protocol, proper case selection, judicious use of embolic agents, and use of provocative testing agents can result in safe embolization of lesions supplied by the ophthalmic artery.

Embolization of neurosurgical lesions involving the ophthalmic artery. Lefkowitz M, Giannotta SL, Hieshima G, Higashida R, Halbach V, Dowd C, Teitelbaum GP. Neurosurgery 1998 Dec; 43 (6), pp. 1298–303.

Parasympathetic Innervation: Ophthalmic *Physostigmine*

Cellular/Molecular Mechanism of Action: Exerts parasympathomimetic activity dependent on the existence of an intact second neuron capable of releasing endogenous stores of neurotransmitter (indirect parasympathomimetic mechanism of action).
Diagnostic Application: Diagnostic evaluation of compromised parasympathetic innervation to the pupillary constrictor muscle.
Dosage: Physostigmine (0.5%) ophthalmic solution applied as a single drop topically to the eye.
Considerations: In normal individuals or those who have lost function of either the upper motor neuron or first lower motor neuron (preganglionic), topical physostigmine in the eye causes relatively rapid pupillary constriction.
Interpretation and Analysis: Lack of rapid pupillary constriction following topical ophthalmic application implies loss of 2nd lower motor neuron function. Normal eyes constrict within 40 to 60 minutes in contrast to eyes with a UMN or preganglionic lesions.

Parasympathetic Innervation: Ophthalmic *Pilocarpine*

Cellular/Molecular Mechanism of Action: Pilocarpine is a cholinomimetic agent that functions as a cholinergic/parasympathomimetic agonist that binds to and activates acetylcholine receptor complexes.
Diagnostic Application: Diagnostic evaluation of compromised parasympathetic innervation to the pupillary constrictor muscle. Pilocarpine has been used to facilitate the examination of conditions such as plateau iris syndrome.
Route of Administration and Dosage: Pilocarpine (2.0%) ophthalmic solution applied as a single drop topically to the eye.
Interpretation and Analysis: Topical pilocarpine will cause a relatively rapid constriction of the denervated pupil that is more extensive and of longer duration than the response observed in a normal eye. An exaggerated response is noted when a lower motor neuron deficit exists. Therefore, lower motor neuron deficits affecting either preganglionic or postganglionic axons will produce the same response to topical pilocarpine. In the normal eye, topical pilocarpine will result in constriction of the pupil in approximately 20 minutes.
Instrumentation: Ophthalmascope.

Parasympathetic Innervation: Ophthalmic *Atropine*

Cellular/Molecular Mechanism of Action: Direct blockade of the muscarinic subclass of acetycholine membrane receptor sites resulting in parasympatholytic activity due to competitive inhibition of the neurotransmitter, acetylcholine at postsynaptic receptor sites.
Diagnostic Application: Dilate the pupil of the eye for diagnostic procedures and to evaluate the integrity of smooth muscle tissue function within the pupil.
Route of Administration: Atropine is effective applied in a topical fashion to the corneal surface of the eye.
Considerations: In neonates of species known to be sensitive to the effects of atropine (e.g. equine), cases may demonstrate clinical signs of gastrointestinal ileus following topical application.

Phenylephrine, Proparacaine, Tropicamide/ Antidote Reversal *Dapiprazole*

Application: Dapiprazole can be used to reverse topical ophthalmic proparacaine 0.5%, tropicamide 1.0%, and phenylephrine 2.5% (1 drop each).
Dosage: Proparacaine 0.5%; tropicamide 1.0%; and phenylephrine 2.5% (1 drop each).
Consideration: The portion of accommodation recovery if any is attributable to a ciliary muscle effect, and what portion results from an increased depth of field attending pupillary constriction is uncertain.
Implementation: Dapiprazole given 30 minutes after dilation with 1 drop each of proparacaine 0.5%, tropicamide 1.0%, and then 5 minutes later another drop of tropicamide 1.0%. Pupil diameter, amplitude of accommodation, conjunctival injection, and intraocular pressure are evaluated. Each of these variables is measured (i) before

instillation of the diagnostic agents; (ii) before the instillation of dapiprazole; and (iii) at 30, 60, 120, and 180 minutes after the final application of dapiprazole.

Human Model: Cases administered topical agents (n = 30 subjects with findings reported from a random study design, masked with placebo, and one eye of each subject used as a control).

Interpretation and Analysis: The average pupillary recovery time for dapiprazole-treated eyes is significantly less than for non-treated eyes. The average pupillary recovery time for dapiprazole-treated eyes is similar to previously published data. Accommodation also shows significantly faster recovery, with comfortable reading ability returning after approximately 30–43 minutes, compared to 66 minutes without dapiprazole. The vast majority of cases exhibit conjunctival hyperemia after dapiprazole administration that persists through the entire 180-minute observation period following dapiprazole administration.

Pupillary Constriction Responsiveness: Normal/ [Anterior Synechia]
Pilocarpine

Cellular/Molecular Mechanism of Action: Pilocarpine is a cholinomimetic agent that functions as a cholinergic/parasympathomimetic agonist that binds to and activates acetylcholine receptor complexes.

Physiological Mechanism of Action: Promotes parasympathomimetic-induced pupillary constriction.

Application: Evaluate the degree of pupillary constriction.

Route of Administration: Ophthalmic (topical).

Dosage: Pilocarpine (4% topical).

Interpretation and Analysis: Slit-image photography before and 30 minutes after the instillation of pilocarpine 4% into one eye demonstrates the range of response of the anterior segment to pilocarpine. Those eyes whose axial anterior chamber depth that becomes more shallow by $\geq$ 0.1 mm reflects shallowing of the periphery of the anterior chamber, while those eyes with axial anterior chamber depth that decreases by $<$ 0.1 mm reflects deepening of the peripheral anterior chamber. The relevance of these findings pertains to the development of peripheral anterior synechiae.

Neoplasia/Ophthalmic Artery Dependent Vision/ Preoperative Risk Evaluation Prior to Selective Ophthalmic Artery Embolization/ [Arteriovenous Malformations of the Orbit/Dural Arteriovenous Fistulae]/[Orbital Meningiomas/ Planum Sphenoidale Meningioma/Juvenile Nasal Angiofibroma]
Lidocaine/Amytal

Background Information: A number of anteriorly located cranial base and extracranial lesions receive their vascular supply wholly or in part from the ophthalmic artery, and embolization of the ophthalmic artery can be helpful in the management of these lesions, either as the primary treatment or as an adjunct to surgery.

Application: Determination of the dependency of visual function on patency of the ophthalmic artery.

Route of Administration: Lidocaine/amytal (intra-arterial catheterization).

Dosage: Lidocaine/amytal.

Implementation: Evaluation of the degree visual function is impared by local delivery of anesthetic agents into branches of the ophthalmic artery that supply intra-occular and extra-occular lesions. Such preliminary examinations can be used to predict to what extent visual sight will be affected if selective embolization therapy is implemented for partial or total resolution of lesions. In this context, lidocaine and amytal can be used as a provocative test prior to embolization procedures to assess the role of the ophthalmic artery in vision. In each case, a Tracker No. 18 microcatheter (Target Therapeutics, Inc. Fremont, CA) is navigated into the ophthalmic artery using a steerable guidewire and digital road mapping. Embolic agents include polyvinyl alcohol particles ranging from 350 to 1500 μm in diameter, 2 mm platinum microcoils, and *n*-butyl-cyanoacrylate. Examples of clinical conditions that can benefit from lidocaine/amytal diagnostic procedures include (i) arteriovenous malformations of the orbit; (ii) dural arteriovenous fistulae; (iii) orbital meningiomas; (iv) planum sphenoidale meningioma; and (v) juvenile nasal angiofibroma.

Interpretation and Analysis: In conditions where provocative testing with lidocaine and amytal indicate that the ophthalmic artery has a substantial effect on vision, then embolization procedures are not performed. Applying this protocol, proper case selection, judicious use of embolic agents, and use of provocative testing agents can result in safe embolization of lesions supplied by the ophthalmic artery.

Embolization of neurosurgical lesions involving the ophthalmic artery. Lefkowitz M, Giannotta SL, Hieshima G, Higashida R, Halbach V, Dowd C, Teitelbaum GP. Neurosurgery 1998 Dec; 43 (6), pp. 1298–303.

Retinal Angiography/Choroid/Retinal Pigment Epithelium/[Premortem Diagnostic Agent]
Rose Bengal/Aluminum Phthalocyanine Tetrasulfonate/Chlorin e6

Cellular/Molecular Mechanism of Action: Rose bengal, aluminum phthalocyanine tetrasulfonate, and chlorin e6 when exposed to certain wavelengths of light can emit visible light energy at different wavelengths.

Physiological Mechanism of Action: Rose bengal, aluminum phthalocyanine tetrasulfonate, and chlorin e6 can emit light energy at different wavelengths that can be cytotoxic to various cell types.

Application: Localization and site of action of photosensitizers in the eye may be important for photodynamic therapy of fundus disorders but remain poorly understood.

Route of Administration: Rose bengal (intravenous), aluminum phthalocyanine tetrasulfonate (intravenous), chlorin e6 (intravenous).

Dosage: Rose bengal (40 mg/kg), aluminum phthalocyanine tetrasulfonate (CASPc) (5 mg/kg), or chlorin e6 (2 mg/kg). Digital fundus fluorescence angiography of rose bengal (2–4 mg/kg), CASPc (2 mg/kg), and chlorin e6 (2 mg/kg).

Implementation: Evaluate the ability of Rose Bengal, aluminum phthalocyanine tetrasulfonate (CASPc), and chlorin e6 to localize intraocular xanthene, phthalocyanine, and chlorin photosensitizers through the application of fluorescence microscopy and digital fundus fluorescence angiography.

The eyes are then enucleated and examined by means of fluorescence microscopy 5, 20, 60, and 120 minutes and 24 hours after dye injection. *In vivo* digital fundus fluorescence angiography can be performed with rose bengal, CASPc, or chlorin e6.

Animal Model: Rabbit (albino).

Interpretation and Analysis: Pathologically, all agents displayed moderate fluorescence from the choroid and retinal pigment epithelium 5 minutes after dye injection. Mild fluorescence detected from the photoreceptor outer segments at 5 minutes is increased by

20 minutes. Angiographic studies with the use of rose bengal, CASPc, and chlorin e6 reveal differences in the pattern and rate of photosensitizer accumulation. Rose bengal, CASPc, and chlorin e6 accumulate rapidly in the choroid and retinal pigment epithelium and less rapidly in the outer retina. Differences in ocular localization of these photosensitizers can be demonstrated. The significance of these findings for potential models for the development of diagnostic agents and photodynamic therapy will require further investigation.
Instrumentation: Fluorescence microscopy.

Localization of rose bengal, aluminum phthalocyanine tetrasulfonate, and chlorin e6 in the rabbit eye. Haimovici R, Ciulla TA, Miller JW, Hasan T, Flotte TJ, Kenney AG, Schomacker KT, Gragoudas ES. Retina 2002 Feb; 22 (1), pp. 65–74.

Retinal Microglial Cell Development: Postnatal/ Optic Nerve Crush Injury
Fluorogold (FG)/4-[4-Didecylaminostyryl]-N-Methylpyridinium Iodide (4Di-10ASP)

Cellular/Molecular Mechanism of Action: Fluorogold (FG) and (4-[4-didecylaminostyryl]-N-methylpyridinium iodide (4Di-10ASP) function as fluorescent dye reagents.
Application: Characterization of retinal microglial cell populations and their development in the postnatal period.
Route of Administration: Injected into the superior colliculus (SC) at postnatal day 0.
Implementation: Fluorogold (FG) or (4-[4-didecylaminostyryl]-N-methylpyridinium iodide (4Di-10ASP) can be injected into the superior colliculus (SC) at postnatal day 0. Retinas can then be examined to quantify microglial cells from P5 to adulthood. Complementary studies can evaluate the reaction of microglia to optic nerve crush in adult animals.
Animal Model: Mouse (postnatal day 0 [P0] to adulthood).
Interpretation and Analysis: Fluorogold (FG) or (4-[4-didecylaminostyryl]-N-methylpyridinium iodide (4Di-10ASP) are transported retrogradely to the RGC soma when either dye is injected into the SC at P0. Some of the labeled RGCs die due to natural apoptosis during this stage of development and are phagocytosed by microglial cells that move into the site of RGC death and become labeled with the same dye. Both dye reagents label RGCs in the contralateral retina and a few RGCs in the retina ipsilateral to the injected SC. The density of labeled RGCs decreases by 22% between P5 and P7. During this phase, microglial cells become visible as they ingest fluorescent detritus of the dying RGCs. Microglial cells are evenly distributed across the entire retinal surface and migrate to the outer plexiform layer. Migrating microglia consecutively alter their morphology from the amoeboid to the ramified form. In terms of intracellular storage of the dyes, resident microglial cells retain the fluorescent dye 4Di-10ASP over a period of 12 months. In contrast, FG is completely transferred from the RGCs and microglial cells to intramural cells (pericytes) of the retinal capillaries after 10 months. This results in delineation of the entire intraretinal vascular network. Finally, resident retinal microglial cells are also activated by injury to the adult optic nerve and actively phagocytose degenerating neurons. Retinal microglial cells can be monitored with vital fluorescent dyes while they migrate across the retina and establish their intraretinal network. It is possible to label microglia with lipophilic dyes, and they remain labeled for an extended period of time. In addition, intramural pericytes can be labeled by slow release of FG from RGCs and microglial cells. Such observations suggest that ingested fluorescent dyes having different properties can be used *in vivo* to study different cell populations of the retina.

Migration of phagocytotic cells and development of the murine intraretinal microglial network: An *in vivo* study using fluorescent dyes. Bodeutsch N, Thanos S. Glia 2000 Oct; 32 (1), pp. 91–101.

Retinal Microvasculature: Pathology/Platelet Endothelium Interactions
Carboxyfluorescein Diacetate Succinimidyl Ester/ Platelets (Fluorescent Labeled)

Cellular/Molecular Mechanism of Action: Carboxyfluorescein diacetate succinimidyl ester interacts with light and functions as a fluorescent indicator/marker molecule suitable for "tracing" the migration of different cell types.
Application: Visualization of *in vivo* platelet behavior in the retinal microcirculation. The methodology allows for quantitative evaluation of platelet dynamics and platelet-endothelial interactions in retinal pathologic conditions.
Route of Administration: Intravascular.
Considerations: Represents the development of a new method for evaluating the *in vivo* dynamics of platelets in the retinal microcirculation and the quantitative investigation of platelet-endothelial interactions.
Implementation: Isolated platelet samples are labeled with carboxyfluorescein diacetate succinimidyl ester. After intravenous administration, platelet behavior in the retinal microcirculation can be evaluated with a scanning laser ophthalmoscope. Images are recorded on S-VHS videotape and analyzed with a computer-assisted image analysis system. The platelet-endothelial interactions in the retinal microcirculation can also be investigated employing lipopolysaccharide-stimulated endothelium or platelets activated with thrombin.
Animal Model: Rat retina.
Interpretation and Analysis: Fluorescent platelets are recognized as distinct dots in the retinal microcirculation that can be traced frame by frame. The velocity of platelets in the retinal arteries, capillaries, and veins is approximately 26.1 ± 6.4, 1.6 ± 0.4, and 19.9 ± 8.2 mm/sec, respectively. In control *in vivo* models, even activated platelets show minimal interaction with retinal endothelial cells. Alternatively, stimulated retinal endothelium shows active platelet-endothelial interactions, with many platelets observed rolling and adhering along the major retinal veins. The interactions between platelets and stimulated endothelial cells are substantially inhibited with the injection of P-selectin monoclonal antibody.

In vivo evaluation of platelet-endothelial interactions in retinal microcirculation of rats. Tsujikawa A, Kiryu J, Nonaka A, Yamashiro K, Nishiwaki H, Tojo SJ, Ogura Y, Honda Y. Invest Ophthalmol Vis Sci 1999 Nov; 40 (12), pp. 2918–24.

Retinal Neuron Visualization
Retrogradely Transportable Fluorescent Dyes

Cellular/Molecular Mechanism of Action: Fluorescent reagents emit color when exposed to certain wavelengths of light energy.
Background Information: Post-traumatic death of mature retinal neurons occurs in glaucoma and after optic nerve injury.
Application: Characterization of dynamic processes associated with cell death applying analytical methods capable of monitoring changes over time.
Implementation: Coupling the development of retrograde-transported fluorescent dyes with modification of conventional epi-

fluorescence microscopy employed to visualize and manipulate retinal neurons applicable to *in vivo* models.

Interpretation and Analysis: Retinal conditions can be effectively monitored, including glaucoma or optic nerve transection, and for evaluating the effectiveness of neuroprotective strategies.

In vivo FM: Using conventional fluorescence microscopy to monitor retinal neuronal death *in vivo*. Thanos S, Indorf L, Naskar R. Trends Neurosci 2002 Sep; 25 (9), pp. 441–4.

Retina: Postischemia/Platelet–Endothelium Interactions
Anti-P-Selectin Immunogloblin/Carboxyfluorescein Diacetate Succinimidyl Ester-Labeled Platelets

Cellular/Molecular Mechanism of Action: Carboxyfluorescein diacetate succinimidyl ester can function as a signal or indicator molecular. Anti-P-selectin monoclonal antibody recognizes and physically binds to membrane-associated P-selectin complexes.

Background Information: Accumulating evidence suggests that platelets play an important role in ischemia-reperfusion injury. To fulfill that role, platelets flowing in the bloodstream would have to interact with retinal endothelial cells and to accumulate in the postischemic retina.

Application: Carboxyfluorescein diacetate succinimidyl ester can be used to label cell populations (e.g. platelets) for the purpose of quantitatively characterizing platelet-endothelial interactions in postischemic retinal structures after transient retinal ischemia.

Route of Administration: Intravenous (labeled platelets).

Implementation: Isolated and partially purified platelet populations are labeled with carboxyfluorescein diacetate succinimidyl ester and administered intravenously after various scheduled reperfusion periods. Platelet-endothelial interactions in postischemic retina are evaluated *in vivo* with a scanning laser ophthalmoscope. Anti-P-selectin monoclonal antibody (mAb) is administered 5 minutes before the injection of labeled platelets. P-selectin gene expression in the postischemic retina is then analyzed by semiquantitative polymerase chain reaction (PCR) analyses.

Animal Model: Rats (Long-Evans strain). Transient retinal ischemia can be induced for 60 minutes by temporal ligation of the ophthalmic nerve.

Interpretation and Analysis: Under basal conditions, infused platelets show minimal interactions with retinal endothelial cells. Conversely, postischemic retinas show active platelet-endothelial interactions. Many platelets can be observed rolling along and adhering to the major retinal veins. The number of rolling and adhering platelets reaches a peak (555 ± 65/mm per minute and 25.8 ± 3.2/mm^2) 12 hours after reperfusion. However, interactions between platelets and postischemic retinal endothelial cells is substantially inhibited by neutralizing P-selectin expressed on endothelial cells using monoclonal antibody. In addition, P-selectin gene expression in postischemic retina corresponds with the time course of platelet-endothelial interactions during the reperfusion period. Platelets actively interact with retinal endothelial cells in the postischemic retina through P-selectin complexes expressed on the retinal endothelial cells.

Instrumentation: Scanning laser ophthalmoscope.

In vivo evaluation of platelet—endothelial interactions after transient retinal ischemia. Nishijima K, Kiryu J, Tsujikawa A, Honjo M, Nonaka A, Yamashiro K, Tanihara H, Tojo SJ, Ogura Y, Honda Y. Invest Ophthalmol Vis Sci 2001 Aug; 42 (9), pp. 2102–9.

Retinal Vascular Permeability Monitoring/ Minimally-Invasive Diagnostic Strategy [Diabetes]
Sodium Fluorescein

Background Information: Diabetic retinopathy is the leading cause of blindness in working-age individuals in the United States. Breakdown of the blood-retinal barrier is one of the earliest events in the progression of diabetic retinopathy. Ideally, therapeutic measures sould be directed at events occurring during this early stage, but there are few sensitive, quantitative methods to assess *in vivo* the retinal vascular barrier.

Application: Quantitative assessment of the retinal vascular barrier.

Implementation: Utilization of 2 fluorescent tracers in combination with fluorescence microangiography to quantitatively assess retinal vascular barrier. A second concept of interest is delineation of the influence of hyperosmolar mannitol (1.6 M) infusions for 5 minutes on the diffusion/penetration of fluorescent tracers.

Animal Model: Rat (Long-Evans strain).

Interpretation and Analysis: Permeability $\times$ surface area/flow (PS/F) describes the characteristics of the retinal vasculature (approximately 0.086 ± 0.031 for $n = 13$). Based on estimates of flow and surface area, estimated permeability of sodium fluorescein is approximately 1.2×10^{-5} cm/sec. Infusion of a hyperosmolar mannitol solution significantly increases PS/F within individual veins and significantly increases flow-weighted PS/F from 0.073 ± 0.028 to 0.16 ± 0.034 ($n = 3$). Quantitative *in vivo* assessment of retinal vasculature can be delineated applying an adapted indicator dilution technique. Dual-tracer fluorescence angiography appears to be a sensitive indicator for detecting increases in the blood-retinal barrier produced by hyperosmolar mannitol. The methodology may be a promising new minimally-invasive strategy that may be adapted to quantitatively track retinal vascular permeability.

Instrumentation: Fluorescence microangiography.

Retinal vascular permeability determined by dual-tracer fluorescence angiography. Russ PK, Gaylord GM, Haselton FR. Ann Biomed Eng 2001 Aug; 29 (8), pp. 638–47.

Retinal Vascular Reperfusion Injury/Leukocyte Rolling Phenomenon Following Ischemic Insult
Acridine Orange

Cellular/Molecular Mechanism of Action: Acridine orange emits a fluorescent color when exposed to certain wavelengths of light energy.

Background Information: Recent reports have shown that ischemic preconditioning induces strong protection against retinal damage from prolonged episodes of ischemia and that such protection is mediated by mechanisms involving the adenosine A1 receptor.

Application: Evaluate quantitatively the effects of ischemic preconditioning on leukocyte-mediated reperfusion injury after transient retinal ischemia and to define the role of the adenosine A1 receptor in these effects.

Implementation: The adenosine A1 receptor antagonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) is administered intramuscularly immediately after ischemic preconditioning. Leukocyte behavior in the retina after 60 minutes of ischemia can then be evaluated *in vivo* with acridine orange digital fluorography.

Animal Model: Rats/male. (Transient retinal ischemia created by temporary ligation of the optic nerve. Ischemic preconditioning [5 minutes of ischemia] is induced 24 hours before 60 minutes of ischemia.)
Interpretation and Analysis: Ischemic preconditioning inhibits leukocyte rolling. The maximum number of rolling leukocytes is reduced to 3.0% at 12 hours after reperfusion ($p < 0.01$). Subsequent leukocyte accumulation is also decreased with ischemic preconditioning. The maximum number of accumulated leukocytes is reduced to 22.6% at 24 hours after reperfusion ($p < 0.01$). These inhibitory effects are suppressed by the administration of DPCPX ($p < 0.0001$). The numbers of rolling leukocytes at 12 hours after reperfusion and accumulated leukocytes at 24 hours after reperfusion is approximately 102.7% (NS) and 83.4% ($p < 0.01$), respectively, compared with numbers without ischemic preconditioning. Ischemic preconditioning, therefore, has an inhibitory effect on leukocyte rolling and subsequent leukocyte accumulation during retinal ischemia-reperfusion injury. Furthermore, the adenosine A1 receptor may play an important role in these inhibitory effects.
Instrumentation: Digital fluorography.

Inhibitory effect of ischemic preconditioning on leukocyte participation in retinal ischemia-reperfusion injury. Nonaka A, Kiryu J, Tsujikawa A, Yamashiro K, Nishijima K, Miyamoto K, Nishiwaki H, Honda Y, Ogura Y. Invest Ophthalmol Vis Sci 2001 Sep; 42 (10), pp. 2380–5.

Sympathetic Innervation: Ophthalmic
Phenylephrine

Cellular/Molecular Mechanism of Action: Adrenergic receptor agonist activity, thereby causing increased sympathetic tone within the autonomic nervous system.
Diagnostic Application: Detect absent or impaired sympathetic (autonomic) nervous system innervation to smooth muscle structures of the pupil (iris).
Route of Administration and Dosage: Ophthalmic (topical) application.
Implementation: Detection of the presence or absence of a dilated pupilary response following topical application to the cornea as a means of detecting and characterizing alterations in adrenergic/sympathetic innervation to ocular anatomical structures.
Interpretation and Analysis: Phenylephrine promotes a hyperactive response in ocular smooth muscles that have lost postganglionic neuron innervation. A normal response analogous to that appreciated in the unaffected contralateral eye is appreciated in instances where postganglionic neuron function is intact. Smooth muscle tissues deprived of lower motor neuron innervation respond in a hyperactive manner when exposed to exogenous (topical) adrenergic neurotransmitter substances or their equivalent pharmacological agonists. Therefore, exposure of ocular structures to phenylephrine after they have lost a substantial amount of sympathetic (autonomic) innervation results in an excessively dilated pupil in contrast to reference (normal) controls.

Sympathetic Innervation: Ophthalmic
Amphetamine

Cellular/Molecular Mechanism of Action: Promotes release of the neuromuscular transmitter norepinephrine from the postganglionic, presynaptic sympathetic lower motor neuron.
Diagnostic Application: Detection and characterization of compromised upper or lower motor neuron dysfunction associated with sympathetic axons innervating ocular structures.
Dosage: Ocular therapeutic preparations formulated for topical application.
Implementation: Differentiation of alterations in preganglionic versus postganglionic adrenergic/sympathetic autonomic nervous system innervation to smooth muscle ophthalmic structures.
Interpretation and Analysis: Detection of the presence or absence of pupillary dilation following topical application. Damage to lower motor neurons results in an absence of functional sympathetic neurotransmitter at the neuromuscular junction. Pupillary smooth muscle tissue that has been deprived of sympathetic (adrenergic) lower motor neuron innervation (autonomic nervous system) is relatively unresponsive to topical amphetamine administration. Explanation for this observation is based upon the concept that amphetamine is incapable of inducing the release of adrenergic neurotransmitter (norepinephrine) if the integrity of the sympathetic lower motor neuron has been seriously compromised or is nonexistent. Alternatively, in the presence of a viable and intact sympathetic lower motor neurons that have been deprived of upper motor neuron innervation, they still can synthesize and release adrenergic neurotransmitter (norepinephrine) from the presynaptic membrane (neuromuscular cleft).

Sympathetic Innervation: Ophthalmic
Dextroamphetamine

Cellular/Molecular Mechanism of Action: Promotes release of adrenergic (catecholamine) neuromuscular transmitter from the sympathetic lower motor neuron.
Application: Identification of the anatomical location of a deficit/lesion affecting input from the adrenergic/sympathetic autonomic nervous system to smooth muscle ophthalmic structures.
Route of Administration: Ophthalmic (topical).
Dosage: Topical application of ophthalmic formulations.
Implementation: Differentiation of alterations in preganglionic versus postganglionic adrenergic/sympathetic autonomic nervous system innervation of smooth muscle ophthalmic structures.
Interpretation and Analysis: Lack of a response can be appreciated when there has been a loss of sympathetic lower moter neuron function. The explanation for this observation is based on the mechanism of dextroamphetamine which only promotes the release of adrenergic neurotransmitter from intact/viable lower motor neurons.

Topical application of dextroamphetamine to the corneal surface when Horner's syndrome is caused by a lesion located above the terminal lower motor neuron of the sympathetic (adrenergic) autonomic nervous system results in a hyperactive pupillary light reflex response. Such a phenomenon is functionally and neuroanatomically analogous to a hyperactive reflex recognized with an upper motor neuron lesion. Detection of a positive response suggests that the postganglionic adrenergic/sympathetic lower motor neuron is viable.
Instrumentation: Ophthalmascope.

SPECIAL SENSES: NON-OPHTHALMIC

Vestibular-Cochlea/Noise-Related Injury/Damage
Gd-DTPA-BMA

Cellular/Molecular Mechanism of Action: The element gandolinium (Gd) is a paramagnetic ion that has its spacial orientation altered within a magnetic fields.
Application: Detection and characterization of normal and noise-damaged cochlea where it can be used as a T1 contrast agent with MRI modalities.

Route of Administration: Gd-DTPA-BMA (intravenous).

Implementation: Evaluate the time course and distribution of the *in vivo* uptake of the gadodiamide chelate bound paramagnetic Gd ion (Gd-DTPA-BMA) throughout the membranous labyrinth of normal and impulse noise-damaged guinea pig cochleae utilizing MRI at 4.7T.

Interpretation and Analysis: Simultaneous signal enhancement of the basal, medial, and apical scala tympani (ST) and scala vestibuli (SV) can be observed within 10 minutes following injection with maximal levels reached at around 100 minutes. Evaluation by ANOVA and post hoc paired t tests reveals statistically significant differences in the levels and rates of Gd uptake-enhancement between the scalae. The basal, medial, and apical ST reveal the most rapid and extensive enhancement throughout the period of active Gd uptake, while the SV show comparatively slower and less enhancement, and the intact scala media (SM) indicate insignificant enhancement. The *in vivo* Gd penetration and enhancement of the membranous SM increases significantly in the noise-damaged cochlea, suggesting lesioning of the cochlear membranes.

Magnetic resonance imaging of the membranous labyrinth during *in vivo* gadolinium (Gd-DTPA-BMA) uptake in the normal and lesioned cochlea. Counter SA, Bjelke B, Borg E, Klason T, Chen Z, Duan ML. Neuroreport 2000 Dec 18; 11 (18), pp. 3979–83.

Vestibular-Cochlear Disease/Ménière's Disease (MD): Predictive Risk and Prediction of Disease Progression/Endolymphatic Hydrops (ELH)
Furosemide and Glycerol/Electrochochleography (EcochG)

Application: Utilization of ECochG and glycerol and furosemide tests to predict the probability that atypical MD will progress to definite MD.

Implementation: Evaluation of vestibular disease conditions utilizing ECochG in combination with glycerol and furosemide tests as a potential avenue for predicting MD.

Human Model: Cases of vestibular disease (n = 1569). The vestibular condition can be preclassified as definite MD, atypical MD, syphilitic labyrinthitis, delayed ELH, sudden hearing loss, cochleovestibulopathy, and sensorineural hearing loss. Cases with atypical MD are divided into 5 categories based on their symptoms.

Interpretation and Analysis: Approximately 97% of cases (e.g. n = 115/118) with definite MD that undergo all 3 tests show a positive result in at least 1 test. In cases that do not satisfy the diagnostic criteria of definite MD but initially have vertigo and/or hearing loss subsequently progress to definite MD. Approximately 92% of cases show at least 1 positive finding in these 3 tests at the initial stage. In those patients that show a negative test result in either ECochG or the glycerol test, the possibility of progression to definite MD is apparently low. Therefore, the combination of ECochG and the glycerol and furosemide tests can assist in diagnosing endolymphatic hydrops (ELH). In this context, ECochG and the glycerol test are effective agents for predicting the progression to definite MD in cases with atypical MD, sudden hearing loss and other cochleovestibular diseases. Such findings also indicate that the pathological state of atypical MD includes both non-ELH and ELH.

Prediction of progression from atypical to definite Ménière's disease using electrocochleography and glycerol and furosemide tests. Kimura H, Aso S, Watanabe Y. Acta Otolaryngol 2003 Apr; 123 (3), pp. 388–95.

3 Endocrine System

GASTROINTESTINAL AND PANCREATIC SYSTEMS

Gastrinoma/Insulinoma/Intestinal Carcinoids
Calcium Ion Infusion with Pentagastrin/Adjunct Secretin Test

Cellular/Molecular Mechanism of Action: Induces the release of gastrin from gastrinoma in response to alterations in serum calcium concentrations.
Application: Detection of endocrine tumors affecting the pancrease and gastrointestinal tract (gastrinoma, insulinoma, intestinal carcinoids)
Route of Administration: Intravenous.
Interpretation and Analysis: Calcium infusion is recommended for the diagnosis of Zollinger-Ellison syndrome when the secretin stimulation test is equivocal. The calcium provocative test in the detection of insulinoma and carcinoid tumors is less reliable than other safer and simpler procedures. Intravenous injection of calcium followed by pentagastrin stimulates the release of somatostatin in patients with somatostatinoma and offers a reliable means for establishing the diagnosis of this tumor. Calcium administration has not proven to be useful in the diagnosis of other endocrine tumors of the digestive system.

Use of calcium provocative test in the diagnosis of gastroenteropancreatic endocrine tumors. Vezzadini C, Poggioli R, Casoni I, Vezzadini P. Panminerva Med 1996 Dec; 38 (4), pp. 255–8.

Gastrinoma/Insulinoma/Intestinal Carcinoids/ Zollinger Ellison Syndrome
Calcium Infusion

Cellular/Molecular Mechanism of Action: Induces release of certain endogenous hormones.
Diagnostic Application: (i) Gastrinoma—gastrin assay; (ii) Zollinger-Ellison syndrome—secretin assay; (iii) somatistatinoma—somatostatin (calcium/pentagastrin combination); (iv) insulinoma—diagnostically not reliable; (v) intestinal carcinoid—diagnostically not reliable.
Interpretation and Analysis: Elevations in gastrin, secretin, and somatostatin following calcium admnistration when above normal reference control values implies the existence of a gastrinoma, Zollinger-Ellison syndrome, or somatistatinoma respectively.

Pancreatic Function/Diabetes (Insulin-Dependent)/ Obesity/Cushing's Syndrome/Acromegaly
Arginine/Glucose Suppression

Physiological Mechanism of Action: Glucose suppresses pancreatic glucagon secretion and increases insulin secretion by beta cells residing within the islets of Langerhans of the pancreas.
Application: Characterization of endocrine/metabolism function in diabetics and conditions of obesity.
Semi-Synthetic Methods: Glucagon can be radioiodinated by the chloramine T technique and purified on QAE-Sephadex A 25 to a specific activity of 225 μCi/μg for use in a glucagon radioimmunoassay method. The standard curve reveals that it is possible to measure (detect) from 12 to 500 pg/ml with sensitivity level of 17.5 pg/ml, precision of 6.3 to 14.9% (CV, within-assay) and 5.6 to 10.7% (CV, between-assay). Recovery is between 82 and 112%.
Implementation: Evaluation of glucagon levels in conditions of diabetes, obesity, acromegaly, and Cushing's syndrome.
Interpretation and Analysis: Fasting plasma glucagon levels in diabetics, obese subjects, acromegalics, and patients with Cushing's syndrome are greater than in normal subjects (22.0 ± 91 pg/ml; mean ± SD). Very low glucagon levels after oral glucose suppression (15.2 ± 3.1 pg/ml) can be detected in normal subjects. Conversely, greatly increased values after arginine can be measured in insulin-dependent diabetics (271.0 ± 132.3 pg/ml).

Evaluation of a sensitive and specific radioimmunoassay for pancreatic glucagon in human plasma and its clinical application. Borghi VC, Wajchenberg BL, Albuquerque RH. Clin Chim Acta 1984 Jan 16; 136 (1), pp. 39–48.

Pancreatic Function in Obesity/Insulin/Glucagon
Glucose

Physiological Mechanism of Action: Glucose suppresses pancreatic glucagon secretion and increases insulin secretion by beta cells residing within the islets of Langerhans of the pancreas.
Route of Administration and Dosage: Glucose: 2-hour glucose infusion (12 mg/kg/min), primed by an initial injection of 0.33 g/kg glucose.
Implementation: Evaluation of pancreatic glucagon (IRG) and insulin (IRI) secretion patterns in conditions of obesity.
Human Model: Obese subjects with normal (n = 7), borderline (n = 5), and pathological carbohydrate tolerance (n = 11), in addition to non-obese healthy controls (n = 19) without a family history of diabetes.
Interpretation and Analysis: Insulin secretion in a very high percentage of obese subjects can be characterized by a significant hyperinsulinemia during the late secretion phase (n = 18/18 or 100%).

The early insulin response (delta IRI-area 0–5 minutes) is significantly reduced in obesity with pathological carbohydrate tolerance. There is no significant difference in fasting IRG levels among controls (29.7 ± 6.1 pmol/l) and pathological glucose tolerance (31.2 ± 4.6 pmol/l). In addition, absolute IRG levels and the IRG concentration pattern during glucose infusion are comparable in all groups confirming no alpha-cell resistance to glucose suppression in obesity, irrespective of normal or impaired carbohydrate tolerance. The molar IRI-IRG ratio is significantly increased during glucose infusion in the vast majority of obese individuals (n = 18/18 or 100%) reflecting a relative anabolic state. There are no correlations between IRG secretion and relative body weight, glucose tolerance, or insulin response to glucose.

Pancreatic glucagon response to glucose in obesity with normal and impaired carbohydrate tolerance. Ratzmann KP, Schulz B, Witt S, Ziegler M. Int J Obes 1981; 5 (2), pp. 163–9.

Pancreatic Neoplasia: Insulin (Islet Cell) Adenoma *Calcium*

Application: Diagnosis of insulin-secreting tumors including islet cell adenoma that are undetectable during the course of preoperative morphology-based imaging modalities.
Route of Administration: calcium test (selective intra-arterial catheterization).
Dosage: calcium gluconate (4 mg/kg/hour) is administered over a 2-hour infusion period.
Considerations: calcium ion *in vitro* plays a fundamental role in regulating insulin secretion but the influence of calcium excess on insulin release *in vivo* has not been clearly defined. The described test is not of diagnostic value for this particular purpose.
Implementation: Evaluate the efficacy of the intra-arterial calcium test for the purpose of localizing sources of hyperinsulinism that remain undetectable with preoperative morphologic studies (e.g., ultrasound, computed tomography, magnetic resonance imaging, endoscopic US, abdominal arteriography). The calcium infusion test, is performed in conjuction with the assay of insulin concentrations in hepatic venous blood after selective intraarterial calcium stimulation.

Human Model: Cases of clinically proven endogenous hyperinsulinism due to tumorous insulin production (e.g., n = 24) Of these cases, approximately 30% (n = 7/24) will have negative morphologic findings (n = 5/7 famales; n = 2/7 males; age range, 30–66 years; mean age, 47 years).
Interpretation and Analysis: Approximately 30% of affected cases will have negative results from morphological analyses (e.g., n = 7/24). Surgical intervention may lead to the detection of solitary insulinomas (e.g., n = 6 = mean diameter, 0.73 cm) and nodular hyperplasia (e.g., n = 1). Calcium tests allow accurate localization of the pathologic source of insulin secretion (e.g., n = 7/7). In < 50% of cases, results of arterial calcium stimulation with hepatic venous sampling (ASVS) may affect intraoperative management (e.g., n = 3/7). Lack of an increase in insulin concentrations after stimulation in the hepatic artery suggests that hepatic metastases is unlikely. ASVS, which is procedurally simpler than transhepatic pancreatic venous sampling, is effective for localizing sources of hyperinsulinism not detected with preoperative morphology-based studies.

Other clinical trials have reported mean calcium plasma levels can increase from 9.6 + 0.4 to 11.6 + 0.8 mg/100 ml. During calcium infusion, blood glucose and plasma insulin concentrations can remain unchanged. Observations noted in these case-based studies suggests that calcium fails to stimulate basal insulin secretion even in cases of organic hyperinsulinism, and that calcium infusion is not helpful as a provocative test in the diagnosis of insulinoma.

Insulinoma and islet cell hyperplasia: value of the calcium intraarterial stimulation test when findings of other preoperative studies are negative. Pereira PL, Roche AJ, Maier GW, Huppert PE, Dammann F, Farnsworth CT, Duda SH, Claussen CD. Radiology 1998 Mar; 206 (3), pp. 703–9.

Pancreatic Neoplasia: VIP Secreting/VIPoma Syndrome: Vasoactive Intestinal Peptide/Pancreatic Peptide/Neurotensin/Enhanced Immunohistopathology Accuracy *Calcium,/Secretin/Pentagastrin*

Diagnostic Application: Detection of patients suffering from pancreatic tumors consistent with VIPoma syndrome.

Background Information: Pancreatic endocrine tumors (PETs) may secrete a variety of peptide hormones, either alone or in combination. Intravenously administered provocative agents have been used to stimulate hormone release to aid in the diagnosis and localization in suspected cases.
Route of Administration: Intravenous injection.
Dosage: Pentagastrin (0.5 mg/kg/5 sec or 0.5 mg/kg/min); rapid calcium infusion (2 mg/kg/min).
Semi-Synthetic Methods: Plasma hormone radioimmunoassays and immunohistochemical studies are performed for a panel of peptide hormones, including VIP, neurotensin, and pancreatic polypeptide (PP). Acid alcohol extracts of tumor specimens are analyzed for the peptide hormones as well.
Implementation: Before surgical intervention, 4 provocative test regimens are administered intravenously after an overnight fast: (i) pentagastrin (0.5 mg/kg/5 sec); (ii) rapid calcium infusion (2 mg/kg/min); (iii) a combination of calcium (2 mg/kg/min) followed by pentagastrin (0.5 μg/kg/min); and (iv) secretin (2 clinical units/kg bolus). Blood samples are collected before each test and 1, 2, 3, 5, and 10 minutes after the infusions.

Case Example: Detailed biochemical investigations and provocative testing in a 26-year-old man with a 5 cm vasoactive intestinal peptide (VIP)-secreting tumor of the head of the pancreas.
Interpretation and Analysis: Increases in the production/release of vasoactive intestinal peptide, neurotensin, and pancreatic polypeptide (PP) can be detected in both serum samples and within tumor biopsies by immunohistochemical analysis. Coexpression of VIP and neurotensin can be seen immunohistochemically within some individual tumor cells. Provocative testing results in maximal stimulation of VIP and neurotensin secretion with pentagastrin administration, which produces increases in plasma levels of VIP and neurotensin over basal levels of 81% and 87%, respectively. Following surgical intervention, plasma levels of VIP, neurotensin, and PP are undetectable before and after administration of pentagastrin. Such observations emphasize the importance of comprehensive biochemical evaluation in VIPoma syndrome cases to detect production of a range of peptide hormones. Administration of intravenous pentagastrin appears to stimulate release of VIP and NT and should be evaluated further as a provocative agent for the diagnosis and follow-up of cases with these tumors.

Stimulation of vasoactive intestinal peptide and neurotensin secretion by pentagastrin in a patient with VIPoma syndrome. Brunt LM, Mazoujian G, O'Dorisio TM, Wells SA Jr. Surgery 1994 Mar; 115 (3), pp. 362–9.

HYPOTHALAMUS AND PITUITARY: GENERAL AND MISCELLANEOUS

Note: Hypothalamic/pituitary functional tests can also be applied to evaluate conditions such as neonatal prematurity and severe cranial trauma.

Anterior Pituitary Function: Combined *Corticotropin-Releasing Factor (CRF)/Growth Hormone-Releasing Factor (GHRF)/Gonadotropin-Releasing Hormone (GnRH)/Thyrotropin-Releasing Hormone (TRH)*

Cellular/Molecular Mechanism of Action: Ovine corticotropin-releasing factor (oCRF) stimulates increased plasma immunoreactive adrenocorticotropin (IR-ACTH) and IR-cortisol.
Dosage: Threshold, half-maximal, and maximal doses that have been applied include 0.01–0.03, 0.3–1, and 3–10 μg/kg, respectively.

Considerations: Cushing's disease patients respond variably, suggesting that oCRF may not be a very useful diagnostic agent in Cushing's syndrome.
Interpretation and Analysis: Side effects occur with increasing frequency, severity, and duration at doses above 1 μg/kg. Ovine CRF has a prolonged duration of action, at least in part because of the long circulating half-life of intact oCRF in plasma. Plasma IR-lipotropins and IR-beta-endorphin rise and fall concomitantly with IR-ACTH after oCRF injection. Arginine vasopressin increases the IR-ACTH response to oCRF 4-fold when given simultaneously with oCRF.

Increasing doses of oCRF given in late afternoon progressively diminish the next morning's circadian rise in plasma IR-ACTH in normal subjects, but not in Addisonian patients or subjects receiving metyrapone, indicating that prolonged oCRF-induced hypercortisolemia is the cause. The combination of oCRF with GHRF, GnRH, and TRH appears to provide a rapid and useful test of combined anterior pituitary function.

Clinical studies with synthetic ovine corticotropin-releasing factor. Orth DN, DeBold CR, DeCherney GS, Jackson RV, Sheldon WR Jr, Nicholson WE, Uderman H, Alexander AN, Island DP, Rivier J, et al. Fed Proc 1985 Jan; 44 (1 Pt 2), pp. 197–202.

Chorea-Acanthocytosis (Familial)/Dopaminergic System
Levodopa/Thyroid-Stimulating Hormone (TSH)/ Thyrotropin-Releasing Hormone (TRH)/Glucose Tolerance

Physiological Mechanism of Action: Levodopa promotes the release of growth hormone-releasing hormone (GHRH).
Application: Assessment of hypothalamic/pituitary function (acromegaly, gigantism, anterior secretion, somatropin secretion). L-dopa can be used to assess growth hormone-releasing hormone synthesis/release. Thyroid-stimulating hormone can be used to evaluate thyroid function and TRH can serve to assess plasma prolactin responses.
Dosage: Glucose (oral tolerance test 75 g).
Implementation: Hypothalamic/pituitary interactions and functionality can be assessed by the collective administration of L-dopa, TSH, TRH, and oral glucose tolerance test. Evaluation of the endocrinology of dopaminergic regulation of the hypothalamic-pituitary axis in conditions of familial chorea-acanthocytosis.

Human Model: Cases of familial chorea-acanthocytosis (n = 3 females, 38–47 years of age).
Interpretation and Analysis: Many cases of familial chorea-acanthocytosis (e.g., n = 3/3) will exhibit low basal levels of triiodothyronine (T-3), in addition to slightly elevated baseline plasma prolactin levels (e.g., n = 2/3). Cases will have delayed plasma TSH responses and plasma prolactin (PRL) excessive responses to TRH, and a low plasma growth hormone-releasing hormone (GRF) response to L-dopa. Such TSH, PRL, and GRF responses represent a secretion pattern due to a hypothalamic disorder that suggests the presence of impaired regulation of hormone secretion by the dopaminergic system, primarily in the hypothalamus. In addition, an increase in growth hormone (GH) response secretion following TRH (paradoxical response) can also be observed in some cases (e.g., n = 2/3), suggesting pituitary involvement. The vast majority of affected cases may display a diabetic profile when evaluated using an oral glucose tolerance test.

Disturbance of hypothalamic-pituitary hormone secretion in familial chorea-acanthocytosis. Terao S, Sobue G, Takahashi M, Miura N, Mitsuma T, Takeda A, Sakakibara T. No To Shinkei 1995 Jan; 47 (1), pp. 57–61.

Cranial Trauma: Hypothalmic/Pituitary Function/Neuroemergency Procedures/Prediction of Unfavorable Neurologic Outcome (Prognosis)/Prolactin (PRL)/Thyroid-Stimulating Hormone (TSH)/Growth Hormone (GH)/Triiodothyronine (T-3)/Thyroxine (T4)
Hypothalamic-Releasing Hormones/Thyrotropin-Releasing Hormone (TRH)

Application: Evaluate the effect of severe head injury on both the basal secretion of pituitary hormones and the response to exogenous synthetic hypothalamic-releasing factor administration.
Route of Administration: Intravenous.
Implementation: Evaluation of daily basal concentrations of GH, PRL, TSH, T-3, and thyroxine during the 1st week following CNS trauma and then again on days 15 and 16 posttrauma. Plasma insulin-like growth factor-I and cortisol are also determined on days 2, 7, and 15. Administration of TRH test can be applied for the evaluation of PRL, TSH, and GH responses on days 1 and 16 after a traumatic incident and a growth hormone-releasing hormone (GHRH) test for the evaluation of GH and PRL responses on days 2, 7, and 15 posttraumatic incident. Outcomes are evaluated at 6 months with the GOS. Triiodothyronine shows low values, even if they are within the normal range; thyroxine remains in the normal range. Significant increases in insulin-like growth factor-I concentrations are observed on both days 7 and 15 compared with day 2 ($p = 0.024$ and $p = 0.034$, respectively).

Human Model: Cases of head injury–induced coma (n = 22) all requiring intubation and mechanical ventilation in addition to invasive monitoring and without previous endocrinologic problems and substitutive therapies.
Interpretation and Analysis: The GH response to GHRH is significantly greater on days 7 and 15 than in the very acute phase ($p < 0.01$ comparing days 7 and 15 vs day 2). Higher GH responses to GHRH can be observed on day 7 in Case Group 1 compared to Case Group 2 (pertaining to both peak and area-under-the-curve values, $p = .018$ and $p = .015$, respectively). No difference in GH response can be detected on days 2 and 15. A "paradoxical" response of GH to TRH can be observed on the day following head trauma (basal vs peak, $p = .002$) but not on day 16. The GH peak response to TRH is greater on day 1 in cases with an unfavorable clinical course (Group 1 vs Group 2, $p < .05$). The TSH response to TRH does not significantly correlate with the severity of trauma but is significantly ($p < .04$) higher in Group 1 cases than in Group 2 cases. Finally, a "paradoxical" PRL response to GHRH administration is present on day 2 (basal vs peak, $p = .0003$), day 7 (basal vs peak, $p = .01$), and on day 15 after the trauma (basal vs peak, $p = .04$). Some of the responses to provocative tests have been identified as "paradoxical" and seem to have a great importance in the definition of prognosis in severe head-injured patients, specifically the GH response to TRH and the PRL response to GHRH that are significantly correlated with outcome.

Provocative hypothalamopituitary axis tests in severe head injury: Correlations with severity and prognosis. Della Corte F, Mancini A, Valle D, Gallizzi F, Carducci P, Mignani V, De Marinis L. Crit Care Med 1998 Aug; 26 (8), pp. 1419–26.

Cranial Trauma: Hypothalamic/Pituitary/Stress Ulceration/Hypothalamic Injury
Thyrotropin-Releasing Hormone (TRH)/Gonadotropin-Releasing Hormone (GnRH)

Background Information: In patients with severe head injury, hypothalamohypophyseal impairment with subsequent hormone

abnormalities has been well documented. Stress ulcer is another commonly encountered problem in such patients. However, little has been reported in the literature about the alterations of pituitary hormones in acute head-injured patients with stress ulcer.

Application: Detection and characterization of alterations in hypothalamic function secondary to detected cranial trauma as modified responses to GnRH and TRH.

Implementation: Evaluate the severity of cranial injury based pituitary function measured by assessment of basal serum levels of pituitary hormones measured before, and in response to TRH, and GnRH.

Human Model: Cases of cranial injury (n = 40 males). Candidate criteria for eligibility include (i) Glasgow coma scale 4–10; (ii) presentation within 24 hours following head injury; (iii) absence of shock or sepsis; and (iv) no past history of peptic ulcer. Stress ulcer is confirmed by endoscopic examination.

Interpretation and Analysis: Approximately two-thirds of cases will show evidence of stress ulcer based upon endoscopic examination (e.g., n = 27/40 or 67.5%). In the absence of stress ulcer, basal serum levels of thyroid-stimulating hormone (TSH), prolactin (PRL), growth hormone (GH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) are within normal range. However, basal levels of PRL in conditions of stress ulcer are abnormally elevated and significantly higher than in the absence of stress ulcers ($p < 0.001$). Basal levels of TSH and GH are significantly lower with stress ulcer than in the absence of stress ulcers ($p < 0.001$). In conditions of stress ulcer, significant increases ($p < 0.001$) in serum TSH, PRL, LH, and FSH levels after thyrotropin-releasing hormone (TRH) and gonadotropin-releasing hormone (GnRH) provocation can be detected. Hypothalamohypophyseal dysfunction and stress ulceration may occur in cases of severe cranial trauma. In the presence of stress ulcers, the abnormalities of pituitary hormones and provocative response of the pituitary with TRH and GnRH reveal normal pituitary function with hypothalamic insufficiency. Therefore, stress ulcers in acute head-injured patients are closely associated with hypothalamic damage.

Hypothalamic dysfunction in acute head-injured patients with stress ulcer. Hwang SL, Lieu AS, Howng SL, Hsieh JS, Huang TJ. Kaohsiung J Med Sci 1998 Sep; 14 (9), pp. 554–60.

Hypopituitary Conditions/Hallerman-Streiff Syndrome (HSS)/Hypothalamic/Pituitary Axis Function
Thyrotropin-Releasing Hormone (TRH)/Adenocorticotropic Hormone (ACTH)

Cellular/Molecular Mechanism of Action: Metyrapone inhibits enzymatic activity of 11β-hydroxylase thereby reducing cortisol production

Application: Evaluation of anterior hypopituitarism in HSS in conditions of ketotic hypoglycemia, micro-genitalia, and short stature.

Interpretation and Analysis: Endocrine evaluation may show low levels of T4 and TSH levels, suggesting hypothalamic hypothyroidism that can be confirmed by TRH stimulation. Performing a metyrapone test can confirm ACTH deficiency as a contributing factor to the ketotic hypoglycemia. A superagonist GnRH test can reveal concominant hypothalamic GnRH deficiency. A growth hormone provocative test in such instances can conclusively demonstrate a complete deficiency of growth hormone production. Imaging studies of the brain using MRI methodologies can detect evidence supportive of hypopituitarism in such cases. Although facial findings may not be completely classical for HSS, it has been suggested racial background may influence such phenotypic characteristics. Endocrine evaluation of HSS patients with clinical signs representative of hypopituitarism provides an opportunity to treat this condition in a manner that will substantially improve the quality of life of these patients.

Hallermann-Streiff syndrome with hypopituitarism contributing to growth failure. Pivnick EK, Burstein S, Wilroy RS, Kaufman RA, Ward JC. Am J Med Genet 1991 Dec 15; 41 (4), pp. 503–7.

Hypopituitary Conditions/Adenocorticotropic Hormone (ACTH) Deficiency/ACTH Reserve Status
Corticotropin-Releasing Hormone (CRH)/Adrenocorticotropin-Releasing Hormone/Metyrapone/Urine 17-OH Corticosteroids/Serum Deoxycorticosterone

Cellular/Molecular Mechanism of Action: Corticotropin-releasing hormone from the hypothalamus promotes release/synthesis of ACTH from the pituitary, which in turn promotes glucocorticoid release/synthesis from the adrenal cortex.

Diagnostic Application: Detection of conditions associated with pituitary dysfunction or developmental abnormalities.

Route of Administration: Corticotropin-releasing hormone (intravenous bolus).

Dosage: Metyrapone administration (450 mg/m^2/dose every 4 hours × 7 doses); ovine CRH (1 μg/kg).

Implementation: Evaluation of hypopituitary conditions as a function of comparative responses of (i) ACTH and cortisol (F) to (ii) CRH administration and its effect on urinary 17-OH corticosteroids (17-OHCS); and (iii) metyrapone-induced alterations in serum deoxycorticosterone (DOC). The CRH test is performed 3 days before or 3 weeks after the metyrapone test for the purpose of establishing ACTH reserve status.

Human Model: Cases of hypopituitary conditions (n = 16 with glucocorticoid therapy withheld for a minimum of 3 weeks before testing.)

Diagnostic Interpretation: In ACTH-intact hypopituitary conditions (e.g., n = 9 cases postmetyrapone 17-OHCS > 12.2 mumol/m^2/d; DOC ≥ 11.5 nmol/L), the peak F (497–773 nmol/L) and ACTH (5.2–22 pmol/L) responses to CRH stimulation are similar to those of normal subjects (F peak = 554–993 nmol/L and ACTH peak = 6–25 pmol/L at 15 to 60 minutes). In cases with partial ACTH deficiency (e.g., n = 1 case: postmetyrapone 17-OHCS = 10.5 mumol/m^2/d; DOC = 6 nmol/L), the peak F response is low and delayed (246 nmol/L at 180 minutes), while the peak ACTH response is normal (7 pmol/L). Severely ACTH-deficient conditions (e.g., n = 6 cases: postmetyrapone 17-OHCS < 5.4 mumol/m^2/d; DOC ≤ 3.4 nmol/L) have a low F response at 15 to 90 minutes in all, with a delayed rise at 120 to 180 minutes in response to CRH administration (n = 3/6), whereas ACTH responses are variable: absent or low, normal, delayed, or persistently exaggerated. Therefore, the CRH-stimulated F response pattern in hypopituitary patients is comparable to urinary 17-OHCS and serum DOC response to metyrapone administration.

Laboratory Instrumentation: ELISA-based immunodiagnostic assay of serum samples.

Comparison of adrenocorticotropin and adrenal steroid responses to corticotropin-releasing hormone versus metyrapone testing in patients with hypopituitarism. Riddick L, Chrousos GP, Jeffries S, Pang S. Pediatr Res 1994 Aug; 36 (2), pp. 215–20.

Multiple Sclerosis (MS): Hyperprolactinemia
Thyrotropin-Releasing Hormone (TRH) Stimulation/Bromocriptine

Cellular/Molecular Mechanism of Action: Thyrotropin-releasing hormone promotes prolactin (PRL) secretion.
Background Information: Before the onset and during experimental allergic encephalomyelitis (EAE; animal counterpart of MS), the peripheral concentrations of PRL have been found to be elevated and bromocriptine has been shown to attenuate such attacks. Prolactin may play a role in the immunology of MS.
Application: Multiple sclerosis cases reportedly display elevations in plasma PRL concentrations.
Interpretation and Analysis: Multiple sclerosis cases have slightly but significantly higher PRL levels at baseline (10.2 ± 1.6 vs 6.4 4 ± 0.57 ng/ml, p = 0.042) than do matched reference control subjects, however, values are within the normal range. Prolactin levels post-TRH are significantly higher in patients with MS with peak PRL levels higher than negative reference controls (57.08 ± 6.144 vs 32.94 ± 4.92 ng/ml, p = 0.006). The area under the curve for PRL is also higher in affected patients than in controls (3421.87 ± 394.53 vs 2317.62 ± 257.22 ng/ml, p = 0.030).

Prolactin secretion is increased in patients with multiple sclerosis. Azar ST, Yamout B. Endocr Res 1999 May; 25 (2), pp. 207–14.

Pituitary: Anterior Pituitary Function/Postop Transsphenoidal Hypophysectomy
Thyrotropin-Releasing Hormone (TRH)/Corticotropin-Releasing Hormone (CRH)/Growth Hormone-Releasing Hormone (GHRH)/Gonadotropin-Releasing Hormone (GnRH)

Physiological Mechanism of Action: Thyrotropin-releasing hormone is produced in the hypothalamus and promotes the release of thyroid-stimulating hormone (TSH) from the anterior pituitary (adenohypophysis). Pituitary adenomas that secrete excessive adenocorticotropic hormone (ACTH) are also responsive to exogenous TRH administration.
Considerations: Much safer than exogenous administration of either ACTH or dexamethasone in instances of pre-existing laminitis in equine patients suffering from Cushing's disease.
Application: Detection and characterization of conditions associated with pituitary-dependent hyperadrenal corticism.
Implementation: Evaluation of anterior pituitary function can be assessed using several hypophysiotropic-releasing hormones including CRH, GHRH, GnRH, and TRH. These agents can be applied simultaneously (combined test) or administered individually.
Following administration, serum concentrations of ACTH, cortisol, growth hormone (GH), luteinizing hormone (LH), and prolactin (PRL) are measured. Complementary analyses can include the determination of TSH pars intermedia function established by the measurement of basal plasma alpha-MSH concentrations, in concert with the assessment of adrenocortical function by measuring baseline urinary corticoid/creatinine ratios.
Interpretation and Assessment: In cases of pituitary-dependent hyperadrenocorticism, excessive elevations in serum (systemic) cortisol can be detected. In normal individuals, exogenous TRH administration does not result in elevated concentrations of systemic cortisol.

In dogs, 8 weeks after hypophysectomy (n = 39), basal plasma ACTH, cortisol, GH, LH, PRL, and TSH concentrations are significantly lower than prior to surgery. In dogs with elevated alpha-MSH concentrations (e.g., n = 7/39), values return to the normal level after surgery. In the combined anterior pituitary function test there are no plasma GH, LH, PRL, and TSH responses to stimulation, whereas plasma ACTH and cortisol responses are usually small but significant. Remission of hyperadrenocorticism may be expected in most dogs (e.g., n = 35/39) compared to a small number of recurrences (e.g., n = 3/39 within 16 months postoperatively). At 8 weeks posthypophysectomy, such dogs are not discernible, with respect to residual pituitary and adrenocortical function, from dogs (e.g., n = 32) with persistent remission. Urinary corticoid/creatinine ratios in the latter group of dogs usually do not increase during the 22-month period after hypophysectomy. In contrast to presurgical findings, at 8 weeks after hypophysectomy there are significant positive correlations between baseline urinary corticoid/creatinine ratios and basal levels and responses for ACTH, indicating return to normal function of the pituitary-adrenocortical axis. Therefore, among the adenohypophyseal cells present in the sella turcica after hypophysectomy, the corticotropes have a distinct behavior. Much more so than the other cell types, the unaffected corticotropes tend to remain functional, or a repressed reserve fraction of corticotropes may become functional. This may be due to the removal of the hypothalamic influence of a postulated corticotropin-release inhibiting factor or a diminished inhibitory influence of a postulated paracrine factor. The corticotropes may maintain normocorticism but may also lead to mild recurrence after relatively long periods of remission.

Residual pituitary function after transsphenoidal hypophysectomy in dogs with pituitary-dependent hyperadrenocorticism. Meij BP, Mol JA, Bevers MM, Rijnberk A. J Endocrinol 1997 Dec; 155 (3), pp. 531–9.

Pituitary Tumors (Non-Functional)/Hypothalamic/Pituitary Function
Corticotropin-Releasing Hormone (CRH)/Growth-Hormone Releasing Hormone (GHRH)/Thyrotropin-Releasing Hormone (TRH)/Luteinizing Hormone-Releasing Hormone (LHRH)/ Lysine Vasopressin (LVP)

Cellular/Molecular Mechanism of Action: Corticotropin-releasing hormone, GHRH, TRH, and LHRH are produced in the hypothalamus and are selectively transported internally to the pituitary gland, where they promote the release of their corresponding stimulating hormone or hormone mediator.
Physiological Mechanism of Action: Corticotropin-releasing hormone promotes the release/synthesis of pituitary adenocorticotropic hormone (ACTH); GHRH promotes the synthesis/release of pituitary growth hormone; TRH promotes the synthesis/release of pituitary thyroid-stimulating hormone (TSH); LHRH promotes the synthesis/release of pituitary leutinizing hormone (LH); LVP exerts properties similar to pituitary antidiuretic hormone (ADH).
Application: Combined anterior pituitary tests can be utilized to evaluate pituitary function in conditions of non-functioning pituitary tumors.
Dosage: Hypothalamic-releasing hormones (CRH: 1 μg/kg; GHRH: 1 μg/kg; TRH: 500 μg; LHRH: 100 μg; and LVP: 5 mU/kg = relatively small dose).
Implementation: Evaluation of non-functioning pituitary tumors utilizing a combined anterior pituitary test consisting of CRH, GHRH, TRH, LHRH, and LVP.
Human Model: Cases of non-functioning pituitary tumors (n = 16; and n = 8 normal healthy reference control volunteers).
Interpretation and Analysis: Non-functional pituitary tumors can be due to a number of conditions, including chromophobe adenoma (e.g., n = 9/16); craniopharyngioma (e.g., n = 3/16); Rathke's

cleft cyst (e.g., n = 2/16); intrasellar cyst (e.g., n = 1/16); and tuberculum sella meningioma (e.g., n = 1/16). In normal subjects, LVP enhances the secretion of ACTH induced by CRH, but has no significant effect on the secretion of other anterior pituitary hormones. In the combined test with 5 releasing hormones, the plasma ACTH and cortisol responses are not impaired in the majority of cases before pituitary surgery. Serum TSH, prolactin (PRL), and follicle-stimulating hormone (FSH) responses are not impaired in approximately 82%, 70%, and 67% of these cases, respectively, while serum LH and GH responses are impaired in 67% and 73% of cases, respectively. Following pituitary surgery, responses of these hormones to combined testing are similarly impaired in more than 75% of patients. These results indicate that plasma ACTH, cortisol, and serum TSH responses are fairly good before pituitary surgery but are impaired significantly after surgery. Few subjects experience any serious adverse effects related to diagnostic testing procedures. Therefore, the combined testing protocol with hypothalamic hormones is a convenient and useful method for evaluating pituitary function.

Combined anterior pituitary function test using CRH, GRH, LH-RH, TRH and vasopressin in patients with non-functioning pituitary tumors. Hashimoto K, Makino S, Hirasawa R, Takao T, Kageyama J, Ogasa T, Ota Z. Acta Med Okayama 1990 Jun; 44 (3), pp. 141–7.

HYPOTHALAMUS, PITUITARY, AND ADRENAL AXIS

Addison's Disease: Adrenal Dysfunction/Primary Adrenocortical Insufficiency (PAI)/Severe Secondary Adrenocortical Insufficiency (SAI)
Adenocorticotropic Hormone (ACTH)/Corticotropin-Releasing Hormone (CRH)/Insulin

Background Information: The rapid ACTH injection test is an indirect screening test for adrenocortical insufficiency. As a supplement to this test, the practicability of single measurements of plasma cortisol, ACTH, aldosterone, and plasma renin activity (PRA) has been evaluated as a definitive diagnostic test of PAI.
Application: Diagnosis and therapeutic surveillance in Addison's disease.
Implementation: Evaluation of the value of PRA measurements during treatment with hydro- and fludrocortisone (HC and FC) as a guide for correct mineralocorticoid substitution utilizing a rapid ACTH test and single measurements of 4 hormones (all tests between 0800–0900 hours) compared. Studies can be complemented by acquiring single-hormone measurements in conditions of pituitary disease (most having mild to severe SAI).

Human Model: Cases with PAI (n = 45); pituitary disease (n = 46; cortisol and ACTH only), most having mild to severe SAI; and normal healthy volunteers (n = 55).
Interpretation and Analysis: The rapid ACTH test is abnormal in the vast majority of case with PAI (e.g., n = 41/41 or 100% PAI). Plasma ACTH, PRA, and the ratios of ACTH/cortisol and PRA/plasma or urinary aldosterone are clearly elevated in the vast majority of cases with PAI (e.g., 100% PAI). The ACTH/cortisol ratio also can distinguish a high percentage of cases with PAI from those with severe SAI (100%), but not always control subjects from those with SAI. Dynamic tests (CRH or insulin tests) are indicated if severe SAI is suspected. Primary adrenocortical insufficiency and involvement of zona fasciculata and glomerulosa function can be diagnosed with high reliability by measuring cortisol, ACTH, aldosterone, and PRA either together with the rapid ACTH test or later, after a short interval of steroid substitution. PRA measurements during treatment with HC and FC correlate better with the mineralocorticoid dose than plasma potassium and sodium levels. PRA measurement is a valuable guide for FC replacement therapy. It should be titrated into the upper normal range to avoid undertreatment and overtreatment.

Diagnosis and therapy surveillance in Addison's disease: rapid adrenocorticotropin (ACTH) *test* and measurement of plasma ACTH, renin activity, and aldosterone. Oelkers W, Diederich S, Bähr V. J Clin Endocrinol Metab 1992 Jul; 75 (1), pp. 259–64.

Addison's Disease: Primary Adrenal Dysfunction/ Adrenocortical Dysfunction/Preclinical Adrenal Dysfunction
Adenocorticotropic Hormone (ACTH) (High- vs Low-Dose)

Background Information: The presence of 21-hydroxylase autoantibodies (21OHAb) is a marker of adrenal autoimmunity and can be used to identify subjects with preclinical Addison's disease. The low-dose (1 μg) ACTH test (LDT) is more sensitive than the high-dose (250 μg) test (HDT) for the diagnosis of pituitary adrenal insufficiency, but no information is available on the use of an LDT in subjects with autoimmune adrenalitis and primary adrenal insufficiency.
Application: Detection and characterization of primary adrenal insufficiency and accurate identification of preclinical adrenal dysfunction conditions.
Implementation: Evaluation of cortisol responses to both an LDT and an HDT preparation for the diagnosis of early adrenocortical dysfunction in cases with adrenal autoantibodies. In all cases evaluated, the LDT is followed by a sequential HDT that can be used as a control test of the sensitivity and specificity of the LDT.

Human Model: Cases with a normal health status (n = 12 volunteers), and cases positive for 21OHAb fractions but without clinical signs of Addison's disease (n = 11 subjected to an LDT) identified by screening 920 patients with one or more organ-specific autoimmune diseases.
Interpretation and Analysis: In healthy subjects, the peak cortisol levels after the LDT are similar to those after the classical HDT. In 21OHAb-positive subjects, the LDT shows a pathological response in approximately 45% of cases (e.g., n = 5/11) and the diagnostic concordance between the results of the LDT and those of the HDT is 100%. The majority of cases with pathological LDT are also positive for adrenal cortex autoantibodies (ACA; n = 5/5), and the majority of these have high levels of basal ACTH (n = 4/5). A limited number of cases with pathological LDT develop clinical Addison's disease within 4 months after performing diagnostic testing procedures (e.g., n = 1). Low-dose ACTH test has a high diagnostic sensitivity and specificity for primary adrenal insufficiency and suggests that it can accurately identify subjects with preclinical adrenal dysfunction.

Low-dose (1 μg) ACTH test in the evaluation of adrenal dysfunction in preclinical Addison's disease. Laureti S, Arvat E, Candeloro P, Di Vito L, Ghigo E, Santeusanio F, Falorni A. Clin Endocrinol (Oxf) 2000 Jul; 53 (1), pp. 107–15.

Adrenal Insufficiency
Basal Cortisol vs Corticotropin-Releasing Hormone (CRH)

Cellular/Molecular Mechanism of Action: Corticotropin-releasing hormone promotes the release of pituitary adrenocorticotropic hormone (ACTH) that in turn promotes the synthesis/release of cortisol from the adrenal cortex.

Application: Detection and evaluation of adrenal insufficiency conditions (comparison of basal cortisol measurements to CRH stimulation tests).
Implementation: Putative peak cortisol cut points for the CRH test and basal cortisol cut points can be determined by receiver operating characteristic (ROC) analysis with the insulin tolerance test as reference test.

Human Model: Cases of suspected hypothalamic-pituitary-adrenal disease (n = 54; n = 20 normal healthy reference controls).
Interpretation and Analysis: In healthy controls, CRH leads to a mean peak cortisol of 594.8 ± 21.7 nmol/liter. The lower limit of a normal response is calculated as approximately 400 nmol/liter. Receiver operating characteristic analysis of peak cortisol levels during CRH testing of patients with suspected hypothalamic-pituitary-adrenal disease suggests an optimal peak cortisol cut point of ≤ 377 nmol/liter for the diagnosis of adrenal insufficiency and a 96% specificity but poor sensitivity of 76%. The baseline cortisol in the healthy control group shows a mean of 439.3 ± 24.9 nmol/liter, resulting in a lower limit of 267 nmol/liter. Receiver operating characteristic analysis of cases suggests the highest accuracy for basal cortisol levels of 285 nmol/liter or more for the diagnosis of adrenal insufficiency (100% sensitivity and 61% specificity). Within such a patient group, a cortisol of more than 98 nmol/liter excludes adrenal insufficiency among those without the disorder, yielding 100% specificity. Using these criteria of upper (285 nmol/liter) and lower (98 nmol/liter) cutoff points with high sensitivity and specificity can reduce the number of individuals who need provocative testing. Basal cortisol is less expensive and is therefore suggested for use as a 1st-line test of adrenal insufficiency. Because of the low sensitivity of the human CRH test, it has not been recommended as a 2nd test procedure.

Diagnosis of adrenal insufficiency: Evaluation of the corticotropin-releasing hormone test and Basal serum cortisol in comparison to the insulin tolerance test in patients with hypothalamic-pituitary-adrenal disease. Schmidt IL, Lahner H, Mann K, Petersenn S. J Clin Endocrinol Metab 2003 Sep; 88 (9), pp. 4193–8.

Adrenal Mineral Corticoid Function: Aldosterone-Producing Adenoma (APA)/Dopamine Excretion: Urinary
Metoclopramide/High-Salt Intake/Low-Salt Intake

Physiological Mechanism of Action: Metoclopramide enhances cholinergic activity at muscarinic synapses and suppresses/antagonizes CNS dopaminergic activity. Normally, dopaminergic input inhibits aldosterone secretion.
Background Information: Impairment of renal dopamine excretion on a high-salt diet (HS) may account for increased blood pressure (BP) in hypertensive subjects. Whether such impairment of dopaminergic activity exists in the adrenal gland is unknown.
Application: Differentiate degrees of dopaminergic inhibition of aldosterone secretion in cases of aldosterone-producing adenomas.
Route of Administration: Metoclopramide (intravenous).
Dosage: Metoclopramide (10 mg).
Implementation: Evaluation of APA conditions on diets of different salt levels at the end of which a 24-hour ambulatory BP recording is obtained in concert with the measurement of daily urine catecholamine and the performance of a metoclopramide test.

Human Model: Cases of unilateral APA (n = 15 APA) fed a low-salt diet (LS) for 1 week, followed by another week on an HS diet. At the end of each diet period, 24-hour ambulatory BP recording, daily urine catecholamine measurement, and a metoclopramide test is performed.

Interpretation and Analysis: A high-salt diet increases both daytime and nighttime blood pressure (BP at $p < 0.001$), and urine dopamine excretion ($p < 0.01$). Intravenous metoclopramide injection increases plasma aldosterone concentrations (PAC) on both diets. The area under the curve for PAC between LS and HS is not different, but the area under the curve for PAC increment is greater on HS ($p < 0.05$). Less than half of affected cases with increment areas on HS greater than those on LS by 50% are termed "suppressible" (n = 6/15) and the remainder are referred to as "non-suppressible." On a high-salt diet, so-called "suppressible" cases have greater urine dopamine and less urine norepinephrine excretions ($p < 0.05$). The "non-suppressible" cases have a greater percentage increase of nighttime BP by HS than the suppressible subjects (for systolic BP, 13.1% vs 4.5%, $p < 0.01$; for mean BP, 12.0% vs 5.1%, $p < 0.01$, respectively), but no difference in daytime BP.

Two subtypes of APA can be defined according to their responses to metoclopramide during salt manipulation. On an HS diet, the non-suppressible subjects, with less dopaminergic inhibition of aldosterone secretion, have less urinary DA excretion and greater BP elevation. The renal and adrenal dopaminergic activities are regulated in a parallel fashion.

Dopaminergic modulation of aldosterone secretions on changes of sodium intake in aldosterone-producing adenoma. Wu KD, Chen YM, Chu TS, Chueh SC, Tsai GC, Tseng YZ, Hsieh BS. Am J Hypertens 2002 Jul; 15 (7 Pt 1), pp. 609–14.

Adrenalcortical Axis/Hypothalamic-Pituitary-Adrenal Function/Influence of Age and Gender
Synthetic Human hCRH (MCI-028)

Cellular/Molecular Mechanism of Action: The synthetic human corticotropin-releasing hormone (hCRH) MCI-028 induces increases in plasma adenocorticotropic hormone (ACTH) concentrations that in turn promote elevations in plasma cortisol.
Application: Evaluation of the integrity and function of anterior pituitary function.
Route of Administration: Synthetic human corticotropin-releasing hormone (IV).
Dosage: Synthetic human corticotropin-releasing hormone (MCI-028 100 μg).
Interpretation and Analysis: Mean maximum concentrations of plasma ACTH and cortisol after intravenous administration of MCI-028 are 3.0 and 2.0 times their basal concentrations, respectively, and there are no significant age or sex differences in responses. Good reproducibility can be observed in responses when a 2nd dose is administered 1–2 weeks later. Although slight adverse reactions such as mild and transient hot flushing may be observed, these sequellae are usually not serious in nature.

Human corticotropin-releasing hormone (hCRH) test: Sex and age differences in plasma ACTH and cortisol responses and their reproducibility in healthy adults. Tanaka K, Shimizu N, Imura H, Fukata J, Hibi I, Tanaka T, Nakagawa S, Fujieda K, Takebe K, Yoshinaga K, et al. Endocr J 1993 Oct; 40 (5), pp. 571–9.

Adrenocortical Insufficiency
Theophylline

Cellular/Molecular Mechanism of Action: In contrast to most processes involved in the activation of endocrine processes, theophylline circumvents binding to receptor complexes and instead directly increases cAMP by inhibiting phosphodiesterase-mediated hydrolysis.

Physiological Mechanism of Action: Theophylline is a nonspecific stimulus of several endocrine processes.
Application: Used for determination of the potential adrenocortical reserve, and also as a diagnostic indicator of pathogenesis.
Route of Administration: Theophylline (intravenous, 4-hour infusion).
Examples of Clinical Implementation: In conditions of documented adrenal insufficiency (lack of cortisol secretion in response to exogenous adenocorticotropic hormone [ACTH]), an infusion of theophylline can stimulate significant increases in serum cortisol in a large percentage of patients. Types of conditions where theophylline infusion has been of diagnostic and therapeutic value include ACTH insensitivity, ACTH deficiency, and idiopathic primary adrenal failure. Conditions that may not respond to theophylline infusion include autoimmune-mediated adrenalitis. Theophylline can also promote renin release, and in situations where an intact zona glomerulosa exists, theophylline can cause a secondary rise in aldosterone equivalent to that produced by diuresis and upright poster.
Interpretation and Analysis: The preservation of cortisol responsiveness to theophylline, after the loss of sensitivity to ACTH, may be related to either the duration of the adrenal insufficiency or to the etiological mechanism. Patients with autoimmune adrenalitis may undergo more rapid and complete adrenocortical destruction, thereby losing sensitivity to both ACTH and theophylline. In contrast, in cases of insufficient or ineffective ACTH stimulation there may be a condition of receptor failure before the loss of intracellular function. Thus, responsiveness to intravenous theophylline may serve not only as a probe of potential adrenocortical reserve but also as an indicator of pathogenesis.

The use of theophylline as an *in vivo* probe of adrenocortical function. Geffner ME, Lippe BM, Kaplan SA, Itami RM. J Clin Endocrinol Metab 1982 Jul; 55 (1), pp. 56–60.

Cushing's Disease: Corticotropin-Releasing Hormone (CRH) Test Failure/Catecholamines (Adrenal)/11β-Hydroxylase/Tyrosine Hydrolase/ Phenylethanolamide/Pituitary Adenocorticotropic Hormone (ACTH)-Dependent Cushing's Syndrome Differential
Metyrapone/Dexamethasone/[ACTH]/CRH

Cellular/Molecular Mechanism of Action: Metyrapone inhibits enzymatic activity of 11β-hydroxylase, thereby reducing cortisol production.
Application: Characterize the role of glucocorticoids on activity of the adrenal gland.
Considerations: The hypothalamic CRH system and the sympathetic nervous system are anatomically and functionally interconnected and hormones of the hypothalamic-pituitary-adrenocortical axis contribute to the regulation of catecholaminergic systems.
Implementation: Evaluation of plasma and adrenal catecholamines, tyrosine hydroxylase (TH), and phenylethanolamine N-methyltransferase (PNMT) mRNA expression following injections of metyrapone or dexamethasone.
Interpretation and Analysis: Metyrapone-induced corticosterone depletion elicits transsynaptic TH activation, implying the occurrence of non-cholinergic neurotransmission. This may involve neuropeptides other than pituitary adenylate cyclase activating polypeptide (PACAP).

The CRH test may sometimes be useful in the differential diagnosis of Cushing's syndrome, because most patients with pituitary ACTH-dependent Cushing's syndrome (Cushing's disease) respond to CRH, but those with other causes of Cushing's syndrome usually do not. However, about 10% of Cushing's disease patients fail to respond to CRH.

Metyrapone-treated rats have significantly lower epinephrine and higher norepinephrine production than control rats. Metyrapone increases TH protein synthesis and TH mRNA expression, whereas its administration does not affect PNMT mRNA expression. Dexamethasone restores plasma and adrenal epinephrine concentrations and increases PNMT mRNA levels, which is consistent with an absolute requirement of glucocorticoids for PNMT expression. Adrenal denervation completely abolishes metyrapone-induced TH mRNA expression. Blockage of cholinergic neurotransmission by nicotinic or muscarinic receptor antagonists does not prevent the metyrapone-induced rise in TH mRNA. Finally, PACAP adrenal content is not affected by metyrapone.

Cushing's Disease/Differentiation: Normal/ Pituitary-Dependent Hyperadrenocorticism (PDH) vs Adrenocortical Tumors
Corticotropin-Releasing Hormone

Application: Differentiation between normal dogs and those suffering from pituitary-dependent hyperadrenocorticism from those with adrenocortical tumors.
Route of Administration: Intravenous (single injection).
Considerations: Corticotropin-releasing hormone is of ovine origin.
Interpretation and Analysis: Normal cases and those suffering from pituitary-dependent hyperadrenocorticism display elevations in plasma adenocorticotropic hormone (ACTH) and cortisol. Conversely, in conditions of adrenocortical tumors, no marked changes in plasma ACTH or cortisol can be detected.

Cushing's Disease/Pituitary vs Adrenal/ Treatment Monitoring
Dexamethasone (Low-Dose)/Dexamethasone (High-Dose)/Adenocorticotropic Hormone (ACTH) (Treatment Monitoring)

Cellular/Molecular Mechanism of Action: Dexamethasone suppresses release/synthesis of CRF, thereby suppressing ACTH release/synthesis. Pituitary ACTH promotes the release of glucocorticoid from the adrenal gland cortex.
Background Information: Some pituitary tumors will have some residual cortisol receptor complexes.
Application: Detection of hyperadrenocorticism and differentiation between primary adrenocortical tumors and pituitary-dependent hyperadrenocorticism.
Route of Administration: Intravenous.
Dosage: Low-dose dexamethasone suppression test; high-dose dexamethasone suppression test (0.1 mg/kg).
Considerations: Adrenal tumors, like many endocrine-related neoplasias, are usually unilateral and are for the most part not responsive to dexamethasone suppression tests. In cases of iatrogenic Cushing's syndrome, cases will have low-normal baseline cortical levels and will not respond to exogenous ACTH administration. Adrenocortical tumors function autonomously.
Implementation: The low-dose dexamethasone suppression test can be applied as an initial screening test in dogs suspected of suffering from Cushing's disease. The high-dose dexamethasone suppression test can be used as a discriminating test for distinguishing between primary adrenal vs primary pituitary conditions. Plasma cortisol concentrations are measured at baseline ($< T = 0$) and then at 4 hours and 8 hours post–dexamethasone administration.

Interpretation and Analysis: Plasma cortisol levels should be below 1.4 μg/dl at 8 hours postinjection. In contrast, following high-dose dexamethasone administration, plasma cortisol concentrations should normally be below 50% of resting values at 4 and 8 hours postadministration. Following the low-dose dexamethasone suppression test, if the observed 4-hour and 8-hour plasma cortisol concentrations are both elevated, then either a primary adrenal or primary pituitary lesion may be the cause of the Cushing's condition. Abdominal ultrasound can then be beneficial in identifying abnormalities in adrenal gland morphology. In situations when the adrenal gland can be imaged with ultrasound (or nuclear scintigraphy) and no abnormalities are detected, then a primary pituitary lesion should be suspected. In situations where abnormal adrenal gland morphology is detected, then an endogenous ACTH or high-dose dexamethasone suppression test can be performed. In scenarios where the ACTH level is normal or elevated and there is evidence of a positive response to the high-dose dexamethasone suppression test (50% suppresion), then the condition is classified as being pituitary-dependent hyperadrenocorticism.

In scenarios where the 4-hour plasma cortisol concentration after the low-dose dexamethasone suppression test is low, but the 8-hour concentration is relatively high, then a primary pituitary lesion is the most likely etiological cause for the condition. In dogs, 85% of Cushing's cases are primary pituitary conditions in contrast to 15% of cases that are primary adrenal cases (often with locally invasive lesions).

Cushing's Disease/Differentiation: Normal/ Pituitary-Dependent Hyperadrenocorticism (PDH) vs Adrenocortical Tumors
Corticotropin-Releasing Hormone

Application: Differentiation between normal dogs and those suffering from PDH from those with adrenocortical tumors.
Route of Administration: Intravenous (single injection).
Considerations: Corticotropin-releasing hormone is frequently of ovine origin.
Interpretation and Analysis: Normal cases and those suffering from pituitary-dependent hyperadrenocorticism display elevations in plasma adenocorticotropic hormone (ACTH) and cortisol. Conversely, in conditions of adrenocortical tumors, no marked changes in plasma ACTH or cortisol can be detected.

Cushing's Disease/Syndrome: Hypothalamic/Pituitary Function/Adenoma: Corticotropic/[Ectopic Adenocorticotropic Hormone (ACTH) Syndrome Differential]
Desmopressin (DDAVP)

Cellular/Molecular Mechanism of Action: Desmopressin promotes pituitary ACTH release.
Application: Utilization of the DDAVP test for the diagnosis of ACTH-dependent Cushing's syndrome. In this context, the DDAVP stimulation test, involving the determination of plasma ACTH levels after DDAVP injection, seems useful for discriminating Cushing's disease from normality, and may serve to facilitate the differentiation between Cushing's disease and ectopic ACTH syndrome.
Route of Administration: DDAVP (intravenous).
Dosage: DDAVP (5 μg).
Implementation: Evaluation of ACTH levels in conditions of Cushing's disease in response to DDAVP administration.

Human Model: Cases of Cushing's disease (e.g., n = 10/10; n = 3 Addison's disease cases; n = 5 Cushing's disease cases in remission; n = 3 cases with ectopic ACTH syndrome).
Interpretation and Analysis: Injection of DDAVP promotes increases in plasma ACTH levels more than 200% of the basal levels in most cases of Cushing's disease (e.g., n = 10/10), but remain < 150% in all normal subjects (n = 11/11); Addison's disease (n = 3/3); Cushing's disease in remission (n = 5/5); and ectopic ACTH syndrome (n = 3/3). Peak levels of plasma cortisol after the DDAVP stimulation are 159 ± 14% in cases with Cushing's disease, and < 150% of the basal levels in other case types (n = 5 case groups). Some cases of Cushing's disease periodically responded to DDAVP only in the active stage. In controlled *in vitro* investigations, DDAVP directly stimulates ACTH release from corticotropic adenoma cells through V1b but not V2 vasopressin receptors.

The DDAVP stimulation test, involving the determination of plasma ACTH levels after 5 μg DDAVP injection, seems useful for discriminating Cushing's disease from normality, and may serve to facilitate the differentiation between Cushing's disease and ectopic ACTH syndrome.

Desmopressin stimulation *test* for diagnosis of ACTH-dependent Cushing's syndrome. Sakai Y, Horiba N, Tozawa F, Sakai K, Kuwayama A, Demura H, Suda T. Endocr J 1997 Oct; 44 (5), pp. 687–95.

Cushing's Disease: Pituitary-Dependent/Thyroid Function
Thyrotropin-Releasing Hormone (TRH)/Corticotropin-Releasing Hormone (CRH) / Growth Hormone-Releasing Hormone (GHRH)/Gonadotropin-Releasing Hormone (GnRH)

Physiological Mechanism of Action: Thyrotropin-releasing hormone is produced in the hypothalamus and promotes the release of thyroid-stimulating hormone (TSH) from the anterior pituitary (adenohypophysis). Pituitary adenomas that secrete excessive adenocorticotropic hormone (ACTH) are also responsive to exogenous TRH administration.
Considerations: Much safer than exogenous administration of either ACTH or dexamethasone in instances of pre-existing laminitis in equine patients suffering from Cushing's disease.
Application: Detection and characterization of conditions associated with pituitary-dependent hyperadrenal corticism.
Implementation: Evaluation of anterior pituitary function can be assessed using several hypophysiotropic releasing hormones including CRH, GHRH, GnRH, and TRH. These agents can be applied simultaneously (combined test) or administered individually.

Following administration, serum concentrations of ACTH, cortisol, growth hormone (GH), luteinizing hormone (LH), and prolactin (PRL) are measured. Complementary analyses can include the determination of TSH pars intermedia function established by the measurement of basal plasma alpha-MSH concentrations, in concert with the assessment of adrenocortical function by measuring baseline urinary corticoid/creatinine ratios.
Interpretation and Assessment: In cases of pituitary-dependent hyperadrenocorticism, excessive elevations in serum (systemic) cortisol can be detected. In normal individuals, exogenous TRH administration does not result in elevated concentrations of systemic cortisol.

In dogs, 8 weeks after hypophysectomy (n = 39), basal plasma ACTH, cortisol, GH, LH, PRL, and TSH concentrations are significantly lower than prior to surgery. In dogs with elevated alpha-MSH

concentrations (e.g., n = 7/39), values return to the normal level after surgery. In the combined anterior pituitary function test there are no plasma GH, LH, PRL, and TSH responses to stimulation, whereas plasma ACTH and cortisol responses are usually small but significant. Remission of hyperadrenocorticism may be expected in most dogs (e.g., n = 35/39) compared to a small number of recurrences (e.g., n = 3/39 within 16 months postoperatively). At 8 weeks posthypophysectomy, such dogs are not discernible, with respect to residual pituitary and adrenocortical function, from dogs (e.g., n = 32) with persistent remission. Urinary corticoid/creatinine ratios in the latter group of dogs usually do not increase during the 22-month period after hypophysectomy. In contrast to presurgical findings, at 8 weeks after hypophysectomy there are significant positive correlations between baseline urinary corticoid/creatinine ratios and basal levels and responses for ACTH, indicating return to normal function of the pituitary-adrenocortical axis. Therefore, among the adenohypophyseal cells present in the sella turcica after hypophysectomy, the corticotropes have a distinct behavior. Much more so than the other cell types, the unaffected corticotropes tend to remain functional, or a repressed reserve fraction of corticotropes may become functional. This may be due to the removal of the hypothalamic influence of a postulated corticotropin-release inhibiting factor or a diminished inhibitory influence of a postulated paracrine factor. The corticotropes may maintain normocorticism but may also lead to mild recurrence after relatively long periods of remission.

Residual pituitary function after transsphenoidal hypophysectomy in dogs with pituitary-dependent hyperadrenocorticism. Meij BP, Mol JA, Bevers MM, Rijnberk A. J Endocrinol 1997 Dec; 155 (3), pp. 531–9.

Cushing's Disease/Syndrome: Hypothalamic/Pituitary Function
Desmopressin/[Corticotropin-Releasing Hormone (CRH) Testing]

Cellular/Molecular Mechanism of Action: Desmopressin stimulates adenocorticotropic hormone (ACTH) and hence cortisol release.
Background Information: To assess the ability of desmopressin administration to stimulate ACTH/cortisol secretion in cases with Cushing's disease, either before or after surgery, and in patients with other states characterized by ACTH hypersecretion, and to compare the results with those obtained after CRH testing.
Application: Desmopressin stimulates ACTH and hence cortisol release in Cushing's disease. It may be a useful test in cases with doubtful responses to corticotropin-releasing hormone (CRH) test, in those exhibiting responses to CRH indistinguishable from those of normal subjects and in the postoperative follow-up of Cushing's disease. In some cases with abolished or reduced cortisol feedback at the hypothalamic-pituitary level, the sensitivity of normal corticotrophs to desmopressin is enhanced.
Route of Administration: Desmopressin (intravenous), CRH intravenous.
Dosage: Desmopressin (10 μg), CRH (1 μg/kg).
Implementation: Evaluation of plasma ACTH and serum cortisol levels following the administration of desmopressin, CRH or saline in conditions of Cushing's disease.

Human Model: Cases of Cushing's disease (n = 17; n = 1/17 occult ectopic ACTH syndrome; n = 5/17 Addison's disease; n = 3/17 bilaterally adrenalectomy for Cushing's syndrome; n = 4/17 normal subjects; n = 13 pituitary adenomectomy for Cushing's disease).

Interpretation and Analysis: In cases of Cushing's disease with microadenoma (e.g., n = 16) a positive ACTH/cortisol rise can occur in a relatively large number of cases after both CRH and desmopressin (e.g., n = 11/16). A small percentage of these cases are responsive only to desmopressin (e.g., n = 2/16) or only to CRH (e.g., n = 2/16) or demonstrate equivocal response (e.g., n = 1/16). The persistence of a hormonal response to desmopressin after pituitary adenomectomy for Cushing's disease correlates with unsuccessful surgery, while, contrary to CRH, absent ACTH/cortisol rises are found in cured cases 1 and 12 months after operation. In some cases of suspected of ectopic ACTH hypersecretion, desmopressin and CRH administration do not cause any ACTH/cortisol rise (e.g., n = 1/1). Significant ACTH rises can occur after both desmopressin and CRH testing in cases of Addison's disease. Majority of cases that have been adrenalectomized for Cushing's syndrome show rises in ACTH levels after CRH (n = 3/3), while a similar response after desmopressin occurs in only a fraction of these cases (e.g., n = 1/3).

Effect of desmopressin on ACTH and cortisol secretion in states of ACTH excess. Colombo P, Passini E, Re T, Faglia G, Ambrosi B. Clin Endocrinol (Oxf) 1997 Jun; 46 (6), pp. 661–8.

Cushing's Disease/Syndrome
Adenocorticotropic Hormone (ACTH) Stimulation/Dexamethasone Suppression/Dexamethasone Clearance

Cellular/Molecular Mechanism of Action: Exposure to pituitary ACTH promotes the synthesis/release of adrenal cortisol. Dexamethasone suppresses hypothalamic corticotropin-releasing hormone (CRH) release, thereby diminishing pituitary ACTH synthesis/release.
Application: Detection and characterization of Cushing's syndrome (canine).
Implementation: Evaluation of cortisol concentrations in conditions of Cushing's syndrome applying dexamethasone-suppression and ACTH-stimulation testing protocols. Complementary analyses can include determination of the clearance of exogenous dexamethasone used in the dexamethasone-suppression test (normal and cushingoid dogs).

Animal Model: Healthy, mixed-breed dogs and dogs with clinical signs of Cushing's syndrome.
Interpretation and Analysis: Absolute concentration of cortisol is less in resting, dexamethasone-suppressed, and ACTH-stimulated plasma samples, when measured by high-performance liquid chromatography (HPLC) relative to cortisol concentrations determined by radioimmunoassay. Diagnosis of Cushing's syndrome can be made using either method. Cortisone and corticosterone concentrations alone are not diagnostic of Cushing's syndrome, but when used in conjunction with cortisol determinations, they provide additional criteria for laboratory confirmation of the clinical diagnosis of Cushing's syndrome. Plasma concentrations of exogenous dexamethasone are constant during the 3-hour test in normal dogs. However, in 75% of dogs with Cushing's syndrome, exogenous dexamethasone is cleared completely in the 3-hour test. Thus, dexamethasone clearance rates are excessively fast in most dogs with Cushing's syndrome.
Instrumentation: High-performance liquid chromatography (cortisone and corticosterone).

Diagnosis of canine Cushing's syndrome based on multiple steroid analysis and dexamethasone turnover kinetics. Lothrop CD Jr, Oliver JW. Am J Vet Res 1984 Nov; 45 (11), pp. 2304–9.

Cushing's Disease/Syndrome/Adrenocortical Tumor: Hyperadrenocorticism/Heat-Resistant Isoenzyme of Alkaline Phosphatase (SIAP)
Dexamethasone/[High-Dose vs Low-Dose]/Alkaline Phosphatase Activity Levels/Cortisol/Creatinine (Urine C/C)

Physiological Mechanism of Action: Dexamethasone suppresses the production/release of hypothalamic corticotropin-releasing hormone that in turn results in suppression of the production/release of pituitary adenocorticotropic hormone (ACTH) release/production, thereby reducing adrenalcorticoid release/synthesis in healthy subjects.
Background Information: Spontaneous hyperadrenocorticism is a common and well-recognized endocrine disorder occurring in dogs. The biochemical diagnosis of hyperadrenocorticism rests on the documentation of excessive glucocorticoid levels or metabolites in urine or blood. The diagnosis of canine hyperadrenocorticism is historically developed from human methods and based on non-dynamic and dynamic tests and visualization. In some cases the different ranges of endocrine parameters or metabolites necessitate the modification of human protocols. Elevation of the activity of alkaline phosphatase (AP) and its heat-resistant isoenzyme (SIAP) induced by endogenous or exogenous glucocorticoid excess raises the suspicion of hyperadrenocorticism. Cortisol values in morning urine are related to creatinine concentrations to correct for differences in urine concentration.
Application: Characterization of hyperadrenocorticism conditions.
Dosage: Dexamethasone (low-dose 0.01 mg/kg of body weight).
Implementation: Evaluation of Cushing's disease/syndrome utilizing the dexamethasone suppression test.
Animal Model: Canine (dogs suffering from hyperadrenocorticism).
Interpretation and Analysis: Theoretically, the administration of dexamethasone (DX) at a relatively "low-dose" level can inhibit the pituitary secretion of ACTH and, in turn, decreasing endogenous cortisol secretion for as long as 24 to 48 hours. Dexamethasone administration to dogs with a functioning adrenocortical tumor does not affect the plasma cortisol concentration at any time following its administration.

The high-dose dexamethasone suppression test (HDDS) is based on the observation that the function of an adrenocortical tumor is independent of pituitary ACTH regulation and they completely suppress ACTH secretion through the autologous production of cortisol; therefore, regardless of dose, dexamethasone is never able to suppress cortisol secretion. HDDS can be combined with the measurement of urinary cortisol/creatinine (c/c) ratio from morning urine samples on 3 consecutive days. In cases of non-suppressible urinary c/c ratios, one has to speculate on differentiating adrenal tumor (AT) from non-suppressible pituitary-dependent hyperadrenocorticism (PDH) due to a pituitary tumor arising from the intermediate lobe. Radiocholesterol scintigraphy is a less frequently used technique in the diagnosis of canine Cushing's syndrome (CCS); however, it has the same advantages in the localization and characterization of adrenocortical diseases as in humans.

Diagnosis of hyperadrenocorticism in dogs as compared to human diagnostic methods: a review. Thuróczy J; Balogh L; Huszenicza G; Jánoki GA; Kulcsár M. Acta Vet Hung 1998; 46 (2), pp. 157–73.

Cushing's Disease/Syndrome
Adrenocorticotropic Hormone (ACTH)

Cellular/Molecular Mechanism of Action: Promotes glucocorticoid production/release from the adrenal cortex.
Diagnostic Application: (i) Apply systemically in an attempt to differentiate between adrenal and pituitary lesions. (ii) Determine the relative degree of neonatal prematurity by establishing the functional integrity of the thalamic-pituitary-adrenal triad.
Route of Administration and Dosage: Porcine aqueous gelatin ACTH (2.2 IU/kg), or synthetic ACTH (0.25 mg/dog or 0.5 mg/dog of synthetic tetracosactrin) injected intramuscularly.
Considerations: Administration of ACTH has been proposed to be a simple test of practical value for the diagnosis of juvenile adrenocortical function. In equine patients, TSH has been used successfully to diagnosis Cushing's syndrome. Since corticosteroids readily promote equine laminitis, provocative testing with TSH is considered to be much safer.
Implementation: Approximately 30 minutes before, and then 30-, 60- (dog), and 120-minute blood samples are collected following ACTH injection for the measurement of plasma cortisol concentrations.
Diagnostic Interpretation: Excessively high concentrations of cortisol measured following an ACTH administration are diagnostic for Cushing's disease/syndrome. In this context, mean plasma cortisol levels are approximately 184% higher than baseline values after administration and there are no significant differences related to age or sex. Increased diagnostic value of ACTH can be achieved when applied in combination as the dexamethasone suppression/ACTH stimulation test (CDS/AST). In dogs, approximately 86% of pituitary-dependent Cushing's cases have an abnormal cortisol concentration following ACTH administration.
Laboratory Instrumentation: Assay of cortisol concentrations by either RIA or ELISA.

Cushing's Disease/Syndrome
Dexamethasone Suppression and Adenocorticotropic Hormone (ACTH) Stimulation Test

Cellular/Molecular Mechanism of Action: Depresses synthesis and release of ACTH at the level of the hypothalamus, which is mediated through a negative feedback mechanism.
Diagnostic Application: Differentiation between pituitary and adrenal lesions. The normal cortisol negative feedback mechanism becomes dysfunctional in patients with ACTH-secreting pituitary adenomas. In cases with an intact pituitary adrenal axis, cortisol suppresses pituitary ACTH secretion.
Route of Administration and Dosage: Dexamethasone is administered by intravenous injection at a low and high dosage level of 0.010 to 0.015, and 0.1 mg/kg body weight, respectively.
Implementation: Dexamethasone at any dosage fails to suppress cortisol concentrations in conditions of pituitary adenoma. Alternatively, high dexamethasone doses can suppress ACTH secretion in most cases (canine) of pituitary-dependent hyperadrenal corticism.
Laboratory Instrumentation: Assay of cortisol concentrations by either RIA or ELISA.

Cushing's Disease/Syndrome
Metyrapone

Cellular/Molecular Mechanism of Action: Metyrapone inhibits the enzymatic activity of 11β-hydroxylase, thereby reducing normal cortisol production.
Diagnostic Application: Differentiation between pituitary-dependent hyperadrenocorticism (PDH) and adrenal tumor (AT).
Route of Administration: Metyrapone (oral).
Dosage: Metyrapone (25 mg/kg q6 hours for 4 consecutive treatments begining at noon).
Considerations: Diagnostic results may be considered invalid if excessively high premetyrapone cortisol concentrations are detected. Another test method (e.g., adenocorticotropic hormone [ACTH] assay, high-dose DST) or repeating the procedure is recommended if postmetyrapone 11-DOC is between 1.2 and 2.0 μg/dl, or inadequate postmetyrapone cortisol suppression occurs with and 11-DOC < 2.0 μg/dl, or if the premetyrapone cortisol value is > 13 μg/dl. Sequelae that may be observed while performing this provocative test relate to the increased risk for developing acute adrenal insufficiency. If signs of weakness develop, immediately discontinue administration, collect an appropriate blood sample, and administer a glucocorticoid (IM, IV).

The corticotropin-releasing hormone (CRH) test may sometimes be useful in the differential diagnosis of Cushing's syndrome, because most patients with pituitary ACTH-dependent Cushing's syndrome (Cushing's disease) respond to CRH, but those with other causes of Cushing's syndrome usually do not. However, about 10% of Cushing's disease patients fail to respond to CRH.
Implementation: Metyrapone is administered (4 consecutive treatments) and postmetyrapone blood samples are collected into EDTA at 6 hours for measurement of cortisol and 11-DOC following administration of the last dose.
Interpretation and Analysis: Patients (e.g., canine) that are suffering from PDH display an accumulation of 11-deoxycortisol (11-DOC, precortisol metabolite), which occurs simultaneously with a decline in systemic cortisol concentrations. In contrast, patients suffering from AT do not significantly increase 11-DOC concentrations but do reflect a decline in cortosol levels. Advantage of this test and the endogenous plasma ACTH assay is their ability to positively identify AT patients.

Postmetyrapone cortisol concentrations should be $\leq$ 50% of preadministration levels. Patients should be suspected of suffering from PDH when postmetyrapone 11-DOC concentrations are ≥ 2 μg/dl (2–12.5 μg/dl), while values ≤ 1.2 μg/dl (0.1–1.2 μg/dl) strongly suggest a diagnosis of AT.
Laboratory Instrumentation: Assay techniques require the application of either ELISA or RIA methodologies.

Cushing's Disease/Syndrome/Cortisol/Growth Hormone
Metyrapone

Cellular/Molecular Mechanism of Action: Inhibits enzymatic activity of 11β-hydroxylase, thereby reducing cortisol production.
Background Information: Transsphenoidal surgery (TSS) is considered the primary treatment for Cushing's disease (CD). Options for treatment of postoperative persisting hypercortisolemia are pituitary radiotherapy (RT), repeat TSS, or bilateral adrenalectomy.
Application: Delineation of the effect of the early morning rise in plasma cortisol concentration on plasma GH concentrations. Metyrapone is administered early in the morning to reduce plasma cortisol concentrations.
Dosage: Metyrapone (750 mg, 4 hourly from 3.00 am). Plasma GH and cortisol concentrations are measured every 30 and 60 minutes, respectively, from 22.00 until 14.00.
Considerations: Exogenous steroids affect plasma growth hormone (GH) concentrations and hypothalamic somatostatin levels either directly, by stimulating the anterior pituitary gland, or indirectly by partially inhibiting the response of the pituitary gland to stimuli. The effect of the circadian rhythm of cortisol on plasma GH concentrations is unknown. In normal subjects, highest plasma GH concentrations are recorded within the 1st 2 hours of onset of sleep. During the early morning the plasma GH concentration decreases and the plasma cortisol concentration increases.
Interpretation and Analysis: Metyrapone causes a significant reduction in the rise of plasma cortisol concentration, but the GH concentration is identical on both occasions. The morning rise in cortisol concentration has no acute regulatory effect on the plasma GH concentration.

Cushing's Disease/Syndrome
Metyrapone/Corticotropin-Releasing Hormone (CRH)/Arginine Vasopressin (AVP)

Cellular/Molecular Mechanism of Action: Metyrapone inhibits enzymatic activity of 11β-hydroxylase, thereby reducing cortisol production.
Application: Metyrapone can be exploited for its additive or synergistic effect as an adenocorticotropic hormone (ACTH) secretagogue (reduces glucocorticoid inhibition of CRH → ACTH releasing effect).
Route of Administration: (i) Ovine CRH (intravenous) alone; (ii) AVP (intramuscular) alone; (iii) metyrapone (oral).
Dosage: (i) Ovine CRH (1 μg/kg BW) alone; (ii) AVP (10 U) alone; (iii) combinations of CRH and AVP; and (iv) CRH after pretreatment with metyrapone (1 g every 4 hours for 3 doses; CRH + MET).
Considerations: The CRH test may sometimes be useful in the differential diagnosis of Cushing's syndrome, because most patients with pituitary ACTH-dependent Cushing's syndrome (Cushing's disease) respond to CRH, but those with other causes of Cushing's syndrome usually do not. However, about 10% of Cushing's disease patients fail to respond to CRH.

In normal subjects, plasma pregnenolone sulfate (PS) levels are high at birth but are decreased during the 1st year of life in relation to the pattern of involution of the fetal adrenal zone. Thereafter, PS levels, in contrast with those of DHAS, do not show the abrupt rise characteristic of the adrenarche but increase very progressively till adulthood. The response of PS to various provocative tests of adrenal and pituitary function (ACTH and metyrapone stimulation, dexamethasone suppression) has been established in normal subjects. The measurement of plasma PS levels in basal conditions as well as in response to dynamic tests is very useful in the diagnosis of various adrenal and pituitary diseases in children.

In pediatric patients, endogenous Cushing's syndrome is an infrequent condition almost always due to either adrenal gland tumors or Cushing's disease. Adrenal gland tumors account for 70% of Cushing's syndromes in young pediatric patients. They cause rapidly progressive hypercorticism not due to increased ACTH production (elevated plasma and urine cortisol levels, very low ACTH and LPH levels unchanged by dexamethasone, metyrapone, or CRH). Imaging techniques determine the size and spread of the tumor and look for

metastases. Following surgical removal, patients with indicators of malignant disease (tumor weight above 30 g, extracapsular spread or metastases, independently from pathological data) are given op'DDD. The 2nd etiology in pediatric patients is attributed to Cushing's disease and in peripubertal patients causes overweight with delayed statural gain. Due to the possibility that elevated ACTH production (based on interpretation of a positive dexamethasone suppression test and provocative metyrapone and CRH tests) may be due to pituitary adenoma, the existence and characteristics of such lesions should be further pursued by magnetic resonance imaging methodologies. Resolution by removal of such lesions results in recovery in approximately 50% of affected cases. Other therapeutic tools include (i) op'DDD; (ii) radiation therapy delivered to the pituitary; and (iii) bilateral adrenalectomy as the last resort given the high risk of post-adrenalectomy pituitary tumor (50% of pediatric patients). Other causes are exceedingly rare: primary nodular hyperplasia of the adrenal glands and production of ACTH by a non-pituitary tumor. Corticosteroid treatment is the most common cause of Cushing's syndrome in children.

Interpretation and Analysis: The rates of non-response (ACTH increment, $< 35\%$; cortisol increment, $< 20\%$) to AVP and CRH alone are 26% and 8%, respectively. Essentially all patients respond to CRH applied in combination with AVP. The lack of response is not due to improper administration or rapid metabolism of the agonist, because plasma CRH and AVP concentrations are similar in responder and non-responder patients. A synergistic ACTH response to the combination of CRH and AVP occurs in 65% of the patients. Pretreatment with metyrapone increases basal plasma ACTH levels in most patients and induces the greatest mean peak ACTH response to CRH. However, approximately 8% of patients do not respond to the combination of CRH and metyrapone with an ACTH increment of 35% or more. Because all Cushing's disease patients in previous reports responded to CRH in combination with AVP, whereas 8% failed to respond to CRH alone, it has been proposed that CRH in combination with the administration of AVP may provide a more reliable test in the differential diagnosis of ACTH-dependent Cushing's syndrome than administration of CRH alone. Whether this improved sensitivity is accompanied by unaltered specificity for Cushing's disease must be tested in patients with chronic ectopic ACTH syndrome.

Plasma corticotropin and cortisol responses to ovine corticotropin-releasing hormone (CRH), arginine vasopressin (AVP), CRH plus AVP, and CRH plus metyrapone in patients with Cushing's disease. Dickstein G, DeBold CR, Gaitan D, DeCherney GS, Jackson RV, Sheldon WR Jr, Nicholson WE, Orth DN. J Clin Endocrinol Metab 1996 Aug; 81 (8), pp. 2934–41.

Cushing's Disease/Syndrome
Exogenous T_3

Cellular/Molecular Mechanism of Action: Thyroid hormone (T_3) functions in a negative feedback mechanism to inhibit the release of thyrotropin-releasing hormone (TRH) from the hypothalamus, which in turn regulates the secretion/release of thyroid-stimulating hormone (TSH) from the pituitary. Ultimately, elevations in T_3 result in decreased release of endogenous thyroid hormone.

Diagnostic Application: #1: Utilized in the T_3 suppression test based upon the concept that exogenous thyroid hormone inhibits secretion of TSH in normal individuals. Conversely, in instances when endogenous thyroid hormone secretion occurs in an autonomous fashion (independent of TSH regulation), then exogeneous T_3 has little influence on the secretion of thyroid hormone. The T_3 suppression test is of particular diagnostic benefit in patients (e.g., feline) with high-normal T_3 and T_4 concentrations while simultaneously displaying signs of hyperthyroidism.

Diagnostic Application: #2: Patients suffering from Cushing's syndrome may suffer from secondary hypothyroidisms caused by corticosteroid suppression of pituitary TSH secretion. In addition, corticosteroids decrease peripheral deiodination of T_4 to T_3, and binding of thyroid hormone to plasma proteins that enhance metabolism. Dogs with Cushing's syndrome will display an elevation in T_4 following a TSH stimulation test, but both baseline levels and post-TSH serum concentrations of T_4 are well below normal.

Route of Administration and Dosage: In feline conditions, the T_3 suppression test can be performed by determining basal serum concentrations of T_4, administering exogenous T_3 at a dosage of 25 μg every 8 hours for 2 days with the last and 7th dose administered on the morning of the 3rd day. Serum is collected 96 hours after the last T_3 injection and T_4 concentrations measured.

Interpretation and Analysis: Suppression of the T_4 concentration in a blood sample collected at this time period is approximately $\geq 50\%$ depressed in a normal feline patient (≤ 1.5 μg/ml).

Laboratory Instrumentation: Assay of T_3/T_4 concentrations by either RIA or ELISA.

Cushing's Disease/Syndrome: Hypothalamic-Pituitary Dysfunction
Dexamethasone/[Cortisone, Corticosterone, and Cortisol]/[High-Performance Liquid Chromatography (HPLC) vs Radioimmunoassay]

Cellular/Molecular Mechanism of Action: Dexamethasone suppresses hypothalamic corticotropin-releasing hormone production, thereby decreasing the release/production of pituitary adenocorticotropic hormone (ACTH), which in turn then decreases production/release of cortisol from the adrenal cortex under normal conditions.

Background Information: Previous investigations have compared cortisol concentrations measured by HPLC and radioimmunoassay using samples collected from healthy, mixed-breed dogs and in dogs with clinical signs of Cushing's syndrome. Absolute concentrations of cortisol are less in resting, dexamethasone-suppressed, and ACTH-stimulated plasma samples, when measured by HPLC, relative to cortisol concentrations determined by radioimmunoassay. Diagnosis of Cushing's syndrome can be made using either method. Plasma concentrations of cortisone and corticosterone can be determined by HPLC. Cortisone and corticosterone concentrations alone are not diagnostic of Cushing's syndrome, but when used in conjunction with cortisol determinations, they provide additional criteria for laboratory confirmation of the clinical diagnosis of Cushing's syndrome.

Application: Dexamethasone can be applied to detect and characterize conditions of Cushing's disease/syndrome.

Implementation: Evaluation of Cushing's syndrome by measuring the clearance of exogenous dexamethasone used in the dexamethasone-suppression test.

Animal Model: Canine (cases suffering from Cushing's disease).

Interpretation and Analysis: Plasma concentrations of exogenous dexamethasone are constant during 3-hour tests in normal dogs. However, in 75% of the dogs with Cushing's syndrome, exogenous dexamethasone is cleared completely in 3-hour test protocols. Thus, dexamethasone clearance rates are excessively fast in most dogs with Cushing's syndrome.

Diagnosis of canine Cushing's syndrome based on multiple steroid analysis and dexamethasone turnover kinetics. Lothrop CD Jr, Oliver JW. Am J Vet Res 1984 Nov; 45 (11), pp. 2304–9.

Cushing's Disease/Syndrome: Hypothalamic/Pituitary Dysfunction/Hyperadrenocorticism: Pituitary Dependent/Evaluation of Therapeutic Efficacy: Trilostane

Dexamethasone/Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: Trilostane is a competitive 3-beta hydroxysteroid dehydrogenase inhibitor.

Physiological Mechanism of Action: Dexamethasone suppresses the release of hypothalamic corticotropin-releasing hormone, thereby suppressing pituitary production/release of adenocorticotropic hormone (ACTH).

Background Information: Trilostane has been used successfully to control clinical signs and cortisol excess in canine pituitary dependent hyperadrenocorticism.

Implementation: Evaluation of equine cases of Cushing's syndrome treated with trilostane utilizing the combined dexamethasone suppression and TRH stimulation tests. Horses affected by equine Cushing's disease/syndrome receive 0.4–1 mg/kg (mean 0.5 mg/kg) trilostane once daily.

Animal Model: Equine (n = 20 horses; mean age = 21 years) diagnosed with equine Cushing's disease syndrome followed over a 1- or 2-year period.

Interpretation and Analysis: Clinical signs assessed over 1 or 2 years reveal a reduction in lethargy in all horses post–trilostane treatment. Similarly, polyuria and/or polydipsia, if originally present, become significantly reduced (e.g., n = 11/11).

Recurrent or chronic laminitis, if originally present, improves in a large percentage of cases (e.g., n = 13/16 or 81%). Combined dexamethasone suppression and TRH stimulation tests detect significant differences before and 30 days after initiation of therapy. There is a significant reduction ($p = 0.01$) of cortisol following TRH administration before (160 ± 53.0 nmol/l) and after (130 ± 46.1 nmol/l) trilostane. Trilostane causes improvement in clinical signs in horses, without side effects, and a corresponding decrease in cortisol response to TRH administration. Trilostane may be a useful therapy for the treatment of ECS. Further work comparing the effects of trilostane and pergolide is warranted.

Efficacy of trilostane for the treatment of equine Cushing's syndrome. McGowan CM, Neiger R. Equine Vet J 2003 Jun; 35 (4), pp. 414–8.

Cushing's Disease/Syndrome: Hypothalamic/Pituitary Dysfunction/Pituitary Pars Intermedia Dysfunction/Plasma Cortisol: Diurinal Variation

Dexamethasone/Adenocorticotropic Hormone (ACTH) (Natural)/ACTH (Synthetic)

Physiological Mechanism of Action: Adenocorticotropic hormone is produced in the pituitary and, upon its release, it promotes cortisol synthesis/release at the level of the adrenal cortex.

Background Information: Pituitary pars intermedia dysfunction is a slowly progressive disorder that afflicts most breeds of horses. Because it shares features with human Cushing's disease, it has been referred to as equine Cushing's disease. A variety of tests of pituitary-adrenocortical function can be performed on horses with evidence of pituitary pars intermediate dysfunction, and results are then compared with those observed in healthy control horses.

Route of Administration: Adenocorticotropic hormone (intramuscular); dexamethasone (intramuscular); synthetic ACTH (intravenous).

Dosage: Adenocorticotropic hormone (1 U of natural ACTH gel/kg); dexamethasone (10 mg and 5, 10, 20, and 40 μg/kg); synthetic ACTH (100 mg IV).

Implementation: Evaluation of diurnal variations in plasma cortisol concentration in equine conditions of pituitary pars intermedia dysfunction can be determined through the use of an ACTH stimulation test. Alternatively, a combined dexamethasone suppression test and synthetic ACTH stimulation test can also been applied in attempts to distinguish between normal reference control horses and those affected by dysfunction of the pituitary pars intermedia.

Interpretation and Analysis: Diurnal variations in plasma cortisol concentration are not statistically different between control horses and those with pituitary pars intermedia dysfunction. An ACTH stimulation test or a combined dexamethasone suppression test and ACTH stimulation test fail to distinguish between horses with pituitary pars intermedia dysfunction and control unaffected horses.

A significant ($p < 0.001$) dose-related suppression of cortisol concentration in response to increasing doses (5, 10, 20, and 40 μg/kg) of dexamethasone can be detected in control horses but not in those with pituitary pars intermedia dysfunction. On the basis of plasma cortisol concentration, the dexamethasone suppression test, using 40 μg/kg—whether initiated at 5 P.M. with sample collection at 15 (8 A.M.) and 19 (12 P.M.) hours after dexamethasone administration, or initiated at 12 A.M. with sample collection at 8 (8 A.M.), 12 (12 P.M.), 16 (4 P.M.), 20 (8 P.M.), and 24 (12 A.M.) hours after dexamethasone administration]—is capable of reliably distinguishing between control horses and those with pituitary pars intermedia dysfunction.

Diagnostic testing for pituitary pars intermedia dysfunction in horses. Dybdal NO, Hargreaves KM, Madigan JE, Gribble DH, Kennedy PC, Stabenfeldt GH. J Am Vet Med Assoc 1994 Feb 15; 204 (4), pp. 627–32.

Cushing's Syndrome (Preclinical): Adrenal Incidentaloma/21-Hydroxylase and 11β-Hydroxylase Biochemical Activity/Tetrahydrocortisol, Tetrahydrocortisone, Tetrahydroaldosterone/Potential to Distinguish Between NFI and PCS

1-24 Adenocorticotropic Hormone (ACTH) Stimulation Test

Background Information: Adrenal incidentalomas are mostly non-functioning adrenocortical adenomas (NFI). However, in 5 to 12% of the patients a preclinical Cushing's syndrome (PCS) with autonomous cortisol production by the tumor is present. Since urinary-free cortisol excretion is not sensitive enough to determine subclinical hypercortisolism, in the study described in the referenced paper, more sensitive indicators of daily cortisol production are measured.

A limited amount of information is known about daily aldosterone production.

Route of Administration: 1-24ACTH stimulation test (intravenous).

Dosage: 1-24ACTH stimulation test (250 μg).

Implementation: Evaluation of tetrahydrocortisol, tetrahydrocortisone, urinary-free cortisone together with urinary-free cortisol concentration in conditions of adrenal incidentalomas. Complementary analyses involve the measurement of excreted aldosterone metabolites. The types of steroidogenic enzymes that have altered

activities are assessed with the aid of the 1-24ACTH stimulation test combined with the determination of multiple steroids. In situations where it is assumed that a 21-hydroxylase deficiency, or even an 11β-hydroxylase deficiency, may be involved in adrenal tumorigenesis, the prevalence of germline CYP21B and CYP11B1 mutations can be studied in the same cases that have been evaluated applying the ACTH stimulation test.

Note: The ACTH stimulation test can reveal increased response of precursors of the glucocorticoid and mineralocorticoid pathway.

Human Model: Cases of adrenal incidentalomas (n = 35; n = 29 NFI; n = 6 PCS; n = 35 healthy controls). Performance of the 1-24ACTH stimulation test (n = 25 cases; n = 18 healthy controls).
Interpretation and Analysis: Glucocorticoid metabolites are within the normal range in a small percentage of NFI cases (e.g., n = 3/29). As a group, cases have subtle alterations in cortisol metabolism. Tetrahydrocortisol excretion is elevated in NFI and PCS compared to normal subjects (2.1 ± 0.2 and 2.5 ± 0.5 vs 1.5 ± 0.1 mg/24 h; $p < 0.05$). Accordingly, a 2-fold elevation of the tetrahydrocortisol/free cortisol ratio indicates increases in 5β-reduction of cortisol in the liver. Tetrahydroaldosterone and aldosterone-18-glucuronide excretions are not different relative to controls. In incidentalomas cases, an increased response to ACTH can be appreciated for 17-hydroxyprogesterone (595 ± 133 vs 160 ± 25 ng/dL), 21-desoxycortisol (105 ± 25 vs 29 ± 9 ng/dL) and 11-desoxycortisol (401 ± 40 vs 293 ± 17 ng/dL).

In a small percentage of cases (n = 1/25 or 4%), a heterozygous deletion in exon 3 of the CYP21B gene can be detected. Therefore, even the excretion of the main glucocorticoid metabolites appears not to be a marker that is sensitive enough to distinguish between NFI and PCS. However, it is also possible that alterations in cortisol secretion are qualitative rather than quantitative. Zona glomerulosa function is not influenced. The elevation of 21-desoxycortisol serves to argue against an impairment of 11β-hydroxylase and is instead better explained by a decrease in 21-hydroxylase activity. The remainder of cases evaluated will have wild-type sequences of both genes. In conclusion, neither 21-hydroxylase deficiency nor 11β-hydroxylase deficiency are predisposing factors for adrenal tumorigenesis.

Metabolism of glucocorticoids and mineralocorticoids in patients with adrenal incidentalomas. Maser-Gluth C, Reincke M, Allolio B, Schulze E. Eur J Clin Invest 2000 Dec; 30 Suppl 3, pp. 83–6.

Cushing's Syndrome: Human vs Canine/Adrenal Tumor vs Pituitary-Dependent Hyperadrenocorticism (PDH)
Dexamethasone/Dexame

Application: Spontaneous hyperadrenocorticism is a common and well-recognized endocrine disorder occurring in dogs. The biochemical diagnosis of hyperadrenocorticism rests on the documentation of excessive glucocorticoid levels or metabolites in urine or blood. The diagnosis of canine hyperadrenocorticism is historically derived from human methods and based on non-dynamic and dynamic tests and visualization. In some cases the different ranges of endocrine parameters or metabolites necessitate the modification of human protocols. Elevation of the activity of alkaline phosphatase (AP) and its heat-resistant isoenzyme (SIAP) induced by endogenous or exogenous glucocorticoid excess raises the suspicion of hyperadrenocorticism. Cortisol values in morning urine are related to creatinine concentrations to correct for differences in urine concentration. Theoretically, the administration of dexamethasone (DX) at a relatively low dose (0.01 mg/kg of body weight) can inhibit the pituitary secretion of adenocorticotropic hormone (ACTH) and, in turn, decrease endogenous cortisol secretion for as long as 24 to 48 hours. Therefore, DX administration to dogs with a functioning adrenocortical tumor would not affect the plasma cortisol concentration at any time following its administration. The high-dose dexamethasone suppression test (HDDS) is based on the observation that the function of adrenocortical tumors is independent of pituitary ACTH and they completely suppress ACTH secretion; therefore, regardless of its dose, DX is never able to suppress cortisol secretion. The HDDS can be combined with the measurement of urinary cortisol/creatinine (c/c) ratio from morning urine samples on 3 consecutive days. In case of non-suppressible urinary c/c ratio, there must be speculation on differentiating adrenal tumor (AT) from non-suppressible PDH due to a pituitary tumor arising from the intermediate lobe. Radiocholesterol scintigraphy is a less frequently used technique in the diagnosis of canine Cushing's syndrome (CCS); however, it has the same advantages in the localization and characterization of adrenocortical diseases as in humans.

Diagnosis of hyperadrenocorticism in dogs as compared to human diagnostic methods: A review. Thuróczy J, Balogh L, Huszenicza G, Jánoki GA, Kulcsár M. Acta Vet Hung 1998; 46 (2), pp. 157–73.

Cushing's Syndrome/Hypercorticism: Adrenal vs Pituitary/Urinary 17-Ketogenic Steroids (17-KGS)/Tetrahydrocortisol/Tetrahydrocortisone (THF/THE) Ratio/Cortisol Production Rate
Adenocorticotropic Hormone (ACTH) Stimulation/Dexamethasone Suppression/Insulin Tolerance Test/Lysine-Vasopressin (LVP) Test/Metopirone (Metyrapone) Test

Physiological Mechanism of Action: Increases in exogenous ACTH promote the release/synthesis of adrenal glucocorticoid while dexamethasone suppresses hypothalamic corticotropin releasing hormone synthesis/release thereby reducing pituitary ACTH synthesis/release. Insulin promotes intracellular transfer of glucose. Metopirone (metyrapone) reduces cortisol production by inhibiting 11β-hydroxylation reactions in addition to inhibition of side-chain cleavage to some degree, but the latter effect is largely offset by ACTH stimulation of the adrenal gland. The biosynthetic pathway is terminated at 11-desoxycortisol, which has essentially no inhibitory influence on ACTH secretion.
Background Information: (i) Arginine vasopressin increases the immunoreactive (IR) ACTH response to corticotropin-releasing factor (CRF) 4-fold when given simultaneously with CRF. (ii) The combination of ovine-CRF with growth hormone-releasing factor (GHRF), gonadotropin-releasing hormone (GnRH), and thyrotropin-releasing hormone (TRH) appears to provide a rapid and useful test of combined anterior pituitary function. (iii) The desmopressin (DDAVP) stimulation test, involving the determination of plasma ACTH levels after 5 μg DDAVP injection, seems useful for discriminating Cushing's disease from normality, and may serve to facilitate the differentiation between Cushing's disease and ectopic ACTH syndrome.
Application: Detection and characterization Cushing's syndrome (dexamethasone suppression test) in addition to delineating the cause of the condition (LVP test and metyrapone test).
Implementation: Evaluation of hypercorticism in conditions of Cushing's syndrome as a function of estimated urinary neutral steroid metabolites, plasma cortisol, percent unbound-cortisol, cortisol production rate, and plasma ACTH. Assessment of these measurements can be facilitated by the utilization of several provocative response procedures including the (i) dexamethasone suppression test;

(ii) ACTH stimulation test; (iii) metyrapone test; (iv) LVP test; and (v) insulin tolerance test.

Human Model: Cases affected by Cushing's syndrome (n = 16).

Interpretation and Analysis: Measurements of plasma cortisol late in the day and single-dose dexamethasone suppression test appear to be the most useful procedures for the diagnosis of hypercorticism because of their reliability and simplicity. Urinary 17-ketogenic steroids (17-KGS), tetrahydrocortisol/ tetrahydrocortisone (THF/THE) ratio, cortisol production rate, and low-dose dexamethasone suppression test are also useful, whereas the insulin test and LVP test are less valuable for this purpose. Identification of the cause of Cushing's syndrome can most reliably be determined applying the LVP test and metyrapone test. Plasma ACTH is also useful for this purpose, while the insulin test and ACTH stimulation test are less valuable.

The diagnostic value of hypothalamic-pituitary-adrenocortical function tests in patients with Cushing's syndrome. Hashimoto K. Acta Med Okayama 1975 Apr; 29 (2), pp. 111–26.

Cushing's Syndrome: Hypertension Mechanism/ Epinephrine/Norepinephrine/Adrenomedullary Phenylethanolamine N-Methyltransferase
Glucagon

Cellular/Molecular Mechanism of Action: Stimulates hepatic glycogenolysis and liberation of glucose into the intravascular compartment.

Diagnostic Application: Glucagon tolerance test for screening Cushing's syndrome.

Considerations: The glucagon tolerance test can not distinguish between diabetic patients (dogs), and those with both overt diabetes meletus and Cushing's syndrome; patients (dogs) with mild secondary diabetes due to Cushing's syndrome and those with type III diabetes mellitus; iatrogenic Cushing's syndrome, and spontaneous Cushing's syndrome; and lack of appreciation for Cushing's syndrome patients that do not have significant insulin antagonism. Value of the test remains to be further established.

Implementation: Delineate if chronic endogenous hypercortisolism might alter adrenomedullary phenylethanolamine N-methyltransferase activity, by measuring epinephrine/norepinephrine (E/NE) ratios in the adrenal venous blood. Complementary investigations can include (i) evaluation of adrenomedullary secretory activity in Cushing's syndrome by measuring basal E plasma levels; (ii) characterizing adrenomedullary response to glucagons; and (iii) determination if chronic endogenous hypercortisolism modifies E plasma levels through a modification of E metabolism involving the measurement of E MCR (e.g., n = 4 cases; n = 4 age-matched controls).

Human Model: Cases with Cushing's syndrome undergoing surgery (n = 8 and n = 12 control subjects undergoing surgery for left kidney diseases) employed for measurements of epinephrine/norepinephrine in adrenal venous blood. Cases of Cushing's syndrome evaluated for adrenomedullary secretory activity (n = 24 cases; n = 32 age- and sex-matched normal controls). Adrenomedullary response to glucagons (n = 9 cases; n = 22 age /sex-matched reference controls).

Interpretation and Analysis: Mean (± SEM) E/NE ratio in adrenal venous blood is similar in patients with Cushing's syndrome (4.61 ± 0.78) and in the control group (4.71 ± 0.74). Mean (± SEM) basal plasma E is significantly lower in patients with Cushing's syndrome (98.2 ± 10.9 vs 184 ± 25.1 pmol/L, $p < 0.01$) than in controls. Similarly, plasma NE is also reduced (0.75 ± 0.09 vs 1.10 ± 0.07 nmol/L, $p < 0.01$). In patients with Cushing's syndrome the E response to glucagon is significantly reduced ($p < 0.01$). E MCR is almost identical in patients with Cushing's syndrome (1.48 ± 0.10 L/min.m^2) and in control subjects (1.51 ± 0.10 L/min.m^2). Such data demonstrates that (i) chronic endogenous hypercortisolism is not able to change adrenomedullary phenylethanolamine N-methyltransferase activity and therefore the quality of adrenomedullary secretion; and (ii) chronic endogenous hypercortisolism causes a decrease in basal and stimulated adrenomedullary activity without altering E MCR significantly. Therefore the adrenal medulla does not seem to play a pathogenetic role in the hypertension of Cushing's syndrome.

Laboratory Instrumentation: Standard clinical pathology laboratory methodology for measuring plasma glucose concentrations.

Adrenal medulla secretion in Cushing's syndrome. Mannelli M, Lanzillotti R, Pupilli C, Ianni L, Conti A, Serio M. J Clin Endocrinol Metab 1994 Jun; 78 (6), pp. 1331–5.

Cushing's Syndrome (Iatrogenic): Hypothalamic/ Pituitary Function/ Electroacupuncture (EA) Efficacy Evaluation
Adenocorticotropic Hormone (ACTH) Stimulation Test

Cellular/Molecular Mechanism of Action: Increases in exogenous ACTH mimic pituitary ACTH in a manner that promotes the synthesis/release of adrenal glucocorticoids.

Application: The ACTH stimulation test can be applied as a validation technique to evaluate the effectiveness of EA to modulate adrenocortical function in conditions of canine iatrogenic Cushing's syndrome (ICS).

Implementation: Evaluation of the potential efficacy of acupuncture for the treatment of Cushing's syndrome utilizing ACTH stimulation tests (selection of the most effective acupuncture point to treat ICS). Dogs are treated bilaterally with EA for 15 minutes at loci BL22 + BL23 + BL24, ST36, or a non-locus control point on M. brachialis. Complementary investigations involve treatment of the ST36 site bilaterally with EA for 30 minutes, 3 times per week, for 3 consecutive weeks. For the control, a non-locus point on M. brachialis is treated bilaterally with the same protocol. Each dog is tested at all 3 sites in rotation. Blood samples are collected before and 0, 15, and 60 minutes after EA, and serum cortisol levels are measured applying radioimmunoassay techniques.

Animal Model: Canine (n = 6 healthy adult female dogs; n = 8 dogs given prednisolone acetate [2 mg/kg/day IM × 21 days] and then randomly divided into ST36 and control groups of 4 dogs each).

Interpretation and Analysis: Electroacupuncture at ST36 results in the highest response of serum cortisol levels among the 3 treatments. Evaluation of the effectiveness of EA at ST36 in the treatment of ICS in dogs reveals that after the 1st week of EA, serum cortisol levels of the ST36 and control groups are 0.9 ± 0.1 and 0.5 ± 0.1 μg/dl ($p < 0.005$) baseline and 2.5 ± 0.2 and 1.4 ± 0.4 μg/dl ($p < 0.05$) and after ACTH stimulation test, respectively. After the 3rd week of EA treatment, the results are 1.0 ± 0.1 and 0.6 ± 0.2 μg/dl ($p < 0.05$) baseline and 4.0 ± 0.5 and 1.7 ± 0.5 μg/dl ($p < 0.001$) after ACTH stimulation, respectively. Electroacupuncture at ST36 therefore can restore the adrenocortical hypofunction resulting from ICS in dogs.

Treatment of iatrogenic Cushing's syndrome in dogs with electroacupuncture stimulation of stomach 36. Lin JH, Su HL, Chang SH, Shien YS, Wu LS. Am J Chin Med 1991; 19 (1), pp. 9–15.

Cushing's Syndrome: Hypothalamic/Pituitary Function/Pars Intermedia Pituitary Adenoma
Dexamethasone Suppression/Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: Dexamethasone suppresses hypothalamic corticotropin-releasing hormone (CRH) synthesis/release, which in turn decreases adenocorticotropic hormone (ACTH) synthesis.
Application: Detection and characterization of horses affected by pars intermedia pituitary adenoma. To evaluate results of a combined dexamethasone suppression/TRH stimulation test in horses clinically suspected of having a pars intermedia pituitary adenoma (PIPA).
Route of Administration: Dexamethasone (intravenous); TRH (intravenous).
Dosage: Dexamethasone (40 μg/kg [18 μg/lb] of body weight); TRH (1.1 mg).
Implementation: Evaluation of changes in cortisol concentrations in conditions of PIPA induced by dexamethasone administration. Blood samples are collected at baseline prior to dexamethasone suppression and then at 3 hours postinjection. A dose of TRH is then administered, followed by the serial collection of blood samples at 15, 30, 45, 60, and 90 minutes and 21 hours after TRH administration (24 hours after dexamethasone injection). Cortisol concentrations are measured in all blood samples collected for analysis.

Animal Model: Equine (n = 5 horses suspected of having PIPA; n = 7 healthy adult horses).
Interpretation and Analysis: Baseline cortisol concentrations are significantly lower in horses suspected to have a PIPA than in healthy horses. Cortisol concentrations are suppressed by dexamethasone in both groups; however, after TRH administration, cortisol concentration returns to baseline values in horses suspected to have a PIPA, but not in healthy horses. Concentrations are still less than baseline values 24 hours after dexamethasone administration in healthy horses.

The combined dexamethasone suppression/TRH stimulation test may be a useful diagnostic test in horses suspected of having PIPA. For clinical application, collection of a blood sample 30 minutes after TRH administration is recommended.

Results of a combined dexamethasone suppression/thyrotropin-releasing hormone stimulation test in healthy horses and horses suspected to have a pars intermedia pituitary adenoma. Eiler H, Oliver JW, Andrews FM, Fecteau KA, Green EM, McCracken M. J Am Vet Med Assoc 1997 Jul 1; 211 (1), pp. 79–81.

Cushing's Syndrome: Hypothalamic/Pituitary/Adrenalcortical Axis Function
Metyrapone/Adenocorticotropic Hormone (ACTH) and Compound-S (CMP-S)

Cellular/Molecular Mechanism of Action: Metyrapone inhibits enzymatic activity of 11β-hydroxylase, thereby reducing cortisol production.
Application: Assess the diagnostic accuracy of combined stimulation of ACTH and CMP-S.
Dosage: Metyrapone (2 g).
Considerations: The corticotropin-releasing hormone (CRH) test may sometimes be useful in the differential diagnosis of Cushing's syndrome because most patients with pituitary ACTH-dependent Cushing's syndrome (Cushing's disease) respond to CRH, but those with other causes of Cushing's syndrome usually do not. However, about 10% of Cushing's disease patients fail to respond to CRH.
Implementation: Evaluation of conditions of pituitary/adrenal dysfunction as a function of response to metyrapone tests and determination of the safety and practicality of such tests for use as an outpatient procedure. Example: Performance of 327 metyrapone tests analyzed retrospectively (e.g., n = 113 cases with 1 test; n = 72 cases with 2 and 6 tests over 1 to 3 years). Metyrapone is given at 2400 hours (outpatient procedure). Blood samples for analysis of ACTH, CMP-S, and cortisol are collected at 0730 hours.

Human Model: Cases of pituitary/adrenal dysfunction (n = 185, with mean age = 50.3 ± 15.2 years with most patients suffering from pituitary adenomas [60 macroadenomas, 63 microadenomas] or other pituitary lesions [n = 29]).
Interpretation and Analysis: Stimulation of adrenal CMP-S and cortisol by pituitary ACTH demonstrates a dose-response curve with the shape of half a geometric parabola. Compound-S reaches a plateau when ACTH rises above 175 ng/liter ($r = 0.661$, $p < 0.0001$ for ACTH < 175 ng/liter; $r = 0.083$, p = ns for ACTH > 175 ng/liter), cortisol "flattens" at ACTH levels above 230 ng/liter ($r = 0.633$; $p < 0.0001$ for ACTH < 230 ng/liter; p = ns for ACTH > 230 ng/liter). Alternatively, the sum of CMP-S plus cortisol also "flattens" when ACTH rises above 230 ng/liter ($r = 0.696$; $p < 0.0001$ for ACTH < 230; p = ns for ACTH > 230 ng/liter). Receiver operating curve analysis defining a cutoff for ACTH at 150 ng/liter demonstrates a sensitivity of 47% and 67% at a cutoff level for CMP-S at 200 or 260 nmol/liter, respectively. The respective specificity is 82% and 68% for CMP-S. This compares with a sensitivity of 71% and specificity of 69% if the sum of CMP-S plus cortisol of 450 nmol/liter can be used as a cutoff. The response curve between CMP-S and ACTH implies a maximally stimulated adrenal cortex at circulating ACTH levels above 175 ng/liter. Single measurement of CMP-S using the cutoff at 200 nmol/liter, as suggested in the literature, yields a poor sensitivity of only 47% compared with ACTH.

Despite the relatively high cross-reactivity of CMP-S in the cortisol assay, the sum of CMP-S and cortisol levels with a cutoff value of 450 nmol/liter yields a better diagnostic accuracy compared with CMP-S alone.
Instrumentation: The development and validation of a direct-injection high-performance liquid chromatography (HPLC) method, with column switching, for the determination of metyrapol enantiomers and metyrapone in human plasma has been described. The system used in this work is composed of a restricted access media (RAM) bovine serum albumin (BSA) octyl column coupled to an amylose tris(3,5-dimethoxyphenylcarbamate) chiral column. Water is used as eluent for the 1st 5 minutes at a flow rate of 1.0 ml/min for the elution of the plasma proteins and then acetonitrile-water (30:70 v/v) for the transfer and analysis of metyrapol enantiomers and metyrapone, which can be detected by UV at lambda = 260 nm. The total analysis time is about 32 minutes. The calibration curves for each enantiomer and for the metyrapone are linear in the ranges 0.075–0.75 μg/ml and 0.150–1.50 μg/ml, respectively. Recoveries, intra- and interday precision, and accuracy can be determined using 3 quality controls, 1 low (0.18 μg/ml), 1 medium (0.75 μg/ml), and 1 high (1.35 μg/ml) plasma concentration. Quantitative recoveries and good precision and accuracy can be obtained. The limit of quantitation is 0.045 μg/ml for both enantiomers and for metyrapone.

Combined stimulation of adrenocorticotropin and compound-S by single dose metyrapone test as an outpatient procedure to assess hypothalamic-pituitary-adrenal function. Berneis K, Staub JJ, Gessler A, Meier C, Girard J, Müller B. J Clin Endocrinol Metab 2002 Dec; 87 (12), pp. 5470–5.

Hyperadrenalcorticism: Stress-Induced/ Hemodialysis-Induced Dysfunction/Chronic Stress: Depression/Anorexia Nervosa
Corticotropin-Releasing Hormone (CRH)/Adenocorticotropic Hormone (ACTH)

Physiological Mechanism of Action: Corticotropin-releasing hormone is produced by the hypothalamus and modulates the secretion of pituitary ACTH.
Background Information: A state reminiscent of Cushing's syndrome has been reported to be precipated by hemodialysis procedures.
Application: Corticotropin-releasing hormone has been shown to be useful as a provocative test for evaluationg HPA axis function.
Route of Administration: Ovine CRH (oCRH) (intravenous bolus).
Dosage: oCRH.
Implementation: Evaluation of the influence of hemodialysis on hypothalamic-pituitary-adrenal (HPA) axis function by determining responses in plasma ACTH and cortisol concentrations following administration of exogenous ovine corticotropin-releasing hormone (oCRH).

Human Model: Cases subjected to hemodialysis (n = 13).
Interpretation and Analysis: The plasma concentrations of immunoreactive CRH following oCRH administration are similar in cases subjected to hemodialysis and controls. In the vast majority of cases, oCRH given intravenously as a bolus injection causes a further increase in already elevated levels of cortisol (n = 13/13). The mean basal plasma levels of ACTH are within the normal range. There is, however, a blunted ACTH response to oCRH. The HPA axis in chronic HD conditions retains the ability to respond to exogenous oCRH. The patterns of the ACTH and cortisol responses to this peptide resemble patterns observed with chronic stress (depression, anorexia nervosa). In addition, the kinetics for the disappearance of oCRH indicates that the kidney may not be the major organ that metabolizes oCRH.

Ovine corticotropin-releasing hormone stimulation test in patients with chronic renal failure: Pharmacokinetic properties, and plasma adrenocorticotropic hormone and serum cortisol responses. Siamopoulos KC, Eleftheriades EG, Pappas M, Sferopoulos G, Tsolas O. Horm Res 1988; 30 (1), pp. 17–21.

Hypopituitary Conditions/Adenocorticotropic Hormone (ACTH) Deficiency/ACTH Reserve Status
Corticotropin-Releasing Hormone (CRH)/ Adrenocorticotropin-Releasing Hormone/ Metyrapone/Urine 17-OH Corticosteroids/Serum Deoxycorticosterone

Cellular/Molecular Mechanism of Action: Corticotropin-releasing hormone from the hypothalamus promotes release/synthesis of ACTH from the pituitary, which in turn promotes glucocorticoid release/synthesis from the adrenal cortex.
Diagnostic Application: Detection of conditions associated with pituitary dysfunction or developmental abnormalities.
Route of Administration: Corticotropin-releasing hormone (intravenous bolus).
Dosage: Metyrapone administration (450 mg/m^2/dose every 4 hours $\times$ 7 doses); ovine CRH (1 μg/kg).
Implementation: Evaluation of hypopituitary conditions as a function of comparative responses of (i) ACTH and cortisol (F) to (ii) CRH administration and its effect on urinary 17-OH corticosteroids (17-OHCS); and (iii) metyrapone-induced alterations in serum deoxycorticosterone (DOC). The CRH test is performed 3 days before or 3 weeks after the metyrapone test for the purpose of establishing ACTH reserve status.

Human Model: Cases of hypopituitary conditions (n = 16 with glucocorticoid therapy withheld for a minimum of 3 weeks before testing).
Diagnostic Interpretation: In ACTH-intact hypopituitary conditions (e.g., n = 9 cases postmetyrapone 17-OHCS $>$ 12.2 mumol/m^2/d; DOC $\geq$ 11.5 nmol/L), the peak F (497–773 nmol/L) and ACTH (5.2–22 pmol/L) responses to CRH stimulation are similar to those of normal subjects (F peak = 554–993 nmol/L and ACTH peak = 6–25 pmol/L at 15 to 60 minutes). In cases with partial ACTH deficiency (e.g., n = 1 case: postmetyrapone 17-OHCS = 10.5 mumol/m2/d; DOC = 6 nmol/L), the peak F response is low and delayed (246 nmol/L at 180 minutes), while the peak ACTH response is normal (7 pmol/L). Severely ACTH-deficient conditions (e.g., n = 6 cases: postmetyrapone 17-OHCS $<$ 5.4 mumol/m^2/d; DOC $\leq$ 3.4 nmol/L) have a low F response at 15 to 90 minutes in all, with a delayed rise at 120 to 180 minutes in response to CRH administration (n = 3/6), whereas ACTH responses are variable: absent or low, normal, delayed, or persistently exaggerated. Therefore, the CRH-stimulated F response pattern in hypopituitary patients is comparable to urinary 17-OHCS and serum DOC response to metyrapone administration.
Laboratory Instrumentation: ELISA-based immunodiagnostic assay of serum samples.

Comparison of adrenocorticotropin and adrenal steroid responses to corticotropin-releasing hormone versus metyrapone testing in patients with hypopituitarism. Riddick L, Chrousos GP, Jeffries S, Pang S. Pediatr Res 1994 Aug; 36 (2), pp. 215–20.

Pheochromocytoma
Clonidine/[^{131}I]-MIBG

Pheochromocytomas are rare tumors of catecholamine-producing chromaffin cells leading to hypertension and symptoms of catecholamine excess. They can be benign or malignant, sporadic or familial tumors. Genetic syndromes associated with pheochromocytoma are MEN II, VHL disease, and neurofibromatosis type 1. Usually, pheochromocytomas occur in the adrenal medulla. Clinical manifestations include hypertension (which can be intermittent, stable, or in the form of hypertensive peaks) and symptoms related to catecholamine excess such as headache, palpitations and tachycardia, pallor, anxiety and nervousness, nausea, vomiting, and weight loss. This clinical syndrome can be mimicked by various hyperkinetic and hyperadrenergic states. When pheochromocytoma is suspected, the first diagnostic step is represented by the measurement of catecholamines and their metabolites (metanephrines) in urine and plasma. Chro-mogranin A quantification can be useful. The clonidine suppression test may be helpful in ruling out other conditions that may elevate catecholamines and metanephrines. Localization and staging of pheochromocytoma is based on MRI, which is more sensitive than CT scan, and [^{131}I]-MIBG scintiscan. The best therapeutic option for pheochromocytoma is surgery with a laparoscopic approach. An appropriate pre-, intra- and postoperative medical management of the patient is mandatory. In the absence of optimal medical treatment, intraoperative mortality reaches 50%.

Recent advances in diagnosis and treatment of pheochromocytoma. Veglio F, Morello F, Morra Di Cella S, Del Colle S, Rabbia F, Mulatero P. Minerva Med 2003 Aug; 94 (4), pp. 267–71.

Pheochromocytoma/Urinary Vanillylmandelic Acid, Metanephrine, Normetanephrine
Glucagon/[^{125}I]-Thyr10-Glucagon/ Des-His1[Glu9]Glucagon Amide

Background Information: Pheochromocytoma cases frequently have elevated plasma concentrations of adrenaline and noradrenaline in addition to increases in urinary vanillylmandelic acid, metanephrine, and/or normetanephrine.
Application: Detection and characterization of pheochromocytoma in addition to conditions of essential hypertension, thyroid disease, diabetes mellitus, and acromegaly.
Route of Administration: Pheochromocytoma and chromaffin granules of the pig adrenal medulla in experimental *ex vivo*/*in vitro* scenarios.
Dosage: Glucagon (10^{-4}) infusion for 10 minutes following 2 hours of preincubation.
Considerations: Most patients suffering from pheochromocytoma are diagnosed by measuring urine concentrations of vanillylmandelic acid, metanephrine, and/or normetanephrine in addition to plasma catecholamine concentrations. However, a subset of patients suffering from the condition will not have elevated concentrations of the metabolites in the plasma or urine.

Administration of phenotolamine (blocking agent) prior to histamine challenge test in order to protect against hypotension or catecholamine-induced arrythmias.
Implementation (Clinical): Evaluation of conditions of suspected pheochromocytoma as a function of catecholamine and blood pressure response to glucagon challenge. Examples: (i) Study of pig adrenal medulla or human pheochromocytoma to determine the influence of glucagon infusion. Given this objective, a continuous-flow incubation system can be employed in which the secretory response to these drugs is characterized by a serial fluorimetric assay of catecholamines in the effluent medium. (ii) Characterization of the *in vivo* effect of glucagon on blood pressure and urinary catecholamine levels of healthy control subjects, for comparison to cases of essential hypertension, thyroid disease, diabetes mellitus, and acromegaly.

Human Model: Extra-adrenal pheochromocytoma.
Interpretation and Analysis: During *in vitro* preparations, glucagons (10^{-4}) for 10 minutes following a 2-hour incubation period result in abrupt increases in adrenaline and noradrenaline (epinephrine to 0.08 μg/mg, and norepinephrine to 0.07 μg/mg). Systemically (*in vivo*), there is initially a massive release of catecholamines that declines to basal levels (0.02 μg/mg) after 1.5 hours. During the course of *in vivo* administration trials, glucagon induces a slight but constant increase in blood pressure. By contrast, no significant urinary catecholamine elevation may be evoked. Adjunct diagnostics can include detection using [^{131}I]-metaiodobenzylguanidine (MIBG) scintigraphy.

Pheochromocytoma: Adrenal Incidentaloma
Metoclopramide

Background Information: Pheochromocytoma cases occasionally are identified incidentally on examination.

Case Example: Left adrenal mass (3.0 cm) detected by abdominal computed tomography.
Considerations: Cases may have to be observed and treated conservatively due to the possible occurrence of arterial hypotension after tumor resection.

Human Example: Pheochromocytoma detected by abdominal computed tomography as a left adrenal mass (3.0 cm). (Signalment: 52-year-old male patient with weight loss of 3 kg over a 3-month period.)
Implementation: Measurement of plasma adrenaline and noradrenaline levels; metaclopramide provocative test; [^{123}I]-metaiodobenzylguanidine (MIBG) scintiscan.
Interpretation and Analysis: Plasma adrenaline and noradrenaline in cases of pheochromocytoma may increase to 521 pg/ml and 1,341 pg/ml, respectively. Metoclopramide provocative tests are usually positive, while scintiscan using [^{123}I]-MIBG will demonstrate accumulation of the radionuclide in the adrenal tumor region. Patients may need to undergo observation and conservative treatment due to the possible occurrence of arterial hypotension after resection of a tumor.

Pheochromocytoma in a long-term hemodialysis patient, discovered as an adrenal incidentaloma. Asaka S, Takayama Y, Tagawa S, Ito Y, Yoshimura A, Masunaga T, Oiwake H, Shinozaki K, Takeda R. Intern Med 1997 Jun; 36 (6), pp. 403–7.

Pheochromocytoma/[Elevated Glucagon-Receptor Expression]
Des-His(1)[Glu$_9$]Glucagon Amide/ [^{125}I-Thyr$_{10}$]Glucagon

Cellular/Molecular Mechanism of Action: [^{125}I-Thyr$_{10}$]-glucagon is a radiolabeled analog of glucagon. Des-His(1)[Glu$_9$] glucagon amide is a glucagon receptor antagonist.
Background Information: Pheochromocytoma lesions expressed glucagon receptor complexes at elevated membrane densities.
Application: Potential diagnostic parameter for detecting conditions of pheochromocytoma. Des-His(1)[Glu$_9$]glucagon amide (GR-A) abolishes the secretory response to glucagon by pheochromocytomas.
Route of Administration: Experimental (*in vitro*/*ex vivo*).
Dosage: Experimental (*in vitro*).
Implementation: Evaluation of glucagon mRNA expression and glucagon receptor expression in pheochromocytoma lesions.

Human *Ex Vivo* Model: Pheochromocytoma lesions (n = 3 and n = 4 normal adrenal medullas).
Interpretation and Analysis: Glucagon-receptor mRNA can be detected by reverse transcription-polymerase chain reaction in human pheochromocytomas, but not in normal adrenal medullas. Quantitative autoradiography demonstrates the presence of abundant [^{125}I-Thyr$_{10}$]glucagon binding sites in pheochromocytomas, which can be displaced by both cold glucagon and the glucagon receptor antagonist Des-His(1)[Glu$_9$]glucagon amide (GR-A). The adrenal medulla is weakly labeled, and binding is not displaced by GR-A. Glucagon enhances epinephrine and norepinephrine release by pheochromocytoma slices, minimal and maximal effective concentrations being 10^{-8} M and 10^{-6} M. Adrenomedullary slices evoke a weak catecholamine response only to 10^{-5} M glucagon.

GR-A abolished the secretory response to glucagon by pheochromocytomas, but not of adrenal medullas. Collectively, these findings indicate that human pheochromocytomas, but not adrenal medulla, express glucagon receptors and possess a marked secretory response to glucagon, thereby providing the rationale to explain the specificity of the glucagon provocative test in the diagnosis of pheochromocytoma.

Human pheochromocytomas, but not adrenal medulla, express glucagon-receptor gene and possess an *in vitro* secretory response to glucagon. Albertin G, Aragona F, Gottardo L, Malendowicz LK, Nussdorfer GG. Peptides 2001 Apr; 22 (4), pp. 597–600.

Pheochromocytoma
Metoclopramide

Cellular/Molecular Mechanism of Action: Metoclopramide functions as a dopamine antagonist agent.
Route of Administration: Metoclopramide (intravenous).
Dosage: Metoclopramide (5 mg).
Application: Detection and characterization of the condition of pheochromocytoma.
Implementation: Evaluation of the cardiovascular and plasma catecholamine responses to metoclopramide in cases of pheochromocytoma (e.g., n = 5), essential hypertension (e.g., n = 12); and normotensive subjects (e.g., n = 9) that display symptoms suggestive of pheochromocytoma and on a constant daily intake of sodium (100 mEq) and potassium (80 mEq).
Instrumentation: Significant pressor responses to metaclopramide (producing no serious pressor episodes and no other undesirable side effects) are found only in cases of pheochromocytoma. In contrast, cases of essential hypertension and normotensive individuals experience a slight depressor response.

Following curative surgery for pheochromocytoma, metoclopramide-induced pressor effects return to normal. Furthermore, the enhanced pressor effects of metaclopramide in patients with pheochromocytoma are associated with increases in plasma norepinephrine (NE) concentrations. However, the plasma epinephrine (E) concentrations remain unchanged after metaclopramide IV injection. In brief, the 5 mg dose of MCP appears to be a more suitable vasopressor provocative agent in the pharmacological diagnosis of pheochromocytoma compared to currently used agents.

Metoclopramide in the diagnosis of pheochromocytoma. Kawabe H, Itaya Y, Suzuki H, Kondo K, Saruta T. Jpn Heart J 1985 Jul; 26 (4), pp. 557–66.

Pheochromocytoma
Histamine/Methacholine/Glucagon/Phentolamine

Background Information: Pheochromocytoma accounts for about 0.1% of patients with diastolic hyperstension. It mimics many diseases varying from anxiety psychoneurosis to intracranial tumors. Cardinal symptoms include severe headache (72–92%), sweating (60–70%), palpitations (51–73%), and hypertension (> 90%) of which 50% is sustained, 50% paroxysmal. Many drugs (phenothiazines, Saralasin, antiemetics, steroids, etc.) have been reported as precipitating factors.
Diagnostic Application: Provocative testing for pheochromocytoma.
Implementation: Provocative agents (histamine, glucagon, tyramine) are needed rarely. Administration of phenotolamine (blocking agent) prior to histamine challenge test is sometimes applied in order to protect against hypotension or catecholamine-induced arrythmias. Preoperative localization of the tumor can be done with nephrotomography IVP, computerized axial tomography, ultrasound, [^{131}I]-19-iodocholesterol scan, arteriography, and venography.

Human Model: Clinical signs suggestive of pheochromocytoma include (i) all symptomatic patients with sustained or paroxysmal hypertension; (ii) asymptomatic hypertension; (iii) all patients with MEA 2a,b (hyperparathyroidism, medullary carcinoma of the thyroid, neurocutaneous lesions) and their 1st-degree relatives, even if the latter are asymptomatic and normotensive; (iv) hypertension plus diabetes mellitis or hypermetabolism; (v) hypertensive episode during induction of anesthesia or radiologic procedure; and (vi) hypertensive response during histamine administration, (i.e., gastric analysis).
Interpretation and Analysis: Most patients suffering from pheochromocytoma are diagnosed by measuring urine concentrations of vanillylmandelic acid, metanephrine, and/or normetanephrine in addition to plasma catecholamine concentrations. Urinary metanephrine is the single best screening test. However, a subset of patients suffering from the condition will not have elevated concentrations of the metabolites in the plasma or urine. Plasma catecholamine determination is particularly helpful when collected before and immediately after an attack.

Pheochromocytoma: Clinical manifestations and diagnostic tests. Juon D. Urology 1981 Jan; 17 (1), pp. 1–12.

Pheochromocytoma: Asymptomatic/Multiple Endocrine Neoplasia Type 2 (MEN-2 Carriers)
Exercise Test

Cellular/Molecular Mechanism of Action: Exercise-induced release of plasma adrenaline, noradrenaline, and dopamine.
Application: Early detection of asymptomatic pheochromocytoma.

Plasma catecholamines before and after submaximal exercise measured in MEN-2 gene carriers (e.g., n = 26; n = 8/26 asymptomatic pheochromocytomas; n = 9/26 medullary thyroid carcinoma; n = 10/26 following uni- or bilateral adrenalectomy). Comparisons can be made to normal healthy controls (e.g., n = 17) and cases of neurovegitative lability with symptoms mimicking pheochromocytoma (e.g., n = 11).
Considerations: Asymptomatic pheochromocytoma is a major risk for patients with MEN-2.
Implementation: Characterization of pheochromocytoma conditions utilizing a physiological test that has a high sensitivity and specificity. It is practical and well suited for repeated examinations and seems to be of value for the detection of early pheochromocytoma in MEN-2 patients. Furthermore, the test could be used in the differential diagnosis between pheochromocytoma and neurovegetative lability. An example of the diagnostic application of the test can involve the measurement of plasma catecholamine levels before and after submaximal exercise.

Human Model: Cases suffering from pheochromocytoma (MEN-2 gene carriers [e.g., n = 26; n = 8/26 asymptomatic pheochromocytomas; n = 9/26 medullary thyroid carcinoma; n = 10/26 following uni- or bilateral adrenalectomy]). Comparisons can be made to normal healthy controls (e.g., n = 17) and cases of neurovegitative lability with symptoms mimicking pheochromocytoma (e.g., n = 11).
Interpretation and Analysis: Plasma adrenaline, noradrenaline, and dopamine increase after exercise except for adrenaline after bilateral adrenalectomy. The postexercise levels of adrenaline and the adrenaline/dopamine ratio are significantly higher in the pheochromocytoma patients compared to the healthy controls and the patients with neurovegetative lability, while the patients with medullary thyroid carcinoma represented an intermediate group with a high probability of developing adrenal tumors.

Pheochromocytoma
Clonidine/Glucagon/Metoclopramide/Naloxone

Cellular/Molecular Mechanism of Action: Clonidine (central acting α_2-adrenergic agonist); glucagon (promotes hyperglycemia); naloxone (competitive antagonist at μ-, δ-, κ- and σ-opioid receptor complexes); and metoclopramide (enhances the action of acetylcholine at muscarinic receptor complexes and in the central nervous system antagonizes dopamine).
Physiological Mechanism of Action: Clonidine (reduced heart rate, reduced stroke volume, reduced peripheral vascular resistance that parallels reductions in systemic norepinephrine concentrations); glucagon (most significantly regulated by plasma glucose concentrations and primarily antagonizes the hormonal effects of insulin); naloxone (reverses or attenuates vascular hypertension); and metoclopramide (parasympathomemitic).
Application: Clonidine, glucagons, naloxone, and metoclopramide have been applied in the detection and monitoring of pheochromocytoma disease states.
Background Information: Some clinical investigations have shown that clonidine, which is widely used in clonidine suppression test, is sometimes fallible for the diagnosis of pheochromocytoma.
Route of Administration: Clonidine (oral); glucagons (intravenous); naloxone (intravenous); and metoclopramide (intravenous).
Dosage: Clonidine (150 μg); glucagons (1 mg); naloxone (10 mg); and metoclopramide (5 mg).
Implementation: Distinguishing pheochromocytoma positive cases from negative pheochromocytoma suspect cases through the measurement of plasma norepinephrine and epinephrine concentrations.

Human Model: Cases of pheochromocytoma (n = 6); and suspect but non-pheochromocytoma (n = 19).
Interpretation and Analysis: In comparisons between the diagnostic tests employing suppression (clonidine) and provocative agents (glucagon, metoclopramide, naloxone) performed in cases of pheochromocytoma (n = 6) and suspect but non-pheochromocytoma patients (n = 19), the blood pressure response does not predict well the presence of pheochromocytoma applying any of the tests. Plasma norepinephrine (NE) concentrations measured at 120 and 180 minutes following clonidine (150 μg per os) produces false negative results in approximately 2 out of 5 cases with pheochromocytoma. Both plasma norepinephrine and epinephrine concentrations measured before and sequentially after each provocative agent reveal that neither of the 2 agents respond to glucagons (1 mg IV) in some cases with pheochromocytoma (e.g., n = 2/4 or 50%). Determination of the peak level, peak increment, and % peak increment of norepinephrine and epinephrine following naloxone (10 mg IV) does not aid in distinguishing between the 2 groups. The % peak increments of both norepinephrine and epinephrine in all cases of pheochromocytoma (e.g., n = 4) given metoclopramide (5 mg IV) exceed the mean + 3 SD values for pheochromocytoma negative cases (norepinephrine = 25 ± 28%; epinephrine = 25 ± 42%). These results suggest that, when performed with judicious patient selection (ambiguous plasma or urinary catecholamine levels), the measurement of plasma catecholamines in response to metoclopramide can be a useful adjunctive tool in the diagnosis of pheochromocytoma.

Evaluation of clonidine suppression and various provocation tests in the diagnosis of pheochromocytoma. Koshida H, Miyamori I, Soma R, Matsubara T, Okamoto S, Ikeda M, Takeda R. J Endocrinol Invest 1990 Nov; 13 (10), pp. 807–15.

Pheochromocytoma (Silent/Subclinical)
Clonidine/Glucagon/[^{131}I]-Metaiodobenzylguanidine

Cellular/Molecular Mechanism of Action: Glucagon promotes catecholamine production/secretion.
Background Information: Pheochromocytomas have elevated membrane expression densities for glucagons receptor complexes.
Application: Diagnosis of subclinical/silent pheochromocytoma.
Considerations: Cases with pheochromocytoma present with clinical signs of hypertension, elevated serum catecholamine levels, elevated urinary norepinephrine concentrations, and/or unexpected detection of an abdominal mass.
Implementation: The glucagon provocation test promotes increased norepinephrine production/release while clonidine-suppression tests reduce norepinephrine production/secretion in normal individuals.
Interpretation and Analysis: A glucagon provocative test and [^{131}I]-metaiodobenzylguanidine scintigram can be useful in diagnosing conditions of atypical pheochromocytoma. The clonidine suppression test can be helpful in ruling out other conditions that may elevate catecholamines and metanephrines, or when catecholamines are only moderately elevated, or for any other reason when a diagnosis of pheochromocytoma is still uncertain.

A case of metastatic extra-adrenal pheochromocytoma 12 years after surgery. Mori S, Okura T, Kitami Y, Takata Y, Nakamura M, Watanabe S, Iwata T, Hiwada K. Hypertens Res 2002 Jan; 25 (1), pp. 141–4.

Cervical pheochromocytoma: A rare localization and a difficult diagnosis. Becker G, Jockenhövel F, Bauer R, Lederbogen S, Lange R, Reinwein D. J Endocrinol Invest 1992 Nov; 15 (10), pp. 767–70.

Pituitary Macroadenomas (Adenocorticotropic Hormone [ACTH]-Secreting)/Pituitary Surgery Response Evaluation
Dexamethasone/Corticotropin-Releasing Hormone (CRH)

Cellular/Molecular Mechanism of Action: Exposure to pituitary ACTH promotes the synthesis/release or adrenal cortisol. Dexamethasone suppresses hypothalamic CRH release, thereby diminishing pituitary ACTH synthesis/release.
Background Information: Cushing's disease due to large pituitary tumors is rare.
Appliation: Evaluation of pituitary/adrenal function in suspected cases of pituitary ademoma.
Implementation: Evaluation of conditions of ACTH-secreting pituitary macroadenomas through the measurement of plasma ACTH, serum cortisol, and 24-hour urinary free cortisol (UFC) levels. Complementary analyses include performing a high-dose dexamethasone (dexa) suppression test. Cases are then reevaluated following surgical intervention and, if not cured, a 2nd surgical procedure is performed in addition to , radiotherapy, and/or ketoconazole treatment. The follow-up periods can range over a time frame of 78 ± 10 months. In this manner, it is possible to establish certain biochemical characteristics at the time of clinical presentation and profile both results of 1st surgical approach, and adjuvant therapeutic strategies during a long-term follow-up period.

Human Model: Cases of ACTH-secreting pituitary macroadenoma (n = 26 cases; n = 9/26 male, n = 17/26 female; 42.5 ± 12.7 years, mean ± s.e.; tumor dimensions = 11–40 mm diameter).

Cases of ACTH-secreting pituitary macroadenomas evaluated with a high-dose dexamethasone (dexa) suppression test (n = 22); or CRH (n = 20 cases).

Interpretation and Analysis: Before surgery, dexamethasone decreases ACTH (> 50% of baseline) in approximately 50% of cases (e.g., n = 14/26). The CRH-stimulated ACTH/cortisol response is normal in < 25% of cases (e.g., n = 6/26); impaired in slightly < 25% of cases (e.g., n = 6/26), and exaggerated in < 33% of cases (e.g., n = 8/26). Following surgical intervention, < 33% are cured (e.g., n = 8/26), slightly > 33% have normalized cortisol levels (n = 9/26), and > 33% are not cured (e.g., n = 9/26).

Presurgery, mean ACTH values are significantly higher in cases not curred of the condition than in those normalized ($p < 0.05$) and cured ($p < 0.01$); the ACTH response to CRH can be impaired in some cases not curred (e.g., n = 6). Tumor diameter is significantly less in cured patients ($p < 0.02$) and in normalized patients ($p < 0.05$) compared to cases not cured of the condition. Magnetic resonance imaging (MRI) shows invasion of the cavernous sinus in some normalized cases (e.g., n = 2/9), and in not-cured cases (e.g., n = 6/9). After surgery, ACTH, cortisol and UFC are significantly lower than at entry in cured and in normalized cases, but not in not-cured cases. In the cured group, the disease can reoccur in some cases (e.g., n = 1 unsuccessfully treated with ketoconazole). In normalized case types, a relapse can occur (e.g., n = 8); in addition to potential outcomes including radiotherapy and ketoconazole induced cortisol normalization (e.g., n = 1), hypoadrenalism (e.g., n = 1); ineffective (e.g., n = 1); or lost to follow-up (e.g., n = 5). In not-cured case types, some may require a 2nd attempt at surgical intervention, radiotherapy and/or ketoconazole (e.g., n = 8), while a small number may be lost to follow-up (e.g., n = 1). Therapies can induce cortisol normalization (e.g., n = 2) or hypoadrenalism (e.g., n = 1). A subset of patients with ACTH-secreting pituitary macroadenoma show low sensitivity to high doses of dexamethasone and to CRH. Pituitary surgery cures Cushing's disease in a minority of patients. High baseline ACTH levels, impaired ACTH responses to CRH, increases in tumor size or invasion of the cavernous sinus are unfavorable prognostic factors for surgical intervention. A 2nd attempt at surgical intervention, radiotherapy, and/or ketaconazole can cure or normalized hypercortisolism in approximately half of cases with recurrence or not cured.

Long-term results of treatment in patients with ACTH-secreting pituitary macroadenomas. Cannavò S, Almoto B, Dall'Asta C, Corsello S, Lovicu RM, De Menis E, Trimarchi F, Ambrosi B. Eur J Endocrinol 2003 Sep; 149 (3), pp. 195–200.

HYPOTHALAMUS AND PITUITARY: GROWTH HORMONE

Acromeglia/Pituitary Dwarfism
Clonidine

Cellular/Molecular Mechanism of Action: Clonidine is an α-adrenergic agonist (xylazine is a structural analog). Systemically, it promotes the release of growth hormone (GH) mediated through induced secretion or liberation of growth hormone-releasing factor.

Diagnostic Application: Diagnosis of acromeglia and pituitary dwarfism (e.g., canine) in scenarios that fail to display resting elevations in growth hormone concentrations.

Route of Administration and Dosage: Intramuscular injection at a dosage of 10 μg/kg. Alternatively human growth hormone-releasing factor (hGHRF) can be administered at a dosage of 1 to 5 μg/kg.

Considerations: Clonidine can cause bradycardia and profound hypotension. Atropine can be administered to prevent or correct the induction of bradycardia. Antagonists such as phentolamine and yohimbine (α-adrenergic antagonists) can be applied to reverse hypotensive sequela.

Interpretation and Analysis: Blood samples (2 ml) are collected at intervals of 15, 30, 45, 60, and 120 minutes into EDTA anticoagulant tubes.

Laboratory Instrumentation: Assay of either growth hormone (GH) concentrations by either RIA or ELISA methodologies.

Acromegaly: Postoperative Growth Hormone (GH) Function/Hypothalamic/Pituitary Dysfunction
Thyrotropin-Releasing Hormone (TRH)/Glucose Tolerance Test (GTT)/Lanreotide

Cellular/Molecular Mechanism of Action: Exogenous or endogenous TRH and glucose can promote the release of pituitary GH in conditions of acromegaly.

Route of Administration: Thyrotropin-releasing hormone test (intravenous); glucose (oral).

Dosage: TRH test (400 μg); glucose (75 g).

Implementation: Evaluation of active postoperative acromegaly before and after long-term slow-release (SR) lanreotide therapy (30 mg IM every 10–14 days) achieved by measuring alterations in plasma GH in response to the oral glucose tolerance test (OGTT) and TRH stimulation test. The OGTT and TRH test are repeated before and after 6, 12, 24, and 36 months.

Human Model: Cases of active postoperative acromegaly (n = 10, of which n = 7/10; n = 2/7 males; age 29–71 years; cases that during therapy maintained plasma GH and insulin-like growth factor-I (IGF-I) concentrations under 5 μg/l and 450 μg/l, respectively, are considered as responders and studied for 24 [n = 1 case] to 36 months [n = 6 cases] in addition to n = 3/10 cases; n = 1/3 male; age = 46–61 years with levels of GH and IGF-I above those values studied for 12 months).

Interpretation and Analysis: The GH response to OGTT is abnormal (nadir: > 2 μg/l) at 6 and 12 months in poorly responsive patients. This response is normalized in all responsive patients. Nonetheless, some responsive patients show abnormal GH values after OGTT throughout the 36-month study period (n = 2). The GH response to TRH is characterized by great variability and exhibits unpredictable behavior throughout the study period both in responsive and in poorly responsive cases. Only 2 patients in the responsive group show persistent normal GH levels (peak: ≤ 5 μg/l) after TRH for 3 years. In conclusion, SR lanreotide treatment gives rise to a correct control of GH hypersecretion and to a normalization of GH response to oral glucose in 7 out of 10 patients, although it does not abolish the paradoxical reaction of GH to TRH in all responders. The effect of SR lanreotide on GH response to GTT is not paralleled by GH response to TRH.

Growth hormone responses to oral glucose and intravenous thyrotropin-releasing hormone in acromegalic patients treated by slow-release lanreotide. Díez JJ, Iglesias P, Gómez-Pan A. J Endocrinol Invest 2001 May; 24 (5), pp. 303–9.

Acromegaly/Pituitary Dwarfism
Glucose

Cellular/Molecular Mechanism of Action: Absorbed from the proximal small intestine resulting in elevated synthesis and secretion of pancreatic insulin. Transport of glucose across intact cell

membranes is regulated (promoted) by insulin. When the renal threshold is exceeded, glucose is excreted into the urine.

Diagnostic Application: Detection and characterization of pituitary-based acromegaly.

Route of Administration and Dosage: A Glucose Suppression Test is performed by administering glucose either orally or by intravenous injection.

Dosage: Glucose (1 gm/kg).

Considerations: Glucose given orally in horses can promote the onset of laminitis.

Implementation: Glucose Suppression Test for identification and characterization of acromegaly and pituitary dwarfism conditions.

Animal Model: Feline.

Interpretation and Analysis: Cases suffering from pituitary-based acromegaly display elevated concentrations of growth hormone (GH) within the systemic circulation. Glucose suppresses pituitary GH secretion and this finding can be utilized as a means of verifying a diagnosis of acromegaly. In normal reference control subjects, systemic concentrations of GH are suppressed to concentrations $<$ 5 ng/ml within 60 minutes after glucose infusion. Presistently elevated GH levels following administration of glucose are diagnostically suggestive of acromegaly.

Laboratory Instrumentation: Measurement of spectrophotometric absorbance.

Acromegaly/Short Stature
Growth Hormone-Releasing Hormone (GHRH)/GRF_{1-37}-OH, GRF_{1-40}-OH, GRF_{1-44}-NH_2

Cellular/Molecular Mechanism of Action: Promotes the synthesis/secretion of growth hormone. Control of the GHRH secretion by peptidergic hypothalamic neurons occurs through 4 principal monoaminergic systems such as dopaminergic, noradrenergic, adrenergic, and serotoninergic 1s, and also by cholinergic fibers and by endogenous opiates, all acting to cause the release of GHRH into the hypothalamo-hypophyseal portal circulation.

Application: Diagnosis and characterization of acromegaly and short-stature conditions. Preparations may also be beneficial when applied as a therapeutic agent for children with GH deficiency and may improve current understanding about the hypothalamic pathogenesis of short stature.

Considerations: Beginning in 1982, multiple publications have reported the application of 3 GRF preparations, including GRF_{1-37}-OH, GRF_{1-40}-OH, GRF_{1-44}-NH_2. The later preparations in concert with immunohistochemical methods produced results similar to hypothalamic hGHRH.

Interpretation and Analysis: Some clinical investigators have concluded that GHRH testing has limited diagnostic usefulness in the clinical evaluation of acromegaly but allows discrimination of acromegalic patients with ectopic production of GHRH from those with pituitary tumors.

In patients with short stature, they demonstrate a level of GH deficiency that is detectable through the exogenous administration of GHRH demonstrating a level of hypothalamic disregulation and not a pure pituitary deficiency as has been supposed before GHRH discovery.

Delayed Growth: Constitutional Growth Delay (CGD)/Hypogonadotropic Hypogonadism (HH)
Gonadotropin-Releasing Hormone (GnRH)/Nafarelin

Background Information: Previous investigations have observed nocturnal luteinizing hormone (LH) equal to 5.5 $\pm$ 0.9 IU/I for CGD and 2.7 $\pm$ 0.7 IU/I for HH that represents a statistically significant difference. Mean nocturnal follicle-stimulating hormone (FSH) has been reported to be 5.1 $\pm$ 1.0 and 2.5 $\pm$ 0.2 IU/I, whereas mean nocturnal T concentrations are statistically different at approximately 4.2 $\pm$ 0.8 and 0.7 $\pm$ 0.2 nmol/I for CGD compared to HH, respectively. Peak LH responses to nafarelin are approximately 36.9 $\pm$ 8.9 IU/I for CGD, and 7.0 $\pm$ 2.0 IU/I for HH (statistically significant). Peak FSH released by nafarelin is about 14.2 $\pm$ 2.4 IU/I for CGD and 4.8 $\pm$ 2.0 IU/I for HH (statistically significant). Peak Ts are reached at 24 hours following nafarelin injection and are equivalent to 5.7 $\pm$ 1.7 nmol/I for CGD and 0.3 $\pm$ 0.2 nmol/I for HH (statistically significant).

Application: Distinguish between CGD in boys with Tanner stage I of sexual development and patients with HH.

Route of Administration: Subcutaneous.

Dosage: Nafarelin (1 μg/kg up to 100 μg).

Implementation: Evaluation of hypothalamic/pituitary function based on the interpretation of changes in LH, FSH, T, and E2 concentrations following nafarelin administration. Blood samples are collected at timed intervals every 15 minutes for 24 hours for the measurement of LH, FSH, T, and E2 (e.g., RIA, ELISA). Pretreatment baseline values are obtained by collecting blood samples every 15 minutes during a 12-hour overnight schedule.

Human Model: Cases of suspected CGD from HH.

Interpretation and Analysis: Stimulated release of plasma LH, FSH, and T is significantly higher with nafarelin compared to GnRH, which also takes a longer period of time to reach maximum peak concentrations. Experimental findings indicate that in early stages of puberty (before detectable changes of sexual maturation) the nafarelin test combined with the measurement of LH, FSH, and T in the blood or urine is superior to and more practical than overnight hormonal estimates to clearly distinguish CGD from HH.

Instrumentation: Instrumentation and facilities necessary to perform RIA- or ELISA-based methodologies.

Gonadotropin-releasing hormone agonist analog (nafarelin): A useful diagnostic agent for the distinction of constitutional growth delay from hypogonadotropic hypogonadism. Kletter GB, Rolfes-Curl A, Goodpasture JC, Solish SB, Scott L, Henzl MR, Beitins IZ. J Pediatr Endocrinol Metab 1996 Jan–Feb; 9 (1), pp. 9–19.

Growth Hormone Deficiency (GHD): Insulin-Like Growth Factor
Clonidine

Application: Identification of conditions associated with GHD.

Route of Administration: Clonidine (oral).

Dosage: Clonidine.

Considerations: Serum levels of total insulin-like growth factor I (IGF-I) and IGF-binding protein-3 (IGFBP-3) reflect endogenous GH secretion in healthy children, which makes them good diagnostic markers for screening of GHD in short children, although some controversy still exists. Only a minor fraction of the total IGF-I circulates in "free form", which is believed to be the 1 that exerts the highest level of biological activity. However, our knowledge of the clinical or physiological value of determination of free IGF-I in serum is limited at present. In adults, the diagnostic value of total IGF-I and IGFBP-3 determinations in patients suspected of GHD has only been reported in a few studies, whereas no previous reports on the diagnostic value of free IGF-I levels in adults suspected of GHD exist.

Implementation: Evaluation of serum levels of free IGF-I utilizing a immunoradiometric assay (Diagnostic Systems Laboratories) to establish valid normative data for this analysis. Complementary

investigations can assess the diagnostic value of free IGF-I in relation to total IGF-I and IGFBP-3 determinations in adults suspected of having GHD. A GH provocative test, using oral clonidine, is performed in cases previously treated with GH in childhood.

Human Model: Cases without evidence of disease (n = 1430 children, adolescents, adults; n = 108 previously treated with GH in childhood and received oral clinidine)

Interpretation and Analysis: In healthy subjects, free IGF-I levels increase during childhood, with the highest mean values detected during puberty. After puberty, a subsequent decline in serum levels of free IGF-I occurs. Unmeasurable free IGF-I values may be detected in approximately 3.3% (e.g., n = 34) of prepubertal children. The vast majority of individuals over 8 years of age have measurable free IGF-I levels that amount to approximately 1% of the total IGF-I concentrations (e.g., 100% of cases). Free IGF-I levels are below normal in most GHD cases (e.g., n = 56/79 GHD; sensitivity = 71%) and above 2 SD in most patients with a normal GH response (e.g., n = 24/29, specificity = 83%). Multiple linear regression analyses demonstrate that free IGF-I is significantly dependent on peak GH levels, duration of the disease, and number of other pituitary axes affected. Therefore, free IGF-I serum levels increase during childhood with a peak in puberty, whereafter free IGF-I levels return to prepubertal levels. Three percent of healthy prepubertal children have unmeasurable free IGF-I levels using this assay. Determination of the free IGF-I serum concentration may predict the outcome of a GH provocative test in adults suspected of GHD, but a single determination of free IGF-I offers no significant advantage compared to determination of total IGF-I or IGFBP-3 serum levels.

Free insulin-like growth factor I serum levels in 1430 healthy children and adults, and its diagnostic value in patients suspected of growth hormone deficiency. Juul A, Holm K, Kastrup KW, Pedersen SA, Michaelsen KF, Scheike T, Rasmussen S, Müller J, Skakkebaek NE. J Clin Endocrinol Metab 1997 Aug; 82 (8), pp. 2497–502.

Growth Hormone Deficiency (GHD)
Growth Hormone-Releasing Hormone/Arginine (ARG)

Cellular/Molecular Mechanism of Action: Growth hormone-releasing hormone promotes the release of pituitary GH.

Application: Detection and characterization of GHD including idiopathic inflammatory pituitary stalk thickness, Langerhans cell histiocytosis (LCH) affecting the hypothalamic-pituitary area, and craniopharyngioma.

Implementation: Evaluation of conditions of acquired GHD including idiopathic inflammatory pituitary stalk thickness, Langerhans cell histiocytosis (LCH) affecting the hypothalamic-pituitary area, and craniopharyngioma.

Interpretation and Analysis: A high percentage of patients show GH response < 10 μg/liter after 2 pharmacological stimuli and tested with GHRH + ARG (mean age of 11.2 ± 4.1 years). All cases (mean age, 9.6 ± 3.1 years; range, 5.6–20.8) show GH response < 10 μg/liter after 2 pharmacological stimuli and tested with GHRH + ARG at a mean age of 11.2 ± 4.1 years. Acquired GHD cases will also often display vasopressin deficiency, TSH deficiency, gonadotropin deficiency, and ACTH deficiency. The median peak GH response to the insulin test is approximately 2.1 μg/liter (range, 1.1–2.9) compared to 1.5 μg/liter (range, 1.3–2.4) after arginine. The median peak GH response to insulin is significantly lower in patients with craniopharyngioma (1.4 μg/liter; range, 0.8–1.7) than in the patients with idiopathic pituitary stalk thickness (2.2 μg/liter; range, 1.0–2.4) or with LCH (2.6 μg/liter; range, 2.0–4.3, p = 0.02). The median peak GH response to arginine is significantly lower in patients with idiopathic inflammatory pituitary stalk thickness (1.3 μg/liter; range, 0.8–1.8) in contrast to those with craniopharyngioma (1.5 μg/liter; range, 1.1–1.6) or with LCH (2.8 μg/liter; range, 1.9–3.2, p = 0.00007). The median peak GH response after GHRH + ARG is significantly lower in the overall patient population (8.3 μg/liter; range, 4.4–28.4) than in age-matched controls (49.8 μg/liter; range, 39.9–81.6, p < 0.00001). The median peak GH response is significantly lower in craniopharyngioma patients (4.6 μg/liter; range, 3.6–6.3) than in those with LCH (8.9 μg/liter; range, 4.4–28.4) or with idiopathic pituitary stalk thickness (12.6 μg/liter, range, 6.4–24, p = 0.07). Some affected patients may have a GH response of more than 20 μg/liter after GHRH + ARG. There is often a trend toward a decrease in peak GH response to GHRH + ARG (r = −0.57, p = 0.06) as patient age increases. For cutoff values of 20 μg/liter, the sensitivity of GHRH + ARG is approximately 75% (95% CI, 57.8–87.9%) and the specificity 96.4% (95% CI, 89.9–99.2%); whereas, for cutoff values of 24.2 μg/liter, sensitivity is 86.1% (95% CI, 70.5–95.3%), and specificity 95.2% (95% CI, 88.2–98.7%). The median insulin-like growth factor-I (IGF-I) level does not differ between children with idiopathic pituitary stalk thickness (57 μg/liter; range, 46–68), and those with either LCH (55 μg/liter; range, 34–63), or craniopharyngioma (41 μg/liter; range, 39–49).

Interpretation the clinical findings confirmed the diagnostic potential of the GHRH + ARG test in children with acquired GHD caused by hypothalamic-pituitary lesion. It stimulates GH secretion to a greater extent in those patients with GHD with primary involvement of the hypothalamic area, for example, patients with idiopathic pituitary stalk thickness or LCH, than in those with both hypothalamic and pituitary lesion, as in craniopharyngioma. In some patients, the GHRH + ARG test stimulates GH response to a so-called normal value, suggesting that pituitary responsiveness to GHRH + ARG may fail to recognize acquired GHD. Finally, the number of pituitary hormone deficits and the patient's age affect the GH response to GHRH + ARG.

GHRH + arginine in the diagnosis of acquired GH deficiency of childhood-onset. Maghnie M, Cavigioli F, Tinelli C, Autelli M, Aricò M, Aimaretti G, Ghigo E. J Clin Endocrinol Metab 2002 Jun; 87 (6), pp. 2740–4.

Growth Hormone Deficiency (GHD): Radiation Injury/Somatotropic Axis Function
Arginine/Insulin

Background Information: Growth hormone provocative tests remain the mainstay for the diagnosis of GHD, with the insulin tolerance test (ITT) serving as the gold standard methodology for a number of years. There are, however, a variety of other stimulation tests used in clinical practice. Each necessitates the use of a specific cutoff derived from normative data, but there remains a widely held view that the implications from a "failed" test are independent of the nature of the stimulus.

Application: Assessment of GH production in conditions of suspected injury/damage to the somototropic axis (e.g., radiation exposure).

Implementation: Evaluation of the integrity of the somatostatin axis by assessing plasma somatostatin responses following arginine and insulin administration. Non-acromegalic patients can be identified following the completion of an arginine stimulation test (AST) and an ITT within a 3-month period.

Human Model: Non-acromegalic cases (n = 161). Groups are divided into those tested before (n = 81; n = 48 males) and those tested after (n = 80; 36 males) completion of growth and puberty. Case selection for inclusion is based on a history of cranial irradia-

tion and a GH response to 1 provocative test of < 8 μg/L (suggesting some damage to the GH axis). Reference controls can consist of cases of normal adults (n = 35 adults; n = 18 males) and prepubertal children (n = 16, n = 10 males).

Interpretation and Analysis: The median peak (range) GH response to an ITT is significantly greater ($p < 0.0001$) than that to the AST in adult controls: 24.9 (4.1–76.9) vs 12.2 (0.88–35.0) μg/L, respectively. However, in patients the GH responses are similar ($p = 0.28$): 2.2 (0.2–25.7) vs 1.4 (0.2–12.8) μg/L to the ITT and AST, respectively. In contrast to the pattern seen in the adult controls, responses to an ITT in childhood controls are of a similar magnitude ($p = 0.5$) to AST: 17.5 (8.1–40.0) vs 19.4 (7.3–53.8) μg/L, respectively. However, in patients, the GH response to AST is greater than that to the ITT ($p < 0.0001$): 4.3 (0.7–17.2) vs 3.0 (0.4–18.1) μg/L, respectively. Therefore, the impact of irradiation on GH responsiveness to provocative agents is stimulus dependent. The GH response to an AST appears to be more resistant to the effects of irradiation than to the ITT. When investigating the impact of irradiation on GH secretory status, the GH response to an AST may be a less sensitive guide to the functional ability of the GH axis.

The impact of irradiation on growth hormone responsiveness to provocative agents is stimulus dependent: Results in 161 individuals with radiation damage to the somatotropic axis. Lissett CA, Saleem S, Rahim A, Brennan BM, Shalet SM. J Clin Endocrinol Metab 2001 Feb; 86 (2), pp. 663–8.

Growth Hormone Deficiency (GHD): Spontaneous Hyperadrenocorticism/Mitotane (o,p'DDD) Therapeutic Response
Xylazine

Cellular/Molecular Mechanism of Action: Xylazine is an α-adrenergic agonist (clonidine is a structural analog) that promotes the release of growth hormone (GH) through elevated secretion or liberation of growth hormone-releasing factor (GHRF).

Diagnostic Application: Diagnosis of acromeglia and pituitary dwarfism that fail to display elevations in growth hormone following xylazine administration (e.g. hyperadrenal corticism).

Route of Administration and Dosage: Intramuscular administration at a dosage of 100 to 300 μg/kg. Alternatively human growth hormone-releasing factor (hGHRF) can be administered at a dosage of 1 to 5 μg/kg.

Considerations: Xylazine can cause bradycardia and profound hypotension. Atropine can be administered to prevent or correct the induction of bradycardia. Antagonists such as phentolamine and yohimbine (α-adrenergic antagonists) can be applied to reverse hypotensive sequela.

Implementation: Evaluation of plasma growth hormone response to the xylazine provocative agent before and after therapeutic intervention for hyperadrenocorticism. Blood samples (2 ml) are collected at intervals of 15, 30, 45, 60, and 120 minutes into EDTA anticoagulant tubes.

Animal Model: Canine (n = 4 with spontaneous hyperadrenocorticism), before and after therapy.

Interpretation and Analysis: Before treatment of the hyperadrenocorticism, no significant increase in growth hormone concentration can usually be detected following xylazine administration (e.g., n = 0/4). A significant increase in growth hormone concentrations following xylazine administration may be appreciated in conditions of hypophysis (pituitary)-dependent hyperadrenocorticism after treatment with mitotane (e.g., n = 2/3) or following surgical removal of a hyperfunctional adrenal adenoma (e.g., n = 1/1). In instances where impaired growth hormone response may persist, the condition may respond to xylazine after hyperadrenocorticism as been controlled for a longer period of time. Such findings demonstrate that in dogs, as in humans,, the excessive production of endogenous corticosteroids associated with either hypophysis-dependent hyperadrenocorticism or hyperfunctional adrenal tumor can induce suppression of growth hormone release but is reversible following treatment.

Laboratory Instrumentation: Assay of either growth hormone (GH) concentrations by either RIA or ELISA methodologies.

Suppression of growth hormone secretion in spontaneous canine hyperadrenocorticism and its reversal after treatment. Peterson ME, Altszuler N. Am J Vet Res 1981 Nov; 42 (11), pp. 1881–3.

Growth Hormone Deficiency (GHD)
Hexarelin/Arginine

Physiological Mechanism of Action: Growth hormone secretagogue.

Application: Evaluation of GH endocrinology.

Background Information: Due to persistent qualitative abnormalities in GH secretion following treatment and lack of a sensitive marker of GHD in mid-adult life, it is extremely difficult to diagnose GHD in treated acromegalic patients. The diagnosis of GHD in patients with pituitary disease relies on provocative tests of GH reserve. Arginine releases GH by reducing somatostatin inhibition of GH release, whereas GH secretagogues (GHS) affect GH release by direct stimulation of the GHS receptor, though an intact GH-releasing hormone (GHRH) axis is a prerequisite. The peak GH response to insulin-induced hypoglycemia and arginine in acromegalic patients, in whom basal serum GH levels of < 5 mU/l have been achieved, is greatly diminished in those treated by hypothalamo-pituitary irradiation.

Route of Administration: Arginine (intravascular infusion over 30 minutes); hexarelin (intravenous bolus).

Dosage: Arginine (20 g/m^2); hexarelin (1.5 mcg/kg).

Considerations: Increasing total fat mass results in a blunted GH response following subcutaneous hexarelin.

Implementation: Assess the effect of body composition and gender on GH-releasing capacity (hexarelin-induced) in successfully treated acromegalic cases in view of the different putative mechanism of action of hexarelin, in addition to determining if it has any value in the diagnosis of GHD in case subsets of this type. In an example diagnostic protocol, case subjects undergo 20 minutes of blood sampling to provide a 24-hour GH profile. Serum insulin-like growth factor-I (IGF-I) is measured from a sample drawn between 0900 hours and 1000 hours. On a 2nd occasion, arginine is infused and blood samples collected before infusion and at 30-minute intervals thereafter for 180 minutes. At the final visit hexarelin is administered (t = 0) and blood drawn at 15-minute intervals from −30 to +180 minutes.

Human Model: Cases of acromegaly in whom mean serum GH levels below 5 mU/l have been achieved through treatment (n = 19; n = 8 treated by surgery alone [Case Group Type A]; n = 11 receiving primary or postoperative irradiation [Case Group Type B]).

Interpretation and Analysis: The vast majority of Group Type A cases will show an increment in serum GH following hexarelin (DeltaGHHEX) > 20 mU/l, a normal response to arginine, and a mean 24-hour GH > 0.5 mU/l. In Group Type B cases, less than half (e.g., n = 5/11) will achieve a DeltaGHHEX > 20 mU/l, producing a response of < 2 mU/l (e.g., n = 4/11). Approximately 80% of cases with a DeltaGHHEX < 2 mU/l will also demonstrate a mean 24-hour GH of < 0.5 mU/l and serum IGF-I SDS $< +0.5$ (e.g., n = 4/5). The vast majority of Group Type B cases achieving a DeltaGHHEX > 20 mU/l will show an absent or minimal GH response to

arginine (e.g., n = 4/4). Despite loss of the GH response to arginine, the DeltaGHHEX is retained in a proportion of those patients in whom "safe" GH levels have been achieved following irradiation. From the putative mechanisms of action of these provocative agents a plausible explanation would be that the GHRH axis is more resilient than endogenous somatostatin-secreting neurones to radiation-induced damage. Furthermore, GH secretagogues may have a role, in combination with serum IGF-I levels, in the diagnosis of GHD in treated acromegaly.

Note: Total fat mass appears to be a useful predictor of peak GH response even in normal individuals. This indicates that there is a continuum of effect of fat mass on hexarelin-stimulated GH release. Any impact of gender on the GH response to hexarelin is almost certainly indirect and mediated via differences in body composition. This observation will have an impact on the potential diagnostic and therapeutic uses of hexarelin and related GH secretagogues.

The diagnosis of growth hormone deficiency (GHD) in successfully treated acromegalic patients. Murray RD, Peacey SR, Rahim A, Toogood AA, Thorner MO, Shalet SM. Clin Endocrinol (Oxf) 2001 Jan; 54 (1), pp. 37–44.

Growth Hormone Deficiency (GHD)/ Geriatric
Hexarelin

Cellular/Molecular Mechanism of Action: Hexarelin is a GH-releasing peptide (GHRP) hexapeptide that induces the release of GH.

Background Information: Growth hormone release is influenced by several factors including age, gender, physical exercise, nutritional status, sex steroids, and body composition. The relationship with body composition is complex. Obesity is accompanied by suppression of spontaneous and stimulated GH release. As increasing body fat reduces stimulated GH secretion following a standard provocative test, the potential clinical uses of GHRPs, therapeutically or diagnostically, may be dependent on the relationship between body fat and GHRP-stimulated GH release.

Application: Evaluation of GH production and release.

Route of Administration: Hexarelin (subcutaneous injection).

Dosage: Hexarelin (1.5 μg/kg).

Implementation: Blood samples are collected at −10, 0, 10, 20, 30, 40, 50, 60, 90, 120, 170, and 180 minutes following hexarelin administration.

Human Model: Twenty-one (8 male) healthy elderly subjects with a median (range) age of 68 (60–81) years and BMI of 26 (19–30) kg/m^2.

Interpretation and Analysis: Peak GH responses correlate negatively with fat mass, BMI, percentage body fat, and weight ($r = -0.72$, $p = 0.0001$; $r = -0.56$, $p = 0.009$; $r = -0.63$, $p = 0.002$, and $r = -0.48$, $p = 0.029$, respectively). The area under the curve (AUC) for GH concentrations correlates negatively with fat mass, BMI, and percentage fat mass ($r = -0.58$, $p = 0.006$; $r = -0.51$, $p = 0.019$; and $r = -0.66$, $p = 0.001$, respectively). Using multiple linear regression analyses, fat mass can be found to be the most useful predictor for both peak GH response ($r^2 = 0.61$, $p < 0.0001$) and AUC GH ($r^2 = 0.38$, $p = 0.003$). Gender is not a significant variable. Increasing total fat mass results in a blunted GH response following subcutaneous hexarelin. Total fat mass appears to be a useful predictor of peak GH response even in normal individuals. This indicates that there is a continuum of effect of fat mass on hexarelin-stimulated GH release. Any impact of gender on the GH response to hexarelin is almost certainly indirect and mediated via differences in body composition. This observation will have an impact on the potential diagnostic and therapeutic uses of hexarelin and related GH secretagogues.

Hexarelin enhances the diagnostic value of performing a conventional provocative test for GHD.

Instrumentation: Facilities and instrumentation necessary to perform immunoassay procedures (e.g., RIA or ELISA). Dual-energy X-ray absorptiometry (DEXA) can be used to assess body composition.

The effect of body composition on hexarelin-induced growth hormone release in normal elderly subjects. Rahim A, O'Neill P, Shalet SM. Clin Endocrinol (Oxf) 1998 Nov; 49 (5), pp. 659–64.

Growth Hormone Deficiency (GHD)
GH-Releasing Peptides (GHRPs)/(Hexarelin Alternative)

Cellular/Molecular Mechanism of Action: Growth hormone-releasing peptides and their non-peptidyl mimetics are synthetic molecules that possess marked, dose-related, and reproducible GH-releasing effect even after oral administration. Hexarelin is a GHRP hexapeptide.

Background Information: Clinical investigations imply that GHRPs are a powerful stimulus of GH secretion in pubertal children and young adults only. Alternatively, the age-related variations in the GH response to GHRPs probably limit their reliability for the evaluation of GH-releasable pool in prepubertal children and elderly subjects.

Application: Diagnosis of GHD.

Route of Administration: Hexarelin (IV); hexapeptide GHRH (IV); arginine (IV).

Dosage: Hexarelin (2 μg/kg), and GHRH (1 μg/kg); arginine (0.5 g/kg).

Considerations: The potent stimulatory effect of GHRPs on GH secretion suggests their usefulness as a provocative test for the diagnosis of GHD.

Implementation: Comparison of the GH response to the maximal effective dose of hexarelin with that of GHRH alone and combined with arginine (likely acts via inhibition of hypothalamic somatostatin release).

Interpretation and Analysis: In prepubertal children (n = 6; 4 boys and 2 girls, age 2.6–12.2 years) the GH response to HEX (19.0 ± 4.6 μg/l; 611.5 ± 121.4 μg/l/h) is lower than that to GHRH (27.4 ± 12.7 μg/l; 1209.0 ± 590.9 μg/l/h) but such differences are not statistically significant Both these responses are, in turn, lower ($p < 0.05$) than that to ARG + GHRH (57.9 ± 15.1 μg/l; 2483.6 ± 696.6 μg/l/h). In pubertal children, the GH response to HEX (67.6 ± 12.7 μg/l; 2755.3 ± 547.3 μg/l/h) is higher than that to ARG + GHRH (49.1 ± 8.9 μg/l; 2554.1 ± 356.6 μg/l/h) but this difference does not attain statistical significance; both these responses are, in turn, clearly higher ($p < 0.05$) than that to GHRH alone (23.1 ± 7.9 μg/l; 1004.8 ± 214.3 μg/l/h). In young adults, the GH response to HEX (60.9 ± 8.0 μg/l; 2401.0 ± 376.2 μg/l/h) is similar to ARG + GHRH (68.9 ± 11.7 μg/l; 3035.7 ± 466.6 μg/l/h) and both are clearly higher ($p < 0.001$) than that to GHRH alone (21.6 ± 3.6 μg/l; 790.0 ± 137.0 μg/l/h). In elderly subjects, the GH response to HEX (22.4 ± 4.9; 855.0 ± 199.0 μg/l/h) is higher ($p < 0.01$) than that to GHRH (3.6 ± 0.8 μg/l; 151.8 ± 24.6 μg/l/h) but lower ($p < 0.05$) than to ARG + GHRH (48.1 ± 4.6 μg/l; 1758.2 ± 149.1 μg/l/h).

Instrumentation: Facilities and instrumentation necessary to perform immunoassay procedures (e.g., RIA or ELISA). Dual-energy X-ray absorptiometry (DEXA) can be used to assess body composition.

Hexarelin, a synthetic GH-releasing peptide, is a powerful stimulus of GH secretion in pubertal children and in adults but not in prepubertal children and in elderly subjects. Bellone J, Bartolotta E, Sgattoni C, Aimaretti G, Arvat E, Bellone S, Deghenghi R, Ghigo E. J Endocrinol Invest 1998 Sep; 21 (8), pp. 494–500.

Growth Hormone Deficiency (GHD): (Pituitary Dwarfism): Insulin Resistant Diabetes
Insulin/Glucose

Cellular/Molecular Mechanism of Action: Promotes transport of glucose across cellular membranes into the cytosol.
Diagnostic Application: Pituitary-based (feline) acromegaly.
Route of Administration: Subcutaneous injection.
Dosage: See under interpretation and analysis.
Interpretation and Analysis: Patients (feline) displaying insulin-resistant diabetes mellitus (persistent hyperglycemia) following administration of insulin at a dose $\geq$ 25 U/day should be considered to be possibly suffering from pituitary-based acromegaly. Additional clinical signs that support the diagnosis of acromegaly would include the presence of arthropathy and cardiomyopathy. Acromegaly patients will have excessively high systemic concentrations of GH within the intravascular compartment. Further diagnostic pharmacology strategies can be utilized to verify a diagnosis of acromegaly through the application of a Glucose Suppression Test since glucose suppresses pituitary GH secretion.
Laboratory Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Growth Hormone Deficiency (GHD)/Preadult
Estradiol and Arginine/Clonidine

Route of Administration: Aerosolized E2 estradiol followed by arginine/clonidine-induced GH production.
Interpretation: Estradiol enhances GH-insulin-like growth factor (GH-IGF) induced by arginine/clonidine. Enhances the diagnostic value of an existing provocative test for GHD.

Growth Hormone Deficiency (GHD)
Arginine/Clonidine/Glucagon/Insulin

Physiological Mechanisms of Action:
Clonidine: Central acting α_2-adrenergic agonist.
Glucagon: Recognizes and binds to glucagon receptor complexes.
Insulin: Recognizes and binds to insulin receptor complexes resulting in enhanced intracellular glucose uptake.
Arginine: Arginine functions to potentiate the release of GH in response to growth hormone-releasing hormone (GHRH).
Clonidine: Promotes release of GH through elevated secretion or liberation of growth hormone-releasing factor.
Glucagon: Promotes hyperglycemia and is most extensively regulated by systemic blood glucose concentrations.
Insulin: Promotes hypoglycemia and is most extensively regulated by systemic blood glucose concentrations.
Application: Characterization of GH synthesis/secretion capacity in suspect cases of GHD. The most profound GH release is seen after insulin-induced hypoglycemia. Glucagon appears to be more effective at inducing GH release than arginine. Clonidine at a dose of 100 or 200 μg is no more effective than placebo.
Route of Administration: Insulin (intravenous); arginine (intravenous infusion over 30 minutes); clonidine (oral); glucagon (IM).
Dosage: Insulin (0.2 IU/kg); arginine (20 g/m^2) as an IV infusion over 30 minutes; clonidine (either 100 or 200 μg); glucagon (1 mg).
Considerations: In adults, there is limited information regarding GH responses to provocative stimuli other than insulin-induced hypoglycemia.
Implementation: In comparisons of 4 different growth hormone secretagogues, blood samples are collected from an intravenous catheter for GH concentrations at −30, −15, and 0 minutes (e.g., normal healthy adult males post–overnight fast). Provocative agents are then administered in a randomized manner on different days as indicated (insulin 0.2 IU/kg IV; arginine 20 g/m^2 as an IV infusion over 30 minutes; oral clonidine at either 100 or 200 μg; glucagon 1 mg IM). Additional blood samples are taken at 15-minute intervals for 180 minutes for GH estimation.
Interpretation and Analysis: The median (range) GH peak response that can be appreciated for each diagnostic agent includes insulin 107.7 (28.1–200) mU/l; arginine 22.3 (3.1–72.9) mU/l; glucagon 42 (11.8–200) mU/l; 100 μg clonidine 7.2 ($<$ 1–22.2) mU/l; 200 μg clonidine 8.2 (1.1–88) mU/l, and placebo 2.4 ($<$ 1–30.2) mU/l. Peak GH response to insulin-induced hypoglycemia (ITT) is significantly greater than for any other agent ($p < 0.0001$). The peak GH response to glucagon is significantly greater than for arginine ($p < 0.05$), clonidine at 100 and 200 μg ($p < 0.01$), and placebo ($p < 0.01$). The peak GH response following administration of arginine is significantly greater than for clonidine 100 and 200 μg ($p < 0.05$), and placebo ($p < 0.01$). The peak GH response following clonidine 200 μg is not significantly greater than observed with clonidine 100 μg ($p = 0.38$) or placebo. In 1 clinical investigation, n = 2/18; n = 6/18, and n = 15/18 test cases failed to achieve a peak GH level of $>$ 20 mU/l to glucagon, arginine, and clonidine, respectively. In complete contrast only 1 subject achieved a peak response of $<$ 40 mU/l (28.1 mU/l) to ITT.

The assessment of growth hormone status in normal young adult males using a variety of provocative agents. Rahim A, Toogood AA, Shalet SM. Clin Endocrinol (Oxf) 1996 Nov; 45 (5), pp. 557–62.

Growth Hormone Deficiency (GHD)
Growth Hormone-Releasing Hormone (GHRH)/Growth Hormone-Releasing Peptide (GHRP)-6 (Single 30-Minute Assay)

Application: The GHRH + GHRP-6 test biochemically classifies patients into 3 groups; those with a stimulated GH peak $\geq$ 20 μg/l are considered normal and those with peaks at $\leq$ 10 μg/l as GH deficient.
Route of Administration: Growth hormone-releasing hormone (IV) and GHRP-6 (IV).
Dosage: Growth hormone-releasing hormone (1 μg/kg) and GHRP-6 (1 μg/kg).
Considerations: The diagnosis of GHD in adults is based on the provocative testing of GH secretion. When testing a patient with suspected GHD, clinicians assess the whole secretory curve and select the GH peak as an index of secretory capability. This procedure is time consuming and the determination of GH in several samples is necessary. The combined administration of GHRH + GHRP-6 is an effective test of GH secretion, and it has been unambiguously demonstrated that the elicited GH peak is capable of segregating normal GH secretion subjects from GH-deficient patients on an individual basis.

The GHRH + GHRP-6 test is a convenient, safe, and reliable, provocative test of GH reserve in adults, which can be reduced to a single fixed GH determination 30 minutes after stimulus.

Interpretation and Analysis: A high degree of correlation can be observed between GH values at 30 minutes and GH peaks ($r = 0.994$, $p < 0.0001$). Evaluation of 30-minute values instead of the peak in GH-deficient patients in previous clinical trials results in only 2 out of 146 cases being reclassified from uncertain to a diagnosis of GHD. Thus, better diagnostic classification can be provided for patients. Administration of GHRH (1 μg/kg IV) + GHRP-6 (1 μg/kg IV) reveals that GHRP-6 evokes GH peaks in controls and patients and values do not correlate with GH basal values, making this determination useless for test validation.

Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Single growth hormone (GH) determination is sufficient for the diagnosis of GH-deficiency in adult patients using the growth hormone-releasing hormone plus growth hormone releasing peptide-6 test. Leal A, Lage M, Popovic V, Torres E, Koppeschaar HP, Paramo C, Micic D, Garcia-Mayor RV, Dieguez C, Casanueva FF. Clin Endocrinol (Oxf) 2002 Sep; 57 (3), pp. 377–84.

Growth Hormone Deficiency (GHD)
Ghrelin/Insulin, Growth Hormone-Releasing Hormone [GHRH]/Arginine Alternative

Cellular/Molecular Mechanism of Action: Ghrelin is a 28 amino acid acylated peptide that is a natural ligand of the GH secretagogues (GHS) receptor (GHS-R) that is specific for synthetic GHS and expressed in the hypothalamus and pituitary. In addition to GH stimulation, ghrelin and synthetic GHSs are reported to stimulate the hypothalamo-pituitary-adrenal (HPA) axis (*in vivo*).

Application: Determination of the influence of ghrelin on GH, in addition to prolactin, adenocorticotropic hormone (ACTH), and cortisol levels in adult cases of isolated severe GHD.

Route of Administration: Systemic intravenous or intracerebroventricular (ghrelin), and intravenous routes of application (ghrelin, insulin, GHRH, arginine).

Dosage: Ghrelin (1 μg/kg), insulin-induced hypoglycemia (ITT, 0.1 IU regular insulin); GHRH (1 μg/kg) + arginine (ARG, 0.5 g/kg). Dosages described in other reports report the administration of ghrelin in an amount between 100 nM and 1,000 nM.

Considerations: Similar to synthetic GHS, ghrelin strongly stimulates GH secretion but also displays significant stimulatory effects on lactotroph and corticotroph secretion. It has been hypothesized that isolated GHD could reflect hypothalamic impairment that would theoretically involve a defect in ghrelin activity. Cases of GHD and normal controls have overlapping prolactin (1 μg/l = 32 mU/l) (10.0 ± 1.4 vs 14.9 ± 2.2 μg/l), ACTH (22.3 ± 5.3 vs 18.7 ± 4.6 pmol/l), and cortisol responses (598.1 ± 52.4 vs 486.9 ± 38.9 nmol/l).

Interpretation and Analysis: Cases assessed for GH response to insulin-induced hypoglycemia (ITT, 0.1 IU regular insulin IV) and GHRH (1 μg/kg IV) + arginine (ARG, 0.5 g/kg IV) reveal that with respect to GH, levels of insulin-like growth factor-I (IGF-I) are markedly lower than in age-matched controls (69.8 ± 11.3 vs 167.9 ± 19.2 μg/l, $p < 0.003$). Ghrelin administration induces significant increases in GH, prolactin (PRL), ACTH, and cortisol levels in the vast majority of GHD-affected cases. The GH response is usually higher with ghrelin compared to GHRH + ARG, which itself is higher ($p < 0.05$) than observed with insulin (9.2 ± 4.1 vs 5.3 ± 1.7 vs 1.4 ± 0.4 μg/l). Given this consideration, GH responses (1 μg/l = 2 mU/l) in GHD are markedly lower ($p < 0.0001$) than those measured in age-matched controls (ghrelin vs GHRH + ARG vs insulin 92.1 ± 16.7 vs 65.3 ± 8.9 vs 17.7 ± 3.5 μg/l). Furthermore, cases of GHD display the highest individual GH peaks in response to ghrelin but are markedly lower than the lowest peak GH response in age-matched controls (28.5 vs 42.9 μg/l).

The findings noted in some preliminary investigations collectively suggest that ghrelin is 1 of the most powerful provocative stimuli of GH secretion, even in those patients with isolated severe GHD. In this condition, however, the somatotroph response is markedly reduced while the lactotroph and corticotroph responsiveness to ghrelin is fully preserved, indicating that this endocrine activity is fully independent of mechanisms underlying the GH-releasing effect. These results do not support the hypothesis that ghrelin deficiency is a major cause of isolated GHD but suggest that ghrelin might represent a reliable provocative test to evaluate the maximal GH secretory capacity provided that appropriate cutoff limits are assumed.

Ghrelin (100 and 1,000 nM) stimulates significant release of GHRH from hypothalamic explants (100 nM: 39.4 ± 8.3 vs basal 18.3 ± 3.5 fmol/explant, $n = 49$, $p < 0.05$) but does not affect either basal or 28 mM KCl-stimulated somatostatin release. Ghrelin (10, 100, and 1,000 nM) stimulates the release of both corticotropin-releasing hormone (CRH) (100 nM: 6.0 ± 0.8 vs basal 4.2 ± 0.5 pmol/explant, $n = 49$, $p < 0.05$) and arginine vasopressin (AVP) (100 nM: 49.2 ± 5.9 vs basal 35.0 ± 3.3 fmol/explant, $n = 48$, $p < 0.05$), while ghrelin (100 and 1,000 nM) also stimulates the release of neuropeptide Y (NPY) (100 nM: 111.4 ± 25.0 vs basal 54.4 ± 9.0 fmol/explant, $n = 26$, $p < 0.05$) from hypothalamic explants (*in vitro*). The HPA axis is stimulated (*in vivo*) following acute intracerebroventricular administration of ghrelin 2 nmol (ACTH 38.2 ± 3.9 vs saline 18.2 ± 2.0 pg/ml, $p < 0.01$; corticosterone 310.1 ± 32.8 ng/ml vs saline 167.4 ± 40.7 ng/ml, $p < 0.05$), but not following intraperitoneal administration of ghrelin 30 nmol. Such findings suggest a hypothalamic site of action and imply that the mechanisms of GH and ACTH regulation by ghrelin may include hypothalamic release of GHRH, CRH, AVP, and NPY.

Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Endocrine responses to ghrelin in adult patients with isolated childhood-onset growth hormone deficiency. Aimaretti G, Baffoni C, Broglio F, Janssen JA, Corneli G, Deghenghi R, van der Lely AJ, Ghigo E, Arvat E. Clin Endocrinol (Oxf) 2002 Jun; 56 (6), pp. 765–71.

Growth Hormone Deficiency (GHD)
Growth Hormone-Releasing Hormone (GHRH)/ Arginine (ARG)

Cellular/Molecular Mechanism of Action: Growth hormone-releasing hormone promotes the release/synthesis of growth hormone. The influence of GHRH on GH release/synthesis is potentiated by arginine.

Considerations: The relationship between the hypothalamus-pituitary morphology and the somatotroph responsiveness to maximal provocative tests exploring the GH releasable pool is still unclear. In has been shown in some preliminary investigations that the partial integrity of the hypothalamic pituitary connections is essential for GHRH + arginine to express its GH-releasing activity. Investigations have also shown that this provocative test is able to stimulate GH secretion to a greater extent in those patients with GHD, but with a residual vascular component of the pituitary stalk. This test is reliable in the diagnosis of congenital hypopituitarism in both children and adults when associated with complete pituitary stalk agenesis and MPHD. In younger children with congenital GHD but less severe impairment of the pituitary stalk the GH response to GHRH + ARG may be within the normal range; deterioration of

pituitary GH reserve with a GH response of < 10 μg/L after 20 years of age makes this test very sensitive in the diagnosis of adult GHD.

Interpretation and Analysis: In studies comparing the GH-releasing effect of GHRH + ARG in cases of congenital GHD relative to their pituitary magnetic resonance imaging findings for the anterior pituitary hypoplasia, stalk agenesis (neural and or vascular component), and posterior pituitary ectopia. In children, the median peak GH response to GHRH + ARG (7.6 μg/L; range, 2.4–40.2 μg/L) is significantly higher than that in the adults (1.8 μg/L; range, 0.8–37.4 μg/L; p = 0.0039), and is also significantly higher in the isolated GHD patients (18 μg/L; range, 3.3–40.2 μg/L) than in those with MPHD (1.9 μg/L; range, 0.8–7.6 μg/L; p = 0.00004). In the patients with residual vascular component of the pituitary stalk the median peak GH response to GHRH + ARG (19.1 μg/L; range, 1.6–40.2 μg/L) is significantly higher than that found in cases with complete pituitary stalk agenesis (2.2 μg/L; range, 0.8–8.8 μg/L; p = 0.00005).

A tendency is often noticed toward a decrease with age in peak GH response to GHRH + ARG: Mean serum insulin-like growth factor I (IGF-I) levels are 36 ± 7.1 μg/L in children and 63.5 ± 22.6 μg/L in adults (p = 0.0001). The mean IGF-I levels do not differ between the children with (35.7 ± 4.8 μg/L) and those without (36.3 ± 8.7 μg/L) the pituitary stalk, but are much higher in the adults with residual vascular pituitary stalk (81.1 ± 17.7 μg/L) than in those with complete pituitary stalk agenesis (47.7 ± 12.5 μg/L; p = 0.0002). An IGF-I level of 36.1 ± 6.7 μg/L in the isolated GHD children and 36 ± 8.6 μg/L in those with MPHD has been reported with levels of 82.1 ± 19.4 and 52.7 ± 16.8 μg/L, respectively, described for adults (p = 0.003).

Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Relationship between the morphological evaluation of the pituitary and the growth hormone (GH) response to GH-releasing hormone plus arginine in children and adults with congenital hypopituitarism. Maghnie M, Salati B, Bianchi S, Rallo M, Tinelli C, Autelli M, Aimaretti G, Ghigo E. J Clin Endocrinol Metab 2001 Apr; 86 (4), pp. 1574–9.

Growth Hormone Deficiency (GHD)
Estradiol (E2)

Application: Determine the influence of estradiol on GH-insulin-like growth factor (GH-IGF) axis in prepubertal GHD and idiopathic short-stature children.

Dosage: Micronized estradiol E2 (1 or 2 mg) for 3 days followed by a sequential arginine-clonidine test.

Considerations: The growth hormone stimulation tests after E2 priming had the highest diagnostic efficiency. Our findings suggest that the effect of estrogen priming on GH stimulated levels, by reducing the number of false nonresponders, might be useful to better discriminate between normal and abnormal GH status in short-stature children.

Interpretation and Analysis: In short-stature children, GH maximal responses are approximately 27.9 ± 14.5 μg/L with estrogen (17.8 ± 10.9 placebo: p < 0.0001). The lower 95% confidence limits for GH maximal response shifts from 3.7 μg/L (without E2) to 8.3 μg/L (on E2). In GHD children, no significant stimulatory effect of estrogen on GH levels can be appreciated. After placebo, a cutoff limit of 3.7 μg/L (the lower 95% confidence interval limit) results in 73% sensitivity, 95% specificity, and an overall 90% diagnostic efficiency. After E2, a cutoff limit of 8.3 μg/L results in a sensitivity of 87%, a specificity of 98%, and a diagnostic efficiency of 95%. After placebo, short-stature children (68%) show normal IGF-I levels, and the mean does not change on E2 (13.7 ± 6.3 vs 14.3 ± 6.8 nmol/L, not significant). In almost all short stature children (93%) IGF binding protein (IGFBP)-3 levels are normal with placebo evaluation. Estradiol E2 produces mean IGFBP-3 that does not change significantly (2.63 ± 0.70 vs 2.70 ± 0.70 mg/L). In the vast majority of GHD cases (14/15), IGF-I values are below normal with placebo, and the group mean does not change after E2 administration. During placebo, most growth hormone deficient children (e.g., n = 13/15) GHD present with low IGFBP-3 values. Estradiol produces a small significant increase IGFBP-3 values (1.06 ± 0.58 vs 1.20 ± 0.69 mg/L, p < 0.02). The highest diagnostic efficiencies for IGF-I and IGFBP-3 that can be expected to be observed with placebo are approximately 75% and 91%, respectively.

Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Estrogen priming effect on growth hormone (GH) provocative test: A useful tool for the diagnosis of GH deficiency. Martínez AS, Domené HM, Ropelato MG, Jasper HG, Pennisi PA, Escobar ME, Heinrich JJ. J Clin Endocrinol Metab 2000 Nov; 85 (11), pp. 4168–72.

Growth Hormone Deficiency (GHD)
Growth Hormone-Releasing Hormone (GHRH) and Arginine/Insulin-Induced Hypoglycemia (ITT) Alternative

Cellular/Molecular Mechanism of Action: Growth hormone-releasing hormone and arginine promote the release of pituitary growth hormone. Arginine functions to potentiate the release of GH in response to GHRH.

Application: Detection of GHD.

Route of Administration: Growth hormone-releasing hormone (IV) and arginine (IV).

Dosage: Growth hormone-releasing hormone (1 μg/kg) and arginine (0.5 g/kg).

Considerations: Patients with childhood-onset GHD need retesting in late adolescence or young adulthood to verify whether they have to continue recombinant human GH treatment. Provocative testing with GHRH + arginine (GHRH + ARG) is the most reliable alternative to the insulin-induced hypoglycemia test (ITT) for the diagnosis of GHD in adulthood, provided that appropriate cutoff limits are assumed (normal limits, 16.5 μg/L as 3rd and 9.0 μg/L as 1st centile).

In conclusion, given appropriate cutoff limits, GHRH + ARG is as reliable as ITT for retesting patients who have undergone GH treatment in childhood. Among these patients, severe GHD in adulthood is generally confirmed in organic hypopituitarism with GHD (oGHD), is frequent in idiopathic isolated GHD (iGHD), but never occurs in GH neurosecretory dysfunction (GHNSD).

Interpretation and Analysis: The GH response to a single GHRH (1 μg/kg iv) + ARG (0.5 g/kg iv) test has been described in young patients that have received GH replacement in childhood, based on the following diagnosis: (i) oGHD with GH peak < 10 μg/L after 2 classical tests; (ii) iGHD: GH peak < 10 μg/L after 2 classical tests; and (iii) GHNSD: GH peak > 10 μg/L after classical test but mGHc < 3 μg/L. Responses in GH synthesis/release in these groups following GHRH + ARG administration reveal insulin-like growth factor I levels in oGHD subjects (61.5 ± 13.7 μg/L) that are lower (p < 0.001) than those in iGHD subjects (117.2 ± 13.1 μg/L); with the latter being lower than those in GHNSD subjects (210.2 ± 12.9 μg/L), which, in turn, are analogous to those in age-matched reference controls (220.9 ± 7.1 μg/L). The mean GH peak after GHRH + ARG in oGHD (2.8 ± 0.8 μg/L) is lower (p < 0.001) than that in

iGHD (18.6 ± 4.7 μg/L), which, in turn is markedly lower ($p < 0.001$) than that in GHNSD (31.3 ± 1.6 μg/L). The GH response in GHNSD is lower than that in age-matched controls (65.9 ± 5.5 μg/L), but this difference does not attain statistical significance. Regarding the 3rd centile limit of GH response in young adults (i.e., 16.5 μg/L), retesting confirms GHD in all oGHD, in 65.2% of iGHD, and in none of the GHNSD subjects. In the 1st centile limit of GH response (i.e., 9.0 μg/L), retesting reveals severe GHD in oGHD (94%) and iGHD (52.1%). All oGHD and iGHD with a GH peak after GHRH + ARG that are lower than 9 μg/L also have GH peaks lower than after ITT (3 μg/L). In cases that have GHD confirmed by retesting, the mean GH peak after GHRH + ARG is higher than values observed after ITT (3.4 ± 0.5 vs 1.9 ± 0.4).

Instrumentation: Laboratory facilities and instrumentation necessary for performing immunoassay procedures (RIA or ELISA).

Retesting young adults with childhood-onset growth hormone (GH) deficiency with GH-releasing-hormone-plus-arginine test. Aimaretti G, Baffoni C, Bellone S, Di Vito L, Corneli G, Arvat E, Benso L, Camanni F, Ghigo E. J Clin Endocrinol Metab 2000 Oct; 85 (10), pp. 3693–9.

Growth Hormone Deficiency (GHD)/ Childhood

Acipimox/Arginine/Growth Hormone-Releasing Hormone (GHRH)/Arginine (ARG)/GHRH

Cellular/Molecular Mechanism of Action: Growth hormone-releasing hormone/arginine induces the release of GH. Acipimox reduces plasma free fatty acids in a manner that enhances GH response after stimulation by GHRH.

Background Information: The hormonal diagnosis of GHD in childhood is conventionally based on the GH response to at least 2 provocative stimuli. Among these, arginine has long been considered a classical, centrally mediated stimulus of GH secretion. Arginine is also able to potentiate the GH response to GHRH, likely inhibiting hypothalamic somatostatin; this combined test is 1 of the most potent to explore the maximal secretory capacity of somatotroph cells.

Application: Diagnosis of childhood GHD (48 normal short children; 35 M and 13 F, 12.0 ± 0.4 years, PS 1: 255 II-IV: 23). Testing with the sequential administration of arginine and ARG + GHRH may allow the single-step evaluation of the somatotroph response to central and pituitary stimuli in short children.

The acipimox/GHRH test is a potential additional tool to detect GHD in patients with pituitary disease, in particular in cases with a perturbation of fatty acid metabolism. The acipimox/GHRH test leads to GH responses similar to those of the GHRH/arginine test, and to higher peak GH values if compared with the insulin tolerance test (ITT) when applied in patients displaying such types of physiological abnormalities.

Route of Administration: Arginine (IV), GHRH (IV).

Dosage: Arginine (0–+30 minutes) followed by a co-administration of arginine (from +120 to 150 minutes) plus GHRH (1 μg/kg at +120 minutes).

Considerations: Reduction of plasma free fatty acids leads to enhanced GH response after stimulation by GHRH.

Implementation: Evaluate the sequential administration of arginine and ARG + GHRH to determine if it can feasibly serve as a single-step provocative test to evaluate the GH-releasable pool in short children.

Interpretation and Analysis: Arginine alone elicits a clear GH response (mean peak vs baseline: 12.1 ± 1.7 vs 2.0 ± 0.4 μg/l, $p < 0.001$, Cmax range 12–51.0 μg/l). Following this GH rise, the hormonal levels at +120 minutes approach baseline levels (4.2 ± 0.8 μg/l) but then show marked response to the co-administration of ARG + GHRH. The GH peak following ARG + GHRH (mean peak: 47.8 ± 3.3 μg/l, $p < 0.001$; Cmax 22.4–150.0 μg/l) is clearly higher ($p < 0.001$) than that recorded after arginine alone. The GH responses to both arginine and ARG + GHRH are independent of gender, puberty, height velocity, body mass index (BMI), and insulin-like growth factor-I (IGF-I) levels. Some normal short children (e.g., n = 9/56 or 16%) have GH peaks lower than 7 μg/l after arginine alone, while a very low number will show GH peaks below 20 μg/l after ARG + GHRH (e.g., n = 0/56). Thus, arginine alone is a good stimulus of GH secretion but false positive responses frequently occur in normal short children. ARG + GHRH is a more potent stimulus giving no false positive responses even after previous challenge with arginine alone.

In cases after pituitary surgery (mean age 53.0 years; mean BMI 26.7 kg/m^2), comparisons of GH responses after acipimox and GHRH with GH responses during an ITT or a GHRH/arginine test reveal that mean (± SEM) peak GH is almost 4-fold higher after acipimox/GHRH (6.94 ± 1.07 μg/l, range, 0.46–23.1; $p < 0.001$) and after GHRH/arginine (8.32 ± 1.23 μg/l, range, 1.1–49.2; $p < 0.001$) than after ITT (1.84 ± 0.46 μg/l, range, 0.01–11.9). According to results from ITT, affected cases usually are found to be severely GH deficient (peak GH < 3.0 μg/l). Peak GH levels after acipimox/GHRH in controls range from 7.5 to 78.4 μg/l (mean 29.3 ± 3.5). Growth hormone peak values during the acipimox/GHRH test significantly correlate with values from ITT ($r = 0.63$, $p < 0.01$) and GHRH/arginine tests ($r = 0.87$, $p < 0.001$). Areas under the curve (AUC) also correlate. According to generally accepted cutoff peak GH levels for the ITT and GHRH/arginine test, a GH peak exceeding 11.2 μg/l excludes severe GH deficiency after acipimox/GHRH. Therefore the cutoff level is lower at older age. The acipimox/GHRH test leads to GH responses similar to those of the GHRH/arginine test, and to higher peak GH values if compared with the ITT. The acipimox/GHRH test is a potential additional tool to detect GHD in patients with pituitary disease, in particular in patients with a perturbation of fatty acid metabolism.

Diagnosis of growth hormone deficiency after pituitary surgery: The combined acipimox/GH-releasing hormone test. van Dam PS, Dieguez C, Cordido F, de Vries WR, Veldhuyzen BF, van Thiel E, Casanueva FF, Koppeschaar HP. Clin Endocrinol (Oxf) 2003 Feb; 58 (2), pp. 156–62.

Growth Hormone Deficiency (GHD)

Arginine/Insulin-Mediated Hypoglycemia/L-dopa/ Clonidine/Growth Hormone-Releasing Hormone (GHRH)

Cellular/Molecular Mechanism of Action: Arginine, insulin hypoglycemia, L-dopa (dopaminergic) and clonidine (α-adrenergic), and GHRH all promote elevations in serum GH normal control subjects.

Application: Determine the integrity of dopaminergic and α-adrenergic neurotransmitter regulation of GH secretion in children with decreased GH secretion. The spectrum of cases (children) that can be evaluated include those with (i) GH neurosecretory dysfunction (GHND; n = 16); (ii) classical GH deficiency (n = 9); and (iii) short but otherwise normal children (n = 12).

Considerations: Growth hormone deficiency can be defined as children with height in the 1st percentile or below, growth velocity of 4 cm/year or less, low plasma somatomedin-C for age, delayed skeletal age by 2 or more years, peak serum GH responses to any 1 (or more) provocative test of 10 ng/ml or more, and mean 24-hour GH concentration below 3 ng/ml.

Implementation: Detection and evaluation of potential GHD cases. Subjects undergo a 24-hour GH study (blood sampling every

20 minutes for 24 hours) and provocative tests using arginine, insulin hypoglycemia, L-dopa (dopaminergic) and clonidine (a-adrenergic), and GHRH.

Interpretation and Analysis: Growth hormone neurosecretory dysfunction and GH-deficient children have reduced endogenous GH secretion, expressed as mean serum 24-hour GH concentration (1.6 ± 0.1 [± SEM] and 2.1 ± 0.1 vs 6.1 ± 0.5 ng/ml [GH-deficient and GHND vs normal, respectively]; $p < 0.01$). The mean peak serum GH levels after arginine (8.2 ± 2.0 vs 20.8 ± 6.6 ng/ml [GHND vs normal]; $p < 0.05$) and insulin (9.3 ± 1.0 vs 16.2 ± 1.7 ng/ml [GHND vs normal]; $p < 0.01$) are lower in GHND children. The mean peak responses after L-dopa (13.4 ± 3.4 vs 14.6 ± 4.7 ng/ml [GHND vs normal]; p = ns) and clonidine (19.0 ± 2.2 vs 23.3 ± 3.8 ng/ml [GHND vs normal]; p = ns) are preserved in GHND children. In GH-deficient children, mean peak serum GH concentrations after all 4 provocative tests are low (arginine, 2.7 ± 0.8; insulin, 2.6 ± 0.8; L-dopa, 3.0 ± 0.9; clonidine, 3.4 ± 1.0 ng/ml; all $p < 0.01$ vs normal). The mean peak serum GH concentration after GHRH is blunted in GH-deficient children (9.1 ± 1.7 ng/ml) compared to those in GHND (32.9 ± 8.5 ng/ml) and normal (43.2 ± 6.4 ng/ml) children ($p < 0.01$). The area under the GH curve after GHRH stimulation is greater for normal than GHND children ($p < 0.05$). Therefore, dopaminergic and α-adrenergic neurotransmitter pathways are preserved in GHND children. Such findings further suggest a defect in the release of pituitary GH secondary to an abnormality in alternative neurotransmitter pathways resulting in decreased GHRH and/or increased somatostatin secretion.

Preservation of dopaminergic and α-adrenergic function in children with growth hormone neurosecretory dysfunction. Bercu BB, Root AW, Shulman DI. J Clin Endocrinol Metab 1986 Oct; 63 (4), pp. 968–73.

Growth Hormone Deficiency (GHD): Adult Onset
GHRH and Arginine/L-dopa and Arginine/Arginine/L-dopa/Insulin (Insulin Tolerance Test [ITT])

Application: Characterization of adult-onset GHD accompanied either (i) with multiple pituitary hormone deficiencies; or (ii) with no more than 1 additional hormone abnormality.

Route of Administration: Arginine test (intravenous); GHRH (intravenous bolus at 0 minutes).

Dosage: Arginine test (0.5 g/kg from 0 to +30 min, up to a maximum of 30 g); GHRH (1 μg/kg at 0 minutes). The protocol for these tests generally includes measurement of GH in blood samples collected every 15 minutes from baseline up to 90 to 120 minutes.

Implementation: Evaluation of the primary end point (peak serum GH responses) to 5 GH stimulation tests administered in random order at 5 separate visits: ITT, arginine (ARG), levodopa (L-dopa), ARG + L-dopa, and ARG + GHRH. Serum IGF-I concentrations can be measured on 2 separate occasions. Three diagnostic cut-points are calculated for each test to provide optimal separation of multiple pituitary hormone deficient and control subjects according to 3 criteria: (i) to minimize misclassification of control subjects and deficient patients (balance between high sensitivity and high specificity); (ii) to provide 95% sensitivity for GHD; and (iii) to provide 95% specificity for GHD.

Human Model: Cases with adult-onset hypothalamic-pituitary disease and multiple pituitary hormone deficiencies studied in comparison with age, sex, and estrogen status (n = 39; n = 26 male, n = 13 female; n = 34 body mass index–matched controls n = 20/34 male, n = 14 female). A 3rd group of patients (n = 21) with adult-onset hypothalamic-pituitary disease have no more than 1 additional pituitary hormone deficiency. For purposes of analysis, cases with multiple pituitary hormone deficiencies are assumed to be GH deficient.

Interpretation and Analysis: The greatest diagnostic accuracy ($p = 0.001$) occurs with the ITT and the ARG + GHRH test (patients prefer the latter). Using peak serum GH cut-points of 5.1 μg/liter for the ITT and 4.1 μg/liter for the ARG + GHRH test, high sensitivity (96 and 95%, respectively) and specificity (92 and 91%, respectively) for GHD have been achieved. To obtain 95% specificity, the peak serum GH cut-points can be lowered to 3.3 μg/liter and 1.5 μg/liter for the ITT and ARG + GHRH test, respectively. There is substantial overlap between patients and control subjects for the ARG + L-dopa, ARG, and L-dopa tests, but test-specific cut-points can be defined for all 3 tests to provide 95% sensitivity for GHD (peak GH cut-points: 1.5, 1.4, and 0.64 μg/liter, respectively). However, 95% specificity can be achieved with the ARG + L-dopa and ARG tests only with very low peak GH cut-points (0.25 and 0.21 μg/liter, respectively) and not at all with the L-dopa test. Although serum IGF-I levels provide less diagnostic discrimination than all 5 GH stimulation tests, a value below 77.2 μg/liter is 95% specific for GHD. In conclusion, the diagnosis of adult GHD can be made without performing an ITT, provided that test-specific cut-points are used. The ARG + GHRH test represents an excellent alternative to the ITT for the diagnosis of GHD in adults. Either in children or in adults, arginine alone and combined with GHRH (GHRH + ARG) are reliable tests for the diagnosis of GHD.

After arginine alone, taking into account data from +15 to +105 minutes, GH values above the 3rd centile limit of arbitrary cutoff (7 or 10 μg/l in C and 5 μg/l in A) occur in 85% or 64% and 94% of the subjects (11.3 ± 0.4 years vs 30.0 ± 0.6 years, respectively). After GHRH + ARG tests, taking into account only data at +30, +45, +60 minutes GH values above the 3rd centile limit (20 μg/l in Group C and 16.5 μg/l in Group A) occurred in 99% of subjects in both groups. Taking into account only these 3 timing points, the percentage of GH peak above the 3rd centile limits after arginine alone is never higher than 60% in Group C and 85% in Group A. Therefore, the single GHRH + ARG test can be reliably performed in a shortened, easier, and cheaper procedure for clinical practice.

Sensitivity and specificity of six tests for the diagnosis of adult GH deficiency. Biller BM, Samuels MH, Zagar A, Cook DM, Arafah BM, Bonert V, Stavrou S, Kleinberg DL, Chipman JJ, Hartman ML. J Clin Endocrinol Metab 2002 May; 87 (5), pp. 2067–79.

Growth Hormone Deficiency (GHD)
Arginine/Growth Hormone-Releasing Hormone (GHRH)

Cellular/Molecular Mechanism of Action: Induces the release of GH.

Application: Either in children or in adults, arginine (ARG) alone and combined with GHRH (GHRH + ARG) are reliable tests for the diagnosis of GHD.

Route of Administration: Arginine (intravenous) and/or GHRH (intravenous bolus).

Dosage: Arginine (0.5 g/kg from 0 to +30 min, up to a maximum of 30 g) and/or GHRH (1 μg/kg bolus at 0 minutes).

Implementation: The procedures for the arginine and the combined arginine/GHRH (GHRH + ARG) tests generally include GH measurement every 15 minutes from baseline up to 90 to 120 minutes.

Human Model: Children (case groups defined as growing children and adolescents (n = 117 M and n = 56 F, age: 11.3 ± 0.4 years), while adult case groups are represented by young and middle-aged normal adults (A, n = 68 M and n = 57 F, age: 30.0 ± 0.6 years).

Interpretation and Analysis: Following arginine alone (taking into account data from +15 to +105 minutes), GH values above the 3rd centile limit of arbitrary cutoff (children = 7 or 10 μg/l, and adult = 5 μg/l) occur in 85% or 64% and 94% of subjects, respectively. After the GHRH + ARG test (taking into account only data at +30, +45, and +60 minutes), GH values above the 3rd centile limit (children = 20 μg/l, and adult = 16.5 μg/l) occur in 99% of subjects in both groups. Taking into account only these 3 timing points, the percentage of GH peak above the 3rd centile limits after ARG alone is never higher than 60% in children and 85% in adults. Therefore, a single GHRH + ARG test can be reliably performed in a shortened procedure, which makes clinical practice easier and further reduces costs.

Growth hormone deficiency in the transition adolescent: Should treatment be continued in adult life? Aimaretti G, Corneli G, Bellone S, Baffoni C, Camanni F, Ghigo E. J Pediatr Endocrinol Metab 2001; 14 Suppl 5, pp. 1233–42; discussion 1261–2.

Growth Hormone Deficiency (GHD) (Adult)
Arginine (ARG)/Hexarelin (HEX)/Growth Hormone-Releasing Hormone (GHRH)/GHRH + ARG vs GHRH + HEX

Application: Validation of the reliability of hexarelin and GHRH for the diagnosis of adult GHD.

Background Information: Growth hormone deficiency in adults must be shown by provocative testing of GH secretion. Insulin-induced hypoglycemia (ITT) is the test of choice, and severe GHD, treated with recombinant human GH replacement, is defined by a GH peak response to ITT of < 3 μg/L. GHRH + ARG is a more provocative test and is as sensitive as ITT provided that appropriate cutoff limits are assumed. GH secretagogues are a family of peptidyl and nonpeptidyl GH-releasing molecules that strongly stimulate GH secretion and, even at low doses, truly synergize with GHRH.

Route of Administration: Hexarelin (IV) and GHRH (IV).

Dosage: Hexarelin (0.25 μg/kg) and GHRH (1 μg/kg).

Considerations: Previous investigations have generated laboratory results that have defined the normal limits for GH responses to stimulation with low-dose HEX + GHRH in normal adults. Observations noted in these clinical trials reveal that the test is as sensitive as ITT for the diagnosis of adult GHD provided that appropriate cutoff limits are considered.

Implementation: Evaluation of GH response to GHRH + HEX administration, and comparison between GHRH + HEX, the ITT test with insulin, and GHRH + ARG normal controls and in conditions of suspected GHD and hypopituitaric adults.

Human Model #1: Cases without any known disease abnormalities (n = 25; 18 men and 7 women; age, 28.5 ± 0.6 years; n = 11 subjected to 2nd verification provocative test).

Human Model #2: Cases without any known disease abnormality (n = 33; 12 men and 21 women; age, 34.1 ± 1.5 years) and hypopituitaric adults with GHD (n = 19; 10 men and 9 women; age, 39.9 ± 2.2 years; GH peak < 5 μg/L after ITT).

Human Model #3: Cases with GHD (n = 19) and normal subjects (n = 77; n = 40 men; n = 37 women; age, 28.1± 0.6 years).

Interpretation and Analysis: The mean GH peak after GHRH + HEX in normal subjects (NS) is 83.6 ± 4.5 μg/L; the 3rd and 1st percentile limits of the normal GH response are 55.5 and 51.2 μg/L, respectively. The GH response to GHRH + HEX in NS shows good intraindividual reproducibility. In GHD the mean GH peak after GHRH + HEX (2.6 ± 0.7 μg/L) is similar to that after GHRH + ARG (3.6 ± 1.0 μg/L), and both are higher ($p < 0.001$) than that after ITT (0.6 ± 0.1 μg/L); the GH responses to GHRH + HEX are positively associated with those to ITT and GHRH + ARG. Analyzing individual GH responses, approximately 100% have severe GHD after ITT (GH peak, < 3 μg/L). After GHRH + HEX all GHD have GH peaks below the 3rd percentile limit of normality appropriate for this test (i.e., 55.5 μg/L). Approximately 68.4% (n = 13/19) of GHD cases have GH peaks below 3 μg/L after GHRH + HEX but the vast majority (e.g., n = 19/19 or 100%) have GH peaks below the 1st percentile limit of normality (i.e., 51.2 μg/L). The GH responses to GHRH + HEX are highly concordant with those after GHRH + ARG.

Low-dose hexarelin and growth hormone (GH)-releasing hormone as a diagnostic tool for the diagnosis of GH deficiency in adults: Comparison with insulin-induced hypoglycemia test. Gasperi M, Aimaretti G, Scarcello G, Corneli G, Cosci C, Arvat E, Martino E, Ghigo E. J Clin Endocrinol Metab 1999 Aug; 84 (8), pp. 2633–7.

Growth Hormone Deficiency (GHD) (Adult and Elderly)
Arginine/Growth Hormone-Releasing Hormone (GHRH)/Pyridostigmine/GHRH/Insulin Tolerance Test Alternatives

Cellular/Molecular Mechanism of Action: Promotes the release of GHRH.

Background Information: Presently, there is no therapeutic approach that can function as an alternative to recombinant human growth hormone (rhGH) for adult and elderly patients with GHD and/or for the somatopause. Growth hormone-releasing substances need the functional integrity of somatotroph cells to induce the release of GH. Probably only patients with childhood-onset, isolated GHD (frequently hypothalamic-dependent) could benefit from treatment with GHRH or GH secretagogues (GHS). Whenever restoration of the activity of the GH/insulin-like growth factor-I (IGF-I) axis in the elderly would be of use, GHRH and/or GHSs would be good candidates. In fact, the existence of a considerable pool of releasable growth hormones has been demonstrated in the elderly.

Application: Detection and evaluation of GH endocrinology (e.g., deficiency and overproduction).

Implementation: Determine if there are any alternative provocative tests equal to, or even better than, the insulin tolerance test (ITT), the so-called gold standard, for the diagnosis of GHD in adults and the elderly.

Interpretation and Analysis: Growth hormone-releasing hormone, when combined with arginine or pyridostigmine, becomes 1 of the most potent and reproducible tests for distinguishing patients with severe GHD from normal subjects. Owing to its tolerability and its suitability for use in the elderly, the GHRH + arginine test is the best alternative choice and is at least as sensitive as the ITT provided that appropriate cutoff limits are given.

Diagnostic and therapeutic uses of growth hormone-releasing substances in adult and elderly subjects. Ghigo E, Arvat E, Aimaretti G, Broglio F, Giordano R, Camanni F. Baillieres Clin Endocrinol Metab 1998 Jul; 12 (2), pp. 341–58.

Growth Hormone Deficiency (GHD)
Pyridostigmine and Growth Hormone-Releasing Hormone (GHRH)

Cellular/Molecular Mechanism of Action: Pyridostigmine (acetylcholinesterase inhibitor) potentiates the GH response to GHRH involving inhibition of somatostatin release.

Application: Assess the combination of pyridostigmine (PD) and GHRH as a reliable test probing pituitary somatotropic function.
Background Information: Diagnosis of GHD is currently based on failure to increase plasma GH levels to an arbitrary cutoff point of 7 or 10 μg/l in response to 2 provocative stimuli. False negative responses to these tests, however, frequently occur, thus reducing their diagnostic reliability.
Route of Administration: Pyridostigmine (PO) and GHRH (IV).
Dosage: Pyridostigmine (60 mg oral PD 60 minutes before GHRH) and GHRH (1 μg/kg).
Implementation: Evaluation of the combination PD + GHRH as a test for GHD. Results obtained by PD + GHRH are compared with those obtained by testing with GHRH, clonidine (CLON), and PD alone and by studying spontaneous nocturnal GH secretion over 8 hours.

Human Model: Cases of normal health (n = 27 children and adolescents) and a large group of short children classified as having familial short stature (FSS, n = 24), constitutional growth delay (CGD, n = 34), and GHD (organic, oGHD, n = 6; idiopathic, iGHD, n = 10).
Interpretation and Analysis: Assuming 7 μg/l as minimum normal GH peak, a positive response occurs in only 18/24, 11/12, and 12/13 NS for GHRH, CLON, and PD, respectively. In contrast, even assuming a minimum normal GH peak as high as 20 μg/l, PD + GHRH induces a positive response in 27/27 NS all having a nocturnal GH mean concentration (MC) ≥ 3 μg/l. Therefore PD + GHRH test produces no false negative responses and this is true not only in NS but even in all FSS and CGD having a GH MC ≥ 3 μg/l. On the other hand, PD + GHRH induces a negative GH response in all oGHD and in 8/10 iGHD patients. In the remaining 2 iGHD patients, PD + GHRH demonstrates a normal pituitary GH reserve in spite of a GH MC < 3 μg/l and low insulin-like growth factor-I (IGF-I) level, thus pointing to a hypothalamic pathogenesis for GHD. Considering FSS and CGD children having a GH MC < 3 μg/l, PD + GHRH shows a primary pituitary GH deficiency in 3/12 CGD with low plasma IGF-I levels. Therefore, in slowly growing children PD + GHRH test is the most reliable provocative test for the diagnosis of primary pituitary GHD being capable of discriminating between an unequivocally normal and impaired somatotropic function.

A new test for the diagnosis of growth hormone deficiency due to primary pituitary impairment: Combined administration of pyridostigmine and growth hormone-releasing hormone. Ghigo E, Imperiale E, Boffano GM, Mazza E, Bellone J, Arvat E, Procopio M, Goffi S, Barreca A, Chiabotto P, et al. J Endocrinol Invest 1990 Apr; 13 (4), pp. 307–16.

Growth Hormone Deficiency (GHD): Lack of Diagnostic Efficacy
Diazepam

Background Information: Diazepam as a provocative stimulus for hGH secretion has been suggested as a simple, reliable test in clinical hGH assessment of pituitary disorders.
Application: Detection and evaluation of pituitary disorders as a function of plasma hGH and human prolactin (hPRL) levels. Preliminary investigations imply that diazepam is not a suitable diagnostic pharmaceutical for this purpose.
Route of Administration: Intramuscular.
Dosage: Diazepam (10 mg).
Implemenation: Determination of the influence of diazepam on plasma hGH and hPRL concentrations.

Human Model: Cases of normal health (n = 5); and acromegalic subjects (n = 7).
Interpretation and Analysis: No significant variations in hGH and hPRL levels can be observed in any of the studied subjects. These findings indicate that the drug is ineffective on hGH and hPRL release and that it cannot be considered a valid provocative test either in normal or acromegalic subjects. Diazepam is not a viable diagnostic pharmaceutical for the purpose of characterizing cases of acromegaly.

Lack of effect of IM diazepam administration on hGH and hPRL secretion in normal and acromegalic subjects. Zaccaria M, Giordano G, Ragazzi E, Sicolo N, Foresta C, Scandellari C. J Endocrinol Invest 1985 Apr; 8 (2), pp. 167–70.

Growth Hormone Deficiency (GHD)/ Infantile Malnutrition
Growth Hormone-Releasing Hormone (GHRH)

Background Information: Growth hormone kinetics in infantile malnutrition are characterized by high basal values and decreased responses to various provocative stimuli. The mechanism of this alteration has not been explained.
Application: Detection and characterization of infantile malnutrition as a function of GH kinetics.
Route of Administration: Growth hormone-releasing hormone (1–44) NH_2 (IV bolus).
Dosage: Growth hormone-releasing hormone (1–44) NH_2 (1 mcg/kg).
Implementation: Determine if altered sensitivity to GHRH plays a role in alterated GH kinetics in infantile malnutrition. One approach to achieving this objective can involve diagnostic testing of infants with GHRH that suffer from primary malnutrition of grades II and III (evaluation before and again 6 weeks after nutritional rehabilitation).
Interpretation and Analysis: In affected infants (n = 19), mean baseline GH maximum elevation above baseline (delta GH), and area under the GH response curve (sigma GH) are measured. The injections stimulate a rapid rise in GH that reaches a maximum at 15 to 30 minutes after GHRH. There are no significant differences in the magnitude or time course of the responses between infants in the malnourished and recovering states (delta GH 29 ± 7 vs 34 ± 5 ng ml: sigma GH 3379 ± 571 vs 3459 ± 397 ng min/ml, respectively), and responses are similar to those of normal prepubertal children. Altered sensitivity of pituitary to GHRH appears not to underlie the alterations of GH dynamics observed in malnutrition.

Growth Hormone Deficiency (GHD)
L-dopa/Propanolol

Cellular/Molecular Mechanism of Action: Promotes the release of GH.
Application: Evaluation of GH secretion in short children.
Considerations: The low cost of L-dopa and propranolol, the simplicity and safety of the test, and the acceptable rate of low-responders make the test an effective screening test for GHD.
Implementation: Evaluation of hormones related to growth and maturation. The pituitary release mechanism for GH can be assessed using the propanolol/L-dopa stimulation test. In addition, blood levels of testosterone, sex hormone binding globulin, estradiol, thyroxine, prolactin, cortisol, follicle-stimulating hormone, and luteinizing hormone can be measured as points of reference.

Human Model: Children with idiopathic scoliosis (n = 95); normal reference controls (n = 60); ages between 7 and 17 years. Girls can be divided into age groups and all results evaluated according to chronological and skeletal age.

Interpretation and Analysis: Given the population evaluated, a large number of children will be deemed to have successfully passed the screening test when a GH concentration of > 15 miu/L is elicited after stimulation (n = 133 children passed). A fairly large number of children may fail the screening test (e.g., n = 52; with n = 33/52 with GHD with inadequate GH response to insulin-induced hypoglycemia). The residual cases may be classified as low-responders (e.g., n = 19) associated with the display of adequate GH response to insulin tolerance test (ITT). The low-responder rate to L-dopa-propranolol provocative test among short children who are not GH deficient is 12.5% approximately.

In the evaluation of children diagnosed with idiopathic scoliosis, girls display a significantly higher response to the GH stimulation test than controls between the ages of 7 and 12 years, whereas no significant difference can be detected in older girls. In girls with a skeletal age between 9 and 12 years, significantly higher mean serum levels of testosterone are present ($p < 0.05$). No significant differences can be demonstrated for the remaining hormones. Growth hormone and testosterone are the most important growth factors in prepubertal and pubertal children. Thus, the present findings suggest a hormonal basis for the increased stature in children with idiopathic scoliosis that has previously been reported.

Growth related hormones in idiopathic scoliosis. An endocrine basis for accelerated growth. Skogland LB, Miller JA. Acta Orthop Scand 1980 Oct; 51 (5), pp. 779–80.

Growth Hormone Deficiency (GHD): Obesity/ Hypopituitary Conditions/Hyposomatotropism vs Hypopituitarism: Hypothalamic/Pituitary Function
Growth Hormone-Releasing Hormone (GHRH) + Growth Hormone-Releasing Peptide (GHRP)-6 Test

Background Information: It has been gradually realized that GH may have important physiological functions in adult humans. The biochemical diagnosis of adult GHD is established by provocative testing of GH secretion. The insulin tolerance test (ITT) is the best validation provocative test. However, the insulin-based ITT has been challenged because of its low degree of reproducibility and lack of normal range, and is contra-indicated in common clinical situations. Furthermore, in severely obese subjects the response to the ITT frequently overlaps with those found in non-obese adult patients with GHD.

Application: Detect and evaluate alterations in GH endocrinology.

Implementation: Evaluate the diagnostic capability of 4 different stimuli of GH secretion: ITT, GHRH, GHRH plus acipimox (GHRH + Ac), and GHRH + GHRP-6, in 2 pathophysiological situations (e.g., hypopituitarism and obesity). In this context, in cases of hyposomatotropism of hypopituitarism, the combined test GHRH + GHRP-6 most accurately distinguishes both conditions, without the side effects of ITT.

Route of Administration: Insulin-tolerance test (intravenous insulin), GHRH (intravenous), GHRH (intravenous) preceded by acipimox (oral/per os) (GHRH + Ac), and GHRH (intravenous) plus GHRP-6 (intravenous) (GHRH + GHRP-6).

Dosage: Insulin-tolerance test (0.1 U/kg, 0.15 U/kg for obese, 0 minutes), GHRH (100 μg, 0 minutes), GHRH (100 μg, 0 minutes) preceded by acipimox (250 mg, at −270 minutes and −60 minutes) (GHRH + Ac); and GHRH (100 μg, 0 minutes) plus GHRP-6 (100 μg, 0 minutes) (GHRH + GHRP-6).

Implementation: Individual cases are evaluated with 4 separate provocative tests including ITT; GHRH preceded by acipimox (GHRH + Ac); and GHRH + GHRP-6. Serum GH levels are then measured by radioimmunoassay. Statistical analyses can be performed using the Wilcoxon rank sum and by Mann-Whitney tests.

Human Model: Cases of adult hypopituitarism (n = 8; n = 4/8 female, n = 4/8 male; age = 41–62 years [48.8 ± 1.4 years]; n = 10 normal obese; n = 5/10 female, n = 5/10 male; age = 38–62 years [48.1 ± 2.5 years], body mass index = 34.2 ± 1.2 kg/m^2; n = 10 normal subjects; n = 5/10 female; age = 33–62 years [48.1 ± 2.8 years]).

Interpretation and Analysis: After the ITT the mean peak GH secretions are 1.5 ± 0.3 μg/l for hypopituitary, 10.1 ± 1.7 μg/l ($p < 0.05$ vs hypopituitary) for obese, and 17.8 ± 2.0 μg/l ($p < 0.05$ vs hypopituitary) for normal. GHRH-induced GH secretions are 2 ± 0.7 μg/l for hypopituitary, 3.9 ± 1.2 μg/l (p = NS vs hypopituitary) for obese and 22.2 ± 3.8 μg/l ($p < 0.05$ vs hypopituitary) for normal. After GHRH + Ac, mean peak GH secretions are 3.3 ± 1.4 μg/l for hypopituitary, 14.2 ± 2.7 μg/l ($p < 0.05$ vs hypopituitary) for obese, and 35.1 ± 5.2 μg/l ($p < 0.05$ vs hypopituitary) for normal. GHRH + GHRP-6 induced mean peak GH secretion of 4.1 ± 0.9 μg/l for hypopituitary, 38.5 ± 6.5 μg/l ($p < 0.05$ vs hypopituitary) for obese, and 68.1 ± 5.5 μg/l ($p < 0.05$ vs hypopituitary) for normal subjects. Individually considered, after ITT, GHRH, or GHRH + Ac, the maximal response in hypopituitary cases is lower than the minimal response in normal but higher than the minimal response in obese subjects. In contrast, after GHRH + GHRP-6 the maximal response in hypopituitary cases is lower than the minimal response in normal and obese subjects. In study groups evaluated to date, although both acipimox and GHRP-6 partially reverse the functional hyposomamotropism of obesity after GHRH but are unable to reverse the organic hyposomatotropism of hypopituitarism, the combined test GHRH + GHRP-6 most accurately distinguishes both situations, without the side effects of ITT.

Comparison between insulin tolerance test, growth hormone (GH)-releasing hormone (GHRH), GHRH plus acipimox and GHRH plus GH-releasing peptide-6 for the diagnosis of adult GH deficiency in normal subjects, obese and hypopituitary patients. Cordido F, Alvarez-Castro P, Isidro ML, Casanueva FF, Dieguez C. Eur J Endocrinol 2003 Aug; 149 (2), pp. 117–22.

Growth Hormone Deficiency (GHD): Hypothalamic/Pituitary
Combined Hormonal-Stimulation Test (CHST)/ Thyrotropin-Releasing Hormone (TRH)/Gonadotropin-Releasing Hormone (GnRH)/Levodopa (L-dopa)/ Insulin

Application: Detection and characterization of alterations in GH production in children with pathological growth patterns.

Implementation: Evaluation of children with conditions of short stature to determine their GH production capacity utilizing a CHST involving the sequential administration of insulin, TRH, GnRH, and L-dopa. Growth hormone, thyrotropin, gonadotropins, cortisol, and prolactin levels are sampled over a period of 2 hours.

Human Model: Children with short stature and/or pathologic growth (n = 51).

Interpretation and Analysis: Children with appropriate predicted adult heights, delayed bone ages, and normal growth velocities of 4.0 cm/year or greater demonstrate normal pituitary responses. A small percentage of cases with predicted heights 2.5 standard deviations lower than target height and normal growth velocity demonstrate isolated GHD (e.g., n = 2/12). Conversely, a relatively large percentage of suspected cases have pathologic GHD or panhypopituitarism (e.g., n = 9/11). Evaluation of pituitary function by

combined sequential hormonal stimulation is fruitful in children with pathologic growth patterns but not in children with normal growth velocities and normal predicted adult height.

Pituitary function assessment in short stature by a combined hormonal-stimulation test. Pugliese M, Lifshitz F, Fort P, Cervantes C, Recker B, Ginsberg L. Am J Dis Child 1987 May; 141 (5), pp. 556–61.

Growth Hormone Insufficiency: Noonan's Syndrome (Childhood)/Evaluation of Posttreatment Response
Glucagon

Application: Characterization of the role of GH insufficiency in the pathogenesis of short stature in Noonan's syndrome.
Implementation: Evaluation of spontaneous 12-hour overnight GH secretion by continuous sampling analyzed using Pulsar, plasma insulin-like growth factor-I (IGF-I) and IGFBP-3 levels, and 24-hour urinary GH excretion measured at the start of GH treatment. Insulin-like growth factor-I and IGFBP-3 are remeasured after 1 year of GH treatment. Biological variables measured include height and height velocity, which are monitored before and after 1 year of GH treatment.

Human Model: Cases of Noonan's syndrome (n = 17; n = 13 boys, 4 aged 4.8–13.3; mean 9.2 years) and short stature prior to the initiation of GH treatment.
Interpretation and Analysis: A considerable percentage of children will have a mean overnight GH concentration below the lower limit of the normal range (e.g., n = 9/17). Close to 1/3 of cases will display overnight GH profiles with high trough GH concentrations (e.g., n = 6/17). Glucagon stimulation tests are normal in the vast majority of affected cases (e.g., n = 16/17).

Mean IGF-I levels are below normal (−0.4 SD). None of the parameters regarding GH secretion obtained from the overnight profile or provocative test are related to height or height velocity, nor to 1st-year response to GH treatment. Insulin-like growth factor-I and IGFBP-3 do not correlate with any of the GH secretion data. Insulin-like growth factor-I and IGFBP-3 are related to height and height velocity at the start of GH treatment ($r = 0.53$ [$p < 0.01$] and $r = 0.61$ [$p < 0.03$], respectively). Rises in IGF-I and IGFBP-3 under GH treatment are related to the increment in height velocity ($r = 0.70$ [$p < 0.01$] and $r = 0.71$ [$p < 0.02$], respectively). Abnormalities in GH secretion are frequent in patients with Noonan's syndrome and short stature. These abnormalities are not related to auxology at start of, or response to, GH treatment. Insufficiency of GH is clinically not important in Noonan's syndrome and monitoring spontaneous GH secretion is not necessary before the start of GH treatment.

Growth hormone (GH) secretion in children with Noonan's syndrome: Frequently abnormal without consequences for growth or response to GH treatment. Noordam C, van der Burgt I, Sweep CG, Delemarre-van de Waal HA, Sengers RC, Otten BJ. Clin Endocrinol (Oxf) 2001 Jan; 54 (1), pp. 53–9.

Growth Hormone (GH) Synthetic Capacity/(Children of Short Stature)
Growth Hormone-Releasing Peptide-2 (GHRP-2)/Aginine/Insulin/L-dopa

Cellular/Molecular Mechanism of Action: Hypothalamic-releasing hormones GHRH regulate the secretion of GH. Growth hormone-releasing peptide-2, an investigational biopharmaceutical, is 1 of the most potent members of the GHRP family.
Background Information: The secretion of GH is primarily regulated by the hypothalamic-releasing hormones GHRH and somatostatin. Additionally, several neurotransmitters act at the hypothalamus and pituitary to modulate GH release. The agents commonly used in clinical practice to diagnose GH deficiency, such as arginine, insulin, and L-dopa, act through the neural GH network. Many children with a poor GH response to conventional agents have a significant serum GH response to GHRH (IV). Growth hormone-releasing peptides are synthetic peptides that like GHRH act directly on pituitary somatotrophs to stimulate GH release.
Application: The investigational drug GHRP-2 is one of the most potent members of the GHRP family and can be used to detect abnormalities such as GH deficiency in children of short stature.
Route of Administration: Hypothalamic-releasing GHRP-2 has been shown to be effective in adults.
Dosage: Hypothalamic-releasing hormones (GHRP-2) can induce a significant response in GH secretion over a single dose range between 5 and 20 μg/kg.
Considerations: The intranasal preparation is well tolerated.
Implementation: Preparations of GHRP-2 can be applied to evaluate GH responses and determine their relative effectiveness in this regard compared to other provocative agents in children of short stature. In this context, GHRP-2 is administered intravenously or intranasally to children with short stature and compared to the administration of a combination of GHRP-2 (IV) and GHRH in the same subjects. Comparisons can also be made with conventional agents (arginine, L-dopa/exercise, insulin) in cases being evaluated for GH deficiency (e.g., n = 24 cases) intravenous GHRH and GHRP-2.
Interpretation and Analysis: The GH responses to GHRH or GHRP-2 are similar in children, and both agents are equally reliable predictors of pituitary reserve. Conventional agents used in GH testing are less likely to predict the capacity of pituitary GH release than are either GHRH or GHRP-2. There is no correlation between maximal GH response to standard tests with GH responses to GHRH or GHRP-2. Subsets of children that have a robust response to GHRP-2 (IV) and are then given GHRH + GHRP-2 simultaneously reveal that in such scenarios, these 2 agents exert a synergistic effect similar to previous observations reported in adults of normal stature. Furthermore, children that have a robust response to GH-releasing factors and subsequently receive intranasal GHRP-2 have a significant GH response over a dose range of 5 to 20 μg/kg per dose. The mean peak GH response to 15 μg/kg is 31.3 μg/L.

Diagnostic studies with intravenous and intranasal growth hormone-releasing peptide-2 in children of short stature. Pihoker C, Middleton R, Reynolds GA, Bowers CY, Badger TM. J Clin Endocrinol Metab 1995 Oct; 80 (10), pp. 2987–92.

Growth Hormone (GH)/Thyroid-Stimulating Hormone (TSH) Response/Influence of Fatty Acids on Plasma Levels
Thyrotropin-Releasing Hormone (TRH)

Background Information: Supplemental dietary fat provides excess fatty acids (FA) that can alter circulating concentrations of several hormones.
Route of Administration: Thyrotropin-releasing hormone (intramuscular).
Implementation: Evaluation of the effects of fatty acid isomer type on systemic hormone concentrations and possible sites of regulation. One approach to achieving this objective involves the abdominal infusion of fat mixtures high in cis-C18:1 FA (iCIS), high in trans-C18:1 FA (iTRS), or no infusion (NI) and perform intravenous arginine (ARG) and intramuscular TRH challenges. Test challenges are conducted on days 10 (ARG) and 12 (TRH) after initiation of fat infusion on each of 3 4-week experimental periods. Assessment of fat regulation of the thyroid axis can be tested directly *in vitro* by

characterizing the ability of fatty acids dissolved with sodium taurocholate to affect Type I 5′-deiodinase (5′D) activity in bovine liver homogenates.

Animal Model: Bovine.

***Ex Vivo* Model:** Bovine liver (homogenates).

Experimental Design: Replicated 3 × 3 Latin square.

Interpretation and Analysis: Plasma concentrations of insulin-like growth factor-I (IGF-I) are lower ($p < 0.01$) when cows received iCIS or iTRS compared with no fat infusion. Plasma insulin concentrations increase with ARG but responses are not affected by FA. Plasma GH remains unchanged after ARG. Peak plasma GH and TSH responses to TRH are blunted ($p < 0.05$ and $p < 0.1$, respectively), whereas thyroxine (T4) and triiodothyronine (T3) responses are augmented post-TRH ($p < 0.01$) when cows receive either FA isomer. Prolactin responses to TRH are not different between infusion treatments, although basal plasma concentrations before TRH are higher in cows infused with iTRS ($p < 0.05$). Homogenate 5′D is not affected by C2:0-C10:0 fatty acids, but decreases linearly ($p < 0.01$) with increasing concentrations of C12:0-C16:0 and C18:1 isomers. Cis C18:1 decreases 5′D more than the trans-isomer ($p < 0.01$), but the difference is only apparent at concentrations > 0.25 mM. The data suggest that various aspects of pituitary hormone regulation are differentially affected by FA composition. Fatty acid infusion may accentuate end organ responses in the thyroid axis and decrease IGF-I in the somatotropic axis. The data also suggest that FA isomer may alter patterns of extrathyroidal generation of thyroid hormones via direct influences on 5′D.

Dietary fatty acids modulate hormone responses in lactating cows: Mechanistic role for 5′-deiodinase activity in tissue. Romo GA, Elsasser TH, Kahl S, Erdman RA, Casper DP. Domest Anim Endocrinol 1997 Nov; 14 (6), pp. 409–20.

HYPOTHALAMIC/PITUITARY FUNCTION: REPRODUCTION

Amenorrhea: Pituitary Disturbances
Luteinizing Hormone-Releasing Hormone (LHRH) Gonadorelin/[Progesterone]/[Clomiphene]

Cellular/Molecular Mechanism of Action: Gonadorelin LHRH is a synthetic polypeptide that promotes the release of gonadotropin.

Application: Detection and evaluation of alterations in gonadotropin endocrinology.

Route of Administration: Intravenous.

Dosage: Gonadorelin LHRH (80 μg for the 1st and 2nd administered doses).

Considerations: The "Gonadorelin-test" diagnostically complements the progesterone and clomiphene-test.

Implementation: Evaluation of gonadotropin levels in women during their menstrual cycle in the middle of the follicle phase.

Human Model: Female cases with a normal menstrual cycle during the middle of the follicular phase (n = 11) in addition to cases of secondary amenorrhea (n = 10).

Interpretation and Analysis: Gonadorelin is effective in provoking a typical gonadotropin release. Conditions of secondary amenorrhea respond to the 1st Gonadorelin administration based on the detection of peak gonadotropins levels, in particular with LH levels, after 30 to 60 minutes (delta 1 = for 1st peak level − 0′ level). The relative ascent of gonadotropins (delta 2 = 2nd peak level − 120′ level) after the 2nd step administration at 120 minutes is not significantly higher than delta 1. The profile of pituitary LHRH production/release does not immediately depend on the basal level of gonadotropin values. It reflects the severity of the hypothalamic-pituitary functional disturbance.

Clinical use of Gonadorelin as a diagnostic agent in one- and two-step tests. Vesper B, Rohde W, Groot-Wassink T. Zentralbl Gynakol 1986; 108 (23), pp. 1442–52.

Endometriosis/Prolactin Response: Lack of Discrimination
Thyrotropin-Releasing Hormone (TRH)/Insulin Challenge

Application: Detection and characterization of endometriosis conditions.

Implementation: Evaluation of prolactin secretion applying a thyrotropin-releasing releasing hormone (TRH) test and an insulin challenge test in conditions of female endometriosis.

Human Model: Female cases of endometriosis (n = 10) treated with danazol at a dose of 200 mg 3 times daily for 6 months (evaluated after the reappearance of 2nd menses). Reference controls include normal females (n = 10 follicular phase (test performed only once).

Interpretation and Analysis: The absence of a significant difference in basal prolactin levels, or responses to the TRH and insulin challenge tests between controls and patients with endometriosis, before and after danazol treatment, supports the view that hyperprolactinemia should not be considered as a cause of infertility in endometriotic women. Furthermore, significant reductions in prolactin response to provocative tests during danazol treatment may be associated with the low estrogen levels caused by the medication. Finally, inadequate prolactin responses to insulin-induced hypoglycemia in cases with endometriosis and in normal women shows that this provocative test is not effective for hypothalamic stimulation of prolactin.

Provocative tests of prolactin before, during and after long-term danazol treatment in patients with endometriosis. Panidis D, Vavilis D, Rousso D, Panidou E, Kalogeropoulos A. Gynecol Endocrinol 1992 Mar; 6 (1), pp. 19–24.

Gonadal-Pituitary-Hypothalamic Function/ Estradiol/Luteinizing Hormone (LH)/Follicle-Stimulating Hormone (FSH)
Naltrexone

Cellular/Molecular Mechanism of Action: Opioid antagonist that stimulates LH and FSH in women during the early follicular phase of the menstrual cycle.

Application: Characterization of anterior pituitary function pertaining to LH, FSH, and prolactin (PRL) synthesis and release.

Route of Administration: Naltrexone (intravenous).

Dosage: Naltrexone (0.25, 0.50, and 1.0 mg/kg).

Considerations: These data are not concordant with clinical studies that report significant naltrexone stimulation of LH in men and in women during the early follicular phase.

Implemenation: Evaluation of the acute effects of naltrexone on anterior pituitary (LH, FSH, PRL) and gonadal steroid (T or E2) hormones. Integrated plasma samples can be collected at 20-minute intervals for 60 minutes before and for 300 minutes after intravenous infusion of naltrexone over 10 minutes.

Animal Model: Primate (rhesus/mucaca mulatta; n = 7 female and n = 4 male).

Interpretation and Analysis: In females studied during the early follicular phase (cycle days 1–3), naltrexone does not stimulate LH and significantly suppresses E2 ($p < 0.0003$–0.0001) and FSH

($p < 0.006$–0.0001). Naltrexone (0.50 and 1.0 mg/kg) also does not stimulate LH release in late follicular-phase females (cycle days 10–12) when estradiol levels are in the peri-ovulatory range. Follicle-stimulating hormone and E2 are significantly suppressed ($p < 0.01$–0.05) after 1.0 mg/kg naltrexone, but not after 0.5 mg/kg naltrexone. However, in males all doses of naltrexone significantly stimulate LH ($p < 0.003$–0.0001) and T ($p < 0.001$–0.0001) but not FSH. Luteinizing hormone increases significantly above baseline within 20 to 40 minutes and T increases significantly within 60 minutes. Such gender differences in naltrexone's effects on pituitary gonadotropins and gonadal steroid hormones are unanticipated.

Naltrexone effects on pituitary and gonadal hormones in male and female rhesus monkeys. Mello NK, Mendelson JH, Bree MP, Skupny A. Pharmacol Biochem Behav 1988 Nov; 31 (3), pp. 683–91.

Gonadotropin Insufficiency/[Luteinizing Hormone (LH) and Follicle-Stimulating Hormone (FSH) Response]/[Example: Iron Toxicity Induced]
Gonadotropin-Releasing Hormone (GnRH)

Cellular/Molecular Mechanism of Action: Gonadotropin-releasing-hormone (promotes the synthesis/release of gonadotropins (e.g., LH, FSH).
Application: Detection and characterization of gonadotropin insufficiency conditions.
Route of Administration: Gonadotropin-releasing-hormone (IV bolus).
Dosage: Gonadotropin-releasing-hormone (100 mg bolus).
Implementation: Determine whether iron toxicity in blood transfusion dependent beta-thalassemic patients with pubertal failure is associated with gonadotropin (GTH) insufficiency based on responses to spontaneous/dynamic tests. In this context, GnRH-GTH secretory dynamics can be studied by serial ultradian GTH profiles and a GnRH IV bolus test.

Human Model: Cases of beta-thalassemia major patients with failed puberty ($n = 28$ males in FP group; $n = 5$ healthy, non-thalassemic prepubertal males).
Interpretation and Analysis: According to pulse profiles, FP group cases can be subdivided into apulsatile (no FSH and LH pulses, $n = 16$; AFP group) and pulsatile (defective pulse profile, $n = 12$; PFP group) subsets. Groups of FP cases have lower basal FSH ($p < 0.01$), LH ($p < 0.01$) and GnRH stimulated FSH ($p < 0.001$) and LH levels ($p < 0.001$) than the controls. However, basal and GnRH-stimulated FSH ($p < 0.01$ for basal and $p < 0.001$ for peak) and LH ($p < 0.01$ for both basal and peak) levels are lower in the AFP than PFP case groups. Serum ferritin levels in GnRH-non-responders are higher than those in responders ($9{,}052.63 \pm 579.14$ mg/l vs $5{,}933.33 \pm 1{,}819.65$ mg/l; $p < 0.05$). Similarly, symptomatic organ damage is higher in AFP than in PFP case groups (81% vs 42%; $p < 0.001$).

Iron toxicity/overload appears to be a major cause of GnRH-GTH deficiency in cases of failed puberty that suffer from thalassemic conditions. Comparison between spontaneous and dynamic test levels show that there is concordance between the degree of pulse defect and magnitude of LH response to GBT. However, ultradian GTH profiling is a more reliable method for identifying the degree of GTH insufficiency than GBT. Severity of the defect is heterogeneous, ranging from very severe (apulsatile) to less severe (pulsatile) subsets. Such information may be useful for better understanding the pathophysiology of hypogonadotrophic hypogonadism (HH), thereby promoting therapeutic options for induction of puberty and spermatogenesis.

Hypogonadotropic Hypogonadism (HH)/Delayed Growth: Constitutional Growth Delay (CGD)
GnRH/Nafarelin

Background Information: Previous investigations have observed nocturnal luteinizing hormone (LH) levels equal to 5.5 ± 0.9 IU/I for CGD, and 2.7 ± 0.7 IU/I for HH that represent a statistically significant differences. Mean nocturnal follicle-stimulating hormone (FSH) has been reported to be 5.1 ± 1.0 and 2.5 ± 0.2 IU/I, whereas mean nocturnal T concentrations are statistically different at approximately 4.2 ± 0.8 and 0.7 ± 0.2 nmol/I for CGD compared to HH, respectively. Peak LH responses to nafarelin are approximately 36.9 ± 8.9 IU/I for CGD, and 7.0 ± 2.0 IU/I for HH (statistically significant). Peak FSH released by nafarelin is about 14.2 ± 2.4 IU/I for CGD group and 4.8 ± 2.0 IU/I for HH (statistically significant). Peak T are reached by 24 hours following nafarelin injection and are approximately 5.7 ± 1.7 nmol/I for CGD and 0.3 ± 0.2 nmol/I for HH (statistically significant).
Application: Distinguish between CGD in boys with Tanner stage I of sexual development and patients with HH.
Route of Administration: Subcutaneous.
Dosage: Nafarelin (1 μg/kg up to 100 μg).
Implementation: Evalaution of hypothalamic/pituitary function based on the interpretation of changes in LH, FSH, T and E2 concentrations following nafarelin administration. Blood samples are collected at timed intervals every 15 minutes for 24 hours for the measurement of LH, FSH, T, and E2 (e.g., RIA, ELISA). Pretreatment baseline values are obtained by collecting blood samples every 15 minutes during a 12-hour overnight schedule.

Human Model: Cases of suspected constitutional growth delay from hypogonadotropic hypogonadism.
Interpretation and Analysis: Stimulated release of plasma LH, FSH and T is significantly higher with nafarelin compared to GnRH which also takes a longer period time to reach maximum peak concentrations. Experimental findings indicate that in early stages of puberty (before detectable changes of sexual maturation), the nafarelin test combined with the measurement of LH, FSH, and T in the blood or urine is superior to and more practical than overnight hormonal estimates to clearly distinguish CGD from HH.
Instrumentation: Instrumentation and facilities necessary to perform RIA- or ELISA-based methodologies.

Gonadotropin-releasing hormone agonist analog (nafarelin): A useful diagnostic agent for the distinction of constitutional growth delay from hypogonadotropic hypogonadism. Kletter GB, Rolfes-Curl A, Goodpasture JC, Solish SB, Scott L, Henzl MR, Beitins IZ. J Pediatr Endocrinol Metab 1996 Jan–Feb; 9 (1), pp. 9–19.

Infertility: Female/Prolactin: Latent Hyperprolactinaemia/Luteinizing Hormone (LH)/Follicle-Stimulating Hormone (FSH)/17-beta Estradiol (E2)/Testosterone (T) Total
Metoclopramide

Cellular/Molecular Mechanism of Action: Metoclopramide enhances cholinergic activity at muscarinic synapses and suppresses/antagonizes CNS dopaminergic activity.
Implementation: Evaluation of latent hyperprolactinaemia in the midfollicular phase of the cycle in cases of female infertility. Metoclopramide is given to determine prolactin response profiles. Just before metoclopramide is given, blood samples are collected for measuring levels of LH and FSH, 17-beta estradiol (E2) and total testosterone.

Human Model: Cases of female infertility in the midfollicular phase of the cycle (n = 174 randomly chosen; n = 54/174 latent hyperprolactinaemia defined as having prolactin (PRL) levels of at least 150 ng/ml after metoclopramide). Just before metoclopramide is administered, blood is taken to measure levels of LH and FSH, 17-beta estradiol (E2), and total testosterone.

Interpretation and Analysis: Women with latent hyperprolactinaemia have significantly lower levels of LH ($p < 0.01$) and E2 ($p < 0.001$) and higher levels of T ($p < 0.05$) in the midfollicular phase when compared with women without this condition. FSH levels showed no statistically significant difference.

The influence of latent hyperprolactinaemia on the levels of LH, FSH, E2 and T in the midfollicular phase of the cycle. Kostál M; Tosner J. Arch Gynecol Obstet 1997; 259 (2), pp. 65–8.

Infertility and Fertility: Female/Follicular Phase of the Menstrual Cycle/Polycystic Ovarian Syndrome (PCOS): Luteinizing Hormone (LH) Response/ Conserved Central Opioid Tone

Naltrexone

Cellular/Molecular Mechanism of Action: Naltrexone is an opioid antagonist.

Application: Characterization of the endocrinology of normal adult females (e.g., women) during the early follicular phase of the menstrual cycle (day 1 to day 4 following onset of menstruation).

Route of Administration: Naltrexone (oral).

Dosage: Naltrexone (50 mg); gonadotropin-releasing hormone (GnRH)-stimulated LH release (10 μg).

Considerations: Orally administered naltrexone appears to be a safe and effective compound for assessing function of the hypothalamic-anterior pituitary axis in women.

Implementation: Evaluation of enhanced LH levels in females with PCOS to determine if the condition is a consequence of an absent hypothalamic opioid inhibitory control and/or an increased sensitivity of gonadotroph to GnRH, induced by the sensitizing effects of circulating opioid peptides. Delineation of this objective can achieved through the administration of Naltrexone due to its capacity to induce significant elevations in plasma LH, prolactin, adenocorticotropic hormone (ACTH), and cortisol levels. In this context, pulsatile LH secretion (10-minute sampling for 6 hours) and GnRH-stimulated LH release can be characterized in conditions of PCOS before and after a 5-day administration protocol of either a placebo (n = 7) or the opioid antagonist naltrexone.

Human Model: Female with PCOS (n = 14 PCOS; n = 7/14 placebo controls). Seven age- and weight-matched normal cycling women in follicular phase function as controls.

Interpretation and Analysis: In comparison with normal cycling women, PCOS cases show normal frequency and increased amplitude LH pulses, elevated mean LH levels, and increased LH response to GnRH. In PCOS, placebo administration is not associated with any LH modification, whereas naltrexone enhances the frequency and decreases the amplitude of LH pulses, without modifying mean LH levels and the LH response to GnRH. Therefore, naltrexone-induced increment of LH frequency reveals the presence of conserved central opioid tone in PCOS. Reduced LH pulse amplitude, induced by naltrexone, is not associated with a reduced LH response to GnRH or with a reduction in mean LH levels. Present data do not support a role for endogenous opioid peptides in the pathogenesis of increased LH levels in PCOS.

Prolonged opioid blockade with naltrexone and luteinizing hormone modifications in women with polycystic ovarian syndrome. Cagnacci A, Soldani R, Paoletti AM, Falqui A, Melis GB. Fertil Steril 1994 Aug; 62 (2), pp. 269–72.

Infertility: Male/Prolactin (Induced)/Sperm Morphology Correlation/Luteinizing Hormone (LH) Stimulation/Spermiogenetic Defects/Testosterone (Stimulated) Positive Correlation with Sperm Morphology/Estrogen (Stimulated) Negative Correlation with Sperm Morphology/Follicle-Stimulating Hormone (FSH) Poststimulation Response/Male Fertility

Gonadotropin-Releasing Hormone (GnRH)/ Thyrotropin-Releasing Hormone (TRH)/ Adrenocorticotropin Hormone (ACTH)

Background Information: The recognition that discreet hormonal abnormalities may cause ovulation disorders in women suggests that the male partner of infertile women might also suffer from unrecognized hormonal dysfunction amendable to substitution therapy.

Implementation: Evaluation of the combined stimulation test with GnRH, TRH, and ACTH. Concentrations of the following hormones are then determined: estradiol (E), thyroid-stimulating hormone (TSH), prolactin, testosterone (T), dihydrotestosterone (DHT), androstenedione(A), 17-OH-pregnenolone (17-OH-Preg), 17-OH-progesterone (17-OHP), dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), cortisone (F), and 21-desoxycortisone (21DF).

Human Model: Cases (n = 225) characterized as males with childless spouses that have actively attempted to have children for at least 1 year.

Interpretation and Analysis: Basal and stimulated, adrenal-testicular steroids with and without ACTH stimulation fail to demonstrate a relevant relationship to semen parameters. Gonadotropin levels have a significant negative correlation to all important semen parameters (testicular volume, sperm count, motility, morphology, and vitality) and are positively correlated to spermiogenetic defects. Stimulated LH values are more clearly associated with spermiogenetic defects than basal LH. Nonetheless, basal FSH concentrations are more informative than LH. Stimulated prolactin values positively correlate with both gonadotropin and with sperm morphology. Estrogen concentrations have a significant positive correlation with both basal and poststimulation DHEAS values, and show a highly negative correlation with sperm count, morphology, and vitality. In comparison, good sperm parameters are associated with high poststimulation testosterone concentrations. Basal FSH and estrogen concentrations, as well as the stimulated LH, testosterone, and prolactin determinations, should be included in the evaluation of male sterility.

Hormone load tests in infertile male patients. Gerhard I, Lenhard HK, Eggert-Kruse W, Runnebaum B. Arch Androl 1991 Nov–Dec; 27 (3), pp. 129–47.

Oocyte Retrieval Prediction (Mature)/Estradiol (E2) Plasma Profiles/Predictor of Performance in the Flare-up IVF Cycle

Gonadotropin-Releasing Hormone Agonist (GnRH-a)

Application: Prediction of the potential yield of retrievable mature oocytes and pregnancy.

Implementation: Evaluation and comparison of the initial versus the early patterns of estradiol (E2) changes after the administration of a GnRH-a. In this context, the GnRH-a stimulation test is compared to E2 patternsas predictors of ovarian response and pregnancy in *in vitro* fertilized (IVF) patients stimulated with a "flare-up" protocol. Candidates are stimulated with a GnRH-a flare-up protocol beginning on menstrual day 2.

Human Model: Cases without any known health abnormalities (n = 228; n = 0 anticipated to have polycystic ovarian disease; n = 0 single ovary; n = 0 ovarian cyst(s)).
Interpretation and Analysis: The GnRH-a stimulation test but not E2 patterns can function as a predictive indicator of the number of mature oocytes that can be retrieved ($r = 0.53$, $p \leq 1 \times 10^{-5}$) and pregnancy ($chi^2 = 8.5$, $p = 0.04$). The E2 pattern is predictive of the duration and number of ampules of gonadotropin required for stimulation. The GnRH-a stimulation test is a sensitive predictor of performance in the flare-up IVF cycle.

The gonadotropin-releasing hormone agonist stimulation test-a sensitive predictor of performance in the flare-up *in vitro* fertilization cycle. Winslow KL, Toner JP, Brzyski RG, Oehninger SC, Acosta AA, Muasher SJ. Fertil Steril 1991 Oct; 56 (4), pp. 711–7.

Oxytoxin and Vasopression Physiology
Glucagon-Like Peptide-1 (7-36)

Application: Characterization of pituitary endocrine function.
Route of Administration: Glucagon-like peptide-1 (7-36) by intracerebroventricular injection.
Dosage: Glucagon-like peptide-1 (7-36) at a dose of 1 μg.
Implementation: Evaluation of the possible effects of glucagon-like peptide-1 (7-36) amide on vasopressin and oxytocin release induced by acute peripheral or central osmotic stimulation. Study Design #1: Intraperitoneally injected isotonic (0.15 M) or hypertonic (*1.5* M) NaCl solutions and then, intracerebroventricular injection of either glucagon-like peptide-1 (7-36) amide dissolved in 5 microl of isotonic saline or with vehicle only. Study Design #2: Glucagon-like peptide-1 (7-36) amide, dissolved in isotonic or hypertonic (0.6 M) saline, is injected into the cerebroventricular system. Control rats are treated with isotonic or hypertonic saline only. All animals are decapitated 10 minutes after the intracerebroventricular injection.

Animal Model: Rat.
Interpretation and Analysis: Glucagon-like peptide-1 (7-36) amide enhances significantly the basal secretion of vasopressin and oxytocin. Moreover, this peptide increases additionally the release of both neurohypophysial hormones stimulated previously by peripheral osmotic challenge. On the other hand, the peptide increases the oxytocin but not vasopressin secretion brought about by an intracerebroventricular injection of hypertonic saline thus suggesting that the central osmotic stimulation decreases the sensitivity of vasopressin neurons to glucagon-like peptide-1 (7-36) amide. Therefore, glucagon-like peptide-1 (7-36) amide may affect the secretory activity of the hypothalamo-neurohypophysial system under acute osmotic challenge.

Effects of glucagon-like peptide-1 (7-36) amide on neurohypophysial hormone secretion induced by acute hyperosmotic challenge. Bojanowska E, Stempniak B. Neuropeptides 2003 Feb; 37 (1), pp. 45–50.

Prolactin: Functional Hyperprolactemia/[Lack of Diagnostic Efficacy]
Metoclopramide/Thyrotropin-Releasing Hormone (TRH)

Application: Detection and characterization of conditions related to alterations in prolactic secretion.
Route of Administration: Thyrotropin-releasing hormone (intravenous); metoclopramide (intravenous).
Dosage: Thyrotropin-releasing hormone (200 μg); metoclopramide (10 mg).
Implementation: Evaluate the diagnostic validity of prolactin response tests by comparing the stimulating effect of TRH and metoclopramide on prolactin secretion in conditions of hyperprolactinemia. Prolactin response studies with TRH and metaclopramide are performed on the 7th, 8th, or 9th day of the follicular phase under standardized conditions (08.00–09.00, after a 1-hour rest and overnight fasting).

Human Model: Cases of functional hyperprolactinemia (n = 18 defined according to prolactin serum levels ≥ 16 and < 50 ng/ml during the follicular phase without evidence of prolactinoma). Reference controls are of a similar age that have normal serum prolactin levels (n = 18). Tests can be done on the 7th, 8th, or 9th day of the follicular phase under standardized conditions (at 08.00 to 09.00, after a 1-hour rest and overnight fasting) with TRH or metoclopramide IV.
Interpretation and Analysis: Higher maximal prolactin concentrations are achieved in affected cases and reference controls after metoclopramide than after TRH (metoclopramide mean: 243 ± 62 ng/ml vs 181 ± 100 ng/ml, U-test: $p = 0.0019$; TRH mean: 101 ± 23 ng/ml vs 41 ± 20 ng/ml, U-test: $p = 0.0001$). There is no significant difference in the relative increment of prolactin serum levels between both groups, neither after metoclopramide nor after TRH (after metoclopramide, mean: 13.5 ± 5.8 vs 17.2 ± 9.2, U-test: $p = 0.137$; after TRH, mean 3.6 ± 1.1 vs 3.8 ± 1.9, U-test: $p = 0.899$). No correlation exits between prolactin basal and peak levels, either after TRH or after metoclopramide neither in the study (metoclopramide test: $p = 0.738$; TRH test: $p = 0.076$) nor in the control group (metoclopramide test: $p = 0.331$; TRH test: $p = 0.360$). While significantly higher prolactin peaks are recorded after metoclopramide compared to TRH in both groups, no difference in the response to TRH and metoclopramide, regarding absolute and relative increment, can be detected.

Prolactin response to metoclopramide and thyrotropin-releasing hormone in normoprolactinemic and hyperprolactinemic women: A comparison of diagnostic validity. Bussen S, Brosemann N, Steck T. Gynecol Endocrinol 1996 Apr; 10 (2), pp. 83–90.

Prolactin Suppression: Ethanol-Induced/ Hypothalamic/Pituitary Dysfunction
Thyrotropin-Releasing Hormone (TRH)/Sulpiride

Physiological Mechanism of Action: Thyrotropin-releasing hormone is produced in the hypothalamus and promotes the synthesis/release of pituitary thyroid-stimulating hormone (TSH).
Route of Administration: Ethanol (indwelling atrial catheter, implanted on day 3 of lactation).
Dosage: Ethanol (0.0, 1.0 or 2.0 g/kg body weight) daily for 8 days from day 5 to 12 of lactation. Following the administration of the initial alcohol dose, infusion is continued at rates required to maintain blood alcohol levels (BALs) for 4 hours every day.
Implementation: Evaluation of the mechanism of action of alcohol-induced inhibition of suckling-induced prolactin release during lactation. Alcohol is administered from day 5 to 12 of lactation. Prolactin responses to sulpiride and TRH are then tested on day 12.

Animal Model: Rat (lactating females).
Interpretation and Analysis: Alcohol administration for 8 days and maintaining the blood alcohol levels for 4 hours daily does not affect the basal or sulpiride and TRH-stimulated plasma prolactin release. Since the prolactin-releasing capacity of pituitary lactotropes of the lactating rat is not compromised following chronic alcohol exposure, it can be concluded that alcohol does not act at the anterior pituitary level to inhibit the suckling-induced prolactin release but probably acts by other mechanisms: either via the hypothalamic and/or higher central nervous system or by disrupting the neural impulse transmission, engendered at the nipples in response to suckling.

Prolactin secretion in lactating rats following chronic alcohol exposure: Provocative tests with secretagogues. Subramanian MG. Life Sci 1995; 57 (6), pp. 533–9.

Puberty (Central): Female/Central Precocious Puberty (CPP)/Premature Thelarche (PT)
Gonadotropin-Releasing Hormone (GnRH)

Cellular/Molecular Mechanism of Action: Gonadotropin-releasing hormone is produced in the hypothalamus and promotes the release of pituitary hormones including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
Background Information: Precocious puberty is characterized by breast development in girls prior to 8 years old who may have acne, growth spurt, and menstruation. The GnRH stimulation test is the conventional gold standard for diagnosis of CPP but it is a time-consuming procedure that is not practical on an outpatient basis.
Application: Diagnosis of CPP through the evaluation of basal FSH levels in a manner capable of saving time and financial cost.
Implementation: Evaluation of hormonal profiles in response to GnRH stimulation tests.

Human Model: Female cases with breast development, n = 51 at < 8 years old classified as with either CPP (n = 24) or PT (n = 27). In addition, another test group can include comparisons between PT (n = 13) and thelarche variants (TV; n = 12) that develop puberty approximately 1 year later as confirmed by GnRH stimulation test.
Interpretation and Analysis: Girls with CPP have large bone-to-age and bone-to-chronological-age ratios in addition to advanced stages of breast development. Girls with TV have a greater level of basal LH, peak LH, and 120-minute estradiol levels than girls with PT. Basal LH and FSH ratio > 0.2 can be used to diagnose CPP with 75% sensitivity, 85% specificity, 82% positive predictive value (PPV), and 82% negative predictive value (NPV). Girls with CPP have a basal LH/FSH ratio > 0.2 and this can be used as a cutoff point for the diagnosis of CPP.

Basal luteinizing hormone/follicle stimulating hormone ratio in diagnosis of central precocious puberty. Supornsilchai V, Hiranrat P, Wacharasindhu S, Srivuthana S, Aroonparkmongkol S. J Med Assoc Thai 2003 Jun; 86 Suppl 2, pp. S145–51.

Sclerosis/Scleroderma (Systemic)/Follicle-Stimulating Hormone (FSH)/Luteinizing Hormone (LH)/Prolactin/Skin Sclerosis/Prolactin/Peripheral Vascular Involvement/Prolactin/Pulmonary Involvement
Gonadotropin-Releasing Hormone (GnRH)/Thyroid-Stimulating Hormone (TSH)

Application: Evaluation of systemic scleroderma conditions.
Implementation: Evaluation of basal and dynamic levels of pituitary gonadotropin release in female systemic sclerosis (SSc) patients of childbearing age and in postmenopausal SSc patients. One approach to achieving this objective can involve determining responses to GnRH and TSH stimulation tests during the early follicular phase by measuring serum concentrations of FSH, LH, and prolactin. Blood samples are also collected from postmenopausal women with systemic sclerosis after TSH stimulation; only serum prolactin concentrations are determined, because elevated basal concentrations of FSH and LH can be expected to be observed. Hormone concentrations are estimated by radioimmunoassay. Comparisons are made with healthy control women matched for age and reproductive status.

Human Model: Female cases in their childbearing years with systemic sclerosis (n = 12 SSc with mean age [SEM] 34.8 ± 2.4 years). In addition, postmenopausal female cases (n = 6) with systemic sclerosis (mean age 46.8 ± 2.4 years).
Interpretation and Analysis: In cases with systemic sclerosis of childbearing age, basal FSH, LH, and estradiol (E2) levels are not significantly different from reference controls, whereas basal prolactin concentration are significantly higher than reference controls ($p = 0.0001$). After the stimulation test, the peak concentrations of FSH ($p = 0.0001$) and prolactin ($P < 0.0001$) are significantly higher than controls. The net integrated response curves (net area under the curve [AUC]) for FSH and LH do not differ significantly between systemic sclerosis cases and controls. On the contrary, the net AUC for prolactin in response to TSH stimulation is significantly higher than reference controls ($p = 0.001$). In postmenopausal patients, basal estrogen E2, FSH, LH, and prolactin levels are not significantly different between women with systemic sclerosis and controls. However, after TSH stimulation, peak levels and net AUC for prolactin are not significantly higher in cases than those in reference controls. No significant correlations can be appreciated between basal and stimulated FSH, LH, and prolactin levels and the severity of involvement of various organ systems. Multiple regression analysis reveals that basal and stimulated prolactin concentrations can be associated with skin sclerosis and peripheral vascular and lung involvement. Our results suggest that subclinical primary hypogonadism can occur in SSc patients. They also confirm an alteration in the mechanism for prolactin secretion and release, which may not only contribute to further disturbance of the reproductive axis but may also have an influence on the disease.

Assessment of pituitary gonadotropin release to gonadotropin-releasing hormone/thyroid-stimulating hormone stimulation in women with systemic sclerosis. La Montagna G, Baruffo A, Pasquali D, Bellastella A, Tirri G, Sinisi AA. Rheumatology (Oxford) 2001 Mar; 40 (3), pp. 310–4.

Testicular Function: Cryptorchidism (Unilateral or Bilateral) vs Unilateral or Bilateral Castration/ Aggressive Cryptorchid Behavior
Human Chorionic Gonadotropin (hCG)

Cellular/Molecular Mechanism of Action: Human chorionic gonadotropin induces synthesis and release of testosterone from testicular Leydig cells.
Application: Detection of conditions of cryptorchidism (unilateral or bilateral) when it is uncertain if cases may actually be normal but have previously been subjected to bilateral or unilateral castration.
Background Information: Horses with cryptorchidism tend to be ill-tempered. Sometimes insufficient history is available to know if a horse has or has not been previously castrated (e.g., non-castrated cryptorchid vs unilateral castration).
Considerations: Horses < 3 years of age and all donkeys cannot be evaluated using a single measurement of (resting) blood esterone sulfate for the purpose of detecting the presence of cryptorchidism conditions.
Route of Administration: Human chorionic gonadotropin (intravenous injection).
Dosage: Intravenous injection of hCG at a dosage of 6,000 IU per 450 kg with blood sample collected prior to and 30–120 minutes after injection.
Implementation: Detection of conditions of unilateral or bilateral cryptorchidism by measuring increases in serum testosterone levels induced by hCG administration compared to preinjection concentrations.

Interpretation and Analysis: Cryptorchid patients have basal systemic esterone sulfate concentrations in excess of 400 pg/ml. Alternatively, in situations where the esterone sulfate assay is not an appropriate diagnostic approach, the administration of hCG will induce increases in blood testosterone levels. Prior to hCG administration, cryptorchid cases will have resting testosterone levels in excess of 100 pg/ml, whereas horses not affected by cryptorchidism will have resting testosterone concentrations below 40 pg/ml that will not change following hCG administration.
Laboratory Instrumentation: Assay of growth hormone (GH) concentrations by either RIA or ELISA.

Cryporchidism. Cox JE (pp. 571–3). Current Therapy in Equine Medicine 2, ed Robinson NE. WB Saunders, Philadelphia (Copyright 1987).

Is human chorionic gonadotropin useful for identifying and treating nonpalpable testis? Bukowski TP, Sedberry S, Richardson B. J Urol 2001 Jan; 165 (1), pp. 221–3.

Testicular Function/Gonadotropin: Basal Plasma Concentrations
Gonadotropin-Releasing Hormone (GnRH)

Background Information: Provocative GnRH stimulation testing indirectly assesses testicular function with more sensitivity than determination of basal gonadotropin levels alone. Unfortunately, the drawbacks of multiple blood sampling and high cost have limited the clinical usefulness of this particular test.
Implementation: Evaluation of gonadotropin (luteinizing hormone [LH]/follicle-stimulating hormone [FSH]) production using a simplified, 2-point, 30-minute GnRH stimulation test.

Human Model: Cases without any known health abnormalities (n = 55 men with normal baseline gonadotropin levels).
Interpretation and Analysis: Statistical analysis of data reveal that the simplified test is just as accurate as the traditional test ($p \leq 0.0001$) without the latter's attendant difficulties. In addition, normal basal gonadotropin levels have little correlation to the actual responses obtained from GnRH stimulation testing ($r = 0.20$ and $r = 0.39$ for LH and FSH, respectively).

Simplified gonadotropin-releasing hormone (GnRH) stimulation test. Fisch H, Laor E, Lipshultz LI. Urology 1990 Sep; 36 (3), pp. 260–3.

Testicular Function: Cystinosis/Luteinizing Hormone (LH) Response/Gonadotropin-Releasing Hormone (GnRH)/Follicle-Stimulating Hormone (FSH) Response
Human Chorionic Gonadotropin (hCG)

Application: Detection and characterization of reproductive function in conditions of cystinosis.
Implementation: Tanner staging, serum gonadotropin determinations, and testosterone and testosterone-binding globulin assessments. Selected patients also have an hCG stimulation test, a GnRH stimulation test, and serial samplings collected for measurement of LH.

Human Model: Cases of nephropathic cystinosis (n = 10, age = 15–28 years with nephropathic cystinosis and renal allografts) and reference controls (n = 11 renal transplant recipients with a primary renal disorder other than cystinosis, matched with study cases for age and renal function).
Interpretation and Analysis: Although testosterone levels are within normal limits in approximately 70% of cases with cystinosis (e.g., n = 7/10; mean testosterone level in cystinosis = 11.5 ± 2.0 nmol/L compared to 24.2 ± 3.0 nmol/L in control patients $p < 0.005$). Cases with cystinosis reach Tanner stage 5 (full pubertal development), whereas most controls do not (e.g., n = 9/11).

Elevations in LH or FSH can be appreciated in approximately 70% of cases with cystinosis (e.g., n = 7/10), thereby suggesting the presence of testicular failure. Such cases usually also have normal LH and FSH responses after GnRH stimulation, increases in LH pulse frequency, and reduced testosterone response after hCG stimulation. In contrast, a relatively small number of control cases may have minimally elevated gonadotropin levels (e.g., n = 3/11), but the vast majority of these subjects have normal testosterone levels (e.g., n = 11/11). Microscopic testicular examination in some cases shows cystine crystals, germinal dysplasia, increased fibrosis, and Leydig cell hyperplasia (e.g., n = 1). Abnormalities in the pituitary-testicular axis are common in male patients with cystinosis. These changes appear to be related to the disease cystinosis and not to treated renal failure per se.

Pituitary-testicular function in nephropathic cystinosis. Chik CL, Friedman A, Merriam GR, Gahl WA. Ann Intern Med 1993 Oct 1; 119 (7 Pt 1), pp. 568–75.

Testicular Function: Varicoceles
Gonadotropin-Releasing Hormone (GnRH)

Background Information: Ipsilateral testicular catch-up growth has been reported to occur in approximately 80% of adolescents with varicoceles following unilateral varicocelectomy. Observations have noted not only catch-up growth but hypertrophy (left at least 10% larger than right testicular volume) in some adolescents postoperatively. To our knowledge this phenomenon has not been previously described.
Application: Gonadotropin-releasing hormone response can be applied as 1 of the indicator parameters for justifying surgical intervention for testicular varicocele.
Implementation: Assessment of the incidence of left testicular hypertrophy following ipsilateral varicocele ligation and whether it is related to age at operation and/or procedure performed.

Indications for surgery include ipsilateral (left) testicular hypotrophy and exaggerated response to GnRH stimulation test and/or persistent pain. Testes are measured using the Takihara ring orchidometer with relative volume of the left testis expressed as a percentage of the right testis. Results are compared in different age groups as well as by procedure performed to correct the varicocele using chi^2 analysis. Testicular volume is determined before and after surgery, and all patients are followed for a minimum of 6 months.

Human Model: Cases of asymptomatic varicoceles that are candidates for unilateral left varicocelectomy (n = 42; n = 23/42 ipsilateral left testicular hypotrophy; n = 5 grade 2–3 varicocele with palpably softer ipsilateral left testicle; n = 12 grade 3+ varicoceles; n = 1 abnormal GnRH stimulation test; n = 1 persistent pain). Average patient age at operation is 14.7 years (range 9–22) and average follow-up is 22 months (range 6–84). Patients are stratified according to Palomo versus modified Ivanissevich technique and age at operation.
Interpretation and Analysis: Left testicular hypertrophy develops in approximately 43.8% of cases (e.g., n = 13/32) that undergo Palomo repair and in approximately 30% that undergo a modified Ivanissevich repair (e.g., n = 3/10). When compared by age at operation, 40% (e.g., n = 8/20) 14.7 years old or younger have left testicular hypertrophy compared to 36.4% (e.g., n = 8/22) older than 14.7 years. Differences between groups are not statistically significant. Ipsilateral testicular hypertrophy occurs in a substantial

number of adolescents following varicocele ligation. This phenomenon does not seem to be dependent on age at surgery or type of varicocele repair.

The adolescent varicocele I: Left testicular hypertrophy following varicocelectomy. Gershbein AB, Horowitz M, Glassberg KI. J Urol 1999 Oct; 162 (4), pp. 1447–9.

Testicular Function: Varicoceles
Gonadotropin-Releasing Hormone (GnRH)/[Inhibin-B, Follicle-Stimulating Hormone (FSH), Luteinizing Hormone (LS), Testosterone]/Lack of Diagnostic Benefit

Background Information: The impact of varicoceles on gonadal function in adolescents has been evaluated using several parameters, including size of testes, hormonal levels, and provocative endocrine testing. Inhibin B is decreased in men with testicular damage from conditions other than varicocele.
Application: Evaluation of conditions of varicocele in adolescent boys.
Implementation: Evaluation of conditions of left or bilateral varicoceles using a GnRH stimulation test and the measurement of basal inhibin B, FSH, LH, and testosterone levels. One objective of such a study is to determine if inhibin B levels are low in varicocele conditions, and if there is a relationship between inhibin B and an exaggerated response to GnRH stimulation testing, testicular hypertrophy, and/or varicocele bilaterality.

Human Model: Cases at Tanner stages III–V of pubertal development who had either left or bilateral varicoceles (n = 9 adolescent boys).
Interpretation and Analysis: The vast majority of cases have essentially normal inhibin B levels for Tanner stage. Less than half of boys have an exaggerated response to GnRH stimulating testing (e.g., n = 4/9). Inhibin B levels do not vary significantly either with the presence of bilateral or unilateral varicoceles or asymmetric testis. The lack of correlation between inhibin B levels and the aforementioned parameters fails to suggest that inhibin B has a significant role in the clinical assessment of testicular function in adolescents with varicocele. Further studies of larger populations may further elucidate the value of inhibin B levels and varicoceles.

Serum inhibin B levels and the response to gonadotropin stimulation test in pubertal boys with varicocele. Carrillo A, Gershbein A, Glassberg KI, Danon M. J Urol 1999 Sep; 162 (3 Pt 1), pp. 875–7.

HYPOTHALAMUS, PITUITARY, AND THYROID AXIS

Carcinoma (Thyroid Medullary)/(Familial Chromaffinomatosis)
Oral Whisky/Pentagastrin

Physiological Mechanism of Action: Induces or promotes the secretion of calcitonin.
Background Information: Familial medullary carcinoma of thyroid (MCT) can be diagnosed early by measuring stimulated plasma calcitonin following provocation with oral whisky, or pentagastrin. The calcitonin release, however, can be variable following both stimuli.
Diagnostic Application: Detection of cases associated with thyroid medullary carcinoma.
Route of Administration: Whisky (oral ingestion); pentagastrin (intravenous).
Dosage: Whisky (50 ml); pentagastrin (0.5 $\mu g\ kg^{-1}$).
Implementation: Determine whether a humoral mechanism might be involved in mediating calcitonin release assessed by measuring 9 intestinal (gut) peptides, histamine, alcohol, calcium, and calcitonin plasma concentrations.

Human Model: Cases affected by multiple endocrine neoplasia Type II syndrome (n = 8).
Interpretation and Analysis: Pentagastrin produces significant rises in plasma calcitonin, histamine and pancreatic polypeptide. Whisky produces a variable rise in plasma alcohol, but significant rises in plasma calcitonin, histamine and pancreatic polypeptide as well as insulin ($p < 0.05$). Such observations suggest that histamine may be the mediator of calcitonin release following provocation by either pentagastrin or alcohol (ethanol). Histamine infusion requires evaluation as a screening test for MCT in MEN II syndrome.

Multiple endocrine neoplasia type II: The role of gastrointestinal humoral factors in calcitonin release following alcohol and pentagastrin stimulation. Fletcher DR, Gamvros O, Man WK, Ahmed Y, Trayner I, Adrian T. Aust N Z J Surg 1984 Jun; 54 (3), pp. 271–5.

Whisky: A new provocative test for calcitonin secretion. Dymling JF, Ljungberg O, Hillyard CJ, Greenberg PB, Evans IM, MacIntyre I. Acta Endocrinol (Copenh) 1976 Jul; 82 (3), pp. 500–9.

Carcinoma: Thyroid Medullary: (Hereditary)/(C-Cell Disease)
Omeprazole/Pentagastrin

Cellular/Molecular Mechanism of Action: Pentagastrin and omeprazole both induce the synthesis/release of calcitonin that becomes excessively increased within the plasma in conditions of medullary thyroid carcinoma.
Application: Diagnosis of medullary thyroid carcinoma through induction of serum calcitonin production/release.
Route of Administration: Omeprazole (oral).
Dosage: Omeprazole (20 mg twice a day for 4 days); pentagastrin (0.5 μg/kg of body weight).
Implementation and Validation: Evaluation of conditions of hereditary medullary thyroid carcinoma.
Interpretation and Analysis: In conditions of hereditary medullary thyroid carcinoma, pentagastrin administration produces a significantly higher increase in serum calcitonin than does omeprazole. Occasional, unpleasant side effects are associated with the administration of pentagastrin injection including substantial "tightness" being appreciated in almost all cases. Alternatively, omeprazole is not associated with creating any significant adverse side effects. A direct positive correlation exists between calcitonin-% (ratio of calcitonin peak to basal value $\times$ 100) and gastrin-% (ratio of gastrin peak to basal value $\times$ 100) during the omeprazole test in medullary thyroid carcinoma patients ($r = 0.73$; $p < 0.001$). In spite of several adverse effects, pentagastrin remains the best provocative test for the diagnosis of medullary thyroid carcinoma. Omeprazole may be useful when pentagastrin is contraindicated or refused because of the unpleasant side effects, but further validation is needed.
Instrumentation: Laboratory facilities and reagents necessary for calcitonin radioimmunoassay or ELISA-based methodologies.

Comparison of two provocative tests for calcitonin in medullary thyroid carcinoma: Omeprazole vs pentagastrin. Vitale G, Ciccarelli A, Caraglia M, Galderisi M, Rossi R, Del Prete S, Abbruzzese A, Lupoli G. Clin Chem 2002 Sep; 48 (9), pp. 1505–10.

Carcinoma (Thyroid Medullary)/(Induced Calcitonin Secretion)
Histamine/Calcium/Pentagastrin Infusion/Glucagon

Cellular/Molecular Mechanism of Action: Histamine promotes a secretagogue effect on calcitonin in conditions of medullary thyroid carcinoma.
Application: Characterization of cases of medullary thyroid carcinoma due to its abilty to induce secretion of calcitonin. Glucagon and calcium are other known stimuli for calcitonin secretion in cases of medullary thyroid carcinoma. Histamine will not replace these agents in provocative test, but can provide better insight into the behavior of this neoplastic cell type.
Implementation: Determination of the relative effectiveness of histamine, calcium/pentagastrin, and glucagon as calcitonin secretagogues in cases of medullary thyroid carcinoma.
Interpretation and Analysis: In cases of medullary thyroid carcinoma with undetectable levels of basal plasma calcitonin (e.g., n = 7/15), calcium and pentagastrin can promote detectable elevations in plasma calcitonin concentrations. Similar responses can not be appreciated for histamine or glucagon administration. Alternatively, in cases of modullary thyroid carcinoma that do express detectable base-line levels of calcitonin (e.g., n = 8/15) significant responses can be seen in response to glucagon, calcium/pentagastrin and histamine but the calcium/pentagastrin combination induces the most potent secretagogue effect. Blockade of H2-receptor complexes with cimetidine has no effect on basal calcitonin concentrations and does not suppress responses to histamine, calcium or pentagastrin. The variable secretagogue effect of histamine may be mediated through H1-receptors, through nonspecific vascular dilation "washing out" of preformed calcitonin, or through its destruction to varying degrees by histaminase, present in most medullary thyroid tumors. Histamine is unlikely to replace calcium/pentagastrin as the most discriminative, provocative diagnostic agent in medullary thyroid carcinoma, but correlation of secretory responses with tissue histaminase concentrations and attempted blockade with differing antihistamines will further our understanding of this tumor type.

Some laboratories have proposed that a definitive diagnosis can be established by measuring calcitonin and CEA levels in sera. Cases with normal levels of calcitonin and CEA, the provocative test (Ca-gluconate plus pentagastrin) can be useful (e.g., (pt. no. 11,K.N.)).

Histamine and calcitonin release from medullary thyroid carcinoma. Farndon JR, Lewis KR, Dale JK, Hinshaw WM, Dilley WG, Wells SA Jr. Cancer 1983 Apr 1; 51 (7), pp. 1221–5.

Cancer: Thyroid
Thyroid-Stimulating Hormone (TSH)

Background Information: Detection of recurrent thyroid cancer tumor requires TSH stimulation for radioiodine scanning and thyroglobulin (Tg) measurement. Temporary thyroid hormone withdrawal has previously been used, but causes hypothyroidism and rarely, tumor progression.
Implementation: Evaluation of recombinant thyrotropin (rTSH) assessed in 2 randomized clinical trials in which cases have [^{131}I] and Tg testing twice; (i) initially after rTSH, and (ii) after thyroid hormone withdrawal. Note: Quality of life comparisons have subsequently been made in preliminary investigations.
Interpretation and Analysis: In trials with positive-scan cases (49% of total), rTSH is equivalent to withdrawal in 66%, superior in 5%, and inferior in 29% ($p < 0.05$), suggesting a lesser sensitivity for rTSH scans. In a 2nd trial employing enhanced techniques for patients with positive scans (49%), there are no difference in the number of superior rTSH and withdrawal scans. Furthermore, among all cases with withdrawal study evidence of residual thyroid tissue; 74% of all patients with residual thyroid tissue; and 100% of cases with tumor metastases have rTSH-stimulated thyroglobulin values above 2 ng/mL. Naturally, cases experience significantly more symptoms and diminished quality of life with hypothyroidism than after rhTSH. Therefore, combined rTSH-stimulated radioiodine and Tg testing is as sensitive as thyroid hormone withdrawal to detect recurrent thyroid cancer, and causes less morbidity.

Recombinant thyrotropin for detection of recurrent thyroid cancer. Ladenson PW. Trans Am Clin Climatol Assoc 2002; 113, pp. 21–30.

Cancer: Multiple Endocrine Neoplasia/Multiple Endocrine Neoplasia Type 2A Syndrome (MEN 2A)/Multiple Endocrine Neoplasia Type 2B (MEN 2B)/Familial Medullary Thyroid Carcinoma (FMTC)
Pentagastrin and Calcium Chloride/[Pentagastrin and Calcium Gluconate]

Cellular/Molecular Mechanism of Action: Combined influence of pentagastrin and calcium chloride ($CaCl_2$) promotes the release of calcitonin from certain types of endocrine neoplasias.
Application: Characterization and detection of multiple endocrine neoplasia Type 2A. The pentagastrin provocative test and biochemical screening can be applied to rule out either hyperparathyroidism or pheochromocytoma.

Medullary thyroid carcinoma is a malignancy of the thyroid C-cells that comprises 5–10% of all thyroid cancers. It occurs in both sporadic and familial forms, the latter making up 25% of all MTCs and being comprised of 3 distinct syndromes—MEN 2A, MEN 2B, and FMTC. To date, screening for MTC has been performed using the pentagastrin stimulation test, which is a provocative test for calcitonin release.
Route of Administration: Pentagastrin (intravenous bolus); calcium chloride (intravenous over 5 minutes).
Dosage: Pentagastrin (0.5 μg/kg); calcium infusions (2 mg/kg).
Considerations: RET proto-oncogene analysis can be carried out by automatic DNA sequencing in concert with adequate digestion of PCR amplified products for exons 10 and 11. Two distinct mutations in the RET proto-oncogene have been identified. A T >A transition at position 1783 (codon 618) in exon 10 has been detected in 1 family, and a G >A replacement at position 1832 (codon 634) in exon 11 in others. Germline mutations in the RET proto-oncogene have been identified in families manifesting these syndromes and genetic screening of individuals at risk of 1 of these syndromes has become integral to their clinical management. Majority of the mutations associated with MEN 2A and FMTC are tightly clustered in a cysteine-rich region of the RET receptor. A single mutation associated with MEN 2B is in the tyrosine kinase domain of the RET receptor.
Implementation: Evaluation of MEN 2A as a function of calcitonin release in response to pentagastrin and calcium chloride administration.
Human Model: Cases (n = 44) related to 3 individuals with proven MEN 2A and negative reference controls.
Interpretation and Analysis: Peak calcitonin (CT) levels are usually reached within 2 to 5 minutes after administration of provocative stimulus. Normal subjects have no significant difference in the mean basal CT levels between males (54.8 ± 21.7 pg/ml) and females (56.5 ± 34.8 pg/ml). Mean peak response values for males

is 146.3 ± 120.6 pg/ml, which is significantly different from the mean value of females, namely 71.6 ± 39.0 pg/ml. No significant correlations exists among the basal CT level, peak CT response, and age.

Calcium infusions (2 mg/kg/5 min) in normal individuals (e.g., n = 18 males; n = 37 females) yield a significantly greater secretory response than does pentagastrin (0.5 μg/kg bolus). In cases with medullary thyroid carcinoma (e.g., n = 12), pentagastrin is a better secretagogue than calcium ($p < 0.001$). Therefore, some have recommended routine measurement of plasma silica-extractable calcitonin and pentagastrin injection as the provocative test of choice for the detection and management of medullary thyroid carcinoma. The short calcium-infusion test is a good alternative.

In cases from families with a history of MEN 2A, approximately 20% display exaggerated calcitonin responses to combined pentagastrin/$CaCl_2$ sufficient to warrant thyroidectomy. Histological examination can confirm the presence of C-cell hyperplasia (CCH) (n = 1/9) or medullary thyroid carcinoma (n = 8/9). A relatively high percentage of cases (33%) will have high basal plasma calcitonin. Postoperatively, basal plasma calcitonin levels decline and response to pentagastrin/$CaCl_2$ produces a flat baseline concentration profile. Screening of cases with histological proof of MTC or CCH for a genetic linkage to the gene for MEN 2A using an MCK2 probe usually shows some correlation.

Several families (n = 10) with familial medullary thyroid carcinoma due to V804M mutation have been reported in the literature. Some reports have also described kindreds with not only heterozygous but also homozygous members with the V804M mutation. In gene carriers with the V804M mutation (e.g., n = 4 homozygous; n = 22 heterozygous) the pentagastrin stimulation test result is within normal range for the vast majority of heterozygous gene carriers (thyroidectomy not indicated). Therefore, in some cases, the V804M mutation in heterozygous cases seems not to be enough to express the full disease.

In non-gene carriers, false-positive results for basal calcitonin (6.6%) and for the pentagastrin provocative test (15.4%) can be observed. Based on these observations, the specificity of basal and pentagastrin-stimulated calcitonin is rather limited and RET proto-oncogene analysis is considered by many investigators and clinicians to be the 1st-line screening procedure of choice for the identification of gene carriers.

Experience with provocative and genetic tests strongly supports the concept of the indolent behavior of V804M RET proto-oncogene mutation. Counseling for preventive total thyroidectomy, the specific mutation of RET proto-oncogene, and also the natural history of the disease within a particular family should be considered.

Instrumentation: Scintillation counter and minor laboratory instrumentation necessary for the utilization of a commercial radioimmunoassay for the measurement of serum calcitonin. Radioimmunoassays for human calcitonin in whole plasma are limited in sensitivity and specificity; basal values of calcitonin are often undetectable in normal plasma, and non-specific increases are occasionally found in seemingly healthy persons. Such problems can be avoided by applying a silica-cartridge extraction-concentration technique for calcitonin assay, and the effectiveness of 2 calcitonin stimulation tests in healthy volunteers and patients with medullary thyroid carcinoma has been compared. The radioimmunoassay can be improved by using a new antiserum and a sequential incubation procedure that reduces the previously used sample-volume requirement and incubation period substantially. The method can be used to measure mean basal plasma levels of calcitonin (± SD) in 45 normal men (8.2 ± 5 pg/ml) and 47 normal women (4.8 ± 4 pg/ml) ($p < 0.001$).

Euthyroidism/Euthyroid State: Serum Total Thyroxine (TT4) Response
Thyroid-Stimulating Hormone (TSH)

Physiological Mechanism of Action: Thyrotropin-releasing hormone is produced in the hypothalamus and promotes synthesis/release of pituitary TSH. In turn, recombinant human thyroid-stimulating hormone (rhTSH) induces enhanced thyroid function and the synthesis/release of thyroid hormones.

Background Information: Until a clinically useful canine TSH assay is available, a valid test of thyroid hypofunction should (i) take into consideration valid (or at least predictive) measurement of the free T4 concentration in order to factor out the binding effects of drugs and non-thyroidal illness, and (ii) should assess thyroid functional reserve. A validated equilibrium dialysis measurement of free T4 and the TSH stimulation test provide the most useful diagnostic combination of tests now available. A therapeutic trial with L-thyroxine, despite being relatively safe, should be reserved once any other diagnoses have been ruled out, and should be reevaluated to assure a clinical response that can be attributable to the medication.

Application: Evaluation of normal and diseased thyroid function.

Route of Administration: Thyroid-stimulating hormone (intravenous, intramuscularly, or subcutaneously).

Dosage: Thyroid-stimulating hormone (25 μg, 50 μg, and 100 μg IV compared to 50 μg IM and SQ).

Implementation: Evaluate the effects of rhTSH on serum total thyroxine (TT4) concentration (e.g., euthyroid dogs). Protocol I: TSH response tests can be performed using rhTSH at 3 different total dose levels (IV). Protocol II and Protocol III: TSH response tests are performed using 50 μg of rhTSH (IM vs SQ, respectively).

Animal Model: Canine (n = 6 healthy beagle dogs used in each of the 3 investigation phases).

Interpretation and Analysis: In each phase and following all administered rhTSH doses, an increase in serum TT4 concentration can be appreciated but may not always be significant. Protocol I produces an obvious increase in serum TT4 concentrations. Such observations have fostered the conclusion that 50 μg is the optimal intravenous dose for rhTSH. Conversely, Protocol II and and Protocol III produce no significant increases in serum TT4 after rhTSH administration. Therefore, speculation suggests that rhTSH could be a good substitute for bovine TSH, when used by the intravenous route, for the TSH stimulation test in dogs. Further studies are required to confirm its clinical usefulness.

Use of recombinant human thyroid-stimulating hormone for thyrotropin stimulation test in euthyroid dogs. Sauvé F, Paradis M. Can Vet J 2000 Mar; 41 (3), pp. 215–9.

Hypothyroid Obesity/Euthyroid Obesity
Glucocorticoids/Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: Hypothalamic TRH promotes the release of pituitary thyroid-stimulating hormone (TSH), while glucocorticoids inhibit TSH secretion at the level of the hypothalamus.

Application: Distinguishing conditions of euthyroid obesity from subclinically hypothyroid obese patients.

Route of Administration: Thyrotropin-releasing hormone tests (intravenous bolus injection); dexamethasone (orally).

Dosage: Thyrotropin-releasing hormone test (200 μg) and dexamethasone (2 mg/d in 4 divided doses for 3 days).

Considerations: The presence of an abnormally high TSH response to TRH makes it difficult to distinguish some euthyroid obese subjects from subclinically hypothyroid obese patients.
Interpretation and Analysis: Total thyroxine and triiodothyronine concentrations can be expected to be in the normal range in a high percentage of patients.

Based on the measurement of basal and TRH-stimulated serum thyrotropin (TSH) concentrations, patients can be divided into 3 possible groups including (i) Group I (n = 10), euthyroid subjects; (ii) Group II, euthyroid subjects with normal basal but abnormally elevated TSH responses to TRH; and (iii) Group III (n = 10), subjects with elevated basal and TRH-induced TSH levels (subclinical hypothyroidism). Basal TSH levels are approximately 1.8 ± 0.4 mU/L in Group I, 1.7 ± 0.3 in Group II, and 6.0 ± 0.7 in Group III. In both Groups II and III, TRH-induced TSH increments are above the normal range (maximal increment > 15 mU/L) and significantly higher than values noted for Group I patients. After the 2nd treatment with TRH, pretreatment with dexamethasone significantly decreases both basal TSH levels and peak TSH responses to TRH in all groups. However, a striking percentage of euthyroid obese Group I and Group II patients demonstrate decreases (> 50%) in TRH-induced peak TSH responses, whereas hypothyroid subjects of Group III show only a slight decrement (< 25%). Therefore, it has been proposed that the sensitivity of the TSH secretory system to glucocorticoid inhibitory action is preserved in obese subjects with abnormally elevated TSH response to TRH, but not in subclinically hypothyroid obese patients. The TRH in combination with dexamethozone might be useful in future studies to understand the mechanisms underlying alterations in TSH secretion in obesity.

Thyroid Cancer: Differentiated/Distant Metastatic Disease
Recombinant Thyrotropin

Cellular/Molecular Mechanism of Action: Recombinant thyrotropin stimulates iodine uptake in thyroid tissue.
Application: Detection of differentiated thyroid cancer (± metastasis).
Dosage: Recombinant thyrotropin.
Considerations: Recombinant thyrotropin is a safe and effective diagnostic agent for cases that require radioiodine scanning for routine follow-up. The use of recombinant thyrotropin has fewer adverse effects than does the alternative, which is withdrawal of thyroid hormone replacement, although nausea and headache have been reported. Recombinant thyrotropin is relatively expensive.
Interpretation and Analysis: A serum thyroglobulin > 2 ng/mL and/or a positive whole body scan after recombinant thyrotropin stimulation suggests residual thyroid tissue or neoplastic disease. The combined application of measured serum thyroglobulin concentrations, and whole-body radioiodine scintigraphy can identify virtually all patients with distant metastatic disease.

The use of recombinant thyrotropin in the follow-up of patients with differentiated thyroid cancer. Basaria M, Graf H, Cooper DS. Am J Med 2002 Jun 15; 112 (9), pp. 721–5.

Thyroid Function/Triiodothyronine (T-3); Thyroxine (T4); Free Thyroxine (fT4)/Assay Validation: Phenylbutazone Interference
Thyroid-Stimulating Hormone (TSH)

Application: The TSH stimulation test can be applied to evaluate thyroid function under various physiological conditions, in response to exogenously administered pharmaceutical agents; or validate various analytical assay systems.
Route of Administration: Thyroid-stimulating hormone (intravenous).
Dosage: Thyroid-stimulating hormone (5 IU).
Implementation: Evaluation of the influence of TSH administration on serum concentrations of triiodothyronine (T-3), thyroxine (T4), and free thyroxine (fT4); in addition to determining their serum concentrations at rest and following phenylbutazone administration in healthy horses (7-day administration period).

Animal Model: Equine (normal healthy horses ± phenylbutazone therapy for 7 days).
Interpretation and Analysis: Baseline values range from 0.21 to 0.80 ng of T-3/ml, 6.2 to 25.1 ng of T4/ml, and 0.07 to 0.47 ng of fT-3/dl. Following TSH administration, serum T-3 values increase to 6 times baseline values in 2 hours. Thyroxine values increase to 3 times baseline values at 4 hours and remain high at 6 hours. Free T4 values increase to 4 times baseline values at 4 hours and remain high at 6 hours. Administration of 4.4 mg of phenylbutazone/kg, every 12 hours for 7 days significantly decreases T4 and fT4 values, but does not significantly affect serum T-3 concentrations. Therefore, the TSH stimulation test should be performed when hypothyroidism is suspected. Measurement of serum fT4 concentrations, by the single-stage radioimmunoassay, does not provide any additional information about thyroid gland function over that gained by measuring T4 concentrations. Phenylbutazone given at a dosage of 4.4 mg/kg every 24 hours, for 7 days does significantly decrease resting T4 and fT4 concentrations, but does not significantly affect T-3 concentrations in horses.

Serum triiodothyronine, total thyroxine, and free thyroxine concentrations in horses. Sojka JE, Johnson MA, Bottoms GD. Am J Vet Res 1993 Jan; 54 (1), pp. 52–5.

Thyroid Function/Stimulation Test Optimization (Feline)
Recombinant Human Thyroid-Stimulating Hormone (rhTSH)

Physiological Mechanism of Action: Pituitary or recombinant human TSH activates thyroid gland function and promote the release/synthesis of thyroid hormones.
Application: Evaluate responses of euthyroid cats to the administration of recombinant human thyroid-stimulating hormone (rhTSH).
Route of Administration: Recombinant human TSH (intravenous).
Dosage: Recombinant human TSH (0, 0.025, 0.050, 0.100, and 0.200 mg).
Implementation: Evaluation of serum concentrations of total thyroxine (TT4) and free thyroxine (fT4) measured immediately before each injection (time 0) and 2, 4, 6, and 8 hours after administration of each dose of rhTSH (e.g., n = 5 test doses). Each rhTSH test dose is evaluated at 1-week intervals.

Animal Model: Feline (n = 7 healthy cats).
Interpretation and Analysis: Overall TT4 response does not differ significantly among cats when administered doses are ≥ 0.025 mg. Serum TT4 concentrations peak 6 to 8 hours after administration for all doses ≥ 0.025 mg. For all doses ≥ 0.025 mg, mean ± SEM TT4 concentration at 0, 6, and 8 hours are approximately 33.9 ± 1.7, 101.8 ± 5.9, and 101.5 ± 5.7 nmol/L, respectively. For all doses ≥ 0.025 mg, mean fT4 concentration at 0, 6, and 8 hours are approximately 38.7 ± 2.9, 104.5 ± 7.6, and 100.4 ± 8.0 pmol/L, respectively. At 8 hours, the fT4 response to 0.025 and 0.050 mg is less

than the response to 0.100 and 0.200 mg. Adverse reactions after rhTSH administration usually are not appreciated. The TSH stimulation test can be performed in cats by IV administration of 0.025 to 0.200 mg of rhTSH and measurement of serum TT4 concentrations at time of injection and 6 or 8 hours later. Clinical validation of the TSH stimulation test would facilitate development of additional tests of thyroid gland function, such as a TSH assay.

Use of recombinant human thyroid-stimulating hormone for thyrotropin-stimulation testing of euthyroid cats. Stegeman JR, Graham PA, Hauptman JG. Am J Vet Res 2003 Feb; 64 (2), pp. 149–52.

Thyroid Function/Influence of Physiological Processes and Nutritional Status/Obesity
Thyroid-Stimulating Hormone (TSH)

Cellular/Molecular Mechanism of Action: Thyroid-stimulating hormone is normally produced in the pituitary and when released promotes enhanced thyroid function and the synthesis/release of thyroid hormones.
Background Information: Obesity and weight loss have been shown to alter thyroid hormone homeostasis in humans. In dogs, obesity is the most common nutritional problem encountered and weight loss is the cornerstone of its treatment. Therefore, it is important to clarify how obesity and weight loss can affect thyroid function test results in that species.
Application: Detection and characterization of alterations in thyroid function.
Route of Administration: Thyroid-stimulating hormone test (intravenous).
Dosage: Thyroid-stimulating hormone test (TSH 75 μg).
Implementation: Evaluate thyroid function in obese dogs compared to lean dogs and to explore the effects of caloric restriction and weight loss on thyroid hormone serum concentrations in obese dogs. One approach to achieving this objective is the assessment of thyroid function through the measurement of serum concentrations of total thyroxine (TT4), free thyroxine (FT4), total triiodothyronine (TT-3), thyrotropin (TSH), and reverse triiodothyronine (rT-3) as well as a TSH stimulation test using recombinant human TSH preparations (rhTSH). Complementary investigations can involve the evaluation of obese conditions (e.g., beagles) fed an energy-restricted diet (average 63% maintenance energy requirement [MER]) until an optimal weight is obtained. Blood samples for determination of TT4, FT4, TT-3, TSH, and rT-3 are taken at the beginning and then weekly during periods of weight loss.

Animal Model: Canine (n = 12 healthy lean beagles; n = 12 obese beagles).
Interpretation and Analysis: Only TT-3 and TT4 serum concentrations are significantly higher in obese dogs as compared to lean dogs. In situations where obese dogs are fed an energy-restricted diet, weight loss is associated with a significant decrease in TT-3 and TSH serum concentrations. Thus obesity and energy restriction significantly alter thyroid homeostasis in dogs, but the observed changes are unlikely to affect interpretation of thyroid function test results in clinics.

Evaluation of thyroid function in obese dogs and in dogs undergoing a weight loss protocol. Daminet S, Jeusette I, Duchateau L, Diez M, Van de Maele I, De Rick A. J Vet Med A Physiol Pathol Clin Med 2003 May; 50 (4), pp. 213–8.

Thyroid Function: Hypothyroidism
Thyrotropin-Releasing Hormone (TRH)/Thyroid-Stimulating Hormone (TSH)

Cellular/Molecular Mechanism of Action: Thyrotropin-releasing hormone is produced in the hypothalamus and promotes release of pituitary TSH, which in turn activates the thyroid gland and promotes the release of thyroid hormone.
Application: Characterization of the value of diagnostic tests for the identification of hypothyroid conditions.
Implementation: Evaluation of conditions of hypothyroidism applying the thyrotropin-releasing hormone (TRH) and TSH stimulation tests.

Animal Model: Canine cases with dermatological signs suggestive of hypothyroidism (n = 22; n = 5 normal healthy dogs).
Interpretation and Analysis: Thyroxine (T4) after TRH stimulation is significantly lower than that obtained by TSH stimulation. It is not possible to identify hypothyroid dogs with the TRH-stimulation test, because some euthyroid dogs have either decreases in T4 or only slight increases in T4 concentrations after TRH stimulation. In addition, dogs with pyoderma have decreased responses in serum T4 after TRH stimulation that usually become normal following treatment with antibiotics. Alternatively, the combination of results from a TSH stimulation test, and response to thyroid hormone replacement can be used as a basis for diagnosing hypothyroidism in dogs (e.g., n = 6). It has been concluded that TRH stimulation is not a useful means of diagnosing hypothyroidism in dogs.

Comparison of thyrotropin-releasing hormone (TRH) to thyrotropin (TSH) stimulation for evaluating thyroid function in dogs. Frank LA. J Am Anim Hosp Assoc 1996 Nov–Dec; 32 (6), pp. 481–7.

Thyroid Function: Hyperthyroidism/Critically Ill vs Critically Ill with Hyperthyroidism
Thyroid-Stimulating Hormone (TSH)

Cellular/Molecular Mechanism of Action: Pituitary or recombinant TSH activates the thyroid and promotes synthesis/release of thyroid hormones.
Implementation: Evaluation of conditions of suspected hyperthyroidism. Basal serum thyroxine (T4) concentration and the thyrotropin-releasing hormone (TRH) stimulation test are performed to assess thyroid function.

Animal Model: Feline (n = 22 critically ill hyperthyroid cats with underlying or complicating disease states). Clinical signs include palpable thyroid nodules, and abnormal thyroid gland histology (study group). Cats classified as critically ill that are not hyperthyroid (n = 14).
Interpretation and Analysis: The TRH stimulation test reveals increases in serum T4 of < 50% of the baseline concentration in a large percentage of affected cats (e.g., n = 18/22 or 82% compared to n = 6/22 or 43% of reference controls). Based on the results of serum T4 determinations and the TRH stimulation tests, it is not possible to differentiate between cats with clinical and histologic evidence of thyroid dysfunction (hyperthyroidism) and cats with severe nonthyroidal illnesses.

Thyrotropin-releasing hormone stimulation test to assess thyroid function in severely sick cats. Tomsa K, Glaus TM, Kacl GM, Pospischil A, Reusch CE. J Vet Intern Med 2001 Mar–Apr; 15 (2), pp. 89–93.

Thyroid Function: Hypothyroidism/Euthyroid/Sick Euthyroid
Thyrotropin-Releasing Hormone (TRH)/(Canine Thyroid-Stimulating Hormone [cTSH] Measurement)

Physiological Mechanism of Action: Thyrotropin-releasing hormone is released from the hypothalamus and promotes release of TSH from the pituitary gland.
Application: Adjunct test for characterizing conditions of hypothyroidism, euthyroidism, and sick euthyroidism.
Implementation: Evaluation of cTSH concentrations measured in a variety of clinical conditions. Cases are classified as euthyroid, sick euthyroid, hypothyroid, or hypothyroid on non-thyroidal therapy on the basis of their history, clinical signs, laboratory results (including total thyroxine concentrations and, where indicated, TRH stimulation tests), and response to appropriate therapy. Additional samples are taken during some of the TRH stimulation tests to measure cTSH responses (concentrations) following TRH administration. A reference range can be calculated from the basal concentrations of cTSH (e.g., 0.0–0.41 ng/ml for n = 41 euthyroid dogs).
Animal Model: Canine (n = 72).
Interpretation and Analysis: Approximately 66% of cases of confirmed hypothyroidism will have basal cTSH concentrations above the reference range (e.g., n = 6/9), whereas the remainder will be within the normal range. Some of the remaining cases that do not show a rise in cTSH concentration following TRH stimulation may be due to the presence of pituitary dwarfism (e.g., n = 1/3 or 33%). In contrast, only approximately 15% hypothyroid dogs that have been on non-thyroidal treatment within the previous 4 weeks will have increases in basal cTSH concentrations (e.g., n = 1/6 or 15%). In addition, approximately 30% of dogs with sick euthyroid syndrome have increased cTSH concentrations (e.g., n = 6/15). Therefore, cTSH measurements are a useful additional diagnostic test in cases of suspected hypothyroidism in dogs, but dynamic testing is still required to confirm the diagnosis of hypothyroidism.

Thyroid-stimulating hormone and total thyroxine concentrations in euthyroid, sick euthyroid and hypothyroid dogs. Ramsey IK, Evans H, Herrtage ME. J Small Anim Pract 1997 Dec; 38 (12), pp. 540–5.

Thyroid Function: Hypothyroidism
Thyroid-Stimulating Hormone (TSH)

Cellular/Molecular Mechanism of Action: Thyroid-stimulating hormone is produced in the anterior pituitary (adenohypophysis) and stimulates the production of thyroid hormone by the thyroid gland.
Diagnostic Application #1: The principal application of TSH is for the diagnosis of primary hypothyroidism (e.g., dogs).
Diagnostic Application #2: Hyperthyroid patients (e.g., feline) that display "borderline" or only slightly increased T_3 and T_4 concentrations can be diagnosed with the aid of a TSH response test. Under these circumstances, there is little or no increase in resting T_4 concentrations ($\leq$ 2-fold) within 4 to 6 hours following exogenous TSH administration.
Route of Administration and Dosage: Intravascular injection administered at a dosage of 1.0 IU/kg in feline patients. In canine hypothyroid patients, TSH is administered either intramuscularly or intravenously. Dogs weighing over 20 kg should receive a total dose of 5 IU.
Implementation: Evaluation of thyroid function. Blood samples should be collected from cats prior to TSH administration for the measurement of serum or plasma T_4 concentrations. In dogs, blood samples should be collected at 6 to 8 hours (intravenous TSH), or 8 to 12 hours (intramuscular TSH).
Interpretation and Analysis: Application #1: Pre-TSH T_4 concentrations in the dog are 1.0–4.0 μg/dl, while post-TSH T_4 levels approach 3.5 μg/dl. In cats, pre-TSH T_4 concentrations are 0.8–4.0 μg/dl, with post-TSH T_4 levels $>$ 3.0 μg/dl. Low pre-TSH and post-TSH concentrations of T_4 (less than a 0.5 μg/dl increase) suggest a diagnosis of primary hypothyroidism.
Laboratory Instrumentation: Assay of either cortisol or T_3/T_4 concentrations by either RIA or ELISA.

Thyroid Function/Levothyroxine Efficacy Evaluation
Thyroid-Stimulating Hormone (TSH) Test/Thyrotropin-Releasing Hormone (TRH) Stimulation Test

Cellular/Molecular Mechanism of Action: The stimulating hormone TSH normally is produced in the pituitary, thereby promoting thyroid gland activation and synthesis/release of thyroid hormone.
Application: Characterization of the efficacy of biopharmaceutical agents utilized in the therapeutic intervention for conditions of hyperthyroidism and hypothyroidism.
Implementation: Prospective evaluation of the clinical interchangeability between 2 brands of levothyroxine, Synthroid (Boots Pharmaceuticals, Inc., Lincolnshire, IL) and Levoxine (Daniels Pharmaceuticals, Inc., St. Petersburg, FL) utilizing clinical scores established for hyperthyroidism and hypothyroidism based on the variables/parameters of free thyroxine index (FTI), sensitive TSH, and TRH stimulation testing. This objective can be achieved by delineating observed differences noted with a change in medication from Synthroid to Levoxine (Case Type SL) or Levoxine to Synthroid (Case Type LS). After switching, dosages are kept constant in combination with the recording of clinical scores for hypothyroidism and hyperthyroidism (Billewicz and Crooks scoring systems, respectively), basal FTI, and TRH stimulation test results before and 4 months after therapeutic switching. Comparison of the variables before and after switching is performed separately in each case type (LS or SL) and in the entire group.
Human Model: Cases of hypothyroidism (n = 23/31 with long-standing primary hypothyroidism; n = 6 male; n = 25 female; age range = 30–71 years, mean 47.2 ± 2.2 SEM).
Interpretation and Analysis: No statistically significant differences in the hypothyroid clinical scores (−40.1 ± 1.2 versus −39.7 ± 1.2), the hyperthyroid clinical scores (−19.6 ± 0.9 vs −19.2 ± 1.0), FTI (9.6 ± 0.3 vs 9.6 ± 0.3), basal TSH levels (1.4 ± 0.2 vs 1.4 ± 0.2 mIU/L), or the magnitude of TSH response to TRH (mean delta TSH 9.4 ± 1.5 vs 9.2 ± 1.4 mIU/L) can be detected if they are receiving either Synthroid or Levoxine. Switching does not result in substantial clinical or laboratory changes in any individual patient and the 2 brands of levothyroxine are clinically interchangeable.

Assessment of interchangeability of two brands of levothyroxine preparations with a third-generation TSH assay. Escalante DA, Arem N, Arem R. Am J Med 1995 Apr; 98 (4), pp. 374–8.

Thyroid Hormone Receptor Complex Expression
3,5,3′-triiodo-L-thyronine Analog (GC-1)

Cellular/Molecular Mechanism of Action: High selective binding affinity and activation of thyroid receptor-beta.
Application: Selective detection of thyroid receptor-beta expression that might be useful as an *in vivo* probe for the study of the physiological roles of different thyroid hormone receptor isoforms.
Considerations: Thyroid hormones regulate many different physiological processes in different tissues in vertebrates. Most of the actions of thyroid hormones are mediated by the thyroid hormone receptor (TR), which is a member of the nuclear receptor superfamily of ligand-activated transcription regulators. There are 2 different genes that encode 2 different TRs, TR alpha and TR beta, and these 2 TRs are often co-expressed at different levels in different tissues. Most thyroid hormones do not discriminate between the 2 TRs and bind both with similar affinities.
Molecular Design and Semi-Synthesis: The compound GC-1 has been designed to solve synthetic problems that limit thyroid hormone analog preparation, and contains several structural changes with respect to the natural T-3 hormone (3,5,3′-triiodo-L-thyronine). These changes include replacement of the 3 iodines with methyl and isopropyl groups, replacement of the biaryl ether linkage with a methylene linkage, and replacement of the amino-acid sidechain with an oxyacetic-acid sidechain.
Interpretation and Analysis: The agent GC-1 is a member of a new class of thyromimetic compounds that are more synthetically accessible than traditional thyromimetics and have potentially useful receptor binding and activation properties. The TR beta selectivity of GC-1 is particularly interesting and suggests that GC-1 might be a useful *in vivo* probe for studying the physiological roles of the different thyroid hormone receptor isoforms.

A high-affinity subtype-selective agonist ligand for the thyroid hormone receptor. Chiellini G, Apriletti JW, Yoshihara HA, Baxter JD, Ribeiro RC, Scanlan TS. Chem Biol 1998 Jun; 5 (6), pp. 299–306.

Thyroid-Stimulating Hormone (TSH) and Growth Hormone (GH) Response/Influence of Fatty Acids on Plasma Levels
Thyrotropin-Releasing Hormone (TRH)

Background Information: Supplemental dietary fat provides excess fatty acids (FA) that can alter circulating concentrations of several hormones.
Route of Administration: Thyrotropin-releasing hormone (intramuscular).
Implementation: Evaluation of the effects of fatty acid isomer type on systemic hormone concentrations and possible sites of regulation. One approach to achieving this objective involves the abdominal infusion of fat mixtures high in *cis*-C18:1 FA (iCIS), high in *trans*-C18:1 FA (iTRS), or no infusion (NI) and performed intravenous arginine (ARG) and intramuscular TRH challenges. Challenges are conducted on days 10 (ARG) and 12 (TRH) after initiation of fat infusion on each of 3 4-week experimental periods. Assessment of fat regulation of the thyroid axis can be tested directly *in vitro* by characterizing the ability of fatty acids dissolved with sodium taurocholate to affect Type-I 5′-deiodinase (5′D) activity in bovine liver homogenates.
Animal Model: Bovine and bovine liver homogenates.
Experimental Design: Replicated 3 × 3 Latin square.
Interpretation and Analysis: Plasma concentrations of insulin-like growth factor-I (IGF-I) are lower ($p < 0.01$) when cows receive iCIS or iTRS compared with no fat infusion. Plasma insulin concentrations increase with ARG but responses are not affected by FA. Plasma GH remains unchanged after ARG. Peak plasma GH and TS) responses to TRH are blunted ($p < 0.05$ and $p < 0.1$, respectively), whereas thyroxine (T4) and triiodothyronine (T-3) responses are augmented post-TRH ($p < 0.01$) when cows receive either FA isomer. Prolactin responses to TRH are not different between infusion treatments, although basal plasma concentrations before TRH are higher in cows infused with iTRS ($p < 0.05$). Homogenate 5′D is not affected by C2:0-C10:0 fatty acids, but decreases linearly ($p < 0.01$) with increasing concentrations of C12:0-C16:0 and C18:1 isomers. *Cis* C18:1 decreases 5′D more than the *trans*-isomer ($p < 0.01$), but the difference is only apparent at concentrations > 0.25 mM. The data suggest that various aspects of pituitary hormone regulation are differentially affected by FA composition. Fatty acid infusion may accentuate end organ responses in the thyroid axis and decrease IGF-I in the somatotropic axis. The data also suggest that FA isomer may alter patterns of extrathyroidal generation of thyroid hormones via direct influences on 5′D.

Dietary fatty acids modulate hormone responses in lactating cows: Mechanistic role for 5′-deiodinase activity in tissue. Romo GA, Elsasser TH, Kahl S, Erdman RA, Casper DP. Domest Anim Endocrinol 1997 Nov; 14 (6), pp. 409–20.

PARATHYROID

Hyperparathyroidism (Primary): Normocalcemia
Calcium Gluconolactate

Route of Administration: Calcium gluconolactate (oral).
Dosage: Calcium gluconolactate (1 g).
Implementation: Evaluation of normocalcemic primary hyperparathyroidims using the oral calcium-loading test (OCLT). Calcium and parathyroid hormone (PTH) levels are measured before and 60, 120, and 180 minutes after calcium gluconolactate administration.
Human Model: Cases with high circulating PTH levels (e.g., n = 102 consecutive females) and reference control subjects (e.g., n =25). Patients can be classified as Group A, patients with a parathyroid adenoma identified by 2 imaging modalities; Subgroup AO, hyperparathyroid patients (n = 13, mean age 59 years [SD = 10]) evaluated prior to parathyroidectomy; Subgroup AH, non-operated hypercalcemic patients (n = 29, age 63 years [SD = 11]); Subgroup AN, normocalcemic non-operated women (n = 14, age 59 years [SD = 8]); Group B, normocalcemic individuals (n = 46, age 58 years [SD = 11]) with negative parathyroid imaging; and Group C, control patients (n = 25, age 56 years [SD = 12]).
Interpretation and Analysis: The concentrations of calcium and PTH may overlap in the normocalcemic groups during the OCLT. Product P, defined as circulating PTH nadir (pg/ml) × peak calcium concentration (mg/dl), better discriminates Subgroup AN from Group B, AUC = 0.98 (95% CI 0.95, 1.00) than does Ratio R, defined as relative PTH decline/relative calcium increment, AUC = 0.86 (95% CI 0.73, 0.99). Assuming a normal threshold of Product P and Ratio R at 260 and 17, respectively, the combined parameters diagnose normocalcemic hyperparathyroid patients with 100% sensitivity and 87% specificity.

Diagnosis of normocalcemic hyperparathyroidism by oral calcium loading test. Hagag P, Revet-Zak I, Hod N, Horne T, Rapoport MJ, Weiss M. J Endocrinol Invest 2003 Apr; 26 (4), pp. 327–32.

Hyperparathyroidism: Secondary
Calcium Gluconate/Sodium Citrate

Background Information: The parathyroid glands play a critical role in the maintenance of calcium homeostasis. It has been suggested that the set-point for calcium-regulated parathyroid hormone

(PTH) release is higher in uremic patients than normal subjects. However, these assessments of parathyroid gland function have been performed using methods that differ from the original 4-parameter model.

Route of Administration: Calcium gluconate and sodium citrate (infusion).

Implementation: Dynamic testing of the parathyroid glands can be performed with standardized infusions of calcium gluconate and sodium citrate for the evaluation of conditions of secondary hyperparathyroidism and the efficacy of calcitriol therapy (intermittent over a 4-month period).

Human Model: Cases on dialysis with secondary hyperparathyroidism and normal healthy control volunteers.

Interpretation and Analysis: Derived values for the set-point are 1.21 ± 0.04 mmol/l and 1.24 ± 0.06 mmol/l, respectively in control and dialyzed patients. Furthermore, the values for set-point are 1.21 ± 0.01 and 1.22 ± 0.01 mmol/l (NS), before and after calcitriol therapy. In addition, when subjects are grouped according to severity of secondary hyperparathyroidism, the set-point calcium-regulated PTH release does not differ between case group types. Calcitriol therapy alters the secretory capacity of the parathyroid glands during hypocalcemia. The degree of parathyroid enlargement and the type of cell proliferation may be more important determinants of the severity of secondary hyperparathyroidism.

Parathyroid gland function in secondary hyperparathyroidism. Salusky IB, Goodman WG. Pediatr Nephrol 1996 Jun; 10 (3), pp. 359–63.

Parathyroid Hormone (PTH) Secretion
Calcium

Physiological Mechanism of Action: Acute hypercalcemia suppresses both the pulsatile and the tonic component of PTH secretion.

Route of Administration: Intravascular (intravenous).

Implementation: Evaluate instantaneous PTH secretion as a function of alterations in ionized calcium concentration. Blood sampling (1 minute) is performed under conditions of normo-, hypo-, and hypercalcemia. The characteristics of PTH secretion are analyzed by a deconvolution technique, accounting for subject-specific plasma PTH disappearance half-life, as measured during the 1st 15 minutes of calcium infusion (range, 2.04–2.93 minutes). The process regularity of pulsatile PTH secretion is evaluated by an approximate entropy statistic.

Human Model: Cases without health abnormalities (n = 7 young healthy volunteers).

Interpretation and Analysis: After a baseline period of 75 minutes, ambient ionized calcium is either increased or decreased by 0.2 mmol/L for 105 minutes by clamped infusion of calcium gluconate or sodium citrate. Under baseline conditions, 32% of total PTH secretion is released in a pulsatile fashion, with a burst frequency of 6.9 ± 0.8 h-1 and a PTH mass per burst of 2.6 ± 0.9 pmol/L. The remaining 68% of total secretion is attributed to tonic hormone release. During the initial 30 minutes of induced hypocalcemia, pulsatile secretion increases by 1,140%, whereas tonic secretion does not change. The preferential increase in pulsatile PTH secretion is mediated by a combined rise in burst frequency and mass released per burst. During subsequent steady state hypocalcemia, the tonic secretion rate increases (255% of baseline), whereas burst frequency and burst mass decreases (to 103% and 189% of the baseline values), restoring the baseline ratio of tonic to pulsatile PTH secretion. The regularity of PTH release increases during steady state hypocalcemia. During hypercalcemia, tonic secretion, burst mass, and burst frequency decreases by 75%, 82%, and 32%, respectively, and remains constant throughout the clamp period. Acute hypocalcemia therefore, elicits an immediate pulsatile and a delay in tonic secretory response of the parathyroid gland with increased regularity of PTH release. Acute hypercalcemia suppresses both the pulsatile and the tonic component of PTH secretion.

Control of pulsatile and tonic parathyroid hormone secretion by ionized calcium. Schmitt CP, Schaefer F, Bruch A, Veldhuis JD, Schmidt-Gayk H, Stein G, Ritz E, Mehls O. J Clin Endocrinol Metab 1996 Dec; 81 (12), pp. 4236.

Pseudohypoparathyroidism/Hypoparathyroidism
Synthetic Parathyroid Hormone Fragment (PTH-1-34)/ [cAMP]

Cellular/Molecular Mechanism of Action: A synthetic amino-terminal fragment of PTH (PTH-1-34) has recently been released for clinical testing of PTH responsiveness.

Application: Clinical testing of PTH responsiveness in conditions including pseudohypoparathyroidism and idiopathic hypoparathyroidism.

Route of Administration: Intravenous over a 10-minute time span.

Dosage: Synthetic amino-terminal fragment of PTH, PTH-1-34 (3U/kg BW [200 U maximum]).

Considerations: Induction of hypercalcemia can fail to restore normal cAMP responses to PTH-1-34 infusion in cases of pseudohypoparathyroidism. The synthetic parathyroid hormone fragment (PTH-1-34) is effective for the study of renal responsiveness to PTH. Protocols have been described that facilitate reliable differentiation between pseudohypoparathyroidism from hypocalcemia due to other causes.

Implementation: Synthetic amino-terminal fragment of PTH (PTH-1-34) can be applied to evaluate conditions of pseudohypoparathyroidism and hypoparathyroidism. Urinary cAMP and phosphaturic responses are measured in urine samples collected at 30-minute intervals in addition to the analysis of 4 blood samples drawn following PTH infusion.

Interpretation and Analysis: Calculation of the urinary excretion of cAMP in response to PTH-1-34 in nanomoles/dL of glomerular filtrate during the 1st 30 minutes after infusion provides better differentiation among groups than other parameters of cAMP metabolism. Calculating the phosphaturic response as the percent fall in tubular maximum for phosphate reabsorption during the 1st hour after infusion gives the best degree of statistical separation among groups.

In cases of pseudohypoparathyroidism (hypocalcemia with increased serum immunoreactive PTH concentrations) it is possible to differentiate between suspected pseudohypoparathyroidism, surgical hypoparathyroidism, and normal patients. Pseudohypoparathyroidism conditions are recognized by blunted cAMP and phosphaturic responses to PTH-1-34 administration compared to those of either normal or hypoparathyroid subjects.

Synthetic human parathyroid hormone-(1-34) for the study of pseudohypoparathyroidism. Mallette LE, Kirkland JL, Gagel RF, Law WM Jr, Heath H 3rd. J Clin Endocrinol Metab 1988 Nov; 67 (5), pp. 964–72.

4 Gastrointestinal System

DENTISTRY, ORAL CAVITY, AND SALIVARY GLANDS

Calcium-Binding Peptides
Enamel Proteins/Sheathlin

Cellular/Molecular Mechanism of Action: Enamel proteins possess binding avidity for Ca^{++} cation.
Background Information: Dental enamel is believed to form by the transfer of ions from solution, primarily calcium, phosphate, hydroxyl, and carbonate, to the surface of solid-state mineral. Such precipitation phenomena can be controlled by regulating the degree of saturation of the solution with respect to the potential solid phases that can form. The concentration of free calcium is the factor that most affects the degree of saturation for calcium hydroxyapatite, and its buffering by calcium-binding proteins has been proposed as the mechanism that determines the mineral structure of enamel.
Application: Detection of calcium cation, physically binding to solid calcium containing matrixes dependent upon or involving mechanisms of competitive inhibition of an enzyme requiring calcium as a biochemical co-factor.
Implementation: Application of staining reagents that can be used to identify and isolate calcium-binding proteins from the enamel matrix and to determine their structures and association constants for calcium.
Animal Model: Porcine.
Interpretation and Analysis: Proteolytic cleavage fragments derived from the C-terminus of sheathlin, with apparent molecular weights of 13-kDa, 15-kDa, 27-kDa, and 29-kDa, can be characterized by amino-terminal protein sequencing, amino acid analysis, and sugar, phosphate, and sulphate determinations. Sheathlin C-terminal cleavage products have been shown to have no N-linked glycosylations or phosphorylated amino acids, but Pro(350) is hydroxylated, and there is 1 sulphated O-linked glycosylation at Thr(386), containing galactose and N-acetylgalactosamine. The calcium-binding association constants for enamel proteins range from a high of 1.2×10^4 M(-1) to a low of 4.4×10^1 M(-1). The relative strengths of binding in order of decreasing affinity are: 13-kDa and 15-kDa calcium-binding domain of sheathlin $>$ 27-kDa and 29-kDa calcium-binding proteins $>$ 32-kDa enamelin $>$ 89-kDa enamelin $>$ 6.5-kDa, 25-kDa, 23-kDa, 20-kDa, 13-kDa, 5.3-kDa amelogenins. If enamel proteins have similar calcium-binding properties *in vivo* as they possess when measured *in vitro*, they would tend to buffer the free calcium ion concentration in enamel fluid.

Calcium binding of enamel proteins and their derivatives with emphasis on the calcium-binding domain of porcine sheathlin. Yamakoshi Y, Tanabe T, Oida S, Hu CC, Simmer JP, Fukae M. Arch Oral Biol 2001 Nov; 46 (11), pp. 1005–14.

Dental Caries
Red Acid Dye

Cellular/Molecular Mechanism of Action: Selectively stains dental caries. Deposits of demineralized dentine are preferentially stained in a manner that can be directly visualized.
Application: Detection of dental caries.
Route of Administration: Topical/oral.
Implementation: Determination of the effectiveness of red acid dye in detecting dental caries.
Interpretation and Analysis: A high percentage of junior dental students fail to remove all demineralized dentine without the use of a caries detector reagent (stage 1 = 96% and stage 2 = 79%). In comparison, all senior dental students may fail to diagnose dental caries without the use of a dental caries detector (stage 1 = 100% and stage 2 = 0%). Unlike junior students, a majority (e.g., all) of the senior students during the 2nd stage of their training program will remove all of the demineralized dentine. Without the use of a caries detector dye, the risks of the dental students leaving demineralized dentine is high. This technique may be particularly helpful for the 4th-year students who are performing their 1st restorative treatment.
Instrumentation: None.

In vivo diagnostic assessment of dentinal caries by junior and senior students using red acid dye. Tassery H, Déjou J, Chafaie A, Camps J. Eur J Dent Educ 2001 Feb; 5 (1), pp. 38–42.

Dental Caries
Red Acid Dye/Povidone Iodine Dye

Cellular/Molecular Mechanism of Action: Selectively stains dental caries but does not stain the surface of intact ("mineralized") enamel.
Application: Identification of carious dentin.
Route of Administration: Topical/oral.
Dosage: Acid red (1% acid red in propylene glycol wt/wt) and povidone-iodine (8% povidone-iodine in water wt/vol).
Implementation: Evaluation of the ability for acid red and povodine iodine to detect dental lesions (n = 221 cavities in a double blind study design; n = $\geq$ 2/case).
Interpretation and Analysis: Acid red and povidone-iodine positively stain defects in the dental enamel. Their application reveals that molars and premolars do not appear to be positively stained more frequently by either 1 of the dye formulations. Approximately one-third (36.7%) of teeth may test postive to 1 of the 2 dye reagents. Application of either acid red or povidone-iodine dyes is of value in clinical decision-making processes regarding cavity size while restoring dentinal lesions. However, povidone-iodine may be preferred in clinical settings where acid red is expensive and/or difficult to obtain. Further research is necessary to establish accurately the mechanism of staining by povidone-iodine.

In vivo diagnostic assessment of dentinal caries utilizing acid red and povidone-iodine dyes. Maupomé G, Hernández-Guerrero JC, García-Luna M, Trejo-Alvarado A, Hernández-Pérez M, Díez-de-Bonilla J. Oper Dent 1995 May–Jun; 20 (3), pp. 119–22.

Oral Cancer Lesions/Differentiation: Premalignant vs Malignant Lesions
5-Aminolevulinic Acid (5-ALA)-Induced Protoporphyrin IX (PPIX) Fluorescence

Cellular/Molecular Mechanism of Action: 5-aminolevulinic acid is capable of promoting the fluorescence from protoporphyrin IX compounds.
Background Information: 5-aminolevulinic acid induces fluorescence of PPIX that provides a 95–100% sensitivity level for detecting oral cancer with a corresponding specificity level of only approximately 50–60%.
Application: Differentiation of premalignant from malignant forms of oral cancer applying PPIX fluorescence endoscopy and fluorescence image quantification.
Route of Administration: Topical.
Implementation: Characterization of oral premalignant and malignant lesions applying PPIX fluorescence endoscopy and fluorescence image quantification. To improve diagnostic specificity, 5-ALA mediated digitized fluorescence endoscopic imaging systems have been designed that enable on-line image acquisition, analysis, and fluorescence quantification for early detection of oral cavity neoplasms.

Human Model: Cases of suspected premalignant and malignant lesions of the oral cavity (e.g., n = 16).
Interpretation and Analysis: Head and neck clinical trials have shown that the red-to-blue intensity ratio of malignant tissue is larger than that of benign tissue. By applying the intensity ratio as a diagnostic algorithm, both high specificity and sensitivity can be achieved for discriminating malignant tissue from benign tissue, and the capability of classifying different histopathological stages of oral lesions has also been demonstrated. Red fluorescence intensity distribution in lesion areas could also be obtained to better understand PPIX tissue accumulations. Our initial results indicate that the digitized endoscopic imaging system combined with the fluorescence image quantification method and the ratio diagnostic algorithm has the potential to significantly improve the non-invasive *in vivo* diagnosis of early oral neoplasms.

Detection of neoplasms in the oral cavity by digitized endoscopic imaging of 5-aminolevulinic acid-induced protoporphyrin IX fluorescence. Zheng W, Soo KC, Sivanandan R, Olivo M. Int J Oncol 2002 Oct; 21 (4), pp. 763–8.

Oral Lesions/Differentiation: Oral Premalignant vs Malignant Squamous Cell Carcinoma
5-Aminolevulinic Acid (5-ALA)-Induced Protoporphyrin IX (PPIX) Fluorescence

Background Information: Studies of 5-ALA-induced PPIX fluorescence have shown a sensitivity of 95 to 100% for oral cancer diagnosis, but the specificity is only about 50 to 60%.
Application: Quantifying PPIX fluorescence imaging for specific diagnostic detection of early oral lesions (differentiation of premalignant from malignant disease states).
Implementation: Fluorescence endoscopy and imaging are performed on cases with suspected premalignant or malignant oral cavity lesions in conjunction with the collection of biopsy samples (e.g., n = 70) from tissue sites that will be evaluated by histological analysis. The red-to-blue and red-to-green intensity ratios are calculated from fluorescent images for correlation with histology analysis.

Human Model: Cases with known or suspected premalignant or malignant neoplasia of the oral cavity (e.g., n = 28).
Interpretation and Analysis: Suspicious lesions display bright reddish fluorescence, while normal mucosas exhibit blue color background in the fluorescence images. The red-to-blue and red-to-green intensity ratios of malignant tissues are larger than those of benign tissues. Combining the 2 ratio diagnostic algorithms yields a sensitivity and specificity of 95% and 97%, respectively, exceeding each diagnostic algorithm alone for discriminating malignant tissue from benign tissue. Quantifying PPIX fluorescence endoscopic images combined with ratio diagnostic algorithms has the potential to significantly improve the *in vivo* non-invasive diagnosis of oral cavity lesions.
Instrumentation: Fluorescence endoscopy.

Detection of squamous cell carcinomas and pre-cancerous lesions in the oral cavity by quantification of 5-aminolevulinic acid induced fluorescence endoscopic images. Zheng W, Soo KC, Sivanandan R, Olivo M. Lasers Surg Med 2002; 31 (3), pp. 151–7.

Salivary Gland Secretory Function: Xerostomia
Muscarinic Agonists/Pilocarpine Hydrochloride (CAS 54-71-7)/Cevimeline (CAS 153504-70-2)

Cellular/Molecular Mechanism of Action: Pilocarpine hydrochloride ((3S,4R)-3-ethyl-dihydro-4-[(1-methyl-1H-imidazole-5-yl)methyl]-2(3H)-furanone monohydrochloride, CAS 54-71-7) and cevimeline [(±)-*cis*-2-methylspiro[1,3-oxathiolane-5,3′-quinuclidine] hydrochloride, hemihydrate, CAS 153504-70-2) bind to and stimulate parasympathetic muscarinic receptors (agonist activity).
Physiological Mechanism of Action: Parasympathomimitic activity.
Application: Assess secretion from the submandibular/sublingual (SM/SL) salivary glands relevant to various disease states including xerostomia.
Route of Administration: Pilocarpine hydrochloride (i.d.) and cevimeline (i.d.).
Dosage: Pilocarpine hydrochloride (0.1–0.8 mg/kg) and cevimeline (3–30 mg/kg) in rats.
Implementation: Evaluate the influence of pilocarpine hydrochloride ((3S,4R)-3-ethyl-dihydro-4-[(1-methyl-1H-imidazole-5-yl)methyl]-2(3H)-furanone monohydrochloride, CAS 54-71-7) and cevimeline ((±)-cis-2-methylspiro[1,3-oxathiolane-5,3′-quinuclidine] hydrochloride, hemihydrate, CAS 153504-70-2), muscarinic receptor agonists, on salivary secretion. To clarify their pharmacological safety profiles, the 2 drugs can be further compared with regard to subtype selectivity for muscarinic receptors (M1, M2, and M3) and central nervous, respiratory, and cardiovascular effects.

Animal Model: Rat submandibular/sublingual salivary gland (normal and x-radiation induced xerostomia [15 Gy dose]).
Interpretation and Analysis: Pilocarpine hydrochloride and cevimeline induce dose-dependent increases in salivary flow rate and total salivary volume over a 120-minute period from SM/SL glands in both normal and irradiated rats, the minimum effective doses for their sialagogic effects being 0.2 and 10 mg/kg, respectively. Both drugs also increase protein output from SM/SL glands to a degree that depends on the increase in salivary volume in normal and irradiated rats. In binding studies using radiolabeled antagonists, neither pilocarpine hydrochloride nor cevimeline displays subtype selectivity for muscarinic receptors, indicating non-selective muscarinic agonist

activity. Effects on the central nervous system (CNS) are assessed by monitoring changes in body temperature in conscious normal rats. Pilocarpine hydrochloride (0.4–4 mg/kg p.o.) has no effect on body temperature, but cevimeline (30 and 100 mg/kg p.o.) causes significant hypothermia. In terms of respiratory and cardiovascular effects in anesthetized normal rats, there is no clear difference in safety margin between pilocarpine hydrochloride and cevimeline because both drugs induce significant changes in respiratory rate, heart rate, and blood pressure at doses close to those inducing sialagogic effects. Pilocarpine hydrochloride could be used as a sialagogic drug for postirradiation-induced xerostomia with fewer adverse effects on the CNS.

Effects of pilocarpine hydrochloride and cevimeline on submandibular/sublingual salivation in rat xerostomia model produced by x-ray irradiation. Omori Y, Asari T, Maruyama K, Kusama H, Kojima M, Shibata N. Arzneimittelforschung 2003; 53 (5), pp. 342–50.

ESOPHOGEAL FUNCTION AND DISORDERS

Achalasia and Idiopathic Diffuse Esophageal Spasm (IDES)
Pentagastrin

Route of Administration: Subcutaneous.
Dosage: Pentagastrin (6 μg/kg).
Considerations: Thoracic pain or dysphagia can occur after pentagastrin administration in cases suffering from IDES (e.g., n = 4/9 cases) or achalasia (e.g., n = 7/12). Pentagastrin is not a suitable provocative test for establishing a diagnosis of IDES conditions.
Implementation: Assessment of esophageal motility in conditions of achalasia in cases with idiopathic diffuse esophageal spasm (IDES). Pentagastrin is not an effective diagnostic pharmaceutical for achieving this objective.
Interpretation and Analysis: Pentagastrin in cases of achalasia and IDES produces increases in mean lower esophageal sphincter pressure, amplitude of contractions, esophageal pressure, and repetitive wave activity.

In cases with clinically suspected esophageal motor disease with non-diagnostic routine radiologic and manometric profiles it is invariably almost impossible to establish IDES as a diagnosis.

Pentagastrin in diffuse esophageal spasm. Wexler RM, Kaye MD. Gut 1981 Mar; 22 (3), pp. 213–6.

Achlasia: Idiopathic Diffuse Esophogeal Spasm (IDES)
Pentagastrin

Physiological Mechanism of Action: Pentagastrin produces an increase in mean lower esophageal sphincter pressure, amplitude of contractions, esophageal pressure, and repetitive wave activity in cases of achalasia and IDES.
Application: Differentiation between cardiac and esophageal-associated chest pain.
Route of Administration: Pentagastrin (subcutaneous injection).
Dosage: Pentagastrin (6 μg/kg).
Considerations: Chest pain or dysphagia can occur after pentagastrin administration (4/9 IDES and 7/12 achalasia). Preliminary findings do not support the use of pentagastrin as a provocative test for IDES.
Implementation: Evaluation of esophageal motility in cases with suspected esophageal motor disease (achalasia/idiopathic diffuse esophageal spasm) that have normal radiologic and manometric profiles.
Interpretation and Analysis: Symptoms or manometric changes cannot be appreciated to assist in establishing a diagnosis of IDES. Preliminary findings therefore suggest that pentagastrin is unsuitable for the specific purpose of differentiating esophageal verses cardiac associated causes for chest pain.

The effects of pentagastrin in achalasia and diffuse esophageal spasm. Orlando RC, Bozymski EM. Gastroenterology 1979 Sep; 77 (3), pp. 472–7.

Esophogeal Function: Diffuse Spasmodic Activity
Edrophonium

Application: Detection of diffuse esophogeal spasms. Because of the intermittent nature of the associated symptoms, edrophonium functions as an effective provocative agent to increase diagnostic yield/accuracy.
Route of Administration: Edrophonium (intravenous).
Dosage: Edrophonium (10 mg bolus).
Implementation: Evaluation of esophageal function in conditions of suspected esophageal spasm. Transnasal monometry can be performed using instrumentation with 6 internal transducers arranged at 5 cm intervals from the catheter tip (e.g., Gaeltec system).

Human Model: Criteria for diffuse esophageal spasm (DOS) candidates include the observation of dysphagia and chest pain. Esophageal manometry shows retention of peristalsis with the presence of synchronous contractions in response to wet swallows.
Interpretation and Analysis: A reproduction of symptoms with typical manometry of diffuse esophageal spasms indicates a positive provocation test response. There are no significant side effects that can be detected. Diffuse esophageal spasms can be diagnosed either by typical manometry or a positive edrophonium provocation test. Approximately 66% of positive patients will have diagnostic baseline manometry measurements, and close to 50% of these cases will display a positive provocation test. About 33% of the cases that have normal baseline manometry measurements have positive provocation tests following edrophonium injection. Therefore, without the application of the edrophonium provocation test, about a 3rd of patients would not have been diagnosed as having diffuse esophageal spasms.

Edrophonium provocation test in the diagnosis of diffuse esophageal spasm. Linsell J, Owen WJ, Mason RC, Anggiansah A. Br J Surg 1987 Aug; 74 (8), pp. 688–9.

Esophogeal Motor Function Disorders/ Esophogeal/Gastroesophogeal Reflux
Edrophonium

Cellular/Molecular Mechanism of Action: Edrophonium binds to and directly inactivates the biochemical activity of acetylcholine esterase. As a consequence of acetylcholine esterase inhibition, acetylecholine neurotransmitter concentrations accumulate within the synaptic cleft thereby increasing the (over) stimulation of cholinergic receptor complexes.
Physiological Mechanism of Action: Increased parasympathetic tone.
Application: Diagnosis of esophageal contraction abnormalities involving either painful spasms or acalasia. In this context, edrophonium has been shown to be the most effective and best tolerated provocative agent for the evaluation of esophageal function.
Implementation: Evaluation of the contractile activity of the esophageal body and of the upper and lower esophageal sphincter (LOS) that can reliably be portrayed by means of low compliance

recording systems, either pneumohydraulic or with strain gauge force transducers, and at least 2 pressure sensors. LOS resting pressure can be assessed by both station and rapid pull-through techniques, or by the sleeve method. Conditions of disordered LOS function, such as achalasia, can be diagnosed dependably only by manometric means. Manometry is of high diagnostic yield for motor disorders of the esophageal body as well, although generally accepted diagnostic criteria are still lacking. In patients with angina-like chest pain, provocation tests can prove that esophageal contraction abnormalities cause the symptoms.

Interpretation and Analysis: Transport of swallowed material through the esophagus can reliably be recorded by radionuclide transit studies. Such studies are valuable in identifying patients with absent or impaired peristalsis and in evaluating treatment effects (e.g., effects of mechanic dilatation in achalasia). Gastroesophageal reflux should be recorded not only qualitatively but also quantitatively, although a definition of what is pathologically normal has not been universally standardized. Recording of esophageal intraluminal pH over longer periods of time, preferably 24 hours may have the best diagnostic yield. The advent of computer-aided analysis techniques will replace the cumbersome handscoring of motor and pH tracings and, hopefully, contribute to a better understanding and classification of esophageal pathophysiology.

Methods for measuring the motor activity of the esophagus and gastroesophageal reflux. Stacher G. Z Gastroenterol 1986 Sep; 24 Suppl 2, pp. 26–34.

Esophogeal Motor Function/Gastroesophogeal Reflux Disease (GERD)
Cisapride/Mosapride

Cellular/Molecular Mechanism of Action: Cisapride is a gastric prokinetic agent that promotes acetylcholine release through an action on presynaptic serotonin (5-HT4) receptors.

Application: To evaluate the efficiency of the 5-HT4 agonist and 5-HT3 antagonist mosapride, as compared with cisapride, on esophageal acid reflux variables and esophageal motor function in patients with chronic GERD.

Dosage: Mosapride (60 mg BID); mosapride (30 mg TID); cisapride (20 mg BID) for 7 days (alternating in a randomized order and separated by a washout period of at least 5 days).

Implementation: Evaluation of GERD conditions applying mosapride, mosapride, and cisapride. Recordings of 24-hour gastric pH and motility obtained in an ambulatory manner within 2 weeks before the start of each pharmaceutical exposure period and on day 7 of each exposure period.

Animal Model: Cases of proven GERD (n = 41). Design: double blind, randomized, double-dummy, 3-way crossover study; n = 24/41 ambulatory cases with 24-hour measurement of pH and motility; n = 18/41 cases with acquisition of ambulatory 24-hour pH recordings only on treatment day 7 of each treatment period.

Interpretation and Analysis: Mosapride has no significant effect on the total number of contractions in the esophagus, or on the effectiveness, or possible effectiveness, of the propagations. Significant but numerically small effects on peristaltic durations and amplitudes can be noted during both mosapride and cisapride treatment as compared with baseline values. The effect on acid reflux for both mosapride and cisapride is most pronounced for the duration of the longest reflux episode. The fraction of time with pH < 4 is reduced by mosapride 30 mg TID in the supine position and by cisapride both totally and in the supine position. The number of reflux episodes is reduced significantly only by cisapride. Esophageal clearance is reduced significantly by cisapride only in the supine position. Mosapride has small but statistically significant effects, comparable to those of cisapride, on acid reflux variables and esophageal motor function in patients with GERD.

The effect of mosapride on esophageal motor function and acid reflux in patients with gastroesophageal reflux disease. Ruth M, Finizia C, Cange L, Lundell L. Eur J Gastroenterol Hepatol 2003 Oct; 15 (10), pp. 1115–21.

Thoracic Pain: Atypical Non-Specific/ (Esophagitis Postive Cases)
Bernstein Test (Intraesophageal Acid Perfusion)

Application: Characterization of atypical non-specific thoracic pain.

Considerations: Treatment with either ranitidine or antacids had equivalent effectiveness.

Implemenation: Detection and characterization of thoracic pain of non-cardiac origin.

Human Model: Cases with signs of thoracic pain without signs of heartburn or other characteristic symptoms of esophagitis (n = 60).

Interpretation and Analysis: A positive Bernstein test result in children with non-specific chest pain indicates that thoracic pain is likely associated with esophageal disease. In cases of atypical chest pain without heartburn or other characteristic symptoms of esophagitis, a relatively high percentage (n = 45) have esophagitis. In this subcategory (18/45 or 40%), pain replicating the usual symptoms develops during esophageal acid perfusion. Conversely, cases without esophagitis (n = 15), chest pain does not develop during esophageal acid perfusion. A small number of cases with esophagitis (n = 3), esophageal manometric abnormalities and chest pain developed as a result of esophageal acid perfusion.

Esophageal sensitivity and symptom perception in gastroesophageal reflux disease. Shi G, Tatum RP, Joehl RJ, Kahrilas PJ. Curr Gastroenterol Rep 1999 Jun; 1 (3), pp. 214–9.

The symptom index: A clinically important parameter of ambulatory 24-hour esophageal pH monitoring. Wiener GJ, Richter JE, Copper JB, Wu WC, Castell DO Am J Gastroenterol 1988 Apr; 83 (4), pp. 358–61.

Utility of upper endoscopy in the evaluation of non-cardiac chest pain. Hsia PC, Maher KA, Lewis JH, Cattau EL Jr, Fleischer DE, Benjamin SB. Gastrointest Endosc 1991 Jan–Feb; 37 (1), pp. 22–6.

Thoracic Pain: Non-Cardiac Associated (Esophagitis)
Hypertonic Glucose/Esophogeal HCl/Saline/ Endrophonium

Application: Detection and characterization of non-cardiac related causes of thoracic pain and discomfort.

Route of Administration: Edrophonium (IV); HCl (esophageal perfusion); hypertonic glucose.

Dosage: Hypertonic glucose, compared to esophageal perfusion with HCl (0.1 N) and normal saline; edrophonium (10 mg).

Implementation: Continuous esophageal manometric recordings are performed at the time of testing. The patients' symptoms are monitored every minute. The effect of these solutions and edrophonium on lower esophageal sphincter (LES) pressure and amplitude of esophageal contractions can also be evaluated.

Interpretation and Analysis: Preliminary findings indicate that hypertonic glucose is not effective as a provocative test for non-cardiac chest pain, nor does it contribute to the chest pain in esophagitis. It also has no significant effect on the amplitude of esophageal contractions or LES pressure.

Esophageal perfusion with hypertonic glucose, saline, or acid has no significant effect on LES pressure or amplitude of esophageal contractions in most patients. Edrophonium, however, creates a significant rise in the amplitude of esophageal contractions and the LES pressure in all case groups studied. Hypertonic glucose results in chest pain in 13.6% of cases with non-cardiac chest pain and 20% of those with esophagitis, whereas edrophonium reproduces pain in 38.7 and 37%, respectively. Edrophonium continues to be a relatively sensitive test for non-cardiac chest pain.

Comparison of hypertonic glucose to other provocative tests in patients with non-cardiac chest pain. Nasrallah SM, Hendrix EA. Am J Gastroenterol 1987 May; 82 (5), pp. 406–9.

Thoracic Pain: Non–Cardiac Associated
Endrophonium

Application: Differentiation of cardiac and non-cardiac associated causes for thoracic pain.
Route of Administration: Edrophonium (intravenous bolus).
Dosage: Edrophonium (80 μg/kg of body weight when asymptomatic).
Implemenation: Esophageal motility disorders may be an important cause of non-cardiac chest pain. To improve our diagnostic yield, edrophonium can be applied as a provocative agent for inducing esophageal chest pain in conditions without coronary artery disease.

Human Model: Cases with a history of thoracic pain (n = 50 without coronary artery disease; n = 25 age-matched controls).
Interpretation and Analysis: Edrophonium induces chest pain in about 30% of cases but not in control subjects. Edrophonium increases esophageal amplitude and repetitive contractions to a similar degree in all subjects, but the change in duration (101 ± 13% [SE]) is significantly greater ($p < 0.02$) in patients with induced chest pain. Assessment of drug specificity during cardiac catheterization (n = 9) reveals no significant change detected in coronary artery diameter, blood pressure, or heart rate. Further clinical testing using a placebo control confirms a positivity rate of 28% in cases with chest pain (n = 125 unselected cases) but false-positive tests are infrequent (5.6%). No important side effects can usually be appreciated. Edrophonium is useful for provoking esophageal chest pain

GASTRIC FUNCTION AND DISORDERS

Carboxylic Acid Metabolism: Gastrectomy/ Nitrogen Metabolism/Hepatic Failure, Renal Failure, Myotonic Dystrophy
1-[^{14}C]-Alpha-Ketoisovaleric Acid (KIV)

Cellular/Molecular Mechanism of Action: 1-[^{14}C]-alpha-ketoisovaleric acid is a keto analogue of valine that can function as a biochemical substrate for assessing mechanisms of carboxylic acid metabolism.
Background Information: The keto analogues of essential amino acids represent a promising therapeutic modality in hereditary and acquired disorders of nitrogen metabolism. The utilization of these substances in humans has been assayed primarily by nitrogen balance studies.
Application: Endogenous biochemical metabolism of KIV can be measured using the [$^{14}CO_2$] breath excretion test. In this context, the agent can be applied as a tool for evaluation of certain diet formulations.
Route of Administration: Oral.
Implementation: Assessement of the *in vivo* decarboxylation of KIV measurement of [$^{14}CO_2$] using a simple and accurate breath excretion test. Protein diets (5 g) supplemented with essential amino acids and KIV (in place of valine) are then evaluated. Diets of 120 g protein/day are then reevaluated in normal volunteers and gastrectomy cases.

Human Model: Normal volunteers and cases with various disease states (n = 6 diseased; gastrectomy, hepatic failure, renal failure, and myotonic dystrophy).
Interpretation and Analysis: In situations of low protein intake, 13–32% of ingested KIV undergoes rapid decarboxylation, and this proportion appeares to correlate inversely with damage to organ systems containing the branched-chain keto acid dehydrogenase. With high protein intake, the proportion of decarboxylated analog increases from 44% to 53%. Such findings confirm that the decarboxylation of KIV in man varies under different conditions of dietary intake and metabolic disease. The [$^{14}CO_2$] breath excretion test is applicable to other related analyses of carboxylic acid metabolism in human subjects.

Decarboxylation of alpha-ketoisovaleric acid after oral administration in man. Epstein CM, Chawla RK, Wadsworth A, Rudman D. Am J Clin Nutr 1980 Sep; 33 (9), pp. 1968–74.

Gastric Acid Secretory Capacity/Antisecretory Agent Evaluation: Transforming Growth Factor-Alpha (TGF-α), Epidermal Growth Gactor (EGF), and Urogastrone (UG)
S-[3-(N,N-Dimethylamino)Propyl]Isothiourea

Cellular/Molecular Mechanism of Action: S-[3-(N,N-Dimethylamino)propyl]isothiourea (dimaprit) functions as a highly specific histamine H2-receptor agonist. The H2-receptor specificity of dimaprit in causing depressor and vasodilator effects was also demonstrated in the cat, in which it had 18–20% of the H2-receptor activity of histamine.
Application: Stimulation of gastric acid secretion (rat, dog, cat).
Considerations: Induces 19%, 58%, and 400–500% the level of activity provided by histamine, respectively, in rats, dogs, and cats. Parallel line assays showed that *in vitro* at H2-receptors dimaprit had approximately 17.5% the activity of histamine on the rat uterus and 71% on the guinea pig right atrium, with similar maximal responses; it had less than 0.0001% the activity of histamine on H1-receptors. The absence of marked cardiovascular effects at doses maximal for the stimulation of gastric acid secretion, as seen in the cat studies, could lead to this compound being of value as a diagnostic agent in the measurement of maximal acid secretory capacity.
Implementation: Evaluation of EGF, UG, and TGF-α and its derivative for their ability to suppress dimaprit- and pentagastrin-induced gastric acid secretion and on acidified ethanol (AE)-evoked ulcer formation in anesthetized rats. Epidermal growth factor, TGF-α, and UG administered subcutaneously (s.c.) 30 minutes before dimaprit inhibited gastric acid secretion.
Interpretation and Analysis: Dimaprit induces 19%, 58%, and 400–500% the level of biological activity exerted by histamine in rats, dogs, and cats, respectively. In the dog and cat the maximum

secretory response to dimaprit is significantly greater than that obtained to histamine.

Against pentagastrin-stimulated secretion, TGF-α inhibits, while EGF and UG potentiate acid secretion dose-dependently. Intraduodenal administration of TGF-α and UG have no effect, while EGF potentiates secretagogue-induced acid secretion in the same dosage schedule. Administration of either EGF, UG, or TGF-α (bolus IV) in response to continuous infusion of dimaprit results in a significant ($p < 0.05$–$p < 0.001$) inhibition of acid secretion that is transient and returns to normal within 30 to 45 minutes for UG while it slowly returns to normal for EGF and TGF-α. The truncated form of TGF-α (amino acids 34–43) does not show any antisecretory effect when administered parenterally. Acidified ethanol produces gastric hemorrhagic lesions in rats 1 hour after oral administration. The gastric mucosal protective effects of TGF-α, EGF, and UG administered either orally or subcutaneously 30 minutes before the administration of AE are dose-dependent against this model of ulcer induction. Indomethacin (Indo), administered 15 minutes before AE to inhibit prostanoids biosynthesis, significantly ($p < 0.001$) reduces the cytoprotective effects of TGF-α, EGF, and UG and aggravates the ulcer index when administered subcutaneously. Results reveal that PGs may be involved in mediating the protective effects of the 3 growth factors. Administration of NG-nitro-L argininemethylester (L-NAME) 15 minutes prior to TGF-α, EGF, and UG s.c. or orally significantly ($p < 0.001$) decreases the degree of ulcer indices and is able to reduce the protective effects of TGF-α, EGF, and UG, thus including the role of NO in mediating the protective effects of these growth factors. In conclusion, these results have demonstrated that EGF, UG, and TGF-α have a short and reversible inhibitory effect on dimaprit-stimulated gastric acid secretion and each is effective parenterally but not orally. Urogastrone and EGF potentiate, while TGF-α inhibits pentagastrin-stimulated acid secretion. In addition, TGF-α seems to lose its activity when it is truncated from the C terminus. The present study also suggests that EGF, UG, and TGF-α are equally effective against AE-induced gastric ulcer and bring about their cytoprotective action through their reduction of acid secretion and through PG and NO pathways.

Comparison of the antisecretory and antiulcer activity of epidermal growth factor, urogastrone and transforming growth factor alpha and its derivative in rodents *in vivo*. Bastaki SM, Chandranath SI, Singh J. Mol Cell Biochem 2002 Jul; 236 (1–2), pp. 83–94.

Gastric Antrum (Retained) vs Zollinger-Ellison/ [Postop Partial Gastrectomy with Billroth II Reconstruction]
Secretin/Barium Sulfate/[^{99m}Tc]

Cellular/Molecular Mechanism of Action: Secretin promotes pancreatic exocrine secretion.
Background Information: If recurrent peptic ulceration follows partial gastrectomy (Billroth II reconstruction), a retained antrum on the duodenal stump may be the culprit. Moderate hypergastrinemia and a high basal acid output (BAO) to maximal acid output (MAO) ratio on gastric analysis should alert the clinician.
Application: Differentiation between retained gastric antrum and Zollinger-Ellison syndrome in postoperative cases that have received a partial gastrectomy using the Billroth II reconstrucution procedure.
Implementation: Careful filling of the afferent loop for barium image analysis or a [^{99m}technetium] meal-scan may serve to verify the diagnosis. The secretin provocative test may be helpful in distinguishing retained antrum from the Zollinger-Ellison syndrome by eliciting a decrease in serum gastrin levels in patients with retained antrum and an increase in serum gastrin levels in patients with Zollinger-Ellison syndrome.
Interpretation and Analysis: Cases suffering from Zollinger-Ellison syndrome will demonstrate elevations in serum gastrin following secretin administration.

Serum gastrin levels in the differential diagnosis of recurrent peptic ulceration due to retained gastric antrum. Webster MW, Barnes EL, Stremple JF. Am J Surg 1978 Feb; 135 (2), pp. 248–52.

Gastric Emptying
Acetaminophen (Paracetamol)

Cellular/Molecular Mechanism of Action: Acetaminophen (paracetamol) is classified as a non-steroid anti-inflammatory agent (cyclooxygenase inhibitor).
Background Information: The delivery rate of enteral nutrition in critically ill patients given via the nasogastric route is often decreased or stopped because of large gastric residual volumes.
Application: Estimation of approximate gastric-emptying rate.
Route of Administration: Acetaminophen (paracetamol) can be given by oral ingestion or nasogastric tube.
Examples of Clinical Implementation: Evaluation of gastric emptying in cases receiving enteral nutrition via a nasogastric tube that have residual volume (assessed every 8 hours) of > 150 ml, or more than twice the hourly infusion rate using the acetaminophen (paracetamol) absorption test.
Interpretation and Analysis: The acetaminophen (paracetamol) absorption test can provide valuable information in cases receiving enteral nutrition. Prokinetic agents facilitate the continuation of enteral nutrition in most (88%) of cases with evidence of abnormal gastic emptying. The paracetamol absorption test may be normal in patients with relatively high gastric residual volumes. These patients may continue to receive enteral nutrition.

The paracetamol absorption test: A useful addition to the enteral nutrition algorithm? Cohen J, Aharon A, Singer P. Clin Nutr 2000 Aug; 19 (4), pp. 233–6.

Gastric Emptying/Amylin
Acetaminophen (Paracetamol)

Diagnostic Cellular/Molecular Mechanism of Action: Non-steroidal anti-inflammatory agents inhibit the biochemical activity of cyclooxygenase similar to other pharmaceutical agents in this class.
Background Information: Amylin is a novel 37 amino acid peptide secreted together with insulin from the pancreas in response to enteral nutrient intake. As a potent inhibitor of gastric motility it plays an important role in the control of carbohydrate absorption.
Application: Evaluation of gastric-emptying function.
Dosage: Paracetamol 6-hour absorption.
Implementation: Evaluation of gastric emptying.
Interpretation and Analysis: Acetominophen (paracetamol) is highly absorbed from the gastrointestinal tract and reaches peak concentration in the blood at about 30 to 60 minutes postoral administration and is subsequently distributed extensively throughout the intravascular compartment and extravascular tissues. The paracetamol absorption test can be used as a parameter for the detection of delayed gastric emptying ($p \leq 0.01$). Median serum amylin concentrations are significantly higher in human (neonate/children) cases of delayed gastric emptying and feed-intolerance. A positive correlation is observed between serum amylin and insulin ($r = 0.46$, $p = 0.02$) but not between amylin and glucose ($r = 0.25$, $p = 0.23$). High

serum amylin levels are associated with delayed gastric emptying in some conditions of chronic disease. Correlation between serum amylin and insulin levels indicates a degree of preservation of pancreatic hormonal co-release.

Amylin is associated with delayed gastric emptying in critically ill children. Mayer AP, Durward A, Turner C, Skellett S, Dalton N, Tibby SM, Murdoch IA. Intensive Care Med 2002 Mar; 28 (3), pp. 336–40.

Gastric Emptying/Orocecal Transit Time *[^{13}C]-Acetate Breath Test*

Background Information: Caffeine is suspected to affect gastrointestinal function.
Implementation: Evaluation of the influence of caffeine supplementation (150 mg/l) in carbohydrate-electrolyte formulations (sports drinks) on gastrointestinal variables compared with a normal CES and water can be established using a standardized rest-exercise-rest protocol. Esophageal motility, gastroesophageal reflux, and intragastric pH can be measured by use of a transnasal catheter. Orocecal transit time can be measured using breath-H_2 measurements. Evaluation of intestinal permeability and glucose absorption can be established using sugar absorption tests, in contrast to the determination of gastric emptying, which can be measured by the [^{13}C]-acetate breath test.
Interpretation and Analysis: Caffeine significantly lowers mid-esophogeal pressures in postexercise periods compared to caffeine-free reference controls ($p = 0.017$). Gastric pH and reflux during pre-exercise periods, cycling exercise, and postexercise time frames, gastric emptying, orocecal transit time, and intestinal permeability are unaffected by caffeine intake.

Gastrointestinal function during exercise: Comparison of water, sports drink, and sports drink with caffeine. Van Nieuwenhoven MA, Brummer RM, Brouns F. J Appl Physiol 2000 Sep; 89 (3), pp. 1079–85.

Gastric Emptying/Motility *[^{13}C]-Acetate/[Breath Test]*

Cellular/Molecular Mechanism of Action: [^{13}C]-acetate is a radioactive analog of acetic acid that is absorbed from the gastrointestinal tract, enters the portal circulation, is removed from the portal circulation by the liver, and is then metabolized within hepatocytes in a manner that results in the generation of [$^{13}CO_2$] that is subsequently exhaled by the respiratory system.
Background Information: Elderly people frequently have symptoms of fullness and appetite loss due to impaired gastric motor activity. These symptoms may cause malnutrition, immunosuppression, and other complications.
Application: Evaluation of gastric motility by [^{13}C]-acetate breath test in combination with electrogastrography techniques.
Route of Administration: [^{13}C]-acetate (oral ingestion).
Implementation: Electrogastrography evaluation of gastric emptying before and after oral ingestion of [^{13}C]-acetate-mixed liquid meal. Expired air is then sampled every 10 minutes for measurement of [$^{13}CO_2$] concentrations.

Human Model: Cases of advanced age ($n = 7$ active/healthy; $n = 7$ reduced mental/physical capacities with inactive behaviors; $n = 7$ young healthy volunteers).
Interpretation and Analysis: The ratio of the incidence of the 3-cpm wave (gastric intrinsic frequency) during the postprandial period compared to the fasting state is reduced in active and inactive geriatric cases compared to young adults. Such reductions are greater in inactive elderly cases than in active elderly cases. The ratio of the amplitude of the peak frequency during the postprandial period to that in the fasting state (power ratio) also decreases with advanced age. The time of peak [$^{13}CO_2$] expiration is delayed in the active elderly cases, but more so in the elderly that are inactive. Postprandial peristalsis and gastric contractile force are reduced in the elderly, and gastric emptying is delayed, indicating a reduction in gastric motor activity.

Evaluation of gastric motor activity in the elderly by electrogastrography and the (13)C-acetate breath test. Shimamoto C, Hirata I, Hiraike Y, Takeuchi N, Nomura T, Katsu K. Gerontology 2002 Nov–Dec; 48 (6), pp. 381–6.

Gastric Emptying/Motility: Prokinetic Activity *Mosapride*

Physiological Mechanism of Action: Mosapride exerts digestive tract prokinetic properties.
Background Information: Delay of gastric emptying is 1 of the factors responsible for unfavorable glycemic control.
Dosage: Mosapride (15 mg per day for 6 months).
Implementation: Evaluation of the effects of the digestive tract prokinetic properties of mosapride on glycemic control in diabetic patients complicated with gastropathy. Gastric emptying can be evaluated according to a marker method (administration of a capsule containing 20 pieces of radiopaque marker during breakfast, followed by abdominal x-ray imaging 3 and 5 hours later; $n = 17$ cases).

Human Model: Cases of diabetes mellitus complicated by gastropathy (e.g., $n = 36$ type II diabetic patients presenting with mild digestive tract symptoms).
Interpretation and Analysis: In approximately 50% of cases, HbA(1C) is improved by more than 0.3% for 6 months (e.g., $n = 18$ with improvement). The other approximately 50% of cases are classified non-improvement cases (e.g., $n = 18$). In gastric-emptying studies, the basal number of residual markers before administration of mosapride is determined 3 and 5 hours later and reveals 18.3 ± 1.8 and 7.6 ± 5.1, respectively, in "improved" cases, while after administration, values decline to 11.2 ± 5.1 and 1.4 ± 2.5, respectively. In sharp contrast, the basal counterparts in the non-improvement group are approximately 19.1 ± 1.5 and 16.4 ± 3.4, respectively, whereas administration fails to reduce the number of the residual markers and they remain high (up to 19.0 ± 1.4 and 11.1 ± 6.4, respectively). Gastric motility in "improved" cases is much more improved by mosapride administration relative to "non-improved" cases. Mosapride might elicit improvement in glycemic control in the patients with diabetic gastropathy.

Effect of mosapride on glycemic control and gastric emptying in type 2 diabetes mellitus patients with gastropathy. Asakawa H, Hayashi I, Fukui T, Tokunaga K. Diabetes Res Clin Pract 2003 Sep; 61 (3), pp. 175–82.

Gastric Emptying/Motility: Functional Dyspnea *[^{13}C]-Octanoic Acid/[Breath Test]*

Background Information: As a non-invasive modality by which to evaluate the gastric emptying of a solid meal, the [^{13}C]-octanoic acid breath test has recently become more widely used. Previously, ultrasonography has also been reported as another non-invasive and reliable method for assessing gastric motility.
Application: Evaluation of gastric motility.
Route of Administration: [^{13}C]-octanoic acid (oral).
Dosage: [^{13}C]-octanoic acid (100 mg).
Implementation: Evaluation of gastric emptying applying the solid meal test consisting of a scrambled egg labeled with [^{13}C]-octanoic acid (100 mg) served with a bowl of rice and boiled chicken

(total 424 kcal). After ingestion of the test meal, examination is performed in a sitting position. Ultrasonography images are obtained every 15 minutes for 3 hours. Breath sampling follows the same time schedule as for ultrasonographic imaging, with an additional 3 hours of sampling at 30-minute intervals. Results are applied to establish half-emptying times ($T_{1/2}$) and lag phase.

Human Model: Cases of functional dyspnea (n = 17 compared to n = 10 normal healthy volunteers).

Interpretation and Analysis: The $T_{1/2}$ values determined by ultrasonography-based methods and the breath test are positively correlated ($r^2 = 0.638$); however, there is no significant agreement between study groups. Both the $T_{1/2}$ and the lag phase are prolonged in cases of functional dyspepsia compared with healthy volunteers, regardless of the method of measurement. The lag phase significantly correlates ($r^2 = 0.864$) with the $T_{1/2}$ established with breath test methods. Although the [^{13}C]-octanoic acid breath test cannot assess gastric emptying of solids as reliably as ultrasonography, both tests are useful for evaluating functional dyspepsia patients with delayed gastric emptying.

Evaluation of gastric emptying measured with the ^{13}C-octanoic acid breath test in patients with functional dyspepsia: Comparison with ultrasonography. Aoki S, Haruma K, Kusunoki H, Hata J, Hara M, Yoshida S, Tanaka S, Chayama K. Scand J Gastroenterol 2002 Jun; 37 (6), pp. 662–6.

Gastric Motility
[^{13}C]-Octane Acid/[Breath Test]/[^{99m}Tc]-Sulphur Colloid

Cellular/Molecular Mechanism of Action: [^{13}C]-octane acid is a radioactive analog of octane acid that is absorbed from the gastrointestinal tract, enters the portal circulation, is removed from the portal circulation by the liver, and is then metabolized within hepatocytes, resulting in the generation of [$^{13}CO_2$] that is then exhaled by the respiratory system.

Background Information: Disorders of gastric motility may be a significant factor in the pathogenesis of many equine conditions. Although tests for liquid phase emptying rate have been validated in the horse, there are no effective tests for solid phase emptying measurement that can be performed routinely in the field.

Application: Assessment of a stable isotope technique, the [^{13}C]-octane acid breath test (^{13}C-OABT), for the measurement of gastric emptying of solid ingesta, compared to the optimum method of gastric scintigraphy.

Implementation: A test meal is used containing baked egg yolk labeled with both [^{13}C]-octanoic acid and [^{99m}Tc]-sulphur colloid. Simultaneous, serial lateral gastric scintigraphic images and expiratory breath samples are obtained after voluntary test meal ingestion. Analysis of breath [$^{13}CO_2$:$^{12}CO_2$] ratio is then performed by mass spectrometry. Power regression is then used to determine the gastric emptying coefficient, the gastric half-emptying time ($T_{1/2}$), and duration of the lag phase (T_{lag}).

Animal Model: Equine (n = 12 healthy horses).

Interpretation and Analysis: Significant correlations ($p < 0.001$) can be appreciated between the 2 techniques for both $T_{1/2}$ and T_{lag} measurements. In addition, the scintigraphic $T_{1/2}$ is significantly correlates with breath test gastric-emptying coefficients ($p < 0.001$).

In has been proposed that the [^{13}C]-octanoic acid breath test is a reliable diagnostic procedure for measuring gastric-emptying rate of solids in the horse. Being safe, non-invasive, and easy to perform, this test has potential value as both sensitive diagnostic modality and humane research tool for motility studies.

Instrumentation: Continuous flow isotope ratio mass spectrometry.

Validation of the ^{13}C-octanoic acid breath test for measurement of equine gastric emptying rate of solids using radioscintigraphy. Sutton DG, Bahr A, Preston T, Christley RM, Love S, Roussel AJ. Equine Vet J 2003 Jan; 35 (1), pp. 27–33.

Gastric Motility Activity: Detection of Stimulation or Inhibition/Identifying Drug-Evoked Changes in Gastric Emptying
Propantheline/Corticotropin-Releasing Factor (CRF)/Metoclopramide/Bethanechol

Physiological Mechanism of Action: Propantheline and CRF inhibit gastric emptying, in contrast to metoclopramide and bethanechol, which accelerate gastric emptying.

Background Information: The increased availability of transgenic mice prompts a need for the adaptation to mice of whole-animal assays traditionally performed in larger laboratory animals. Gastric-emptying studies are frequently conducted in dogs and rats. Mouse-based gastric-emptying models currently available often use inert, non-nutrient liquid meals containing non-absorbable markers or radionuclides. A gastric-emptying assay has been developed in the mouse that features a favorable throughput and the use of a semi-solid, high-calorie meal.

Application: Detection of either stimulation or inhibition of gastric motor activity. This assay should prove useful for identifying drug-evoked changes in gastric emptying as well as assessment of gastric motility effects of altered gene expression in genetically modified mice.

Route of Administration: Propantheline (sq); CRF (ip); metoclopramide (ip); bethanechol (ip).

Dosage: Propantheline (0.3–10 mg/kg); CRF (3–100 nmol/kg); metoclopramide (1–10 mg/kg); bethanechol (91–30 mg/kg).

Implementation: Evaluation of agents known to either inhibit (propantheline, CRF) or accelerate (metoclopramide, bethanechol) gastric emptying. A single time-point variation of the assay can be used for quickly screening compounds for effects on gastric emptying.

A carbohydrate- and protein-rich semisolid test meal is prepared from common laboratory reagents. Gastric emptying is determined by subtracting the mass of test meal remaining in the stomach from the mass of test meal administered. A time-course study of basal emptying of a semisolid, paste-like test meal high in carbohydrate and protein from the stomachs of overnight-fasted is conducted.

Animal Model: Murine.

Interpretation and Analysis: In time-course studies, the test meal empties from the stomach with a half-emptying time of 30.6 minutes (95% CI: 27.3–34.7). The gastric-emptying data can be successfully modeled by a 2-parameter exponential decay function. No lag phase can be observed, indicating that the meal empties from the stomach as a liquid. The anticholinergic agent propantheline increases gastric half-emptying time ($T_{1/2}$) approximately 3-fold, while metoclopramide decreases gastric half-emptying time approximately 2-fold compared to basal emptying. Single time-point screening studies correctly detect the gastrokinetic activity of bethanechol and the inhibitory effect of CRF. The mouse gastric-emptying assay is simple, inexpensive, and not labor-intensive. It is capable of detecting either stimulation or inhibition of gastric motor activity. This assay should prove useful for identifying drug-evoked changes in gastric emptying as well as for assessing the gastric motility effects of altered gene expression in genetically modified mice.

An improved method of evaluation of drug-evoked changes in gastric emptying in mice. Osinski MA, Seifert TR, Cox BF, Gintant GA. J Pharmacol Toxicol Methods 2002 Mar–Apr; 47 (2), pp. 115–20.

Gastric Motility: Detection/[Recurrent Gastric Ulcers]
Acetaminophen

Cellular/Molecular Mechanism of Action: Acetaminophen is a non-steroidal analgesic agent that has minimal anti-inflammatory properties. However, in the context of being applied for characterizing gastric motility, it simply serves as a marker molecule where its rate of absorption into the systemic circulation directly corresponds to rates of gastric emptying.
Background Information: The existence of abnormal gastric motility in gastric ulcer disease remains controversial.
Application: Delineation of gastric motility as a function of plasma acetaminophen concentrations measured 45 minutes after oral ingestion.
Route of Administration: Acetaminophen (oral).
Dosage: Acetaminophen (20 mg/kg).
Implementation: Evaluation of gastric motility in conditions of recurrent gastric ulcers. Gastric motility is evaluated by cutaneous electrogastrography (EGG) and by gastric semi-liquid meal emptying. The EGG is recorded before and after ingestion of a test meal containing 20 mg/kg of acetaminophen. Patients with a dominant EGG frequency of greater than 0.06 Hz are defined as tachygastria, while those with a frequency of less than 0.04 Hz can be defined as bradygastria.

Human Model: Cases of recurrent gastric ulcer based on gastrointestinal endoscopy (n = 24; compared to n = 10 controls).
Interpretation and Analysis: A transient frequency decrease, called postprandial dip (PD), can be identified visually. The degree of gastric emptying is determined from the serum acetaminophen concentration 45 minutes after the meal. Control subjects show no irregularity in their dominant EGG frequency in either fasting or postprandial states. A PD can be observed in a relatively large percentage of reference controls (e.g., n = 8/10). In patients presenting with active gastric ulcers, abnormal patterns in the dominant EGG frequency (either as tachygastria or bradygastria) can be appreciated in slightly greater that 50% of affected cases (e.g., n = 14/24) during fasting or in postprandial states (e.g., n = 15/24). After successful treatment, the number of cases with abnormal patterns in their dominant EGG frequency remains unchanged, while PD can be observed in slightly < 50% of cases (e.g., n = 11/24). No significant difference can be observed in the EGG power ratio as a result of successful treatment. Gastric emptying is significantly delayed compared with controls in both the active and healed stages. These findings suggest that abnormal gastric motility, including gastric electrical abnormalities and delayed gastric emptying, plays an important role in the pathophysiology of recurrent gastric ulcers.

Gastric motility in patients with recurrent gastric ulcers. Kamiya T, Kobayashi Y, Hirako M, Misu N, Nagao T, Hara M, Matsuhisa E, Ando T, Adachi H, Sakuma N, Kimura G. J Smooth Muscle Res 2002 Apr; 38 (1–2), pp. 1–9.

Gastric Motor and Sensory Function
Acetaminophen (Paracetamol)/[^{13}C]-octanoic Acid/Spirulina Breath Tests/Tensostat/Water/Nutrient Drink Test

Background Information: Sensitive and reproducible tests are essential to investigate the mechanisms of gastric motility and sensation in healthy humans and patients with unexplained upper gastrointestinal symptoms. Electrogastrography, manometry, scintigraphic emptying, and barostat studies with an intragastric balloon have been used to better understand the physiology and pathophysiology of gastric motility. However, manometry and barostat studies are time-consuming, costly, and invasive, thus reducing their widespread clinical application.
Implementation: Evaluation of gastric-emptying characteristics can be measured using the paracetamol absorption test, [^{13}C] breath tests, ultrasound, or MRI methodologies. The paracetamol absorption test can measure the gastric emptying of liquids while [^{13}C] breath test can measure gastric emptying of solids or liquids and can achieve accuracy comparable with gastric scintigraphy.
Interpretation and Analysis: The water/nutrient (satiety) test is a non-invasive test proposed as an alternative to sensory studies performed with an intragastric balloon. The satiety test cannot measure gastric accommodation; interpretation of sensory tests usually has required independent assessment of accommodation or compliance. The tensostat can be used as a gastric sensation test because it measures gastric wall tension, which is related to the perception of gastric distention. Ultrasonography requires special skills, and MRI requires costly equipment. To measure gastric accommodation to a meal, ultrasound, MRI, and SPECT have been proposed as effective modalities. The recently introduced SPECT requires an intravenous injection of [^{99m}Tc]-pertechnetate, which the gastric mucosa specifically takes up, and specialized imaging and analysis, which have potential to be automated. Thus, novel, non-invasive approaches assess different dimensions of gastric motility and sensation testing. With further development of these techniques, refinement of their conduct and analysis, and validation of clinical usefulness, they are likely to be applicable in clinical practice to enhance cost-effective, evidence-based management of upper gastrointestinal symptoms. Such applications may provide an alternative to sequential empirical trials for symptoms.

Novel testing of human gastric motor and sensory functions: Rationale, methods, and potential applications in clinical practice. Kim DY, Myung SJ, Camilleri M. Am J Gastroenterol 2000 Dec; 95 (12), pp. 3365–73.

Gastric Ulceration: Stress Associated/Cerebral Trauma/Hypothalamic Injury
Gonadotropin-Releasing Hormone (GnRH)/Thyrotropin-Releasing Hormone (TRH)

Background Information: In patients with severe head injury, hypothalamohypophyseal impairment with subsequent hormone abnormalities has been well documented. Stress ulcers are another commonly encountered problem in such patients. However, little has been reported in the literature about the alterations of pituitary hormones in acute head-injured patients with stress ulcer.
Application: Detection and characterization of alteration in hypothalamic function secondary to cranial trauma reflected by modified responses to gonadotropin-releasing hormone (GnRH) and thyrotropin releasing hormone (TRH).
Implementation: Evaluation of basal serum levels of pituitary hormones measured before, and in response to thyrotropin-releasing hormone (TRH), and gonadotropin-releasing hormone (GnRH) in order to measure pituitary function in conditions of cranial injury.

Human Model: Cases of cranial injury (n = 40 males). Candidate criteria for eligibility may include (i) Glasgow coma scale 4 to 10; (ii) presentation within 24 hours following head injury; (iii) absence of shock or sepsis; and (iv) no past history of peptic ulcer. Stress ulcers can be confirmed by endoscopic examination.
Interpretation and Analysis: Approximately 2/3 of cases show evidence of stress ulcer by endoscope (e.g., n = 27/40 or 67.5%). In the absence of stress ulcer, basal serum levels of thyroid-stimulating hormone (TSH), prolactin (PRL), growth hormone (GH), luetinizing hormone (LH), and follicle-stimulating hormone (FSH) are within

normal range. However, the basal levels of PRL in conditions of stress ulcers are abnormally elevated and are significantly higher than in the absence of stress ulcers ($p < 0.001$). Basal levels of TSH and GH are significantly lower with stress ulcers than in the absence of stress ulcers ($p < 0.001$). In stress ulcer conditions, significant increases ($p < 0.001$) in serum TSH, PRL, LH and FSH levels after thyrotropin-releasing hormone (TRH) and gonadotropin-releasing hormone (GnRH) provocation can be detected. Hypothalamohypophyseal dysfunction and stress ulceration may occur in cases of severe cranial trauma. In the presence of stress ulcers, the abnormalities of pituitary hormones production/release and provocative response of the pituitary to TRH and GnRH reveal normal pituitary function with hypothalamic insufficiency. Therefore, stress ulcers in acute head-injured patients is closely associated with hypothalamic damage.

Hypothalamic dysfunction in acute head-injured patients with stress ulcer. Hwang SL, Lieu AS, Howng SL, Hsieh JS, Huang TJ. Kaohsiung J Med Sci 1998 Sep; 14 (9), pp. 554–60.

Gastric Ulcers/Peptic Ulcer (Recurrent): Post–Partial Gastrectomy/(Billroth II Reconstruction)
Secretin/[^{99m}Tc]-Barium Meal

Application: Differentiation between peptic ulcer and Zollinger-Ellison syndrome.
Implementation: Evaluation of recurrent peptic ulcers following partial gastrectomy.
Interpretation and Analysis: Careful filling of the afferent loop on barium meal or [^{99m}technetium] scanning may verify the diagnosis. The secretin provocative test may be helpful in distinguishing retained antrum from Zollinger-Ellison syndrome by eliciting a decrease in serum gastrin levels in conditions with retained antrum and an increase in serum gastrin levels in patients with Zollinger-Ellison syndrome. In instances of recurrent peptic ulceration following partial gastrectomy with Billroth II reconstruction, a retained antrum on the duodenal stump may be the cause for the complication. Moderate hypergastrinemia and a high basal acid output (BAO) to maximal acid output (MAO) ratio on gastric analysis should initially function as a diagnostic indicator.

Serum gastrin levels in the differential diagnosis of recurrent peptic ulceration due to retained gastric antrum. Webster MW, Barnes EL, Stremple JF. Am J Surg 1978 Feb; 135 (2), pp. 248–52.

Gastric Urease Activity (Intragastric)/Helicobacter pylori (H. pylori)
[^{13}C]-Urea Breath Test

Application: Detection and characterization of *H. pylori* populations residing within the gastrointestinal tract. The reagent can also be applied to evaluate the efficacy of therapeutic agents.
Implementation: Assessment of intragastric urease activity by the [^{13}C]-urea breath test is performed before and after 1 day of dosing with either De-Noltabs (tripotassium dicitrato bismuthate, 1 tablet 1 q.d.s.), Pepto-Bismol liquid (bismuth salicylate 30 ml q.d.s.), or Roter tablets (bismuth subnitrate, 1 tablet q.d.s.) in 12 H. pylori–positive patient volunteers.
Interpretation and Analysis: There is a significant decrease in [$^{13}CO_2$] after 1 day of dosing with each of the 3 bismuth compounds, but analysis of variance detects no difference between the effects of the 3 compounds. Systemic absorption of bismuth following oral dosing with either Pepto-Bismol or Roter is minimal, yet both compounds have a suppressive effect on *H. pylori* similar to that of De-Noltab. The action of all 3 bismuth compounds is within the gastric lumen, and that systemic absorption of bismuth is not necessary for activity against *H. pylori*.

Comparison of 1-day oral dosing with three bismuth compounds for the suppression of Helicobacter pylori assessed by the ^{13}C-urea breath test. Prewett EJ, Luk YW, Fraser AG, Lam WM, Pounder RE. Aliment Pharmacol Ther 1992 Feb; 6 (1), pp. 97–102.

Gastroesophogeal Reflux Disease (GERD)/ Esophogitis/Non-Cardiac Chest Pain (MIBI Negative NCCP)
High-Dose Omeprazole/[^{99m}Tc-SestaMIBI (MIBI)]

Cellular/Molecular Mechanism of Action: Omeprazole inhibits H^+/K^+-ATPase that exchanges hydrogen ion for potassium ion within parietal cell populations. In this fashion, less hydrochloric acid is available for secretion into the gastric lumen.
Background Information: Non-cardiac chest pain presents as a frequent diagnostic challenge, with patients tending to use a disproportionate level of health care resources. Gastroesophageal reflux disease is the most frequent cause of NCCP.
Application: Detection of non-cardiac chest pain etiologies due to esophogistic and gastric esophageal reflux disease in order to avoid nuclear scintigraphy evaluation of cardiac function/physiology.
Route of Administration: Omeprazole (oral).
Dosage: Omeprazole (40 mg twice daily).
Considerations: Gastroesophageal reflux disease is the most frequent cause of NCCP rest/stress perfusion.
Implementation: Evaluation of recurrent chest pain conditions utilizing a prospective, double blind, placebo-controlled, crossover trial using high-dose omeprazole. Findings are then compared with those of endoscopy, manometry, and ambulatory 24-hour 2-channel esophageal pH monitoring. Initial diagnostic upper endoscopy, esophageal manometry, and 24-hour pH monitoring are also applied as evaluation parameters. Cases are then randomly assigned to either placebo or omeprazole for 14 days, washed out for 21 days, and then crossed over. Patient's symptoms are determined using a Visual Analogue Scale to measure the severity of chest pain before and after each period.

Human Model: Cases ($n = 18$ men; $n = 24$ women; age 22–77 years) of recurrent chest pain complaints of a non-cardiac etiology, as determined by rest/stress perfusion imaging with technetium [^{99m}Tc]-sestaMIBI (MIBI).
Interpretation and Analysis: Improvement in perceived chest pain can be detected in approximately 71% of cases receiving omeprazole compared to only 18% for placebo reference controls. Abnormal results on manometry (20%), 24-hour pH monitoring (42%), or endoscopy with visual evidence of esophagitis (26%) can be appreciated less frequently. Application of combinations of the 3 tests does not significantly increase their usefulness. In NCCP patients with GERD, as defined by positive results on a 24-hour pH test or presence of esophagitis on endoscopy, omeprazole treatment results in a response in 95% of cases, whereas 90% of GERD-positive patients treated with placebo do not respond. Of NCCP patients determined to be GERD negative, approximately 39% will respond to omeprazole. Therefore, omeprazole as a 1st diagnostic tool in the evaluation of MIBI-negative NCCP is sensitive and specific for determining the cause of NCCP. Endoscopy, manometry, and 24-hour pH monitoring are not only less sensitive in diagnosing NCCP, they are significantly more expensive.

Short course of omeprazole: A better first diagnostic approach to non-cardiac chest pain than endoscopy, manometry, or 24-hour esophageal pH monitor-

ing. Pandak WM, Arezo S, Everett S, Jesse R, DeCosta G, Crofts T, Gennings C, Siuta M, Zfass A. J Clin Gastroenterol 2002 Oct; 35 (4), pp. 307–14.

Gastroesophogeal Reflux Disease (GERD): Esophogeal Sphincter
Bethanechol/Metoclopramide

Route of Administration: Oral.
Dosage: Metoclopramide (single 20 mg dose) prior to meal ingestion. Esophogeal sphincter function; metoclopramide (10 and 20 mg); bethanechol (25 mg).
Implementation: Evaluation of symptoms of heartburn and regurgitation recognized following a test meal challenge utilizing metoclopramide as a pharmaceutical probe.

In scenarios for the evaluation of lower esophageal sphincter pressure, metoclopramide and bethanechol can be applied.

Human Model: Cases with symptoms of GERD and basal LESP less than 11 mm Hg (n = 15 males).
Interpretation and Analysis: Metoclopramide can prevent symptoms of heartburn and regurgitation induced by a provocative meal challenge. Adverse reactions are rare to non-existent. Metoclopramide reduces the severity of heartburn from the onset, its effect reaching statistical significance within 2 hours and persisting for at least 5 hours. Eighty percent of cases receiving metoclopramide, compared with only 30% of placebo-treated patients, are completely free of heartburn at the end of clinical trials. A significant reduction in regurgitation during the 1 and one-half–4 hours after the test meal is also noted with metoclopramide.

In conditions with symptoms of GERD and basal LESP, metaclopramide and bethanecol produces a significant increase in LESP compared to placebo. Metoclopramide, 20 mg, produces a greater increase than either metoclopramide, 10 mg, or bethanechol, 25 mg. Serum gastrin concentrations are not altered by any of the drugs. Side effects are usually unremarkable. The LESP increasing effect of metoclopramide might be useful in the evaluation/treatment of GERD.

Comparative effects of metoclopramide and bethanechol on lower esophageal sphincter pressure in reflux patients. McCallum RW, Kline MM, Curry N, Sturdevant RA. Gastroenterology 1975 May; 68 (5 Pt 1), pp. 1114–8.

Gastrointestinal Bacteria: Gastric Helicobacter pylori (H. pylori) Detection
[^{13}C]-Urea Breath Test

Background Information: Infection with *H. pylori* is thought to be an important factor in the pathogenesis of gastritis, peptic ulcer, and gastric cancer.
Application: The [^{13}C]-urea breath test (^{13}C-UBT) can be used as a convenient and non-invasive method for the detection of gastric *H. pylori* populations.
Route of Administration: [^{13}C]-urea.
Dosage: [^{13}C]-urea.
Implementation: Assessment of intragastric urease activity using the [^{13}C]-urea breath test is performed before and after 1 day of dosing with either with our without the presence of De-Noltabs (tripotassium dicitrato bismuthate, 1 tablet 1 q.d.s.), Pepto-Bismol liquid (bismuth salicylate 30 ml q.d.s.), or Roter tablets (bismuth subnitrate, 1 tablet q.d.s.).

Human Model: *H. pylori*–positive patient volunteers (n = 12).
Interpretation and Analysis: There is a significant decrease in the excess of [$^{13}CO_2$] after 1 day of dosing with each of the 3 bismuth compounds, but analysis of variance detects no difference between the effects of 3 different bismuth compounds. Systemic absorption of bismuth following oral dosing with either Pepto-Bismol or Roter is minimal, yet both compounds have a suppressive effect on *H. pylori* similar to that of De-Noltab. The action of all 3 bismuth compounds is within the gastric lumen, and that systemic absorption of bismuth is not necessary for activity against *H. pylori.* Compared to histology evaluations, the [^{13}C]-urea breath test (^{13}C-UBT) is more sensitive, specific, and accurate.
Instrumentation: The [$^{13}CO_2$]/[$^{12}CO_2$] ratio is measured by using infra-red spectroscopy (IR) and gas chromatography/mass spectrometry(GC-MS). The IR analyzer should be particularly useful for the diagnostic test of *H. pylori* infection using [$^{13}CO_2$]-UBT.

Comparison of one-day oral dosing with three bismuth compounds for the suppression of Helicobacter pylori assessed by the [^{13}C]-urea breath test. Prewett EJ, Luk YW, Fraser AG, Lam WM, Pounder RE. Aliment Pharmacol Ther 1992 Feb; 6 (1), pp. 97–102.

[^{13}C]-urea breath test. Oshima H, Kajiwara M. Nippon Rinsho. 2003 Jan; 61 (1), pp. 67–71.

Gastrointestinal Bacteria/Helicobacter pylori (H. pylori)
[^{15}N]Urea/Sodium [^{13}C]-Acetate

Application: Detection of gastrointestinal *H. pylori* populations.
Route of Administration: Oral in 75 ml orange juice as a test drink.
Dosage: 150mg [^{15}N]urea and 75 mg sodium [^{13}C]-acetate in 75 ml orange juice as a test drink.
Considerations: The protocols for [^{13}C] and [^{15}N] *H. pylori* tests stipulate that the diagnostic agent should be taken on an empty stomach. It is presumed that food intake prior to the tests leads to less reliable test results due to a prolongation of the gastric residence time of the diagnostic agent urea. This might allow bacteria to split a higher proportion of urea, resulting in an increased number of false positives.

Food intake prior to the test drink does not have much of an influence on the gastric residence time of urea or on qualitative *H. pylori* test results. Due to identical behaviour of [^{13}C]-urea and [^{15}N]-urea in the stomach, this influence is believed to be independent on the labeling isotope. For survey purposes, no fasting conditions are required for the *H. pylori* tests.
Implementation: Evalaution of [^{15}N]-urea as an agent for the diagnosis of gastric *H. pylori* colonization. The [^{15}N] tests are evaluated using a urine sample of the 2nd hour after test start. [^{13}C]-acetate served as a marker of the gastric emptying of water-soluble food including the urea under the influence of food intake. Breath air samples are taken to calculate the gastric-emptying half-life (EHL) and the apparent resorption time (RT) of the urea. The double tests are carried out 4 times within 4 weeks using identical test protocols but different standardized time periods of pretest fasting: overnight, 2 hours prior to test, 1 hour prior to test, and no fasting at all. The food intake amount is standardized.
Interpretation and Analysis: Five probands testing positive in the overnight fasting test are also found to be positive in the other test variants with more or less empty stomachs. Seven other probands testing negative after overnight fasting tested negative in the other test variants as well.

Helicobacter pylori *in vivo* diagnosis after food intake: Results of simultaneous [^{15}N]-urea urine and [^{13}C]-acetate breath tests. Krumbiegel P, Müller DM. Isotopes Environ Health Stud 2000; 36 (2), pp. 99–110.

PANCREAS

Gastric Neoplasia/Carcinoma/Metastasis

In vivo tumor delivery of the green fluorescent protein gene to report future occurrence of metastasis. Hasegawa S, Yang M, Chishima T, Miyagi Y, Shimada H, Moossa AR, Hoffman RM. Cancer Gene Ther 2000 Oct; 7 (10), pp. 1336–40.

Gastritis (Symptomatic): Bile Reflux Associated
Sodium Hydroxide (Intragastric Infusion)

Application: Detection of symptomatic bile reflux gastritis.
Route of Administration: Blind sequential intragastric infusion of each test solution utilizing a nasogastric tube.
Dosage: Blind sequential administration of HCl (0.1 N, 20 ml); normal saline (0.9%, 20 ml); 0.1 N NaOH, (0.1 N, 20 ml) and endogenous gastric contents (20 ml). Each formulation is given twice.
Considerations: Alkaline reflex gastritis is a disabling clinical syndrome, occurring most often after gastric surgery. It is characterized by abdominal pain and bilious vomiting, and, presumably, is due to gastric irritation by regurgitated duodenal contents. The only known effective treatment is by surgical diversion to prevent the duodenal reflux. Unfortunately, the clinical diagnosis is difficult to prove, and the results of surgery are too often disappointing because of inaccurate patient selection.

The test is simple and appears to be a sensitive, specific, and accurate means for selecting patients for surgical treatment of alkaline reflux gastritis.
Interpretation and Analysis: A positive test is defined as reproduction of pain by NaOH and/or gastric contents equivalent to that experienced during pretest clinical signs. No discomfort is recognized with acid or saline infusions. Cases with clinical symptoms and endoscopic findings suggestive of bile gastritis have positive alkali infusion tests (15/21), while very few (1/18) normal controls or controls with other causes of abdominal pain (0/17) have positive test responses ($p < 0.001$). Of cases with clinical-endoscopic bile gastritis, a relatively large proportion (15/21) have had surgical treatment (Roux-en-Y gastrojejunostomy). In patients with a positive test result, a large number (9/10) will experience excellent symptomatic relief after surgery. Few patients (e.g., 0/5) with a negative test may be relieved of pain after the operation.

Gastritis Syndrome: Alkaline Reflux/Bile Gastritis
Sodium Hydroxide (Intragastric)

Background Information: Accurate diagnosis of the alkaline reflux gastritis syndrome is often difficult to establish and contributes to the relatively high failure rate associated with surgical treatment schemes especially pertaining to pain relief.
Application: Accurate diagnosis of the alkaline reflux gastritis syndrome.
Route of Administration: Intragastric infusion with each test solution administered in a random blind fashion.
Dosage: Diagnostic formulations include (i) saline solution; (ii) hydrochloric acid (HCl 0.1 N); (iii) sodium hydroxide solutions (NaCl 0.1 N); and (iv) endogenous gastric aspirates.
Considerations: Evaluation of the *in vivo* test reveals that positive alkali infusion test results predict that symptoms will likely respond best to surgical diversion of duodenal contents, and that negative test results should be a strong deterrent to surgical diversion. The test is safe, simple, and deserves further trial.
Implementation: Detection of alkaline reflux gastritis syndrome.

Human Model: Cases (n = 147) with symptoms and endoscopic findings suggestive of bile gastritis (asymptomatic controls; n = 19).
Interpretation and Analysis: A positive test result is defined as perceived pain with sodium hydroxide but not with saline solution or hydrochloric acid infusion. Essentially all control subjects have negative test results. Monitoring of symptomatic patients (mean 4.3 years, minimum 1 year) reveals that a large percentage (47/128) suffer from Roux-Y gastrojejunal reconstruction to divert duodenal contents from the stomach. Correlation of test results and the subsequent clinical status shows that those with negative test results (87%) improve spontaneously or with other treatment compared to cases with positive test results ($p < 0.001$) and a large percent (78%) with positive test results have lasting relieve of pain following surgical diversion compared to a 30% success rate if the test results are negative ($p < 0.01$).

Diagnosis of symptomatic alkaline reflux gastritis and prediction of response to bile diversion operation by intragastric alkali provocation. Rutledge PL, Warshaw AL. Am J Surg 1988 Jan; 155 (1), pp. 82–7.

INTESTINAL ABSORPTION BREATH TESTS

Intestinal Absorption: Malabsorption and Compromised Integrity/[Renal Failure]
D-Xylose Absorption/Hydrogen Breath Test

Application: Kinetic analysis of D-xylose absorption and D-xylose breath testing can be performed in an effort to establish an effective absorption test in functionally anephric patients.
Background Information: Evaluation of malabsorption in renal failure is difficult because most absorptive testing requires urinary collections.
Route of Administration: D-xylose (oral and intravenously).
Dosage: D-xylose 15 gram (oral) and 10 gram (intravenous) dosage schemes.
Examples of Clinical Implementation: Evaluation of intestinal absorption. Serum samples are collected and measured for D-xylose in order to calculate the kinetic rate constants and extent of absorption. After the oral D-xylose, end expiratory breaths are collected every 15 minutes for 3 hours and are analyzed for H_2 applying gas chromatography.

Human Model: In fasting renal failure patients with no diarrhea or symptoms suggesting malabsorption on 2 separate non-dialysis days after receiving D-xylose on day 1 (oral) and day 2 (IV).
Interpretation and Analysis: The mean absorption rate constant (Ka) and bioavailability (F) are similar to published values for normal subjects using the 15-g dose (0.936 min^{-1}; range, 0.227–1.96; and 74%, range 46–99, respectively). A number of cases will have a normal 1-hour serum D-xylose concentration (> 20 mg/dL). There is no clear inverse correlation between the rate constant for absorption or bioavailability and peak breath hydrogen or the area under the curve for breath H_2 vs time. Using 15 g of oral D-xylose, mean bioavailability and absorption rate constants are normal in functionally anephric patients with no clinical evidence of malab-

sorption. A small number of cases will have elevated breath peak H_2 concentrations, but there is no clear inverse correlation between bioavailability and the breath H_2 values. A 1-hour serum D-xylose concentration > 20 mg/dL may be considered normal in this patient group, similar to patients with normal renal function.

Instrumentation: Gas chromatography (hydrogen gas measurement).

D-xylose kinetics and hydrogen breath tests in functionally anephric patients using the 15-gram dose. Craig RM, Carlson S, Ehrenpreis ED. J Clin Gastroenterol 2000 Jul; 31 (1), pp. 55–9.

Intestinal Absorption: Malabsorption and Compromised Integrity/Intestinal Permeability/ Gastric Emptying
Glucose Absorption/Lactulose/Rhamnose Absorption Ratio/[^{13}C]-Acetate Breath Test

Background Information: Exercise decreases splanchnic bloodflow to the extent that exercise may induce alterations in gastrointestinal (GI) function.

Application: (i) Glucose and 3-O-methyl-D-glucose can be utilized to assess the presence/integrity of active transport mechanisms within the mucosa of the proximal small intestine; (ii) D-xylose is transported by a passive carrier-mediated process; (iii) L-rhamnose traverses the intestinal mucosal membrane by non-mediated absorptive processes and does not normally cross normal intact intsinal mocosal; (iv) the lactulose:rhamnose ratio serves as a measure of increased intestinal permeability (large-pore defect/ small-pore defect, respectively). In this context, lactulose, mannitol, and rhamnose are not metabolized in the small intestine but may be metabolized in the large intestine. Lactulose and rhamnose are poorly absorbed across intact mucosal surfaces while mannitol is normally absorbed across intact small intestinal mucosa. Lactulose/rhamnose ratios can be applied to detect large-pore/small-pore permeability defects, respectively. The [^{13}C]-acetate breath test can be applied to assess gastric emptying.

Route of Administration: Oral.

Dosage: Lactulose/rhamnose regular dose (50 mg/50 mg) or a high dose (250 mg/250 mg) in humans.

Examples of Clinical Implementation: Evaluate the influence of high-intensity physical exercise on gastrointestinal physiology processes including esophageal motility, gastro-esophageal reflux, gastric pH, gastric emptying, orocecal transit time (OCTT), intestinal permeability and glucose absorption simultaneously. Esophageal motility, gastroesophageal reflux, and intragastric pH can be measured using a trans-nasal catheter while the orocecal transit time is measured using a breath H_2 measurement. A sugar absorption test is used to determine intestinal permeability and glucose absorption. Lastly, gastric emptying is measured using the [^{13}C]-acetate breath test.

Interpretation and Analysis: During exercise, peristaltic velocity is greater than values noted at rest 4.92 (2.86) vs. 4.03 (1. 48) cm s-1, p = 0.015). Mid-esophogeal peristaltic contraction pressure and the duration of the peristaltic contractions at the mid- and distal esophagus are lower during intense exercise. Conversely, no differences can be appreciated between pre-exercise, intraexercise and postexercise measurements for gastric pH values. Exercise does not create noticeable differences in either gastric emptying or orocecal transit time. In contrast, lactulose/rhamnose ratios and intestinal glucose absorption are significantly decreased in response to moderate to intense exercise activity. Normal intestinal absorption profiles reveal absorption of glucose and lactulose but relatively minimal systemic absorption of rhamnose. If the integrity of the small intestinal mucosa is compromised, an increased amount of rhamnose will enter into the systemic circulation. Conversely, if there is a compromise of intestinal mucosa absorptive function, then depressions in glucose and lactulose absorption can be appreciated.

The effect of physical exercise on parameters of gastrointestinal function. van Nieuwenhoven MA, Brouns F, Brummer RJ. Neurogastroenterol Motil 1999 Dec; 11 (6), pp. 431–9.

INTESTINAL ABSORPTION AND PERMEABILITY: NON-BREATH TESTS

Enteropathy: Childhood
D-Xylose Absorption Test/Lactose Breath Hydrogen Test/[Jejunal Biopsy Alternative]

Cellular/Molecular Mechanism of Action: Lactose and D-xylose are normally absorbed across the surface of normal/healthy intestinal mucosa.

Background Information: Three widely used screening tests for enteropathy in childhood are the lactose breath hydrogen test, the 1-hour serum D-xylose absorption test, and the 72-hour fecal fat determination.

Application: Lactose and D-xylose can be applied to detect alterations in the absorptive function of the intestinal mucosa.

Route of Administration: Lactose and D-xylose (oral/per os).

Implementation: Correlate findings from the lactose hydrogen breath test, D-xylose absorption test, and 72-hour fecal fat determination with results from jejunal biopsy evaluations in cases of juvenile enteropathy.

Interpretation and Analysis: Results from D-xylose and fecal fat tests each significantly correlate with jejunal biopsy results (e.g., normal result of either test was highly predictive of a normal biopsy finding). Combining the results of 2 or more screening tests does not improve predictive value. The xylose test is preferable on the basis of greater sensitivity and ease of patient compliance.

Screening tests for enteropathy in children. Levine JJ, Seidman E, Walker WA. Am J Dis Child 1987 Apr; 141 (4), pp. 435–8.

Gastrointestinal Permeability/Mucosal Function
Lactulose/Xylose/Methylglucose/Sucrose

Cellular/Molecular Mechanism of Action: Lactulose, rhamnose, xylose, methylglucose, and sucrose are sugar carbohydrates. Lactulose (L) and rhamnose are not significantly absorbed across intact intestinal mucosa. Alternatively, xylose and methylglucose are normally absorbed across healthy intestinal mucosal surfaces of the jejunum by carrier-mediated transport mechanims. Neither lactulose nor mannitol is metabolized to any significant degree in the small intestine but may be metabolized in the large intestine. Injury to intact intestinal mucosa can promote increases in sucrose absorption.

Application: To describe the kinetics of urinary recovery (UR) of 5 sugars used for gastrointestinal permeability and mucosal function testing following orogastric administration of lactose, rhamnose, xylose, methylglucose, and sucrose. The lactulose/rhamnose ratio can be used to detect large-pore/small-pore defects in mucosal permeability.

Route of Administration: Lactulose, rhamnose, xylose, methylglucose, and sucrose (orogastric intubation).

Implementation: Evaluation of the urinary excretion of sugar solution containing lactulose, rhamnose, xylose, methylglucose, and sucrose following administration by orogastric intubation. Urine samples are collected immediately before sugar solution administration (baseline) and at 2-hour intervals thereafter. Percent urinary recovery (%UR) of the total UR up to 12 hours after sugar solution administration is calculated for each sugar type at 2-hour intervals.

Animal Model: Canine (n = 7 healthy male beagles).

Interpretation and Analysis: Mean %UR exceeds 85% for all 5 sugars at 6 hours after orogastric administration of the sugar solution and exceeds 90% after 8 hours. In healthy dogs, a urine collection period of 6 hours is sufficient for gastrointestinal permeability and mucosal function testing following orogastric administration of lactulose, rhamnose, xylose, methylglucose, and sucrose.

Instrumentation: Analysis of sugars applying high-pressure liquid chromatography and pulsed amperometric detection.

Kinetics of urinary recovery of five sugars after orogastric administration in healthy dogs. Steiner JM, Williams DA, Moeller EM. Am J Vet Res 2002 Jun; 63 (6), pp. 845–8.

Gastrointestinal Permeability/Gastrointestinal Absorption/Primary Biliary Cirrhosis/Cirrhosis
Sucrose/Lactulose/Mannitol

Cellular/Molecular Mechanism of Action: Lactulose is not absorbed across the surface of normal, intact intestinal mucosa. Mannitol is normally absorbed across the surface of healthy small intestinal mucosa. Lactulose and mannitol are not metabolized to any significant degree within the small intestine but may be metabolized in the large intestine. Injury or damage to gastroduodenal mucosal promotes enhanced sucrose absorption.

Application: Lactulose can be applied to detect increases in intestinal permeability, while mannitol is useful in recognizing declines in intestinal absorptive capacity. Sucrose can detect alterations in gastro-duodenal permeability, while lactulose can detect large-pore defects in intestinal permeability

Route of Administration: Lactulose, mannitol, and sucrose can be administered orally for assessing gastrointestinal permeability/absorptive parameters.

Implementation: Evaluation of gastrointestinal permeability in conditions of primary biliary cirrhosis (PBC) determined by measuring the sucrose (gastro-duodenal) and lactose-mannitol (intestinal) excretion profiles as a sensitive method for detecting mucosal epithelial damage Results can then be correlated with the Mayo score, histological stage, ascites, spontaneous bacterial peritonitis, endoscopic signs of portal hypertension and *Helicobacter pylori* infection.

Human Model: Cases of primary biliary cirrhosis or PBC (n = 50) and cirrhosis due to other causes (n = 39). Celiac disease is not evident in any of the case groups.

Interpretation and Analysis: Sucrose excretion was above the limit in both PBC and non-PBC patients. In almost a quarter of primary biliary cirrhosis cases (22%), the lactulose-mannitol test is increased compared to 12.8% of non-PBC cirrhotic patients. Cases of primary biliary cirrhosis (PBC) have high sucrose excretion levels, irrespective of the presence of any esophageal varices, that significantly increase gastroduodenal permeability in non-PBC patients only when associated with hypertensive gastropathy. Sucrose urinary excretion is significantly enhanced by hypertensive gastropathy in non-PBC patients ($p < 0.001$) but not in PBC patients. No significant correlation can be appreciated for gastrointestinal permeability and other parameters in either primary biliary cirrhosis or non-primary biliary cirrhosis. Gastrointestinal permeability is increased in PBC. Portal hypertension contributes to altered gastric mucosal permeability in non-PBC cirrhosis, whereas different epithelial dysfunction can be hypothesized in PBC.

Gastroduodenal and intestinal permeability in primary biliary cirrhosis. Di Leo V, Venturi C, Baragiotta A, Martines D, Floreani A. Eur J Gastroenterol Hepatol 2003 Sep; 15 (9), pp. 967–73.

Intestinal Absorption
D-Xylose/D-Glucose

Cellular/Molecular Mechanism of Action: D-xylose and D-glucose are both carbohydrate sugars that are absorbed across intact mucosal surface of the small intestine (jejunum)involving passive (D-xylose) and active (D-glucose) carrier-mediated transport mechanisms.

Application: Evaluation of the absorptive capacity/function of the small intestine.

Implementation: Evaluation of the potential for D-xylose to accumulate *in vitro* in jejunal mucosa from healthy horses and rabbits.

Animal Model: Equine and rabbit jejunal mucosal preparations.

Interpretation and Analysis: Incubation of jejunal mucosal tissue sheets with D-xylose (1 mM) for 60 minutes, reveals that it accumulates against a concentration gradient within *ex vivo* mucosal preparations from both species. There is no accumulation when equine specimens are incubated with D-xylose (5 mM). By comparison, equine jejunum accumulates D-glucose against a concentration gradient when incubated in 5 mM D-glucose. In equine and rabbit jejunum, 13.3 ± 7.0% and 36 ± 11.0%, respectively, of accumulated D-xylose is phosphorylated when sheets are incubated in 1 mM D-xylose. Short-circuit current and potential difference are lower in equine jejunum than in rabbit jejunum, possibly because of differences in tissue thickness. None of the transmucosal electrical measurements increase after addition of D-xylose (1 mM and 5 mM) or D-glucose (5 mM). The active transport system for D-xylose has a low affinity for this sugar and becomes saturated at low intraluminal concentrations. Therefore, abnormal D-xylose absorption test results in horses are more likely caused by abnormalities in mucosal surface area and mucosal permeability than by abnormalities of nutrient carbohydrate absorption.

In vitro concentrative accumulation of D-xylose by jejunum from horses and rabbits. Freeman DE. Am J Vet Res 1993 Jun; 54 (6), pp. 965–9.

Intestinal Absorption: Neonatal/Colostrum Dietary Intact
D-Xylose

Cellular/Molecular Mechanism of Action: D-xylose is a carbohydrate molecule that is absorbed across the intact mucosa of the small intestine by passive carrier-mediated transport mechanisms.

Background Information: Colostrum intake is important for health and postnatal development of neonatal calves.

Application: Detection and characterization of alterations in intestinal absorptive capacity.

Considerations: Note: Neonatal calves are essentially a simple-stomached animal at this stage of the development of their gastrointestinal tract.

Implementation: Evaluate the influence of enhanced 1st colostrum feeding on growth, health status, and metabolic and endocrine traits and intestinal absorption capacity as measured by the xylose absorption test.

Animal Model: Bovine (7-day old calves). Group 1 calves are fed colostrums from milkings 1–6 twice daily during the 1st 72 hours

of life (n = 7) followed by milk replacer supplementation (MR) for up to 7 days. Group 2 calves are fed colostrum of the 1st milking during the 1st 3 days and then colostrum (of the 1st milking) twice daily, which on day 4, 5, 6, and 7 is diluted with 25, 50, 75, and 75 parts of milk-replacer (MR), respectively (n = 7). Pre- and postprandial blood samples are taken on days 1, 2, 3, and 7 for determination of various metabolic and endocrine traits. On day 5, intestinal absorption capacity is measured using the xylose absorption test.

Interpretation and Analysis: Rectal temperatures and fecal scores are higher ($p < 0.05$) in Group 2 than Group 1 calves. Plasma concentrations of total protein and albumin are higher ($p < 0.05$) on day 7, IgG on days 2 and 3, and urea on days 2, 3, and 7 in Group 2 than in Group 1 calves. Plasma concentrations of triglycerides are higher ($p < 0.05$) on day 2 and of phospholipids and cholesterol are higher ($p < 0.01$) on day 7 in Group 2 than in Group 1 calves. Plasma insulin and glucagon concentrations are higher ($p < 0.05$) in Group 2 than in Group 1 calves, whereas prolactin and growth hormone concentrations are higher ($p < 0.05$) in Group 1 than in Group 2 calves. Enhanced colostrum intake has no effects on xylose absorption on day 5 measurements. Higher plasma protein, urea, and lipid concentrations in Group 2 partly mirror higher protein and fat intake but additionally point to higher protein synthesis and lipid turnover.

Influence of feeding different amounts of first colostrum on metabolic, endocrine, and health status and on growth performance in neonatal calves. Rauprich AB, Hammon HM, Blum JW. J Anim Sci 2000 Apr; 78 (4), pp. 896–908.

Intestinal Absorption: Malabsorption and Compromised Mucosal Integrity
D-Xylose

Cellular/Molecular Mechanism of Action: D-xylose is absorbed from the small intestine (jejunum) by passive carrier-mediated transport mechanisms.

Route of Administration: D-xylose (oral).

Clinical Implementation: Colostrum intake is important for health and postnatal development of neonatal calves. Based on the interpretation of xylose absorption tests performed on day-5, and enhancement of colostrum intake has no significant effect on the absorptive capacity within the intestine.

Influence of feeding different amounts of first colostrum on metabolic, endocrine, and health status and on growth performance in neonatal calves. Rauprich AB, Hammon HM, Blum JW. J Anim Sci 2000 Apr; 78 (4), pp. 896–08.

Intestinal manipulation during elective aortic aneurysm surgery leads to portal endotoxaemia and mucosal barrier dysfunction. Lau LL, Halliday MI, Lee B, Hannon RJ, Gardiner KR, Soong CV. Eur J Vasc Endovasc Surg 2000 Jun; 19 (6), pp. 619–4.

Intestinal Absorption/Escherichia Coli (E. Coli) Enterotoxin-Induced Diarrhea
D-Xylose/[^{51}Cr]-Labeled Ethylenediaminetetraacetic Acid (EDTA)

Cellular/Molecular Mechanism of Action: [^{51}Cr]-EDTA is an organic chelate of radioactive [^{51}chromium] and is normally not significantly absorbed across intact, normal intestinal mucosa. Alternatively, D-xylose is absorbed across the surface of the small intestine (jejunum) mucosa involving passive carrier-mediated transport mechanisms.

Application: Detection and characterization of alterations in the intestinal permeability of [^{51}Cr]-EDTA and absorptive capacity including conditions associated with *E. coli* enterotoxin-induced diarrhea.

Route of Administration: D-xylose and [^{51}Cr]-EDTA can be administered orally for the purpose of evaluating intestinal absorption and permeability.

Implementation: Evaluation of alterations in intestinal absorptive capacity in diarrhea induced by the administration of *E. coli* enterotoxins. Intestinal absorption is evaluated using D-xylose and [^{51}Cr]-EDTA absorption tests.

Animal Model: Murine (*E. coli* heat-stable, heat-labile, and both heat-stable and heat-labile enterotoxin-induced diarrhea).

Interpretation and Analysis: The absorption of D-xylose is greatest 45 minutes after ingestion in both control and enterotoxin-treated groups. There is a significant ($p < 0.01$) decrease in xylose absorption at 45 minutes following exposure to all 3 entertoxin formulations compared to reference control groups. Such findings may be due to change in membrane fluidity and hence changes in membrane permeability, whereas [^{51}Cr]-EDTA absorption is at its maximum 15 minutes after ingestion in both controls and following enterotoxin exposure. No significant ($p < 0.05$) increase can be appreciated for [^{51}Cr]-EDTA absorption in enterotoxin-treated groups as compared with the control group. Findings of this nature suggest a change in tight junctional permeability that may be due to changes in the cytoskeletal microfilaments. Both these tests do, however, demonstrate that *E. coli* enterotoxin-induced diarrhea results in absorption and permeability changes.

[^{51}Cr]-labeled ethylenediaminetetraacetic acid and D-xylose absorption test in Escherichia coli enterotoxin-induced diarrhea in mice. Verma M, Ganguly NK, Majumdar S, Walia BN. Scand J Gastroenterol 1995 Sep; 30 (9), pp. 886–91.

Intestinal Absorption: Malabsorption and Compromised Mucosal Integrity
Glucose

Mechanism of Action: Absorbed from the small intestine by membrane-associated active transport mechanisms.

Diagnostic Application: Diagnosis of malabsorption attributed to the small intestinal segment of the gastrointestinal tract.

Route of Administration and Dosage: Following a 12-hour period of fasting, glucose is administered orally, usually by nasogastic intubation at a dose of approximately 1 g/kg (10% solution). Venous blood samples should be collected at 0, 0.5, 1.0, 1.5, 2.5, 3.0, 3.5, and 4.0 hours into tubes containing fluoride anticoagulant. Peak plasma concentrations are observed at approximately 2 hours, at which time at least a doubling of the systemic glucose concentration should be observed.

Interpretation and Analysis: (i) Solutions greater than 10% concentration will promote delayed gastric emptying, which serves as an artifact complicating interpretation of serum glucose concentrations (false negative). (ii) Glucose is subject to metabolism by gastrointestinal flora and can complicate interpretation of serum glucose concentrations. An example includes diarrhea of an infectious etiology. (iii) Horses on a low carbohydrate plane display higher peak xylose concentrations.

Laboratory Instrumentation: Measured directly through the application of glucose oxidase that rather specifically oxidizes this monosaccharide. An additional specific assay of glucose can be achieved with ortho-toluidine reagent, which reacts with aldohexoses. In the peripheral blood, dextrose is the predominant aldohexose. Many commercial instruments apply this methodology for the assay of serum glucose. Non-specific glucose assay methods include Nelson-Somogyi, ferricyanide, and Folin-Wu.

Intestinal Absorption: Malabsorption and Compromised Mucosal Integrity
Galactose/Glucose

Cellular/Molecular Mechanism of Action: Hydrolysis in the luminal bulk fluid by secreted enzymes is the major pathway for the breakdown of polysaccharides to oligosaccharides, and further hydrolysis is accomplished by a battery of carbohydrases in the brush border of the mature enterocytes. The glucose, galactose, and fructose produced are absorbed across the enterocytes of the upper half of the villus. Glucose and galactose (and other glucalogues) are actively transported into the enterocyte by a Na^+-glucose co-transporter via the trans-membrane electrochemical Na^+ gradient, and exit across the basolateral membrane by a glucose transporter. Fructose absorption is by an Na^+-independent transport system that has not been fully characterized. Absorption of monosaccharides from disaccharides appears to have a kinetic advantage (disaccharide-related transport system). Hexose absorption is enhanced by dietary intake of hexoses by increased activity of Na^+-glucose co-transporter and basolateral-membrane associated glucose transporter and by increased enterocyte numbers. Despite many kinetic and other types of studies in animals, and some in humans that suggest multiple Na^+-glucose transporters, only Na^+-glucose co-transporter is expressed in enterocytes.
Application: Evaluation of intestinal absorption capacity.
Route of Administration: Oral.
Dosage: Swine: Experimental meals containing 392 g dry matter of either hydrolyzed or non-hydrolyzed lactose together with a protein-mineral-vitamin mixture (200 g).
Interpretation and Analysis: Cadmium compounds decrease both D-galactose accumulation in the jejunum tissue, and D-galactose mucosal-to-serosal transepithelial fluxes in a dose-dependent manner. In this context, cadmium does not seem to modify sugar diffusion across the intestinal epithelium. The inhibitory mechanism associated with cadmium is non-competitive and it is partly reversed with dithioerythritol (thiol groups protector). The interpretation of these results implies that cadmium decreases carrier-mediated intestinal absorption of sugar (in rabbits).

The rates of glucose and fructose transport are greater in the proximal intestine prior to weaning and but are highest in mid-intestine after weaning. Galactose transport remains highest in the proximal intestine. Postnatal increases in Km values for galactose, but not glucose indicates that there are multiple aldohexose transporters that undergo separate patterns of development. The presence of fructose transport in neonatal pigs implies that this species may have a more advanced state of development than neonatal rats and rabbits, or may reflect the presence of an adaptation necessary to facilitate early weaning. Changes in fructose-to-glucose and galactose-to-glucose transport ratios before weaning suggest transporter development is at least in part genetically regulated and facilitates weaning in piglets. Curiously, fructose-to-glucose transport ratios are lower than those observed in the rat and rabbit, but closely paralleled those of some carnivorous feline species.

In swine receiving oral lactose (hydrolyzed and non-hydrolyzed), measurements of portal and arterial blood concentrations of glucose, galactose and amino nitrogen together with portal blood flow rate are taken during a postprandial period of 8 hours after oral lactose ingestion. Amounts of hexoses appearing in the portal blood after hydrolyzed-lactose intake are 3- and 2-fold larger within 2 hours and 8 hours, respectively, in contrast to the intake of non-hydrolyzed lactose. Enzymatic hydrolysis within the intestine is therefore the limiting factor of lactose digestion in unadapted pigs. Irrespective of the lactose form ingested, glucose chronologically appears earlier and in larger amounts in the portal blood than does galactose. Following hydrolyzed-lactose intake, the amount of glucose entering the portal blood exceeds the amount administered after 5 hours of intake. The significance of this observation is that a fraction of galactose is transformed into glucose during enterocyte transport.

Intestinal Absorption/Short Bowel Syndrome (SBS): Experimental
3-0 Methylglucose (3-0 MG)/Lactulose/Mannitol

Cellular/Molecular Mechanism of Action: The carbohydrate molecule 3-0 methylglucose is absorbed across the mucosal surface of the small intestine usually involving carrier-mediated processes residing within the jejunum. The lactulose:mannitol ratio can serve as a measure of increased intestinal permeability (large-pore-diameter defects). Lactulose is normally not absorbed across intact intestinal mucosa, while rhamnose and mannitol are absorbed across intact intestinal mucosal surfaces. In this context, lactulose and mannitol are not metabolized in the small intestine but may be metabolized in the large intestine.
Background Information: Inert carbohydrate probes are widely used to study intestinal permeability and examine the passive uptake of markers.
Application: Detection and characterization of alterations in intestinal absorptive capacity and permeability similar to those recognized in SBS.
Implementation: Evaluation of quantitative absorption in an SBS model facilitated by the use of 3-0 MG as a marker of intestinal surface area and active nutrient transport capability. Test solutions containing 3-0 MG, lactulose, and mannitol are gavaged (day 7) followed by a 16-hour period of urine collection. Urine recovery of probes is quantified using high-performance liquid chromotography. Intestinal morphology is then evaluated grossly and by light microscopy.

Animal Model: Rat SBS (sham operation [intestinal transection only], 50% resection [R50], 75% resection [R75], and 90% resection [R90; n = 6 to 8 in each group]). Animals can be pair-fed, and over days 5 and 6 postoperation, a balance study done to quantify absorption of dietary fat, protein, and carbohydrate.
Interpretation and Analysis: Increased extent of surgical resection results in reduced absorption of dietary nutrients and 3-0 MG, which reaches significance in the R90 resected animals. 3-0 MG absorption significantly correlates with intestinal surface area and the absorption of dietary protein and fat ($p < 0.01$ for all comparisons). Interestingly, 3-0 MG absorption does not significantly correlate with the absorption of dietary carbohydrate. Absorption of 3-0 MG is a useful marker of functional intestinal surface area and of the absorption of dietary fat and protein in experimental SBS. 3-0 MG may be a useful marker of nutrient absorptive capacity in patients with SBS but further study is indicated.
Instrumentation: High-performance liquid chromotography.

3-0 methylglucose absorption *in vivo* correlates with nutrient absorption and intestinal surface area in experimental short bowel syndrome. Martin GR, Meddings JB, Sigalet DL. JPEN J Parenter Enteral Nutr 2003 Jan–Feb; 27 (1), pp. 65–70.

Intesinal Absorption: Short Bowel Syndrome
Mannitol/Lactulose/Hydrolyzed Protein vs Non-Hydrolyzed Protein

Cellular/Molecular Mechanism of Action: Lactulose is normally not absorbed across intact intestinal mucosa, in contrast to mannitol, which is absorbed across intact small intestinal mucosal surfaces. In this context, lactulose and mannitol are not metabolized to any significant degree in the small intestine but they can be metabolized in the large intestine.

Application: The lactulose/mannitol ratio can be applied to detect increased small intestinal permeability (large-pore defects).
Implementation: Carbohydrate absorption tests employing lactulose and mannitol as probes to evaluate intestinal mucosa function and integrity have been utilized to evaluate the appropriateness of enteral formulations in cases of neonatal short bowel syndrome. In young children (4.08 ± 2.45 months) several parameters have been measured in attempts to determine the relative benefit of hydrolyzed protein compared to standard fomula properations in conditions of short bowel syndrome.
Interpretation and Analysis: Based on the calculations of intestinal permeability measured by a carbohydrate absorption test (lactulose/mannitol excretion ratio), energy, and nitrogen balance, there are no short-term advantages of hydrolyzed protein preparations (lactulose/mannitol ratio reference control 0.85 ± 0.85; hydrolyzed formula 0.59% ± 0.51%; non-hydrolyzed formula 0.69% ± 0.72%).

Hydrolyzed versus non-hydrolyzed protein diet in short bowel syndrome in children. Ksiazyk J, Piena M, Kierkus J, Lyszkowska M. J Pediatr Gastroenterol Nutr 2002 Nov; 35 (5), pp. 615–8.

Intestinal Absorption: Malabsorption and Compromised Integrity/[Intestinal Cryptosporidiosis]
Lactose Intolerance/Glucose Absorption

Application: Intestinal function and integrity evaluation.
Clinical Implementation: Lactose tolerance test performed to evaluate intestinal lactose intolerance. Glucose is administered for the evaluation of intestinal absorption capacity/function.

Animal Model: Caprine (2-week-old Toggenburg kid with persistent diarrhea and poor body condition).

History: The herd had high morbidity and mortality associated with diarrhea in neonatal kids.
Interpretation and Analysis: Lactose intolerance can be diagnosed on the basis of results of a lactose tolerance test and glucose absorption test. Clinically normal herdmates can be used as control animals. In the clinical case described, the kid responded to lactase supplementation. Cryptosporidium organisms had been detected in feces of several affected kids during episodes of acute diarrhea. Lactose intolerance therefore appears to be a clinical feature associated with intestinal cryptosporidiosis.

Secondary lactose intolerance in a neonatal goat. Weese JS, Kenney DG, O'Connor A. J Am Vet Med Assoc 2000 Aug 1; 217 (3), pp. 372–5.

Intestinal Absorption: Malabsorption and Compromised Integrity
Lactulose/Mannitol

Application: (i) Glucose and 3-O-methyl-D-glucose can be utilized to assess the presence/integrity of active-transport mechanisms within the mucosa of the proximal small intestine; (ii) D-xylose is transported by a passive carrier-mediated process; (iii) lactulose is not absorbed across the surface of intact intestinal mucosa; (iv) mannitol is absorbed across the surface of intact small intestinal mucosa; (v) the lactulose:mannitol ratio serves as a measure of increased intestinal permeability (large-pore defects). Neither lactulose nor mannitol is metabolized to any significant degree in the small intestine but may be metabolized in the large intestine. The [^{13}C]-acetate breath test can be applied to assess gastric emtyping.
Examples of Clinical Implementation: D-xylose absorption tests can be used to investigate the effect of intestinal manipulation on intestinal function and permeability such as the changes that occur during conditions of endotoxaemia associated with elective abdominal aortic aneurysm (AAA) surgery.
Interpretation and Analysis: Applying the D-xylose absorption test, significant increases in intestinal permeability can be detected postoperative day 1 in patients that undergo either transperitoneal or extraperitoneal correction strategies (day 1:0.107 ± 0.04, mean ± S.E.M.). In addition, there is a significant positive correlation between portal endotoxaemia and intestinal permeability ($r = 0.955$ $p = 0.001$). A significantly higher concentration of portal endotoxin can be identified intraoperatively in cases corrected by the transperitoneal approach compared to those corrected applying the extraperitoneal methods ($p < 0.05$). No correlation appears to exist between increased intestinal permeability and aortic clamp time, operation time, amount of blood lost or transfused. In addition, there is a significant positive correlation between portal endotoxaemia and intestinal permeability ($r = 0.955$ $p = 0.001$).

Intestinal manipulation during elective aortic aneurysm surgery leads to portal endotoxaemia and mucosal barrier dysfunction. Lau LL, Halliday MI, Lee B, Hannon RJ, Gardiner KR, Soong CV. Eur J Vasc Endovasc Surg 2000 Jun; 19 (6), pp. 619–24.

Intestinal Absorption: Malabsorption and Compromised Integrity
Lactulose/ Mannitol/Sucrose/[Hyperosmolar vs Non-Hyperosmolar]

Background Information: (i) Lactulose is not absorbed across the surface of intact intestinal mucosa; (ii) mannitol is absorbed across the surface of intact intestinal mucosa; (iii) the lactulose:mannitol ratio serves as a measure of increased intestinal permeability whereby lactose detects the presence of large-pore defects; (iv) increased sucrose absorption occurs with damage/injury to intestinal mucosa. Neither lactulose nor mannitol is metabolized to any significant degree in the small intestine but may be metabolized in the large intestine.
Application: Evaluation of intestinal absorption and permeability as parameters of mucosal integrity.
Dosage: After an overnight fast, individuals are administered a hyperosmolar sugar absorption test solution (2 g mannitol, 5 g lactulose, and 40 g sucrose/100 ml [around 1,560 mmol/l]). A 2nd administration strategy involves the administration of a low-osmolar sugar solution (2 g mannitol and 5 g lactulose/100 ml [around 375 mmol/l]).
Considerations: Reliability of differential sugar absorption tests is hampered by a lack of standardization of the content and osmolarity of the test solutions.
Examples of Clinical Implementation: Evaluation of the effect of sugar test solution osmolality on the 5-hour urine excretion of orally administered lactulose and mannitol. All urine from the 5-hour period following ingestion of the test solution is then collected for analysis.
Interpretation and Analysis: Normal mannitol concentrations imply normal intestinal absorptive capacity and low mannitol concentrations suggest diminished gastrointestinal absorptive capacity. Low lactulose absorption levels suggest that the intestinal mucosa is normal, in contrast to situations of increased passive intestinal lactulose abosorption, which implies that the integrity of the intestinal mucosa barrier has been compromised. Hyperosmolar sugar formulations appear to discriminate better between normal and damaged mucosa of the small bowel such as villous atrophy due to a relative increase in permeability for lactulose.

The sensitivity of hyperosmolar SAT solution and low-osmolar solution for the detection of mucosal abnormalities in celiacs is 64% and 43%, respectively.

Instrumentation: Gas chromatography analysis of lactulose and mannitol urine concentrations.

Sensitivity of a hyperosmolar or "low"-osmolar test solution for sugar absorption in recognizing small intestinal mucosal damage in celiac disease. Uil JJ, van Elburg RM, Janssens PM, Mulder CJ, Heymans HS. Dig Liver Dis 2000 Apr; 32 (3), pp. 195–200.

Intestinal Absorption/Accelerated Physical Development/Correction of Coarctation of the Aorta vs Intestinal Absorption
Xylose

Cellular/Molecular Mechanism of Action: Xylose is absorbed by the intestinal mucosa of the small intestine.
Application: Evaluation of intestinal absorption capacity.
Route of Administration: Xylose (oral/per os).
Implementation: Delineation of surgical correction of coarctation of the aorta or improved intestinal absorption contributes to postoperative accelerated physical development in children.

Human Model: Postoperative surgical correction of coarctation of the aorta (n = 9).
Interpretation and Analysis: Lowered values of the oral xylose absorption *test* are found in all cases prior to surgical correction. In all postoperative cases, sphigmo-oscillometry reveals increases in pulsatile character of the blood flow, pulsatile volume in the lower extremities, and a rise of mean arterial blood pressure in this area. On the other hand, surgical repair has no influence on renal blood flow as evidenced by PAH clearance and isotope renography. There is no correlation between diuresis and the xylose excretion test. Increased values of the xylose test after operation for coarctation of the aorta are due to the increased intestinal absorption rather than to improved renal function. Improved intestinal absorption may be a factor responsible for the accelerated physical development of children operated on for coarctation of the aorta.

Xylose absorption test before and after surgical repair of coarctation of the aorta. Markiewicz A, Wojczuk K, Zmudzicanski J. Acta Hepatogastroenterol (Stuttg) 1975 Apr; 22 (2), pp. 112–7.

Intestinal Absorption (Carrier-Mediated Transport)/Intestinal Permeability (Unmediated Diffusion)/Influence of Age and Body Size
Lactulose:L-Rhamnose Ratio/D-Xylose:3-O-Methyl-D-Glucose Ratio

Cellular/Molecular Mechanism of Action: Lactulose, L-rhamnose, D-xylose, and 3-O-methyl-D-glucose are molecular carbohydrate sugars. Lactulose (L) and rhamnose (R) are not significantly metabolized in the intestine. Lactulose and rhamnose are not normally absorbed across intact mucosal surfaces of the small intestine. The lactulose/rhamnose ratio can be used as an indicator of increased intestinal permeability (large-pore/small-pore defects, respectively). Similarly, xylose and methylglucose are normally absorbed across healthy intestinal mucosa, which is dependent upon carrier-mediated mechanisms residing primarily within the jejunum.
Application: Evaluation of intestinal permeability (unmediated diffusion) as measured by the ratio of urinary lactulose to L-rhamnose (L:R ratio) and intestinal absorption (carrier-mediated transport) as measured by the ratio of urinary D-xylose to 3-O-methyl-D-glucose (X:MG ratio).
Route of Administration: Oral.
Implementation: Evaluation of the influence of the variables of age and body size on estimates of intestinal permeability and absorption using lactulose, rhamnose, xylose, and 3-O-methyl-D-glucose as investigative molecular probes. In this context, solutions containing lactulose and rhamnose (L:R); or xylose and 3-O-methyl-D-glucose (X:MG) are administered orally. Urine is then collected 6 hours later, and urinary L:R and X:MG concentration ratios calculated. Fecal moisture and scoring are recorded during the same periods. Measures of intestinal absorption (unmediated diffusion) and intestinal permeability (carrier-mediated transport) are assessed through the measurement/calculation of urinary L:R ratios and urinary X:MG ratios, respectively. These findings are then compared to the properties of fecal samples to identify possible correlating variables.

Animal Model: Canine (age = 12, 22, 36, and 60 weeks old; n = 6 miniature poodles, n = 6 standard schnauzers, n = 6 giant schnauzers, and n = 6 Great Danes).
Interpretation and Analysis: Age and breed do not appear to affect intestinal absorption. A relationship between X:MG and fecal variables also does not appear to exist. Alternatively, significant effects of age and body size on intestinal permeability can be detected. Puppies (12 weeks old) and large dogs have higher intestinal permeability levels than adult (60 weeks old) and small dogs. The increased intestinal permeability in large dogs is associated with lower fecal quality as indicated by the significant positive correlations between L:R ratio and fecal moisture (r, 0.61) and L:R ratio and fecal scores (r, 0.86) in adult dogs. Such observations indicate that age and body size should be considered when assessing intestinal permeability by use of the L:R urinary excretion test in dogs. High intestinal permeability could be a possible cause of poor fecal quality in large dogs.

Influence of age and body size on intestinal permeability and absorption in healthy dogs. Weber MP, Martin LJ, Dumon HJ, Biourge VC, Nguyen PG. Am J Vet Res 2002 Sep; 63 (9), pp. 1323–8.

Intestinal Absorption: Malabsorption and Compromised Mucosal Integrity
Mannitol/Raffinose/Sucrose/Lactulose

Cellular/Molecular Mechanism of Action: Lactulose and raffinose are poorly absorbed from the small intestine. Mannitol is normally absorbed across the surface of intact small intestinal mucosa. In conditions of injury to the small intestine, sucrose and lactulose absorption increases. Ratios of lactulose/mannitol for example can be therefore be applied to detect increases in intestinal permeability. Lactulose, mannitol, and raffinose are not metabolized in the small intestine, but they can be metabolized in the large intestine.
Application: Detection of conditions associated with increased intestinal permeability.
Implementation: Four enzyme (biochemical-based) methods have been developed for the measurement of the urinary concentration of the probe sugars mannitol, raffinose, lactose and sucrose. Mannitol, lactose and sucrose are measured directly through the use of mannitol dehydrogenase, beta-galactosidase and invertase, respectively. Raffinose measurement needs a 3-hour preincubation with alpha-galactosidase, after which biochemically generated sucrose is measured.

The analytical performance parameters such as within- and between-run precision, linearity, lowest detection limit, interference of other sugars and comparison with a gas chromatographic methods have been described.

Assessment of intestinal permeability: Enzymatic determination of urinary mannitol, raffinose, sucrose and lactose on Hitachi analyzer. Hessels J, Snoeyink EJ, Platenkamp AJ, Voortman G, Steggink J, Eidhof HH. Clin Chem Lab Med 2003 Jan; 41 (1), pp. 33–8.

Intestinal Absorption: Malabsorption and Compromised Integrity/Bacterial Overgrowth: Small Intestine
D-Xylose/[^{14}C]D-Xylose

Cellular/Molecular Mechanism of Action: D-xylose is absorbed from the small intestine (jejunum) by glucose active transport mechanisms. D-xylose compared to L-xylose is relatively poorly metabolized.
Diagnostic Application: Diagnosis of malabsorption attributed to the small intestinal segment of the gastrointestinal tract.
Route of Administration and Dosage: D-xylose can be give as an alternative to glucose at a dose rate of 0.5 to 1.0 g/kg orally as a 10% solution following a 12-hour period of fasting (e.g., equine). Similar to glucose, preparations of D-xylose can be administered orally by nasogastric intubation (e.g., equine). In humans, 25 g is 1 of the "standard" D-xylose doses used diagnostically.
Considerations: D-xylose is superior to glucose for the detection of small intestinal malabsorption because it is more resistant to catabolism by gastrointestinal bacterial flora.
Implementation: The standard D-xylose test in human adults is based on analysis of 5-hour urine collection and a 1-hour serum sample.
Interpretation and Analysis: The D-xylose test can help discriminate between normal subjects and conditions of proximal small intestinal malabsorption with greater than 95% specificity and sensitivity. The 1-hour serum level measured after administering this dose is also useful in evaluating malabsorption in cases with intermediate degrees of renal insufficiency and in geriatric cases. The 1-hour serum test after administration of 5 g of D-xylose should be used in human (and possibly equine) pediatrics and is greater than 91% sensitive and close to 100% specific. The [^{14}C]D-xylose breath test with 1 g of D-xylose has been useful in identifying malabsorption caused by bacterial overgrowth in the small intestine in humans.

D-xylose testing: A review. Craig RM, Atkinson AJ Jr. Gastroenterology 1988 Jul; 95 (1), pp. 223–31.

Intestinal Absorption: Malabsorption Due to Acute Graft vs Host/Myeloablative Conditioning
[^{51}Cr]-Labeled Ethylenediaminetetraacetic Acid (EDTA) Absorption

Application: Detection of alterations in intestinal absorption.
Background Information: The efficacy of allogeneic, hemopoietic stem cell transplantation is limited by concomitant toxicity. This has led to the development of less toxic, reduced intensity conditioning (RIC) protocols, whose therapeutic benefit is largely related to an associated, immunity-mediated graft vs malignancy effect rather than by the cytotoxic treatment itself. Murine hemopoietic stem cell transplantation models suggest that acute graft vs host disease increases with the intensification of the conditioning regimen mediated by loss of integrity of the gut mucosa barrier.
Implementation: Evaluation of gastrointestinal permeability during allogeneic hemopoietic stem cell transplantation procedures can be performed utilizing the [^{51}Cr]-EDTA absorption test.
Interpretation and Analysis: In treatment protocols classified as reduced-intensity conditioning, significant increases in intestinal permeability are not appreciated. Alternatively, in myeloablatively conditioned cases there may be a significant increase in intestinal permeability the day before stem cell infusion ($p < 0.005$), on day 4 ($p < 0.005$), on day 7 ($p < 0.01$), and on day 14 ($p < 0.005$) after stem cell infusion, compared with baseline values. Myeloablative conditioning is also associated with increases in intestinal permeability on day 7 compared with reduced-intensity conditioning ($p < 0.05$). The finding of preserved intestinal-barrier function during allogeneic hemopoietic stem cell transplantation with reduced intensity conditioning is believed to be consistent with the hypothesis that GI tract damage may be an important event in the initiation of acute graft vs host reactions.

The gut mucosa barrier is preserved during allogeneic, hemopoietic stem cell transplantation with reduced intensity conditioning. Johansson JE, Brune M, Ekman T. Bone Marrow Transplant 2001 Oct; 28 (8), pp. 737–42.

Intestinal Absorption/Permeability
Lactulose/Mannitol Excretion Ratio [Urinary]

Cellular/Molecular Mechanism of Action: Lactulose and mannitol are both carbohydrate molecules. Lactulose is not normally absorbed in significant amounts across the surface of intact, healthy intestinal mucosa. In contrast, mannitol is absorbed across the surface of normal small intestinal mucosa. Neither lactulose nor mannitol is metabolized to any significant degree in the small intestine but may be metabolized in the large intestine.
Background Information: The dysfunction of the intestinal barrier is a factor that has been related to bacterial translocation from lumen to extraintestinal sites and consequently to the development of spontaneous bacterial peritonitis.
Application: Detection and characterization of alterations in intestinal mucosal absorptive capacity and assessment of the function of this anatomical structure as an effective barrier (e.g., permeability). In this context, lactulose can be used to detect large-pore defects.
Route of Administration: Lactulose (oral/per os) and mannitol (oral/per os).
Dosage: Lactulose (10 grams) and mannitol (5 g).
Implementation: Evaluation of intestinal permeability in conditions of hepatic cirrhosis utilizing measurements of lactulose/mannitol urinary excretion ratios. Concentrations are measured in amounts of urine collected over a 5-hour period following administration.
Human Model: Cases of hepatic cirrhosis ($n = 79$; $n = 25$ negative reference controls).
Interpretation and Analysis: Lactulose/mannitol ratios are significantly higher in cirrhotic patients than in negative reference controls ($p = 0.03$). The pattern becomes more evident in cases of end-stage cirrhosis. Patients with ascites, or encephalopathy show a statistically significant increase in lactulose/mannitol ratio compared to cases without these complications. Increases in intestinal permeability are related to the progression of liver disease and is more relevant with overt clinical complications. This is due to an increased absorption of lactulose. However, as liver disease progresses, mannitol absorption progressively decreases, probably due to a reduced surface of absorption, and these events are more relevant in patients with overt clinical complications.

Intestinal permeability is increased in patients with advanced cirrhosis. Pascual S, Such J, Esteban A, Zapater P, Casellas JA, Aparicio JR, Girona E, Gutiérrez A, Carnices F, Palazón JM, Sola-Vera J, Pérez-Mateo M. Hepatogastroenterology 2003 Sep–Oct; 50 (53), pp. 1482–6.

Intestinal Absorptive Capacity Posttrauma or during Sepsis/Post-Blunt Trauma/Severe Sepsis
D-Xylose

Cellular/Molecular Mechanism of Action: D-xylose is absorbed across the mucosa surface of the small intestine (jejunum) by passive carrier-mediated transport mechanisms.

Background Information: Although clinical studies suggest enteral, as opposed to parenteral, feeding lowers morbidity and mortality rates following severe trauma and after sepsis, it is unknown whether gut absorptive capacity (GAC) is indeed maintained under such conditions.
Application: Detection and characterization of alterations in intestinal absorptive capacity.
Route of Administration: D-xylose (nasogastric tube).
Dosage: D-xylose (25 g in 200 mL water).
Implementation: Evaluation of gut absorptive capacity (GAC) applying a 1-hour D-xylose absorption test in cases of blunt trauma or sepsis. Trauma and intra-abdominal sepsis cases receive an initial D-xylose test within 24 to 48 hours of admission, at 72 to 96 hours, and then weekly until D-xylose absorption had returned to normal.

Human Model: Cases of blunt trauma ($n = 8$); intense sepsis ($n = 11$); or normal reference controls ($n = 8$) excluding those with ileus, nasogastric output of more than 600 mL/24 hours, or residual gastric content of more than 25 mL after the D-xylose test. Trauma patients (ISS 8-14) and patients with intra-abdominal sepsis are acceptable candidates for being analyzed with the D-xylose test. Cases of ileus, nasogastric output of more than 600 mL/24 hours, or residual gastric content of more than 25 mL after the D-xylose test are excluded.
Interpretation and Analysis: Analyses reveal that gut absorptive capacity is depressed at 24 to 96 hours in both groups but returns to normal by 1 to 3 weeks after trauma or resolution of sepsis. Thus (1) gut absorptive capacity is severely depressed early after trauma and after the onset of sepsis; and (2) the 1-hour D-xylose absorption test represents a simple, quantitative assessment of GAC in critically ill patients. Hence, therapeutic agents that restore gut absorptive capacity may be useful for further reducing morbidity and mortality rates following trauma or the onset of sepsis.

Severe depression of gut absorptive capacity in patients following trauma or sepsis. Singh G, Harkema JM, Mayberry AJ, Chaudry IH. J Trauma 1994 Jun; 36 (6), pp. 803–8; discussion 808–9.

Intestinal Absorptive Function/ Intestinal Permeability
Lactulose (L)/Rhamnose (R)/D-Xylulose (X)/ 3-O-Methylglucose

Cellular/Molecular Mechanism of Action: D-xylulose (X) and 3-O-methylglucose are normally absorbed across healthy mucosa of the small intestine involving passive and active carrier-mediated transport mechanisms, respectively, residing within the jejunum. Alternatively, lactulose and rhamnose are not absorbed across intact intestinal mucosal surface. Neither lactulose nor rhamnose is metabolized to any significant degree within the small intestine but metabolism may occur within the large intestine.
Application: Evaluation of intestinal function and integrity. The lactulose/rhamnose ratio can be applied to detect increased intestinal permeability (large-pore/small-pore defects, respectively).
Route of Administration: The sugar analogs D-xylulose (X), 3-O-methylglucose (G), lactulose (L), and rhamnose (R) can be administered orally.
Implementation: Evaluation of intestinal function applying a differential sugar analog challenge. Intestinal absorption can be evaluated using D-xylulose (X) and 3-O-methylglucose (G). In contrast, intestinal permeability can be assessed using lactulose (L) and rhamnose (R) as molecular probes.

Animal Model: Canine ($n = 48$ healthy Irish setter dogs).
Interpretation and Analysis: Urinary L/R ratios in 48 Irish setters from 1 to 12 years old vary from 0.03 to 0.18, with a mean (SEM) of 0.10 ± 0.01; X/G ratios vary from 0.46 to 0.81, with a mean (SEM) of 0.59 ± 0.01. There are no significant differences between L/R or X/G ratios of dogs of different sex ($p > 0.2$) or age ($p > 0.5$), using analysis of covariance. Lactulose/rhamnose ratios of ≥ 0.18 and X/G ratios ≥ 0.43 are considered normal, defined by the respective mean $\pm$ 2SD. Repeatability is established by performing 3 permeability and function tests at monthly intervals in 12 of the dogs. Analysis of repeated L/R and X/G ratios by means of linear models procedure reveals no significant differences between measurements made on successive occasions ($p > 0.15$), confirming the repeatability of the test.

Reference range and repeatability of a combined intestinal permeability and function test in clinically healthy Irish setter dogs. Garden OA, Rutgers HC, Sørensen SH, Daniels S, Walker D, Batt RM. Res Vet Sci 1997 Nov–Dec; 63 (3), pp. 257–61.

Intestinal Malabsorption and Compromised Mucosal Integrity
Lactulose/Mannitol

Cellular/Molecular Mechanism of Action: Mannitol is, but lactulose is not, absorbed across the surface of intact mucosa of the small intestine. Neither mannitol nor lactulose is metabolized within the small intestine but they may be metabolized within the large intestine. Lactulose and mannitol are both excreted into the urine.
Background Information: In conditions of gastrointestinal cancer, the mean permeability index (PI) significantly increases after chemotherapy compared with the prechemotherapeutic values ($p < 0.01$). No significant difference in PI is observed with most neoplastic states affecting organ systems outside the gastrointestinal tract.
Application: Assessment of the extent of mucosal damage as a consequence of infectous disease and chemotherapeutic administration. In this context, the lactulose/mannitol ratio can be used to detect the presence of increased intestinal permeability.
Implementation: The permeability index (PI) for the intestine is measured by establishing the urinary recovery ratio of excreted lactulose and mannitol.
Interpretation and Analysis: Because the oral L/M absorption test is useful for assessing the degree of mucosal damage and measurement of intestinal permeability, this form of analysis should be recommended to determine the optimum timing and the adequate dosage of antineoplastic chemotherapeutic agents.

Assessment of the intestinal permeability following postoperative chemotherapy for human malignant disease. Inutsuka S, Takesue F, Yasuda M, Honda M, Nagahama S, Kusumoto H, Nozoe T, Korenaga D. Eur Surg Res 2003; 35 (1), pp. 22–5.

Intestinal Malabsorption and Compromised Mucosal Integrity/Neonate Intestinal Integrity and Functional Capacity
Lactulose/Rhamnose/D-Xylose/3-O-Methyl-D-Glucose

Cellular/Molecular Mechanism of Action: Lactulose and rhamnose are not absorbed across intact intestinal mucosal surfaces. Neither lactulose nor rhamnose is metabolized within the small intestine but may be metabolized within the large intestine. The lactulose/rhamnose ratio can be used to detect large-pore/small-pore intestinal defects. In conditions of increased intestinal permeability, both lactulose and rhamnose enter the intravascular compartment and are excreted into the urine. D-xylose and 3-O-methyl-D-glucose are absorbed across the intestinal mucosa by passive and carrier-mediated monosaccharide absorptive mechanisms, respectively, residing largely within the jejunum.

Background Information: Immaturity of intestinal epithelial barrier function and absorptive capacity may play a role in the pathophysiology of intestinal complications in preterm neonates during the early postnatal period.
Application: Evaluation of intestinal mucosal integrity and functional capacity.
Implementation: Establishing the urinary concentration ratios of lactulose and rhamnose following their oral administration can be used to identify conditions of increased intestinal permeability. Urinary excretion percentages of D-xylose and 3-O-methyl-D-glucose can be calculated to assess passive and active carrier-mediated monosaccharide mucosal absorption, respectively.
Interpretation and Analysis: In humans, the barrier function of the intestinal epithelium transiently decreases during the 1st week after birth in preterm neonates who are not enterally fed. Diminished barrier function and low monosaccharide absorptive capacity, particularly in neonates < 28 weeks, can increase vulnerability to the development of intestinal complications during the early postnatal period.

Intestinal permeability transiently increases between day 1 and day 7 in human neonates ($p < 0.05$). Carrier-mediated monosaccharide absorption increases between day 1 and day 14 in neonates of 28 to 30 weeks ($p < 0.05$) to the level observed in the neonates of 30 to 32 weeks gestation. In neonates > 28 weeks, intestinal permeability at day 7 is higher ($p < 0.05$) and carrier-mediated monosaccharide absorption at day 14 is lower ($p < 0.01$) compared with neonates $\geq$ 28 weeks of age.

Intestinal permeability and carrier-mediated monosaccharide absorption in preterm neonates during the early postnatal period. Rouwet EV, Heineman E, Buurman WA, ter Riet G, Ramsay G, Blanco CE. Pediatr Res 2002 Jan; 51 (1), pp. 64–70.

Intestinal Malabsorption and Compromised Mucosal Integrity
Maltose Absorption

Background Information: Successful small bowel transplantation requires effective immunosuppression that preserves intestinal function but avoids opportunistic infection.
Application: Evaluation of intestinal function and integrity.
Example of Clinical Implementation: Maltose absorption studies have been applied to evaluate various types of immunosuppressant agents.
Interpretation and Analysis: Control allografts (heterotopic small bowel transplants) without the benefit of immunosuppressive therapy are abnormal on day 7 and reflect the presence of severely damaged intestinal architecture that can be visualized on histopathological examintion. In contrast, subjects receiving immunosuppressive therapy display well-protected intestinal structure and normal maltose absorption on days 7 and 21. Subnormal plasma concentrations of maltose following administration implies the existence of abnormal function of small intestinal tissues.

Recipient FK506 pretreatment regimens in rat small bowel transplantation: Allograft survival, function, and systemic infection. Guo WH, Tian L, Yuen ZW, Chan KL, Wo JY, Nicholls G, Dallman M, Tam PK. J Pediatr Surg 2000 Nov; 35 (11), pp. 1600–5.

Intestinal Permeability: Crohn's Disease/Genetic Carriers
Polyethylene Glycol 400/Lactulose/ Rhamnose/Mannitol

Background Information: Lactulose, mannitol, and rhamnose are not metabolized in the small intestine but may be metabolized in the large intestine. Lactulose and rhamnose are normally not absorbed across intact intestinal mucosa, in contrast to mannitol, which is absorbed across intact small intestinal mucosal surfaces.
Application: Lactulose/mannitol and lactulose/rhamnose ratios can be applied to detect injury to small intestinal mucosa surfaces (e.g., increased permeability). The lactulose/rhamnose ratio can be used to detect large-pore/small-pore defects in intestinal permeability.
Implementation: Evaluation of intestinal mucosa integrity and function in healthy relatives of cases with Crohn's disease previously found to have increased intestinal permeability to polyethylene glycol 400. Alternative probe carbohydrates that can be applied for this purpose include lactulose, rhamnose, and mannitol.
Human Model: Cases of Crohn's disease ($n = 25$); healthy relatives of Crohn's disease cases ($n = 41$); healthy negative reference controls without a history of inflammatory bowel disease ($n = 29$).
Interpretation and Analysis: Patients with Crohn's disease have increased lactulose permeability when compared with relatives or controls. Lactulose absorption by patients with Crohn's disease is $0.41\% \pm 0.07\%$ (mean $\pm$ SE), whereas that of their relatives and unrelated controls is $0.28\% \pm 0.03\%$ and $0.26\% \pm 0.03\%$, respectively. There is no significant difference between the relatives and controls, but both groups differed from the patients ($p < 0.05$ and $p < 0.025$, respectively). The patients' lactulose/rhamnose ratio is approximately $70.5\% \pm 9.2\%$ vs $37.2\% \pm 3.3\%$ in relatives and $40.6\% \pm 5.7\%$ in unrelated controls ($p < 0.0005$ and $p < 0.0025$, respectively). The 2 intermediate-sized probes, rhamnose and mannitol, are not able to detect permeability differences among the 3 groups. The inability of lactulose, rhamnose, or mannitol to detect permeability abnormalities in healthy relatives of patients with Crohn's disease suggests that these probes penetrate the intestinal barrier by routes or mechanisms that are different from those of polyethylene glycol 400. Lactulose, in particular, detects permeability changes in patients with intestinal inflammation, and polyethylene glycol 400 is able to detect permeability changes in the healthy relatives of patients. Such findings indicate that permeability may be abnormal as a secondary result of inflammation or as a result of a primary genetic abnormality.

Intestinal permeability in patients with Crohn's disease and their healthy relatives. Katz KD, Hollander D, Vadheim CM, McElree C, Delahunty T, Daf-dufalza VD, Krugliak P, Rotter JI. Gastroenterology 1989 Oct; 97 (4), pp. 927–31.

ABSORPTION AND TRANSIT TIME: NON-CARBOHYDRATE-BASED AGENTS

Intestinal Absorption: Idiopathic Bile Acid Malabsorption (IBAM)/Diarrhea as a Rare Etiology
[^{75}Se]-Homocholic Acid Taurine (^{75}SeHCAT)

Cellular/Molecular Mechanism of Action: [^{75}Se]-homocholic acid taurine is a radiolabeled analog of homocholic acid taurine, which is an endogenous bile acid.
Background Information: Idiopathic bile acid malabsorption is a rare cause of diarrhea.
Application: Assessment of IBAM utilizing [^{75}Se]HCAT.
Implementation: Measurement of the proportion of [^{75}Se]-HCAT retained 7 days after its ingestion in cases of IBAM.
Human Model: Cases of IBAM ($n = 23$; $n = 3$ lost to follow-up; $n = 3$ died from malignancy; $n = 3$ inflammatory bowel disease). The mean period of follow-up for the remaining 14 patients = 99.2 months (range 48–140).

Cases that had previously responded well to treatment with a bile acid chelator (cholestyramine or aluminium hydroxide).

Questionnaires relating to current clinical symptoms and prescriptions had been sent to cases and their general practitioners.

Interpretation and Analysis: Many cases show an improvement in symptoms and no longer require treatment with cholestyramine (n = 7/23). Approximately one-third of symptomatic cases (e.g., n = 7/23) experience diarrhea that is well controlled with continued treatment with cholestyramine (n = 5) or standard antidiarrheal treatment (n = 2). In symptomatic (e.g., n = 7/7) and asymptomatic cases (e.g., n = 3) that undergo repeat 7-day [^{75}Se]HCAT tests, tests reveal that asymptomatic cases essentially all improve so that the retention of the tracer after 7 days is above 5%; all but a low percentage of symptomatic cases (e.g., n = 2/7) still have values under 5%. (Note: Small numbers of asymptomatic and symptomatic cases can preclude performing statistical analyses.) Idiopathic bile acid malabsorption is a rare cause of diarrhea and should be diagnosed only after malignancy and inflammatory bowel disease have been excluded by rigorous investigations. Cases should be followed up as some develop other serious gastrointestinal diseases. Approximately 50% of cases have remitted spontaneously and no longer require medication with bile acid chelators or antidiarrheal agents.

Idiopathic bile acid malabsorption: Long-term outcome. Luman W, Williams AJ, Merrick MV, Eastwood MA. Eur J Gastroenterol Hepatol 1995 Jul; 7 (7), pp. 641–5.

Intestinal Absorption: Idiopathic Bile Acid Malabsorption (IBAM)
[^{75}Se]-Homocholic Acid Taurine (^{75}SeHCAT)

Cellular/Molecular Mechanism of Action: [^{75}Se]-homocholic acid taurine is a radiolabeled analog of homocholic acid taurine, which is an endogenous bile acid component.

Application: Detection of cases suffering from IBAM.

Implementation: Assessment of chronic diarrhea of unknown etiology using the [^{75}Se]HCAT test as a "late-stage" diagnostic procedures due to the potential for the condition to be associated with IBAM.

Repeated [^{75}Se]HCAT tests applied in combination with clinical follow-up with patient interview and information from medical records. In this manner, it is possible to describe the long-term clinical course of the disease and assess the reliability of the [^{75}Se]HCAT test in diagnosing IBAM.

Human Model: Cases suffereing from chronic diarrhea (n = 150); chronic diarrhea cases affected by IBAM (n = 20; n = 16/20 that have completed both clinical follow-up and a new [^{75}Se]HCAT test; n = 6/30 lost to follow-up; n = 4/30 excluded from reexamination because of old age [> 80 years] or bowel resection). Median duration of symptoms before initial [^{75}Se]HCAT tests = 2.5 years (1- to 30-year range).

Interpretation and Analysis: On basis of low [^{75}Se]HCAT values and response to cholestyramine treatment, cases can initially be classified as having IBAM (e.g., n = 33/150). The diagnosis of having IBAM may have to be revised in some previously evaluated cases (n = 3; n = 2 inflammatory bowel disease; n = 1 *Clostridium difficile*). In a large percentage of cases (n = 13/16) symptoms persist, and [^{75}Se]HCAT values remain low and almost identical to initial values after a median observation time of 88 (51–113) months. Despite initial response to treatment with cholestyramine, in some instances, treatment has to be discontinued because of adverse effects or other compliance problems (e.g., n = 6/16 cases). In a small percentage of cases (e.g., n = 3/16) the [^{75}Se]HCAT value substantially increases, and bowel function correspondingly normalizes. The [^{75}Se]HCAT test appears to be reliable for diagnosing conditions of IBAM. Despite adult onset of symptoms, only a few patients improve after several years of observation. Treatment with cholestyramine is generally effective but not always tolerated.

Prognosis of adult-onset idiopathic bile acid malabsorption. Rössel P, Sortsøe Jensen H, Qvist P, Arveschoug A. Scand J Gastroenterol 1999 Jun; 34 (6), pp. 587–90.

Intestinal Absorption: Malabsorption of Bile Acid/Chronic Diarrhea and Collagenous Colitis
[^{75}Se]-Homocholic Acid Taurine ([^{75}Se]HCAT)

Cellular/Molecular Mechanism of Action: [^{75}Se]-homocholic acid taurine is a radiolabeled analog of homocholic acid taurine, which is an endogenous bile acid component.

Background Information: Bile acid malabsorption may be observed in patients with collagenous colitis.

Application: Characterization of bile acid malabsorption in conditions like collagenous colitis as a cause of chronic diarrhea.

Implementation: Evaluate the occurrence of bile acid malabsorption and the effect of bile acid binders prospectively in conditions of chronic diarrhea and collagenous colitis. Diagnostic intervention strategies can include the application of gastroscopy with duodenal biopsy, colonoscopy with biopsies, and analysis utilizing the [^{75}Se]HCAT test for bile acid malabsorption. Irrespective of diagnostic findings with [^{75}Se]HCAT, cases are treated with a bile acid binder (n = 24 cases with cholestyramine; n = 3 cases with colestipol).

Human Model: Cases of chronic diarrhea.

Interpretation and Analysis: In cases of collagenous colitis (n = 28; n = 6/28 men, n = 22/28 women), a large percentage have persistent symptoms (n = 27/28). A small number of cases (e.g., n = 4) have had a previous cholecystectomy or a distal gastric resection. The [^{75}Se]HCAT test is abnormal in approximately 44% of cases (e.g., n = 12/27) with collagenous colitis patients with [^{75}Se]HCAT values 0.5–9.7%, and normal in about 56% of cases (e.g., n = 15/27). Bile acid binding treatment is followed by a rapid, marked, or complete improvement in about 78% of collagenous colitis cases (e.g., n = 21/27). Rapid improvement occurs in approximately 92% of cases (e.g., n = 11/12) with bile acid malabsorption compared with 67% (e.g., n = 10/15) of cases with normal [^{75}Se]HCAT tests. Bile acid malabsorption is common in cases with collagenous colitis and is probably an important pathophysiological factor. Because of a high response rate without serious side effects, bile acid binding treatment should be considered for collagenous colitis, particularly patients with bile acid malabsorption.

Role of bile acids and bile acid binding agents in patients with collagenous colitis. Ung KA, Gillberg R, Kilander A, Abrahamsson H. Gut 2000 Feb; 46 (2), pp. 170–5.

Intestinal Absorption: Malabsorption and Compromised Integrity
Cobalamin/[Vitamin B_{12}]

Physiological Mechanism of Action: Cobalamin is normally absorbed across the ileal mucosa of the distal small intestine.

Background Information: Malabsorption of food-bound cobalamin is generally presumed to arise from gastritis and/or achlorhydria.

Application: Evaluation of gastrointestinal absorptive function.

Route of Administration: Cobalamin (oral).

Considerations: Decreased serum vitamin B_{12} can be appreciated with bacterial overgrowth of the small intestine as can occur with hypochlorhydria in atrophic gastritis.

Interpretation and Analysis: In conditions of documented severe malabsorption, histiological evidence of pathology can be appreciated along with lower acid and pepsin secretion values compared to normal reference control subjects. Statistically, there can be an overlap of these same parameters between conditions of severe vs mild malabsorption/achlorhydria/gastric atrophy. In humans, food cobalamin malabsorption is not always synonymous with atrophic gastritis and achlorhydria, and hypochlorhydria does not always guarantee food cobalamin malabsorption.

Heterogeneity of gastric histology and function in food cobalamin malabsorption: Absence of atrophic gastritis and achlorhydria in some patients with severe malabsorption. Cohen H, Weinstein WM, Carmel R. Gut 2000 Nov; 47 (5), pp. 638–45.

Intestinal Absorption: Malabsorption and Compromised Integrity/Jejunum Brush Border
Folic Acid/[Pteroylpolyglutamates]

Physiological Mechanism of Action: Dietary folates (pteroylpolyglutamates) are selectively absorbed from primarily the jejunum and ileal segments of the small intestine.
Background Information: Dietary folates exist as pteroylpolyglutamates (PteGlun) that undergo hydrolysis to pteroylmonoglutamate (PteGlu) forms during the process of intestinal absorption.
Diagnostic Application: Diagnosis of intestinal malabsorption conditions affecting the distal small intestine (ileum) based upon the observation of abnormally low folic acid concentrations following oral administration.
Route of Administration: Oral administration either by ingestion or nasogastric tube.
Considerations: Elevations in serum folic acid concentrations occurs with bacterial overgrowth of the small intestine.
Implementation: Evaluation of jejunal folate hydrolysis applying the technique of jejunal perfusion with separately labeled folate preparations. Note: In clinical practice, "cold" and radiolabeled folate can be applied as diagnostic probes.
Interpretation and Analysis: Pteroylpolyglutamates are hydrolyzed on the surface of the jejunum and is a prerequisite for folate absorption. An intestinal brush border pteroylpolyglutamate hydrolase (BB-PPH) has been identified in human and pig jejunum with characteristics that are distinct from those of an intracellular hydrolase (IC-PPH). Functional parallels of BB-PPH with *in vivo* hydrolysis of PteGlun in human and pig intestine and the clinical responsiveness of BB-PPH to different disease states indicate that this enzyme plays the major physiological role in folate absorption. Folate malabsorption is found in diseases that affect the jejunal mucosa and in response to various drugs. In most of these clinical conditions, folate malabsorption results from suppression of both of the processes of hydrolysis of PteGlun and jejunal uptake of PteGlu. Studies in miniature pigs have defined the sequence of development of folate malabsorption in chronic alcoholism.

The intestinal absorption of dietary folates in health and disease. Halsted CH. J Am Coll Nutr 1989 Dec; 8 (6), pp. 650–8.

Intestinal Absorption: Malabsorption and Compromised Integrity
Theophylline

Application: Evaluation of gastrointestinal absorption capacity, pharmaceutical bioavailability, and owner/patient non-compliance.
Route of Administration: Theophylline (regional perfusion example).
Dosage: Theophylline (5 mg/kg).
Implementation: Evaluation of intestinal integrity and function relative to theophylline absorption. One approach to achieving this objective includes simultaneous perfusion of 4 segments of equal length (jejunum, ileum, right colon and left colon) with saline solution containing [^{3}H]-polyethylene glycol 4000 to measure water shifts and theophylline at a total dose of 5 mg/kg, a typical neonatal dose. Absorption *of* theophylline, appearance in serum, and the effects of the drug on water and electrolyte movement in the intestinal segments are then monitored. Serum concentrations of theophylline after an intravenous and oral dose repesent a more practical approach to the clinical application of theophylline absorption studies.
Animal Model: Swine: (n = 13 newborn piglets; ages 9–14 days with surgically exposed segments of the intestine).
Interpretation and Analysis: Theophyllin displays excellent absorption of the drug from all intestinal segments studied (jejunum 0.97 ± 0.16, ileum 0.7 ± 0.13, right colon 0.7 ± 0.13, and left colon 0.88 ± 0.19 μg/cm/min), despite a concomitant secretion of sodium chloride and water. No statistical differences in absorptive capacity can be appreciated between different segments. The results suggest that as little as 100 cm of residual intestine could, theoretically, absorb a 5 mg dose of theophylline if presented slowly. These findings have ramifications for neonates who may receive theophylline orally or rectally.

Absorption of theophylline from the small and large intestine of the neonatal piglet. Murray RD, Breech L, Ailabouni A, Zingerelli J, Nahata MC. Eur J Drug Metab Pharmacokinet 1993 Oct–Dec; 18 (4), pp. 375–9.

Pharmacokinetic analysis of theophylline to assess non-compliance in therapy. Konishi H, Nakatsuka T, Yoshida M, Tamaki S, Minouchi T, Yamaji A, Kinoshita M. Ann Pharmacother 2002 May; 36 (5), pp. 835–8.

Intestinal Absorption: Malabsorption Syndromes/ Compromised Integrity/Cholestasis
Vitamin D

Cellular/Molecular Mechanism of Action: Cholecalciferol is absorbed from the small intestine and is converted to 1-hydroxycholecalciferol in the liver and to 1,25-dihydroxycholecalciferol in the kidney.
Physiological Mechanism of Action: Vitamin D is absorbed from the duodenum and proximal jejunum. Because vitamin D is a fat-soluble vitamin, its absorption is directly linked to fat absorption and bile production/secretion.
Background Information: Vitamin D is essential for the maintenance of calcium and bone metabolism in humans. The recommended daily allowance (RDA) for vitamin D in the United States of 200 IU (5.0 μg) is reasonable for adults who receive some exposure to sunlight; however, in the absence of any exposure to sunlight, this recommendation may be 2 to 3 times lower than that actually required to satisfy the body's needs. Vitamin D was 1st measured by bioassays. However, bioassays became obsolete in light of the revelation that vitamin D must be activated 1st in the liver to 25-hydroxyvitamin D (25-OH-D) and then in the kidney to 1,25-dihydroxyvitamin D [1,25(OH)2D] before becoming biologically functional. Current assays measure circulating concentrations of vitamin D, 25-OH-D, or 1,25(OH)2D.

Rickets and osteopenia, common problems in chronic childhood cholestasis, have been attributed to vitamin D malabsorption leading to reduced serum levels of 25(OH)-vitamin D. D-alpha-Tocopheryl

polyethylene glycol-1000 succinate (TPGS), a water-soluble form of vitamin E, forms micelles at low concentration.
Application: Potential marker for abnormalities in intestinal integrity and function.
Route of Administration: Vitamin D_3 (oral).
Dosage: Vitamin D_3 1,000 IU/kg (maximum dose of 50,000 IU).
Implementation: Evaluation of the potential role of TPGS in enhancing vitamin D absorption in conditions of cholestasis or intestinal dysfunction. One approach to delineating this objective involves the administration of vitamin D_3 with and without TPGS (25 IU/kg). Serial serum vitamin D_3 levels and areas under the curve are then measured.

Human Model: Cases of severe childhood chronic cholestasis (n = 8; age 5 months–19 years; n = 3 extrahepatic biliary atresia; n = 3 non-syndromic intrahepatic cholestasis; n = 2 Alagille syndrome).
Interpretation and Analysis: Serum concentration of 25-OH-D is the most valuable parameter for determining the overall vitamin D status of an individual, because it is an average of dietary and sunlight-induced vitamin D. The measurement of the serum 1,25(OH) 2D concentrations has been most useful in evaluating disorders in calcium and bone metabolism related to acquired and inborn errors in the conversion of 25-OH-D to 1,25(OH)2D.

d-Alpha-tocopheryl polyethylene glycol-1000 succinate enhances the absorption of vitamin D in chronic cholestatic liver disease of infancy and childhood. Argao EA, Heubi JE, Hollis BW, Tsang RC. Pediatr Res 1992 Feb; 31 (2), pp. 146–50.

Intestinal Absorption/Small Bowel Transplant Rejection: Orthotopic/Jejunum vs Ileum vs Colon vs Rectum

Acetaminophen (Paracetamol)/Indomethacin/ [Acetylsalicylic Acids-Acylsalicylic Acids]/ [Butyrylsalicylic Acylsalicylic Acids]/ [Propionyl Acylsalicylic Acids]

Physiological Mechanism of Action: Lipophilic indomethacin has similar absorption profiles within the large and small intestines, while intermediately lipophilic acetaminophen is more rapidly absorbed in the small intestine than in the large intestine.
Application: Evaluation of small intestine integrity (e.g., transplant viability, reference controls for evaluation of candidate pharmaceutical agents).
Route of Administration: Intragastic.
Dosage: Acetaminophen (0.15 g/kg).
Example of Clinical Implementation: Detection of orthotopic small bowel transplantation rejection.
Implementation: Evalution of profiles for absorption vs drug molecular weight and absorption vs drug lipophilicity within both the small and large intestines. In this context, acetaminophen, indomethacin, and acylsalicylic acid analogs can be applied as a reference control for characterizing the absorption-molecular weight profiles for various experimental compounds (e.g., different-sized polyethylene glycols [PEGs]) to determine if differences occur between the small and large intestines).

Animal Model: Rats (intestine situ loop method).
Interpretation and Analysis: In the application of acetaminophen for assessing small intestine integrity/function, declines in absorption parameters correspond with histological evidence of progressive acute graft rejection (e.g., postoperative day 3 vs day 7).

Alternatively, acetaminophen can serve well as a reference control for assessing intestinal integrity/function. In this context, it has been shown that large-intestinal absorption of PEGs with molecular weights larger than 300 is poor, while PEGs with molecular weights up to 600 are relatively well absorbed in the small intestine. Paracellular route for drug penetration in the large intestine is restricted more than in the small intestine. The absorption-lipophilicity profiles can also be examined in various regions (loops of 6 cm) of (rat) intestine using 3 acylsalicylic acids, acetyl-, propionyl-, and butyrylsalicylic acids. The absorption rates of the acylsalicylic acids varies within different regions of the intestine: the jejunum > the ileum > the colon > the rectum. In each region, the absorption rates increase with the drug lipophilicity. However, it has been shown that the absorption rates in the small intestine tend to reach a ceiling at high lipophilicity. To confirm this tendency, the absorption rates of acetaminophen and indomethacin can be compared in the 4 intestinal regions. The absorption rates of highly lipophilic indomethacin are similar in the large and small intestines, while intermediately lipophilic acetaminophen is more rapidly absorbed in the small intestine than in the large intestine. A thicker unstirred water layer adjacent to the small intestinal mucosa would be 1 of the factors that cause such varying absorption-lipophilicity profiles.

Drug absorption from large intestine: Physicochemical factors governing drug absorption. Kimura T, Sudo K, Kanzaki Y, Miki K, Takeichi Y, Kurosaki Y, Nakayama T. Biol Pharm Bull 1994 Feb; 17 (2), pp. 327–33.

Evaluation of the acetaminophen absorption test for early detection of orthotopic small bowel transplant rejection. Miyauchi T, Ishikawa M, Tashiro S. Surg Today 2001; 31 (8), pp. 695–700.

Intestinal Absorption (Calcium): Changes during Menopause

Strontium Absorption

Cellular/Molecular Mechanism of Action: Strontium is absorbed from the intestinal tract.
Application: Evaluation of intestinal calcium absorption.
Route of Administration: Strontium (oral).
Dosage: Strontium (2.5 mmol).
Examples of Clinical Implementation: Evaluation of the influence of estrogen on intestinal strontium absorption in normal postmenopausal states. To determine the variation within individuals, studies can be performed twice with the 2nd diagnostic test performed 10 days after the 1st procedures in order to obtain 2 baseline strontium absorption values. Fractional absorption and the area-under-the-concentration-time-curve (AUC) are calculated 4 hours after an oral strontium administration (2.5 mmol).
Interpretation and Analysis: The within-subject variation of fractional excretion values (240 hours) and AUC (0–240 hours) are 2.3 ± 0.76 and 1.2 ± 0.41, respectively. Estrogen administration does not influence the magnitude of these parameters. Interpretation of these measurements implies that normal postmenopausal women do not experience a modulating effect of short-term (supra) physiological dose estrogen on intestinal calcium absorption as measured by the strontium absorption test.

Effect of estrogen on intestinal strontium absorption in postmenopausal women. Dijkgraaf-ten Bolscher M, Neele SJ, Barto R, van der Vijgh WJ, Netelenbos JC. Maturitas 2000 Oct 31; 36 (3), pp. 195–201.

Intestinal Absorption: Fat Malabsorption

[^{13}C]-Palmitic Acid

Background Information: Classic fat balance studies detect fat malabsorption but do not discriminate between the potential causes of malabsorption, such as impaired intestinal lipolysis or reduced uptake of fatty acids.

Application: Selective and sensitive detection of impaired intestinal absorption of long-chain fatty acids.
Examples of Clinical Implementation: Evaluation of the absorption and appearance in the plasma of [^{13}C]-palmitic acid in conditions of fat malabsorption due either to chronic bile deficiency (permanent bile diversion) or to oral administration of the lipase inhibitor orlistat (200 mg/kg diet). Comparisons can also be made between [^{13}C]-palmitic acid and the percent absorption of ingested dietary fat determined by fat balance.

Animal Model: Rat (fat malabsorption due to bile deficiency).
Interpretation and Analysis: Decreases in [^{13}C]-palmitate acid absorption compared to negative reference control subjects or normal reference values suggest the detection of impaired intestinal absorption of long-chain fatty acids selectively and sensitively. Examples include the identification of fat malabsorption due to bile deficiency in a rat model. Laboratory data strongly support the use of the [^{13}C]-palmitate acid absorption test for the diagnosis of clinical fat malabsorption syndromes.

Detection of impaired intestinal absorption of long-chain fatty acids: Validation studies of a novel test in a rat model of fat malabsorption. Kalivianakis M, Minich DM, Havinga R, Kuipers F, Stellaard F, Vonk RJ, Verkade HJ. Am J Clin Nutr 2000 Jul; 72 (1), pp. 174–80.

Intestinal Absorptive Capacity/Pancreatic Exocrine Function/[Cystic Fibrosis]/[Celiac Sprue] Maldigestion vs Malabsorption
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)/[$^{13}C_6$]PABA/Xylose

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (BT-PABA or Bentiromide) is still a synthetic substrate for exocrine pancreatic enzyme fractions. Xylose is absorbed from intact small intestinal mucosal surfaces.
Application: Xylose can be applied to assess small intestinal absorptive capacity/integrity. N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid is of diagnostic value in detecting conditions of suboptimal exocrine pancreatic function.
Route of Administration: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid and xylose (both can be delivered orally per os).
Implementation: Characterize the potential of a single-step non-invasive stable isotope method of assessing digestive function to selectively identify cases of pancreatic insufficiency (maldigestion) or small bowel dysfunction (malabsorption), in addition to delineating if cases of maldigestion can be simultaneously distinguished from conditions of malabsorption. One approach that can be applied in pursuit of this objective entails the evaluation of the diagnostic attributes of ingesting a liquid test meal in concert with the oral intake of bentiromide, [$^{13}C_6$]PABA, and xylose (PABAX test). Serum is collected 1 hour postadministration and analyzed for PABA, [$^{13}C_6$]PABA, and xylose by stable isotope dilution methods.

Human Model: Cases of cystic fibrosis (n = 18); adult celiac sprue (n = 4); normal volunteers (n = 40).
Interpretation and Analysis: Cases of cystic fibrosis almost invariably have abnormal pancreatic function test results, but a large percentage of sprue cases also have abnormal pancreatic function test results (e.g., n = 3/4). Additionally, a large number of sprue cases have abnormally low bowel absorption test results (e.g., n = 4/4), compared to cases of adult cystic fibrosis that apparently have normal intestinal function. The 1-step, 1-hour PABAX test can reliably separate normal subjects from those with either maldigestion or malabsorption and can also separate subjects with maldigestion from those with malabsorption.
Instrumentation: Gas chromatography mass spectrometry.

A non-invasive stable-isotope method to simultaneously assess pancreatic exocrine function and small bowel absorption. Deutsch JC, Santhosh-Kumar CR, Kolli VR. Am J Gastroenterol 1995 Dec; 90 (12), pp. 2182–5.

Intestinal Malabsorption
Cholicalciferol/Vitamin D

Background Information: Vitamin D is essential for the maintenance of calcium and bone metabolism in humans. The recommended daily allowance (RDA) for vitamin D in the United States of 200 IU (5.0 μg) is reasonable for adults who receive some exposure to sunlight; however, in the absence of any exposure to sunlight, this recommendation may be 2 to 3 times lower than that actually required to satisfy the body's needs. Vitamin D was 1st measured by bioassays. However, bioassays became obsolete in light of the revelation that vitamin D must be activated 1st in the liver to 25-hydroxyvitamin D (25-OH-D) and then in the kidney to 1,25-dihydroxyvitamin D [1,25(OH)2D] before becoming biologically functional.
Interpretation and Analysis: Current assays measure circulating concentrations of vitamin D, 25-OH-D or 1,25(OH)2D. The serum vitamin D concentration is of value for determining the role of sunlight in producing vitamin D in skin and as a provocative test to determine the absorption of vitamin D in patients with malabsorption syndromes. The serum concentration of 25-OH-D is most valuable for determining the overall vitamin D status of an individual, because it is an average of dietary and sunlight-induced vitamin D. The measurement of the serum 1,25(OH)2D concentrations has been most useful in evaluating disorders in calcium and bone metabolism related to acquired and inborn errors in the conversion of 25-OH-D to 1,25(OH)2D.

The use and interpretation of assays for vitamin D and its metabolites. Holick MF. J Nutr 1990 Nov; 120 Suppl 11, pp. 1464–9.

PERMEABILITY AND ULCERATION

Note: See related references in Absorption section of this chapter.

Intestinal Injury: Small Intestine/Diamine Oxidase
Heparin

Application: Assess the extent and severity of acute, severe, small intestinal mucosal injury (adult rats).
Dosage: Heparin (400 U/kg).
Considerations: Diamine oxidase (DAO; EC 1.4.3.6) is an enzyme found in high activity in the mature cells of the upper villus of rat small intestinal mucosa, but has much lower activity in all other tissues in the non-pregnant rat.
Implementation: Determine whether a provocative test for increasing the level of plasma DAO activity by heparin administration can be used to monitor the extent and severity of acute, severe, small intestinal mucosal injury. Plasma postheparin diamine oxidase activity (180 minutes after 400 U/kg i.p. heparin) is measured 7 hours after initiation of perfusion.

Animal Model: Rat (acute small intestinal mucosal injury can be induced by perfusion with sodium sulfate solution [2,100 mosM] for 60 minutes, resulting in damage to villus epithelium).
Interpretation and Analysis: Increasing length of intestinal mucosal injury, precipitates a progressive decrease in both basal and plasma PHD activity. The decrease in plasma postheparin-diamine-oxide activity closely reflects the length of intestinal mucosa injured ($n = 128$, $r = 0.86$, $p < 0.001$), and it is much more sensitive (threshold limit of detection = 13% of total length, range = 67 U/ml

for 100% length of injury) than unstimulated basal levels of plasma diamine oxide (threshold = 40%, range = 2.1 U/ml). Some reports have suggested that diamine oxide is unique among intestinal mucosal enzymes in that circulating levels can serve as a marker of mucosal injury. However, related investigations have demonstrated that low-dose heparin administration enhances the use of diamine oxide even further as a sensitive, quantitative, circulating marker for monitoring the extent of small intestinal mucosal injury in the rat.

Plasma postheparin diamine oxidase. Sensitive provocative test for quantitating length of acute intestinal mucosal injury in the rat. Luk GD, Bayless TM, Baylin SB. J Clin Invest 1983 May; 71 (5), pp. 1308–15.

Intestinal Injury: Devitalization of Structures *Fluorescein Dye*

Cellular/Molecular Mechanism of Action: Functions as a detectable dye marker in biological systems. Reacts with ultraviolet light to produce a fluorescent green color.
Diagnostic Application: Detecting devitalized segments of the gastrointestinal tract.
Route of Administration and Dosage: Intravenous infusion prior to surgical intervention for the purpose of detecting devitalized segments of gastrointestinal tract.
Considerations: Fluorescein dyes can on occasion diffuse rather rapidly across intact barriers such as in the urinary bladder. For this reason, the interval between infusion and collection must be of a relatively short duration. Alternatively, fluorescein dye can be conjugated to large molecular weight substances, such as in a polypeptide protein or dextran molecule, that do not readily diffuse across intact anatomical structures such as the bladder or diaphragm.
Interpretation and Analysis: Segments of affected intestinal tract can be appreciated by direct visual observation based upon localization of fluorescein dye in ischemic, devitalized tissues.
Laboratory Instrumentation: In a clinical environment, presence of fluorescein dye localized within devitalized segments of devitalized intestinal tract or within abdominal fluid samples is usually accomplished by visual observation.

Permeability: Intestinal Permeability/Gastric Permeability/Small Intestinal Permeability/Small Intestinal Mucosa Function *Methylglucose/Rhamnose/Xylose/Sucrose/Lactulose*

Cellular/Molecular Mechanism of Action: Lactulose, rhamnose, xylose, methylglucose, and sucrose are sugar carbohydrates. Lactulose (L) and rhamnose (R) are not significantly absorbed across intact intestinal mucosa. Alternatively, xylose and methylglucose are normally absorbed across healthy intestinal mucosal surfaces in the jejunum and are dependent upon passive and active carrier-mediated transport mechanisms, respectively. Neither rhamnose nor lactulose is significantly metabolized within the small intestine but may be metabolized within the large intestine. Sucrose is absorbed across damaged/injured gastroduodenal mucosa.
Application: Methylglucose, rhamnose, xylose, sucrose, and lactulose can potentially be applied for the simultaneous evaluation of gastric permeability, small intestinal permeability, and small intestinal mucosal function in dogs with gastrointestinal disorders. The lactulose/rhamnose ratio can be applied to detect large-pore/small-pore permeability defects.
Route of Administration: Methylglucose, rhamnose, xylose, sucrose, and lactulose (oral).
Implementation: Develop and validate a method for concurrent separation and quantification of methylglucose, rhamnose, xylose, sucrose, and lactulose in canine urine by using high-pressure anion exchange liquid chromatography and pulsed amperometric detection. The method can be validated by evaluating dilutional parallelism, spiking recovery, intra-assay variability, and interassay variability.
Animal Model: Canine.
Interpretation and Analysis: Ratios for 3 urine samples, and all sugars, range from 77.6% to 106.9% for a 1:2 dilution, 85.2% to 121.4% for a 1:4 dilution, and 91.6% to 163.7% for a 1:8 dilution. Expected ratios for spiking recovery of all sugars, and 5 different spiking solutions, range from 85.5% to 116.7% (mean ± SD, 100.5 ± 6.0%; n = 3 urine samples). Intra-assay coefficients of variation are 1.6%, 3.4%, and 4.7% for methylglucose; 1.6%, 2.0%, and 3.6% for rhamnose; 2.7%, 1.4%, and 1.1% for xylose; 9.8%, 3.4%, and 4.0% for sucrose; and 3.2%, 3.3%, and 3.3% for lactulose. Interassay coefficients of variation are approximately 3.2%, 5.7%, and 4.2% for methylglucose; 4.3%, 5.4%, and 6.4% for rhamnose; 3.3%, 5.0%, and 4.2% for xylose; 9.4%, 9.9%, and 9.4% for sucrose; and 6.1%, 4.9%, and 2.7% for lactulose. Therefore, methodologies exist that can facilitate the simultaneous separation and quantification of 5 different sugars in canine urine (established and found to be linear, accurate, precise, and reproducible). The method may prove useful in the simultaneous evaluation of gastric permeability, small intestinal permeability, and small intestinal mucosal function in dogs with gastrointestinal disorders.
Instrumentation: High-pressure anion exchange liquid chromatography.

Development and validation of a method for simultaneous separation and quantification of 5 different sugars in canine urine. Steiner JM, Williams DA, Moeller EM. Can J Vet Res 2000 Jul; 64 (3), pp. 164–70.

Permeability: Enteropathy/Protein-Losing Conditions/Langerhans Cell Histiocytosis (LCH) *[^{57}Cr]-Radiolabeled Albumin*

Cellular/Molecular Mechanism of Action: Functions as a marker for extravascular leakage or vascular perfusion.
Background Information: Symptomatic involvement of the gastrointestinal (GI) tract as a prominent symptom in LCH is uncommon, occurring in < 1–5% of all cases, even when the disease is in its disseminated form. Up to now, there have been reports of 18 cases of LCH with GI manifestations, including the 2 cases from the referenced study, with diarrhea (77.7%), protein-losing enteropathy (33.3%), and bloody stool being the most frequent findings.
Diagnostic Application: Detection of protein-losing enteropathy conditions.
Dosage: Intravenous injection.
Considerations: Non-specific diagnostic modality.
Implementation: Evaluation of cases susptected of suffering from protein-losing enteropathy conditions utilizing [^{51}Cr]-labeled albumin in "leakage"-based studies.
Human Model: Cases with severe diarrhea, refractory hypoalbuminemia, and protein-losing enteropathy.
Interpretation and Analysis: [^{51}Cr]-labeled albumin can be effectively applied as a marker molecule in imaging studies for the detection of protein-losing enteropathy conditions. A review of the literature indicates that the presence of GI symptoms is often associated with systemic disease as well as with poor prognosis, mainly under 2 years of age. Radioisotopes are useful for documenting protein loss in several diseases with high specificity and sensitivity, and their utilization in such cases can function as an accurate diagnostic procedure as well as a tool for improved therapeutic management.

Disseminated Langerhans cell histiocytosis and massive protein-losing enteropathy. Santos-Machado TM, Cristófani LM, Almeida MT, Maluf PT, Costa PA, Pereira MA, Brito JL, Odone-Filho V. Braz J Med Biol Res 1999 Sep; 32 (9), pp. 1095–9.

Permeability: Gastrointestinal Mucosa
Sucralose/Mannitol

Cellular/Molecular Mechanism of Action: Sucralose and mannitol are carbohydrates that are not metabolized (degraded). Mannitol is normally absorbed across the mucosal surface of the small intestine.
Application: Molecular probes for the detection of alterations in intestinal permeability. Sucralose has also been evaluated as a probe for the measurement of whole gut permeability.
Route of Administration: Sucralose and mannitol (per os).
Analytical Method: Comparison of capillary column gas chromatography (CCGC) and packed column gas chromatography (PCGC) for their ability to accurately measure urinary sucralose (S) and 3 other sugar probes including, sucrose, lactulose (L), and mannitol (M). The 4 sugars can be detected precisely, without interference.
Implementation: Measurement of urinary sucralose (S) and 3 other sugar probes including, sucrose, lactulose (L) and mannitol (M) as *in vivo* molecular probes for the detection of alterations in intestinal permeability using 5- and 24-hour urine collections. Metabolism of the sugars can be evaluated by incubating the intestinal bacteria with an iso-osmolar mixture of mannitol, lactulose, and sucralose at 37°C for 19 hours. Sugar concentrations and the pH of the mixture are then monitored.

Human Model: (n = 14 healthy volunteers).
Interpretation and Analysis: The use of CCGC methodologies improves the detection of sucralose compared to PCGC. The average coefficient of variation decreases from 15% to 4%. It also increases the sensitivity of detection by 200- to 2,000-fold. The GC assay is linear between sucralose concentrations of 0.2 and 40 g/l ($r = 1.000$). Intestinal bacteria metabolize lactulose and acidify the media but do not metabolize sucralose or mannitol. The method for measurement of urinary sucralose permits the simultaneous quantitation of sucrose, mannitol, and lactulose, and is rapid, simple, sensitive, accurate, and reproducible. Because neither S nor M is metabolized by intestinal bacteria, and because only a tiny fraction of either sugar is absorbed, this pair of sugar probes appears to be available for absorption throughout the gastrointestinal tract. Thus, the 24-hour urinary concentrations of S and M, or the urinary S/M ratio following an oral dose of a sugar mixture, might be good markers for whole gut permeability.

Gas chromatographic method for detection of urinary sucralose: Application to the assessment of intestinal permeability. Farhadi A, Keshavarzian A, Holmes EW, Fields J, Zhang L, Banan A. J Chromatogr B Analyt Technol Biomed Life Sci 2003 Jan 25; 784 (1), pp. 145–54.

Permeability: Gastorintestinal Mucosa/Bacterial Translocation: Postoperative Hepatic Resection Conditions
Phenolsulfonphthalein (PSP)

Application: Primarily applied in the gastrointestinal system to determine mucosal integrity/permeability. The peroral PSP test appears to be a possible predictor of bacterial translocation after hepatic resection surgery.
Route of Administration: Phenolsulfonphthalein (peroral).
Dosage: Phenolsulfonphthalein (30 mg).
Implementation: Evaluate perioperative changes in intestinal PSP permeability relevant to conditions of hepatic resection. In this context, peroral PSP tests can be scheduled prior to surgery and then on postoperative days 3, 7, and 14, followed by urine collection over a 24-hour period after surgical intervention. Urinary PSP can be measured applying a colorimetric assay. The correlations between the preoperative PSP value and various clinical variables, such as perioperative changes in urinary PSP excretion, and the relationship between the postoperative PSP value and postoperative complications are then determined.

Human Model: Cases of hepatic resection (n = 50; n = 16 postoperative complications; n = 10/16 sepsis).
Interpretation and Analysis: Preoperative urinary PSP excretion increases in a manner proportional to the degree of liver dysfunction. In contrast, urinary PSP excretion does not significantly change during the perioperative period. However, urinary PSP excretion on postoperative day 3 in patients with postoperative infectious complications (27.3%) is significantly greater than in cases without infectious complications (17.4%; $p < 0.05$). Furthermore, PSP excretion on postoperative day 3 in cases with infectious complications is also significantly greater as compared to the preoperative level. Cases with a urinary PSP excretion level on postoperative day 3 of $> 25\%$ exhibit infectious complications more frequently than patients with a level under 25% (60% vs 10.3%, respectively; $p < 0.05$). The peroral PSP test is thus suggested to be a possible predictor of bacterial translocation after hepatic resection.

Significance of the peroral phenolsulfonphthalein test in hepatic resection: A possible predictor of bacterial translocation. Shimada M, Takenaka K, Fujiwara Y, Gion T, Hasegawa H, Shirabe K, Sugimachi K. Hepatogastroenterology 1998 Mar–Apr; 45 (20), pp. 483–7.

Permeability and Absorption: Gastrointestinal Mucosa/[Feline]
Lactulose/Rhamnose/Xylose/Methylglucose/Sucrose

Cellular/Molecular Mechanism of Action: Lactulose, rhamnose, xylose, methylglucose, and sucrose are sugar carbohydrates. Lactulose (L) and rhamnose (R) are not significantly absorbed across intact mucosa of the small intestine, and neither of these saccharides is metabolized in the small intestine. Alternatively, xylose and methylglucose are normally absorbed across healthy small intestinal mucosal surfaces of the jejunum and are dependent upon passive and active carrier-mediated transport mechanisms, respectively. Sucrose is absorbed across damaged/injured gastroduodenal mucosa.
Application: Lactulose, rhamnose, xylose, methylglucose, and sucrose can be utilized to evaluate intestinal permeability and mucosal function. Selection of these sugar types as investigative probes is based on their prior use for intestinal permeability and mucosal function testing in humans and dogs. The lactulose/rhamnose ratio can be applied to detect large-pore/small-pore permeability defects.
Route of Administration: Lactulose, rhamnose, xylose, methylglucose, and sucrose (intravenous).
Dosage: Isotonic sugar solutions containing lactulose, rhamnose, xylose, methylglucose, and/or sucrose.
Implementation: Determine the kinetics of urinary recovery and evaluate the effects of postmucosal factors on urinary recovery of 5 intravenously administered saccharides. The experimental design of such studies involves the intravenous administration of isotonic sugar solutions containing lactulose, rhamnose, xylose, methylglucose, and sucrose. Urethral catheterization with a closed collection system is then used for the collection of cumulative urine

samples prior to and 2, 4, 6, 8, 10, 12, and 24 hours after sugar solution administration.

Animal Model: Feline (n = 10 cats).

Interpretation and Analysis: Twenty-four-hour cumulative urinary recovery for each sugar in cats is lower than expected compared to dogs and humans. All 5 sugars have the highest percentage of urinary recovery during the 1st 2 hours after administration. Mean sugar elimination rate constants and half-lives range between 0.268/hour for methylglucose to 0.415/hour for lactulose and 1.67/hour for lactulose to 2.59/hour for methylglucose, respectively. Metabolism and incomplete urine collection are possible reasons for lower cumulative urinary recoveries of these 5 sugars in cats compared with dogs. Although these 5 sugars are not ideal marker molecules, they may still be useful for intestinal permeability and mucosal function testing in cats.

Instrumentation: High-pressure anion exchange liquid chromatography with pulsed amperometric detection can be used to measure the concentrations of each sugar in the urine and calculate urinary recovery.

Kinetics and postmucosal effects on urinary recovery of 5 intravenously administered sugars in healthy cats. Krecic MR, Steiner JM, Kern MR, Williams DA. Can J Vet Res 2003 May; 67 (2), pp. 88–93.

Permeability Tendency/Integrity: Gastrointestinal Mucosa
Phenolsufonphthalein (PSP)

Cellular/Molecular Mechanism of Action: Phenolsufonphthalein is a passive marker molecule that is absorbed into the systemic intravascular compartment from the gastrointestinal tract much more extensively in conditions of mucosal damage/injury.

Background Information: The oral PSP absorption test can be used as a simple and non-invasive method for the assessment of either the extent of the permeability of or damage to the gastrointestinal mucosa.

Application: Assessment of gastrointestinal tract mucosa permeability.

Route of Administration: Phenolsufonphthalein (per os).

Dosage: Phenolsufonphthalein (30 mg).

Implementation: Evaluation of the permeability of the gastrointestinal mucosa in conditions of liver cirrhosis and postoperative gastrointestinal surgery cases utilizing oral PSP and subsequent measurement of PSP urine concentrations (e.g., urinary recovery rate).

Interpretation and Analysis: The urinary PSP excretion in conditions of liver cirrhosis (n = 8; 28.8 ± 6.0%) is significantly higher than in cases subjected to vascular surgery (n = 8; 10.0 ± 1.7%; $p < 0.01$). Such findings reflect the presence of increased gastrointestinal mucosa permeability in conditions of liver cirrhosis. The urinary PSP excretion rate in patients who undergo a total gastrectomy with Roux-en-Y reconstruction is 17.3 ± 1.7% (n = 5 and significantly higher than values observed in controls; $p < 0.05$), while the same rates in cases subjected to a partial gastrectomy (n = 10) or colectomy (n = 10) is approximately 10.2 ± 1.8% or 10.6 ± 0.7%, respectively. Parameters of this nature suggest that the intestinal mucosa is damaged by a total resection of the stomach. The oral PSP absorption test, which is non-invasive, simple, and inexpensive, is thus considered to be useful for assessing the degree of damage to the permeability of the gastrointestinal mucosa under various conditions.

Assessing the permeability of the gastrointestinal mucosa after oral administration of phenolsulfonphthalein. Toh Y, Korenaga D, Maekawa S, Matsumata T, Muto Y, Ikeda T, Sugimachi K. Hepatogastroenterology 1997 Jul–Aug; 44 (16), pp. 1147–51.

Permeability: Intestinal/Post–Abdominal Surgery
Enteral Nutrition/Post–Abdominal Surgery
Parenteral Nutrition
Lactulose/Mannitol Urine Ratio

Cellular/Molecular Mechanism of Action: Lactulose and mannitol are carbohydrate molecules that are variably absorbed within the intestinal tract. Lactulose is not normally absorbed across the surface of normal, healthy intestinal mucosa. Conversely, mannitol is normally absorbed across mucosal surfaces of the small intestine. Neither lactulose nor mannitol is significantly metabolized within the small intestine but may be metabolized within the large intestine.

Application: To study the intestinal permeability (IP) following stress of abdominal operation and the different effects on IP of enteral nutrition and parenteral nutrition. The lactulose/mannitol ratio can be applied to detect large-pore permeability defects.

Route of Administration: Lactulose (orally), mannitol (orally).

Dosage: Lactulose (10 g); and mannitol (5 g).

Implementation: Evaluation of the influence of abdominal surgery on intestinal permeability. Lactulose and mannitol are administered as probes to evaluate the integrity of the intestinal mucosa followed by collection of urine samples over a period of 6 hours in order to measure urine excretion ratios for lactulose and mannitol (L/M).

Human Model: Cases of abdominal surgery (n = 40 divided into groups managed with enteral nutrition or parenteral nutrition). Each case group receives nutritional support of the same nitrogen and calories from postoperative day (POD) 3 to POD 11. On the day before surgical intervention (POD−1), POD 7, and POD 12 intestinal permeability studies are performed.

Interpretation and Analysis: The lactulose/mannitol ratios for abdominal surgery cases receiving enteral nutrition group on POD−1, POD 7, and POD 12 are approximately 0.026 ± 0.017, 0.059 ± 0.026, and 0.027 ± 0.017, respectively, and those receiving parenteral nutrition group are 0.025 ± 0.013, 0.080 ± 0.032, and 0.047 ± 0.021, respectively. Cases receiving either parenteral or enteral nutrition have elevated L/M ratios on POD 7 compared to POD−1. The L/M ratio returns toward control levels with enteral nutrition by POD 12, compared to parenteral nutrition cases that still have elevated L/M ratios on POD 12. The L/M ratio increases for a period of time after surgical trauma and the loss of gut mucosal integrity can be reversed by substitution of enteral nutrition.

Intestinal permeability in patients after surgical trauma and effect of enteral nutrition versus parenteral nutrition. Jiang XH, Li N, Li JS. World J Gastroenterol 2003 Aug; 9 (8), pp. 1878–80.

Permeability: Intestinal/Chronic Diarrhea
Lactulose/Mannitol

Cellular/Molecular Mechanism of Action: Lactulose and mannitol are carbohydrate molecules that are variably absorbed within the intestinal tract. Lactulose is not normally absorbed across the surface of normal, healthy intestinal mucosa. Conversely, mannitol is normally absorbed across mucosal surfaces of the small intestine. Neither lactulose nor mannitol is metabolized to any significant degree within the small intestine but they may be metabolized within the large intestinal lumen.

Background Information: Diagnosis of chronic diarrhea in the absence of a distinctive clinical pattern is often challenging, as bio-

chemical tests prescribed at the 1st evaluation do not show enough sensitivity and specificity to tailor further investigation.

Application: Characterization of intestinal absorption and permeability that reflect the presence of mucosal damage/injury. The lactulose/mannitol ratio can be applied to detect large-pore permeability defects.

Implementation: Evaluate the diagnostic value of the lactulose/mannitol (L/M) test in cases of chronic diarrhea.

Human Model: Cases of chronic diarrhea (n = 120 [46%] organic cause for chronic diarrhea; n = 141 [54%] cases with functional conditions).

Interpretation and Analysis: Multivariate logistic regression analysis reveals that the L/M test and C-reactive protein are independent predictors for the final diagnosis of organic causes of chronic diarrhea, with odds ratios of 1.5 (95% CI = 1.29–1.78) and 5.2 (95% CI = 1.90–14.12), respectively. The area under the receiver operating characteristic (ROC) curve of the adjusted model is 0.82, with positive predictive value of 80.4% and negative predictive value of 77.7%. The L/M test appears to be a powerful tool for workup in patients with chronic diarrhea. Introducing the L/M test as 1st-level test effectively improves the selection of patients who need further evaluation.

Lactulose/mannitol test has high efficacy for excluding organic causes of chronic diarrhea. Di Leo V, D'Incà R, Diaz-Granado N, Fries W, Venturi C, D'Odorico A, Martines D, Sturniolo GC. Am J Gastroenterol 2003 Oct; 98 (10), pp. 2245–52.

Permeability: Intestinal/Endotoxemia: Bacterial LPS
Lactulose/Mannitol [Urine]

Cellular/Molecular Mechanism of Action: Lactulose is a carbohydate sugar that is not normally absorbed across the surface of healthy intestinal mucosa. Conversely, mannitol is a carbohydrate sugar that is extensively absorbed across the intact, healthy intestinal mucosa. Neither lactulose nor mannitol is metabolized within the small intestine but they may be metabolized within the large intestine.

Application: Evaluation of intestinal permeability (e.g., protective effect and mechanism of glutamine on the intestinal barrier function in total parenteral nutrition [TPN] rats with trauma or endotoxemia). The lactulose/mannitol ratio can be applied to detect the presence of large-pore permeability defects.

Route of Administration: Lactulose (oral gavaged) and mannitol (oral gavaged).

Dosage: Lactulose (66 mg) and mannitol (50 mg) in 2 ml of saline (rats).

Implementation: Evaluation of intestinal permeability using lactulose and mannitol administered by oral gavage. Urine is collected over a 24-hour period in the presence of a preservative and kept at −20°. The intestine, liver, mesenteric lymph nodes, and blood are then harvested for examination.

Animal Model: Rat (n = 34 male, adult Sprague-Dawley strain rats). Animals can be divided into groups (e.g., n = 8 controls; n = 8 surgical trauma; n = 9 TPN; n = 8 trauma and endotoxemia; n = 9 trauma and endotoxemia with glutamine supplementation). All groups except the control group are given TPN solutions in a 7-day experimental period. For the glutamine group, 1,000 mg/kg/d of glutamine is added to TPN solution during day 1–6. Lactulose and mannitol are administered on day 7 by oral gavaged. On day 8, under intraperitoneal anesthesia using 100 mg/kg ketamine, the intestine, liver, mesenteric lymph nodes, and blood can be collected for examination.

Interpretation and Analysis: Body weight decreases the most in subjects receiving LPS fractions. The structure of small intestinal mucosa with TPN group, LPS, and Gln group show impairments of variable degrees, and the damage of small intestinal mucosa following glutamine is remarkably alleviated. The concentrations of interleukins in small intestine mucosa are lower (for IL-4 and IL-6) or the lowest (IL-10) following glutamine administration. Concentrations of IgA in the blood plasma and the mucosa are highest with glutamine as supplementation. Urine lactulose/mannitol test values reveal that intestinal permeability following bacterial LPS is lower than with TPN ($p < 0.001$), but there is no difference with LPS vs glutamine exposure. The rate of bacterial translocation with glutamine is lower than with LPS exposure ($p < 0.02$). Prophylactic treatment with glutamine could minimize the increments of intestinal permeability and bacterial translocation caused by trauma and endotoxemia in rats treated with TPN.

Effects of glutamine on intestinal permeability and bacterial translocation in TPN-rats with endotoxemia. Ding LA, Li JS. World J Gastroenterol 2003 Jun; 9 (6), pp. 1327–32.

Permeability/Absorption of Intestine: Traumatic Injury Influence
Lactulose/Rhamnose/3-O-Methyl-D-Glucose/Xylose

Cellular/Molecular Mechanism of Action: Lactulose, rhamnose, 3-O-methyl-D-glucose, and xylose are carbohydrate sugars. Lactulose and rhamnose are normally not absorbed across intact surfaces of the intestinal mucosa and neither of the saccharides is metabolized within the small intestine, although metabolism may occur within the large intestine. Conversely, methyl-D-glucose and xylose are normally absorbed across the surface of normal small intestinal mucosa of the jejunum involving active and passive carrier-mediated transport mechanisms, respectively.

Application: Evaluation of intestinal absorption and permeability in canine cases of traumatic injury. The lactulose/mannitol ratio can be applied to detect large-pore permeability defects.

Route of Administration: Lactulose, rhamnose, 3-O-methyl-D-glucose, and xylose can be administered via nasoesophageal tube.

Implementation: Assess the feasibility of using urinary recovery of sugars to evaluate intestinal permeability and absorption in dogs with traumatic injury and to determine if intestinal permeability and absorption becomes altered in dogs with traumatic injury.

After a 6-hour fast, a sugar solution containing lactulose, rhamnose, 3-O-methyl-D-glucose, and xylose is administered via nasoesophageal tube. Urine samples are then collected and quantitated over the 6-hour study period via closed-system collection urinary catheters. Urinary sugar recoveries are measured by high-pressure anion exchange liquid chromatography and pulsed amperometric detection. Urinary sugar recoveries in the trauma group at 24, 48, and 72 hours after trauma are compared to normal controls. In addition, severity of trauma is compared to urinary sugar recoveries.

Animal Model: Canine (n = 12 dogs suffering from clinical traumatic injury; n = 6 healthy negative reference controls).

Interpretation and Analysis: Lactulose recovery and the lactulose:rhamnose recovery ratio are significantly higher in trauma cases at 48 hours but are no longer different from controls by 72 hours. Xylose recovery is significantly higher in canine trauma cases when compared to controls at 72 hours, whereas 3-O-methyl-D-glucose recovery is significantly lower in the trauma group at 24 hours. The xylose:3-O-methyl-D-glucose ratio is higher in the canine cases with trauma at all time points. Significant correlation is found between the severity of trauma and xylose and 3-O-methyl-D-glucose

recoveries 24 hours after injury. Clinical studies therefore support the hypothesis that intestinal permeability and absorption are altered in dogs subjected to traumatic injury.

Instrumentation: High-pressure anion exchange liquid chromatography and pulsed amperometric detection.

Intestinal permeability and absorption in dogs with traumatic injury. Streeter EM, Zsombor-Murray E, Moore KE, Rush JE, Steiner JM, Rozanski EA, Michel KE, Williams DA, Freeman LM. J Vet Intern Med 2002 Nov–Dec; 16 (6), pp. 669–73.

Permeability/Absorption: Intestinal/Chronic Diarrhea/Predictive Value: Organic Etiologies
Lactulose/Mannitol/[Urinary Excretion Ratio]

Cellular/Molecular Mechanism of Action: Lactulose is not but mannitol is significantly absorbed across normal mucosal surfaces of the small intestine. Neither lactulose nor mannitol is metabolized within the small intestine.

Background Information: Diagnosis of chronic diarrhea in the absence of a distinctive clinical pattern is often challenging, as biochemical tests prescribed at the 1st evaluation do not show enough sensitivity and specificity to tailor further investigation.

Application: Intestinal permeability to sugars is an accurate test for detecting intestinal damage. The lactulose/mannitol ratio can be applied to detect large-pore permeability defects.

Route of Administration: Lactulose and mannitol can be administered orally/per os for the purpose of evaluating intestinal absorption/permeability parameters.

Implementation: Evaluate the diagnostic value of the lactulose/mannitol (L/M) test in chronic diarrhea. Complementary biochemical tests include complete blood cell count, acute phase reactive proteins, serum albumin and iron, and stool cultures for bacteria, ova, and parasites.

Human Model: Cases of chronic diarrhea (n = 261; n = ≥ 3 bowel movements per day for ≥ 3 weeks).

Interpretation and Analysis: Approximately 46% of cases have an organic etiology as a cause for their chronic diarrhea (e.g., n = 120/261). Conversely, the remaining cases (e.g., n = 141/261) display evidence of suffering from functional conditions. Multivariate logistic regression analysis reveals that the L/M test and C-reactive protein are independent predictors for the final diagnosis of organic causes of chronic diarrhea, with odds ratios of 1.5 (95% CI = 1.29–1.78) and 5.2 (95% CI = 1.90–14.12), respectively. The area under the receiver operating characteristic (ROC) curve of the adjusted model can be approximately 0.82, with positive predictive value of 80.4% and negative predictive value of 77.7%. The L/M test is a powerful tool for workup in patients with chronic diarrhea. Introducing the L/M test as 1st-level test effectively improves the selection of patients who need further evaluation.

Lactulose/mannitol test has high efficacy for excluding organic causes of chronic diarrhea. Di Leo V, D'Incà R, Diaz-Granado N, Fries W, Venturi C, D'Odorico A, Martines D, Sturniolo GC. Am J Gastroenterol 2003 Oct; 98 (10), pp. 2245–52.

Permeability/Absorption: Intestinal/[Feline]
D-Xylose/3-O-Methyl-D-Glucose/L-Rhamnose/Lactulose/[^{51}Cr]-Labeled Ethylenediaminetetraacetic Acid (EDTA)

Cellular/Molecular Mechanism of Action: Lactulose, rhamnose, xylose, and methylglucose are sugar carbohydrates. Lactulose (L) and rhamnose (R) are not significantly absorbed across intact intestinal mucosa. Neither lactulose nor rhamnose is metabolized within the small intestine. Alternatively, xylose and methylglucose are normally absorbed across healthy intestinal mucosal surfaces by passive and active carrier-mediated transport mechanisms. [^{51}Cr]-EDTA is an organic chelate of radioactive [^{51}Cr] that is not normally absorbed across intact, normal, healthy intestinal mucosa.

Application: The sugars D-xylose, 3-O-methyl-D-glucose, L-rhamnose, and lactulose and the chelation product [^{51}Cr]-EDTA can be applied for the evaluation of intestinal permeability and absorption in the presences of variations in intestinal microflora and dietary intake. The lactulose/rhamnose ratio can be applied to detect large-pore/small-pore permeability defects, respectively.

Route of Administration: Intragastric.

Implementation: Evaluation of a sugar solution containing D-xylose, 3-O-methyl-D-glucose, L-rhamnose, lactulose, and [^{51}Cr]-EDTA administered intragastrically for the purpose of evaluating intestinal absorption and permeability. Urine samples are collected for analysis in order to determine the extent the exogenous sugars are excreted 5 hours after initial administration. After the same cats receive metronidazole for 1 month, the study is repeated. A final study is performed while cats are maintained on a new diet differing in composition and processing.

Animal Model: Feline (n = 6 healthy domestic shorthairs).

Interpretation and Analysis: Lactulose-to-rhamnose ratios, reflecting intestinal permeability, are higher in cats, compared with values for humans or dogs, and values obtained before and after metronidazole administration (mean ± SEM; before, 0.40 ± 0.08; after, 0.45 ± 0.09) are not significantly different. Intestinal absorption also is unaltered after antibiotic administration, and the xylose-to-glucose ratio is 0.70 ± 0.03 before and 0.71 ± 0.06 after metronidazole administration. Sugar recovery does not differ significantly while cats are maintained on canned or dry food.

Reference ranges have been established for the percentage urinary recovery of orally administered D-xylose, 3-O-methyl-D-glucose, L-rhamnose, lactulose, and [^{51}Cr]-EDTA obtained after 5 hours in healthy cats. The intestines of cats appear to be more permeable than those of other species, although the normal bacterial microflora do not appear to influence the integrity or function of the feline intestine, because values obtained for the measured variables before or after antibiotic administration are not significantly different. In addition, differences cannot be detected when dietary intake is completely altered.

Use of an orally administered combined sugar solution to evaluate intestinal absorption and permeability in cats. Johnston KL, Ballèvre OP, Batt RM. Am J Vet Res 2001 Jan; 62 (1), pp. 111–8.

Ulceration: Chronic Duodenal Ulcer vs Pancreatic Gastrinoma (Zollinger-Ellison Syndrome)/[Gastrin-Secreting Tumor]
Secretin/Cimetadine

Application: Characterization of chronic duodenal ulcer case compared to Zollinger-Ellison syndrome.

Route of Administration: Cimetadine (oral and IV).

Dosage: Cimetadine (1 g/day–1.4 g/day).

Considerations: Results from preliminary investigations suggest that previous cimetidine treatment does not alter, and may even increase, the diagnostic sensitivity of the secretin provocative test.

Implementation: Evaluation of conditions that may be either duodenal ulcer or Zollinger-Ellison syndrome using secretin and cimetadine response tests.

Human Model: Cases of chronic duodenal ulcer (n = 16) and Zollinger-Ellison syndrome (n = 5).

Interpretation and Analysis: In cases of chronic duodenal ulcer, a 2nd secretin test can be done during acute cimetidine administration (IV). Only slight variations in plasma gastrin can be detected compared with results from the 1st tests (n = 4 cases). A 3rd test in the same cases with chronic duodenal ulcers after 1 month of cimetidine treatment (1 g/day per os) reveals a time-zero gastrin concentration that is significantly higher than values observed in the previous 2 tests ($p < 0.01$).

Integrated gastrin response after secretin is usually significantly lower in the 3rd test than in the 1st ($p < 0.05$). In Zollinger-Ellison syndrome cases treated with 1.0 and 1.4 g/day cimetidine for 3 months (n = 2 cases), gastrin at time-zero is not markedly increased, whereas compared with the 1st test gastrin levels are higher at each time interval after secretin administration.

Secretin-induced gastrin response in the Zollinger-Ellison syndrome and chronic duodenal ulcer patients before and after cimetidine treatment. Quatrini M, Basilisco G, Conte D, Bardella MT, Bozzani A, Bianchi PA. Am J Gastroenterol 1984 May; 79 (5), pp. 345–7.

INTESTINAL INFLAMMATION

Note: Refer to Section III, Contrast and Image-Enhancing Agents.

Inflammation/Intestinal Lesions: Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)/Intestinal Lesions: Crohn's Ileitis *[^{111}In]-Leukocytes/Tauro 23 [^{75}Se]-Selena-25-Homocholic Acid/[^{58}Co]-Labeled Cyanocobalamin*

Cellular/Molecular Mechanism of Action: The agent tauro 23 [^{75}Se]-selena-25-homocholic acid is a bile acid analog, while [^{58}Co]-labeled cyanocobalamin is an analog of vitamin B_{12}. Radiolabeled [^{111}In]-leukocytes behave *in vivo* like endogenous leukocytes of the same cell type.

Background Information: The referenced study examines small intestinal absorption-permeability, intestinal inflammation, and ileal structure and function in HIV-positive male homosexuals.

Application: The agents tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamin can be applied to evaluate intestinal absorption. Conversely, [^{111}In]-leukocytes can be used to detect foci of inflammation and sepsis.

Implementation: Evaluation of small intestinal absorption-permeability, intestinal inflammation, and ileal structure and function. ^{111}Indium leukocyte studies can be used to detect and characterize intestinal inflammation (e.g., HIV-positive cases). Complementary studies that can be utilized to characterize AIDS cases include the dual radioisotopic ileal function test (whole body retention of tauro 23-[^{75}Se]-selena 25-homocholic acid and ^{58}cobalt-labeled cyanocobalamin). Clinical cases that are HIV positive can also be evaluated using ileocolonoscopy in concert with terminal ileal biopsy.

Human Model #1: Cases of HIV that are seropositive (n = 30 at various stages of disease).

Human Model #2: Cases of AIDS (n = 26; n = 17/26 evaluated by ileocolonoscopy and terminal ileal biopsy).

Interpretation and Analysis: Normal intestinal absorption-permeability can be appreciated in well, HIV-infected cases, but both functions are impaired upon the development of AIDS. The median fecal excretion of ^{111}indium in well patients (0.66%) does not differ significantly ($p > 0.5$) from controls (0.46%), but subjects with AIDS who are well or who have diarrhea have significant ($p < 0.005$) intestinal inflammation (1.33% and 2.18%, respectively). The median 7-day retention of tauro 23-[^{75}Se]-selena 25-homocholic acid in well patients with AIDS (38.9%) does not differ significantly ($p > 0.2$) from controls (39.3%), whereas the absorption of ^{58}cobalt-labeled cyanocobalamin is significantly ($p < 0.05$) lower than controls (32.1% and 59.4%). Patients with AIDS diarrhea have significant ($p < 0.001$) malabsorption of both the bile acid (7.7%) and vitamin B_{12} (8.9%), which is more severe than in Crohn's ileitis (14.2% and 30.3%, respectively). Morphometric analyses of ileal biopsies is unremarkable in AIDS. Such findings depict the presence of low-grade enteropathy in conditions of AIDS, severe ileal malabsorption in cases with AIDS diarrhea, and relatively minor ileal morphologic changes. Malabsorption of bile acids may play a pathogenic role in patients with AIDS and diarrhea.

Intestinal inflammation, ileal structure and function in HIV. Bjarnason I, Sharpstone DR, Francis N, Marker A, Taylor C, Barrett M, Macpherson A, Baldwin C, Menzies IS, Crane RC, Smith T, Pozniak A, Gazzard BG. AIDS 1996 Oct; 10 (12), pp. 1385–91.

Inflammation/Intestinal Lesions: Non-Steroidal Anti-Inflammatory Drug (NSAID)-Associated/Intestinal Lesions: Crohn's Ileitis *[^{111}In]-Leukocytes/Tauro 23 [^{75}Se]-Selena-25-Homocholic Acid/[^{58}Co]-Labeled Cyanocobalamin*

Cellular/Molecular Mechanism of Action: The agent tauro 23 [^{75}Se]-selena-25-homocholic acid is a bile acid analog, while [^{58}Co]-labeled cyanocobalamin is an analog of vitamin B_{12}. Radiolabeled [^{111}In]-leukocytes behave *in vivo* like endogenous leukocytes of the same cell type.

Application: The agents tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamin can be applied to evaluate intestinal absorption. Conversely, [^{111}In]-leukocytes can be used to detect foci of inflammation and sepsis.

Route of Administration: Intravenous.

Implementation: Evaluation of residual inflammatory lesions following discontinuation of NSAIDs using [^{111}In]-leukocyte scintigraphy imaging methodologies.

Human Model #1: Cases of rheumatoid arthritis (n = 90) and osteoarthritis (n = 7).

Human Model #2: Cases treated with NSAIDs (n = 19); healthy controls (n = 20); and Crohn's ileitis (n = 13).

Interpretation and Analysis: Using [^{111}In]-leukocyte imaging techniques reveals that cases of rheumatoid arthritis and osteoarthritis administered NSAIDs are associated with gastrointestinal lesions. More specifically, approximately two-thirds of all cases evaluated on long-term treatment display inflammatory lesions that may persist for up to 16 months following discontinuation. The prevalence and magnitude of the intestinal inflammation is unrelated to the type and dose of non-steroidal drugs and previous or concomitant 2nd-line drug treatment. There is a significant inverse correlation ($r = -0.29$, $p < 0.05$) between fecal [^{111}In] excretion and hemoglobin levels in cases treated with NSAIDs. The kinetics of fecal [^{111}In] excretion in cases treated with NSAIDs is almost identical to that of patients with small bowel Crohn's disease. Small bowel radiological examination of cases on NSAIDs reveals that approximately one-sixth have asymptomatic ileal disease with ulceration and strictures (e.g., n = 3/18 cases). Evaluation of cases on anti-inflammatory agents, normal healthy controls, and cases of Crohn's ileitis with tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamin reveals several abnormalities. On day 4, more than half the cases with rheumatoid arthritis have evidence of bile acid malabsorption, but the ileal dysfunction is much milder than seen in patients with Crohn's ileitis.

Non-steroidal anti-inflammatory drug-induced intestinal inflammation in humans. Bjarnason I, Zanelli G, Smith T, Prouse P, Williams P, Smethurst P, Delacey G, Gumpel MJ, Levi AJ. Gastroenterology 1987 Sep; 93 (3), pp. 480–9.

Mucosal Pathology/Erosions/Histopathological Imaging (*In Vivo*)
Cresyl Violet

Cellular/Molecular Mechanism of Action: Cresyl violet functions as a fluorophore.
Application: Cresyl violet can function as a dye reagent that is compatible in viable biological systems.
Route of Administration: Variable.
Implementation: Confocal laser scanning microscope analysis of *ex vivo* esophageal and gastric mucosa preparations. A series of images is recorded for different ranges of cresyl violet concentrations ranging from 0.1% to 10% with staining performed over a time period of 2 minutes after mucolysis with acetylcysteine.

Animal Model: Swine (esophageal and gastric mucosa).
Interpretation and Analysis: Staining with 2% cresyl violet can facilitate the identification of nuclei and cell membranes. Lower concentrations are associated with a lack of homogeneous dye absorption in particular in the gastric mucosa. Cresyl violet is a clinically usable fluorophore for confocal laser scanning microscopy. Its use in combination with an endoluminally applicable system has the potential to allow *in vivo* histopathology analyses.

Cresyl violet as a fluorophore in confocal laser scanning microscopy for future *in vivo* histopathology. George M, Meining A. Endoscopy 2003 Jul; 35 (7), pp. 585–9.

MOTILITY AND TRANSIT TIME OF INTESTINAL TRACT

Colon Motility: Serotonin 5-HT(4)-Receptor Distribution
Mosapride Citrate/Cisapride

Cellular/Molecular Mechanism of Action: Function as 5-HT(4)-receptor agonists.
Route of Administration: Mosapride and cisapride (intragastric).
Dosage: Mosapride and cisapride 3–30 mg/kg.
Considerations: The 5-HT(4) receptors in the colon of guinea pigs show a distribution similar to that in humans.
Interpretation and Analysis: The enhancing effect of mosapride on the colon motility is antagonized by atropine or 5-HT(4)-receptor antagonist (GR113808), but not by methysergide [5-HT(1)- and 5-HT(2)-receptor antagonist]; ondansetron, [5-HT(3)-receptor antagonist]; or CP-99994 [tachykinin NK(1)-receptor antagonist]. *In vitro* receptor autoradiography has shown that mosapride and cisapride inhibit the specific binding of [^{125}I]-SB207710, a selective radioligand of 5-HT(4) receptors, in the colon of guinea pigs. Mosapride therefore enhances colonic motility through 5-HT(4)-receptor activation in guinea pigs and may be useful for treating constipation in patients with colonic motility dysfunction.

Effects of mosapride citrate, a 5-HT4 receptor agonist, on colonic motility in conscious guinea pigs. Inui A, Yoshikawa T, Nagai R, Yoshida N, Ito T. Jpn J Pharmacol 2002 Dec; 90 (4), pp. 313–20.

Colonic Pseudo-Obstruction: Acute
Neostigmine

Cellular/Molecular Mechanism of Action: Neostigmine inhibits acetylcholine esterase, thereby diminishing the enzymatic degradation of acetylcholine and increased stimulation of acetycholine receptor complexes.
Application: Detection or characterization of postoperative ilius, atropine overdose.
Route of Administration: Neostigmine (intravenous) with electrocardiographic monitoring.
Dosage: Neostigmine (2.0 mg over 3–5 minutes).
Implementation: Evaluation of the efficacy of neostigmine in conditions of acute colonic pseudo-obstruction defined as colonic distention with a cecal diameter of at least 10 cm on plain radiographs and no radiographic evidence of mechanical obstruction. Immediately following neostigmine infusion, clinical response is evaluated (passage of flatus or stools associated with decreased abdominal distention within 30 minutes) and sustained response with decreased abdominal girth and reduced colonic dilation on radiographs 3 hours after infusion.

Human Model: Cases failing to respond to conventional management (nothing by mouth, nasogastric suction, postural changes, IV fluids, electrolyte replacement, and discontinuation of any drugs that affect colonic motility) for 24 hours.

Study Design: N = 20 cases in a prospective, randomized, double blind, placebo-controlled study.

Cases with bradycardia (heart rate $<$ 60/minutes), hypotension (systolic blood pressure $<$ 90 mm Hg), active bronchospasm, clinical or radiographic evidence of perforation, history of partial colonic resection, active gastrointestinal bleeding, pregnancy, or serum creatinine $>$ 3 mg/dL are not suitable study candidates.
Interpretation and Analysis: Neostigmine produces an immediate clinical response (median time, 4 minutes) compared to none in the placebo group ($p < 0.001$). Some cases receiving neostigmine (e.g., n = 3/10) or placebo (e.g., n = 8/10) fail to show sustained improvement 3 hours after infusion ($p = 0.04$). Some cases that fail to respond (e.g., n = 1/10 neostigmine; and n = 7/8 placebo) can receive open-label treatment with neostigmine. "Open-label" neostigmine administration ultimately results in a high rate of response (e.g., n = 1/7 placebo group lack of response and eventually required colonic resection).

Therefore, in cases treated with neostigmine, 94% (n = 17/18) have an immediate clinical response, and 89% (n = 16) do not have recurrent colonic dilation. The most common side effect is crampy abdominal pain (e.g., n = 13), although usually mild (n = 9/13). Symptomatic bradycardia may occur in some cases and require atropine intervention therapy (e.g., n = 2).

Neostigmine infusion: New standard of care for acute colonic pseudo-obstruction? Amaro R, Rogers AI. Am J Gastroenterol 2000 Jan; 95 (1), pp. 304–5.

Gastrointestinal-Transit-Absorption (GITA) Model
Salicylazosulfanilic Acid (SASA)

Cellular/Molecular Mechanism of Action: Salicylazosulfanilic acid functions as a prodrug that is converted to the "parent" (active) drug, 5-aminosalicylic acid (5-ASA), after dosing.
Application: The GITA model is useful for the analysis and the prediction of the absorption behavior of drugs orally administered as solutions.

Route of Administration: Salicylazosulfanilic acid (oral).
Implementation: Prediction of plasma concentration-time profiles for SASA and 5-ASA is performed based on a GITA model using parameters describing GI-transit kinetics, the absorption in each GI segment, and the regeneration of 5-ASA within the cecum.
Interpretation and Analysis: Plasma concentration-time profiles of both SASA and 5-ASA after oral administration of SASA are predicted very well by introducing a factor for the 1st-pass elimination of 5-ASA into the GITA model. The simulation study using the parameters shows that about 94.7% of SASA reaches the cecum, where 5-ASA is regenerated very rapidly and 76.0% of 5-ASA is subsequently absorbed into the systemic circulation. Furthermore, the bioavailability of 5-ASA is estimated to be 0.330 because of the 1st-pass elimination through both cecum and liver. In conclusion, the absorption behaviors of a prodrug and its regenerated parent drug can be predicted very well and be clarified successfully using the GITA model. Some concerns exist that because the prodrug SASA is metabolized in the cecum, the estimation of gastrointestinal transit/absorption may be influenced by a relatively large number of variables.

Analysis and prediction of absorption behavior of colon-targeted prodrug in rats by GI-transit-absorption model. Yokoe J, Iwasaki N, Haruta S, Kadono K, Ogawara K, Higaki K, Kimura T. J Control Release 2003 Jan 17; 86 (2–3), pp. 305–13.

Ileus/Adenosine Receptor Antagonist/Ligand Ileus: Reversible (Postoperative)
FK352/DPCPX

Cellular/Molecular Mechanism of Action: (R)-1-[(E)-3-(2-phenylpyrazolo[1,5-a]pyridin-3-yl) acryloyl]-piperidin-2-yl acetic acid (FK352) and 8-cyclopentyl-1, 3-dipropylxanthine (DPCPX) function as adenosine A(1) receptor antagonists.
Physiological Mechanism of Action: Reversal of declines in colonic motility.
Application: Diagnostic interpretation of postoperative ileus.
Implementation: Colonic propulsive motility is evaluated according to migration of dye injected within the lumen of the colon following either pentobarbital anesthesia or surgical trauma (partial gastrectomy, cecectomy, or gentle touching of the colon with fingers).
Animal Model: Rat (unrestrained).
Interpretation and Analysis: Propulsive motility significantly decreases after anesthesia or partial gastrectomy. (R)-1-[(E)-3-(2-phenylpyrazolo[1,5-a]pyridin-3-yl) acryloyl]-piperidin-2-yl acetic acid (FK352) and 8-cyclopentyl-1, 3-dipropylxanthine (DPCPX) (intravenous administration) function as adenosine A(1) receptor antagonists and reverse the slowing of colonic propulsion activity in experimental ileus models. Blockade of adenosine A(1) receptors therefore can potentially be utilized for the diagnosis of intestinal ileus (postoperative).

Adenosine A(1) receptor blockade reverses experimental postoperative ileus in rat colon. Kadowaki M, Nagakura Y, Tokita K, Hanaoka K, Tomoi M. Eur J Pharmacol 2003 Jan 1; 458 (1–2), pp. 197–200.

Neuromuscular Disorders (Colonic): Pediatric/Stimulation of High-Amplitude-Propagating Contractions/Colon Monometry
Bisacodyl/[Edrophonium]

Physiological Mechanism of Action: Functions as a stimulant laxative, thereby promoting accumulation of water and electrolytes within the colonic lumen.
Application: Stimulation of high-amplitude-propagating contractions that can be of benefit during the conduction of pediatric colonic manometry procedures.
Implementation: Evaluation of defecation disorders employing water-perfused manometry catheters inserted into the right colon. Colonic motility is measured during a 3-hour test session (e.g., an hour fasting; an hour after a meal; and 30 minutes after administration of a provocative test agent).
Human Model: Cases suspected of suffering from defecation disorders.
Interpretation and Analysis: Bisacodyl is superior to edrophonium as a stimulant for inducing high-amplitude-propagating contractions. Bisacodyl-induced high-amplitude-propagating contractions are similar in amplitude, duration, propagation velocity, and sites of origin and extinction to naturally occurring high-amplitude-propagating contractions. The effect of intrarectal bisacodyl is similar to that of intracecal bisacodyl, except for a delay of 10 minutes in onset. Bisacodyl induces high-amplitude-propagating contractions in essentially all children (e.g., n = 28/28 children; n = 22/28 with spontaneous high-amplitude-propagating contractions) without evidence of neuromuscular disease and in children with colonic neuromuscular disorder and no spontaneous high-amplitude-propagating contractions (e.g., n = 2/9). In review of the findings noted with bisacodyl, the high-amplitude-propagating contractions it induces are quantitatively and qualitatively similar to naturally occurring high-amplitude-propagating contractions. In selected cases, such as in children receiving total parenteral nutrition or restricted fluid intake, it may be possible to shorten diagnostic colonic manometry using bisacodyl rather than waiting for spontaneous high-amplitude-propagating contractions.

Bisacodyl and high-amplitude-propagating colonic contractions in children. Hamid SA, Di Lorenzo C, Reddy SN, Flores AF, Hyman PE. J Pediatr Gastroenterol Nutr. 1998 Oct; 27 (4), pp. 398–402.

Transit Time (Orocecal): Infants (< 8 months)
Lactose-[^{13}C]-Ureide Breath Test (LUBT)

Background Information: The lactose-[^{13}C]ureide breath test is a novel, non-invasive test to determine orocecal transit time. Lactose ureide resists the action of brush border enzymes and is metabolized by colonic bacteria.
Application: Gastrointestinal tract tracer that can be used to determine orocecal transit time in infants < 8 months of age. In this context, studies have evaluated the potential ability to adapt the LUBT for children of various age groups and to determine whether it can be applied in infants, newborns, and preterms to study the development of small intestinal motility.
Dosage: 500 mg unlabeled lactose ureide; 250 mg lactose-[^{13}C]ureide.
Implementation: A breath test is performed after induction of unlabeled lactose ureide (500 mg) 3 times a day over a 24-hour period. A liquid test meal (chocolate milk) with lactose-[^{13}C]ureide (250 mg) is also ingested. Breath samples are collected every 15 minutes for 10 hours. In a 2nd investigation (age range, 0–3 years), only the *in vitro* stool analysis is performed.

Stools are collected from each subject for *in vitro* stool incubation analyses. The procedure involves utilization of a blank stool sample and a sample produced after induction with unlabeled lactose ureide and then incubated with 10 mg lactose-[^{13}C]ureide within a small, sealed bottle. Ten-milliliter CO_2 samples are aspirated from the bottle using a needle and a syringe every 30 minutes for 24 hours.

The LUBT results are then compared with findings from *in vitro* stool sample analyses.

Human Model: Children (n = 20 at 3 to 17 years of age, compared to n = 32 of which n = 6 at 1 to 3 years; n = 6 infants 6–12 months; n = 13 infants 0–6 months; n = 7 preterm infants).

Interpretation and Analysis: The mean orocecal transit time in cases 3–17 years of age is 255 minutes (range, 165–390 minutes). Stool incubations demonstrated a clear [$^{13}CO_2$] peak in all infants more that 8 months of age, indicating that their colonic bacterial enzymic activity hydrolyzes lactose ureide. However, in all infants < 6 months of age, and in preterm infants, the [$^{13}CO_2$] signal is absent, indicating that those subjects are unable to hydrolyze lactose ureide. Infants < 6 months of age do not host the appropriate bacterial enzymic activity for splitting lactose ureide. The authors of the referenced study conclude that the LUBT can be applied in infants more than 8 months of age, after weaning to solid foods, to determine orocecal transit time.

Lactose-[^{13}C]ureide breath test: A new, non-invasive technique to determine orocecal transit time in children. Van Den Driessche M, Van Malderen N, Geypens B, Ghoos Y, Veereman-Wauters G. J Pediatr Gastroenterol Nutr 2000 Oct; 31 (4), pp. 433–8.

PANCREAS FUNCTION AND DISEASE

Pancreas: Chronic Pancreatitis/Pancreatic Insufficiency
Secretin/N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid is a substrate for exocrine pancreatic enzyme fractions. Secretin induces exocrine pancreatic function.

Application: Detection and characterization of exocrine pancreatic insufficiency.

Route of Administration: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (oral).

Interpretation and Analysis: The secretin test (ST) is necessary to establish a diagnosis of chronic pancreatitis, especially the non-calcified form, and tubeless tests demonstrate insufficient sensitivity for the diagnosis of chronic pancreatitis.

However, the combined application of the tubeless tests is specific enough to diagnose severe exocrine dysfunction. The sensitivity of the ST for the definitive diagnosis of chronic pancreatitis is 87% (approximately). In patients with probable chronic pancreatitis (CP), 60% have mild exocrine insufficiency and 40% have normal function. The false-positive rate of the ST is 5% for non-pancreatic disease states with the exception of diabetes mellitus.

The correlation between morphological changes in endoscopic retrograde pancreatography (ERP) and exocrine function evaluated by secretin (ST) is 74%. In patients with calcified CP, 81% have parallel results between ERP and the ST, but in non-calcified CP, 47% have parallel results. In cases with severe or moderate exocrine insufficiency demonstrated by the ST, abnormally low levels are observed in 63% by the BT-PABA test, 61% by fecal chymotrypsin test (FCT), and 44% by pancreatic amylase (PA). In patients with normal exocrine function demonstrated by the ST, abnormally low levels can be appreciated in 28% of cases with the BT-PABA test, 28% of cases with the FCT, and 10% with the PA test. A combination assay of BT-PABA test, FCT, and PA improved the specificity for diagnosing CP but not the sensitivity.

Evaluating exocrine function tests for diagnosing chronic pancreatitis. Kitagawa M, Naruse S, Ishiguro H, Nakae Y, Kondo T, Hayakawa T. Pancreas 1997 Nov; 15 (4), pp. 402–8.

Pancreas: Exocrine Function/Efficacy Evaluation of Pancreas, Pankreon, and Pankreatin
[^{14}C]-Triolein-[^{3}H]-Oleic Acid

Cellular/Molecular Mechanism of Action: The agent [^{14}C]-triolein-3H-oleic acid can function as a substrate for pancreatic enzyme fractions. Proteolysis of [^{14}C]-triolein-3H-oleic acid therefore directly corresponds to exocrine pancreatic functional capacity.

Application: [^{14}C]-triolein-[^{3}H]-oleic acid can be used to evaluate exocrine pancreatic function or exocrine pancreatic enzyme supplementation efficacy.

Route of Administration: [^{14}C]-triolein-[^{3}H]-oleic acid (oral).

Implementation: Evaluation or estimation of duodenal enzyme activity and fecal fat excretion related to the efficacy of pancreatic enzyme supplements (e.g.,Pancreas, Pankreon, and Pankreatin) in cases of chronic pancreatitis and severe exocrine insufficiency.

Human Model: Cases of chronic pancreatitis and severe exocrine insufficiency (n = 23).

Interpretation and Analysis: The 3 pancreatic enzyme supplements do not produce any significant difference in treating steatorrhoea. Pankreatin increases the meal-stimulated duodenal enzyme activity ($p < 0.01$) and causes reductions in the fecal fat excretion ($p < 0.05$), whereas no change in these variables is observed with Pankreon or Pancreas. The fecal [^{14}C]-triolein-[^{3}H]-oleic acid test reveals significant improvements in [^{14}C]-triolein digestion with all 3 preparations ($p < 0.01$). The fecal [^{14}C]-triolein-[^{3}H]-oleic acid test is most reliable when monitoring outpatients.

Monitoring the effect of substitution therapy in patients with exocrine pancreatic insufficiency. Jørgensen BB, Pedersen NT, Worning H. Scand J Gastroenterol 1991 Mar; 26 (3), pp. 321–6.

Pancreas: Exocrine Function
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)/Xylose

Cellular/Molecular Mechanism of Action: The BT-PABA reagent is a substrate for chymotrypsin resulting in the liberation of the PABA moiety. Proteolytic digestion of BT-PABA can be detected by measurement of released PABA at 405 nm.

Diagnostic Application: Utilized for the diagnosis of exocrine pancreatic insufficiency (EPI) based upon the concept that chymotrypsin is found primarily within the proximal segment of the small intestine. Accuracy of the test is greatly improved if combined with the oral administration of xylose in order to verify gastric emptying has occurred.

Route of Administration and Dosage: Following oral administration, blood samples are collected at 30, 60, 90, 120, and 180 minutes. Assay of para-aminobenzoic acid (PABA) concentrations is assessed by measurement of spectrophotometric absorbance at 405 nm.

Interpretation and Analysis: The PABA moiety of BT-PABA is a detectable chemical marker that is compatible with biological (*in vivo*) systems and can be measured in biological fluid samples. Plasma PABA concentrations should rise above approximately 27 μmol/l within 60 minutes of administration. Markedly low PABA concentrations within the serum in the presence of normal xylose absorption imply that gastric emptying has occurred normally and that there is strong evidence supporting the presence of EPI.

Laboratory Instrumentation: Spectrophotometric absorbance is measured at 405 nm.

Pancreas: Exocrine Function
Porcine Secretin

Cellular/Molecular Mechanism of Action: Secretin promotes exocrine pancreas secretory function.
Dosage: Porcine secretin 1 CU/kg compared to synthetic porcine secretin 0.05, 0.2, and 0.4 μg/kg.
Considerations: Biologically derived porcine secretin has been used as a diagnostic agent in clinical gastrointestinal practice for many years. Pure synthetic porcine secretin is now available for investigational clinical use. Adverse reactions are infrequent and include mild and transient flushing after 0.2 and 0.4 μg/kg doses of synthetic porcine secretin and after the 1 CU/kg dose of biologically derived porcine secretin. Both preparations are considered safe and well tolerated. Experimental evidence justifies the substitution of synthetic porcine secretin for biologically derived porcine secretin.
Interpretation and Analysis: Measurement of bicarbonate concentration and total bicarbonate production in duodenal aspirates reveals that 0.2 and 0.4 μg/kg doses of synthetic porcine secretin are not different from the 1 CU/kg dose of biologically derived porcine secretin for volume, bicarbonate concentration, and total output from 0 to 60 minutes. Synthetic porcine secretin has identical pharmacologic effects to biologically derived porcine secretin in normal subjects.

Comparative effects of synthetic and natural secretin on pancreatic secretion and on secretin, insulin, and glucagon levels in man. Beglinger C, Gyr K, Werth B, Keller U, Girard J. Dig Dis Sci 1982 Mar; 27 (3), pp. 231–3.

Pancreas: Exocrine Insufficiency/Autoimmune-Mediated Pancreatitis/Salivary β_2-Microglobulin
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid can function as a synthetic substrate for exocrine pancreatic enzyme fractions.
Background Information: Autoimmune pancreatitis (AIP) is a distinct clinical entity in which an autoimmune mechanism may be involved in the pathogenesis.
Application: To investigate salivary gland function in addition to pancreatic endocrine and exocrine function in patients with AIP, and to determine changes occurring after steroid therapy. Detection and characterization of exocrine pancreatic insufficiency.
Implementation: Evaluation of AIP conditions applying (i) BT-PABA excretion test; (ii) sialochemistry; (iii) parotid gland scintigraphy; (iv) fasting serum glucose levels; (v) oral glucose tolerance tests; or (vi) glycosylated hemoglobin values in conditions of AIP.
Human Model: Cases of AIP (n = 19). N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid excretion test, sialochemistry, and parotid gland scintigraphy (e.g., n = 8 cases). Some cases may demonstrate evidence of diabetes mellitus (e.g., n = 8).
Interpretation and Analysis: Steroid therapy can improve insulin secretion and glycemic control (n = 3/5 cases). Pancreatic exocrine function is reduced in a large percentage of cases (88%). Impaired pancreatic exocrine function improves after steroid therapy in approximately 50% of cases (e.g., n = 3/6) and these same cases usually/often show treatment-related improvement in endocrine function. Concentration of β_2-microglobulin in saliva is significantly elevated in AIP cases compared to negative reference controls ($p < 0.05$). The ratio of cumulative peak count to injected radionuclide and washout ratio in parotid scintigraphy in AIP conditions is significantly lower than controls ($p < 0.01$). Salivary gland dysfunction improves after steroid therapy in most affected cases (e.g., n = 5/5). Pancreatic endocrine and exocrine and salivary gland function are frequently impaired in conditions of AIP, and steroid therapy is occasionally effective for these dysfunctions.

Pancreatic endocrine and exocrine function and salivary gland function in autoimmune pancreatitis before and after steroid therapy. Kamisawa T, Egawa N, Inokuma S, Tsuruta K, Okamoto A, Kamata N, Nakamura T, Matsukawa M. Pancreas 2003 Oct; 27 (3), pp. 235–8.

Pancreas: Exocrine Function/Intestinal Absorptive Capacity/Maldigestion vs Malabsorption/[Cystic Fibrosis]/[Celiac Sprue]
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)/[$^{13}C_6$]PABA/Xylose

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (BT-PABA or Bentiromide) is a synthetic substrate for exocrine pancreatic enzyme fractions proteolytic activity. Xylose is absorbed from intact small intestinal mucosal surfaces.
Application: Xylose can be applied to assess small intestinal absorptive capacity/integrity. N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid is of diagnostic value for detecting conditions of suboptimal exocrine pancreatic function.
Route of Administration: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid and xylose (both can be delivered orally per os).
Implementation: Characterize the potential of a single-step non-invasive stable isotope method of assessing digestive function to selectively identify cases of pancreatic insufficiency (maldigestion) or small bowel dysfunction (malabsorption), in addition to delineating if cases of maldigestion can be simultaneously distinguished from conditions of malabsorption. One approach that can be applied in pursuit of this objective entails the evaluation of the diagnostic attributes of ingesting a liquid test meal in concert with the oral intake of bentiromide, [$^{13}C_6$]PABA, and xylose (PABAX test). Serum is collected 1 hour postadministration and analyzed for PABA, [$^{13}C_6$]PABA, and xylose by stable isotope dilution methods.
Human Model: Cases of cystic fibrosis (n = 18); adult celiac sprue (n = 4); normal volunteers (n = 40).
Interpretation and Analysis: A very high percentage of cystic fibrosis cases have abnormal pancreatic function test results (e.g., n = 18/18), while a large percentage of sprue cases have abnormal results from pancreatic function tests (e.g., n = 3/4 or 75%). A large number of sprue cases have abnormal small bowel absorption tests (e.g., n = 4/4)), compared to cases of adult cystic fibrosis that apparently have normal intestinal function. The 1-step, 1-hour PABAX test can reliably separate normal subjects from those with either maldigestion or malabsorption and can also separate subjects with maldigestion from those with malabsorption.
Instrumentation: Gas chromatography mass spectrometry.

A non-invasive stable-isotope method to simultaneously assess pancreatic exocrine function and small bowel absorption. Deutsch JC, Santhosh-Kumar CR, Kolli VR. Am J Gastroenterol 1995 Dec; 90 (12), pp. 2182–5.

Pancreatic Disease
[^{125}I]-L-3 Iodo-α-Methyl Tyrosine

Background Information: The difficulty of a reliable diagnosis of pancreatic diseases by scintiscanning is mainly derived from the lack of adequate radiopharmaceuticals.
Application: The reagent [^{125}I]-L-3 iodo-α-methyl tyrosine (^{125}I-IMT) has been studied for its ability to detect pancreatic disease and has also been used for the diagnosis of different kinds of brain tumors.

Semi-Synthetic Methods: Quick and easy technique for the synthesis and purification of [^{125}I]-L-3 iodo-α-methyl tyrosine (^{125}I-IMT) in order to be used in a nuclear medicine service. The analog L-alpha-methyl tyrosine can be labeled with [^{125}I] using I-/$I0_3$ and afterward purified by an anionic exchange resin. The labeling yield obtained is approximately 96.0 ± 0.5% when a 15-minute incubation period is employed. No significant statistical differences can be appreciated when the incubation time is extended to 1 hour.
Implementation: Biodistribution investigation performed in mice to determine degree of pancreatic incorporation.
Interpretation and Analysis: Biodistribution studies in mice reveal that the percent of injected dose activity within the pancreas is approximately 34.24 ± 14.03% at 15 minutes postinjection and remains constant for 30 minutes. The pancreas/liver ratio 15 minutes after the injection of the labeled product is 12.22 ± 3.59 and remains constant for an additional 45 minutes. These results demonstrate that [^{125}I]-IMT can be used as a diagnostic agent for pancreatic diseases. The reagent can also be radioiodinated with [^{123}I], [^{124}I], and [^{131}I] if desired.

New methodology for pancreatic scintiscanning imaging using ^{125}I-L-3 iodo-alpha-methyl tyrosine. Zubillaga MB, Bocciot JR, Gentile A, Mitta AE, Nicolini JO, Caro RA. Acta Physiol Pharmacol Ther Latinoam 1996; 46 (2), pp. 83–9.

Pancreatic Exocrine Function/Assessment of Pancreatic Enzyme Replacement
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid is a synthetic peptide substrate for pancreatic enzyme fractions (e.g., chymotrypsin).
Background Information: The clinical diagnosis of chronic pancreatitis is usually based on imaging studies, pancreatic function tests, and the presence of characteristic clinical features. However, the secretin test (a duodenal intubation test) and the combination of non-invasive tests, BT-PABA, and fecal chymotrypsin (FCT) can be applied to characterize exocrine pancreatic function in conditions of chronic pancreatitis.
Implementation: Evaluation of the diagnostic value of non-invasive tests compared to the secretin test.
Interpretation and Analysis: Although non-invasive tests are less sensitive and specific for determining exocrine pancreatic dysfunction than the secretin test, greater reliability for diagnosing chronic pancreatitis can be obtained by performing the BT-PABA and FCT simultaneously. Assessment of exocrine pancreatic function is important not only for the diagnosis of chronic pancreatitis but also to decide a treatment method with pancreatic enzyme preparation.

Assessment of exocrine pancreatic dysfunction in chronic pancreatitis. Kataoka K, Hosoda M, Yasuda H, Sakagami J, Kato M, Kashima K. Digestion 1999; 60 Suppl 1, pp. 86–92.

Pancreatic Exocrine Function/Pancreatic Exocrine Dysfunction/Chronic Pancreatitis
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)/P-Aminosalicylic Acid

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid and *p*-aminosalicylic acid can function as proteolytic substrates for exocrine pancreatic enzyme fractions.
Application: Characterization of pancreatic exocrine function and the efficacy of exocrine pancreatic supplementation.
Analytical Method: Evaluation of spectrofluorimetry as an alternative to HPLC for determining (measuring) *p*-aminobenzoic acid (PABA) and *p*-aminosalicylic acid.
Implementation: Measurement of PABA and *p*-aminosalicylic acid in the BT-PABA/*p*-aminosalicylic acid test of pancreatic exocrine function. Urine specimens are hydrolyzed for 30 minutes in 4 M NaOH at 100°C. The fluorescence of PABA is measured in dimethyl sulphoxide solution (DMSO lambda ex = 300 nm, lambda em = 340 nm) and that of *p*-aminosalicylic acid in sodium acetate buffer, pH 4.0 (lambda ex = 297 nm, lambda em = 394 nm). The linear range is between 0.038 to 8 mM for PABA and 0.051 to 12 mM for *p*-aminosalicylic acid. The level of within-batch precision is approximately 2.2% and 5.5%, respectively, and the entire analysis can be completed within 40 minutes.
Interpretation and Analysis: Although not eliminated, drug interference is greatly reduced in comparison with colorimetry. During the course of 23 consecutive pancreatic function tests there is an excellent correlation between the PABA/*p*-aminosalicylic acid excretion index obtained by fluorimetry and the results from HPLC analysis ($y = 0.914x + 0.070$, $r = 0.987$, $p < 0.001$). The method is simple and cost-effective and may be particularly valuable in developing countries with a high incidence of chronic pancreatitis.
Instrumentation: Spectrofluorimetry.

Spectrofluorimetric determination of urinary p-aminobenzoic and p-aminosalicylic acids in the BT-PABA/PAS test of pancreatic function. Pemberton PW, Gagjee P, Chaloner C, Braganza JM, Lobley RW. Clin Chim Acta 1991 Jul 15; 199 (3), pp. 253–62.

Pancreatic Exocrine Function/[Severe Systemic Sepsis Influence]
Secretin-Cholecystokinin

Background Information: Sepsis in critical illness is associated with the progressive failure of multiple organs.
Application: Detection and characterization of exocrine panacreatic function (e.g., insufficiency conditions) in conditions of severe sepsis.
Implementation: Evaluation of pancreatic exocrine function using a secretin-cholecystokinin test.
Human Model: Cases classified as critically ill (n = 21 mechanically ventilated with sepsis according to criteria of the American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee [ACCP/SCCM]; n = 11 shock cases; n = 10 cases without shock; n = 7 healthy reference controls).
Interpretation and Analysis: Duodenal fluid volume is not statistically different among the 3 case groups. Sepsis patients without shock have significantly reduced content of amylase and chymotrypsin in duodenal juice compared with healthy controls ($p < 0.01$). Secretion of amylase, chymotrypsin, trypsin ($p < 0.01$ each), and bicarbonate in duodenal fluid ($p < 0.05$) is impaired in cases of septic shock compared with healthy controls. The content of trypsin is different between sepsis patients and septic shock patients ($p < 0.05$). Spearman correlation analysis is significant between the amylase secretion and the APACHE III and SOFA scores ($p < 0.01$). The SOFA score is also related to secretion of trypsin ($p < 0.05$). In patients on pressor therapy, use of norepinephrine is associated with a significant decrease in bicarbonate secretion ($p < 0.05$). Sepsis is associated with secretory pancreatic dysfunction that is worse in septic shock than in sepsis without shock. Impaired exocrine function significantly correlates with APACHE III and SOFA scores.

Exocrine pancreatic dysfunction in sepsis. Tribl B, Sibbald WJ, Vogelsang H, Spitzauer S, Gangl A, Madl C. Eur J Clin Invest 2003 Mar; 33 (3), pp. 239–43.

Pancreatic Exocrine Function: Chronic Pancreatitis/[Chronic Abdominal Pain]
Secretin/Cholecystokinin (CCK)

Physiological Mechanism of Action: Secretin or CCK are potent hormones that markedly influence exocrine pancreatic function.
Application: Hormonal stimulation with secretin or CCK is the most sensitive means of assessing pancreatic function. Secretin is not available, and current CCK tests are cumbersome, requiring dual tube intubation and marker perfusion techniques.
Route of Administration: Cholecystokinin (intravenously).
Dosage: Cholecystokinin (40 ng/kg/hr infused at a constant rate).
Implementation: Test the efficacy of a new CCK-stimulated pancreatic function test measuring peak lipase concentrations. A Dreiling gastroduodenal tube is inserted to the ligament of Treitz, and fluid is collected on ice for 80 minutes in 4 (20-minute) aliquots. Cholecystokinin is infused. Gastric aspirations are discarded. Duodenal aspirates are ultimately analyzed for volume and enzyme concentration with a clinical laboratory autoanalyzer.

Human Model: Cases of chronic pancreatitis (n = 18) and healthy volunteers (n = 19).
Interpretation and Analysis: Lipase concentration and secretory volume display a peak response by 40 minutes of stimulation, whereas amylase response is variable. The mean peak lipase concentrations (± SEM) for normal volunteers and mild, moderate, and advanced chronic pancreatitis patients are 16.9 ± 1.9, 7.9 ± 1.7, 3.7 ± 1.2, and 2.1 ± 0.6 × 10 5 IU/L, respectively. Lower peak lipase concentrations are significantly associated with more advanced chronic pancreatitis ($p < 0.001$). The receiver operating characteristic curve area for all chronic pancreatitis patients is approximately 0.944 (95% CI = 0.825–0.985). A peak lipase concentration of 780,000 IU/L provides a sensitivity and specificity of 0.833 and 0.867, respectively. A CCK test of this design is well tolerated and is usually associated with no complications. Lipase concentration in duodenal fluid increases nearly 3-fold from baseline after CCK stimulation in healthy volunteers but is markedly reduced in patients with chronic pancreatic disease. Peak lipase concentration are a significant predictor of chronic pancreatitis and correlate with the severity of pancreatic disease. Aspiration of duodenal drainage fluid with a Dreiling tube and analysis with a laboratory autoanalyzer are less cumbersome than marker perfusion and back titration techniques. Measurement of enzyme concentration instead of output can lead to the development of an endoscopic or through-the-scope screening method for assessing patients with suspected chronic pancreatitis or chronic abdominal pain.

Cholecystokinin-stimulated peak lipase concentration in duodenal drainage fluid: A new pancreatic function test. Conwell DL, Zuccaro G, Morrow JB, Van Lente F, Obuchowski N, Vargo JJ, Dumot JA, Trolli P, Shay SS. Am J Gastroenterol 2002 Jun; 97 (6), pp. 1392–7.

Pancreatic Exocrine Function/Lipase Secretion
Cholecystokinin (CCK)

Physiological Mechanism of Action: Cholecystokinin is a potent stimulant of pancreatic exocrine secretion, particularly the release of lipase fractions.
Background Information: Hormonal stimulatory agents can be used to assess pancreatic function. Biologically derived secretin, the most widely used pancreatic secretagogue, is no longer available in the United States. Existing secretory tests using CCK alone are cumbersome, requiring a unique dual tube (gastric and duodenal) collection system and constant perfusion of a non-absorbable marker to calculate enzyme output (in international units [IU]). A simpler, quantitative CCK stimulation test that measures enzyme concentrations (in international units per liter [IU/L]) instead of total output would obviate need for marker perfusion/collection.
Application: Detection and evaluation of alterations in exocrine pancreatic secretory function in duodenal fluid following CCK stimulation.
Route of Administration: Cholecystokinin (intravenous).
Dosage: Cholecystokinin (40 ng/kg/hr infused at a constant rate).
Implementation: A Dreiling tube is inserted endoscopically into the ligament of Treitz. Gastric and duodenal aspiration ports are connected to low intermittent suction. A 20-minute baseline is obtained to clear the gastric and duodenal lumina of residual fluid. Cholecystokinin is then infused and duodenal fluid samples collected on ice for 80 minutes (4 20-minute aliquots). Aspirated fluid is then analyzed for enzyme concentration with an automated chemistry analyzer in the hospital biochemistry laboratory.

Human Model: Healthy cases (n = 19).
Interpretation and Analysis: The mean volume (± SEM) of duodenal fluid collected is 85 ± 4.4 mL (range, 48–118 mL). Fluid analysis reveals a significant rise in mean lipase concentration (± SEM) from a baseline of 595,680 ± 11,930 IU/L to a peak of 1,778,847 ± 171,204 IU/L (mean difference = 1,183,167 IU/L; 95% CI = 664,459 IU/L to 1,701,875 IU/L; $p < 0.001$, Student test). Increases in amylase concentrations are markedly less pronounced and do not reach statistical significance. Mean peak lipase concentration occurs within 50 minutes of acinar cell stimulation. The vast majority of cases tolerate tube placement, and there are usually no episodes of acute pancreatitis or abdominal pain. Pancreatic lipase concentrations in duodenal fluid increase nearly 3-fold after CCK stimulation in healthy volunteers. This magnitude of enzyme secretory response may be a marker of pancreatic function and could potentially lead to a more clinically useful and simpler pancreatic function test. This physiologic study serves as the basis for further investigation of CCK-stimulated lipase concentrations as a new test in the assessment of pancreatic insufficiency.

Analysis of duodenal drainage fluid after cholecystokinin (CCK) stimulation in healthy volunteers. Conwell DL, Zuccaro G, Morrow JB, Van Lente F, O'Laughlin C, Vargo JJ, Dumot JA. Pancreas 2002 Nov; 25 (4), pp. 350–4.

Pancreatic Exocrine Insufficiency
N-Benzoyl-L-Tyrosyl-P-Aminobenzoic Acid (BT-PABA)

Cellular/Molecular Mechanism of Action: N-benzoyl-L-tyrosyl-*p*-aminobenzoic acid is a synthetic peptide substrate for pancreatic enzyme fractions (e.g., chymotrypsin).
Background Information: Exocrine pancreatic insufficiency in the dog can be assessed by the oral administration of the synthetic peptide BT-PABA functioning as a specific substrate for pancreatic chymotrypsin. The subsequent assay of PABA in either the plasma or the urine clearly differentiates control animals from those with exocrine pancreatic insufficiency (EPI). The results are not affected by simultaneously performing the pancreatic function with a xylose absorption test.

Implementation: Evaluation of the possible interference of the specificity of the peptide test for the diagnosis of EPI in conditions of small intestinal disease. Previous investigations have delineated if absorption tests compromise the specificity of peptide tests for the diagnosis of EPI.

Animal Model: Canine (n = 6 with small intestinal disease).

Interpretation and Analysis: Assay of PABA in either the plasma or the urine can clearly differentiate control animals from those with EPI, the results being unaffected by combining pancreatic function tests with a xylose absorption test. In animals with features resembling chronic tropical sprue in man, the results are comparable to those of the control group (n = 4).

In a small number of cases, results may be indistinguishable from those of EPI cases, the estimation of sodium PABA absorption and the assay of proteolytic activity in the duodenal juice demonstrating that this is due to defective hydrolysis of the peptide. Conditions of diffuse intestinal lymphosarcoma and marked villous atrophy can be associated with an apparent reduction in the absorption of sodium PABA. However, although the plasma PABA concentrations following oral BT-PABA are subnormal, they are distinctly higher than those of EPI cases. Such observations suggest that small intestinal abnormalities do not affect PABA absorption sufficiently to interfere with the specificity of the peptide test for the detection of severe EPI in the dog. Such insufficiency may occasionally be secondary to small intestinal disease.

Specificity of the BT-PABA test for the diagnosis of exocrine pancreatic insufficiency in the dog. Batt RM, Mann LC. Vet Rec 1981 Apr 4; 108 (14), pp. 303–7.

Pancreatic Exocrine Insufficiency/[Renal Failure: Anuria]
Pancreolauryl Test

Cellular/Molecular Mechanism of Action: Pancreolauryl is proteolytically degraded by pancreatic enzymes within the lumen of the intestinal tract. Fluoroscein is subsequently liberated and absorbed across the surface of the intestinal mucosa.

Application: Although patients with chronic renal failure have a high incidence of chronic pancreatic disease, the condition is frequently overlooked. Pancreolauryl can be applied to detect and characterize alterations in exocrine pancreatic function in conditions of anuria.

Route of Administration: Pancreolauryl (oral).

Implementation: Modification of the pancreolauryl test as an indirect pancreatic function test for application in cases of anuria.

Interpretation and Analysis: The test permits good discrimination between patients with chronic pancreatic disease and those with a normal pancreas when serum levels of fluorescein are measured 10 hours following administration with a standard meal. The sensitivity at this time interval is 80% in concert with an 83% specificity level. Pancreolauryl test with serum measurements provides a simple, non-invasive, and reliable diagnostic test for chronic pancreatic disease in conditions of simultaneous anuria and chronic renal failure.

Diagnostic value of indirect pancreatic function test in serum of anuric patients with chronic renal failure. Lerch MM, Nolte I, Riehl J, Gladziwa U, Mann H, Sieberth HG, Matern S. Scand J Clin Lab Invest 1994 May; 54 (3), pp. 247–50.

Pancreatic Exocrine Insufficiency/Efficacy of Pancreatic Proteolytic Enzyme Supplementation
Schilling Test

Background Information: The pancreatic Schilling test (PST) is a non-invasive, sensitive pancreatic function test.

Application: Detection of pancreatic insufficiency.

Implementation: Evaluation of the ability of the PST to detect pancreatic proteolytic enzyme replacement in conditions of pancreatic insufficiency. The test is performed following supplementation with the enzyme preparations (i) Viokase (4 tablets), (ii) Pancreas (3 capsules), and (iii) Pancreas (10 capsules). The effect of cimetidine on the results of the PST with high-dose Pancreas can also be determined.

Human Model: Cases of well-documented pancreatic insufficiency and with abnormal PST parameters (n = 7). Cimetadine can also be administered to additional case groups (cimetadine and high-dose Pancreass in controls administered to n = 2 affected cases; n = normal reference controls).

Interpretation and Analysis: The PST is a sensitive non-invasive test for detecting the presence of orally administered proteolytic enzymes in subjects with pancreatic insufficiency and in normal cases. Administration of enzymes in a form of enteric-coated microspheres does not enhance the delivery of proteolytic enzymes to the small intestine when compared to conventional high-dose enzyme replacement. Cimetidine appears to decrease the inactivation of the proteolytic enzymes in enteric-coated microspheres, suggesting that a low pH in the small intestine and stomach are responsible for the poor delivery of the enzymes into the small intestine.

Use of pancreatic Schilling test to determine efficiency of pancreatic enzyme delivery in pancreatic insufficiency. Brugge WR, Goldberg HJ, Burke CA, Depping BJ. Dig Dis Sci 1988 Oct; 33 (10), pp. 1226–32.

Pancreatic Gastrinoma/Insulinoma/Intestinal Carcinoids/Zollinger-Ellison Syndrome
Calcium Infusion

Cellular/Molecular Mechanism of Action: Calcium induces the release of certain endogenous hormones including gastrin, secretin, and somatostatin.

Diagnostic Application: (i) Gastrinoma—gastrin assay; (ii) Zollinger-Ellison syndrome—secretin assay; (iii) somatistatinoma—somatostatin (calcium/pentagastrin combination); (iv) insulinoma—diagnostically not reliable; and (v) intestinal carcinoid—diagnostically not reliable.

Interpretation and Analysis: Elevations in gastrin, secretin, and somatostatin following calcium administration when measured concentrations are above normal reference control values, thereby implying the existence of a gastrinoma, Zollinger-Ellison syndrome, or somatistatinoma, respectively.

Pancreatic Gastrinoma/Zollinger-Ellison Syndrome
Secretin and [Ca^{++}]

Cellular/Molecular Mechanism of Action: Induces gastrin secretion.

Application: To evaluate criteria of "positivity" for, and usefulness of both the secretin and calcium gastrin-provocative tests in conditions of Zollinger-Ellison syndrome.

Route of Administration: Kabi-secretin (intravenous bolus); calcium gluconate (10% intravenous).

Dosage: Kabi-secretin (2 U/kg bolus); calcium gluconate 10% (54 mg/kg/hr as 5 mg/kg/hr of calcium continuously infused for 3 hours).

Considerations: The distinct advantages (short test period, low patient morbidity, and relatively great potency) of the calcium plus secretin test make it an attractive alternative to other previously described provocative tests for the diagnosis of gastrinoma. There are usually no false-positive or false-negative tests with the calcium plus secretin.

Implementation: Evaluation of suspected cases of gastrinoma as a function of response to Kabi-secretin and calcium gluconate (10%) (54 mg/kg.h [5 mg/kg.h of calcium]) given by continuous intravenous infusion for 3 hours. Serum gastrin is measured at −15 and −1 minutes before and 2, 5, 10, 15, 20, and 30 minutes after secretin, or every 30 minutes for 3 hours during calcium infusion. Serum calcium and serum gastrin are measured simultaneously during calcium infusion. Criterion for diagnosis is either a 50% increase or a 200 pg/ml increase above the basal gastrin level.

Human Model: Cases suspected of having Zollinger-Ellison syndrome (n = 80).

Design: Prospective trial in consecutive patients.

Interpretation and Analysis: There is no significant difference in the responses of cases with different extents or locations of the tumor, presence or absence of multiple endocrine neoplasia, type-I, or with fasting gastrin $<$ or $>$ 1,000 pg/mL. In cases with fasting gastrin of $<$ 1,000 pg/mL, sensitivity of the secretin test using the criterion of an increase in gastrin of at least 110 pg/mL is 93% (CI, 76–99%) and for an increase of 200 pg/mL it is 85% (CI, 66–96%, $p > 0.05$). With the calcium infusion test, the sensitivity using the criterion of an increase of 395 pg/mL is 43% (CI, 23–66%) and for an increase of 50% is 74% (CI, 52–90%, $p < 0.01$). The calcium infusion test is positive in 33% of cases with a negative secretin test. Applying the secretin test, 75% of cases have a positive response by 5 minutes, 95% by 10 minutes, 100% by 15 minutes, and 6% only at 2 minutes. Utilizing calcium infusions, cases have positive responses at 120 to 180 minutes. The secretin test is preferred over the calcium test because of its greater sensitivity and simplicity. The recommended criteria are a 200 pg/mL increase for the secretin test and a 395 pg/mL increase for the calcium test. The calcium test should be reserved for patients having a negative secretin test, gastric acid hypersecretion, and a strong clinical suspicion of the Zollinger-Ellison syndrome.

Instrumentation: Laboratory facilities and instrumentation for immunodetection methodologies (RIA, ELISA).

Secretin and calcium provocative tests in the Zollinger-Ellison syndrome. A prospective study. Frucht H, Howard JM, Slaff JI, Wank SA, McCarthy DM, Maton PN, Vinayek R, Gardner JD, Jensen RT. Ann Intern Med 1989 Nov 1; 111 (9), pp. 713–22.

Pancreatic Gastrinoma/Zollinger-Ellison Syndrome: Gastrin-Secreting Tumors
Secretin

Cellular/Molecular Mechanism of Action: Secretin induces the production/synthesis/release of gastrin.

Considerations: The provocative secretin-stimulation test has an important role in the diagnosis and management of gastrin-secreting neuroendocrine tumors. However, the molecular basis for positive and false-negative secretin-stimulation test results in cases with this tumor type has previously been poorly characterized.

Application: The secretin-stimulation test can be used to differentiate between cases that have (i) histologically proven tumors but have a normal serum gastrin level and negative secretin-stimulation test results; and (ii) more typical patients with this syndrome. Ancillary diagnostic test can include immunohistochemistry, reverse-transcription polymerase chain reaction (PCR), receptor binding, and signaling assays.

Experimental Interpretation: Tumor expression of the class B G protein-coupled secretin receptor mediates a positive result. False-negative results can be explained by messenger RNA missplicing, resulting in a receptor variant missing exon 3 that encodes residues 44–79 in the amino-terminal tail of the mature receptor. This variant with an in-frame deletion has been shown to be synthesized and to traffic to the cell surface normally, where it can neither bind secretin nor mediate a secretin-stimulated adenosine 3′,5′-cyclic monophosphate response. It is able to act as a dominant negative inhibitor of wild-type secretin receptor function. Some of the atypical presentations of this syndrome provide important insights into basic mechanisms of disease.

Dominant negative action of an abnormal secretin receptor arising from mRNA missplicing in a gastrinoma. Ding WQ, Kuntz S, Bïhmig M, Wiedenmann B, Miller LJ. Gastroenterology 2002 Feb; 122 (2), pp. 500–11.

Pancreatic Gastrinoma: Zollinger-Ellison Syndrome/[Achlorhydria Differential Exclusion]
Secretin

Cellular/Molecular Mechanism of Action: Secretin promotes elevated production and release of gastrin into the intravascular compartment.

Background Information: The secretin stimulation test has become the preferred provocative test to characterize suspected cases of Zollinger-Ellison syndrome.

Application: Dectection and characterization of Zollinger-Ellison syndrome cases and the exclusion of conditions like achlorhydria as a possible differential diagnoses.

Implementation: Detection and characterization of Zollinger-Ellison syndrome conditions applying a pure secretin preparation, a gastrin-specific radioimmunoassay, and an appropriate sequential sampling protocol. These aspects of the testing procedure are vital to performing a successful and accurate test. Gastric acid analysis is necessary in the assessment of hypergastrinemia to confirm acid hypersecretion and exclude achlorhydria.

Interpretation and Analysis: When properly performed and interpreted, the secretin provocation test offers a safe, expeditious, and reliable means of evaluating conditions of hypergastrinemia. Gastric acid analysis is necessary in the assessment of hypergastrinemia to confirm acid hypersecretion and exclude the occurrence of achlorhydria.

Instrumentation: Laboratory facilities and instrumentation necessary to perform gastrin-specific radioimmunoassay methodologies.

Secretin provocation test in the diagnosis of Zollinger-Ellison syndrome. Brady CE 3rd. Am J Gastroenterol 1991 Feb; 86 (2), pp. 129–34.

Pancreatic Gastrinoma: Zollinger-Ellison Syndrome/Gastrinoma/Insulinoma/Carcinoids (Intestinal)
Calcium Infusion (Rapid)/Calcium Infusion (Slow)/Secretin/Calcium Infusion (Rapid) with Secretin or Pentagastrin

Application: Detection of gastrinoma conditions.

Background Information: Calcium infusion has been advocated as a provocative test for the diagnosis of certain endocrine tumors of the pancreas and gastrointestinal tract (gastrinoma, insulinoma, intestinal carcinoids). The release of gastrin from gastrinoma tissue is very sensitive to alterations in serum calcium levels, and the calcium infusion test is recommended in Zollinger-Ellison syndrome when the results of secretin stimulation are equivocal.

Dosage: Comparison of 4 separate diagnostic schedules: (i) rapid calcium infusion (2 mg Ca^{++}/kg/min); (ii) secretin (2 clinical units [CU]/kg/bolus); (iii) long calcium infusion (12 mg Ca^{++}/kg/3 hr); and (iv) a combination test consisting of a rapid calcium infusion followed immediately by secretin.

Implementation: Evaluation of elevated serum gastrin secretion in conditions of gastrinoma in response to provocative test reagents.

Blood is drawn for serum gastrin levels before and following infusion of test agents

Human Model: Cases of gastrinoma (n = 13; n = 10 normal reference controls; n = 1 of presumed gastrinoma).

Interpretation and Analysis: The rapid administration of calcium followed by secretin provokes the greatest increases in serum gastrin above basal levels in both normals (29%) and patients (362%). Peak gastrin levels in patients are similar following the long calcium infusion (341%) but are less following the rapid calcium infusion alone (124%) and secretin alone (207%). There are usually no false-positive or false-negative tests with the calcium plus secretin when the criterion for diagnosis is either a 50% increase or a 200 pg/ml increase above the basal gastrin level. The distinct advantages (short test period, low patient morbidity, and relatively great potency) of the calcium plus secretin test make it an attractive alternative to other previously described provocative tests for the diagnosis of gastrinoma.

The calcium provocative test in the detection of insulinoma and carcinoid tumors is less reliable than other safer and simpler procedures. Intravenous injection of calcium followed by pentagastrin stimulates the release of somatostatin in cases with somatostatinoma and offers a reliable means for establishing the diagnosis of this tumor. Calcium administration has not proven to be useful in the diagnosis of other endocrine tumors of the digestive system.

Comparison of four provocative tests for the diagnosis of gastrinoma. Romanus ME, Neal JA, Dilley WG, Leight GS, Linehan WM, Santen RJ, Farndon JR, Jones RS, Wells SA Jr. Ann Surg 1983 May; 197 (5), pp. 608–17.

Use of calcium provocative test in the diagnosis of gastroenteropancreatic endocrine tumors. Vezzadini C, Poggioli R, Casoni I, Vezzadini P. Panminerva Med 1996 Dec; 38 (4), pp. 255–8.

Pancreatic Gastrinoma: Zollinger-Ellison Syndrome/Recurrent Gastrinoma Post-Resections
Secretin/Fasting Serum Gastrin

Application: Detection and characterization of gastrinoma/Zollinger-Ellison syndrome.

Implementation: Characterization of the best method for determining freedom from disease after gastrinoma resection and for predicting long-term disease-free status in patients with Zollinger-Ellison syndrome. Cases can be assessed after gastrinoma resection, before discharge, 3 to 6 months after surgery, and yearly thereafter. Evaluation can include secretin provocative testing and fasting serum gastrin determinations. Follow-up examinations after the initial postoperative evaluations can include a clinical assessment, acid secretion studies, a calcium provocative test, and various imaging studies.

Human Model: Cases of Zollinger-Ellison syndrome (n = 81 consecutive patients that underwent surgical exploration for gastrinoma resection).

Interpretation and Analysis: Most suspect cases (96%) will have gastrinomas. Freedom from disease is defined by (i) improvement in symptoms; (ii) reduced acid output and antisecretory drug requirements; and (iii) normal gastrin level, normal imaging studies, and negative gastrin provocative studies. Fifty-two percent of patients (n = 42) may be disease-free immediately after surgery, 44% at 3 to 6 months, 42% at 1 year, and 35% by 5 years (mean follow-up, 39 months).

The secretin provocative test may be the 1st test to become positive in 45% of patients with a recurrence, the serum gastrin determination may be the 1st test to become positive in 36%, while both tests may become positive at the same time in less that one-fifth of all cases (18%). Conditions of "no recurrence" are 1st detected by imaging studies or by calcium provocative testing. Fasting serum gastrin levels and secretin provocative test results at different postoperative times can be used to predict the probability of a patient remaining disease free at 3 years. Patients with a normal gastrin level and a normal secretin provocative test immediately after surgery have a 3-year disease-free probability of 75%, and normal results on both tests at 6 months, 1 year, and 2 years yielded respective probabilities of 88%, 95%, and 100%.

Both the secretin provocative test and determination (assay) of fasting serum gastrin are necessary for the early diagnosis of cases of recurrent disease after gastrinoma resection. The calcium provocative test and imaging studies do not detect any recurrences 1st. Fasting serum gastrin determinations and secretin provocative testing at different postoperative times can be used to predict the probability of a patient remaining disease free at 3 years.

Assessment and prediction of long-term cure in patients with the Zollinger-Ellison syndrome: The best approach. Fishbeyn VA, Norton JA, Benya RV, Pisegna JR, Venzon DJ, Metz DC, Jensen RT. Ann Intern Med 1993 Aug 1; 119 (3), pp. 199–206.

Pancreatic Gastrinoma: Zollinger-Ellison Syndrome vs Chronic Duodenal Ulcer/ [Gastrin-Secreting Tumor]
Secretin/Cimetadine

Application: Characterization of chronic duodenal ulcer case compared to Zollinger-Ellison syndrome.

Route of Administration: Cimetadine (oral and IV).

Dosage: Cimetadine (1 g/day–1.4 g/day).

Considerations: Results from preliminary investigations suggest that previous cimetidine treatment does not alter, and may even increase the diagnostic sensitivity of the secretin provocative test.

Implementation: Evaluation of conditions that may be either duodenal ulcer or Zollinger-Ellison syndrome using secretin and cimetadine response tests.

Human Model: Cases of chronic duodenal ulcer (n = 16) and Zollinger-Ellison syndrome (n = 5).

Interpretation and Analysis: In cases of chronic duodenal ulcer, a 2nd secretin test can be done during acute cimetidine administration (IV). Only slight variations in plasma gastrin may be detected compared with results from the 1st tests (n = 4 cases). A 3rd test in the same cases with chronic duodenal ulcers after 1 month of cimetidine treatment (1 g/day PO) reveals a time-zero gastrin concentration that is significantly higher than values observed in the previous 2 tests ($p < 0.01$).

Integrated gastrin response after secretin is usually significantly lower in the 3rd test than in the 1st ($p < 0.05$). In Zollinger-Ellison syndrome cases treated with 1.0 and 1.4 g/day cimetidine for 3 months (n = 2 cases), gastrin at time-zero is not markedly increased, whereas compared with the 1st test gastrin levels are usually higher at each time period analyzed after secretin administration.

Secretin-induced gastrin response in the Zollinger-Ellison syndrome and chronic duodenal ulcer patients before and after cimetidine treatment. Quatrini M, Basilisco G, Conte D, Bardella MT, Bozzani A, Bianchi PA. Am J Gastroenterol 1984 May; 79 (5), pp. 345–7.

Pancreatic Insufficiency
[^{13}C]-Egg White Breath Test/[Indirect Pancreatic Function Test]

Cellular/Molecular Mechanism of Action: [^{13}C]-egg white can function as a substrate for pancreatic enzyme fractions. The pep-

tide fragments are then absorbed in the gastrointestinal tract and metabolized to [$^{13}CO_2$] that is in turn exhaled from the respiratory tract.

Background Information: The recent availability of egg white protein highly enriched with [^{13}C] has allowed breath test technology to be adapted for the study of protein digestion and absorption. Pancreatic trypsin is considered to be the key enzyme in the proteolytic cascade.

Application: Evaluation of pancreatic trypsin activity within the small intestine in conditions of pancreatic disease using the [^{13}C]-egg white breath test.

Route of Administration: [^{13}C]-labeled egg protein (oral).

Dosage: [^{13}C]-labeled egg protein (22 g).

Implementation: Evaluation of pancreatic disease states with the ingestion of a test meal consisting of [^{13}C]-labeled egg protein. Breath samples are taken before and after ingestion of the meal and analyzed for [$^{13}CO_2$] concentration. Moreover, pancreatic trypsin output after maximal stimulation is also measured.

Human Model: Cases with pancreatic disease (n = 30; and n = 48 normal volunteers). Pancreatic trypsin output after maximal stimulation measured in n = 13/30 affected cases and n = 9/48 healthy volunteers.

Interpretation and Analysis: The 6-hour cumulative [$^{13}CO_2$] excretion in breath is significantly lower in patients than observed in controls (mean [SEM]: 6.23 + 0.82% vs 19.16 + 0. 58%, $p < 0.0001$). An excellent correlation can be appreciated between the 6-hour cumulative [$^{13}CO_2$] excretion and trypsin activity after maximal pancreatic stimulation. The non-invasive [^{13}C]-egg white breath test is promising as an indirect pancreatic proteolytic function test.

^{13}C-egg white breath test: A non-invasive test of pancreatic trypsin activity in the small intestine. Evenepoel P, Hiele M, Geypens B, Geboes KP, Rutgeerts P, Ghoos Y. Gut 2000 Jan; 46 (1), pp. 52–7.

Pancreatic/Duodenum Gastrinoma/Zollinger-Ellison Syndrome: Persistent or Recurrent
Methylene Blue/Secretin

Application: Identification of gastrinoma (e.g., 6 mm) in the duodenum in order to facilitate surgical excision.

Route of Administration: Selective intra-arterial (methylene blue).

Implementation: Evaluation of Zollinger-Ellison syndrome when localizing modalities fail to detect a tumor (e.g., ultrasonography, computed tomography, magnetic resonance imaging, duodenal endoscopy, endoscopic ultrasonography, intraoperative endoscopic transillumination of the duodenum). In addition, postoperatively, a negative secretin provocative test result may also be appreciated.

In difficult cases presenting with this type of profile, an novel method can be utilized that involves selective arterial injection of secretin with hepatic venous gastrin sampling to identify the vessel feeding a gastrinoma lesion. An angiographic catheter is then positioned in this artery. At laparotomy, methylene blue is injected through the catheter to selectively stain gastrinoma lesions thereby facilitating its identification.

Human Model: Cases of persistent Zollinger-Ellison syndrome (n = 1 female 40 years) despite previous excision of a 4-cm duodenal gastrinoma. Localizing studies including ultrasonography, computed tomography, magnetic resonance imaging, duodenal endoscopy, endoscopic ultrasonography, and intraoperative endoscopic transillumination of the duodenum failed to detect a tumor.

Interpretation and Analysis: Selective intra-arterial methylene blue injection can enhance intraoperative detection of small gastrinomas and may improve the rate of curative resection in the Zollinger-Ellison syndrome. Further evaluation of this novel localizing technique is warranted.

Endocrine tumors of the pancreas. Meko JB, Norton JA. Curr Opin Gen Surg 1994; pp. 186–94.

Selective intra-arterial methylene blue injection: A novel method of localizing gastrinoma. Ko TC, Flisak M, Prinz RA. Gastroenterology 1992 Mar; 102 (3), pp. 1062–4.

Sphincter of Oddi Dysfunction (Abdominal Pain)
Morphine-Prostigmin

Background Information: Little data is available on the response of control populations to morphine-Prostigmin, or the reproducibility of this test on different days.

Application: diagnose disease of the sphincter of Oddi in cases with chronic abdominal pain. Test subjects included 10 healthy volunteers, 5 patients with symptoms of irritable bowel syndrome and 4 patients with chronic abdominal pain.

Considerations: Results noted in previous reports suggest that (i) neither enzyme rise nor reproduction of abdominal pain produced by morphine-Prostigmin is specific for disease of the sphincter of Oddi, and (ii) the morphine-Prostigmin test may give different results on different days in the same patient. Major clinical decisions should not be made on the basis of this test.

Interpretation and Analysis: A 2-fold rise in amylase or lipase levels, reproduction of abdominal pain or both have been considered positive responses. A positive morphine-Prostigmin test has been used as a justification for a sphincteroplasty, a surgical procedure with significant morbidity.

Sixty percent of healthy controls and patients with irritable bowel syndrome have marked elevations in amylase and lipase. Forty percent of those with irritable bowel syndrome have a reoccurance of typical abdominal pain after morphine-Prostigmin. Cases with chronic abdominal pain (2/4) have a different response to morphine-Prostigmin following the 2nd vs the 1st administration dose.

Manometric diagnosis of sphincter of Oddi spasm as a cause of postcholecystectomy pain and the treatment by endoscopic sphincterotomy. Tanaka M, Ikeda S, Matsumoto S, Yoshimoto H, Nakayama F. Ann Surg 1985 Dec; 202 (6), pp. 712–9.

The morphine-prostigmin provocative test—Is it useful for making clinical decisions? Steinberg WM, Salvato RF, Toskes PP. Gastroenterology 1980 Apr; 78 (4), pp. 728–31.

NEOPLASIA OF THE INTESTINE AND COLON

Colon Cancer (Intestinal/Colon) Optical Lesion Imaging
Indotricarbocyanine (ITCC)/ITCC-Transferrin/ITCC-Human Serum Albumin

Cellular/Molecular Mechanism of Action: Indotricarbocyanine is a dye that can serve as a detectable marker molecule in biological systems.

Background Information: Macromolecules accumulate in solid tumors and can thus be used as carriers for the delivery of attached contrast agents to tumors.

Application: Indotricarbocyanine can be applied as a contrast agent for the optical imaging of neoplastic lesions.

Route of Administration: Intravascular.

Semi-Synthetic Methods: Production of serum protein-dye conjugates consisting of transferrin (Tf) or human serum albumin (HSA) covalently linked to ITCC derivative.

Implementation: Evaluation of semi-synthetic ITCC-HSA and ITCC-Tf conjugates pertaining to (i) photophysical properties; (ii) ability to bind *in vitro* to tumor cells; and (iii) *in vivo* potential to detect/characterize experimental tumors.

Model: Human HT29 colon cancer cell types propagated *in vitro* in a tissue culture environment and in HT29 tumor-bearing nude mice.

Interpretation and Analysis: In contrast to ITCC-HSA, ITCC-Tf displays *in vitro* receptor-mediated uptake by HT29 human colon cancer cells. After intravenous injection, ITCC-HAS and ITCC-Tf both induce increased *in vivo* fluorescence contrast of tumors. After 24 hours the contrast between tumor and normal tissue is significantly higher for ITCC-Tf than for HAS-ITCC-HSA. Dye-induced fluorescence can be found to be predominantly located in perinecrotic areas of tumor lesions. Furthermore, ITCC-Tf produces fluorescence of viable tumor cells, whereas ITCC-HAS fluorescence can be detected along connective tissue. Therefore, ITCC-labeled Tf and HSA can serve as macromolecular contrast agents for the optical imaging of tumors, with ITCC-Tf showing higher efficiency.

Macromolecular contrast agents for optical imaging of tumors: Comparison of indotricarbocyanine-labeled human serum albumin and transferrin. Becker A, Riefke B, Ebert B, Sukowski U, Rinneberg H, Semmler W, Licha K. Photochem Photobiol 2000 Aug; 72 (2), pp. 234–41.

Colon Carcinoma Adhesion to Endothelium/ Intravital Observation of Cancer Cell/ Microcirculation Interactions
CalceinAM

Refer to Section II, Genetic Disorders, Infectious Disease, Neoplasia, and Metabolic Conditions.

Instrumentation: Intravital fluorescence microscopy.

Colorectal Cancer (Adenocarcinoma): Sentinel Lymph Node (SLN) Mapping
Isosulfan Blue Dye

Cellular/Molecular Mechanism of Action: Isosulfan blue is a pigment-based dye reagent.

Background Information: Sentinel lymph node biopsy is a widely accepted method for staging breast cancer and melanoma, and it has recently been proposed as a means of improving staging in colorectal cancer. However, lymphatic mapping in colorectal cancer has been plagued by studies demonstrating high false-negative rates.

Application: Evaluate possible mechanisms for high false-negative rates after SLN biopsy in colorectal cancer. Poor accuracy may be due to bulky tumor mass or complete replacement of lymph nodes by tumor lesions.

Route of Administration: Isosulfan blue dye (intralesional injection).

Dosage: Isosulfan blue dye (1 ml volumetric).

Implementation: Intraoperative injection of isosulfan blue dye into colorectal adenocarcinoma lesions for the purpose of lymphatic mapping using either an *in vivo* or *ex vivo* technique. Routine pathological evaluations are then performed. Sentinel node can be examined by hematoxylin and eosin stains, and if they are negative they are subsequently evaluated by cytokeratin immunohistochemistry. The patient's age, operation type, tumor stage, tumor diameter, method of SLN detection, presence of palpable nodes, and pathological description of nodes completely replaced by tumor are recorded.

Human Model: Cases undergoing colorectal cancer resection (n = 50; mean age, 62.8, 50% men) subjected to 51 lymphatic mapping procedures.

Interpretation and Analysis: Right- and left-sided colorectal resections are almost equally distributed (48% vs 42%). Sentinel lymph nodes can be successfully identified in a large percentage of cases (e.g., n = 47/51 or 92%). The mean number of SLNs obtained from each specimen is approximately 1.5 (range, 1–5). Routine pathological evaluation demonstrates lymph node metastasis in less than half of cases (e.g., n = 20/47 or 43%) that have SLN identified. The SLN is positive for metastasis in about half of these cases (e.g., n = 10/20) Approximately half of cases with metastasis have a negative SLN resulting in a false-negative rate of 50% (e.g., n = 10/20 cases). The rate of false-negatives is significantly higher in patients undergoing left-sided procedures vs right-sided procedures. Differences among gender, tumor stage, tumor diameter, method of SLN detection, presence of palpable nodes, and pathological description of nodes completely replaced by tumor are not associated with a higher false-negative rate.

Does tumor burden limit the accuracy of lymphatic mapping and sentinel lymph node biopsy in colorectal cancer? Broderick-Villa G, Ko A, O'Connell TX, Guenther JM, Danial T, DiFronzo LA. Cancer J 2002 Nov–Dec; 8 (6), pp. 445–50.

5 Hematopoietic System

HEMATOPOIESIS, HEMATOLOGY, AND HEMOSTASIS

Adhesion: Endothelium Interactions/Colon Carcinoma/Intravital Observation of Cancer Cell/Microcirculation Interactions
CalceinAM

Background Information: Organ-specific tumor cell adhesion within the microcirculation of host organs is an important step in the metastatic cascade. Circulating tumor cells have to adhere endothelial surfaces within the microcirculatory vessels, quickly stabilize, and then de-stabilize their adhesion in order to leave the circulation to avoid toxic effects of hydrodynamic shear forces of circulating blood.
Application: Intravital observation of colon carcinoma cell adhesion within the hepatic microcirculation.
Implementation: CalceinAM is used to label colon carcinoma cell populations (e.g., HT-29 [human] and CC531 [rat]) that are then injected intra-arterially as single-cell suspensions. Intravital fluorescence microscopy is then applied to detect adhesive interactions between circulating tumor cells and endothelial surfaces within the hepatic microcirculation. These interactions are then analyzed regarding their time course and site localization within the vascular tree.

Animal Model: Rats (Sprague-Dawley).
Interpretation and Analysis: Autofluorescence of liver parenchyma is sufficient for distinction of hepatic sinusoids. Intravital microscopy is capable of differentiating early events in adhesion formation within hepatic sinusoid, adhesion stabilization, and extravasation of the tumor cells into the liver parenchyma. Tumor cell adhesion occurs almost exclusively within sinusoidal capillaries; however, the diameter of these vessels is usually larger than that of the tumor cells leaving remaining perfused lumen of the capillaries. Colon carcinoma cells rapidly migrate into the liver parenchyma after successful adhesion within the sinusoids. In contrast to common end point assays of the metastatic cascade, this *in vivo* model allows investigations of metastatic colon carcinoma cell adhesion within the liver microcirculation at specific steps during the formation of hematogenous metastasis and their underlying mechanisms.
Instrumentation: Intravital fluorescence microscopy.

An intravital model to monitor steps of metastatic tumor cell adhesion within the hepatic microcirculation. Haier J, Korb T, Hotz B, Spiegel HU, Senninger N. J Gastrointest Surg 2003 May–Jun; 7 (4), pp. 507–14; discussion 514–5.

Anemia: Fanconi's Syndrome
Nitrogen Mustard (NTM)/[Diepoxybutane (DEB)]

Cellular/Molecular Mechanism of Action: Nitrogen mustards and diepoxybutane can function as DNA alkylating agents.
Background Information: Fanconi's anemia (FA) is an autosomal recessive inherited disorder that is associated with a variety of congenital anomalies. These include morphometric abnormalities involving mainly the head and face, skeletal malformations particularly of the radial ray, growth retardation, abnormal skin pigmentation, deafness, and renal, ocular, genital, and cardiac defects. The cardinal clinical feature is a severe progressive pancytopenia.
Application: Compare 2 different alkylating agents that would permit rapid and unequivocal detection of FA.
Implementation: Evaluate the potential to detect conditions of FA rapidly and accurately applying alkylating agents as screening agents. In this context, NTM and DEB tests are performed in concert with the determination of baseline chromosomal breakage analyses.

Human Model: Cases suspected of suffering from Fanconi's syndrome anemia (n = 271).
Interpretation and Analysis: Chromosomal breakage analyses can facilitate the detection of cases with FA (e.g., n = 72) in contrast to cases unaffected by the condition (e.g., n = 136). Studies of family members of affected FA cases (e.g., n = 63 individuals) reveal that NTM seems more specific to identify chromosomal breakages in FA parents than is possible with DEB.

Differential diagnosis of Fanconi's anemia by nitrogen mustard and diepoxybutane. Deviren A, Yalman N, Hacihanefioglu S. Ann Hematol 2003 Apr; 82 (4), pp. 223–7.

Anemia: Iron Deficiency/Renal Tumor/Infectious Anemia
[^{57}Co]Cl_2

Cellular/Molecular Mechanism of Action: [^{57}Co] mimics non-radioactive cobalt, which is an enzyme co-factor required for certain biochemical synthetic mechanisms.
Background Information: In 1971 Sorbie et al. described a simple [^{57}Co]-excretion test as an aid in the diagnosis of iron deficiency anemia. Renal excretion of a tracer dose of 0.5 muCi [^{57}Co]Cl_2 is significantly elevated in cases with iron deficiency anemia (31% of the administered dose in 24 hours urine) as compared with normal reference controls (18%).
Application: Detection and characterization of different types of anemia.
Route of Administration: [^{57}Co]Cl_2 (oral).
Dosage: [^{57}Co]Cl_2 tracer dose (0.5 muCi).
Implementation: Application of the [^{57}Co]-excretion test to evaluate different types of anemia. A modified version of the test entails measurement of serum activity 1, 2, 3, 7, 11, and 24 hours after the oral administration of the test formulation.

Human Model: Human cases and controls (n = 29 of different types of anemia; n = 10 normal controls).
Interpretation and Analysis: In all anemias as well as in the control group the maximum serum activity occurs 3 hours after the oral administration of the tracer. The 3 hours serum activity is elevated only in cases with iron deficiency anemia (5.53%/1 serum) as compared with normal reference controls (1.92%/1) and renal tumor and infectious anemia (1.20%/1, $p < 0.001$). The [^{57}Co] excretion is moderately elevated in most cases with iron deficiency anemia (average 31.5% [^{57}Co]-activity in 24 hours found in the urine) in comparison to healthy controls (average 25.30%). Contrary to the results

obtained by Sorbie et al., some investigations have therefore discovered a wide range of fluctuations in [^{57}Co]-excretion test within case-group types with a poor statistical significance of $p > 0.005$.

The [^{57}Co]-excretion and absorption test in the diagnosis of iron deficiency anemia. Bekier A, Holdener E. Nuklearmedizin 1976 Jun; 15 (3), pp. 126–30.

Anemia: Diamond-Blackfan
Metaclopramide

Cellular/Molecular Mechanism of Action: Metaclopramide promotes the release of prolactin.
Implementation: In cases of Diamond-Blackfan (congenital hypoplastic) anemia that are refractory to corticosteroids, approximately 33% of patients will respond to metoclopramide therapy.
Route of Administration: Metaclopramide (orally).
Dosage: Metaclopramide (10 mg, 3 times daily). Note: Conditions of anemia will usually not improve until 12 to 15 weeks of therapy have been completed.
Considerations: Several clinical scenarios have reported marked improvements in severe macrocytic anemia in women during their 2nd and 3rd trimesters of pregnancy and while breast-feeding children.
Interpretation and Analysis: Serum prolactin levels can increase from 7 to 133 ng/mL (normal < 20 ng/mL) simultaneously accompanied by elevations in hematocrit from 17% to 22% to 35%. With continued therapy (10 mg orally daily), hematocrit values may range from 30% to 40% over a period of 6 years, although the macrocytosis may persist (mean corpuscular volume, 100–112 fL). In pilot studies, metoclopramide therapy has been administered in patients with Diamond-Blackfan anemia that are refractory to low doses of corticosteroids. In these trials, approximately 33% respond the metaclopramide in a manner that suggests that this approach to therapeutic intervention may be universally beneficial.

Response of Diamond-Blackfan anemia to metoclopramide: Evidence for a role for prolactin in erythropoiesis. Abkowitz JL, Schaison G, Boulad F, Brown DL, Buchanan GR, Johnson CA, Murray JC, Sabo KM. Blood 2002 Oct 15; 100 (8), pp. 2687–91.

Cell Cycle Phases: Subpopulation Identification/Identification of Populations in G_0 and G_1 Phases of the Cell Cycle/Primitive Hematopoietic Stem Cell Characterization
Rhodamine 123/Hoechst 33342/Pyronin

Application: Supravital staining reagents that can be used to characterize cells that are in specific stages of mitotic division.
Implementation: Utilization of the supravital dyes rhodamine 123 (Rh), Hoechst 33342 (Ho), and pyronin (PY) to identify G_0 and G_1 phase subsets of primative hemopoietic stem cells (PHSC) for isolation. A competitive repopulation assay is used to evaluate their *in vivo* function.

***Ex Vivo* Model:** Primitive hematopoietic stem cells at phases G_0 and G_1 of the cell cycle.
Interpretation and Analysis: $Rh_{lo}Lin^{-}Kit^{+}Sca\text{-}1^{+}$ PHSC are relatively quiescent compared with the more mature $Rh_{hi}Lin^{-}Kit^{+}Sca\text{-}1^{+}$ HSC and $Rh_{hi}Lin^{-}Kit^{+}Sca\text{-}1^{-}$ progenitors. In addition, cells with $Rh_{lo}Lin^{-}Kit^{+}Sca\text{-}1^{+}$, $Rh_{lo}Ho_{lo}Lin^{-}Sca\text{-}1^{+}$, or $Rh_{lo}Ho_{sp}Lin^{-}Sca\text{-}1^{+}$ phenotypes identify the same cell population. Further subfractionation of $Rh_{lo}Ho(_{lo}/_{sp})Lin^{-}Sca\text{-}1^{+}$ PHSC can be achieved using PY (e.g., PY_{lo} and PY_{hi} subsets). Limiting dilution analysis reveals that the frequency of long-term *in vivo* competitive repopulating units (CRU) of $PY_{lo}Rh_{lo}Ho_{lo}/_{sp}$ PHSC is 1 in 10 cells, whereas there is at least a 3-fold lower frequency in those isolated at the G_1 phase (PY_{hi}). A dose-dependent PY-mediated cytotoxicity exists that at moderate concentration affects most murine hematopoietic compartment but spares the early HSC compartment. The HSC compartment is hierarchically ordered on the basis of quiescence and this concept further extends to PY-mediated cytotoxicity. Pyronin supravital dye can be used to reveal functional heterogeneity within the $Rh_{lo}Ho_{lo}/_{sp}$ PHSC population but is of limited use in dissecting the relatively more mature hematopoietic stem/progenitor cell population.

Functional heterogeneity within rhodamine 123($_{lo}$) Hoechst 33342($_{lo}$/sp) primitive hemopoietic stem cells revealed by pyronin Y. Huttmann A, Liu SL, Boyd AW, Li CL. Exp Hematol 2001 Sep; 29 (9), pp. 1109–16.

Fibrinogen Consumption: Intravascular $T_{1/2}$
[^{125}I]-Fibrinogen/Disseminated Intrascular Coagulation (DIC)/[^{123}I, ^{124}I, ^{125}I, ^{131}I]/[^{99m}Tc] DTPA-Fibrinogen

Cellular/Molecular Mechanism of Action: Fibrinogen is biochemically cleaved to fibrin monomer by thrombin. Fibrin monomers polymerized with 1 another and are covalently cross-linked by coagulation factor XIIIa*.
Physiological Mechanism of Action: Fibrinogen is the primary protein component of intravascular "clots" (thromboses) following biochemical conversion to fibrin monomer by thrombin.
Application: Detection of accelerated fibrinogen consumption or declines in production, or it can be utilized as a diagnostic imaging agent for the detection of intravascular (intravenous) thrombus formation.
Route of Administration: Intravascular.
Considerations: Excessively high labeling rations can compromise biological activity.
Semi-Synthetic Methods: Radioiodination reagents for biological proteins include Choramine-T, iodogen, and monochloroiodine.
Implementation: Fibrinogen intravascular kinetics and *in vivo* imaging of intravascular thromboses.
Interpretation and Analysis: Declines in the fibrinogen intravascular $T_{1/2}$ suggest the presence of elevated consumption. If fibrinogen levels are low but the intravascular $T_{1/2}$ is unchanged, then abnormalities in hepatic production may be present.
Instrumentation: Scintilation counter (intravascular kinetics), gamma camera (imaging).

Extraction, radioiodination, and *in vivo* catabolism of equine fibrinogen. Coyne CP, Hornof WJ, Kelly AB, O'Brien TR, DeNardo SJ. Am J Vet Res 1985; 46, pp. 2572–7.

Rapid extraction, radioiodination, and *in vivo* catabolism of ^{125}I-labeled fibrinogen in the horse. Coyne CP, Hornof WJ, Kelly AB, O'Brien TR, DeNardo SJ. Am J Vet Res 1985; 46, pp. 2578–81.

Lipemia
Heparin (Sodium or Lithium Salt)

Cellular/Molecular Mechanism of Action: Stimulation of lipoprotein lipase activity.
Application: (Bovine lung, porcine mucosal).
Diagnostic Application: (i) Detection of systemic lipemia and/or the temporary resolution of hyperlipemia in order to facilitate

serum electrolyte analysis. Heparine has also been applied in the therapeutic management of lipemia. (ii) Detection of fibrinolytic activity (FDP formation) and platelet consumption due to disseminated intravascular coagulation (DIC).

Route of Administration and Dosage: Intravenous or subcutaneous only.

Considerations: In man and some animal species, heparin becomes associated with the external surface membrane of RBC populations resulting in their premature removal from the intravascular compartment by the reticuloendothelial (RE) system. In general, heparin preparations of porcine intestinal mucoal origin tend to promote less severe anemia than extracts acquired from bovine lung. Heparin should never be administered intramuscularly due to the high probability of hematoma formation.

Laboratory Instrumentation: Serum is simply inspected visually when attempting to detect resolution of systemic hyperlipidemia.

Neutrophils/Neutrophil Margination, Rapid Demargination, and Slow Marginated Pool Transfer/Intravascular Kinetics and Biodistribution/Multiple-Indicator-Dilution Technique

[^{111}In]-Oxide Labeled Neutrophils/[^{51}Cr]-Labeled Red Blood Cells/Evans Blue-Labeled Albumin

Cellular/Molecular Mechanism of Action: Labeled neutrophils respond to chemotactic stimuli and phagocytized material perceived to be a foreign substance.

Application: Detection and characterization of alterations in neutrophil consumption or utilization (intravascular life span and local sequestration in conditions like pulmonary or gastrointestinal inflammatory disease).

Implementation: Evaluate the kinetics and biodistribution of neutrophils in various disease states or physiolocal conditions. One potential application is in multiple-indicator-dilution experiments performed in lungs involving the simultaneous bolus injection of [^{111}In]-labeled neutrophils, [^{51}Cr]-labeled red blood cells, and Evans blue-labeled albumin. Outflow profiles of labeled neutrophils were analyzed on the basis of a recirculatory pharmacokinetic model of labeled albumin.

Animal Model: Canine lung (n = 13 anesthetized dogs).

Interpretation and Analysis: Concomitant counts of unlabeled neutrophils are similar in pulmonary artery and aortic blood samples, demonstrating a dynamic balance across the lungs in the physiological state. The outflow profiles of the recovered neutrophils can be composed of a throughput component of circulating neutrophils and a component of reversibly marginated neutrophils. They can be interpreted by a model incorporating neutrophil margination (transfer coefficient = 0.195 ± 0.081 s-1), rapid demargination (0.054 ± 0.027 s-1), and transfer to a slow marginated pool (0.023 ± 0.018 s-1). Such investigative protocols can be applied as a research or diagnostic tool to delineate interactions between the pulmonary endothelium and neutrophils in physiological conditions and various diseased states.

Kinetic analysis of pulmonary neutrophil retention *in vivo* using the multiple-indicator-dilution technique. Schwab AJ, Salamand A, Merhi Y, Simard A, Dupuis J. J Appl Physiol 2003 Jul; 95 (1), pp. 279–91.

Note: Related citations have also been provided in sections on immunity and inflammation, infection and sepsis, and cellular delivery modalities.

Neutrophils/Monocytes/Consumption vs Production Abnormalities

[^{111}I]-Oxine Neutrophils/Chemotherapeutics: Doxorubicin

Physiological Mechanism of Action: Neutrophils and macrophages migrate into specific locations (tissues/organs) within the body in response to chemotactic stimuli (move toward a concentration gradient).

Application: Includes characterization of elevated platelet consumption or declines in production within the bone marrow. They can also function as a modality for the selective delivery of pharmaceutical agents for various diagnostic and therapeutic purposes.

Route of Administration: Intravascular.

Considerations: Must be prepared fresh.

Semi-Synthetic Methods: Radioisotope markers or chemotherapeutic agents can be passively "loaded" into neutrophil populations at relatively high concentrations without affecting their response to chemotactic stimuli.

Implementation: Selective delivery to foci of infectious disease or pretargeted neoplasia.

Interpretation and Analysis: Declines in intravascular $T_{1/2}$ values for labeled neutrophils implies accelerated consumption or removal. In scenarios where neutrophil numbers are low but the $T_{1/2}$ value is normal, then abnormalities in hematopoeitic production should be considered

Antineoplastic activity of chemotherapeutic "loaded" neutrophils against human mammary carcinoma. Coyne CP, Fenwick BW, Ainsworth J. Biotherapy 1997; 10, pp. 145–59.

Platelet Consumption/Intravascular Kinetics/ Platelet Consumption: Disseminated Intravascular Coagulation, Autoimmune Thrombocytopenia

[^{111}In]-Merc Platelets/[^{111}In]-Oxine Platelets

Cellular/Molecular Mechanism of Action: Platelets when exposed to activating agents like adenosine diphosphate and collagen monomer become activated, degranulate (phase I & II), and aggregate (reversible and irreversible phases). Platelets also repair defects in the vascular endothelium.

Physiological Mechanism of Action: Participate as cellular components in intravascular (especially intra-arterial) thrombus formation.

Background Information: Labeled platelets can be utilized to characterize intravascular platelet kinetics or as a diagnostic imaging modality.

Application: Detection of alterations in platelet intravascular kinetics in conditions of increased consumption (e.g., disseminated intravascular coagulation, autoimmune thrombocytopenia), or decreased production. Labeled platelets can also be utilized for diagnostic imaging of intravascular thromboses (e.g., deep-vein thromboses), and for the treatment of autoimmune thrombocytopenia (vincristine-loaded platelets become coated with autoimmune immunoglobulin and are subsequently phagocytized by macrophages, which are then suppressed by the chemotherapeutic agent).

Route of Administration: Intravascular.

Semi-Synthetic Methods: Usually, chelating agents are used to label cell populations like platelets because agents like [^{111}In] have a cationic or anionic charge that substantially decreases their ability to penetrate intact cell membrane structures.

Interpretation and Analysis: Decreases in the intravascular kinetic patterns for labeled platelet preparations suggest accelerated/elevated platelet consumption. If the platelet intravascular $T_{1/2}$ is normal, but platelet numbers are low, then a decrease in bone marrow platelet production should be considered.
Instrumentation: Scintilation counter (intravascular kinetics), gamma camera (imaging).

Radiolabeling of equine platelets in plasma with ^{111}In-(2-mercaptopyridine-N-oxide) and their *in vivo* survival in the horse. Coyne CP, Kelly AB, Hornof WJ, O'Brien TR, Phelps MS, Lamb JF. Am J Vet Res 1987; 48, pp. 385–91.

Platelet Intravascular Survival
Aspirin/[^{51}Cr]-Platelets/[^{111}In]-Platelets

Cellular/Molecular Mechanism of Action: Aspirin permanently inactivates platelet cyclooxygenase by acetylation. Because platelets do not have a nucleus, they cannot synthesize more enzyme. New platelets gradually over time replace the population of permanently inactived platelets within the intravascular compartment.
Application: Characterization of disease states associated with alterations in platelet survival (e.g., DIC, autoimmune disease, biochemical disorders).
Route of Administration: Aspirin (single oral intake).
Dosage: Aspirin (500 mg).
Implementation: A simultaneous investigation of platelet regeneration time (PRT) based upon malondialdehyde (MDA) recovery after aspirin ingestion and of platelet survival time (PST) after labeling with [^{51}chromium] or [^{111}indium] oxine.
Human Model: Neoplastic disease (n = 25; and n = 9 pilot study in healthy volunteers).
Interpretation and Analysis: In normal healthy individuals, the MDA assay has a high degree of reproducibility and specificity for platelet cycloxygenase activity. The pattern of MDA recovery after aspirin ingestion is linear in the healthy volunteers and in conditions of cancer presenting both a normal and an accelerated platelet turnover. Platelet survival times are calculated using the 4 mathematical models recommended by the International Committee for Standardization in Hematology and the best fit established by the multiple hit model (e.g., n = 22 cases) and by the linear regression model (e.g., n = 3 cases). The mean results obtained in cases investigated with the [^{51}Cr] are consistently shorter than those obtained in cases investigated with the [^{111}In]-oxine, while the mean PRT is almost identical in the 2 case group types. An excellent correlation between PRT and PST is observed after [^{111}In] oxine labeling and using the weighted mean method for PST determination. These results suggest that the [^{111}In] oxine technique is a better method for platelet labeling and that the results provided by the weighted mean method reflect more closely the *in vivo* platelet turnover than those provided by the multiple hit model.

Platelet regeneration time after aspirin ingestion and platelet survival time after labeling with ^{51}chromium or ^{111}indium oxine—A comparative study. Boneu A, Siá P, Bugat R, Caranobe C, Eber M, Cazenave JP, Boneu B. Thromb Haemost 1985 Apr 22; 53 (2), pp. 260–3.

Platelet Plasma Half-Life/Megakaryocyte Cyclooxygenase Activity
Aspirin

Background Information: The *in vivo* inhibitory effect of aspirin on platelet cyclooxygenase is irreversible and lasts for the entire platelet lifespan. Reappearance of cyclooxygenase activity in blood after aspirin has been proposed as a measure of the formation of new platelets and as an indirect indicator of platelet survival. A delay of 24 to 72 hours in recovery, however, has been observed and it has been suggested that aspirin might also inhibit megakaryocyte cyclooxygenase.
Route of Administration: Intraperitoneal.
Dosage: Aspirin (100 mg/kg rat).
Implementation: Evaluate the possibility that aspirin influences megakaryocyte cycloooygenase production. One approach to achieving this objective involves the administration of aspirin or saline, followed by the creation of thrombocytopenia 2 hours later (platelet count < 5% of basal value) by a specific antiplatelet antiserum. Malondialdehyde (MDA) and thromboxane B2 (TxB2) production by platelets is measured spectrophotometry and by radioimmunoassay, respectively, during the period of platelet count restoration. By 24 hours after induced thrombocytopenia, platelet counts are about 15% of basal values in control and aspirin-treated rats.
Interpretation and Analysis: In controls, MDA and TxB2 production is restored to about 20% of basal values, in contrast to aspirin-treated rats with less than 5% return of activity detected. A marked difference between the 2 groups can still be found 96 hours after induction of thrombocytopenia, when platelet count restoration is similar. Because aspirin disappears very rapidly from the circulation, the delay in recovery of cyclooxygenase activity supports the hypothesis of a megakaryocyte effect of this drug.

Impaired thromboxane production by newly formed platelets after aspirin administration to thrombocytopenic rats. Dejana E, Barbieri B, Cerletti C, Livio M, de Gaetano G. Br J Haematol 1980 Nov; 46 (3), pp. 465–9.

Platelet Regeneration/Survival/Consumption: Thrombocytopenia
Aspirin/[Thiobarbituric Acid/Malondialdehyde]

Cellular/Molecular Mechanism of Action: Permanent inhibition of cyclooxygenase biochemical activity through acetylation, thereby preventing the conversion of arachidonic acid generated by phospholipase A_2 to prostaglandin intermediates such as PGG and PGH.
Diagnostic Application: A systemic dose of aspirin is administered, which permanently inactivates cyclooxygenase activity in all exposed platelet populations residing within the intravascular compartment. Aspirin permanently (irreversibly) inactivates platelet cyclooxygenase by acetylation of the enzyme. Because platelets are essentially cellular fragments devoid of a functional nucleus, they are incapable of synthesizing additional cyclooxygenase. Therefore, increases in systemic platelet prostaglandin synthesis detected following the initial administration of aspirin directly (proportionally) correlates with the rate at which new platelet populations enter the peripheral intravascular compartment.

In the malondialdehyde assay, the thiobarbituric acid reagent can be applied to detect and evaluate oxidative stress status as a function of lipid membrane peroxidation and prostaglandin synthesis. In this context, it can be applied to evaluate the efficacy of pharmaceutical agents (e.g., non-steroidal anti-inflammatory drugs [NSAIDs]) and detect tissue peroxidation and the entry of new platelet populations into the systemic circulation.
Route of Administration and Dosage: Aspirin can be applied intravenous or oral administration. The assay method employing thiobarbituric acid, however, is performed *ex vivo* with a prepared cell population.

Considerations: Prolonged administration promotes development of lesions such as gastric ulceration and renal papillary necrosis. This is usually associated with vasoconstriction due to decreased synthesis of vasodilatory prostacyclin (PGI_2).

Assay Procedure: The malondialdehyde assay is based on its reactivity at high temperature and low pH toward thiobarbituric acid. This reaction is very sensitive but its specificity, even with improvement of preanalytical (sampling, preservatives) and analytical stages (fluorescence, high-performance liquid chromatography [HPLC]) is still a matter of debate. At present, the concept of "thiobarbituric acid reactive substances" (TBARS) has merged and progressively replaced the initial malondialdehyde assay. Example: After stimulation of the washed human blood platelets by arachidonic acid (AA), the formation of malondialdehyde (MDA) measured using the photometric thiobarbituric acid (TBA) method. Estimation of platelet lipid peroxidation as a function of malondialdehyde (MDA) production, and the formation of thromboxane B2 (TXB_2) measured by gas chromatography, may reveal that the formed MDA exceeds the amount of TXB_2 on a molar base. However, MDA and TXB2 originating from thromboxane synthase activity should be produced in approximately equimolar amounts. By treatment of stimulated platelet samples with stannous chloride it is possible to reduce all peroxidized products of AA that generate MDA otherwise during the TBA reaction and to estimate MDA and TXB_2 in a ratio of nearly 1:1. The stannous chloride treatment does not destroy the MDA and does not influence the TBA reaction with MDA. Therefore the simple and quick TBA method can be used after stannous chloride treatment for estimation of thromboxane synthase activity in AA-stimulated washed human platelets.

Implementation: Evaluation of platelet survival/production as a function of new arrival of intact platelets into the systemic circulation following univeral aspirin-mediated inactivation of cyclooxygenase is systemic platelet populations. Entry of new platelets into the systemic circulation is therefore detected as a rise in platelet-associated malondialdehyde concentrations measured in an *ex vivo* assay system.

The malondialdehyde assay is the most generally used test in the appreciation of the role of oxidative stress in disease. Malondialdehyde is 1 of several products formed during the radical induced decomposition of polyunsaturated fatty acids. Most often, malondialdehyde assay uses its reactivity at high temperature and low pH toward thiobarbituric acid. This reaction is very sensitive but its specificity, even with improvement of preanalytical (sampling, preservatives) and analytical stages (fluorescence, HPLC) is still a matter of debate. At present, the concept of TBARS has merged and progressively replaced the initial malondialdehyde assay. In the future, oxidative stress appreciation will need the precise analytical determination of different molecules triggered by free radicals. The TBARS assay should be considered as a global test, allowing a global approach of lipoperoxidation, whereas specific determination of malondialdehyde can only appreciate 1 of the end product formed during oxidative stress.

Laboratory Instrumentation: Inhibition of platelet PGI_2 synthesis by NSAIDs is detected by direct assay of PGI_2 applying RIA or ELISA methodologies. Alternatively, inhibited platelet PGI_2 synthesis can be detected by measurement of relative malondialdehyde production applying thiobarbituric acid and measuring spectrophotometric absorbance at 625 nm.

Evaluation of lipid peroxidation by measuring thiobarbituric acid reactive substances. Lefèvre G, Beljean-Leymarie M, Beyerle F, Bonnefont-Rousselot D, Cristol JP, Thérond P, Torreilles J. Ann Biol Clin (Paris) 1998 May–Jun; 56 (3), pp. 305–19.

Platelet Vascular Endothelial Repair/Vascular Endothelial Viability/Integrity
Evans Blue Dye Staining

Cellular/Molecular Mechanism of Action: Evans blue dye is a pigment-based reagent that becomes differentially associated with viable vs compromised cell populations (e.g., vascular endothelium).

Physiological Mechanism of Action: Tumor necrosis factor (TNF) soluble receptor (TNFsr) has been shown *in vitro* and *in vivo* to neutralize TNF-mediated biological activity.

Background Information: Tumor necrosis factor-alpha (TNF-α) is expressed locally in arteries at sites of balloon injury. *In vitro* studies have shown that TNF inhibits cell cycle progression and induces apoptosis in endothelial cells.

Application: Evans blue dye staining can be applied to evaluate viable *ex vivo* preparations of vascular structures for integrity of endothelial surfaces.

Implementation: Evaluation of the hypothesis that inhibiting TNF can accelerate endothelial recovery after angioplasty. One approach to achieving such an objective involves the administration of TNFsr vs control IgG by intraperitoneal injection. De-endothelializing balloon injuries are then created, and the resulting induced lesions evaluated 1 week later for evidence of reendothelialization (Evans blue dye staining), and after 2 weeks to evaluate reendothelialization and endothelial function.

Animal Model: Rat (Sprague-Dawley strain).

Interpretation and Analysis: At both time points, blockade of TNF biological activity with TNFsr results in increased reendothelialization, as measured as absolute area and percent area reendothelialized. Tumor necrosis factor soluble receptor also accelerates functional endothelial recovery that manifests as an increase in nitric oxide production. Neointimal thickening can also be appreciated as being inhibited. Blockade of TNF *in vivo* accelerates functional endothelial recovery after barotraumatic de-endothelializing injury. Locally expressed TNF therefore acts to inhibit functional endothelial recovery after angioplasty and transient blockade of TNF may improve the long-term success of angioplasty.

Evans blue staining reagent facilitates detection of a demarcation between viable endothelial cell populations and subendothelial collagen.

In vivo blockade of tumor necrosis factor-alpha accelerates functional endothelial recovery after balloon angioplasty. Krasinski K, Spyridopoulos I, Kearney M, Losordo DW. Circulation 2001 Oct 9; 104 (15), pp. 1754–6.

Platelet/Endothelium Interactions: *In Vivo*
Anti-P-Selectin Monoclonal Antibody/ Carboxyfluorescein Diacetate Succinimidyl Ester-Labeled Platelets

Cellular/Molecular Mechanism of Action: Carboxyfluorescein diacetate succinimidyl ester can function as a signal or indicator molecular. Anti-P-selectin monoclonal antibody recognizes and physically binds to membrane-associated P-selectin complexes.

Background Information: Accumulating evidence suggests that platelets play an important role in ischemia-reperfusion injury. To fulfill that role, platelets flowing in the bloodstream would have to interact with retinal endothelial cells and to accumulate in the postischemic retina.

Application: Carboxyfluorescein diacetate succinimidyl ester can be used to label cell populations (e.g., platelets) for the purpose of quantitatively characterizing platelet/endothelial interactions in postischemic retina after transient retinal ischemia.

Route of Administration: Intravenous.
Implementation: Isolated platelet samples are labeled with carboxyfluorescein diacetate succinimidyl ester and administered intravenously after various reperfusion periods. Platelet/endothelial interactions in postischemic retina are evaluated *in vivo* with a scanning laser ophthalmoscope. Anti-P-selectin monoclonal antibody (mAb) is administered 5 minutes before the injection of labeled platelets. P-selectin gene expression in the postischemic retina is then studied by semiquantitative polymerase chain reaction (PCR) analyses.

Animal Model: Rats (Long-Evans strain). Transient retinal ischemia is induced for 60 minutes by temporal ligation of the optic nerve.
Interpretation and Analysis: Under basal conditions, infused platelets show minimal interactions with retinal endothelial cells. In contrast, postischemic retinas show active platelet/endothelial interactions. Many platelets are observed rolling along and adhering to the major retinal veins. The number of rolling and adhering platelets reach a peak (555 ± 65/mm per minute and 25.8 ± 3.2/mm^2) 12 hours after reperfusion. However, interactions between platelets and postischemic retinal endothelial cells are substantially inhibited by neutralizing P-selectin expressed on endothelial cells. In addition, P-selectin gene expression in postischemic retina corresponds with the time course of platelet/endothelial interactions during the reperfusion period. Platelets actively interact with retinal endothelial cells in the postischemic retina through P-selectin expressed on the retinal endothelial cells.
Instrumentation: Scanning laser ophthalmoscope.

In vivo evaluation of platelet-endothelial interactions after transient retinal ischemia. Nishijima K, Kiryu J, Tsujikawa A, Honjo M, Nonaka A, Yamashiro K, Tanihara H, Tojo SJ, Ogura Y, Honda Y. Invest Ophthalmol Vis Sci 2001 Aug; 42 (9), pp. 2102–9.

Platelet/Endothelium Interactions/[Retinal Microvascular Pathology]
Carboxyfluorescein Diacetate Succinimidyl Ester/Platelets (Fluorescent Labeled)

Cellular/Molecular Mechanism of Action: Carboxyfluorescein diacetate succinimidyl ester interacts with light and functions as a fluorescent marker molecule suitable for "tracing" the migration of different cell types.
Application: Visualization of *in vivo* platelet behavior in the retinal microcirculation. The methodology allows for quantitative evaluation of platelet dynamics and platelet/endothelial interactions.
Route of Administration: Intravascular.
Considerations: Represents the development of a new method for evaluating the *in vivo* dynamics of platelets in the retinal microcirculation and quantitatively investigating platelet/endothelial interactions.
Implementation: Isolated platelet samples are labeled with carboxyfluorescein diacetate succinimidyl ester. After intravenous administration, platelet behavior in the retinal microcirculation can be evaluated with a scanning laser ophthalmoscope. Images are recorded on S-VHS videotape and analyzed with a computer-assisted image analysis system. The platelet/endothelial interactions in the retinal microcirculation can also be investigated employing lipopolysaccharide-stimulated endothelium or platelets activated with thrombin.

Animal Model: Rat retina.
Interpretation and Analysis: Fluorescent platelets are recognized as distinct dots in the retinal microcirculation and can be traced frame by frame. The velocity of platelets in the retinal arteries, capillaries, and veins is approximately 26.1 ± 6.4, 1.6 ± 0.4, and 19.9 ± 8.2 mm/sec, respectively. In control rats, even activated platelets show minimal interaction with retinal endothelial cells. In contrast, stimulated retinal endothelium show active platelet/endothelial interactions, with many platelets observed rolling and adhering along the major retinal veins. The interactions between platelets and stimulated endothelial cells are substantially inhibited with the injection of P-selectin monoclonal antibody.

In vivo evaluation of platelet-endothelial interactions in retinal microcirculation of rats. Tsujikawa A, Kiryu J, Nonaka A, Yamashiro K, Nishiwaki H, Tojo SJ, Ogura Y, Honda Y. Invest Ophthalmol Vis Sci 1999 Nov; 40 (12), pp. 2918–24.

Stem Cell Migration/Hematopoietic/[Parkinson's Disease Research]
Gadolinium Rhodamine Dextran (GRID)

Cellular/Molecular Mechanism of Action: Rhodamine emits light energy while gadolinium functions as an element that can be selectively detected by magnetic resonance imaging.
Background Information: The ability to track stem cell transplants in the brain by *in vivo* neuroimaging will improve current understanding about how these cells mediate functional recovery after neural transplantation. One major challenge for the development and refinement of stem cell transplantation is to map the spatial distribution and rate of *in situ* migration.
Application: Gadolinium rhodamine dextran is a bifunctional contrast agent that can emit light energy and be detected in a magnetic field. These attributes allow it to be applied as a tracer or marker molecule for profiling the migration of transplanted stem cell populations within ischemia-damaged rat hippocampus by magnetic resonance imaging (MRI). The strategies and techniques could also be applied to tracking hematopoietic stem cell migration.
Route of Administration: Intravenous.
Semi-Synthetic Methods: Conjugation of rhodamine to dextran applying cross-linking strategies. Addition of gadolinium to dextran can potentially be achieved by covalent bond formation or through the application of chelation groups.
Implementation: Assessment of stem cell migration applying *in vitro* labeling of populations with the bifunctional contrast agent GRID prior to transplantation. Detection is achieved applying both MRI and fluorescence microscopy, or with PKH26, visible exclusively under fluorescence microscopy. At different time points following engraftment, brains are evaluated by both histology and *ex vivo* MR imaging.
Interpretation and Analysis: Transplanted stem cells can be identified by MRI only if prelabeled with GRID, whereas fluorescence microscopy can detect transplanted cells using either labeling reagent. Distribution of GRID-labeled stem cells established that applying MRI corresponds to results using fluorescence microscopy. Stem cells and their migration can therefore be reliably identified applying GRID-enhanced MRI methodologies.

Tracking transplanted stem cell migration using bifunctional, contrast agent-enhanced, magnetic resonance imaging. Modo M, Cash D, Mellodew K, Williams SC, Fraser SE, Meade TJ, Price J, Hodges H. Neuroimage 2002 Oct; 17 (2), pp. 803–11.

Stem Progenitor Cell Tracking/Hematopoietic
PKH Dyes

Cellular/Molecular Mechanism of Action: PKH dyes serve as marker molecule.

Background Information: The process of hematopoietic stem and progenitor cell (HSPC) seeding in recipient bone marrow (BM) early after transplantation has not been fully characterized
Application: PKH dyes serve as marker molecule that can be utilized to track the *in vivo* migration of cell populations in biological systems.
Implementation: *In vivo* tracking of HSPCs, labeled with PKH dyes, through an optical window surgically implanted on the mouse femur reveals that transplanted cells cluster in the recipient BM.
Interpretation and Analysis: In the 1st 24 hours after intravenous injection, 86 ± 6% the cells seed in clusters ($p < 0.001$ vs scattered cells) in the endosteal surfaces of the epiphyses. Primary clusters are formed by concomitant seeding of 6 to 10 cells over an area of approximately 70 microm, and secondarily injected cells do not join the already existing clusters but form new clusters. Major antigen-disparate HSPCs participate in formation of primary clusters, and T lymphocytes are also incorporated. After 4 to 5 days, some cellular clusters can be observed in the more central regions of the BM, where the brightness of PKH fluorescence decreases, indicating cellular division. These later clusters are classified as secondary, assuming that the mechanisms of migration in the BM may be different from those of primary seeding. Some clusters remain in the periphery of the BM and retain bright fluorescence, indicating cellular quiescence. The number of brightly fluorescent cells in the clusters decreases exponentially to 2 to 3 cells after 24 days ($p < 0.001$). Hematopoietic niche is a functional unit of the BM stromal microenvironment that hosts seeding of a number of transplanted cells, which form a cluster. This may be the site where auxiliary non-HSPC cells, such as T lymphocytes, act in support of HSPC engraftment.

Transplanted hematopoietic cells seed in clusters in recipient bone marrow *in vivo*. Askenasy N, Zorina T, Farkas DL, Shalit I. Stem Cells 2002; 20 (4), pp. 301–10.

Thalassemia (Beta): Transfusion Dependent/Multiple Endocrine Dysfunction
Thyrotropin-Releasing Hormone (TRH) Stimulation Test

Cellular/Molecular Mechanism of Action: Thyroid-stimulating hormone (TSH) release is promoted by TRH.
Application: Assessment of thyroid dysfunction (example: estimation of the prevalence of thyroid dysfunction in homogenous groups of thalassemic patients).
Considerations: Despite improved hematologic care, multiendocrine dysfunction is a common complication in cases of transfusion-dependent beta-thalassemia.
Implementation: Evaluation of thyroid function in response to a TRH stimulation test for the purpose of possibly detecting cases of beta-thalassemia major. Thyroid dysfunction can be defined as (i) overt hypothyroidism (low FT4 and/or FT3 and increased TSH levels); (ii) subclinical hypothyroidism (normal FT4, FT3, increased TSH levels); (iii) exaggerated TSH response: normal FT4, FT3, normal basal TSH, deltaTSH ≥ 21 μIU/mL (TSH levels measured prior to and 30 minutes after intravenous TRH administration).

Human Model: Case subgroup proven to have normal thyroid hormone values; cases are selected randomly and subjected to a standard TRH stimulation test (e.g., n = 26; n = 12 males, n = 14 females; mean age, 23.6 ± 6.8 years; age range, 15–36 years).
Interpretation and Analysis: In populations of patients suffering from beta-thalassemia major (regularly transfused and desferioxamine chelated), the evaluation of thyroid function and iron-load status (assessed through measurements of free thyroxine [FT4], free triiodothyronine [FT3], thyrotropin [TSH], and serum ferritin levels) has aided in determining that normal thyroid hormone values can be expected in approximately 83.5% of affected patients. Of the remaining patients, about 4% will have overt hypothyroidism, while 12.5% will have subclinical hypothyroidism. Exaggerated TSH response to TRH may be seen in about 27% of patients with normal hormone values. Antithyroglobulin and antithyroid peroxidase (TPO) antibody titers are negative in a high percentage of patients (95%). Mean ferritin levels in hypothyroid and euthyroid patients are 2,707.66 + 1,990.5 mg/L and 2,902.9 + 1,997.3 mg/L, respectively ($p = 0.61$), indicating that no correlation exists between ferritin levels and thyroid functional status. Mean ferritin levels in the patients who respond normally to TRH stimulation and in those who overrespond reveal values of 2,586 + 1,791 mg/L and 3,228 + 2,473 mg/L, respectively ($p = 0.46$; ns). Thyroid failure is a rather rare endocrine complication in patients with beta-thalassemia from Greece and has been validated in previous investigations that have failed to identify any cases of central hypothyroidism. Often, no correlations can be found between thyroid functional status and ferritin plasma levels. Approximately 1 of 5 beta-thalassemic patients with normal thyroid hormone values show exaggerated TSH responses to the TRH test.

Assessment of thyroid function in two hundred patients with beta-thalassemia major. Zervas A, Katopodi A, Protonotariou A, Livadas S, Karagiorga M, Politis C, Tolis G. Thyroid 2002 Feb; 12 (2), pp. 151–4.

von Willebrand's Factor Antigen (vW Fag)
Desmopressin (DDAVP)/Stress Test

Cellular/Molecular Mechanism of Action: Desmopressin directly promotes increases in plasma vW Fag.
Application: Differentiation between conditions of vasculitis, systemic lupus erythematosus (SLE), and rheumatoid arthritis compared to normal (negative) controls. Desmopression is also used to not only to diagnose von Willebrand's disease but also to facilitate the classification of this condition (e.g., mild vs moderate).
Route of Administration: Desmopressin (intravenous).
Dosage: Desmopressin (0.3 μg/kg).
Considerations: von Willebrand's factor antigen has been used as a marker for vasculitis and raised levels have been shown to correlate with active disease. However, certain cases of vasculitis have normal vW Fag levels and are difficult to diagnose; this is of importance because of the high mortality associated with these disorders. Venostatic stress can be used as a provocative test for stimulating vW Fag release, thereby improving the speed and sensitivity of diagnosis.

Unfortunately, the venostatic stress with vW Fag measurement does not produce a more sensitive test for vasculitis. Venostasis should be avoided when measuring vW Fag levels.
Interpretation and Analysis: At baseline, although the levels are not outside the laboratory range, patients with active disease have raised vW Fag compared to simultaneously tested controls. Venostatic stress increased vW Fag activity in all disease groups, control levels also increased, and differences between controls and disease groups diminished in significance.

The diagnosis and classification of von Willebrand's factor (vWF) profiles utilizing intravenous desmopressin infusions involves the interpretation of assays for vWF-related antigens contained in plasma samples collected approximately 60 minutes following administration. In patients with Type 1 von Willebrand's disease a number of fractions become elevated including vWF:Ag (3.7-fold increase); propeptide (7.2-fold increase); and vWF:CBA (2.2-fold increase). Unusually large vWF multimers and traces of provWF also appear during this same time period. A more detailed interpretation of desmopressin-induced alterations in the profile for vW FAg in cases with congenital von Willebrand's disease (CvWD) involves the

interpretation of electrophoresis analyses that are able to facilitate the detection of (i) mild to moderate Type I vWD (24 probands); (ii) severe CvWD Type I (6 probands); and (iii) Type 2 CvWD (12 probands). Congenital von Willebrand's disease Type 1 of mild to moderate severity is featured by proportionally decreased levels of vWF antigen (vWF:Ag), vWF ristocetin co-factor activity (vWF:Rcof), and vWF:CBA between 0.20 and 0.60 u/mL and a normal response to DDAVP of factor (F) VIIIc and all vWF parameters. Severe Type 1 CvWD with vWF parameters below 0.10 or 0.20 u/mL is associated with a decreased response to DDAVP of all vWF parameters, indicating a defective synthesis or secretion vWF by endothelial cells, or both. Congenital von Willebrand's disease 2M may present as severe Type 1 CvWD, as Type 1 "platelet-discordant" CvWD, or with the combination of a discrepant vWF:Rcof/Ag ratio and the presence of all vWF multimers. Ristocetin-induced platelet aggregation (RIPA) is normal in Type 1 CvWD. Congenital von Willebrand's disease 2M is typically featured by decreased RIPA, normal or near normal vWF multimers, and no or only a poor response to DDAVP of vWF:Rcof as compared with a fairly good response to DDAVP of vWF:Ag and vWF:CBA. Conditions of CvWD Vicenza are characterized by unusually large vWF multimers and very low levels of FVIIIc, vWF:Ag, and vWF:Rcof. Congenital von Willebrand's disease Vicenza differs from CvWD 2M because the vWF:Rcof/Ag ratios are completely normal before and after DDAVP; the response to DDAVP is equally good for FVIIIc, vWF:Ag, vWF:Rcof, and vWF:CBA and is followed by very short half-life times for FVIIIc and all vWF parameters. Pertinent findings in Type 2A and 2B CvWD include prolonged Ivy bleeding time (BT), low vWF:Rcof/Ag and vWF:CBA ratios, absence of high vWF multimers, and, depending on the severity of the absence of intermediate vWF multimers, pronounced increase of low vWF multimers and vWF degradation products because of increased proteolysis of the high and intermediate vWF multimers. Ristocetin-induced platelet aggregation is normal in CvWD 2A and increased in CvWD 2B. The response to DDAVP in CvWD 2A is normal for FVIIIc and vWF:Ag but is transient with partial correction and short half-life times of vWF:CBA and vWF:Rcof. DDAVP does not correct BT and multimeric patterns in CvWD Type 2B, despite significant increase of vWF parameters. Congenital von Willebrand's disease Types 2C, 2D, and 2E are featured by very low functional vWF parameters, the presence of typically abnormal vWF multimers, a very poor response of vWF:CBA, a decreased response of vWF:Rcof, and a fairly good response of vWF:Ag to DDAVP with no correction of prolonged Ivy BT and no correction of the vWF multimeric pattern as a consequence of a multimerization or dimerization defect of the vWF molecules. Congenital von Willebrand's disease Type 2N usually presents with much lower levels for FVIIIc as compared with vWF, normal Ivy BT, and normal vWF multimeric pattern. The response to DDAVP is normal for all vWF parameters but is decreased for FVIIIc with a shortened half-life within the intravascular compartment.

The von Willebrand's factor-cleaving protease (ADAMTS13) cleaves vWF and regulates its biological/physiologic function. Evaluation of the influence of desmopressin on plasma ADAMS13 reveals that its concentration noticeably decreases compared to the vWF-related parameters of vWF antigen (vWF:Ag), vWF collagen-binding activity (vWF:CBA), vWF-propeptide, provWF, and vWF multimeric composition in healthy volunteers. More specifically, ADAMTS13 activity decreases to about half the initial value but returns to baseline levels at approximately 24 hours. Patients with Type 1 von Willebrand's disease display similar patterns/results. Therefore, the inverse correlation between ADAMTS13 and vWF-related parameters suggests a consumption of ADAMTS13 after the desmopressin-induced release of higher multimers of vWF.

Prevalence, pathophysiology, diagnosis and treatment of von Willebrand syndrome in orthopedic trauma patients. Kurth AA, Ludwig G, Scharrer I. Orthopade 1999 Apr; 28 (4), pp. 366–74.

IMMUNE SYSTEM

Allergen Immune Responses: Nasal/Late Induction/Allergen Identification/Efficacy Evaluation of Anti-Inflammatory Agents and Corticosteroids/Example Allergen: Grass/Pollen Hypersensitivity

Allergen Challenge Test/Fluticasone

Background Information: Allergen-induced late nasal responses are associated with recruitment and activation of T lymphocytes and eosinophils along with preferential mRNA expression for T-helper type 2 (Th2) cytokines.

Implementation: Detection of allergens responsible for inducing allergic reactions and evaluating the efficacy of potential therapeutic agents (e.g., anti-inflammatory agents and corticosteroids). An example in this regard is the application of an allergen challenge to evaluate the efficacy of topical corticosteroids (fluticasone propionate) and their ability to inhibit late responses by suppressing cellular expression of Th2 type cytokine mRNA sequences. Nasal biopsies are taken at baseline and repeated 24 hr after local nasal allergen provocation following 6 weeks treatment (e.g., fluticasone propionate 200 μg or placebo nasal spray twice daily).

Human Model: Cases of grass pollen sensitivity ($n = 48$ adults) analyzed in a randomized double blind placebo-controlled trial.

Interpretation and Analysis: Baseline mRNA expression for interleukin (IL)-4 ($p = 0.01$) and IL-5 ($p = 0.002$) is higher in cases of grass pollen sensitivity. Topical corticosteroid treatment significantly inhibits immediate nasal symptoms, with almost complete inhibition of the late response following allergen challenge. This is associated with a marked decrease in the allergen-induced increases in cells expressing mRNA for IL-4 ($p = 0.002$) but not for IL-5. Inhibition of the late response is also accompanied by decreases in CD25+ cells, presumed to be T lymphocytes and eosinophils. A significant correlation exists between decreases in IL-4 mRNA+ cells and in eosinophils after treatment ($r = 0.46$, $p < 0.05$). Therefore, prolonged treatment with topical corticosteroid inhibits allergen-induced early and late nasal responses and the associated tissue eosinophilia, and that, at least in part, may result from inhibition of cells expressing IL-4 mRNA sequences.

Topical glucocorticosteroid (fluticasone propionate) inhibits cells expressing cytokine mRNA for interleukin-4 in the nasal mucosa in allergen-induced rhinitis. Masuyama K, Jacobson MR, Rak S, Meng Q, Sudderick RM, Kay AB, Lowhagen O, Hamid Q, Durham SR. Immunology 1994 Jun; 82 (2), pp. 192–9.

Allergic Reactions: Inhaled Environmental Allergens

Single Allergen Provocation Test/Nasal Biopsy/[Interleukin (IL)-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, Interferon-Gamma (IFN-γ), RANTES, Tumor Necrosis Factor-Alpha (TNF-α)]

Background Information: The local production and release of a number of cytokines regulates allergic upper airway inflammation.

Medication is usually used at the presentation of the 1st symptoms. There are, however, clues that it is advisable to start taking corticosteroids before the grass pollen season begins.

Application: The single allergen provocation test can be applied to detect natural allergens responsible for inducing hyperactive immune responses *in vivo* in addition to functioning as a tool for evaluating the efficacy of anti-inflammatory and immunosuppressive agents.

Implementation: Evaluation of preventive therapies for inhaled allergic reactions applying the single allergen provocation protocol conducted in autumn (non–hay fever season). Nasal mucosa biopsies are collected twice before provocation (before and after 4 weeks of preventive treatment) and 3 times after allergen provocation (1 hour, 24 hours, and 1 week). Eosinophils and mRNA positive cells (*in situ* hybridization for IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IFN-γ, RANTES, and TNF-α) are then counted in biopsies.

Human Model: Cases receiving either fluticasone propionate aqueous nasal spray (n = 10 administered FPANS) or a placebo (n = 9).

Interpretation and Analysis: Preventive treatment with FPANS out of season resulted in a decrease in eosinophils and mRNA positive cells for IL-5 and IL-6. After allergen provocation, levels of most of the measured cytokines (IL-3, IL-5, IL-6, IL-13, IFN-γ, RANTES, and TNF-α) and eosinophils are reduced using corticosteroids. The number of cells (eosinophils, IL-3, IL-6, and IL-8) correlates with nasal symptoms. Significant correlations in the early and late allergic phase can be appreciated between eosinophils and cytokines (IL-3, IL-10, and IL-13). These results indicate that preventive treatment with FPANS prior to contact with grass pollen is effective in reducing the increase of cytokine mRNA positive cells in reaction to grass pollen contact.

Preventive treatment of intranasal fluticasone propionate reduces cytokine mRNA expressing cells before and during a single nasal allergen provocation. Kleinjan A, Holm AF, Dijkstra MD, Boks SS, Severijnen L, Mulder PG, Fokkens WJ. Clin Exp Allergy 2000 Oct; 30 (10), pp. 1476–85.

Autoimmune: Graves' Ophthamology/Type Th2 Interleukines: IL-4 and IL-10
Methylprednisolone (MP)/Prednisone

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit general protein synthesis, stabilizes cell membrane structures, and inhibits the biochemical activity of phospholipase A2 in a manner that decreases both leukotriene and prostaglandin synthesis.

Physiological Mechanism of Action: Corticosteroids exert anti-inflammatory and immunosuppressive properties.

Application: Elevated expression of serum interleukin (IL)-4 and IL-10 during successful treatment with corticosteroids indicates the possibility of using these cytokines as predictors of the beneficial effect of corticosteroids in Graves' ophthalmopathy.

Route of Administration: Methylprednisolone (intravenous); prednisone (oral).

Dosage: Methylprednisolone (2 series, 3 g each time); prednisone (60 mg per day according to a tapering dose schedule).

Implementation: Evaluation of Graves' ophthalmology conditions related to the estimated influence of corticosteroids on Th1 and Th2 serum cytokine balance. Cytokines of particular interest include interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), IL-4, and IL-10. In addition, complementary analysis involves delineation of the upregulation of Th2 immune response during successful treatment with corticosteroids to determine if there is a correlation with their beneficial effect in Graves' ophthalmopathy. Corticosteroid challenge/exposure consists of intravenous infusions of and subsequent treatment with oral prednisone in a tapering dose schedule. Serum samples are collected 24 hours before MP, 24 hours after MP and 14 days of treatment with prednisone, and at the end of corticosteroid therapy. Levels of IFN-γ, TNF-α, IL-4, and IL-10 in the serum are determined using ELISA. Statistical significance is estimated by the Mann-Whitney U-test.

Human Model: Cases of Graves' disease without ophthalmopathy (n = 20 Gd); cases with clinical symptoms of ophthalmopathy (n = 16 GO with CAS over 3 points, last consultation record for GO less than a year old); and normal healthy volunteers (n = 16).

Interpretation and Analysis: Deviations exist pertaining to systemic Th2 cytokine profile in Graves' disease. In GO cases, a significant increase in serum IL-10 concentration can be detected. In corticosteroid-responsive patients, the balance of serum cytokines IL-4/IFN-γ, IL-4/TNF-α, IL-10/IFN-γ, and IL-10/TNF-α increases and remains upregulated. In non-responders, the balance of serum cytokines studied increases after methylprednisolone but declines markedly during continuation of the therapy with prednisone. Therefore, efficient corticosteroid therapy may be related to its influence on Th2/Th1 profile cytokine balance. The upregulation of serum IL-4 and IL-10 during successful treatment with corticosteroids indicates the possibility of using these cytokines as predictors of the beneficial effect of corticosteroids in Graves' ophthalmopathy.

Serum Th1 and Th2 profile cytokine level changes in patients with Graves' ophthalmopathy treated with corticosteroids. Myśliwiec J, Kretowski A, Topolska J, Siewko K, Jakubczyk D, Szelachowska M, Mikita A, Kinalska I. Horm Metab Res 2001 Dec; 33 (12), pp. 739–43.

Autoimmune: Multiple Sclerosis (MS)/[Central Nervous System (CNS) Autoimmune Disorder]
Thyrotropin-Releasing Hormone (TRH) Stimulation/ Bromocriptine/(Prolactin)

Cellular/Molecular Mechanism of Action: Thyrotropin-releasing hormone promotes prolactin secretion.

Application: Multiple sclerosis cases reportedly display elevations in plasma prolactin concentrations.

Considerations: Before the onset and during experimental allergic encephalomyelitis (EAE) (animal counterpart of MS), the peripheral concentrations of prolactin can be found to be elevated and bromocriptine has been found to attenuate such attacks. Prolactin may play a role in the immunology of MS.

Implementation: Evaluation of prolactin levels in cases of MS as a diagnostic parameter.

Animal Model: Experimental allergic EAE can be applied as a model for human MS.

Interpretation and Analysis: Multiple sclerosis cases have slightly but significantly higher prolactin levels at baseline (10.2 ± 1.6 vs 6.44 ± 0.57 ng/ml, p = 0.042) than do matched reference controls; however, values are within the normal range. Prolactin levels post-TRH are significantly higher in cases with MS with peak prolactin levels being higher than negative reference controls (57.08 ± 6.144 vs 32.94 ± 4.92 ng/ml, p = 0.006). The area under the curve of prolactin is also higher in patients than in controls (3,421.87 ± 394.53 vs 2,317.62 ± 257.22 ng/ml, p = 0.030).

Prolactin secretion is increased in patients with multiple sclerosis. Azar ST, Yamout B. Endocr Res 1999 May; 25 (2), pp. 207–14.

Autoimmune: Multiple Sclerosis (MS)
Metoclopramide/Bromocriptine/Thyrotropin-Releasing Hormone (TRH)

Cellular/Molecular Mechanism of Action: Bromocriptine blunts elevations in prolactin, while TRH promotes the release of prolactin (PRL). Prolactin belongs to the growth and lactogenic hormone family and has potent immunomodulating properties.
Background Information: Mild hyperprolactinemia has been found to enhance several autoimmune diseases and increased PRL plasma levels have been described in natural and experimental MS models. The PRL antagonist bromocriptine suppresses the disease.
Application: Detection of cases suffering from MS.
Considerations: Prolactin concentrations are elevated in MS. Before the onset and during experimental allergic encephalomyelitis (EAE), the animal counterpart of MS, prolactin levels are elevated, while bromocriptine attenuates attacks.
Implementation: Evaluation of the prolactin baseline values as a function of disease course and activity in a large population of MS patients. Furthermore, inhibitory (bromocriptine) and stimulatory (metoclopramide) tests can be performed in a population subsample to gain functional information.

Human Model: Cases suffering from MS (n = 132; n = 39/132 receiving alternating bromocriptine and metoclopramide).
Interpretation and Analysis: No correlation exists between baseline values and disease course or activity. Nevertheless, in the regression analysis of stimulatory test results, 14% of the variance is attributable to disease activity. In conclusion, PRL does not seem to be relevant as an activity marker in the whole MS population.

Prolactin stimulation in multiple sclerosis—An indicator of disease subtypes and activity? Heesen C, Gold SM, Bruhn M, Mönch A, Schulz KH. Endocr Res 2002 Feb–May; 28 (1–2), pp. 9–18.

Autoimmune: Multiple Sclerosis (MS)/Inflammatory Medicator Profile (Tumor Necrosis Factor-Alpha [TNF-α]; Interleukin [IL]-2; IL-4; IL-6; IL-10; IgG)/Clinical Course and Severity
Azathioprine (AZA)/Cyclosporin/ Cyclophosphamide/ Interferon-Beta 1a (IFN-β 1a)/Corticosteroids (CST)

Physiological Mechanism of Action: Azathioprine, cyclosporin, cyclophosphamide, IFN-β 1a, and/or CST each exert immunosuppressive properties through different individual mechanisms.
Implementation: Discovery of the relationship between various therapies and the clinical activity and course of MS with the *in vitro* production of (i) TNF-α; (ii) IL-2; (iii) IL-4; (iv) IL-6; (v) IL-10; and (vi) oligoclonal IgG (IgG OB). Experimental samples used for analysis can include whole blood stimulated with lipopolysaccharide or concanavalin A.

Human Model: Cases of relapsing-remitting, relapsing-progressive, or chronic progressive MS (n = 61) receiving no therapy, AZA, cyclosporin, cyclophosphamide, subcutaneous IFN-β 1a, and/or CST.
Interpretation and Analysis: The cinetics of cytokine production show that (i) in the absence of treatment, TNF-α and IL-6 drop, respectively, after and during the periods surrounding relapse, while IL-4 is increasing before and IL-10 after relapse; (ii) with AZA, TNF-α and IL-6 decreasing before exacerbation, IL-4 has prolonged high levels after and IL-10 before relapse; and (iii) with IFN-β 1a, IL-10 may already be increasing before relapse, while TNF-α may be higher after relapse. When cytokine levels are analyzed independently from MS clinical activity, the use of AZA inhibits IgG OB and TNF-α synthesis ($p = 0.002$) but increases IL-4 ($p = 0.0024$), whereas IFN-β 1a stimulates TNF-α and inhibits IgG OB and IL-4 production. Corticosteroid inhibits TNF-α, IL-6, IL-4, and IgG OB synthesis. Such studies emphasize both the weight of clinical parameters and of methodology used in results obtained in cytokine analysis in MS.

In vitro cytokine profiles as indicators of relapse activity and clinical course in multiple sclerosis. Schluep M, van Melle G, Henry H, Städler C, Roth-Wicky B, Magistretti PJ. Mult Scler 1998 Jun; 4 (3), pp. 198–202.

Autoimmune: Multiple Sclerosis (MS)
Arginine Vasopressin (AVP)

Background Information: In the LEW/N rat model, a decreased hypothalamic-pituitary-adrenal (HPA) axis response to inflammatory and immune mediators confers susceptibility to the development of a variety of inflammatory and immune diseases, including experimental allergic encephalomyelitis. In humans with optic neuritis, early intervention with steroids is associated with a decrease in the number of patients who go on to develop MS.
Application: Multiple sclerosis cases demonstrate a blunted release of adenocorticotropic hormone (ACTH) in response to AVP stimulation test.
Implementation: Evaluate the potential for MS to show evidence of hypoactive HPA axis function before (baseline) and after provocative testing with several agents including (i) ovine corticotropin releasing hormone (CRH); (ii) AVP; and (iii) ACTH stimulation. Results are then compared to negative reference controls.

Human Model: Cases of MS (n = 13).
Interpretation and Analysis: Compared to matched controls, MS cases have significantly higher plasma cortisol levels at baseline. Despite this hypercortisolism and in contrast to cases with depression that had similar elevations in plasma cortisol levels, cases with MS show normal, rather than blunted, plasma ACTH responses to ovine CRH, suggesting that the pathophysiology of hypercortisolism in MS is different than for depression. Patients with MS also show blunted ACTH responses to AVP stimulation and normal cortisol responses to high- and low-dose ACTH stimulation. Taken together, these findings are compatible with data from studies of experimental animals exposed to chronic inflammatory stress, which show mild increased activation of the HPA axis with increased relative activity of AVP in the regulation of the pituitary-adrenal axis. These data do not support a role for hypocortisolism in MS once the disease is established.

Multiple sclerosis is associated with alterations in hypothalamic-pituitary-adrenal axis function. Michelson D, Stone L, Galliven E, Magiakou MA, Chrousos GP, Sternberg EM, Gold PW. J Clin Endocrinol Metab 1994 Sep; 79 (3), pp. 848–53.

Autoimmune: Myasthenia Gravis (MG)
Edrophonium (Tensilon)

Cellular/Molecular Mechanism of Action: Edrophonium exerts a direct inhibitory effect on cholinesterase activity somewhat analogous to organophosphate insecticides. As a result, the neurotransmitter acetylcholine is allowed to accumulate at the motor end plate. In concept, this will theoretically increase the probability of acetylcholine becoming bound to and continually stimulating the postsynaptic membrane receptor sites in MG patients that have to some degree been inactivated by the presence of bound IgG due to an aberrant (autoimmune) humoral response.

Diagnostic Application: Congenital and acquired MG.
Route of Administration and Dosage: Intravenous injection of 0.5 to 5.0 mg. The response is widely variable, which prevents recommendation of a specific dose regimen. If the capacity to perform physical activity is not restored, a higher dosage can be administered in a matter of a few minutes.
Considerations: Because the response is highly variable, signs of weakness in addition to over-stimulation of parasympathetic muscarinic receptor sites may develop such as salivation, miosis, vomiting, and diarrhea (cholinergic crisis).
Interpretation and Analysis: Correction of exercise intolerance conditions that last a duration of 2 to 3 minutes supports the diagnosis of MG.

Approach to generalized weakness and peripheral neuromuscular disease. LoVecchio F, Jacobson S. Emerg Med Clin North Am 1997 Aug; 15 (3), pp. 605–23

Autoimmune: Myasthenia Gravis (MG) *Edrophonium/Neostigmine/Pyridostigmine/ Vecuronium*

Cellular/Molecular Mechanism of Action: Edrophonium (acetylcholinesterase inhibitor that binds selectively to the active site of the enzyme). Alternatively neostigmine (cholinesterase inhibitor) and pyridostigmine (carbamate cholinesterase inhibitor: charged quaternary compound) contain carbamyl ester linkages that are directly hydrolyzed by acetylcholine esterase. Vecuronium (congener of pancuronium) is a bis-quaternary ammonium steroid that is 5 times more potent than d-tubocurarine as a neuromuscular blocking agent but inhibits plasma butyrylcholinesterase to a lesser degree than pancuronium so that less cardiovascular side effects are produced.
Application: Cases with MG are hypersensitive to non-depolarizing neuromuscular blocking drugs. Vecuronium can be applied in an ocular test for the detection of cases suffering from MG. Other tests include (i) Edrophonium chloride: 2 mg IV followed in 45 seconds by another dose of 8 mg if no improvement is observed. Excessive doses should be avoided in order to prevent weakness from generalized depolarization of motor end plates. (ii) Oral test: Neostigmine (7.5 mg); or pyridostigmine (30 mg); or ambenonium (2.5 mg). Signs for improvement in neuromuscular strength are monitored. In an hour, the dose is then increased 1.5-fold and repeated until a desired effect is achieved. Results can be confirmed with the edrophonium test. (iii) Intravenous test: Neostigmine (0.125 mg) or pyridostigmine (0.5 mg) administered at intervals of several minutes. Atropine (0.4–0.6) is given prior to the initiation of the test to prevent muscarinic side effects. The optimal oral dose is equivalent to 30-fold the intravenous dose that achieved the desired level of effect. (iv) Vecuronium and general anesthesia: 10 μg/kg intravenously under general anesthesia with sevoflurane (2.5%) and nitrous oxide (60%) in oxygen. Neuromuscular transmission measured as twitch tension of the adductor pollicis muscle with supramaximal stimulation can serve as a meaningful evaluation parameter. Following recording of baseline measurements, incremental doses of vecuronium (10 μg/kg IV) are administered sequentially until 90% blockade is exceeded. The degree of blockade and onset time after the initial 10 μg/kg dose of vecuronium are assessed, and the dose required to exceed 90% blockade recorded. In addition, effective doses of 50% and 95% for vecuronium are calculated from a single data point.
Considerations: A diagnosis can usually be obtained from history, presenting complaint, and physical examination, but its differentiation from neurasthenic, infectious, endocrine, neoplastic diseases, or degenerative neuromuscular disorders may be difficult. Provocative testing with an anticholinesterase pharmaceutical agent results in a drastic improvement in conditions of MG.

Although antibodies to the acetylcholine receptor (AChR) often are observed in MG patients, 10–30% of patients do not show an anti-AChR antibody.

In childhood cases of MG, the majority of cases (e.g., 92%, n = 25/27) have localized ocular myasthenia with a median onset of symptoms appreciated at 33 months of age. Approximately 24% of cases progress to generalized MG. A few (8%) may present with respiratory failure that requires ventilatory support with an onset of symptoms being appreciated at about 22 months. Thymectomy (n = 10/27 cases) is used as an option for therapeutic intervention where approximately 70% complete or 26% partial remissions rate can be expected when applied in combination with an immunosuppressant (azathioprine) and a cholinesterase inhibitor (pyridostigmine). The development of a myasthenic crisis is relatively infrequent when patients experience proper management and good follow-up monitoring.
Interpretation and Analysis: Agents should produce a relatively immediate (dramatic) improvement in clinical signs. Seronegative and seropostive MG patients are equally sensitive to vecuronium compared to unaffected negative reference control patients.

The effect of use of pyridostigmine and requirement of vecuronium in patients with myasthenia gravis. Tripathi M, Kaushik S, Dubey P. J Postgrad Med 2003 Oct–Dec; 49 (4), pp. 311–4; discussion 314–5.

Autoimmune: Myasthenia Gravis (MG) *Edrophonium/[Esophogeal Function Screening Test]*

Cellular/Molecular Mechanism of Action: Edrophonium is a short-acting acetylcholinesterase inhibitor.
Background Information: Myasthenia gravis is an autoimmune disease in which impairment of neuromuscular transmission results in a pathological fatigability of striated muscles. Dysphagia is a common symptom in MG. It is caused by a weakness in striated muscles of the pharynx and esophagus.
Application: Evaluate the role of esophageal scintigraphy in the assessment of esophogeal function in MG.
Dosage: Edrophonium chloride (EC; 10 mg).
Implementation: Evaluation of esophageal transit in conditions of MG using scintigraphy with a multiple swallow test protocol. Cases are studied twice: under baseline conditions, and immediately after pharmacological stimulation with edrophonium.

Human Model: Cases of clinically proven MG (n = 15; n = 6/15 oculopharyngeal manifestations; n = 9/15 generalized weakness; n = 10/15 history of dysphagia).
Interpretation and Analysis: Under baseline conditions all cases display impaired esophageal function (emptying [%]= 58 % ± 21; normal range > 85%). In 14/15 individuals esophageal transit improves after administration of EC (emptying [%]= 75% ± 18; $p < 0.01$), reaching the normal range in 6 patients. Some cases show no effects attributable to EC (e.g., n = 1/15). Esophageal transit is often compromised in MG. Functional abnormalities may also be present in patients without a history of dysphagia. Inhibition of cholinesterase positively affects striated muscles in the pharynx and upper esophagus, thus improving esophageal transit. Esophageal scintigraphy may be considered as a simple, non-invasive method for diagnosing impairment of esophageal function in MG and for monitoring the changes under pharmacological stimulation.

Assessment of esophageal function in patients with myasthenia gravis. Linke R, Witt TN, Tatsch K. J Neurol 2003 May; 250 (5), pp. 601–6.

Autoimmune: Myasthenia Gravis (MG)
Vecuronium

Cellular/Molecular Mechanism of Action: Vecuronium is an acetylcholinesterase inhibitor.
Background Information: Conditions of MG are hypersensitive to non-depolarizing neuromuscular blocking drugs. Although antibodies to the acetylcholine receptor (AChR) often are observed in MG patients, 10–30% of patients do not show an anti-AChR antibody. Little is known about differences in sensitivity to non-depolarizing neuromuscular blocking drugs between MG patients with and without anti-AChR antibody.
Application: Determination of the relative sensitivity of seronegative and seropositive MG patients to vecuronium.
Route of Administration: Vecuronium (intravenous).
Dosage: Incremental doses of vecuronium (10 μg/kg) during anesthesia with sevoflurane (2.5%) and nitrous oxide (60%) in oxygen.
Implementation: Measurement and monitoring of neuromuscular transmission can be achieved by assessing twitch tension of the adductor pollicis muscle with supramaximal stimulation. After baseline measurements, 10 μg/kg IV dose increments of vecuronium are administered sequentially until blockade exceeds 90%. The degree of blockade and onset time after the initial 10 μg/kg of vecuronium is assessed, and doses required to exceed 90% blockade recorded. In addition, effective doses of 50% and 95% for vecuronium are calculated from a single data point.
Interpretation and Analysis: Both types of MG patients show increased sensitivity to vecuronium compared with non-MG cases. Therefore, seronegative MG patients, seropositive MG patients, and non-MG patients are equally sensitive to vecuronium.

Vecuronium in the myasthenic patient. Hunter JM, Bell CF, Florence AM, Jones RS, Utting JE. Anaesthesia 1985 Sep; 40 (9), pp. 848–53.

Autoimmune: Rheumatoid Arthritis/Matrix Metalloprotease Protein 3 (MMP-3)
Corticosteroids

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit phospholipase A2 biochemical activity.
Physiological Mechanism of Action: Corticosteroids exert anti-inflammatory and immunosuppressive properties presumably due to their ability to generally suppress protein synthesis and stabilize cellular membrane structures.
Application: Delineation of potential relationships between rheumatoid arthritis, expression profiles for interleukins (IL), and metalloproteases (MMP); and corticosteroid production.
Implementation: Evaluate expression profiles for IL-1β, tumor necrosis alpha-alpha (TNF-α), IL-6, IL-4, IL-10, MMP-1, MMP-3, and MMP-13 in freshly isolated peripheral blood (PBMC) and synovial fluid mononuclear cells (SFMC) in early rheumatoid arthritis (never-treated [ENT-RA] vs non-acute, treated rheumatoid arthritis [NAT-RA]). Characterization of expression profiles entails the application of ELISA and quantitative and semi-quantitative RT-PCR/analyses.

Human Model: Cases suffering from early rheumatoid arthritis (n = 14 RA; n = 7/14 early RA < 1 year of evolution never treated with corticosteroids or disease-modifying antirheumatic drugs; and n = 7/14 non-acute RA > 2 years of evolution treated with disease-modifying antirheumatic drugs). Reference controls: A group of 14 healthy subjects matched for sex and age.

Interpretation and Analysis: Statistically significant differences in protein or transcript levels for the cytokines of interest cannot be appreciated between ENT-RA and NAT-RA case groups. The cytokine mRNA expression by freshly isolated PBMC and SFMC in both case types is IL-1β > TNF-α > IL-10 > IL-6, with no mRNA IL-4 expression. In contrast, cytokine serum levels in ENT-RA and NAT-RA patients exist in an inverse order as follows: IL-6 > IL-10, while IL-1β, TNF-α, and IL-4 are undetectable. MMP-3 mRNA expression by the PBMC of NAT-RA patients is statistically different to that in ENT-RA patients. Similar levels of mRNA expression of MMP-1, MMP-3, and MMP-13 by PBMC and SFMC in both RA groups can be appreciated. A close equilibrium between MMP and pro-/anti-inflammatory cytokine production is observed in ENT-RA and NAT-RA patients. This balance is apparently not influenced by the length of the disease. Highly sensitive methods such as quantitative RT-PCR and ELISA, and even studying freshly isolated MC, show sustained cytokine secretion at the local level (synovial fluid/SFMC) and scarce translation at the peripheral level (serum/PBMC). Expression of MMP mRNA needs to be further evaluated in order to know whether their peripheral expression reflects their local activity in RA patients.

Expression of interleukin-1 beta, tumor necrosis factor-alpha, interleukins-6, -10, and -4, and metalloproteases by freshly isolated mononuclear cells from early never-treated and non-acute treated rheumatoid arthritis patients. Vázquez-Del Mercado M, Delgado-Rizo V, Muñoz-Valle JF, Orozco-Alcalá J, Volk HD, Armendáriz-Borunda J. Clin Exp Rheumatol 1999 Sep–Oct; 17 (5), pp. 575–83.

Autoimmune: Rheumatoid Arthritis: Severe vs Mild-Moderate/Prediction of Disease Severity: G Allele (TT vs TG/GG Genotypes)/Tumor Necrosis Factor-Alpha (TNF-α) Receptor Type II (TNFRII): Exon 6 Polymorphism
Anti-TNF-α Response/Methotrexate

Application: Characterizing severe vs mild-moderate conditions of rheumatoid arthritis as a function of exon 6 TNFRII gene polymorphism. The G allele appears to have utility in predicting the degree of responsiveness to anti-TNF-α treatment while the GG genotype for the exon 6 TNFRII polymorphism may be useful in predicting a more aggressive form of rheumatoid arthritis.
Implementation: Characterization of exon 6 TNFRII gene polymorphism in cases of (i) mild-moderate synovitis classified as responders to methotrexate therapy (e.g., n = 97) for comparison with; (ii) "non-responder" cases receiving anti-TNF-α treatment due to severe and aggressive disease (e.g., n = 78); and (iii) cases with severe rheumatoid arthritis monitored for 6 months during anti-TNF-α therapy. Results are evaluated pertaining to response according to genotype and compared to matched age, sex, and ethnic reference controls (e.g., n = 84).
Interpretation and Analysis: A distinct trend exists toward increases in the frequency of the GG genotype in patients with severe rheumatoid arthritis (6.4%) compared to cases of mild-moderate disease (3.1%) and reference controls (1.2%). Evaluation of the response to anti-TNF-α therapy after 12 weeks of treatment reveals that 37.8% of the TT genotype passes from high to medium-low disease activity. Such observations are in contrast to the 10.7% of the TG/GG genotype that passes from high to medium-low disease activity (p = 0.03).

Collective evaluation of laboratory results therefore suggests that in cases of rheumatoid arthritis classified according to response to the conventional therapy and by disease severity, there is a discern-

able trend toward a higher prevalence of the GG genotype for the exon 6 TNFRII polymorphism in less responsive cases displaying a more aggressive form of disease. In addition, the G allele tends to promote a lower degree of response to anti-TNF-α treatments.

Tumor necrosis factor-alpha receptor II polymorphism in patients from southern Europe with mild-moderate and severe rheumatoid arthritis. Fabris M, Tolusso B, Di Poi E, Assaloni R, Sinigaglia L, Ferraccioli G. J Rheumatol 2002 Sep; 29 (9), pp. 1847–50.

Autoimmune: Systemic Lupus Erythematosis (SLE)/Monocyte Interleukin (IL)-10 and IL-12/ Lymphocyte (CD8+) Poststimulation Interferon-Gamma (IFN-γ) and Tumor Necrosis Factor-Alpha (TNF-α)
Monocyte Activation/Lymphocyte Activation/ Corticosteroids

Application: Detection and characterization of systemic lupus erythematosus (SLE).
Route of Administration: Immersion (*in vitro* tissue culture environment).
Implementation: Determination of the profiles for Th1-type and Th2-type cytokines produced by mononuclear cells in conditions of recent-onset SLE, prior to the initiation of treatment with corticosteroids. Such an objective can be achieved through radioimmunoassay for IL-4, IL-10, IL-12 p40, TNF-α, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF) released into the culture supernatants of various unstimulated and stimulated blood mononuclear cell populations.

Human Model: Cases of SLE (n = 10) assessed in comparison to matched healthy controls studied in parallel (n = 10).
Interpretation and Analysis: In early SLE, monocyte-enriched cells constitutively produce increased amounts of IL-10 and decreased amounts of IL-12 following stimulation. Lymphocyte-enriched cells in SLE produced decreased amounts of IFN-γ and TNF-α following stimulation. In "rested" cells, these defects are accentuated and a defect in IL-12 production has been suggested as an explanation. Depletion studies suggest that CD8+ cells are a major source of TNF-α and IFN-γ in controls, but not in SLE patients.

Increased IL-4 production or abnormalities in GM-CSF production cannot be appreciated. Therefore, in this context, even early in the course of SLE, monocyte production of IL-10 is increased and IL-12 production is decreased. Decreased production of Th1-type cytokines in SLE may be secondary to this imbalance between IL-10 and IL-12. A contributory role of dysfunctional CD8+ cells is suggested.

Decreased production of interleukin-12 and other Th1-type cytokines in patients with recent-onset systemic lupus erythematosus. Horwitz DA, Gray JD, Behrendsen SC, Kubin M, Rengaraju M, Ohtsuka K, Trinchieri G. Arthritis Rheum 1998 May; 41 (5), pp. 838–44.

Autoimmune Disease/Example: Multiple Sclerosis
Metaclopramide/Bromocriptine

Cellular/Molecular Mechanism of Action: Metaclopramide promotes the release/secretion of prolactin, which belongs to the growth and lactogenic family of hormones. Physiologically it has been found to promote profound immunomodulating properties. Alternatively, bromocriptine inhibits prolactin secretion.
Application: Metaclopramide does not appear to be an effective determinant.
Considerations: Mild hyperprolactinemia has been found to enhance several autoimmune diseases and increased PRL plasma levels have been described in experimental multiple sclerosis (MS) models and the PRL antagonist bromocriptine is able to suppress the disease. Various studies of PRL serum levels in MS have led to conflicting findings.
Interpretation and Analysis: No correlation appears to exist between baseline values and disease course or activity. Nevertheless in the regression analysis of stimulatory test results, 14% of the variance is attributable to disease activity. In conclusion PRL does not seem to be relevant as an activity marker in the whole MS population.

Immune Hypersensitivity
Praunsnitz-Kustner (PK) Test

Cellular/Molecular Mechanism of Action: Immunoglobulin (IgE) when it forms Ag/Ab complexes subsequently promotes mast cell degranulation.
Application: Detection of immune hypersensitivity conditions.
Implementation: Serum from a potentially immunohypersensitive individual is injected intradermally into a normal subject. After an incubation period of 24 to 48 hours, antigen is then injected intradermally at the same identical location.
Clinical Interpretation: Serum from hypersensitive individuals produces a marked wheal and flare response at the site of intradermal injection following intravenous administration of purified antigen. Serum from a non-hypersensitive individual would create the same response.

Immune Hypersensitivity: Allergies (Grass Pollen)
Recombinant Allergens for Kentucky Bluegrass Pollen

Background Information: Electrophoresis analysis (SDS-PAGE) of extracts from different strains of Kentucky bluegrass pollen (e.g., n = 2) reveals that there is considerable variability in extract allergen content. The significance of this finding is that such variability affects the quantitation of specific IgE antibodies by different immunoassay procedures.
Implementation: Assessment of concentrations (titers) of IgE antibodies in human sera specific for Kentucky bluegrass pollen in a more objective and consistent manner using recombinant grass pollen allergen (e.g., rKBG8.3) formulated at standardized concentrations.
Interpretation and Analysis: It is possible to design an enzyme-based immunoassay to quantify IgE antibodies specific for even 1 single allergen that may be used to discriminate sera of allergic individuals with respect to IgE specific for grass pollen in general. In this context, there is a positive correlation (r = .82) that exists between the binding of IgG to recombinant allergen and crude extracts of grass pollens. Therefore, a single recombinant allergen or a combination of a few major recombinant allergens can substitute for the crude extract for *in vitro* as well as *in vivo* diagnostic purposes.

Recombinant allergens and diagnosis of grass pollen allergy. Olsen E, Mohapatra SS. Ann Allergy 1994 Jun; 72 (6), pp. 499–506.

Immune Hypersensitivity: Anaphylaxis
Evans Blue Dye/Passive Cutaneous Anaphylaxis Test

Cellular/Molecular Mechanism of Action: Immunoglobulin (IgE) when it forms Ag/Ab complexes subsequently promotes mast cell degranulation..
Diagnostic Application: Detection of immune hypersensitivity conditions.

Implementation: Gradient dilutions of serum potentially containing IgE immunoglobulin are injected intradermally over a grid-like pattern. Purified antigen is then administered by intravenous injection. Simultaneous injection of Evans blue dye markedly increases the sensitivity of visually detecting a positive response. In this context, Evans blue dye "leaks" across capillary structures into the surrounding intracellular matrix due to the reaction of vascular capillary endothelium to histamine released from activated mast cell populations.
Interpretation and Analysis: A striking blue discoloration at the site of injection supports a diagnosis of a hypersensitivity reaction.

Immune Hypersensitivity: Asthma/Asthmatic Responses: Early vs Late/Chemotactic Properties Mediated by Mast Cell vs Mononuclear Cells/ Neutrophil Chemotactic Activity (NCA)
Lysine Aspirin Bronchoprovocation (L-ASA BPT)

Application: Differentiation between "early" and "dual" aspirin-sensitive asthma response based on the liberation of serum chemotactic properties by either mast cell or monocyte cell populations.
Route of Administration: Lysine aspirin (inhalation).
Considerations: Chemotactic activity of human neutrophils can be evaluated using a Boyden chamber apparatus. Histamine can be assayed using an automated fluorometric analyzer.
Implementation: Evaluation of pathogenic mechanisms involved in the early vs late asthmatic response as a function of serum NCA and histamine production following bronchoprovocation with lysine aspirin. Sera is collected before and 30 minutes and 240 minutes after L-ASA BPT.

Human Model: Cases of aspirin-sensitive asthma (n = 13 ASA; n = 7 early responders; n = 6 dual responders).
Interpretation and Analysis: Serum NCA increases significantly after 30 minutes ($p = 0.02$) and decreases significantly at 240 minutes ($p = 0.02$) in aspirin-sensitive asthma cases/early responders, while serum NCA in aspirin-sensitive asthma/dual responders increases significantly at 30 minutes ($p = 0.04$) and tends to increase further up to 240 minutes (not statistically significant). Neutrophil chemotactic activity at 240 minutes in aspirin-sensitive asthma/dual responders is significantly higher than baseline NCA ($p = 0.02$). Serum NCA values collected before and at 240 minutes are significantly higher in aspirin-sensitive asthma/dual responders than in aspirin-sensitive asthma/early responders ($p < 0.05$). There are no significant changes in serum histamine levels during lysine aspirin bronchoprovocation in either case group type.

NCA derived from mast cell may contribute to the development of early asthmatic responses induced by L-ASA inhalation. There may be possible involvement of NCA derived from mononuclear cells during late asthmatic response.
Instrumentation: Boyden chemotactic chamber and automated fluorometric analyzer (histamine assay).

Enhanced serum neutrophil chemotactic activity was noted in both early and late asthmatic responses during lysine-aspirin bronchoprovocation test in ASA-sensitive asthmatic patients. Kim SS, Park HS, Yoon HJ, Lee YM, Lee SK, Nahm DH. J Korean Med Sci 2003 Feb; 18 (1), pp. 42–7.

Immune Hypersensitivity: Asthma/Aspirin-Induced Bronchoconstriction
Lysine Acetylsalicylate (LASA)/Cromoglycate (Sodium)/ Nedocromil (Sodium)

Background Information: The protective activity of nedocromil sodium and of sodium cromoglycate against aspirin-induced asthma has rarely been investigated in controlled studies. Reports have described aspirin-induced platelet-mediated cytotoxic activity *in vitro* is inhibited after treatment *in vivo* with nedocromil but not with cromoglycate.
Application: Partial validation of bronchoconstriction induced by aspirin administration.
Route of Administration: Nedocromil sodium (inhalation), sodium cromoglycate (inhalation) or placebo.
Dosage: Nedocromil sodium (4 mg), cromoglycate (10 mg), or placebo.
Implementation: Delineation of the potential protective activity of nedocromil and cromoglycate against aspirin-induced bronchoconstriction. Three bronchial challenges with a single dose of LASA can be performed that are capable of causing decreases in FEV_1 of 25% or more in a preliminary dose-response tests 30 minutes after inhalation of nedocromil sodium, sodium cromoglycate, or placebo. FEV_1 and SRaw are recorded at intervals for 195 minutes.

Human Model: Cases of aspirin-induced asthma (n = 10).
Interpretation and Analysis: Following a placebo, LASA causes a maximal decrease in FEV_1 that is 42 ± 4% of baseline. After cromoglycate and nedocromil the maximal decrease in FEV_1 is reduced to 20 ± 3% and 18 ± 4%, respectively ($p < 0.01$ vs placebo for both treatments), without significant differences between the 2 treatments. Similar results can be observed for SRaw. Therefore, at recommended therapeutic doses, sodium cromoglycate and nedocromil sodium are equally effective in attenuating aspirin-induced bronchoconstriction and it is therefore unlikely that platelet activation participates in the pathogenesis of aspirin-induced asthma.

Attenuation of aspirin-induced bronchoconstriction by sodium cromoglycate and nedocromil sodium. Robuschi M, Gambaro G, Sestini P, Pieroni MG, Refini RM, Vaghi A, Bianco S. Am J Respir Crit Care Med 1997 Apr; 155 (4), pp. 1461–4.

Immune Hypersensitivity: Asthma (Allergic vs Non-Allergic)/Aspirin-Sensitive and Aspirin-Insensitive Asthma/Histamine Release (HR)/Sulfidoleukotriene Release (LTR)
Interleukin (IL)-3/Anti-IgE/C5a/Basophil Stimulation Test

Cellular/Molecular Mechanism of Action: The immunoglobulin fraction anti-IgE binds to and neutralizes the biological activity of IgE, which is an antibody isotype that binds to the surface membrane of basophils and is intimately involved in the initiation of allergic and anaphylactic immune hypersensitivity reponses following the formation of Ag/Ab complexes. The complement fraction C5a, among its many biological properties, is classified as an anaphylatoxin.
Physiological Mechanism of Action: The interleukin IL-3 appears to be necessary for the development/maturation of mast cell populations. The complement fraction C5a functions as an anaphylatoxin related to the initiation of anaphylactic immune hypersensitivity reactions.
Background Information: The differentiation between allergic and non-allergic asthma (NAA) is a common and important clinical challenge. Rare reports exist describing the *in vitro* diagnostic characteristics that distinguish between these 2 types of asthma.
Application: Differentiation between allergic and non-allergic conditions of asthma, but aspirin-sensitive asthma (ASA) cannot be distinguished from NAA without aspirin tolerance.
Implementation: Characterize and profile mediator release induced by anti-IgE and C5a exposure (basophil stimulation test) in different conditions of bronchial asthma. The *ex vivo* analysis proce-

dures involve the isolation of peripheral blood leucocytes (PBL) by dextran sedimentation. After priming with IL-3, peripheral blood leukocytes are stimulated with anti-IgE and C5a to facilitate the measurement of released HR and LTR into the supernatant. Additionally, purified leukocyte fractions can be evaluated to selectively determine the cellular source of mediator release.

Human Model: Cases of ASA (n = 10); NAA without aspirin tolerance (n = 12); allergic asthma (AA; n = 7); negative healthy reference controls (n = 9).

Interpretation and Analysis: Upon stimulation with anti-IgE, LTR is slightly, but not significantly, lower in ASA and NAA without aspirin tolerance compared to AA and controls. In contrast, C5a-triggered LTR is significantly higher in ASA (14.4 ± 12.88 pg/105 cells) and NAA (22.9 ± 22.61 pg/105 cells) than in AA (9.6 ± 3.29 pg/105 cells) and controls (7.5 ± 7.19 pg/105 cells) ($p < 0.05$). This difference between ASA and NAA vs AA and controls is even more pronounced when determining the quotient C5a-/anti-IgE-induced LTR ($p < 0.001$). At an optimal cutoff point of 1.0, calculated by relative operating characteristics (ROC) analysis, the positive predictive value for a donor to belong to ASA or NAA is 0.94. No significant differences can be detected in HR between conditions of asthma and healthy controls in either condition. Delineation of anti-IgE- and C5a-induced LTR from basophils allows differentiation between allergic and non-allergic asthmatic patients. The quotient C5a-/anti-IgE-induced LTR is diagnostically more significant than considering a single parameter. Aspirin-sensitive asthma cannot be distinguished from NAA.

Differential mediator release from basophils of allergic and non-allergic asthmatic patients after stimulation with anti-IgE and C5a. Abrahamsen O, Haas H, Schreiber J, Schlaak M. Clin Exp Allergy 2001 Mar; 31 (3), pp. 368–78.

Immune Hypersensitivity: Asthma/House Dust Mite (HDM)-Provoked Asthma/Aspirin-Insensitive Asthma (AIA)
Pranlukast/HDM Inhalation Provocation

Cellular/Molecular Mechanism of Action: Panlukast is a leukotriene (LT) receptor antagonist (LTRA).

Background Information: Leukotrienes are important in asthma, and LT modifiers modulate antigen-induced asthma. Overproduction of LT by suppression of cyclooxygenase activity is a relevant occurance in conditions of AIA.

Application: Possible differentiation between HDM-provoked asthma (LT overproduction and Ag/Ab reactions) and AIA (LT overproduction and 5-lipoxygenase shift in the arachidonic cascade).

Route of Administration: Aspirin oral provocation.

Implementation: Evaluation of HDM-sensitive asthmatic inpatients without AIA applying an HDM inhalation provocation test. In addition an aspirin oral provocation test can be employed to evaluate cases of asthma that are insensitive to aspirin administration. Tests are repeated using the same regimen after 7 days of treatment with an LTRA. The effects of an LTRA are assessed on changes in sputum LTC_4-LTD_4, eosinophil cationic protein (ECP), eosinophil count, urinary LTE_4/creatinine, 11-dehydrothromboxane B_2 (11-$dhTXB_2$/creatinine), serum LTC_4-LTD_4, ECP, and peripheral blood eosinophil count, during immediate asthmatic reaction (IAR) and late asthmatic reaction (LAR) in the HDM group and during IAR in AIA cases for each test, which are then compared.

Human Model: Cases of house dust mite sensitive asthma without AIA (n = 6 HDM group type); and AIA conditions (n = 7 AIA group type).

Interpretation and Analysis: In cases of house dust mite sensitive asthma without aspirin insensitivity, immediate (IAR) and late (LAR) asthmatic reactions can be observed. Sputum LTC_4-LTD_4 and urinary LTE_4/creatinine both increase significantly during IAR and LAR. Sputum eosinophil cationic protein (ECP) increases during IAR and further increases during LAR. Eosinophil count in the sputum does not increase during IAR but significantly increases during LAR. LT receptor antagonism (Pranlukast) suppresses declines in FEV_1 both during IAR and LAR (73.8% and 51.9%, respectively) and inhibits increases in sputum eosinophil count during LAR and sputum ECP during IAR and LAR. In cases of AIA, aspirin-induced IAR is associated with a fall in urinary 11-$dhTXB_2$/creatinine and increases in levels of sputum LTC_4-LTD_4 and ECP and urinary LTE_4/creatinine. LT receptor antagonism (Pranlukast) suppresses IAR and inhibits increases in the level of sputum ECP, but fails to change aspirin-induced LT production in the sputum and urine. The levels of sputum LTC_4-LTD_4 and urinary LTE_4/creatinine in the stable phase in the ASA group are significantly greater than those in the HDM group. Therefore, it appears that HDM-provoked asthma is associated with overproduction of LT with an antigen-antibody reaction, while AIA is associated with overproduction of LT with a shift to the 5-lipoxygenase series of the arachidonate cascade. Leukotriene receptor antagonist may be useful against both types of asthma through inhibition of LT activity and eosinophilic inflammation of the airways.

Effects of pranlukast on chemical mediators in induced sputum on provocation tests in atopic and aspirin-intolerant asthmatic patients. Obase Y, Shimoda T, Tomari SY, Mitsuta K, Kawano T, Matsuse H, Kohno S. Chest 2002 Jan; 121 (1), pp. 143–50.

Immune Hypersensitivity: Asthma (Aspirin-Induced)/Cysteinyl-Leukotriene Production: Peripheral Blood Leukocytes [Diagnostic Value Limited]
Lysine Acetylsalicylic Acid

Background Information: Aspirin-induced asthma (AIA) is a clinical syndrome related to cysteinyl leukotriene overproduction in airways. The confirmation of the diagnosis requires inconvenient provocation tests with acetylsalicylic acid (ASA).

Implementation: Evaluate the *in vitro* influence of ASA stimulation of isolated peripheral blood leukocytes on measurements for the release of cysteinyl leukotrienes (cys-LTs) as a potential diagnostic molecular marker for AIA. Potential validation of this theory can be achieved through the use of a cellular allergen stimulation test (CAST) adapted for the measurement of leukotriene release from isolated leucocytes. Isolated cell preparations are stimulated with (i) Lys-ASA; (ii) formyl-Met-Leu-Phe (*f*MLP); or (iii) both *f*MLP and Lys-ASA, in a buffer containing interleukin (IL)-3 cytokine. Results are then compared with human leukemia cell line (Hl-60) response to Lys-ASA. Cysteinyl leukotrienes can be measured in cell supernatant fluids by ELISA.

Human Model: Cases of aspirin-tolerant (n = 32) and aspirin-intolerant (n = 26) asthmatics.

Interpretation and Analysis: Acetylsalicylic acid has a rather weak stimulatory effect on cys-LTs released in conditions of both aspirin-tolerant and aspirin-intolerant asthma. In contrast to some related reports, some studies have detected no significant difference between cys-LTs released by leucocytes from AIA and ATA or those released by differentiated Hl-60 cells. Measurement of cys-LT release by peripheral blood leucocytes pretreated with aspirin has no value for diagnosis of AIA.

A moderate and unspecific release of cysteinyl leukotrienes by aspirin from peripheral blood leucocytes precludes its value for aspirin sensitivity testing in asthma. Pierzchalska M, Mastalerz L, Sanak M, Zazula M, Szczeklik A. Clin Exp Allergy 2000 Dec; 30 (12), pp. 1785–91.

Immune Hypersensitivity: Asthma (Grain Dust [GD])/Mast Cells: Tryptase Expression/Neutrophils: Elastase Expression/Interleukin (IL)-8 Expression
GD Bronchoprovocation Test/Bronchial Mucosa Biopsy

Background Information: The immunopathological mechanism for occupational asthma induced by GD remains to be clarified. There have been a few reports that have suggested the involvement of neutrophils in the induction of bronchoconstriction after inhalation of GD.
Implementation: Evaluation of the phenotype of leukocytes that infiltrate the bronchial mucosa in conditions of GD-induced asthma. Bronchial biopsy specimens are obtained by fiber-optic bronchoscopy in GD-induced asthmatics. Bronchial biopsy specimens are examined by immunohistochemistry analyses using a panel of monoclonal antibodies to tryptase-containing mast cell (AA1), activated eosinophil (EG2), pan T-lymphocyte (CD3), and neutrophil elastase (NE). Sputum is then collected before and after initiation of the GD-bronchoprovocation test. The IL-8 level in the sputum is also measured using ELISA techniques.

Human Model: Cases of GD-induced asthma (n = 6); and house dust mite sensitivity (n = 6).
Interpretation and Analysis: There is a significant increase in the number of tryptase-containing mast cell (AA1+) and neutrophil elastase positive (NE+) cells in bronchial mucosa of GD-induced asthma, compared with those of allergic asthma ($p = 0.01$, $p = 0.01$, respectively). No significant differences can be observed in the number of EG2+ and CD3+ cells ($p = 0.13$, $p = 0.15$, respectively). IL-8 is abundant in the sputum of all GD-induced asthma patients and significantly increased after the bronchial challenges compared with baseline values ($p = 0.03$). Such findings support the perspective that neutrophil recruitment together with mast cells may contribute to the bronchoconstriction induced by GD antigen. A possible involvement of IL-8 in such processes has been proposed.
Instrumentation: Fiber-optic bronchoscope.

Neutrophil infiltration and release of IL-8 in airway mucosa from subjects with grain dust-induced occupational asthma. Park HS, Jung KS, Hwang SC, Nahm DH, Yim HE. Clin Exp Allergy 1998 Jun; 28 (6), pp. 724–30.

Immune Hypersensitivity: Asthma/Asthma: Predicted Absence
Skin-Prick Test (SPT)/Methacholine

Cellular/Molecular Mechanism of Action: The SPT employs a battery of foreign environmental substances that can function as immunogens. The biological preparations applied in the SPT are recognized by the immune system and if they are perceived as allergens, activate various immune and inflammatory pathways (e.g., antigen recognition by IgE and Ag:IgE complexes binding to Fc receptors expressed on the exterior surface membrane of mast cell populations leading to their activation and subsequent release of inflammatory mediators like histamine).
Background Information: None of the existing tests for the diagnosis of asthma are considered to be definitive. Certain circumstances require prompt diagnosis, and a test able to predict the absence of asthma would be very useful.
Application: The SPT may be valuable in predicting the probability of asthma in young adults.
Dosage: Methacholine administered at an exposure level capable of causing a 20% fall in FEV_1 (PC^{20}) at < 4 mg/mL while utilizing < 8 mg/mL as diagnostic cutoff values for asthma in the methacholine challenge test (MCT).
Implementation: Evaluation of asthmatic conditions utilizing (i) SPT introduction of a battery of common aeroallergens; and (ii) methacholine challenge test (MCT). The sensitivity, specificity, positive predictive value, and negative predictive values (NPV) of the SPT are calculated using provocative concentrations of methacholine. The Bayes' formula can be used to determine posttest probabilities of having asthma, both for positive and negative SPT results.

Human Model: Cases suffering from asthma including 3 groups of subjects aged 18–24 years: Group A, asthmatic patients (n = 175); Group B, control subjects (n = 100); and Group C, subjects with suspected asthma (n = 150) with normal spirometry findings and a negative exercise challenge test result.
Interpretation and Analysis: A positive SPT result to at least 1 allergen can be detected in approximately 95.5%, 54%, and 69% of cases classified as asthmatics, reference control subjects, and suspected asthmatics, respectively. Sensitivity, specificity, and NPV of the SPT are 90.7%, 52.0%, and 84.8%, respectively, with a cutoff value of $PC^{20} < 8$ mg/mL. The lower cutoff, $PC^{20} < 4$ mg/mL, increases the sensitivity and NPV to 98.2% and 97.8%, respectively. A negative SPT result decreases the probability of having asthma by 10-fold to 20-fold in subjects that have a low to moderate pretest probability. Incorporating an SPT into the workup of subjects with suspected asthma can reduce the cost of this process significantly. The SPT may be used as a simple, fast, safe, inexpensive, and reliable method to predict the absence of asthma in young adults.

Value of a negative aeroallergen skin-prick test result in the diagnosis of asthma in young adults: Correlative study with methacholine challenge testing. Graif Y, Yigla M, Tov N, Kramer MR. Chest 2002 Sep; 122 (3), pp. 821–5.

Immune Hypersensitivity: Asthma/Asthma: Mild to Moderate/Hyperresponsive Airway/Cellular Airway Infiltration
Methacholine/Agonists (B_2)/[Corticosteroids]

Cellular/Molecular Mechanism of Action: Methacholine recognize, binds to, and activates parasympathetic/cholinergic receptor sites.
Physiological Mechanism of Action: Methacholine promotes parasympathomimetic-mediated bronchoconstriction.
Background Information: Current guidelines on the management of asthma advocate the use of anti-inflammatory treatment in all but mild disease. They define disease control in terms of clinical criteria such as lung function and symptoms. However, the relationship between the clinical control of the disease and inflammation of the airways is not clear.
Application: The number of infiltrating leukocytes such as mast cells, (activated) eosinophils, CD8+, and CD45RO+ cells in bronchial biopsy specimens in mild to moderate conditions of asthma appears to correspond to the observation of airway hyperresponsiveness to methacholine.
Implementation: Delineate correlations between airway inflammation and measures of clinical control and bronchial hyperresponsiveness (methacholine challenge test) in asthmatic conditions during simultaneous steroid inhalation. Biopsy specimens are taken by fiber-optic bronchoscopy from the carina of the right lower and middle lobes and from the main carina. Immunohistochemical staining is performed on tissue sections with monoclonal antibodies against eosinophil cationic protein (EG1, EG2), mast cell tryptase (AA1), CD45, CD22, CD3, CD4, CD8, CD25, and CD45RO. The number of positively stained cells in the lamina propria is counted twice by using an interactive display system.

Human Model: Cases of mild to moderate asthma (n = 26 atopic adults; baseline $FEV_1 \geq 50\%$ predicted, concentration of histamine causing a 20% fall in FEV_1 [PC20] 0.02–7.6 mg/ml) on regular treatment with inhaled steroids. Histories and bronchoscopic examinations are utilized to determine use of adrenergic agonists (B_2), peak flow variability, and symptom scores.

Investigation Design: Cross-sectional study.

Interpretation and Analysis: No difference exists in cell numbers in biopsy specimens collected from the carina of the right lower and middle lobes and from the main carina. The PC20 for methacholine is inversely related to the average number of total leucocytes, EG1+, and EG2+ cells, mast cells, CD8+, and CD45RO+ cells in the lamina propria. These relationships are usually similar for each of the biopsy sites. Symptom scores, β_2 agonist usage, FEV_1, and peak flow variability do not appear to consistently correlate with tissue biopsy cell counts. Therefore, infiltration of inflammatory cells in the lamina propria of the airways seems to persist in asthmatic outpatients despite regular treatment with inhaled steroids. The number of infiltrating leucocytes such as mast cells, (activated) eosinophils, CD8+, and CD45RO+ cells in bronchial biopsy specimens from these patients appears to be reflected by airway hyperresponsiveness to methacholine, but not by symptoms or lung function. These findings may have implications for the adjustment of anti-inflammatory treatment of patients with asthma.

Instrumentation: Cryostat histology sectioning unit.

Relationship between the inflammatory infiltrate in bronchial biopsy specimens and clinical severity of asthma in patients treated with inhaled steroids. Sont JK, Han J, van Krieken JM, Evertse CE, Hooijer R, Willems LN, Sterk PJ. Thorax 1996 May; 51 (5), pp. 496–502.

Immune Hypersensitivity: Asthma/Airway Reactivity
Methacholine/Corticosteroids/Nitric Oxide (Exhaled)

Cellular/Molecular Mechanism of Action: Methacholine is a parasympathomimetic agent that recognizes, binds to and activates cholinergic receptor complexes. Corticosteroids inhibit phospholipase A2 biochemical activity in a manner that prevents or severely inhibits the subsequent production of prostaglandin species.

Physiological Mechanism of Action: Methacholine can promote bronchoconstriction of the major airways. Salbutamol promotes bronchodilation. Corticosteroids can exert an anti-inflammatory and immunosuppressive response that is in part due to their ability to promote inhibition of protein synthesis and to stabilize biological membrane structures.

Background Information: Bronchial reactivity and exhaled nitric oxide (eNO) are not often used to monitor the control and severity of asthma in clinical practice.

Application: Airway reactivity to methacholine corresponds to alterations in exhaled nitric oxide (eNO) which is also related to conditions of atopy.

Implementation: Evaluation of the relationship between asthma and different physiologic measures (pulmonary function, nonspecific bronchial reactivity, and eNO).

Human Model: Cases of asthma in various stages of severity (n = 392; cross-sectional, hospital-based study design).

Interpretation and Analysis: Inhalation of corticosteroids does not influence eNO levels. However, the percentage of predicted FEV_1 and the provocative dose of methacholine causing a 20% decrease in FEV_1 are significantly lower in inhaled corticosteroids (ICS) case groups compared with cases not receiving inhaled corticosteroids (NICS mean, 83.2%, 95% confidence interval [CI] 80.4–86.0%; vs mean 94.1%, 95% CI 91.1–97.1%, p = 0.001; and geometric mean 0.32 mg, 95% CI 0.23–0.45 mg; vs geometric mean 0.58 mg, 95% CI 0.42–0.81 mg, p = .01, respectively). In conditions with severe bronchial hyperresponsiveness, there is a lower percentage predicted FEV_1 value ($p < 0.001$) and levels of eNO significantly increase with increasing bronchial hyperresponsiveness ($p < 0.001$). There is no relationship between the percentage of predicted FEV_1 and eNO. Conditions of atopy have a significantly higher eNO levels than do nonatopic patients (geometric mean 11.21 ppb, 95% CI 10.07–12.49 ppb; vs geometric mean 7.76 ppb, 95% CI 6.11–9.85 ppb, p = 0.006, respectively). Therefore, values for eNO are not related to the degree of airway obstruction but are related to airway reactivity and atopic status independent of inhaled corticosteroid use. Higher values of eNO are seen with increased airway reactivity.

Relationship among pulmonary function, bronchial reactivity, and exhaled nitric oxide in a large group of asthmatic patients. Langley SJ, Goldthorpe S, Custovic A, Woodcock A. Ann Allergy Asthma Immunol 2003 Oct; 91 (4), pp. 398–404.

Immune Hypersensitivity: Allergic Rhinitis (Seasonal)/Pharmaceutical Efficacy Evaluation/IL-4
Allergen Provocation/Corticosteroids

Cellular/Molecular Mechanism of Action: Allergens stimulate the immune system in a manner that creates a hypersensitivity response.

Application: Detection and characterization of seasonal allergic rhinitis type hyperimmune reactions. Measurement or detection of IL-4 can therefore theoretically be applied as an indicator of disease or a molecular marker for validating pharmaceutical efficacy.

Implementation: Evaluation of conditions of seasonal allergic as a function of cytokine expression analyzed by reverse-transcriptase polymerase chain reaction (RT-PCR). The time-course study during winter includes repeated local allergen provocation test challenges with subsequent nasal biopsies as well as biopsies taken during pollen season.

Human Model: Cases of seasonal allergic rhinitis (n = 17; n = 10 healthy controls).

Interpretation and Analysis: The RT-PCR for CD44 yields positive bands in the vast majority of affected cases (e.g., n = 65/71 cases), in which mRNA sequences for IL-2, IL-4, and IL-5 are then applied for detection by PCR analysis (semi-nested). IL-4 mRNA is almost exclusively expressed by allergic patients. During provocation a significant increase in IL-4 can be detected compared to reference controls (p = 0.043). Similarly, during the natural pollen season, IL-4 mRNA expression is significantly higher in cases not using nasal corticosteroids compared with those who do (p = 0.011). No differences in IL-2 or IL-5 can be appreciated in these same case group types. Such findings, together with the observations of T-cell activation (e.g., phenotype switch toward T-helper 2 (Th2) cells; accumulation (homing) of these T cells in the nasal mucosa) indicate that T cells constitute the main source for IL-4 in the nasal mucosa. Therefore, allergic patients have an increased synthesis of IL-4 when provoked with the allergen, and during natural pollen season this synthesis can be downregulated by corticosteroids. Furthermore, previous investigations illustrate the versatility of molecular biology in surgical pathology and that even low-copy-number cytokine mRNA can be examined in routinely snap-frozen surgical specimens.

Nasal messenger RNA expression of interleukins 2, 4, and 5 in patients with allergic rhinitis. Karlsson MG, Davidsson A, Viale G, Graziani D, Hellquist HB. Diagn Mol Pathol 1995 Jun; 4 (2), pp. 85–92.

Immune Hypersensitivity: Allergen Immune Response/Late Induction (Nasal Mucosa)/ Grass/ Pollen Hypersensitivity Immune Responses/Efficacy Evaluation of Anti-Inflammatory/ Immunosuppresive Agents
Allergen Challenge Test/Fluticasone Proprionate

Background Information: Allergen-induced late nasal responses are associated with recruitment and activation of T lymphocytes and eosinophils and preferential mRNA expression for T-helper Type 2 (Th2) cytokines.
Application: Fluticasone proprionate can be applied as a molecular probe for delineating endogenous inflammatory mediator profiles in conditions of immune hyperreactivity responses and inflammatory reactions in addition to evaluation of the efficacy of immunosuppressive and anti-inflammatory reagents.
Implementation: Detection of allergens responsible for inducing allergic reactions and evaluating the efficacy of potential therapeutic agents (e.g., anti-inflammatory agents and corticosteroids). An example of the use of this investigative strategy involves the application of an allergen challenge to evaluate the efficacy of topical corticosteroids (fluticasone propionate) and their ability to inhibit late responses by suppressing the cellular expression of Th2 type cytokine mRNA sequences. Nasal biopsies are taken at baseline and repeated 24 hr after local nasal allergen provocation following 6 weeks of treatment (e.g., fluticasone propionate 200 μg or placebo nasal spray twice daily).

Human Model: Cases of grass pollen sensitivity (n = 48 adults) analyzed in a randomized double blind placebo-controlled trial.
Interpretation and Analysis: Baseline mRNA expression for interleukin (IL)-4 ($p = 0.01$) and IL-5 ($p = 0.002$) is higher in cases of grass pollen sensitivity. Topical corticosteroid treatment significantly inhibits immediate nasal symptoms, with almost complete inhibition of the late response following allergen challenge. This is associated with a marked decrease in the allergen-induced increases in cells expressing mRNA for IL-4 ($p = 0.002$) but not for IL-5. Inhibition of the late response is also accompanied by decreases in CD25+ cells (presumed T lymphocytes and eosinophils). A significant correlation exists between decreases in IL-4 mRNA+ cells, and in eosinophils after treatment ($r = 0.46$, $p < 0.05$). Therefore, prolonged treatment with topical corticosteroid inhibits allergen-induced early and late nasal responses and the associated tissue eosinophilia, and that, at least in part, may result from inhibition of cells expressing IL-4 mRNA sequences.

Topical glucocorticosteroid (fluticasone propionate) inhibits cells expressing cytokine mRNA for interleukin-4 in the nasal mucosa in allergen-induced rhinitis. Masuyama K, Jacobson MR, Rak S, Meng Q, Sudderick RM, Kay AB, Lowhagen O, Hamid Q, Durham SR. Immunology 1994 Jun; 82 (2), pp. 192–9.

Immune Hypersensitivity: Ctenocephalides Felis
Ctenocephalides Felis Salivary Extract/Protein/S (MW 40kDa and MW 8-12 kDa)

Cellular/Molecular Mechanism of Action: Hypersensitivity immunogen.
Background Information: An 18 kDa protein isolated from saliva of the cat flea, *Ctenocephalides felis*, elicits a positive intradermal skin test (IDST) in 100 and 80% of experimental and clinical flea allergic dogs, respectively. The protein, named Cte f 1, is the 1st novel major allergen described for canine flea allergy. The relative ability of rCte f 1 to bind IgE in the serum of flea allergic animals, produced in these 3 expression systems, matches that of the native allergen. Competition ELISA techniques demonstrate that approximately 90% of the specific IgE binding to native Cte f 1 can be blocked by the different forms of rCte f 1.
Application: Detection of immune hypersensitivity reactions to *Ctenocephalides felis* (saliva).
Considerations: The cat flea, *Ctenocephalides felis*, is the major initiator of flea-bite hypersensitivity in dogs. Previous analyses of whole extracts of the flea and flea salivary secretions have failed to identify the allergens responsible.

These findings suggest that protein with apparent MW 40k and MW 8k-12k are important in flea bite hypersensitivity. This work also supports a previous finding that mice that had been exposed to flea bites had antibodies to proteins with approximately MW 40k that can be detected in salivary secretions of fleas.
Route of Administration: Intradermal.
Dosage: Harvest by desection of approximately > 2,000 salivary glands from adult female fleas. Extracts are produced in buffered saline containing protease inhibitors and fractionation of the extract can be performed using gel permeation HPLC.
Implementation: Evaluation of the allergenicity of components contained within individual salivary gland extracts tested by intradermal injection. Each sample (aliquots) represents a fraction of whole salivary gland extract separated as a column eluate. Histamine (intradermal) can function as a positive reference control. Negative control injections consist of eluate from the column collected prior to fractions containing any protein.

Animal Model: Canine
Interpretation and Analysis: Canine subjects can be classified as hypersensitive to fleas (flea-feeding positive, FF+) or insensitive (flea-feeding negative, FF−) using a provocative test with live fleas. The skin of FF− dogs either does not respond or has a minimal response (a bleb approximately 2 mm larger than the injection blebs at the negative control injection sites) to all fractions and to the whole extract. Histamine control injections consistently produce positive responses (defined as wheals 5 mm greater than the blebs at the negative control injection sites) in all dogs. The skin of some FF+ dogs (e.g., n = 3/9) reacts positively to injection of fractions containing proteins with apparent MW 40k. Other FF+ dogs may react positively to fractions containing proteins with apparent MW 8-12k (e.g., n = 5/9). On a less frequent basis, dogs may respond with very large, red wheals to injection of both the approximately MW 40k and MW8-12k fractions (e.g., n = 1/9).

Identification, cloning, and characterization of a major cat flea salivary allergen (Cte f 1). McDermott MJ, Weber E, Hunter S, Stedman KE, Best E, Frank GR, Wang R, Escudero J, Kuner J, McCall C. Mol Immunol 2000 May; 37 (7), pp. 361–75.

Immune Hypersensitivity: Eczema (Atopic)/Efficacy Prediction of Therapeutic Intervention
Aeroallergen Challenge/Atopy Patch Test

Background Information: Pharmacologic studies in atopic eczema (AE) are difficult to standardize. Patients with AE differ in the stage of their skin disease (acute, subacute, chronic).
Application: Aeroallergen challenge (atopy patch test) can be applied to evaluate the effect of topical anti-inflammatory agents (topical glucocorticoids; tar) on allergic inflammatory reactions in conditions of AE.
Route of Administration: Aeroallergen challenge (atopy patch test: topical/intradermal injection).

Implementation: Evaluation of non-lesional skin regions on dorsal back region of cases suspected of being affected by AE. Segments of skin are treated for approximately 3 weeks at 3 different sites with triamcin-olonacetonide (1%) in cetamacrogol ointment (GCSs), pix liquida (10%) in cetamacrogol ointment (tar), and cetamacrogol ointment (vehicle), respectively. Atopy patch tests (APT) are then performed, and biopsy specimens collected from each test site (time = 0 and 24 hours) for immunohistochemical analysis.

Human Model: Cases atopic eczema (n = 6 AE).

Interpretation and Analysis: Treatment with both GCSs and tar reduces the macroscopic outcome of the atopy patch test (APT) reactions. Furthermore, both treatment modalities have an almost equal inhibiting effect on the influx of T cells, eosinophils, and CD1+, RFD1$^+$, IFN-γ^+, and IL-4$^+$ cells, as well as on the percentage of vessels expressing the adhesion molecules vascular cell adhesion molecule 1 (VCAM-1) and E-selectin in response to epicutaneous aeroallergen challenge. Although both treatments significantly reduce the various cellular constituents of allergic inflammation, all cell types remain present. In this context, aeroallergen challenge (e.g., atopy patch test) can be used to evaluate the effect of topical anti-inflammatory treatments on allergic inflammation in patients with AE.

Modulation of the atopy patch test reaction by topical corticosteroids and tar. Langeveld-Wildschut EG, Riedl H, Thepen T, Bihari IC, Bruijnzeel PL, Bruijnzeel-Koomen CA. J Allergy Clin Immunol 2000 Oct; 106 (4), pp. 737–43.

Immune Hypersensitivity: Fire Ant Venom
Fire Ant Whole-Body Extract (WBE)

Cellular/Molecular Mechanism of Action: Antigens recognized by humoral immunoglobulin produced as a consequence of previous host exposure resulting in complement activation following antigen/antibody complex formation and release of histamine.

Application: Detection of patients that have developed immune hypersensitivity to fire ant venom.

Route of Administration: Intradermal.

Dosage: Fire ant whole-body extract prepared at a concentration of $1{:}5 \times 10^3$, v/v.

Considerations: Evaluation of cases with a history of immediate hypersensitivity to the sting of the imported fire ant based on a comparison between fire ant whole-body extract (WBE) preparations and fire ant venom (IFAV).

Animal Model: Cases with fire ant hypersensitivity (n = 34).

Interpretation and Analysis: Ninety-one percent (31/34) of skin tests in conditions of hypersensitivity using IFAV at a maximal concentration of $1{:}5 \times 10^3$, v/v, demonstrate a wheal response equal to or greater than a histamine control. Fifty-three percent (18/34) of the same case group skin test positive to a WBE preparation. When the criteria for a positive skin test are relaxed, 82% of the hypersensitive group can be identified with the IFAWBE. A comparison of skin test results in sensitive patients reveals variability in the sensitivity of some WBE preparations. Leukocyte histamine release demonstrates a dose-response release of histamine with both IFAV and SIWBEa preparations. Specific venom antisera produced in rabbits can identify a precipitin line of common identity in a gel-diffusion system containing IFAWBE and IFAV. Such findings can be verified by the competitive inhibition of IFAWBE with IFAV in a solid-phase radioimmunoassay system. In summary, fire ant WBEs contain venom constituents and are effective diagnostic agents in up to 82% of patients with hypersensitivity to the sting of the imported fire ant. Marked variability in the responsiveness of sensitive patients to different WBE preparations mandates standardization of these diagnostic preparations.

In vivo and *in vitro* comparison of fire ant venom and fire ant whole-body extract. Strom GB Jr, Boswell RN, Jacobs RL. J Allergy Clin Immunol 1983 Jul; 72 (1), pp. 46–53.

Immune Hypersensitivity: Pharmaceutical/Example: Beta-Lactam Antibiotics
Molecular Determinants Identification

Cellular/Molecular Mechanism of Action: Molecular components of beta-lactam antibiotics that are recognized by (form complexes with) IgE antibodies.

Background Information: Allergies to antibiotics, mainly the beta-lactam antibiotics (penicillins and cephalosporins), are a common, costly, and potentially dangerous clinical problem encountered in everyday practice. Progress has been made in identifying the spectra of allergenic determinants recognized by IgE antibodies in the sera of subjects sensitized to penicillins and cephalosporins, and this is aiding the development of an appropriate battery of drug conjugates for use as diagnostic agents.

Application: Immunochemical identification of allergenic structures in patients that have developed Type I hypersensitivity reactions to penicillins and cephalosporins.

Considerations: Case sensitivity responses to the beta-lactam antibiotics are frequently heterogeneous, and this factor must be taken into account for any diagnostic strategy or future therapy with a penicillin or cephalosporin. Immunoscreening procedures of this nature have been developed most extensively for this class of pharmaceutical agents.

Interpretation and Analysis: Detection of IgE complex formation with molecular components of penicillins and cephalosporins is highly suggestive of the development of a Type I hypersensitivity response to these antibiotic agents.

Immune Hypersensitivity: Pharmaceutical (Erythema Multiforme)
Spironolactone/Immune Desensitization

Cellular/Molecular Mechanism of Action: Immune desensitization.

Application: Desensitization to pharmaceuticals precipitating conditions of erythema multiforme.

Dosage: Spirolactone—using an escalating dosage scheme from 1 mg to 400 mg administered over a 14-day period.

Considerations: In situations where salt/water restriction and other diuretics are ineffective, readministration of spironolactone is sometimes considered appropriate.

Implementation: In the absence of *in vitro* or *in vivo* diagnostic tests for drug allergic responses to spironolactone, it has been reported that serial increases in dose (1 mg to 400 mg administered over a 14 day period) are tolerated uneventfully. Occationally, a mild maculopapular rash appears approximately a month later but resolves despite continuation of spironolactone administration for periods of 20 months or more without developing signs of drug hypersensitivity.
Interpretation and Analysis: Although proven drug hypersensitivity attributable to spironolactone is very infrequent, when allergic manifestations do occur in situations that may require readministration of spironolactone, a suggested protocol for test-dosing should be be considered in order to achieve a successful outcome.

Readministration of spironolactone in the spironolactone-intolerant patient. Greenberger PA, Lazar HP. N Engl Reg Allergy Proc 1986 Jul–Aug; 7 (4), pp. 343–52.

Immune Hypersensitivity (Severe): Bee-Sting Venom
Whole Bee Extract

Cellular/Molecular Mechanism of Action: Antigenic preparations perceived by the immune system as allergens/immunogens.
Application: Stimulation of the immune response for the purpose of surveying for hypersensitivity responses in suspect patients displaying both systemic and localized signs.
Route of Administration: Intradermal skin testing and RAST (Hymenoptera, whole-body extracts of sweet bees, honey bees).
Considerations: Hypersensitivity reactions to sweet-bee stings are distinct and not associated with reactions to other stinging insects. Somewhat infrequently RAST reactions will be observed with whole-body extract of sweat bee. Reliable antigen that is commercially available for diagnosing or treating such conditions is sometimes difficult to find, but sweat bee venom or other venom antigens might be beneficial in patient management.
Interpretation and Analysis: Skin testing and RAST with venom of other Hymenoptera and whole-body extract of sweet bees often reveal negative reactions to many other insect antigens, while less than half of patients will show sensitivity to honey bees.

Whole-body extract of sweat bee causes some irritant reaction when skin testing controls are used for a comparison and it is not a reliable diagnostic agent even though patients are more reactive than controls.

Allergy to honeybee body components: Distinction from bee venom sensitivity. Reisman RE, Hale R, Wypych JI. J Allergy Clin Immunol 1983 Jan; 71 (1 Pt 1), pp. 18–20.

Immune Hypersensitivity and Inflammatory Responses/Bronchoalveolar Lavage Fluid Cell Populations/Endogenous Inflammatory Mediators: Interleukin (IL)-2, IL-4, IL-5, IL-6, IL-10, Interferon-Gamma (IFN-γ), iNOS
Ovalbumin/Aminophylline

Cellular/Molecular Mechanism of Action: Ovalbumin is the avian equivalent to mammalian serum albumin. As a foreign protein, it can function as a potent immunogen/allergen. Aminophylline inhibits guanyl cyclase in a manner that directly inhibits cGMP production and indirectly increases cAMP, thereby promoting bronchial smooth muscle relaxation.
Background Information: Evidence has shown that aminophylline has bronchoprotective, anti-inflammatory, and immunomodulatory effects.
Application: Characterization of immune hypersensitivity respones and intense inflammatory reactions.
Route of Administration: Aminophylline (intraperitoneal).
Dosage: Aminophylline (Group 1 = 25 mg/kg; Group 2 = 5 mg/kg).
Implementation: Evaluate the effect of different doses of aminophylline on the late-phase reaction, bronchial hyperresponsiveness (BHR), and T cell-related cytokine mRNA expression induced by ovalbumin (OA) sensitization.

In this manner, aminophylline can be evaluated at different concentrations/doses to determine its influence on late-phase reactions, BHR, T-cell related cytokine mRNA expression (induced by ovalbumin sensitization), and respiratory function. Pulmonary function tests are used to assess respiratory function and are performed at baseline and after the administration of varying doses of acetylcholine. Thereafter, bronchoalveolar lavage is performed along with histiological analysis of the lungs. Total RNA is extracted from lung tissue and reverse transcriptase-polymerase chain reaction performed using primers for IL-2, IL-4, IL-5, IL-6, IL-10, IFN-γ, inducible nitric oxide synthase (iNOS), and beta-actin.

Animal Model: Rat (n = 40 Brown Norway strain divided into 4 groups. Groups I, II, and III sensitized and subsequently provoked with OA). Group I (aminophylline at 25 mg/kg); Group II (aminophylline at 5 mg/kg); Group III (intraperitoneal normal saline); Group IV (enhaled aerosol saline control).
Interpretation and Analysis: Group III have worse pulmonary function tests, more severe BHR, and more severe lung inflammation, higher IL-4 and IL-10 cytokine levels in bronchoalveolar lavage fluid, and higher IL-4, IL-5, IL-6, IL-10, TNF-α, and inducible nitric oxide synthase (iNOS) mRNA expression than the other 3 groups. Expression of IL-2 and IFN-γ is significantly reduced in Group III. Aminophyllin at both low and high doses is effective in preventing late-phase bronchoconstriction, BHR, and an inflammatory response. Aminopylline decreases T helper cell 2-related cytokine mRNA expression but increases T helper cell 1-related cytokines mRNA expression.

Pulmonary function changes and immunomodulation of Th 2 cytokine expression induced by aminophylline after sensitization and allergen challenge in Brown Norway rats. Lin CC, Lin CY, Liaw SF, Chen A. Ann Allergy Asthma Immunol 2002 Feb; 88 (2), pp. 215–22.

Immune Hypersensitivity Reaction: Asthma/Asthma with Severe Bronchial Obstruction/Aspirin-Intolerant Asthma/Rhinitis
Lysine Acetylsalicylic Acid (L-ASA)

Background Information: Nasal provocation tests with lysine-aspirin have been applied for assessment of aspirin-intolerant asthma.
Application: Nasal challenge with L-ASA can be used as a diagnostic test even in asthmatic patients with severe bronchial obstruction.
Route of Administration: Lysine acetylsalicylic acid (intranasal infusion).
Dosage: Lysine acetylsalicylic acid (25 mg).
Implementation: Evaluate the usefulness of acoustic rhinometry as a non-invasive technique for the diagnosis of aspirin-intolerant asthma/rhinitis. Challenge tests are performed with L-ASA or saline (0.9% NaCl) and 25 mg L-ASA instilled into each nostril of the nose on 2 separate days. Clinical response is evaluated based on nasal symptoms (sneezes, itching, secretion, and blockage). Nasal response is measured by acoustic rhinometry. Symptoms and rhinometry curves are recorded at 10-minute intervals for 3 hours, 1 hour before challenge and 2 hours after challenge.

Human Model: Cases of aspirin-intolerant asthma/rhinitis (n = 15; n = 9/15 females age 54.7 + 14 years; n = 8 aspirin-tolerant asthma/rhinitis; n = 3/8 women mean age = 52.6 + 7.8 years; n = 8 normal healthy volunteers; n = 2/8 women, mean age 32.5 + 9.7 years).

Interpretation and Analysis: L-lysine acetylsalicylic acid challenge induces a significant increase in symptoms in conditions of aspirin-intolerant asthma/rhinitis. No difference in the clinical response can be detected in cases with aspirin-tolerant asthma/rhinitis or healthy subjects. L-lysine acetylsalicylic acid challenge induces a significant decrease in nasal volume measured by acoustic rhinometry in cases of aspirin intolerance. No differences can be detected between challenges in aspirin-tolerant cases. If a 25% decrease in nasal volume is taken as the cutoff point, the specificity of the test is approximately 94% (sensitivity = 73%). The nasal challenge is well tolerated by all subjects. Acoustic rhinometry can be used to effectively study the nasal response to L-ASA.

Instrumentation: Acoustic rhinometry.

Intranasal challenge with aspirin in the diagnosis of aspirin-intolerant asthma: Evaluation of nasal response by acoustic rhinometry. Casadevall J, Ventura PJ, Mullol J, Picado C. Thorax 2000 Nov; 55 (11), pp. 921–4.

Immune Hypersensitivity Reaction/Bronchial Hyperresponsiveness (BHR)/Neutrophil Influx: Differential Response/Allergic Airway Eosinophilia Reaction/Interleukin (IL)-10 and Interferon-Gamma (IFN-γ) Induction: Differential Expression/[IL-2, IL-4, and IL-5]/Type Th1 and Th2 Cytokine Expression Profiles

Ovalbumin/Dexamethasone/Cyclosporin-A

Cellular/Molecular Mechanism of Action: Ovalbumin is the avian equivalent of mammalian serum albumin and can be applied as an immunogenic (antigenic) protein fraction. Dexamethasone is a corticosteroid that has an ability to inhibit phospholipase A2 biochemical activity.

Physiological Mechanism of Action: Dexamethasone is a corticosteroid that promotes immunosuppressive properties in part due to stabilization of cellular membrane structures, which in part inhibits leukocyte degranulation phenomenon and general inhibition of protein synthesis.

Background Information: Cyclosporin A and dexamethasone exhibit different effects on allergic airway eosinophilia and BHR.

Application: Characterization of the molecular pathogenesis of normal and hypersensitivity immune responses including alterations in cytokine production, and changes in the expression profiles for Th1- vs Th2-derived cytokines. Such an investigative strategy can also be applied to delineate the efficacy of various therapeutic agents possessing anti-inflammatory and immunosuppressive properties.

Implementation: Evaluation of the influence of cyclosporine or dexamethasone on the development of immune hypersensitivity reactions to ovalbumin aerosol challenge. Bronchial responsiveness is measured 18–24 hours after aerosol exposure. Airway cellular influx can be determined by bronchoalveolar lavage and tissue immunohistochemistry. Expression of Th1 and Th2 cytokine messenger RNA (mRNA) is then analyzed by reverse transcriptase-PCR.

Animal Model: Rat (Brown Norway rats sensitized to ovalbumin).

Interpretation and Analysis: Ovalbumin exposure induces significant BHR reactions, with increases in eosinophils, lymphocytes, and neutrophils in bronchoalveolar lavage fluid and an increase in eosinophils, CD2+, and CD8+, but not CD4+ T cells, in the airway submucosa. Interleukin 2, IFN-γ, IL-4, and IL-5 mRNA expression in ovalbumin-sensitized lungs increases ($p < 0.05$) compared with controls. Cyclosporin A does not have a significant effect on BHR and neutrophil accumulation but does reduce the number of bronchoalveolar lavage eosinophils ($p < 0.002$), airway submucosal eosinophils, and CD4+ and CD8+ T cells ($p < 0.02$). It also suppresses the induction of mRNA expression for IL-2, IL-4, IL-5, and IFN-γ. By contrast, the inflammatory cell influx and mRNA expression of IL-2, IL-4, and IL-5, as well as BHR, is suppressed by dexamethasone. However, increases in IL-10 and IFN-γ mRNA expression can sometimes not be detected depending on the analytical system evaluated. The differential activities of cyclosporin A and dexamethasone on inflammatory cell influx, particularly neutrophils, or cytokine expression such as IL-10 and IFN-γ may underlie their contrasting effects on BHR.

Differential regulation of cytokine expression after allergen exposure of sensitized rats by cyclosporin A and corticosteroids: relationship to bronchial hyperresponsiveness. Huang TJ, Newton R, Haddad EB, Chung KF. J Allergy Clin Immunol 1999 Sep; 104 (3 Pt 1), pp. 644–52.

Immune System: Lymph Node/Selective Antigen Delivery to Nodes and Processing

[Fluorescein Isothiocyanate]-H-2K(b) CTL Epitope (SIINFEKL)/pH-Sensitive Liposomes

Cellular/Molecular Mechanism of Action: Fluorescein isothiocyanate (FITC) is a molecule that emits fluorescent color when excited by certain wavelengths of light energy. Liposomes that are pH-sensitive provide a modality for protecting their internal contents from metabolic degradation or accelerated elimination but also have the property of degrading upon exposure to environments within a specific hydrogen ion concentration range.

Application: Fluorescein isothiocyanate (FITC) can be applied as a fluorescent tracer molecule in biological systems. Fluorescein isothiocyanate (FITC)-conjugated H-2K(b) CTL epitope (SIINFEKL). Liposomes that have pH-sensitive properties have been designed to release their internal contents through lysis when exposed to environments within a specific pH range.

Interpretation and Analysis: Fluorescence can be initially detected in lymph nodes at 3 hours after immunization, and its intensity reaches a peak value in superficial inguinal lymph node at 9 hours. No trace can be detected in the spleen even with prolonged monitoring for up to 24 hours. These results strongly suggest that the presentation of CTL-peptide antigen vehicled by pH-sensitive liposomes exclusively occurs in lymph nodes. In mice immunized with the H-2K(b) CTL epitope encapsulated pH-sensitive liposomes, peptide-specific CTL responses can be detected on day 3. The response is strongly augmented by a 2nd immunization and persists up to at least 45 days. Therefore, liposomes formulated to be pH-sensitive can function as potential adjuvants of peptide antigens and are useful for the *in vivo* induction of antigen specific CTLsv.

Investigation of antigen delivery route *in vivo* and immune-boosting effects mediated by pH-sensitive liposomes encapsulated with K(b)-restricted CTL epitope. Lee KY, Chun E, Seong BL. Biochem Biophys Res Commun 2002 Apr 5; 292 (3), pp. 682–8.

Immune System: Lymphocyte Function/Skin Test/Organochlorine Exposure/[Gender Differences]
Tetanus Toxoid/Diptheria Toxoid/Candida/ Tricophyton/Streptococcus/Proteus/ Phytohemaglutinin/Concanavalin A (Con-A)/Pokeweed Mitogen

Background Information: Previous studies of gender differences in response to the Multitest CMI skin test have produced conflicting results.
Application: Evaluation of immune system function.
Implementation: Evaluation of immune function applying a skin test using the Multitest CMI skin test to determine if gender influences that nature of observed results. Six of 7 antigens are tested: tetanus toxoid, diphtheria toxoid, Candida, Tricophyton, Streptococcus, and Proteus (excluding tuberculin antigen). Lymphocyte function can also be evaluated *in vitro* using standardized methods of mitogen stimulation with phytohemaglutinin (PHA), concanavalin A (Con-A), and pokeweed mitogen.

Human Model: Cases living near a hazardous waste site containing organochlorine pesticides (n = 297 adults, age = 18–64 years).
Interpretation and Analysis: The frequency of positive responses to the skin tests is significantly ($p < 0.001$) higher among males (80.4%) than among females (55.7%). Males are more likely than females to respond to all 6 test antigens ($p < 0.05$). The mean diameter of positive skin test measurements for males can be found to significantly ($p < 0.05$) exceed female responses to tetanus and diphtheria. Although not statistically significant, male response size exceeds that of females for all other antigens except Trycophyton. Controlling for age, race, smoking, income, and plasma DDE levels do not change these results. Skin test positivity is not associated with mitogen stimulation assay results overall or within gender groups. Significant gender differences in response to the Multitest CMI skin test could limit its use as a marker of anergy in general population studies.

Gender differences in response to the multitest CMI skin test in the general population. Vine MF, Stein L, Weigle K. Ann Allergy Asthma Immunol 2000 Apr; 84 (4), pp. 445–50.

Immunity (Cellular/Humoral Response): Combined Deficiency/Combined Immunodeficiency (CID)/ Arabian Foals Hereditary Disorder
Phytohemagglutinin (PHA)

Cellular/Molecular Mechanism of Action: Promotes activation of T-lymphocyte populations.
Background Information: Breeding with heterozygous male and female creates an inherited autosomal recessive trait in the offspring leading to a deficiency in T-lymphocyte and B-lymphocyte production. Affected foals have normal complement systems, neutrophils and macrophages, produce secretory immunoglobulin components and still produce large granular lymphocytes suggestive of killer cells. Affected foals usually have normal colostrally-derived immunity. However, when passively transferred maternal immunoglobulins begins to decline (become depleted) at 3 to 6 weeks and they experience an increased susceptibility to infectious diease (usually opportunistic microorganisms).

Affected animals display a persistent lymphopenia ($< 1 \times 10^9$/l) and histopathology evaluation reveals aplasia or severe hypoplasia of lymphocyte germinal centers.
Application: Detection of deficiencies in T-lymphocyte numbers or function (*in vivo*).
Route of Administration: Phytohemaglutinin (intradermal).
Implemenation Example: Detection of combined immunodeficiency in Arabian foals or Arabian cross-bred foal. Phytohemaglutinin is injected intradermally at 1 site and an equivalent volume of sterile physiological saline is injected intradermally at another nearby location as a negative reference control.
Interpretation and Analsysis: Phytohemaglutinin (PHA) fails to produced an intradermal reaction/response when the total number T-lymphocyte cell production is severely deficient or their function is severely compromised (e.g., either selective or combined immunodeficiency). Presence of cutaneous edema and "sweating" at the site of intradermal injection is considered a positive (normal/healthy) response.

Immunity (Humoral Response): Hypogammaglo-bulinemia (*In Vitro*)/ [Non-Pharmaceutical Agent]
Zinc Sulfate ($ZnSO_4$)

Cellular/Molecular Mechanism of Action: Becomes associated with the cationic and anionic groups of polypeptide amino acid residues. This generally in a reduction in the ionic charge density of protein fractions thereby decreasing their relative solubility in an aqueous environment.
Diagnostic Application: Approximation of immunoglobulin concentrations within serum. Primarily applied in neonatal patients to determine if sufficient ingestion of colostrum has occurred within the 1st 24 hours following parturition.
Route of Administration and Dosage: Serum samples (0.1 ml) are combined with double distilled water (1.0 ml) and thoroughly mixed. This formulation is then combined with zinc sulfate reagent (5 ml) and the reaction mixture thoroughly mixed at room temperature (25°C). After 1 hour, the absorbance (optical density) of the reaction mixture is measured spectrophotometrically at 485 nm. Results are interpreted according to values generated from a standard

reference control curve. If a spectrophotometer is not available, the ability or relative degree to which newsprint can be read through the reaction tube gives a reasonably good indication of the immunoglobulin content within a serum sample. Zinc sulfate reagent is prepared by dissolving 250 mg of zinc sulfate in 1 liter of boiled water. Following cooling to room temperature, the formulation is decanted into a capped dark glass bottle for storage.

Considerations: The zinc sulfate turbidity test is 1 of the most practical means of screening for immunoglobulin deficiency in a field environment. Zinc sulfate also precipitates other large molecular weight protein fractions such as fibrinogen. This mandates that serum rather than plasma be applied as a test medium. Additionally, zinc sulfate reagent decays over time and results tend to vary in relation to extremes in environmental temperature.

Interpretation and Analysis: Following addition of test serum to zinc sulfate reagent formulations, the solution can be evaluated either visually, or by spectrophotometric absorption. In situations where a total lack of passive transfer of humoral immunity has occurred, the reaction mixture remains essentially clear. Readings of less than 400 mg/dl implies neonatal failure of passive transfer of humoral immunity.

Zinc sulfate turbidity has largely been replaced by more accurate laboratory procedures for the quantitation of serum immunoglobulin concentrations (IgG quantation, anti-equine IgG coated latex bead agglutination)

Immunity (Humoral Response): Suppression
Anti-Leu-2a, Leu-3a, and Leu-5 MoAb

Cellular/Molecular Mechanism of Action: Suppression of humoral immune response.

Application: Anti-Leu-2a, Leu-3a, and Leu-5 immunoglobulin for the suppression of the development of AMIA against T cell-specific monoclonal antibodies (cynomolgus monkeys).

Route of Administration: Intravenous.

Dosage: Anti-Leu-2a (1 mg), Leu-3a (1 mg), and Leu-5 (1 mg) for 10 consecutive days. Additional test groups receives (Group 2) cyclosporine, 12.5 mg/kg daily on days -7 to $+14$; (Group 3) group (PI) can be passively immunized with 0.4 ml of hyperimmune monkey AMIA serum on days -7, -1, 2, 4, 6, and 8; and (Group 4) (TLI) received 1,700 rad fractionated total lymphoid irradiation ending on day -1.

Considerations: Murine monoclonal antibodies stimulate the production of human antimouse immunoglobulin antibodies (AMIA) when administered to patients. This limits their long-term usefulness as therapeutic and diagnostic agents.

Interpretation and Analysis: Animals treated with TLI are markedly delayed in the onset of AMIA, which is suppressed to less than 1% of the control group. The AMIA specific for the constant region of animals receiving PI is also suppressed to one-third of controls. Majority of the AMIA in all the animals is anti-idiotypic and wholly anti-idiotypic in TLI animals.

Immunity (Humoral Response to Infection): Bacteria and Fungal Organisms/Corynebacterium/ Tuberculosis/Fungal Infections
Intradermal Testing/Infectious Disease and Hyperimmune Conditions

Cellular/Molecular Mechanism of Action: Allergens injected intradermally stimulate immunocompetent cell populations (T-lymphocytes, B-lymphocytes, marcrophages).

Diagnostic Application: Detection of hyperimmune responses to specific environmental allergens.

Route of Administration and Dosage: Intradermal injection. Examples of products that are applied for this purpose include blastomycin, coccidiodin, cryptococcin, and histoplasmin. Accuracy of these tests is complicated by a variety of factors such as cross-reactions between fungal species, anergy in cases of dissemination, and positive reactions only indicate exposure, and not necessarily ongoing infection.

In the intradermal tuberculin test, 0.1 ml of mammalian tuberculin purified protein derivative is administered intradermally in the caudal tail fold or mucocutaneous junction of the vulva. The injection site is inspected at 72 ± 6 hours (negative, suspect, reactor). The comparative cervical test is applied to determine the species of Mycobacterium that cattle may have been exposed to; it utilizes mammalian and avian tuberculin injected into 2 separate sites on the same side of the neck. Injection sites are inspected at 72 hours and measured with calipers. Other tests include the subcutaneous and intravenous thermal test with positive cases producing a temperature spike of $>$ 104°F (40°C) within 4 to 8 hours postadministration. Alternatively, the Stormont test involves performing the intradermal test twice at the same site over a 7-day interval. Following the last administration, the 2nd injection is evaluated at 24 hours. An increase in skin thickness of $\geq$ 5 mm is considered to be a positive reaction. Relative hyposensitization occurs 4 to 6 weeks after calving due to substantial transfer of antibody into the colostrum. Cattle exposed (infected) within the 1st 6 months may fail to react, and patients with pulmonary lesions may display anergy.

The procedure applied to diagnose *Mycobacterium paratuberculosis* (Johne's disease) in cattle is the intravenous and intradermal Johnin test. The intravenous Johnin is performed by the intravenous injection of Johnin (2–5 ml) on a day with a moderate ambient temperature. A systemic body temperature and CBC are collected at time zero. At intervals of 4, 6, and 8 hours, the body temperature is recorded with a positive response reflected by an increase in body temperature of 3°F (1.6°C). A 2nd CBC is performed on blood collected at 6 hours post-Johnin injection and a $>$ 2:1 alteration in the neutrophil:lymphocyte ratio is diagnostic.

Considerations: Critically important is the administration of intradermal saline reference negative controls.

False positives may be recognized when performing the intradermal tuberculin test if cattle have been exposed to human or avian tuberculosis, Johne's disease, saprophytic Mycobacterium, Nocardia, and other species.

False-positive results with the Johnin test can be appreciated when cattle have been previously exposed to or infected with other species of mycobacteria, Nocardia, Corynebacterium, Dermatophilus, or Actinomyces agents.

Interpretation and Analysis: Increased edema, swelling and redness at the site of allergen injection without an appreciable response at the saline negative reference control suggests a hyperimmune response exists against that particular test reagent.

Immunity (Humoral/Cellular Response to Infection): Johnes Disease
(Mycobacterium Paratuberculois)/Johnin Antigen

Cellular/Molecular Mechanism of Action: Bacterial immunogen.

Application: Detection of cattle infected with Mycobacterium paratuberculosis.

Route of Administration: Intradermal or intravenous.

Dosage: Intravenous (2–4 ml of standardized prepared Johnin antigen).
Considerations: The intravenous Johnin test is diagnostically more reliable than is the interadermal test.
Implementation: Evaluation of the intravascular Johnin test is performed by measuring changes in body temperature at 4.5, 6.0, and 7.5 hours postinjection.
Interpretation and Analysis: Elevations in rectal temperature of ≥ 3°F (1.6°C) are considered a positive response, but the highest temperature that has to be reached is 39.4°C. The pretest temperature must be below 39.4°C. Intradermal sensitivity: Clinical (60–78%); non-clinical (37.5%); specificity (50–54%). Intravenous sensitivity: clinical (84–92%); non-clinical (22–57%); specificity (84–88.5%).

Immunity (Humoral/Cellular Response to Infection): Tuberculosis *(Mycobacterium Bovis, M. Avium)/Tuberculin Antigen*

Cellular/Molecular Mechanism of Action: Intradermal injection of the preparation into cattle infected with *Mycobacterium bovis, M. avium* induces the development of a Type IV hypersensitivity reaction.
Application: Detection of cattle infected with *Mycobacterium bovis* (tuberculosis).
Route of Administration: Mammalian tuberculin purified protein is injected intradermally in the caudal tail fold of the mucocutaneous junction of the vulva using a tuberculin syringe and a 25-gauge needle.
Dosage: Mammalian tuberculin purified protein derivative or PPD (0.1 ml; 1 mg/ml; 3 mg/ml Australia).
Considerations: Bacterial immunogen, which is a concentrated sterile culture filtrate of tubercle bacilli grown on glycerated beef broth or synthetic media. Injection sites are digitally evaluated at 72 hours postinjection for signs of swelling and heat.
Implementation: Following intradermal injection, the site is evaluated for edema and heat relative to a reference control.
Interpretation and Analysis: Antigenic preparations (tuberculin) are not entirely specific and reactions can be seen with infections due to other strains or species of Mycobacterium. In areas where the disease has been eradicated, positive responses should be reevaluated applying the comparative-cervical test (c-c test). In the United States, only veterinarians specifically approved by the state or federal regulatory agencies are permitted to conduct the c-c test utilizing PPD tuberculins of equal biological potency (established in guinea pigs) in order to determine the dispostion of suspect cattle. During the course of this procedure, biologically "equilibrated" mammalian and avian tuberculin are injected simultaneously in 2 sites on the same side of the neck 12 cm apart and 1 above the other. Results are evaluated at 72 hours using calipers for accurate measurement. A nomograph is used to interpret the finding. Federal veterinarians may also use 0.2 ml cervical test in known infected herds. Other tests are the subcutaneous and intravenous thermal tests in which a temperature spike to > 104 (40°C) in 4 to 8 hours is observed in positive reacting cases. The Stormont Test involves performing the intradermal test twice in the same area (7-day interval) and results reviewed at 24 hours. An increase in skin thickness of > 5 mm is considered positive. A temporary hyposensitization may last for up to 6 months. The postparturition period is also associated with hyporeaction to tubuerculin in part due to the contribution of large amounts of dam immunoglobulin into the colostrum
Instrumentation: None.

Immunity (Humoral/Cellular Response to Infection)/Systemic Fungal Infections *Intradermal Allergy Testing/Blastomycin/ Coccidiodin/ Cryptococcin/Histoplasmin*

Cellular/Molecular Mechanism of Action: Allergens injected intradermally stimulate immunological cell populations (T-lymphocytes, B-lymphocytes, macrophages).
Diagnostic Application: Detection of hyperimmune responses to specific environmental allergens.
Route of Administration and Dosage: Intradermal injection. Examples of products that are applied for this purpose include blastomycin, coccidiodin, cryptococcin, and histoplasmin. Accuracy of these tests is complicated by a variety of factors such as cross-reactions between fungal species, anergy in cases of dissemination, and positive reactions only indicate exposure and not necessarily ongoing infection.
Considerations: Important to administer intradermal saline reference negative controls.
Interpretation and Analysis: Increased edema, swelling, and redness at the site of allergen injection without an appreciable response at the saline negative reference control suggests that a hyperimmune response has developed against that specific test antigen reagent.

INFLAMMATION

Inflammation: Hepatitis (Alcohol-Induced)/H_2O_2 *Corticosteroids/[Neutrophils]/L-Selectin/Interleukin (IL)-8/Tumor Necrosis Factor-Alpha (TNF-α)/IL-10*

Background Information: Several observations point to an important role of interactions between polymorphonuclear neutrophils and cytokines in severe alcoholic hepatitis. The polymorphonuclear neutrophil activation status and the local and systemic pro- and anti-inflammatory cytokine responses are then quantified. The effect of corticosteroids, widely used in this setting, can be evaluated using these parameters.
Application: Potential differentiation of alchohol-induced hepatitis and alcohol-induced cirrhosis without hepatitis and normal reference (healthy) controls.
Implementation: Evaluation of blood polymorphonuclear neutrophil functions pertaining to L-selectin and β_2-integrin expression, H_2O_2 production, and IL-8 and TNF-α synthesis capacity. Complementary analysis includes measurement of plasma and hepatic IL-8, TNF-α, and IL-10 levels. The impact of a 28-day course of corticosteroids on blood neutrophil activation status and cytokine levels has been evaluated in patients with alcoholic hepatitis.
Human Model: Cases of alcoholic hepatitis (n = 15; compared to n = 15 conditions of alcoholic cirrhosis without alcoholic hepatitis; compared to n = 10 healthy volunteers).
Interpretation and Analysis: Blood polymorphonuclear neutrophils in conditions of alcoholic hepatitis are activated, as shown by increases in H_2O_2 production (48 ± 6 vs 29 ± 6 MFI in healthy controls), and decreases in L-selectin expression (300 ± 61 vs 449 ± 59 in healthy controls). Upon stimulation, polymorphonuclear neutrophils synthesize large amounts of IL-8 (21.7 ± 9.2 ng/ml vs 8.8 ± 10 ng/ml in healthy controls) and TNF-α (524 ± 132 pg/ml vs 79 ± 144 pg/ml in healthy controls). Tumor necrosis factor-alpha and IL-8 plasma and tissue levels markedly increase in contrast to IL-10, which is barely detectable in alcoholic hepatitis patients, compared to cirrhotic patients and healthy controls. During steroid therapy, plasma levels of the proinflammatory cytokine IL-8 fall as early as day 14, while levels of the anti-inflammatory cytokine IL-10

increase on day 21. Finally, polymorphonuclear neutrophil functions return to normal after treatment. Severe alcoholic hepatitis appears to be associated with polymorphonuclear neutrophil activation and an imbalance between pro- and anti-inflammatory cytokines; during steroid therapy a normalization of these parameters can be observed.

Blood neutrophil functions and cytokine release in severe alcoholic hepatitis: Effect of corticosteroids. Taïeb J, Mathurin P, Elbim C, Cluzel P, Arce-Vicioso M, Bernard B, Opolon P, Gougerot-Pocidalo MA, Poynard T, Chollet-Martin S. J Hepatol 2000 Apr; 32 (4), pp. 579–86.

Inflammatory Responses and Disease States
Cytokines (Interleukins)

Cellular/Molecular Mechanism of Action: Endogenous mediators of inflammation and immunity facilitated by the expression of membrane-associated receptor complexes on the exterior membrane surface of various cell types, most notably including leukocytes (hence the name interleukin) and vascular endothelium.
Considerations: Cytokines are key mediators of immunity and inflammation. These proteins or glycoproteins act as communication signals between different populations of leukocytes but neither their effects nor their production are restricted to immune cells. In the last few years many new cytokines and their effects have been discovered and it has been proposed that when the amino acid sequence of a new cytokine is established it would be assigned the name interleukin (IL), with an added number (e.g., IL-1 through IL-20). The detection of cytokines in disease states promises to provide useful information for diagnostic purposes. The therapeutic utility of cytokines has been explored in many clinical and preclinical studies and in a wide variety of infectious diseases, autoimmune conditions and neoplasia disorders. Because the production of cytokines is modulated by several biological agents such as hormones, prostaglandins, and drugs, these may also serve as therapeutic targets for immunomodulation.

Neutrophils/Monocytes/Consumption vs Production Abnormalities
[^{111}I]-Oxine Neutrophils/Chemotherapeutics: Doxorubicin

Physiological Mechanism of Action: Neutrophils and macrophages migrate into specific locations (tissues/organs) within the body in response to chemotactic agents (move towards a concentration gradient).
Application: Includes characterization of elevated platelet consumption or declines in production within the bone marrow. They can also function as a modality for the selective delivery of pharmaceutical agents for various diagnostic and therapeutic purposes.
Route of Administration: Intravascular.
Considerations: Must be prepared fresh.
Semi-Synthetic Methods: Radioisotope markers and certain chemotherapeutic agents can be passively "loaded" into neutrophil populations at relatively high concentrations without affecting their response to chemotactic stimuli.
Implementation: Selective delivery to foci of infectious disease or neoplasia.
Interpretation and Analysis: Declines in intravascular $T_{1/2}$ values for labeled neutrophils implies accelerated consumption or removal. In scenarios where neutrophil numbers are low but the $T_{1/2}$ value is normal, then abnormalities in hematopoeitic production should be considered

Anti-neoplastic activity of chemotherapeutic "loaded" neutrophils against human mammary carcinoma. Coyne CP, Fenwick BW, Ainsworth J. Biotherapy 1997; 10, pp. 145–59.

Note: Please refer to imaging modality sections for detection and characterization of inflammatory conditions.

EX VIVO LIVING SYSTEMS

CARDIOVASCULAR: *EX VIVO*

Cardiovascular: Cardiomyopathy/Hypertension/ Propanolol β-Adrendergic Receptor Occupancy/ Positron Emission Tomography (PET) vs Single Photon Emission Computed Tomography (SPECT) Spatial Resolution/*Ex Vivo* and *In Vivo* Cardiac and Splenic Tissue Analyses
(1R,2S)-4-[^{18}F]-Fluorometaraminol (4-FM)/[^{125}I]-Iodocyanopindolol/Meta-[^{125}I]-Iodobenzylguanidine (MIBG)

Cellular/Molecular Mechanism of Action: [^{125}I]-Iodocyanopindolol is a radioiodinated analog of propanolol, which is known to have binding avidity for and blocks the activity of β-adrenergic receptor complexes. (1R,2S)-4-[^{18}F]-fluorometaraminol appears to have similar binding-avidity for β-adrenergic receptor complexes. Meta-iodobenzylguanidine is an analog of norepinephrine, which functions as an adrenergic receptor agonist.
Application: [^{125}I]-Iodocyanopindolol can be used to detect alterations in β-adrenergic receptor expression and propanolol β-adrenergic receptor occupancy.
Dosage: [^{125}I]- Iodocyanopindolol (1.5 pmol/L *ex vivo* incubation); propranolol (10 μmol/L *ex vivo* incubation).
Implementation: Evaluation of the biodistribution of no-carrier-added 4-[^{18}F]-FM *in vivo* and *in vitro* in retrograde-perfused hearts. Relevant biodistribution parameters include the assessment of relative uptake, metabolism, and beta-receptor affinity of 4-FM for comparison with analogous values observed for the SPECT pharmaceutical MIBG.

Cardiac and extracardiac distribution can be assessed, in concert with the detection of metabolite formation assessed by thin-layer chromatography techniques. Studies performed *in vivo* are then repeated with no-carrier-added [^{123}I]-MIBG. By means of autoradiography, the beta-receptor affinity of 4-FM can be compared with that of MIBG and propranolol (10 μmol/L) through displacement of [^{125}I]-iodocyanopindolol (1.5 pmol/L) in *ex vivo* tissue slices.

Animal Model: Rats (Wistar-Kyoto (WKY) strain and spontaneously hypertensive [SHR] rats).

***Ex Vivo* Model:** Rat (cardiac and spleen slices).
Interpretation and Analysis: Cardiomyopathic hearts show heterogeneous 4-[^{18}F]-FM uptake with gradients of up to 3.6 *in vivo* and *in vitro* between different regions of the heart. Control hearts display such gradients in 4-[^{18}F]-FM uptake only *in vitro*. [^{125}I]-MIBG exhibits a less heterogeneous *in vivo* distribution in SHR hearts. Extracardiac differences between WKY and SHR can be appreciated for uptake of 4-[^{18}F]-FM in the spleen (63.3% ± 4% vs 38.8% ± 5.7% of cardiac activity) and for renal uptake of [^{125}I]-MIBG (373% ± 27% vs 81.4% ± 17% of cardiac activity). Metabolites of 4-[^{18}F]-FM are found only in the liver and those of [^{125}I]-MIBG are found in the liver and kidney with a nearly equal relative fraction in both types of animals at about 20%, 60%, and 30%, respectively. 4-FM suppresses cardiac-specific beta-receptor binding of [^{125}I]-iodocyanopindolol in heart and spleen of both types of animals significantly, whereas MIBG has almost no effect. The more heterogeneous cardiac distribution of 4-[^{18}F]-FM suggests that it reflects alterations in uptake-1 better than [^{125}I]-MIBG in addition to the possibility of quantification and higher spatial resolution by PET compared with

SPECT. Altered biotransformation in cardiomyopathic diseases may also impair the evaluation of [^{125}I]-MIBG-SPECT data. The beta-receptor binding of 4-[^{18}F]-FM should ideally be further elucidated.

Relative uptake, metabolism, and beta-receptor binding of (1R,2S)-4-[^{18}F]-fluorometaraminol and [^{123}]I-MIBG in normotensive and spontaneously hypertensive rats. Pissarek M, Ermert J, Oesterreich G, Bier D, Coenen HH. J Nucl Med 2002 Mar; 43 (3), pp. 366–73.

Vascular Endothelium: Alpha(V)Beta$_3$ Integrin Complexes/Neoplastic Cell Upregulation *[^{99m}Tc]-(HYNIC)-Arg-Gly-Asp/[^{99m}Tc]-(HYNIC-RGD-4C)*

Cellular/Molecular Mechanism of Action: The peptide amino acids residues, Arg-Gly-Asp (RGD), in vitronectin and fibronectin possess binding-affinity for cell membrane-associated alpha(V)beta$_3$ integrin complexes.

Background Information: Three amino acid residues, Arg-Gly-Asp (RGD), in vitronectin and fibronectin show affinity for alpha(V)beta$_3$ integrins expressed in vascular endothelial cells. That tumor growth can upregulate the expression of these integrins on tumor cells for invasion and metastasis and *in* tissue neovasculature suggests the potential of developing radiolabeled RGD peptides as antagonists of alpha(V)beta$_3$ integrins for broad spectrum tumor specific imaging. The polypeptide RGD-4C, which contains 4 cysteine residues for cyclization, has shown preferential localization on integrins at sites of tumor angiogenesis.

Application: Detection and characterization of neoplastic cell types/tumors that express relatively high alpha(V)beta$_3$ integrin membrane densities.

Route of Administration: Polypeptides RGD-4C and RGE (Arg-Gly-Glu)-4C (intravascular).

Semi-Synthetic Methods: The polypeptide RGD-4C and control RGE (Arg-Gly-Glu)-4C are conjugated with 6-hydrazinopyridine-3-carboxylic acid (HYNIC) to facilitate [^{99m}Tc] radiolabeling. Separation of conjugated products from residual unreacted molecular components can be achieved by C18 chromatography (e.g., Sep-Pak cartridge) applied in combination with 20% methanol solvent. Each of the peptides can be radiolabeled using tricine. For cell binding studies, both [^{99m}Tc] peptides can be further purified by SE HPLC. High specific radioactivity for labeled cyclized RGD/E of about 20 Ci/micromol can be achieved. Both [^{99m}Tc] complexes are stable in the labeling solution for over 24 hours at room temperature.

Implementation: Evaluation of the relative binding avidities of RGD-4C and RGE (Arg-Gly-Glu)-4C peptides for endothelial cell membrane preparations. Determination of such properties can be established by exposure of umbilical vein endothelial (HUVE) to RGD-4C or RGE over an incubation period of 1-hour duration (4°C) at concentrations *in* the picomolar to nanomolar range. Specificity can be approximated by determining at what concentration native cyclized RGD blocks 50% of [^{99m}Tc]-labeled RGD binding to cell preparations.

***Ex Vivo* Model:** Human (umbilical vein endothelium or HUVE).

Interpretation and Analysis: In the human umbilical vein endothelial (HUVE) cell binding-avidity analyses, cell accumulation of [^{99m}Tc] in the case of RGD can be as much as 16 times greater than the RGE control peptide. Specificity analyses reveals that 7 nM of native cyclized RGD blocked 50% binding of [^{99m}Tc]-labeled RGD to cells. The binding percentage of [^{99m}Tc]-labeled RGD to purified alpha(V)beta$_3$ integrin protein, as determined by SE HPLC, increases with integrin concentration while [^{99m}Tc]-labeled RGE displays no binding. The association constant for [^{99m}Tc]-RGD is rather modest at 7×10^6 M^{-1}. In both human renal adenocarcinoma (ACHN) and human colon cancer cell line (LS174T) nude mouse tumor models, the accumulation of [^{99m}Tc]-labeled RGD/E exhibits no statistical difference. In conclusion, possibly because of limited numbers of alpha(V)beta$_3$ integrin receptors per tumor cell and low binding affinity, radiolabeled RGD peptides may have limitations as tumor imaging agents.

In vitro and *in vivo* evaluation of a Technetium-99m-labeled cyclic RGD peptide as a specific marker of alpha(V)beta$_3$ integrin for tumor imaging. Su ZF, Liu G, Gupta S, Zhu Z, Rusckowski M, Hnatowich DJ. Bioconjug Chem 2002 May–Jun; 13 (3), pp. 561–70.

HEPATIC: *EX VIVO*

Hepatic Adrenergic Catechol O-Methyltransferase (COMT)/Genetically Regulated Thermal Stability *Adrenergic Neurotransmitters/(Hepatic Biopsy Specimens)*

Cellular/Molecular Mechanism of Action: Catechol O-methyltransferase activity mediates the biochemical inactivation of epinephrine and norepinephrine neurotransmitters.

Application: Detection of COMT genotypes and characterization of COMT genetic polymorphism.

Considerations: The level of COMT activity and COMT thermal stability in human tissue are controlled by a common genetic polymorphism.

Implementation: Individual hepatic biopsies are collected for analysis (e.g., from individuals with high, low or intermediate COMT biochemical activity and thermal stabilities) to determine if the molecular mass (M_r) and/or isoelectric point (pI) of COMT enzymes differs in tissue from subjects with different presumed genotypes for the COMT genetic polymorphism. Laboratory techniques employed entail the partially purification of COMT from individual hepatic tissue samples by (i) sequential ion exchange and gel filtration chromatography; (ii) photoaffinity labeling performed with [^{3}H-methyl]-S-adenosyl-L-methionine (functions as the methyl donor for the COMT enzymatic reactions); and (iii) 2-dimensional sodium dodecylsulfate polyacrylamide gel electrophoresis (2-D SDS-PAGE) analysis.

Interpretation and Analysis: Two-dimensional sodium dodecylsulfate polyacrylamide gel electrophoresis (2-D SDS-PAGE) analysis of individual samples consistently shows the presence of 3 [^{3}H-methyl]-S-adenosyl-L-methionine photoaffinity-labeled proteins with pI values of 5.4, 5.5 and 5.7 (all 3 have M_r values of approximately 27.1 kDa). The same pattern can be observed in all samples irrespective of COMT phenotype. Western blot analysis of 2-D SDS-PAGE gels performed with rabbit polyclonal antibodies to partially purified human kidney COMT reveals a pattern similar to that found with photoaffinity labeling. Once again, the same pattern is found in all samples irrespective of COMT phenotype. Therefore, neither photoaffinity labeling nor Western blot analysis reveals differences in either M_r or pI of cytoplasmic COMT in hepatic tissue from subjects selected on the basis of different phenotypic expression of the COMT genetic polymorphism.

Catechol O-methyltransferase pharmacogenetics: photoaffinity labeling and western blot analysis of human liver samples. Aksoy S, Klener J, Weinshilboum RM. Pharmacogenetics 1993 Apr; 3 (2), pp. 116–22.

Hepatic Cytochrome P450: Microsomal Fractions *Doxifluridine (5′-DFUR)/Tegafur (FT)*

Cellular/Molecular Mechanism of Action: Doxifluridine (5′-DFUR) and tegafur (FT) are 2 fluoropyrimidine prodrugs that are

metabolized to 5-fluorouracil (5-FU) by hepatic microsomal enzyme fractions.

Application: Characterization of differences in the *in vitro* metabolic profiles for chemotherapeutic agents including doxifluridine (5′-DFUR) and tegafur (FT).

Implementation: Microsomal and cytosolic fractions processed from hepatic tissue (e.g., human liver) are incubated with doxifluridine (5′-DFUR) and tegafur (FT) preparations (500 μM final concentration). Conversion of these 2 fluoropyrimidine prodrugs to 5-FU is measured by high-performance liquid chromatography. The degree of correlation between the 5-FU-forming activities is determined using various cytochrome P450-dependent reactions.

Interpretation and Analysis: Liver microsomes catalyze 5-FU formation from 5′-DFUR at rates of 10.0 to 160.1 pmol/min per mg protein. These findings correlate well with CYP2A6-dependent coumarin 7-hydroxylase activity. The rates of microsomal 5-FU formation from FT range between 44.9 to 808.3 pmol/min per mg protein and correlate with coumarin 7-hydroxylase activity. The cytosol fractions catalyze 5-FU formation from 5′-DFUR at rates of 3,164.6 to 6,026.6 pmol/min per mg protein, or almost 2 orders of magnitude higher than the rates of cytosolic 5-FU formation from FT (46.8–219.0 pmol/min per mg protein). The cytosolic enzymes in hepatic tissue appears to be important for 5-FU formation from 5′-DFUR. Both cytosolic and microsomal enzymes are involved almost equally in 5-FU formation from FT. The increased formation of 5-FU from 5′-DFUR might provide an answer to the question of why similar blood 5-FU levels are retained despite lower blood levels of 5′-DFUR compared to FT concentrations.

Cytosolic and microsomal activation of doxifluridine and tegafur to produce 5-fluorouracil in human liver. Ozawa S, Hamada M, Murayama N, Nakajima Y, Kaniwa N, Matsumoto Y, Fukuoka M, Sawada J, Ohno Y. Cancer Chemother Pharmacol 2002 Dec; 50 (6), pp. 454–8.

HEMATOPOIETIC: LYMPHOCYTES (*EX VIVO*)

Autoimmune: Systemic Lupus Erythematosis (SLE)/Monocyte Interleukin (IL)-10 and IL-12/Lymphocyte (CD8+) Poststimulation Interferon-Gamma (IFN-γ) and Tumor Necrosis Factor-Alpha (TNF-α)

Monocyte Activation/Lymphocyte Activation

Application: Detection and characterization of SLE.

Route of Administration: Immersion (*in vitro* tissue culture environment).

Implementation: Determination of the profiles for Th1-type and Th2-type cytokines produced by mononuclear cells in conditions of recent-onset SLE, prior to the initiation of treatment with corticosteroids. One approach to achieving this objective is the application of radioimmunoassay for the measurement of IL-4, IL-10, IL-12 p40, TNF-α, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF) released into the culture supernatants of various unstimulated and stimulated blood mononuclear cell populations.

Human Model: Cases of SLE (n = 10) assessed for comparison to matched healthy controls studied in parallel (n = 10).

Interpretation and Analysis: In early SLE, monocyte-enriched cells constitutively produce increased amounts of IL-10 and decreased amounts of IL-12 following stimulation. Lymphocyte-enriched cells in SLE produce decreased amounts of IFN-γ and TNF-α following stimulation. In "rested" cells, these defects are accentuated and a defect in IL-12 production has been suggested. Depletion studies suggest that CD8+ cells are a major source of TNF-α and IFN-α in controls, but not in SLE patients.

Increased IL-4 production or abnormalities in GM-CSF production cannot be appreciated. Therefore, in this context, even early in the course of SLE, monocyte production of IL-10 is increased and IL-12 production is decreased. Decreased production of Th1-type cytokines in SLE may be secondary to this imbalance between IL-10 and IL-12. A contributory role of dysfunctional CD8+ cells has therefore been suggested.

Decreased production of interleukin-12 and other Th1-type cytokines in patients with recent-onset systemic lupus erythematosus. Horwitz DA, Gray JD, Behrendsen SC, Kubin M, Rengaraju M, Ohtsuka K, Trinchieri G. Arthritis Rheum 1998 May; 41 (5), pp. 838–44.

Immune Hypersensitivity: Severe Atopy (Helper T-Lymphocytes)/Aeroallergen-Specific T-Helper IL-4 and IL-5 Synthesis/Peripheral Blood Mononuclear Cell Proliferation

Beclomethazone/Hydrocortisone/Mometasone/Phytohemagglutinin

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit protein synthesis, stabilize cell membranes, and inhibit phospholipase A2 biochemical activity.

Background Information: Glucocorticoids play an important role in the treatment of allergic disease. The atopic process, itself, may reduce the response of peripheral blood mononuclear cells (PBMC) to these drugs.

Application: Characterization of severe atopy conditions as a function of differential alterations in PBMC proliferation rate and aeroallergen-specific T-helper type 2 cell (Th2) synthesis/release of IL-4 and IL-5 induced by exposure to hydrocortisone (HC), beclomethasone (BDP), and mometasone (MF) (profile of submaximal response in cells from severely affected cases).

Implementation: Evaluation of the relative influence of hydrocortisone (HC), beclomethasone (BDP), and mometasone (MF) on IL-4 and IL-5 secretion by aeroallergen-specific T-helper type 2 cells (Th2) and proliferation of peripheral blood mononuclear cells (PBMC) isolated from cases suffering from conditions of atopy. Isolated cell populations are incubated with steroid agents before stimulation with phytohemagglutinin subsequently followed by assessment of PBMC proliferation and cytokine secretion (Type Th2).

Interpretation and Analysis: Glucocorticoids concentrations as expected inhibit proliferation and cytokine secretion, but have less of an effect on the proliferation of cells from severe atopic cases than on cells from those whose symptoms require little treatment. The rank order of potency is MF (average IC50 0.01 nM) > BDP (4.0 nM) > HC (250 nM). Glucocorticoids are however, able to inhibit IL-4 and IL-5 secretion by human Th2-like cells and proliferation of PBMC from severely and mildly allergic donors.

Glucocorticoids inhibit proliferation and interleukin-*4* and interleukin-5 secretion by aeroallergen-specific T-helper type 2 cell lines. Crocker IC, Church MK, Newton S, Townley RG. Ann Allergy Asthma Immunol 1998 Jun; 80 (6), pp. 509–16.

Lymphocyte Function/Lymphocyte Stimulation Tests

Concanavalin-A/Phytohemaglutinin/Pokeweed Mitogen

Cellular/Molecular Mechanism of Action: Concanavalin-A (Con-A) and phytohemaglutinin are plant lectins that recognize and bind to specific membrane-associated receptor complexes expressed by T-lymphocyte populations. In this context, they promote T-lymphocyte stimulation in most mammalian species. Alternatively pokeweed mitogen stimulates both T and B cells to undergo blastogenic responses.

Application: Evaluation of lymphocyte-mediated immune function.
Route of Administration: Direct incubation with *ex vivo* hematological preparations or isolated (purified/enriched) lymphocyte populations.
Considerations: Lymphocyte proliferative responses are enhanced by exposure to certain proteases and indomethocin.

Stains have been developed to detect or identify the enzymes, acid phosphatase, β-glucuronidase and acid α-naphthyl that can be used as biochemical marker systems to recognize T-cell populations.

Lymphocyte Function: Skin Test/Organochlorine Exposure/[Gender Differences]
Tetanus Toxoid/Diptheria Toxoid/Candida/ Tricophyton/Streptococcus/Proteus/ Phytohemaglutinin/Concanavalin A (Con-A)/ Pokeweed Mitogen

Background Information: Previous studies of gender differences in response to the Multitest CMI skin test have produced conflicting results.
Application: To determine whether gender is associated with response to the Multitest CMI skin test.
Implementation: Evaluation of immune function applying the Multitest CMI skin test. Six of 7 antigens are tested: tetanus toxoid, diphtheria toxoid, Candida, Tricophyton, Streptococcus, and Proteus (excluding tuberculin antigen). Lymphocyte function can also be evaluated *in vitro* using standardized methods of mitogen stimulation with phytohemaglutinin (PHA), concanavalin A (Con-A), and pokeweed mitogen.

Human Model: Cases living near a hazardous waste sites containing organochlorine pesticides (n = 297 adults [age = 18 to 64 years]).
Interpretation and Analysis: The frequency of positive responses to the skin tests is significantly ($p < 0.001$) higher among males (80.4%) than among females (55.7%). Males are more likely than females to respond to all 6 test antigens ($p < .05$). The mean diameter of positive skin test measurements for males significantly ($p < 0.05$) exceeds female responses for tetanus and diphtheria. Although not statistically significant, male response size exceeds that of females for all other antigens except Trycophyton. Controlling for age, race, smoking, and income, plasma DDE levels do not change these results. Skin test positivity is not associated with mitogen stimulation assay results overall or within gender groups. Significant gender differences in response to the Multitest CMI skin test could limit its use as a marker of anergy in general population studies.

Gender differences in response to the multitest CMI skin test in the general population. Vine MF, Stein L, Weigle K. Ann Allergy Asthma Immunol 2000 Apr; 84 (4), pp. 445–50.

HEMATOPOIETIC: MACROPHAGES AND MONOCYTES (*EX VIVO*)

Autoimmune: Rheumatoid Arthritis (Macrophages)/Matrix Metalloprotease Protein 3 (MMP-3)
Corticosteroids

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit phospholipase A2 biochemical activity.
Physiological Mechanism of Action: Corticosteroids exert anti-inflammatory and immunosuppressive properties presumably due to their ability to generally suppress protein synthesis and stabilize cellular membrane structures, which reduces the ability of leukocytes to degranulate following activation/stimulation.
Application: Delineation of potential relationships between rheumatoid arthritis (RA), expression profiles for interleukins (IL), metalloproteases (MMP), and corticosteroid production.
Implementation: Evaluate expression profiles for IL-1β, tumor necrosis factor-alpha (TNF-α), IL-6, IL-4, IL-10, MMP-1, MMP-3, and MMP-13 in freshly isolated peripheral blood (PBMC) and synovial fluid mononuclear cells (SFMC) in early RA (never-treated [ENT-RA] vs non-acute, treated rheumatoid arthritis [NAT-RA]). Characterization of expression profiles entails the application of ELISA and quantitative and semi-quantitative RT-PCR/analyses.

Human Model: Cases suffering from early RA (n = 14; n = 7/14 early RA [< 1 year of evolution] never treated with corticosteroids or disease-modifying antirheumatic drugs, and n = 7/14 non-acute RA [> 2 years of evolution] treated with disease-modifying antirheumatic drugs). Reference controls: A group of 14 healthy subjects matched for sex and age.
Interpretation and Analysis: Statistically significant differences in the protein or transcript levels for the cytokines of interest cannot be appreciated between ENT-RA and NAT-RA case groups. The cytokine mRNA expression by freshly isolated PBMC and SFMC in both case types is IL-1β > TNFα > IL-10 > IL-6, with no mRNA IL-4 expression. In contrast, cytokine serum levels in ENT-RA and NAT-RA patients exist in an inverse order of IL-6 > IL-10, while IL-1β, TNF-α, and IL-4 are usually undetectable. MMP-3 mRNA expression by the PBMC of NAT-RA patients is statistically different to that in ENT-RA patients. Similar levels of mRNA expression of MMP-1, MMP-3, and MMP-13 by the PBMC and SFMC in both RA groups can be appreciated. A close equilibrium between MMP and pro-/anti-inflammatory cytokine production is observed in ENT-RA and NAT-RA patients. This balance is apparently not influenced by duration of disease. Highly sensitive methods such as quantitative RT-PCR and ELISA, and even studying freshly isolated MC, show sustained cytokine secretion at the local level (synovial fluid/SFMC) and scarce translation at the peripheral level (serum/PBMC). Expression of MMP mRNA needs to be further evaluated in order to determine whether their peripheral expression reflects their local activity in RA patients.

Expression of interleukin-1 beta, tumor necrosis factor-alpha, interleukins-6, -10 and -4, and metalloproteases by freshly isolated mononuclear cells from early never-treated and non-acute treated rheumatoid arthritis patients. Vázquez-Del Mercado M, Delgado-Rizo V, Muñoz-Valle JF, Orozco-Alcalá J, Volk HD, Armendáriz-Borunda J. Clin Exp Rheumatol 1999 Sep–Oct; 17 (5), pp. 575–83.

Autoimmune: Systemic Lupus Erythematosis (SLE)/Monocyte Interleukin (IL)-10 and IL-12/ Lymphocyte (CD8+) Poststimulation Interferon-Gamma (IFN-γ) and Tumor Necrosis Factor-Alpha (TNF-α)
Monocyte Activation/Lymphocyte Activation

Application: Detection and characterization of SLE.
Route of Administration: Immersion (*in vitro* tissue culture environment).
Implementation: Determination of the profiles for Th1-type and Th2-type cytokines produced by mononuclear cells in conditions of recent-onset SLE, prior to the initiation of treatment with corticosteroids. Such an objective can be achieved through radioimmunoassay of IL-4, IL-10, IL-12 p40, TNF-α, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF) released into

the culture supernatants of various unstimulated and stimulated blood mononuclear cell populations

Human Model: Cases of SLE (n = 10) assessed in comparison to matched healthy controls studied in parallel (n = 10).

Interpretation and Analysis: In early SLE, monocyte-enriched cells constitutively produce increased amounts of IL-10 and decreased amounts of IL-12 following stimulation. Lymphocyte-enriched cells in SLE produce decreased amounts of IFN-γ and TNF-α following stimulation. In "rested" cells, these defects are accentuated due to an apparent abnormality in IL-12 production. Depletion studies suggest that CD8+ cells are a major source of TNF-α and IFN-γ in controls, but not in SLE patients.

Increased IL-4 production or abnormalities in GM-CSF production cannot be appreciated. Therefore, in this context, even early in the course of SLE, monocyte production of IL-10 is increased and IL-12 production is decreased. Decreased production of Th1-type cytokines in SLE may be secondary to this imbalance between IL-10 and IL-12. A contributory role of dysfunctional CD8+ cells has been suggested.

Decreased production of interleukin-12 and other Th1-type cytokines in patients with recent-onset systemic lupus erythematosus. Horwitz DA, Gray JD, Behrendsen SC, Kubin M, Rengaraju M, Ohtsuka K, Trinchieri G. Arthritis Rheum 1998 May; 41 (5), pp. 838–44.

Immune Hypersensitivity (Asthma)/Septic Inflammatory Responses Macrophages (Alveolar)/ Molecular Pathogenesis of Inflammatory Responses in Asthma and Sepis
Lipopolysaccharide (LPS)

Cellular/Molecular Mechanism of Action: Lipopolysaccharide is also referred to as bacterial endotoxin and is a structural component of cell-wall structures. Systemically, it can bind to lipopolysaccharide-binding protein and membrane-associated LPS receptor complexes (CD14).

Physiological Mechanism of Action: Bacterial lipopolysaccharide fractions (LPS, endotoxin) promote inflammatory responses in primarily leukocyte and endothelial cell populations.

Background Information: Inflammation in asthma is characterized by a Th2 response. In many experimental systems, this response can be regulated by interleukin (IL)-10 and IL-12. IL-10 deactivates T cells, and IL-12 reorients the response toward a Th1 pattern. Alveolar macrophages (AMs) can secrete both of these cytokines, and thus regulate T-cell behavior in asthma. They can enhance the Th2 response by turning off their secretion of IL-10 and IL-12, or tend to downregulate it by producing these cytokines.

Application: Delineate the molecular-pathogenesis of immune responses and septic inflammatory reactions in addition functioning as a model agent for evaluating the potential efficacy of anti-inflammatory and immunosuppressive agents.

Implementation: Evaluate IL-10 and IL-12 production in AM populations. In this context, alveolar macrophages are recovered by bronchoalveolar lavage (BAL) from the lung. They are isolated and cultured for 24 hours without stimulation or in the presence of lipopolysaccharide (LPS) fractions. Assays are then performed for the measurement of IL-10 and the p40 subunit of IL-12 in BAL fluid samples and in alveolar macrophage (AM) culture supernatants by ELISA.

Human Model: Cases of adult asthma (n = 11; n = 4 normal healthy controls; n = 6 asthmatics treated with inhaled corticosteroids).

Interpretation and Analysis: Spontaneous AM IL-10 production is higher in asthmatics, particularly in treated cases. Alveolar macrophage IL-10 production after LPS stimulation is also elevated in asthmatics, but mainly so in untreated cases. Levels of IL-12 are higher in BAL fluids from untreated cases than healthy reference controls. The production of IL-12 in LPS-stimulated alveolar macrophages from such cases is increased. Alveolar macrophages are at least primed for the production of IL-10 and IL-12 in asthma. Such phenomenon suggests that these cells could be instrumental in the resolution of asthmatic-associated inflammatory processes.

Alveolar macrophage interleukin (IL)-10 and IL-12 production in atopic asthma. Magnan A, van Pee D, Bongrand P, Vervloet D. Allergy 1998 Nov; 53 (11), pp. 1092–5.

Immune Hypersensitivity: Severe Atopy/Peripheral Blood Mononuclear Cell (PBMC) Proliferation/ Helper T-Lymphocytes/Aeroallergen-Specific T-Helper IL-4 and IL-5 Synthesis
Mometasone/Beclomethazone/Hydrocortisone

Cellular/Molecular Mechanism of Action: Corticosteroids inhibit protein synthesis, stabilize cell membranes, and inhibit phospholipase A2 biochemical activity.

Background Information: Glucocorticoids play an important role in the treatment of allergic disease. The atopic process, itself, may reduce the response of PBMCs to this class of pharmaceuticals.

Application: Delineate differential alterations in PBMC proliferation rate and aeroallergen-specific T-helper type 2 cell (Th2) synthesis/release of IL-4 and IL-5 induced by exposure to hydrocortisone (HC), beclomethasone (BDP), and mometasone (MF) that can potentially be applied to identify cases suffering from severe atopy (submaximal response in cells from severely affected cases).

Implementation: Evaluation of the relative influence of hydrocortisone (HC), beclomethasone (BDP), and mometasone (MF) on IL-4 and IL-5 secretion by aeroallergen-specific T-helper type 2 cells (Th2) and proliferation of PBMCs isolated from cases suffering from conditions of atopy. Isolated cell populations are incubated with steroid agents before stimulation with phytohemagglutinin and assessment of proliferation (PBMC) and cytokine secretion (Th2).

Interpretation and Analysis: Glucocorticoids as expected inhibit proliferation and cytokine secretion, but have less of an effect on proliferation of cells from severe atopics than on cells from those whose symptoms require little treatment. The rank order of potency is MF (average IC50 0.01 nM) > BDP (4.0 nM) > HC (250 nM). Glucocorticoids are however, able to inhibit IL-4 and IL-5 secretion by human Th2-like cells and the proliferation of PBMC from severely and mildly allergic donors.

Glucocorticoids inhibit proliferation and interleukin-4 and interleukin-5 secretion by aeroallergen-specific T-helper type 2 cell lines. Crocker IC, Church MK, Newton S, Townley RG. Ann Allergy Asthma Immunol 1998 Jun; 80 (6), pp. 509–16.

Inflammatory Response: Monocyte Function
Pneumolysin/(mRNA/cDNA Microarrays)

Cellular/Molecular Mechanism of Action: Pneumolysin is an important virulence factor of *Streptococcus pneumoniae* that physically interacts with the external membrane of host cells.

Physiological Mechanism of Action: Pneumolysin elicits a multitude of inflammatory responses.

Application: Detection of alterations in monocyte cell function.

Route of Administration: Incubated with (human) monocyte cell populations *in vitro* in a tissue culture environment.

Methodology and Techniques: The THP-1 human monocytic cell line is co-incubated for 3 hours in medium alone, with the

virulent type-2 S. pneumoniae strain D39, or with the isogenic strain PLN, which does not express pneumolysin. Extracts of RNA are isolated from the monocytes and hybridized on cDNA microarray platforms.

Interpretation and Analysis: Approximately 142 gene sequences (total screened = 4,133) have been found to be responsive in a pneumolysin-dependent fashion, whereas 40 have been found to be responsive independent of pneumolysin. Genes that are upregulated in cells exposed to D39 relative to those exposed to PLN include genes encoding proteins such as mannose binding lectin 1, lysozyme, alpha-1 catenin, cadherin 17, caspases 4 and 6, macrophage inflammatory protein 1beta (MIP-1β), interleukin (IL)-8, monocyte chemotactic protein 3 (MCP-3), IL-2 receptor beta (IL-2Rβ), IL-15 receptor alpha (IL-15Rα), interferon receptor 2, and prostaglandin E synthase. Downregulated genes included those encoding complement component receptor 2/CD21, platelet-activating factor acetylhydrolase, and oxidized low-density lipoprotein receptor 1 (OLR1). Pneumolysin-independent responses include down-regulation of the genes encoding CD68, CD53, CD24, transforming growth factor β_2, and signal transducers and activators of transcription 1.

Pneumolysin-dependent and -independent gene expression identified by cDNA microarray analysis of THP-1 human mononuclear cells stimulated by Streptococcus pneumoniae. Rogers PD, Thornton J, Barker KS, McDaniel DO, Sacks GS, Swiatlo E, McDaniel LS. Infect Immun 2003 Apr; 71 (4), pp. 2087–94.

Neoplasia: Acute Myeloid Leukemia (AML; Bone Marrow Samples)
Chemiluminescent Stain

Application: Determine the monocytic component of FAB-M4 and FAB-M5 and distinguish these AML categories.

Background Information: Classically, the monocytic component of acute myelomonocytic (FAB-M4) and acute monocytic/monoblastic (FAB-M5) leukemias is demonstrated by positive nonspecific detection of esterases applying cytochemical staining reagents. Non-specific esterases from normal monocytes can be determined appling chemiluminescent-based methodologies. Similar techniques can be applied to distinguish unique aspects of AML.

Laboratory Methodologies: Bone marrow samples are processed to obtain cell populations that are incubated with a standard reaction mixture and chemiluminescence is measured for 10 min. Two parameters are assessed including peak (PLE) and the integrated light emission (ILE).

Interpretation and Analysis: In bone marrow samples obtained from patients with acute myeloid leukemia (n = 66), both PLE and ILE values are higher in FAB-M4 and FAB-M5 subtypes compared to other acute myeloid leukemia subtypes ($p < 0.001$). In addition, the classification of AML cases into FAB-M4, FAB-M5 and nonmonocytic subtypes based on ILE analysis correlates with alpha-naphthyl acetate esterase (ANAE) activity in cases of acute myeloid leukemia (97%, kappa coefficient 0.94, $p < 0.001$). Based on these findings, the chemiluminescent assay can be applied to determine the monocytic component of FAB-M4 and FAB-M5 cells, and the classification of acute myeloid leukemia subtypes based on chemiluminescent analysis which strongly agrees with cytochemical ANAE-staining. In conclusion, this chemiluminescent assay is a simple, fast and objective method, which may be useful as an alternative tool in establishing an accurate differential diagnosis of acute myeloid leukemia.

Assessment of monocytic component in acute myelomonocytic and monocytic/monoblastic leukemias by a chemiluminescent assay. da Fonseca LM, Brunetti IL, Campa A, Catalani LH, Calado RT, Falcao RP. Hematol J 2003; 4 (1), pp. 26–30.

Oxidative Stress/Peroxidation of Lipid Membranes/ Prostaglandin/Thromboxane Metabolism/ Thiobarbituric Acid Reactive Substances
Thiobarbituric Acid/Malondialdehyde (MDA)/(Aspirin)

Cellular/Molecular Mechanism of Action: Thiobarbituric acid at a low pH and high temperatures reacts with MDA, producing a molecular product that can be detected spectrophotometrically.

Background Information: Malondialdehyde is a metabolic byproduct of lipid membrane peroxidation and the generation of prostaglandin species. The MDA assay is the most generally used test for characterizing the role of oxidative stress in disease. Malondialdehyde is 1 of several products formed during the radical induced decomposition of polyunsaturated fatty acids.

Application: Detection and evaluation of oxidative stress status as a function of lipid membrane peroxidation and prostaglandin synthesis. In this context, it can be applied to evaluate the efficacy of pharmaceutical agents (e.g., non-steroidal anti-inflammatory drugs [NSAIDs]), detect tissue peroxidation, and recognize the entry of new platelet populations into the systemic circulation.

Route of Administration: *Ex vivo* (topical).

Considerations: At present, the concept of "thiobarbituric acid reactive substances" (TBARS) has merged and progressively replaced the initial MDA assay.

Assay Procedure: The MDA assay is based on its reactivity at high temperature and low pH toward thiobarbituric acid. This reaction is very sensitive but its specificity, even with improvement of preanalytical (sampling, preservatives) and analytical stages (fluorescence, high-performance liquid chromatography [HPLC]), is still a matter of debate. Example: After stimulation of the washed human blood platelets by arachidonic acid (AA), the formation of malondialdehyde (MDA) measured using the photometric thiobarbituric acid (TBA) method. Estimation of platelet lipid peroxidation as a function of MDA production, and the formation of thromboxane B2 (TXB_2) measured by gas chromatography, may reveal that the formed MDA exceeds the amount of TXB_2 on a molar base. However, MDA and TXB_2 originating from thromboxane synthase activity should be produced in approximately equimolar amounts. By treatment of stimulated platelet samples with stannous chloride it is possible to reduce all peroxidized products of AA that generate MDA otherwise during the TBA reaction and to estimate MDA and TXB_2 in a ratio of nearly 1:1. The stannous chloride treatment does not destroy the MDA and does not influence the TBA reaction with MDA. Therefore the simple and quick TBA method can be used after stannous chloride treatment for estimation of thromboxane synthase activity in AA-stimulated washed human platelets.

Interpretation and Analysis: In the future, oxidative stress appreciation will need the precise analytical determination of different molecules triggered by free radicals. The TBARS assay should be considered as a global test, allowing a global approach of lipoperoxidation, whereas specific determination of MDA can only appreciate 1 of the end-product formed during oxidative stress.

Laboratory Instrumentation: Inhibition of platelet PGI_2 synthesis by NSAIDS is detected by direct assay of PGI_2 applying RIA or ELISA methodologies. Alternatively, inhibited platelet PGI_2 synthesis can be detected by measurement of relative MDA production

applying thiobarbituric acid and measuring spectrophotometric absorbance at 625 nm or HPLC analysis.

An improved malondialdehyde assay for estimation of thromboxane synthase activity in washed human blood platelets. Panse M, Block HU, Förster W, Mest HJ. Prostaglandins 1985 Dec; 30 (6), pp. 1031–40.

Phagocytic Activity/Macrophage Function: Reticuloendothelial System
Nanoparticles: Copolymer Non-Ionic Surfactants/ Polyoxypropylene and Polyoxyethylene

Background Information: A frequently observed but ignored phenomenon following intravenous injection of such polymer-modified long-circulating colloidal systems is their eventual recognition and clearance by macrophages of the reticuloendothelial system.
Application: Nanoparticles composed of polyoxypropylene and polyoxyethylene copolymer non-ionic surfactants can be applied to detect and characterize the function of macrophage populations.
Route of Administration: Intravascular.
Implementation: Evaluation of the design, handling, and biological assessment of long-circulating nanoparticles composed of polyoxypropylene and polyoxyethylene copolymer non-ionic surfactants. Nanoparticles produced in this fashion are recognized by macrophage populations.
Interpretation and Analysis: The pharmacokinetics as well as the tissue distribution of such so-called "stealth" nanoparticles are altered after repeated intravenous injection in a time-dependent manner. An understanding of immunological and pathological factors that control the pharmacokinetic and biological behavior of long-circulating particles after single or repeated administration is therefore crucial for the design of a system with an optimal diagnostic and/or therapeutic performance.

Capture of stealth nanoparticles by the body's defenses. Moghimi SM, Hunter AC. Crit Rev Ther Drug Carrier Syst 2001; 18 (6), pp. 527–50.

Phagocytic/Phagocytic Killing Index: Macrophages/Neutrophils/Macrophage and Neutrophil Phagocytic Effectiveness
Candida albicans/Staphylococcus aureus

Application: Detection of abnormalities in the ability of neutrophils and macrophages to either phagocytize or kill phagocytized pathogens.
Methodology: Enriched neutrophil and macrophage populations are obtained 1st as a leukocyte buffy coat layer following the centrifugation of fresh whole blood. Separation of cell types can be achieved with the application of density gradient media (e.g., Percoll) used in combination with centrifugation. Because a given cell type (e.g., neutrophil) has different densities across different species, a literature review and preliminary tests in the laboratory are required in order to identify the optimum specific gravity at which density gradient medias should be formulated. Usually, a mononuclear cell layer is formed at the plasma/density gradient media interface and contains a combination of monocytes and lymphocytes. Monocyte-derived macrophages are separated from lymphocytes by their ability to adhere to tissue culture flasks (3–12 hours at 37°C, CO_2 5%). The 2nd layer formed is an enriched population of neutrophils that is visualized either mid-level within the density gradient media or on the surface of the red blood cell layer, depending on the specific gravity of density gradient preparations.

Purified cell populations are then separately incubated with suspensions of both non-viable and viable *Candida albicans* populations. The phagocytic index is approximated by calculating the number of cells that have phagocytized Candida organisms and the total number of organisms located intracellularly within each cell. In addition, the phagocytic killing index is calculated as a ratio of the number of total viable organisms phagocytized compared to the number of living *Candida albicans* that have been successfully killed intracellularly. Differential staining techniques are applied to detect viable and non-viable phagocitized Candida organism.
Interpretation and Analysis: Decreases in the phagocytic index imply phagocytic function is suboptimal, while declines in the phagocytic killing index indicate that following the internalization of pathogens, there is an inability to kill such organisms due to lack of phagosome/lysosome formation (e.g., phagolysosome) or the contents of the lysosome are unable to directly inactivate phagocytized bacterial/fungal organisms.

Example: Phagocytosis of *Rhodococcus equi* organisms by equine foal neutrophils is less than that observed for adult neutrophils when autologous serum is used as the source of opsonins in the assay. The use of adult serum does not significantly improve the ability of foal neutrophils to attach bacteria.

A comparison of foal and adult horse neutrophil function using flow cytometric techniques. McTaggart C, Yovich JV, Penhale J, Raidal SL. Res Vet Sci 2001 Aug; 71 (1), pp. 73–9.

Respiratory/Oxidative Burst Potential (Macrophage/Neutrophil)
Nitroblue Tetrazolium (NBT)/Sulfonated Tetrazolium Salt (WST-1)

Cellular/Molecular Mechanism of Action: Neutrophil respiratory burst activity can be detected in histiological samples through the application of the tetrazolium salt, nitroblue tetrazolium, which is reduced intracellularly to an insoluble formazan by superoxide generated by NADPH oxidase. The water-soluble sulfonated tetrazolium salt, WST-1 produces a soluble formazan that can be detected by a simple colorimetric assay for measuring respiratory burst activation and for screening anti-inflammatory agents.
Application: Detection and characterization of leukocyte oxidative burst activity as a function of cell viability and capacity to resolve phagacytized pathogens.
Methodology: Nitroblue tetrazolium (NBT) dye reduction assay.
Considerations: Activation of the respiratory burst of granulocytes and macrophages by invading microorganisms is a key 1st-line of cellular defense against infection. Failure to generate this response leads to persistent life-threatening infection unless appropriate antibiotic treatment is given. Respiratory burst activity in neutrophils is often measured spectrophotometrically following ferricytochrome-C reduction. In tissue or cell preparations, it is detected by the intracellular reduction of the tetrazolium salt, nitroblue tetrazolium to an insoluble formazan crystal. In both assay systems, reduction is mediated by superoxide generated via NADPH oxidase. Because ferricytochrome-C has a high molecular mass and high background absorbance at 550 nm, the assay lacks sensitivity and is not ideally suited to microplate measurement.
Implementation: (i) In activated populations of human peripheral blood neutrophils, the reduction of WST-1 closely correlates

with ferricytochrome-C reduction across a range of PMA concentrations and with time of activation by PMA and *f*MLP. Reduction of WST-1 is inhibited 98% by superoxide dismutase (20 μg/ml); and 88% by the NADPH oxidase inhibitor, diphenyleneiodinium (10 μM). In contrast, WST-1 reduction is resistant to catalase, azide and the NADH oxidase inhibitor, resiniferatoxin. In comparison investigations, the relatively ability of WST-1 and ferricytochrome-C reduction have also been compared using xanthine/xanthine oxidase to generate superoxide. Under optimised assay conditions, both WST-1 and ferricytochrome-C reduction are directly proportional to the quantity of added xanthine. Approximately a 2-fold greater increase in absorbance can be appreciated with WST-1 generated absorbance measurements than is usually observed for absorbance values associated with ferricytochrome-C at their respective wavelengths. These findings imply a direct relationship to increased assay sensitivity. Addition of the intermediate electron acceptor, 1-methoxy phenazine methosulfate, increases the background of the neutrophil assay but does not affect the overall magnitude of the response. In this context, WST-1 based assays have been utilized as investigative tools to assess human neutrophil dysfunction and to compare anti-inflammatory activity (e.g., pharmaceutical therapy).

(ii) Neutrophil chemotaxis and oxidative burst activity has been used to evaluate the immune competence of workers occupationally exposed to mainly silica. Both types of neutrophil functions are significantly reduced in silica-exposed foundry and pottery workers ($p < 0.001$) compared to healthy controls subjects suggesting that chronic exposure mainly to silica and other chemicals originated from foundry and pottery settings may diminish neutrophil functions. Chemotatic function is measured in a Boyden chemotactic chamber using Zymosan-activated serum as a chemotactic preparation. Oxidative burst activity can be measured using a conventional nitroblue tetrazolium (NBT) dye reduction test (2-hour incubation period).

Interpretation and Analysis: The limitation of tetrazolium-based assays can be minimized or eliminated by using a cell-impermeable, WST-1, which exhibits very low background absorbance and is efficiently reduced by superoxide to a stable water-soluble formazan with high molar absorptivity. Improvements provided by this particular reagent have permitted the adaption of the WST-1 assay to a microplate format while still retaining optimum levels of sensitivity.

Declines in oxidative burst activity implies that a given leukocyte cell type has been compromised or incapable of creating a lethal effect on phagocytized pathogens.

Example Application: In cows with subclinical mastitis caused by *Staphylococcus aureus*, the oxidative burst assay has been utilized to analyze whole blood and fresh milk samples and determine the effectiveness of certain therapeutic strategies.

Instrumentation: Spectrophotometer (530 nm, 570 nm or 590 nm).

HEMATOPOIETIC: NEUTROPHILS (*EX VIVO*)

Adherence: Neutrophil Function/Neutrophil Tissue Infiltration
o-Dianisidine Dihydrochloride/(Myeloperoxidase)

Application: Detection of neutrophils using myeloperoxidase production as a biochemical identification marker. Indirectly can possibly be applied as a vitality marker system due to the relatively short intravascular survival time for neutrophils.

Example Application: The antioxidant system is the primary intracellular defense system of the lung against oxygen toxicity (neutrophil sequestration). One of the major biochemical entities associated with neutrophil function is myeloperoxidase found within cytoplasmic granules. Quantitation of the amount of biochemical activity of this enzyme therefore directly correlates with the degree or extent of neutrophil infiltration within extravascular organ systems and serves as an indirect indicator of lung injury.

In a lamb model of an antioxidant deficient system involving the lung, it has been hypothesized that neutrophil sequestration may play a part in the acute lung injury associated with certain disease states (e.g., congenital diaphragmatic hernia). Preparation of tissue samples prior to performing myeloperoxidase assays involves en bloc dissection of the organ system of interest (e.g., lung) followed by "flash" freezing. Actual processing of tissues and their analysis involves homogenation, sonication, freeze-thawing, and separation of cell types utilizing density gradient media combined with centrifugation. Supernatants are analyzed for myeloperoxidase activity by spectrophotometry with *o*-dianisidine dihydrochloride and hydrogen peroxide at 460 nm. Myeloperoxidase activity is normalized to the protein content/concentration within the supernatant (myeloperoxidase activity/mg protein). In the lamb model for congenital diaphragmatic hernia, myeloperoxidase activity can be found to be significantly higher in ventilated-affected animals than in ventilated-negative controls ($3{,}203 \pm 665$ vs $1{,}220 \pm 194$, $p = 0.001$). Laboratory findings suggest that ventilation and hyperoxia leads to neutrophil accumulation in lung tissue, which is most pronounced in congenital diaphragmatic hernia lung tissue. Such discoveries have provided greater understanding about the pathophysiology of iatrogenic lung injury associated with congenital diaphragmatic hernia. In this context, the myeloperoxidase assay can be used to evaluate antenatal or postnatal antioxidant therapies for iatrogenic lung injury.

In equine studies, flow cytometric assays have been used to compare phagocytic and oxidative burst activity of neutrophils from healthy neonatal foals and adult horses. During the course of these investigations oxidative burst activity of foal neutrophils has been found to be equivalent to that of adult cells. However, when serum or plasma is incorporated into the oxidative burst assay, foal neutrophils demonstrate greatly reduced autofluorescence and a suppressed response to phorbol myristate acetate (PMA), relative to that demonstrated by adult cells. These results suggest that peripheral blood neutrophils from foals have a reduced ability to phagocytose bacteria relative to that exhibited by adult horse neutrophils and that the oxidative burst activity of foal neutrophils is downregulated in response to an unidentified serum factor(s). Such changes may contribute to the increased susceptibility of foals to septic disease.

Methodology: Multi-well tissue culture plates (e.g., 96-well microtiter plate) are coated with fibrinectin (fibronectin [5 μg/ml]) in Hank's Buffered Saline Solution (pH 7.4) incubated with tissue plates overnight (4°C). During the isolation of neutrophils, the plate is washed 3 times (1 minute each) with Hank's solution (200 μl) followed by a 2-hour blocking procedure performed with Hank's

solution containing BSA (1% 250 μl). Fibronectin-coated wells are then rinsed 3 times (1 minute) with Hank's solution containing Tween (1%) followed by a single wash with Hank's solution (200 μl).

Isolated cell populations highly enriched with neutrophils (10^5 to 10^6 cells in 100 μl) are stimulated with either *f*MLP (2×10^{-6} M, final concentration 1×10^{-6}) or PMA (30 ng/ml, final concentration 15 ng/ml) and then incubated at 37°C for 15 minutes (CO_2 5%). A solution of Hanks solution containing bovine serum albumin (1%, 150 μl) is then added into each well and it is sealed with acetate tape. The plate is then centrifuged upside down at 1,200 rpm at 4°C for 5 minutes and the tape removed while the plate is still inverted. In order to detect and quantitatively measure the number of adherent neutrophils, a reaction mixture formulation (100 μl/well) containing *o*-dianisidine (*o*-dianisidine dihydrochloride [1 mM]; H_2O_2 [1 mM]; Triton X-100 [0.1%] in potassium phosphate buffer [100 mM, pH 6.0]) is then pipetted into each fibronective well. Following an incubation period of 30 mintues at 25°C and the spectrophotometric absorbance measured at a wavelength of 450 nm to 460 nm, either Hank's solution with BSA (1%) or cell suspension (100 μl) can be used to generate a standard curve.

Interpretation and Analysis: A direct relationship exists between the amount of myeloperoxidase measured in a tissue/cell sample and the number of neutrophils contained with such preparations.

A comparison of foal and adult horse neutrophil function using flow cytometric techniques. McTaggart C, Yovich JV, Penhale J, Raidal SL. Res Vet Sci 2001 Aug; 71 (1), pp. 73–9.

Myeloperoxidase activity as a lung injury marker in the lamb model of congenital diaphragmatic hernia. McCabe AJ, Dowhy M, Holm BA, Glick PL. J Pediatr Surg 2001 Feb; 36 (2), pp. 334–7.

Chemotactic Activity: Neutrophil Function/Boyden Chemotactic Chamber
formyl-Met-Leu-Phe (fMLP)

Application: Evaluation of neutrophil chemotactic function.
Methodology: Freshly purified populations of neutrophils suspended in MEM growth media are transferred by pipette into individual wells of a Boyden chemotactic chamber. The chemotactic agent *f*MLP (10^{-6} M final concentration) is placed in the well on the opposite side of the membrane filter and the Boyden chamber is then incubated at 37°C for 90 minutes. Non-adherent cells are discarded and the remaining neutrophil population is incubated with 350 μl of calcium/magnesium-free phosphate-buffered saline (CMF-PBS) containing EDTA (20 mM). Following the harvest of this supernatant, this procedure is repeated again. Adherent neutrophils are detected by incubation with MTT vitality staining reagent (375 μl) previously formulated in serum free medium (60 ml/300 ml v/v). The preparations are then incubated at 37°C over a 4-hour period. Cell populations stained with MTT reagent are then destained with isopropyl alcohol (200 μl) at 25°C for 25 minutes with the aid of gently horizontal agitation on a horizontal plateform. The resulting blue/purple supernatant is harvested by pipette and transferred to a 96-well microtiter plate for measurement of spectrophometric absorbance (550nm).
Dosage: Chemotactic agent *f*MLP (10^{-6} M final concentration).
Interpretation and Analysis: Deminished chemotactic responses by neutrophils is an indiction of altered cellular function and may indicate a condition of a reduced ability to control septic disease states.
Instrumentation: Boyden chemotactic chamber and spectrophotometer capable of reading absorbance levels at 550 nm wavelength.

Chemotactic Activity: Neutrophil Function/[Respiratory Burst Activity]/[Bacterial Phagocytic Activity]
Interleukin (IL)-8/formyl-Met-Leu-Phe (fMLP)/Antithrombin/C5a/Protein C

Cellular/Molecular Mechanism of Action: The interleukin IL-8 promotes or functions as a neutrophil chemotactic agent.
Background Information: Activation of protein C by thrombin bound to thrombomodulin is enhanced by endothelial protein C receptor. This pathway may inhibit inflammation.
Implementation: Evaluate the influence of protein C and activated protein C on neutrophils, as well as determine the potential for endothelial protein C receptor to mediate protein C–mediated effects. Achievement of this objective can be determined by isolating neutrophils from venous whole blood. Cell migration, respiratory burst, phagocytic activity, and apoptosis are determined by micropore filter assay and fluorometry. Receptor expression can be delineated by reverse transcriptase-polymerase chain reaction (PCR) for mRNA, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), in combination with autoradiography of immunoprecipitated receptor protein, and fluorescence-activated cell-sorter scanner (FACS) analysis using the antiendothelial protein C receptor antibody RCR-252.

Human Model: Cases without any evidence of disease or physiological abnormalities.
Interpretation and Analysis: Neither protein C nor activated protein C induce migration, yet both agents inhibit neutrophil chemotaxis triggered by IL-8, *f*MLP, antithrombin, or C5a. A protein C activation-blocking antibody against endothelial protein C receptor diminishes inhibitory effects of protein C or activated protein C on migration. No effect of either protein C preparation can be appreciated in neutrophil's respiratory burst, bacterial phagocytosis, or apoptosis assays. Endothelial protein C receptor immunoreactivity can be confirmed on neutrophils by FACS. Reverse transcriptase PCR and immunoprecipitation SDS-PAGE analyses suggest the occurrence of de-novo synthesis of endothelial protein C receptor mRNA expression. Data suggest that an endothelial protein C receptor is expressed by human neutrophils whose active site ligation with either protein C or activated protein C results in arrested directional cell migration. Inhibitory effects of these components of the protein C pathway on neutrophil function may play a role in the protein C–based treatment of severe sepsis.

Expression and function of the endothelial protein C receptor in human neutrophils. Sturn DH, Kaneider NC, Feistritzer C, Djanani A, Fukudome K, Wiedermann CJ. Blood 2003 Aug 15; 102 (4), pp. 1499–505.

Chemotactic Activity: Neutrophil Function/Phagocytic Capacity/Super-Oxide Production/Adherence Characteristics
Interleukin (IL)-8/Phorbol Myristate Acetate

Background Information: Polymorphonuclear granulocyte (PMN) phagocytosis may be affected by many pathological changes.
Dosage (*Ex Vivo*): Interleukin-8 (25 ng/mL); phorbol myristate acetate (10^{-6} mol/L).
Implementation: Evaluation of neutrophil function applying a panel of tests requiring relatively small volumes of blood in order to

establish normal values and to standardize techniques. Utilizing discontinuous Percoll gradient media, PMNs are isolated from whole blood samples. Chemotaxis capacity is determined in a modified Boyden chamber using the leading front method. Phagocytic activity is evaluated by determining the rate of fluorescinated yeast uptake (slide format). Superoxide (SO) production and adherence is established within the wells of a microtitre plate.

Animal Model: Canine (n = 16 healthy dogs).

Interpretation and Analysis: Different aspects of phagocytosis show no correlation with 1 another. Better results can be obtained using a 60-minute incubation period and the application of IL-8 (25 ng/mL) as an activator for chemotaxis, and incubating plates for 30 minutes with phorbol myristate acetate (10^{-6} mol/L) to assess SO production.

Evaluation *in vitro* of canine neutrophil function. Comazzi S, Paltrinieri S, Spagnolo V, Sartorelli P. Vet J 2001 Nov; 162 (3), pp. 219–25.

Degradulation: Neutrophil Function
Complement (C5a)/Calium Ionophor (A23187)/formyl-Met-Leu-Phe (fMLP)/Phorbol Myristate Acetate (PMA)

Mechanisms of Action: (i) Selective induction of specific granule secretion can be achieved with concanavalin-A, phorbol myristate acetate, *f*MLP, and complement (C5a). (ii) Induced secretion of specific and azurophilic granules can be achieved with immune complexes and calcium ionophors (e.g., A23187), and lithium also is capable of promoting similar responses. (iii) Inhibition of degranulation events (possible microtubule disassembly) occurs in the presence of adenylate cyclase stimulation (e.g., β-adrenergic agonists and PGE_1). (iv) Promotion of degranulation events, by microtubule assembly, induction of cGMP synthesis/activation. (v) Lysosomal enzyme release induced by complement (C3a and C5a).

Application: Detection of conditions associated with neutrophil dysfunction.

Glycogen Storage Disease Type Ib (GSD-Ib)/ Neutrophil Respiratory Burst Activity/[Glucose-6-Phosphate Levels]
Phorbol Myristate Acetate (PMA)/Glucose

Background Information: Neutrophils from patients suffering from glycogen storage disease type Ib (GSD-Ib) show several defects, 1 of which is a decreased rate of glucose utilization.

Implementation: Evaluation of the stimulation of the neutrophil respiratory burst by extracellular glucose using phorbol-myristate-acetate as a stimulating agent.

Interpretation and Analysis: The activity of NADPH oxidase in GSD-Ib neutrophils hardly increases upon addition of glucose. In control and GSD-type Ia neutrophils, a clear increase can be observed. The lack of response to extracellular glucose in GSD-Ib neutrophils is correlated with an inability to raise intracellular glucose-6-P levels on glucose addition, thereby limiting the activity of the generation of NADPH in the hexose-monophosphate shunt. The test protocol can be applied for the diagnosis of neutrophil function abnormalities in GSD-Ib conditions.

A convenient diagnostic function test of peripheral blood neutrophils in glycogen storage disease type Ib. Verhoeven AJ, Visser G, van Zwieten R, Gruszczynska B, Tien Poll-The DW, Smit GP. Pediatr Res 1999 Jun; 45 (6), pp. 881–5.

Mononuclear/Neutrophil Phagocytosis (Opsonin Independent)
Fluorescent Polymethacrylic Nanoparticles

Cellular/Molecular Mechanism of Action: Fluorescent polymethacrylic nanoparticles are recognized by and intracellularly assimilated by mononuclear cells and neutrophils.

Application: Quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells. One possible application of the fluorescent nanoparticles is the simultaneous analysis of cell surface antigens and cell phagocytic activity.

Route of Administration: Intravascular or in the use of *ex vivo* cellular preparations.

Semi-Synthetic Methods: Preparation of the nanoparticles, by emulsion copolymerization of methacrylic monomers, and assessment of their physicochemical properties.

Implementation: Evaluation of fluorescent polymethacrylic nanoparticles (0.3 micron) as a flow cytometric reagent in the quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells. In this context, nanoparticles coupled with a fluorescent agent (ethidium bromide) can be used in flow cytometric assays to study opsonin-independent phagocytosis by human polymorphonuclear cells and by human monocytes. Phagocytosis of nanospheres by monocytes is determined by flow cytometry from the fluorescence distribution, while ingestion is visualized by scanning and transmission electron microscopy.

Instrumentation: Flow cytometry and scanning and transmission electron microscopy.

Flow cytometric quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells using fluorescent nanoparticles. Rolland A, Merdrignac G, Gouranton J, Bourel D, Le Verge R, Genetet B. J Immunol Methods 1987 Feb 11; 96 (2), pp. 185–93.

Phagocytic Activity: Neutrophil Function/ Superoxide (O_2^-) Synthetic Capacity/[Neutrophil Bendiazepine Receptors: Peripheral Type]
Diazepam-Binding Inhibitor-Derived Peptides/ Triakontatetraneuropeptide/Eiksoneuropeptide

Cellular/Molecular Mechanism of Action: Triakontatetraneuropeptide (DBI 17-50, TTN) and eiksoneuropeptide (DBI 51-70, ENP) are peptides that form a complex with and block diazepam binding sites.

Application: Triakontatetraneuropeptide (DBI 17-50, TTN) and eiksoneuropeptide (DBI 51-70, ENP) could potentially be applied to detect and characterize neutrophil chemotactic and phagocytic properties.

Implementation: Evaluation of neutrophil function based on changes in free [Ca^{2+}] cation concentrations [Ca^{2+}]; chemotaxis activity; superoxide anion (O_2^-) generation; and phagocytic activity. The 2 diazepam-binding inhibitor (DBI)-derived peptides, triakontatetraneuropeptide (DBI 17-50, TTN) and eiksoneuropeptide (DBI 51-70, ENP) can be applied as molecular probes for evaluating such neutrophil parameters.

Interpretation and Analysis: Both TTN and ENP induce a rapid and transient rise in [Ca^{2+}]i. The effect of TTN depends on the presence of extracellular [Ca^{2+}], whereas the effect of ENP also persists after extracellular [Ca^{2+}] chelation. TTN induces neutrophil chemotaxis, stimulated O_2^- generation, and enhanced phagocytosis. ENP does not affect cell migration or oxidative metabolism but does enhance phagocytosis. Both peptides modulate formyl-Met-Leu-Phe

(*f*MLP) and phorbol myristate acetate-induced O_2^- generation. Because neutrophils express benzodiazepine receptors of the peripheral type (pBRs) and DBI-derived peptides may interact with such receptors, investigations have characterized the possible role of pBRs in TTN- or ENP-induced effects. The synthetic pBR ligand RO 5-4864 increases $[Ca^{2+}]i$ through extracellular Ca^{2+} influx and this effect is prevented by the pBR antagonist PK-11195. RO 5-4864, however, has no effect on neutrophil migration or O_2^- generation and only slightly affects phagocytosis. Moreover, PK-11195 delays $[Ca^{2+}]i$ rises induced by TTN but does not significantly affect its extent, and has no effect on the $[Ca^{2+}]i$ rise induced by ENP. Therefore, it appears that DBI-derived peptides induce $[Ca^{2+}]i$ changes and modulate neutrophil function mainly through pBR-independent pathways. In view of the wide cell and tissue distribution of DBI in the brain and in peripheral organs, modulation of neutrophil function by DBI-derived peptides may be relevant for both the neuroimmune network and the development and regulation of the inflammatory processes.

Diazepam-binding inhibitor-derived peptides induce intracellular calcium changes and modulate human neutrophil function. Cosentino M, Marino F, Cattaneo S, Di Grazia L, Francioli C, Fietta AM, Lecchini S, Frigo G. J Leukoc Biol 2000 May; 67 (5), pp. 637–43.

Phagocytic/Phagocytic Killing Index: Neutrophils/Macrophages Neutrophil and Macrophage Phagocytic Effectiveness
Candida Albicans/Staphylococcus Aureus

Application: Detection of abnormalities in the ability of neutrophils and macrophages to either phagocytize or kill phagocytized pathogens.

Methodology: Enriched neutrophil and macrophage populations are obtained 1st as a leukocyte buffy coat layer following the centrifugation of fresh whole blood. Separation of cell types can be achieved with the application of density gradient media (e.g., Percoll) used in combination with centrifugation. Since a given cell type (e.g., neutrophil) has different densities across different species, a literature review and preliminary tests in the laboratory are required in order to identify the optimum specific gravity of the density gradient media required. Usually, a mononuclear cell layer is formed at the plasma/density gradient media interface and contains a combination of monocytes and lymphocytes. Monocyte-derived macrophages are separated from lymphocytes by their ability to adhere to tissue culture flasks (3–12 hours at 37°C, CO_2 5%). The 2nd layer formed is an enriched population of neutrophils that is visualized either mid-level within the density gradient media or on the surface of the red blood cell layer depending on the specific gravity of the preparation

Purified cell populations are then separately incubated with suspensions of both non-viable and viable Candida albicans preparations. The phagocytic index is approximated by calculating the number of cells that have phagocytized Candida organisms and the total number of organisms located intracellularly within each cell. In addition, the phagocytic killing index is calculated as a ratio of the number of total viable organisms phagocytized compared to the number of living Candidate albicans that have been successfully killed intracellularly.

Differential staining techniques are applied to detect viable and non-viable phagocitized Candida organism.

Interpretation and Analysis: Decreases in the phagocytic index imply phagocytic function is suboptimal, while declines in the phagocytic killing index indicate that following the internalization of pathogens, there is an inability to kill such organisms due to lack of phagosome/lysosome formation (e.g., phagolysosome) or the contents of the lysosome are unable to directly inactivate phagocytized bacterial/fungal organisms. Example: Phagocytosis of *Rhodococcus equi* organisms by foal neutrophils is less than that observed for adult neutrophils when autologous serum is used as the source of opsonins in the assay. The use of adult serum does not significantly improve the ability of foal neutrophils to attach bacteria.

A comparison of foal and adult horse neutrophil function using flow cytometric techniques. McTaggart C, Yovich JV, Penhale J, Raidal SL. Res Vet Sci 2001 Aug; 71 (1), pp. 73–9.

Respiratory/Oxidative Burst (Neutrophils/ Macrophages)
Nitroblue Tetrazolium (Tetrazolium Salt)

Cellular/Molecular Mechanism of Action: Respiratory burst activity can be monitored spectrophotometrically with enzyme-specific substrates that detect ferricytochrome-c reduction reactions, or histiologically through the application of nitroblue tetrazolium (reduced intracellularly to insoluable formazan crystals). Both substrates are reduced by superoxide generated by NADPH oxidase. Sulfonated tetazolium salts are reduced to a water-soluble formazan that has a high molar absorptivity.

Application: Detection of permanent deficiencies or transient dysfunctions in granulocyte and macrophage respiratory burst activity. Evaluation of such properties is important due to their intimate role in cellular defense mechanisms against invading microorganisms that can potentially cause overwhelming (life-threatening) infectious disease in situations where antibiotic therapy has not been initiated in a timely manner. The water-soluble characteristics of formazan (metabolized sulfonated tetrazolium salts or WST-1) and its very low background absorbance levels facilitate its adaptation to microtiter plate formats without loss of assay sensitivity.

Methodology: Biologically viable cell populations are incubated with the cell-impermeable, sulfonated *tetrazolium* salt (WST-1). This reagent exhibits very low background absorbance in a manner that allows adaptation of the WST-1 assay to microplate format with no sacrifice of sensitivity.

Reduction of WST-1 is inhibited (98%) by superoxide dismutase (20 μg/ml) and by the NADPH oxidase inhibitor, diphenyleneiodinium (88% for 10 μM). In contrast, the enzyme substrate is resistant to reduction activity in the presense of catalase, azide and the NADH oxidase inhibitor, resiniferatoxin. The sulfonated tetrazolium salt (WST-1) and ferricytochrome-c reductions have also been compared using xanthine/xanthine oxidase to generate superoxide. Under optimized assay conditions, both WST-1 and ferricytochrome-c reduction occurs in a manner directly proportional to the amount of added xanthine. A 2-fold greater level of absorbance is observed with WST-1 in contrast to ferricytochrome-c at their respective wavelengths. The implications of this result is that it reflects an increased level of assay sensitivity when applying this substrate reagent. Addition of the intermediate electron acceptor, 1-methoxy phenazine methosulfate, increases the background of the neutrophil assay but does not affect the overall magnitude of the response.

Considerations: Because ferricytochrome-c has a high molecular mass and high background absorbance at 550 nm, this assay lacks sensitivity and is not ideally suited to microplate measurements.

Interpretation and Analysis: Reduction of WST-1 by activated peripheral blood neutrophils (human) closely correlates with

ferricytochrome-c reduction across a range of activating agent concentrations (e.g., PMA) and time-initiated activation (e.g., PMA/*f*MLP).

Superoxide produced by activated neutrophils efficiently reduces the tetrazolium salt, WST-1 to produce a soluble formazan: A simple colorimetric assay for measuring respiratory burst activation and for screening anti-inflammatory agents. Tan AS, Berridge MV. J Immunol Methods 2000 Apr 21; 238 (1–2), pp. 59–68.

Respiratory/Oxidative Burst Potential (Neutrophil/Macrophage) *Nitroblue Tetrazolium (NBT)/Sulfonated Tetrazolium Salt (WST-1)*

Cellular/Molecular Mechanism of Action: Neutrophil respiratory burst activity can be detected in histiological samples through the application of the tetrazolium salt, nitroblue tetrazolium, which is reduced intracellularly to an insoluble formazan by superoxide generated by NADPH oxidase. The water-soluble sulfonated tetrazolium salt, WST-1 produces a soluble formazan that can be detected by a simple colorimetric assay for measuring respiratory burst activation and for screening anti-inflammatory agents.
Application: Detection and characterization of leukocyte oxidative burst activity as a function of cell viability and capacity to resolve phagacytized pathogens.
Example Application: In cows with subclinical mastitis caused by *Staphylococcus aureus*, the oxidative burst assay has been utilized to analyze whole blood and fresh milk samples and determine the effectiveness of certain therapeutic strategies.
Methodology: Nitroblue tetrazolium (NBT) dye reduction assay.
Considerations: Activation of the respiratory burst of granulocytes and macrophages by invading microorganisms is a key 1st-line of cellular defense against infection. Failure to generate this response leads to persistent life-threatening infection unless appropriate antibiotic treatment is given. Respiratory burst activity in neutrophils is often measured spectrophotometrically following ferricytochrome-C reduction. In tissue or cell population preparations, it is detected by the intracellular reduction of the tetrazolium salt, nitroblue tetrazolium to an insoluble formazan crystal. In both assay systems, reduction is mediated by superoxide generated via NADPH oxidase. Because ferricytochrome-C has a high molecular mass and high background absorbance at 550 nm, the assay lacks sensitivity and is not ideally suited to microplate measurement.
Implementation: (i) In activated populations of human peripheral blood neutrophils, the reduction of WST-1 closely correlates with ferricytochrome-C reduction across a range of PMA concentrations and with time of activation by PMA and *f*MLP. Reduction of WST-1 is inhibited 98% by superoxide dismutase (20 μg/ml); and 88% by the NADPH oxidase inhibitor, diphenyleneiodinium (10 μM). In contrast, WST-1 reduction is resistant to catalase, azide and the NADH oxidase inhibitor, resiniferatoxin. In comparison investigations, the relatively ability of WST-1 and ferricytochrome-C reduction have also been assessed using xanthine/xanthine oxidase to generate superoxide. Under optimised assay conditions, both WST-1 and ferricytochrome-C reduction are directly proportional to the quantity of added xanthine. Approximately a 2-fold greater increase in absorbance can be appreciated with WST-1 generated absorbance measurements than is usually observed for absorbance values associated with ferricytochrome-C at their respective wavelengths. These findings imply a direct relationship to increased assay sensitivity. Addition of the intermediate electron acceptor, 1-methoxy phenazine methosulfate, increases the background of the neutrophil assay but does not affect the overall magnitude of the response. In this context, WST-1 based assays have been utilized as investigative tools to assess human neutrophil dysfunction and to compare anti-inflammatory activity (e.g., pharmaceutical therapy).

(ii) Neutrophil chemotaxis and oxidative burst activity has frequently been used to evaluate immune competence in workers occupationally exposed to silica. Both types of neutrophil functions are significantly reduced in silica-exposed foundry and pottery workers ($p < 0.001$) compared to healthy controls subjects suggesting that chronic exposure mainly to silica and other chemicals originating from foundry and pottery settings may diminish neutrophil functions. Chemotatic function can be measured in a Boyden chemotactic chamber using Zymosan-activated serum as a chemotactic preparation. Oxidative burst activity is measured using a conventional nitroblue tetrazolium (NBT) dye reduction test (2-hour incubation period).
Interpretation and Analysis: The limitation of tetrazolium-based assays can be minimized or eliminated by using a cell-impermeable, WST-1, which exhibits very low background absorbance and is efficiently reduced by superoxide to a stable water-soluble formazan with high molar absorptivity. Improvements provided by this particular reagent have permitted the adaption of the WST-1 assay to a microplate format while still remaining optimum levels of sensitivity.

Declines in oxidative burst activity implies that a given leukocyte cell type has been compromised or incapable of creating a lethal effect on phagocytized pathogens.
Instrumentation: Spectrophotometer (530 nm, 570 nm or 590 nm).

Alterations of neutrophil functions in foundry and pottery workers. Basaran N, Undeger U, Shubair M. Immunopharmacol Immunotoxicol 2002 Nov; 24 (4), pp. 639–50.

Effect of subcutaneous injection of ginseng on cows with subclinical Staphylococcus aureus mastitis. Hu S, Concha C, Johannisson A, Meglia G, Waller KP. J Vet Med B Infect Dis Vet Public Health 2001 Sep; 48 (7), pp. 519–28.

Superoxide produced by activated neutrophils efficiently reduces the tetrazolium salt, WST-1 to produce a soluble formazan: A simple colorimetric assay for measuring respiratory burst activation and for screening anti-inflammatory agents. HEMATOPOIETIC: PLATELETS (*EX VIVO*)

Activation of Platelets: General Function/P-Selectin Expression/GPIIb/IIIa Receptor: Activated *Collagen-Epinephrine/Collagen-Adenosine Diphosphate (ADP)*

Background Information: Flavanols modulate platelet function *in vitro*, but less is known of their *in vivo* effects and how they compare to pharmacological platelet inhibitors.
Application: Detection and characterization of platelet function.
Route of Administration: Collagen, epinephrine, and ADP are applied in an *ex vivo* manner where they are incubated with highly enriched platelet suspensions.
Dosage: Aspirin (81 mg).
Implementation: Evaluation of separate and collective influences of flavanol-rich cocoa (897 mg/ml) and aspirin on platelet function and activation. Platelet activation can be measured *in vitro* by detection of P-selectin surface expression and PAC-1 binding to the activated GPIIb/IIIa receptor (GPIIb/IIIa-act). Platelet function can be measured on an analyzer (the PFA-100) that measures shear stress-induced platelet plug formation in response to collagen-epinephrine or collagen-ADP.
Human Model: Cases of normal health (n = 16).

Interpretation and Analysis: Plasma epicatechin concentrations peak approximately 2 hours after subjects are given either cocoa or aspirin plus cocoa. After 6 hours, cocoa inhibits epinephrine-induced platelet function. Epinephrine-induced platelet function is inhibited 2 and 6 hours after aspirin, and after aspirin plus cocoa. Epinephrine-stimulated P-selectin expression is inhibited by aspirin at 6 hours, and after 2 and 6 hours by aspirin plus cocoa. Adenosine diphosphate–stimulated P-selectin expression is not affected by the treatments. Cocoa and aspirin, given separately, reduce epinephrine-stimulated GPIIb/IIIa-act expression at 2 and 6 hours, respectively, and at 2 and 6 hours when given together, suggesting an additive effective. Acetylsalicylic acid plus cocoa inhibits ADP-stimulated GPIIb/IIIa-act expression at 6 hours. In summary, flavanol-rich cocoa inhibit epinephrine-stimulated platelet activation and function. These effects are qualitatively similar to aspirin, but less profound. These results emphasize the need to further examine the effects of flavonol-containing foods for platelet modulating effects.

Instrumentation: An analyzer (the PFA-100) capable of measuring shear stress-induced platelet plug formation.

The effects of flavanol-rich cocoa and aspirin on *ex vivo* platelet function. Pearson DA, Paglieroni TG, Rein D, Wun T, Schramm DD, Wang JF, Holt RR, Gosselin R, Schmitz HH, Keen CL. Thromb Res 2002 May 15; 106 (4–5), pp. 191–7.

Adhesion Function: Endothelial Repair Potential/ von Willebrand's Disease (vWD)/Thrombasthenic Platelets

Bead Column

Cellular/Molecular Mechanism of Action: The 2 primary functions of platelets include their participation in hemostatic processes (platelet aggregation), in addition to their role in the repair of the vascular endothelial surface (platelet adhesion function). In part, this process inovolves the recognition of defects in the vascular endothelium and physical attraction to subendothelial (negatively-charged) collagen that is recognized as a foreign surface by circulating platelets. This concept has been utilized in the design of platelet adhesion assays that employ glass bead retention columns because their anionic properties are recognized as a foreign surface.

In the 1st stage, platelets adhere to the glass beads; this requires fibrinogen but not von Willebrand's factor (vWF). The platelet-platelet adhesion in the 2nd stage is dependent on release of ADP, and fails to occur if thrombasthenic platelets are tested.

Application: The platelet retention test provides a measure of the number of platelets retained in a column of glass beads and can be used to detect the presence of acquired, congenital or hereditary abnormalities in platelet adhesion properties. It is also 1 of the few *in vitro* platelet function tests that is abnormal in vWD. Retention is usually normal when blood from a patient with afibrinogenemia are used as Sample-B blood.

Example Application #1: Monoclonal antibodies have been used to elucidate the mechanism of platelet retention. Antibodies directed at 5 different vWF epitopes essentially abolishes platelet retention in the 1-stage test and 2nd stage of 2-stage tests, but has no effect on the 1st stage. Thus, the entire vWF molecule must be free of antibody to function in the platelet-platelet adhesion of the 2nd stage of this test. Binding of the antigen-antibody complex to the Fc receptor of platelets appears to have an insignificant impact in this regard because Fab and $F_{ab'}$[2] immunoglobulin fragments are as effective as intact antibody, and neither heat-aggregated IgG nor a polyclonal antibody to plasma factor IX inhibits retention. Immunoglobulin $F_{ab'}$[2] fragments with binding avidity for platelet GP Ib prevents binding of vWF to platelets and inhibits the 2nd phase of platelet retention. Antibody that inhibits binding of fibrinogen and vWF to GP IIb/IIIa (LJ-CP8) inhibits both the 1st and 2nd stages of platelet retention, whereas LJ-P5 antibody that inhibits only the binding of vWF to GP IIb/IIIa causes only slight inhibition of platelet retention when normal or afibrinogenemic blood is used as sample-B blood. The same antibody also reportedly causes only partial inhibition of ADP-induced platelet aggregation in instances of afibrinogenemia. Interpretation of these *ex vivo* investigations suggests that vWF is altered during rapid passage of blood through the glass-bead column to the extent that it attaches to GP Ib, exposing GP IIb/IIIa, which then binds the altered vWF or fibrinogen, either of which can induce platelet aggregation (platelet-platelet adhesion) and thus retention within the column.

Example Application #2: Platelet glass-bead retection columns have been applied in delineating bleeding tendencies in cases of aortic valvular stenosis. High and low shear platelet function tests performed *in vitro* on normal controls have been compared with that observed in cases with severe aortic valve stenosis with a mean Doppler systolic gradient of 75 (SD = ± 18) mm Hg before and at least 4 months after aortic valve replacement. Affected cases show reduced retention in high shear platelet function tests. More specifically, platelet retention in the filter test is approximately 53.6 (12.6)% in cases of aortic valve stenosis compared to 84.8 (9.6)% in negative reference controls ($p < 0.001$). In addition, retention in the glass bead column test is approximately 49.8 (± 19.2) in affected cases, and 87.4 (± 8.7) in negative reference controls ($p < 0.001$). (c) The standard bleeding time is also longer in cases with aoritic valvular stenosis ($p < 0.06$). Results observed with high shear tests after aortic valve replacement are usually within the normal range. Platelet counts are low but also within normal limits range before surgery and increased postoperatively ($p < 0.01$). Standard clotting tests, plasma, intraplatelet von Willebrand's factor, or platelet aggregation tests using 5 agonists are often no different than negative reference controls.

Laboratory findings from these investigations imply that the high shear hemodynamics of aortic valve stenosis modifies platelet function *in vivo* predisposing to a bleeding tendency. A platelet function abnormality of this type is detectable only *in vitro* using high shear tests. The abnormal function is reversed by aortic valve replacement. High shear forces *in vitro* activate and then inactivate platelets. By this same mechanism aortic valve stenosis seems to lead to high shear damage *in vivo*, resulting in clinically relevant bleeding tendency in certain patients.

Methodology: Enriched preparations of platelets are initially harvested from fresh whole blood collected into sodium citrate or acid-citrate-dextrose anticoagulant (9:1 to 5:1 v/v) in the form of platelet rich plasma following a brief period of low-speed centrifugation. The platelet rich plasma is then harvested after the formation of a leukocyte buffy coat layer on top of the red blood cell layer. Either the platelet rich plasma itself can be used directly in the evaluation of aggregation potential or if necessary, preparations can be recentrifuged at low speed to obtain a platelet pellet that can be suspended in a smaller volume of plasma in order to obtain a more concentrated platelet preparation. Alliquots of fresh whole-blood or platelet rich plasma are then pipetted onto a glass-bead column following performing of a platelet count. The ratio of platelets that become adheared to the glass beads compared to the number that pass through the column is a reflection of the degree of platelet adhesion potential.

In a 2-stage test, 1 mL of blood (Sample A: 5.0 ml) is passed through a glass bead column, followed by isotonic saline (5.0 ml). A

2nd aliquote of blood (Sample-B: 5.0 ml) is applied to the column and the degree of platelet retention measured. With normal blood as A and B, retention is very high in all 5 mL of Sample-B blood.

Interpretation and Analysis: Platelet retention in a standard glass bead column is measured and then compared to values for normal reference controls.

Decreased platelet function in aortic valve stenosis: High shear platelet activation then inactivation. O'Brien JR, Etherington MD, Brant J, Watkins J. Br Heart J 1995 Dec; 74 (6), pp. 641–4.

Effect of monoclonal antibodies against von Willebrand factor and platelet glycoproteins IIb/IIIa on the platelet retention test. McPherson J, Brownlea S, Zucker MB. Blood 1987 Aug; 70 (2), pp. 546–50.

Aggregation of Platelets: (*Ex Vivo*)/Bleeding Disorders (Primary)/von Willebrand's Disease (vWD)/Acetylsalicylic Acid (ASA) Intake: Differential Effect Induced by Adenosine Diphosphate (ADP) and Epinephrine (EPI)
ADP/EPI

Cellular/Molecular Mechanism of Action: Adenosine diphosphate is produced/released by platelets during the process of platelet activation and promotes aggregation phenomenon in addition to the activation of other platelets that may be in close proximity. Epinephrine is another endogenous agent (adrenergic neurotransmitter) that activates platelet populations.

Application: Detection and characterization of primary bleeding disorders (e.g., vWD) and ASA intake that are associated with alterations in platelet function (e.g., adhesion/aggregation), which can be detected applying comparative ADP vs EPI-induced aggregation tests.

Considerations: Evaluation of platelet function applying aggregation methodologies is more sensitive than the evaluation of bleeding times. In this context, EPI is a more sensitive diagnostic reagent than ADP.

Implementation: Evaluation of bleeding disorders. The procedure involves the collection of citrated venous whole blood that is subsequently aspirated through a capillary toward an aperture of a collagen-coated membrane containing either ADP or EPI. The time needed for occluding this aperture by plug formation is called the closure time (CT). A specific type of citrated whole blood has to be prepared for analysis within 0.5 to 4.0 hours after collection. In addition, duplicate measurements are necessary, and results differ between blood samples collected in the morning compared to those obtained in the afternoon.

Human Model: Cases with suspected mild bleeding disorders ($n = 43$; and $n = 70$ normal healthy reference controls).

Interpretation and Analysis: The reference range for the PFA-100 is approximately 82–159 seconds for EPI/closure time (EPI-CT) and 62.5–120.5 seconds for ADP/closure time (ADP-CT). Duplicate analyses reveal a mean coefficient of variations of 7.1% (EPI-CT) and 5.7% (ADP-CT). The EPI- and ADP-CT for blood samples collected during evening hours are significantly longer ($p = 0.002$ and $p = 0.004$, respectively) than the CT for blood samples collected in the morning. Acetylsalicylic acid (100 mg, 300 mg, or 500 mg) administered as a single dose or daily on 10 consecutive days results in prolongation of the EPI-CT, whereas the ADP-CT is not affected. EPI-CT is more sensitive in detecting ASA ingestion than is bleeding time (BT) measurements. Sensitivity and specificity of the PFA-100 for detecting vWD are comparable to the results obtained with BT measurements. The PFA-100 is a simple and easy to use test for the investigation of primary hemostasis. The test procedures are sensitive to the extent that the test can detect ASA intake and vWD. Its use is preferable to BT determination because it is less invasive and more sensitive to abnormalities of primary hemostasis.

Evaluation of a Platelet Function Analyser (PFA-100) in patients with a bleeding tendency. Wuillemin WA, Gasser KM, Zeerleder SS, Lämmle B. Swiss Med Wkly 2002 Aug 10; 132 (31–32), pp. 443–8.

Aggregation of Platelets
Adenosine Diphosphate (ADP)/Collagen Monomer/Epinephrine/Thromboxane (TXA_2)

Cellular/Molecular Mechanism of Action: During the process of platelet activation, ADP is released from intracellular granules (platelet degranulation) and increased amounts of thromboxane (TXA_2) are produced. Exposure of non-activated platelets to ADP promotes platelet activation and platelet aggregation.

Application: Detection of acquired, congenital, or hereditary forms of platelet dysfunction. Examples in this regard include nonsteroidal anti-inflammatory agents (e.g., NSAIDs) such as aspirin due to its ability to irreversibly inactivate cyclooxygnease through direct enzyme acetylation.

Methodology: Enriched preparations of platelets are initially harvested from fresh whole blood collected into sodium citrate or acid-citrate-dextrose anticoagulant (9:1 to 5:1 v/v) in the form of platelet rich plasma following a brief period of low-speed centrifugation. The platelet rich plasma is then harvested after the formation of a leukocyte buffy coat layer on top of the red blood cell layer. Either the platelet rich plasma itself can be used directly in the evaluation of aggregation potential or they can be recentrifuged at low speed to obtain a platelet pellet that can in turn be suspended in a smaller volume of plasma in order to obtain a more concentrated platelet preparation. Alliquots of the platelet rich plasma are pipetted into the wells of a pletelet aggregometer and an activating agent such as ADP are added to promote platelet aggregation. Based on a simple light detection sensor, the amount of transmitted light through the activated platelet rich plasma increases as more and more platelet aggregates are forms. The slope of the reaction curve (light-transmitteance as a function of time) is a reflection of the rate of platelet aggregation and the plateau of the reaction curve represents the degree of total platelet aggregation.

Considerations: Various therapeutic pharmaceuticals can interfer with attempts to diagnose acquired, congenital or hereditary forms of dysfunctional platelet aggregation .

Interpretation and Analysis: Decreases in the steepness of the slope or plateau of the platelet aggregation curve indicate the presence of diminished rate of platelet aggregation (aggretatory dysfunction).

Instrumentation: Platelet aggregometer integrated to either a paper tracing system or computer display.

Aggregation of Platelets: General Function/Device Implantation Evaluation/Pharmaceutical Efficacy/Sequelae Evaluation
Adenosine Diphosphate (ADP)

Cellular/Molecular Mechanism of Action: Adenosine diphosphate promotes the activation of platelets (degranulation, release of ADP, calcium, reversible aggregation, irreversible aggregation, alterations in the expression of suface membrane receptor complexes).

Application: Evaluation of platelet and coagulation function following device implantation or characterization of pharmaceutical efficacy or unexpected sequelae.

Route of Administration: Usually applied in *ex vivo* cell preparations where it is pipetted directly into a suspension and the degree of platelet aggregation measured using various types of instrumentation (e.g., change in light-impedence in a platelet aggregometer well).

Implementation: Evaluation of platelet and coagulation function in 4 different animal species utilizing a clot signature analyzer (CSA). Clot signature analyzer is unique in that it simultaneously measures global platelet and coagulation function under flow using whole blood.

No anticoagulant, chemical, or immunologic agent is required. Three CSA parameters are measurable: platelet mediated hemostasis time (PHT), collagen-induced thrombus formation time (CITF), and clotting time (CT). Bovine, ovine, and canine animal models are appropriate since these species are most frequently used in *in vivo* testing of cardiovascular implants. These parameters, as well as data from whole blood platelet aggregometry (commonly used for platelet function studies because of the response to exogenous agonists), and platelet counts from these animals, are then measured and compared with values observed in humans.

Interpretation and Analysis: In all 3 parameters, the canine species shows distinctively shorter time values than other species, including humans, suggesting that the dog is not an ideal animal model for the evaluation of blood-surface interactions. Ovine and human blood show similar PHT and CT values, but CITF time values are significantly shorter in sheep than in humans. With bovine blood, PHT is most prolonged among the 4 species compared. CT and CITF times in calves are shorter than those in humans, although the difference in CITF time is not statistically significant. Adenosine diphosphate–induced platelet aggregation shows the same order of responsiveness in 4 species as does CITF. It has been observed that the intermeasurement variation is rather high for CSA parameters, especially in PHT, warranting caution when this parameter is used to study time-dependent changes after device implantation.

Evaluation of platelet and coagulation function in different animal species using the xylum clot signature analyzer. Sato M, Harasaki H. ASAIO J 2002 Jul–Aug; 48 (4), pp. 360–4.

Arterial Disease: Platelet Function/Peripheral Arterial Disease (PAD) of the Lower Limb/Carotic Artery Disease/Abdominal Aortic Aneurysm (AAA)
Adenosine Diphosphate (ADP)/Collagen

Cellular/Molecular Mechanism of Action: Adenosine diphosphate is released by platelets during activation phenomenon and promotes activation/aggregation of nearby platelets. Soluble collagen binds membrane-associated receptors expressed by platelets and promotes aggregatory responses.

Background Information: Conditions of PAD are associated with a 3-fold increase in cardiovascular mortality. Standard antiplatelet treatments may not confer uniform benefit in different patient groups.

Application: Detection and chacterization of arterial disease related to alterations in platelet function.

Implementation: Compare platelet function in disease states of lower limb PAD carotid disease and AAA. One viable investigative approach in this regard involves the evaluation of PAD as a function of spontaneous platelet aggregatory (SPA) properties assessed in whole-blood samples applying ADP and collagen to induce aggregation responses. Flow cytometry analyses can also be used to detect platelet P-selectin and the PAC-1 antigen as markers of platelet activation and aggregation.

Human Model: Cases of PAD of the lower limbs ($n = 20$); carotid artery disease ($n = 40$); AAA ($n = 13$); and age-/sex-matched healthy controls ($n = 20$).

Interpretation and Analysis: Conditions of lower limb PAD or AAA have higher baseline SPA compared to normal controls ($p < 0.01$). There is significantly higher collagen-induced aggregation in IC patients compared to normal controls ($p < 0.01$). However, there is no difference in ADP-induced aggregation between lower limb PAD and control patients. There is no difference in PAC-1 binding between control patients and the patients with lower limb PAD, carotid disease, or AAA. Conditions of carotid artery disease express higher levels of P-selectin compared to normal controls ($p < 0.05$).

Evidence therefore exists that suggests platelet hyperactivity is present in conditions of PAD despite the use of antiplatelet therapy. Further antiplatelet strategies may be indicated for the therapeutic management of such disease states.

Instrumentation: Flow cytometry instrumentation.

Increased platelet aggregation and activation in peripheral arterial disease. Robless PA, Okonko D, Lintott P, Mansfield AO, Mikhailidis DP, Stansby GP. Eur J Vasc Endovasc Surg 2003 Jan; 25 (1), pp. 16–22.

Cardiovascular Disease Risk Indicator/Aggregation of Platelets
Garlic Extract (Aged)/(Adenosine Diphosphate [ADP]/Collagen/Epinephrine)/Platelet Adhesion (Collagen/Fibrinogen/von Willebrand's Factor)

Physiological Mechanism of Action: Aged garlic extract (AGE) has previously been shown to have moderate cholesterol-lowering and blood pressure–reducing effects.

Route of Administration: Aged garlic extract administered orally (per os).

Dosage: Aged garlic extract between 2.4 and 7.2 grams/day.

Laboratory Analysis: Measurement of platelet aggregation and adhesion performed at 2-week intervals reveals moderated elevations in the threshold concentrations for epinephrine and collagen compared to preadministration baseline values and individuals receiving a placebo. Only at the highest supplementation level does AGE show a slight increase in the threshold level of ADP-induced aggregation. Platelet adhesion to collagen, fibrinogen, and von Willebrand's factor can also serve as a diagnostic aid in detecting AGE-induced changes in platelet function. Adhesion properties can be determined by perfusing whole blood through a laminar flow chamber under controlled flow conditions. Adherence of platelets is inhibited by AGE in a dose-dependent manner when collagen is applied as an adhesive surface and perfused at low shear rates (approximately 30 s-1). At high shear rates (1,200 s-1), AGE also inhibits platelet adhesion to collagen but only at higher intake levels of the extract. Adhesion to von Willebrand's factor is reduced only at 7.2 g/d AGE, but adherence to fibrinogen is potently inhibited at all levels of supplementation.

Interpretation: Preparations of AGE selectively inhibit platelet aggregation and adhesion. Each of these is a platelet function that may be important for the development of cardiovascular events such as myocardial infarction and ischemic stroke.

Aged garlic extract, a modulator of cardiovascular risk factors: A dose-finding study on the effects of AGE on platelet functions. Steiner M, Li W. J Nutr 2001 Mar; 131 (3s), pp. 980S–4S.

HEMATOPOIETIC: RED BLOOD CELLS (*EX VIVO*)

Anemia: Fanconi's Syndrome
Nitrogen Mustard (NTM)/[Diepoxybutane (DEB)]

Cellular/Molecular Mechanism of Action: Nitrogen mustards and DEB can function as DNA alkylating agents.
Background Information: Fanconi's anemia (FA) is an autosomal recessive inherited disorder that is associated with a variety of congenital anomalies. These include morphometric abnormalities involving mainly the head and face, skeletal malformations particularly of the radial ray, growth retardation, abnormal skin pigmentation, deafness, and renal, ocular, genital, and cardiac defects. The cardinal clinical feature is a severe progressive pancytopenia.
Application: Detection and characterization of Fanconi's syndrome anemia.
Implementation: Evaluate the potential to detect conditions of FA rapidly and accurately applying alkylating agents as components of a screening methodology. In this context, NTM and DEB tests are performed in concert with the determination of baseline chromosomal breakage analyses.
Human Model: Cases screened for evidence of FA (n = 271).
Interpretation and Analysis: Chromosomal breakage analyses can facilitate the detection of cases with FA (e.g., n = 72) in contrast to cases unaffected by the condition (e.g., n = 136). Studies of family members of affected FA cases (n = 63 individuals) contribute to the conclusion that NTM seems more specific for identifying chromosomal breakages in FA parents than is possible with DEB.

Differential diagnosis of Fanconi's anemia by nitrogen mustard and diepoxybutane. Deviren A, Yalman N, Hacihanefioglu S. Ann Hematol 2003 Apr; 82 (4), pp. 223–7.

Organophosphate Intoxication: Red Blood Cells
Acetylcholine Analogs

Molecular Mechanism of Action: Organophosphate insecticides inhibit the biochemical activity of acetylcholine esterase. Red blood cells contain a substantial amount of acetylcholine esterase.
Application: Detection of organophosphate exposure.
Implementation: Evaluation of erythrocytes (RBC) acetylcholine esterase concentrations using acetylcholine analogs as a substrate diagnostic agent.
Interpretation and Analysis: Exposure to organophosphate insecticides is suggested by the detection of suboptimal enzymatic degradation of the test substrate reagent.

Stress-Susceptible and Stress-Resistant Swine: Red Blood Cells (RBCs)
Hydrogen Peroxide

Physiological Mechanism of Action: In part, hydrogen peroxide imposes a degree of oxidative stress on RBC populations.
Application: Detection of stress-susceptible swine.
Route of Administration: *In vitro* incubation of RBCs.
Implementation: Evaluation of erythrocyte (RBC) generation of by-products from lipid peroxidation (measured as thiobarbituric acid-reactive substances [TBARS]) in response to incubation in hydrogen peroxide formulations.
Animal Model: Swine (stress-resistant and stress-susceptible).
Interpretation and Analysis: When incubated with solutions of hydrogen peroxide, erythrocytes of stress-susceptible pigs produce more by-products of lipid peroxidation than do erythrocytes from stress-resistant pigs. Using this technique, discrimination between the 2 swine types is absolute at hydrogen peroxide concentrations of 0.9 and 1.5%. Such findings are in contrast to other methods of identifying stress-susceptible pigs, such as osmotically induced erythrocyte lysis and determination of plasma pyruvate kinase and creatine kinase activities, for which considerable overlap of data can be observed between the 2 swine types. Increased TBARS production by erythrocytes is further evidence for the existence of an antioxidant abnormality in stress-susceptible pigs. However, because there are no discernible differences in the major blood antioxidant-related values between stress-susceptible and stress-resistant pigs, the nature of the defect remains unclear. The production of TBARS by erythrocytes when incubated with hydrogen peroxide provides an improved method for identifying stress-susceptible pigs.

MUSCULOSKELETAL: *EX VIVO*

Malignant Hyperthermia (MH)
Caffeine/Diffusible CO_2

Background Information: Susceptibility to MH can be diagnosed applying a contracture screening test, which requires an open muscle biopsy sample.
Route of Administration: Caffeine (intramuscular).
Dosage: Caffeine (500 μl of an 80 mmol/L formulation).
Implementation: Evaluate the influence of intramuscular caffeine injection on local carbon dioxide pressure (pCO_2) in conditions of MH compared to normal negative reference controls. Measurements for pCO_2 are obtained from the rectus femoris muscle during local stimulation with injected caffeine.
Human Model: Cases susceptible to MH (n = 12) and cases classified as non-susceptible (n = 8) and 7 healthy/normal controls.
Interpretation and Analysis: In susceptible individuals, pCO_2 temporarily increases to a maximum of 63 mm Hg (IQR 61–69) compared with 44 mm Hg (43–47) for non-susceptible participants ($p = 0.003$) and 42 mm Hg (41–46) in controls ($p = 0.003$). Systemic side effects usually cannot be appreciated. Metabolic monitoring of the highly diffusible CO_2 stimulated by caffeine might allow for the development of a minimally invasive test for susceptibility to malignant hyperthermia.

Diagnosis of susceptibility to malignant hyperthermia by use of a metabolic test. Anetseder M, Hager M, Müller CR, Roewer N. Lancet 2002 May 4; 359 (9317), pp. 1579–80.

Malignant Hyperthermia (MH)
Caffeine/Halothane/Calcium-Induced Calcium Release (CICR)

Application: Detection and characterization of MH conditions.
Route of Administration: Topical application (emersion) of muscle biopsy specimens.
Implementation: Comparison of results of the *in vitro* caffeine-halothane contracture test (CHCT) according to the protocols of the North American Malignant Hyperthermia Group (NAMHG) and the European Malignant Hyperthermia Group (EMHG) with the CICR rate test. Muscle biopsies are usually obtained from the musculus vastus lateralis. Diagnostic cutoff points and procedures for CHCT protocols are as described in the original and renewal versions of NAMHG and EMHG. The CICR rate test can be performed according to previously reported protocols.
Human Model: Cases of suspected MH (n = 16; n = 5 normal negative reference controls).

Interpretation and Analysis: All 5 normal controls (e.g., n = 5), and some cases with abortive MH (e.g., n = 2), postoperative hyperthermia (n = 2), and high serum creatine kinase levels (e.g., n = 3) may be observed to have normal values for each of the 3 tests. Patients with MH reactions (e.g., n = 3) or with a history of masseter spasm (e.g., n = 1) may be classified as MH-positive according to NAMHG criteria and MH-susceptible and MH-equivocal according to EMGH criteria. Some cases may display discordant findings between CHCT and CICR rate test results (e.g., n = 5). It has therefore been proposed that a muscle biopsy for diagnosis of MH susceptibility should be used (combine the CHCT with the CICR rate test), which may identify the defective site of Ca^{++} release channels.

Comparison of the *in vitro* caffeine-halothane contracture test with the Ca-induced Ca release rate test in patients suspected of having malignant hyperthermia susceptibility. Oku S, Mukaida K, Nosaka S, Sai Y, Maehara Y, Yuge O. J Anesth 2000 Jan 20; 14 (1), pp. 6–13.

Malignant Hyperthermia (MH) *4-Chloro-m-Cresol (4-CmC)/Caffeine/Halothane*

Background Information: The *in vitro* contracture test (IVCT) for diagnosis of MH in the laboratory has a sensitivity of 100% and a specificity of 93%. Results are equivocal in 10–15%, and supplementary tests may thus be required.
Application: The agents 4-chloro-*m*-cresol, caffeine, and halothane can be applied to detect and characterize conditions of MH.
Implementation: Evaluation of muscle tissue collected as a biopsy specimen applying an *in vitro* contracture test performed by using topical exposure to increasing concentrations of 4-CmC (25, 50, 75, 100, 150, and 200 μmol/l). The corresponding force profiles are recorded as an objective measure of 4-CmC effectiveness. Diagnosis of MH susceptibility can be established with standard halothane and caffeine tests and classified as MHS (MH-susceptible), MHN (MH-negative), or MHE (equivocal result).

Human Model: Cases subjected to skeletal muscle biopsy (n = 41 from n = 7 families).
Interpretation and Analysis: At all concentrations of 4-CmC, the increase in baseline force is significantly greater in the MHS group compared to the MHN group ($p < 0.05$). Muscle from MH-susceptible cases (e.g., n = 15) responds to 4-CmC with increasing force at a threshold concentration of 75 μmol/l or less, whereas muscle tissues from cases classified as MH-non-susceptible (e.g., n = 23) have thresholds of 100 μmol/l or more. The accuracy of the chlorocresol test is approximately 100% (95% confidence limits 90.75–100%) at a threshold of 75 μmol/l. Amplitude of contractures at 2 mmol/l caffeine is not different from contractures at 75 μmol/l of 4-CmC in either the MHS or the MHN group ($p > 0.05$). *In vivo* concentrations of chlorocresol from clinical use of insulin and somatropin are estimated to be 20 times less than the threshold concentration and thus these drugs seem safe in MH cases. Therefore, 4-CmC may be a suitable aid to clarify puzzling results of standard testing of MH susceptibility.

4-Chloro-m-Cresol test—A possible supplementary test for diagnosis of malignant hyperthermia susceptibility. Ording H, Glahn K, Gardi T, Fagerlund T, Bendixen D. Acta Anaesthesiol Scand 1997 Sep; 41 (8), pp. 967–72.

Malignant Hyperthermia (MH) *Midazolam/Caffeine/Halothane*

Cellular/Molecular Mechanism of Action: Midazolam (water-soluble benzodiazepine).
Application: Premedicant for induction of anesthesia, but has occasionally been investigated to determine functionality as a screening agent for patients susceptible to the development of malignant hyperthermia. Midazolam is not an effective diagnostic pharmaceutical for the screening of patients susceptible to the development of malignant hyperthermia.
Dosage: Midazolam (ca 0.5 μg/ml.
Considerations: Midazolam has been applied to determine its influence on the resting tension of directly stimulated muscle biopsies. Interactions between midazolam and the 2 most commonly used MH diagnostic agents (halothane and caffeine) have also been compared.
Interpretation and Analysis: Midazolam, at maximum therapeutic concentrations (ca 0.5 μg/ml), has no detectable effects on muscle contraction in control and MH preparations. However, midazolam does elicit a contracture from control and MH-positive preparations when used within a concentration range between 160 and 1,280 μg/ml. There are no significant differences between control and MH-positive patients in minimum concentration of midazolam causing contracture or the strength of contracture at the respective eliciting concentration. There appears to be no interaction between midazolam and either halothane or caffeine on the resting tension of the directly stimulated muscle twitch preparation.

Effects of midazolam on directly stimulated muscle biopsies from control and malignant hyperthermia positive patients. Fletcher JE, Rosenberg H, Hilf M. Can Anaesth Soc J 1984 Jul; 31 (4), pp. 377–81.

Malignant Hyperthermia (MH)/Genomic Analyses and Provocative Testing Correlation/Arginine 614 → Cysteine (Arg614Cys: RYR1 C1840T) *Caffeine/Halothane*

Physiological Mechanism of Action: In conditions of MH, exposure of muscle tissue to caffeine/halothane promotes an exaggerated contractile response.
Background Information: Malignant hyperthermia is an important cause of anesthesia-induced death. The caffeine/halothane contracture test (CHCT) is highly invasive, expensive, and lacks 100% specificity. Genetic and biochemical evidence provide strong support for the view that the substitution of cysteine for arginine 614 (Arg614Cys) in the human ryanodine receptor gene is 1 of several mutations that are likely to cause human MH.
Application: Detection and characterization of MH conditions.
Route of Administration: Traditionally applied as a topical exposure for an *ex vivo* tissue-based challenge study.
Implementation: Delineation of a possible genetic basis for a predisposition to MH pertaining to the presence of Arg614Cys (RYR1 C1840T) mutations detected through a combination of polymerase chain reaction and restriction endonuclease digestion. Blood samples are utilized as a source of biological material for DNA analyses. Alternatively, detection of MH susceptibility can be established using the *in vitro* CHCT that employs fresh muscle biopsy specimens. Results from CHCT and DNA-based diagnostic parameters are then compared to determine their potential value in predicting MH susceptibility in large MH families that possess Arg614Cys mutations.

Human Model: Cases selected from a large Mennonite malignant hyperthermia kindred identified by an index patient that died at age 45 years of an MH crisis after general anesthesia. Case population: N = 68 family members, n = 19/68 muscle biopsies, n = 1/681 documented crisis without biopsy. Family members can be classified as MH-susceptible or MH-normal on the basis of the CHCT.

Interpretation and Analysis: In some family cohorts, as high as 33% of cases can be found to be heterozygous for the Arg614Cys mutation (n = 22/68) and slightly less than one-fourth have prior positive CHCT results (e.g., n = 5/22), while a small percentage may have an MH crisis without a biopsy procedure. Utilizing DNA testing, it is possible to detect a relatively large number of cases within a related kindred that are normal for the allele (e.g., n = 44). Of these, slightly less than 25% can be classified as MH-normal while some may be determined to be MH-susceptible (e.g., n = 5) on the basis of CHCT evaluations. Based on the interpretation of the data obtained in earlier CHCT diagnoses, the condition of the muscle is poor, with no twitch for approximately 60% of cases of homozygous for the normal allele but originally classified as MH-susceptible (e.g., n = 3/5) and for a small percentage that are homozygous for the normal allele and originally classified as MH-normal. Observations from CHCT results performed for such individuals (e.g., n = 4) can often be considered invalid. The twitch response is good for a small number of cases (e.g., n = 2 remaining) that are homozygous for the normal allele but classified as MH-susceptible if contracture can be observed with appropriately low levels of both caffeine and halothane.

An absolute correlation between DNA test results and CHCT assignment can often not be established. Possible explanations for discordance are that the Arg614Cys mutation is not linked to MH, that a 2nd MH mutation is segregating in the family, or that there are errors in the CHCT. Because there is strong evidence supporting the causal nature of the Arg614Cys mutation, the discordant cases are not closely related within the pedigree as they would be if a 2nd MH mutation was segregated, and the observed CHCT not 100% accurate. It has therefore been proposed that the observed discordance between DNA test results and CHCT assignment in 1 example kindred results from 2 false-positive diagnoses by the CHCT.

Comparison of the segregation of the RYR1 C1840T mutation with segregation of the caffeine/halothane contracture test results for malignant hyperthermia susceptibility in a large Manitoba Mennonite family. Serfas KD, Bose D, Patel L, Wrogemann K, Phillips MS, MacLennan DH, Greenberg CR. Anesthesiology 1996 Feb; 84 (2), pp. 322–9.

Malignant Hyperthermia (MH): Calcium Release (Sarcoplastic Reticulum [SR])/Calcium-Induced Calcium Release (CICR)
Cerivastatin / Dantrolene and Related Analogs

Cellular/Molecular Mechanism of Action: Cerivastatin (HMG-CoA) reductase inhibitors, which promote Ca^{2+} release from the SR.
Physiological Mechanism of Action: Induced release of intracellular calcium from the sarcoplasmic reticulum in skeletal muscle myocytes.
Application: Evaluation and characterization of skeletal muscle function and calcium ion physiology.
Route of Administration: *Ex vivo* (topical).
Semi-Synthetic Methods: Molecular design of specific photoaffinity probes based on the structural modification of dantrolene. Examples include GIF-0082 and GIF-0276 possessing azido- and trifluoromethyldiazirinyl-benzyl groups, respectively, at the hydantoin moiety. [^{125}I]GIF-0082 and [^{125}I]GIF-0276 are synthesized by substituting a stannyl group with [^{125}I] in the corresponding phenylstannane precursors.

The general synthesis of dantrolene analogues with various substituents on its phenyl ring has been developed via palladium-catalyzed cross-coupling reactions, employing the Stille or Suzuki reaction, as the key step. The effects of synthesized analogues have been evaluated by 2 kinds of Ca^{2+} release modes from SR of mouse skeletal muscle fibers based on (i) the measurement of twitch contraction caused by the physiological Ca^{2+} release (PCR) of intact skeletal muscle, and (ii) the rate of CICR in saponin-treated skinned muscle fibers.
Implementation: Evaluation of skeletal muscle function and calcium ion physiology with potential applications relevant to MH. In this manner, they can be applied to capture and identify key molecules that regulate the release of Ca^{2+} cation from the SR of skeletal muscle.

Animal Model: Rat (intact skeletal muscle and saponin-treated skinned muscle fibers).
Interpretation (Cerivastatin): The rates of Ca^{2+} release are increased by cerivastatin over a wide range of Ca^{2+} concentrations. Cerivastatin-induced Ca^{2+} release in the presence of Ca^{2+} is affected by adenosine monophosphate, Mg^{2+}, and procaine in essentially the same way as for caffeine-induced Ca^{2+} release. The Ca^{2+}-uptake capacity of the SR is reduced after co-treatment with ryanodine and cerivastatin at pCa 6.0 to a much greater extent than with ryanodine alone. Thus, cerivastatin-induced Ca^{2+} release in the presence of Ca^{2+} must be a result of the activation of the CICR mechanism of the ryanodine receptor. However, even when CICR is maximally inhibited by Mg^{2+} and procaine, or in the practical absence of Ca^{2+} (pCa > 8), cerivastatin still causes Ca^{2+} release. These results indicate that cerivastatin causes Ca^{2+} release also by activating some other mechanism(s) in addition to the activation of CICR. Either or both of these effects might be related to its adverse effect, rhabdomyolysis.
Interpretation (Dantrolene and Related Analogs): Although dantrolene, a lead compound, inhibits both twitch contraction and CICR, some structurally modified analogues exhibit 1 or the other of these effects. The methoxy congener, GIF-0185, potently inhibits the twitch contraction without affecting the CICR, while GIF-0166 and GIF-0248, the ortho-nitro regioisomer and ortho, ortho-dinitro substituted analogues, respectively, doubly potentiate the CICR exclusively.

The photoaffinity dantrolene analogs, GIF-0082 and GIF-0276, have a highly selective inhibitory effect on PCR without affecting CICR. Successful realization of the sharp discrimination between PCR and CICR has led to the creation of [^{125}I]GIF-0082 and [^{125}I]GIF-0276, which can be synthesized by substituting a stannyl group with [^{125}I] in the corresponding phenylstannane precursors.

Ca^{2+}-releasing effect of cerivastatin on the sarcoplasmic reticulum of mouse and rat skeletal muscle fibers. Inoue R, Tanabe M, Kono K, Maruyama K, Ikemoto T, Endo M. J Pharmacol Sci 2003 Nov; 93 (3), pp. 279–88.

Dantrolene analogues revisited: General synthesis and specific functions capable of discriminating two kinds of Ca^{2+} release from sarcoplasmic reticulum of mouse skeletal muscle. Hosoya T, Aoyama H, Ikemoto T, Kihara Y, Hiramatsu T, Endo M, Suzuki M. Bioorg Med Chem 2003 Mar 6; 11 (5), pp. 663–73.

[^{125}I]-N-[(3-azido-5-iodo)benzyl]dantrolene and [^{125}I]-N-[[3-iodo-5-(3-trifluoromethyl-3H-diazirin-3-yl)]benzyl]dantrolene: Photoaffinity probes specific for the physiological Ca^{2+} release from sarcoplasmic reticulum of skeletal muscle. Hosoya T, Aoyama H, Ikemoto T, Hiramatsu T, Kihara Y, Endo M, Suzuki M. Bioorg Med Chem Lett 2002 Nov 18; 12 (22), pp. 3263–5.

Malignant Hyperthermia (MH): Genetic Predisposition/(*Ex Vivo* Preparation of Skeletal Muscle Biopsies)
Caffeine/Caffeine and Halothane

Application: Caffeine and caffeine/halothane combinations can be applied as investigative probes to characterize certain intrinsic properties of skeletal muscle tissues. In this context, caffeine and caffeine plus halothane can serve as indicator agents for the detection of individuals with a genetic predisposition to the development of MH (potentially fatal complication of general anesthesia).

Implementation: Skeletal muscle *ex vivo* preparations are exposed to caffeine or caffeine plus halothane and the subsequent induction of contracture responses is measured for comparison with negative reference controls.

Interpretation and Analysis: In confirmed or suspect cases of MH and their genetic relatives, the responsiveness of the muscle specimens can often vary over 2 orders of magnitude. Frequency distribution curves suggest that the variation does not represent a continuum but rather is represented as 3 or more clusters of functional variants. Muscle specimens from males are on average more responsive to caffeine than is skeletal muscle collected from female subjects. Correlations within father-son and brother-brother pairs indicate complete heritability of responsiveness. Interestingly, there appears to be a lack of correlation between induced muscle contraction of muscle biopsies collected from mother-daughter pairs. There is an intermediate correlation in father-daughter pairs. The sex difference in heritability could be due to gender-related modifying genes or due to secondary modification of the muscle response in females by sex-related, perhaps hormonal factors. Among the effects of age appeared to be poor development in early childhood of the potentiation of caffeine-induced contracture by halothane.

Pharmacogenetics of caffeine and caffeine-halothane contractures in biopsies of human skeletal muscle. Kalow W, Sharer S, Britt B. Pharmacogenetics 1991 Dec; 1 (3), pp. 126–35.

Malignant Hyperthermia (MH): Skeletal Muscle *Caffeine/Halothane/Haloperidol/Succinylcholine/Caffeine*

Cellular/Molecular Mechanism of Action: Succinylcholine is an analog of the neurotransmitter acetylcholine.

Physiological Mechanism of Action: Droperidol and haloperidol are butyrophenone neuroleptic agents that induce a state of quiescence and reduced motor activity. Ketamine is a dissociative anesthetic agent.

Application: Screening for conditions or a predisposition to the development of MH.

Route of Administration: Halthane (inhalation); succinylcholine (intravenous). Many of the agents used to screen for malignant hyperthermia can also be incubated with *ex vivo* skeletal muscle preparations.

Considerations: If any agent augments the contracture response to the MH triggering or diagnostic agents, then the agent is considered unsafe for use in MH-susceptible patients.

Implementation: Utilized in the *in vitro* diagnostic screening of muscle strips from human patients being diagnostically assessed for malignant hyperthermia and muscle strips from the rat diaphragm where preparations are exposed to droperidol, haloperidol, or ketamine prior to challenge with halothane, succinylcholine, or caffeine (used to screen the MH potential of droperidol, heloperidol, ketamine).

Interpretation and Analysis: Droperidol (10 μmol/l) and ketamine (100 μmol/l) do not induce contractures in human or rat skeletal muscle when added alone, nor do they augment halothane, succinylcholine, or caffeine contractures. Therefore, these agents appear to be safe for use in patients susceptible to malignant hyperthermia. In contrast, haloperidol (10 μmol/l) augments the response to succinylcholine about 1.5-fold and may be contraindicated in MH-susceptible cases.

Effects of droperidol, haloperidol and ketamine on halothane, succinylcholine and caffeine contractures: Implications for malignant hyperthermia. Fletcher JE, Rosenberg H, Lizzo FH. Acta Anaesthesiol Scand 1989 Apr; 33 (3), pp. 187–92.

Rhabdomyolyis: Recurrent/Exertional (Equine)/Myoplasmic Calcium Concentration Estimation/Heritable Myopathy *Caffeine/4-Chloro-m-Cresol (4-CmC)*

Physiological Mechanism of Action: Caffeine promotes contraction of skeletal muscle tissue when exposed as an *in vitro* preparation.

Route of Administration: Topical (*in vitro*) bathing of muscle tissue biopsy specimens.

Implementation: Delineation of alterations in myoplasmic calcium regulation can be identified in muscle cell cultures (myotubes) and intact muscle fiber bundles derived from Thoroughbreds affected with recurrent exertional rhabdomyolysis (RER). Laboratory procedures that can be employed to address such an objective employ myotube cell cultures grown from satellite cells obtained from muscle biopsy specimens from horses affected by RER. Fura-2 fluorescence can be used to measure resting myoplasmic calcium concentration as well as caffeine- and 4-CmC-induced increases in myoplasmic calcium. In addition, intact intercostal muscle fiber bundles are prepared from both types of horses, and their sensitivities to caffeine and 4-CmC-induced contractures determined.

Animal Model: Equine cases of RER (n = 6 related Thoroughbreds with RER; n = 8 clinically normal control Thoroughbred or crossbred horses).

Interpretation and Analysis: Myotubes of RER-affected and control horses have identical resting myoplasmic calcium concentrations. Myotubes from RER-affected horses have significantly higher myoplasmic calcium concentrations than myotubes from control horses following the addition of ≥ 2mM caffeine; however, there is no difference in their response to 4-CmC (≥ 1 mM). Caffeine contracture thresholds for RER and control intact muscle cell bundles (2 vs 10mM, respectively) are significantly different, but 4-CmC contracture thresholds of muscle bundles from RER-affected and control horses (500 μM) do not differ. An increase in caffeine sensitivity of muscle cells derived from a family of related RER-affected horses has been detected *in vitro* by use of cell culture with calcium imaging and by use of fiber bundle contractility techniques. An alteration in muscle cell calcium regulation is a primary factor in the cause of this type of heritable myopathy.

Myoplasmic calcium regulation in myotubes from horses with recurrent exertional rhabdomyolysis. Lentz LR, Valberg SJ, Herold LV, Onan GW, Mickelson JR, Gallant EM. Am J Vet Res 2002 Dec; 63 (12), pp. 1724–31.

NEOPLASTIC DISEASE: *EX VIVO*

Somatostatin Receptor Complexes: Neoplastic Disease/Neuroendocrine Cancers/Gliomas/Mammary Carcinoma/Melanoma/Small Cell Lung Cancer *[^{99m}Tc]-Tricine-(HYNIC-TOC)/[^{99m}Tc]-Ethylenediaminediacetic Acid-(HYNIC-TOC)/[^{99m}Tc]-Tricine-Nicotinic acid-(HYNIC-TOC)/[^{111}In]-Diethylenetriaminepentaacetic Acid (DTPA)-Octreotide/[^{111}In]-DTPA-D-Phe1-Octreotide*

Cellular/Molecular Mechanism of Action: Recognizes and physically binds to somatostatin receptor complexes.

Background Information: Indium-111-labeled DTPA-D-Phe1-octreotide (DTPA-OC, OctreoScan) has been introduced into clinical routine for the detection of somatostatin receptor (SSTR)-positive tumors, which are predominantly of neuroendocrine origin. Potential applications also exist for other SSTR-positive cancers (e.g., small cell lung cancer, breast cancer, melanoma), but such evaluations

have been limited mainly due to restricted availability and high radionuclide costs. Previous attempts to introduce [^{99m}technetium]-labeled analogues of octreotide have not been entirely successful in terms of developing effective labeling procedure, variations in *in vivo* biodistribution patterns, and/or tumor detection capabilities.

Application: Early, rapid imaging-based diagnosis of somatostatin receptor positive neoplastic lesions.

Route of Administration: [^{99m}Tc]-HYNIC-D-Phe1-Tyr3-octreotide and [^{111}In]-DTPA-octreotide (intravascular).

Semi-Synthetic Methods: Production of high specific activity [^{99m}Tc]-radiolabeled hydrazinonicotinyl-Tyr3-octreotide (HYNIC-TOC) activities using tricine, ethylenediaminediacetic acid (EDDA), and tricine-nicotinic acid as co-ligand systems.

Implementation: Evaluation of the *in vitro* properties and *in vivo* biodistribution of [^{99m}Tc]-tricine-HYNIC-TOC, [^{99m}Tc]-EDDA-HYNIC-TOC, and [^{99m}Tc]-tricine-nicotinic acid-HYNIC-TOC compared to [^{111}In]-DTPA-octreotide. Receptor binding analyses can be performed using AR42J rat pancreatic tumor cell membranes. Complementary investigations can involve the characterization of internalization processes and protein binding studies, in addition to establishing *in vivo* biodistribution within pancreatic tumors.

***Ex Vivo* Model:** Rat AR42J pancreatic tumor cell membrane receptor binding analyses.

Animal Model: Murine (AR42J pancreatic tumor-bearing nude mice).

Interpretation and Analysis: The [^{99m}Tc]-labeled HYNIC peptides possess retained somatostatin-receptor binding affinities (Kd $<$ 2.65 nM). Protein binding and internalization rates are dependent on the co-ligand used. Specific tumor uptake between 5.8 and 9.6% of the injected dose per gram (%ID/g) can be appreciated for [^{99m}Tc]-labeled peptides, compared with 4.3 %ID/g for [^{111}In]-DTPA-octreotide. Tricine applied as a co-ligand shows higher activity levels in muscle, blood, and liver, whereas tricine-nicotinic acid produces significant levels of activity in the gastrointestinal tract. Ethylenediaminediacetic acid displays the most promising overall biodistribution profile, with tumor-to-liver and tumor-to-gastrointestinal tract ratios similar to those obtained with [^{111}In]-DTPA-octreotide, lower ratios in blood and muscle, but considerably higher tumor-to-kidney ratios. Molecular TOC can be radiolabeled to high specific activities using HYNIC as a bifunctional chelator. The high specific tumor uptake, rapid blood clearance, and predominantly renal excretion make [^{99m}Tc]-EDDA-HYNIC-TOC a promising candidate for an alternative to [^{111}In]-DTPA-octreotide for tumor imaging.

^{99m}Tc-HYNIC-[Tyr3]-octreotide for imaging somatostatin-receptor-positive tumors: Preclinical evaluation and comparison with ^{111}In-octreotide. Decristoforo C, Melendez-Alafort L, Sosabowski JK, Mather SJ. J Nucl Med 2000 Jun; 41 (6), pp. 1114–9.

RESPIRATORY: *EX VIVO*

Immune Hypersensitivity: Allergic Rhinitis (Nasal Biopsy)/Type Th2 Cytokine Expression Responses/Interleukin (IL)-13 Expression
Grass Pollen Extract/Fluticasone Propionate

Cellular/Molecular Mechanism of Action: Grass pollen extract can function as an allergen in immunehypersensitivity reactions. Fluticasone proprionate can inhibit phospholipase A biochemical activity.

Physiological Mechanism of Action: Fluticasone proprionate can promote immunesuppressive responses and anti-inflammatory properties in part due to its ability to inhibit both protein synthesis and leukocyte degranulation events.

Background Information: The allergen-induced late nasal response (LNR) is associated with high expression of IL-4 and IL-5 messenger RNA (mRNA) in the nasal mucosa, suggesting a role for Th2-type cytokines in the development of the LNR. Moreover, topical corticosteroid-mediated inhibition of the LNR is accompanied by inhibition of IL-4, but not IL-5, mRNA expression. Interleukin-13 shares a number of functions with IL-4, including IgE switching and vascular cell adhesion molecule-1 (VCAM-1) upregulation.

Application: Grass pollen extract can be used to initiate inflammatory and immune responses in conditions of hyperactive immune responses associated with this source of allergen. Fluticasone can be used as a probe to study alterations in the production of endogenous mediators of inflammatory and immune responses to allergen-induced responses.

Implementation: Evaluate the influence of fluticasone propionate on the expression of IL-4 and IL-13 mRNA sequences and immunoreactivity in nasal mucosa tissue biopsy specimens. Design of investigations can involve administration of either topical or inhaled fluticasone propionate in conditions of allergic rhinitis. Nasal biopsies are harvested before treatment and 24 hours after local nasal allergen provocation with a grass pollen extract.

Human Model: Nasal biopsy tissue specimens in conditions of allergic rhinitis (n = 20; n = 10 normal healthy reference controls; n = 10/20 inhaled fluticasone propionate; n = 10/20 topical fluticasone propionate BID for 6 weeks).

Interpretation and Analysis: No significant difference between the allergic rhinitis cases and controls in the expression of IL-13 mRNA and immunoreactivity can be detected prior to treatment.

After allergen provocation/challenge, significant increases in IL-13 mRNA-positive and immunoreactive cells at 24 hours can be detected in the absence of corticosteroid exposure (placebo $p < 0.001$). Inhibition of the LNR after corticosteroid treatment is associated with a marked decrease in allergen-induced IL-13 mRNA-positive ($p < 0.001$) and immunoreactive cells ($p < 0.001$). In the absence of steroid exposure (e.g., placebo), 76.9 + 5.5% of IL-13 mRNA-positive cells after allergen are CD3+, whereas 11.2 ± 2.7% co-express immunoreactivity for mast-cell tryptase. In these cases, increases in cells expressing IL-13 mRNA are greater than for IL-4 mRNA ($p = 0.001$), and double *in situ* hybridization studies reveal that 100% of the IL-4 mRNA-positive cells co-express IL-13 mRNA, whereas 66.6 + 10.5% of IL-13 mRNA-positive cells co-express IL-4 transcripts after allergen challenge. Such findings suggest that IL-13 expression is a prominent feature of the LNR, and that inhibition of the LNR following steroid therapy may be partly attributable to inhibition of IL-13 expression.

IL-13 mRNA and immunoreactivity in allergen-induced rhinitis: Comparison with IL-4 expression and modulation by topical glucocorticoid therapy. Ghaffar O, Laberge S, Jacobson MR, Lowhagen O, Rak S, Durham SR, Hamid Q. Am J Respir Cell Mol Biol 1997 Jul; 17 (1), pp. 17–24.

Immune Hypersensitivity: Asthma Alveolar Macrophages/Blood Monocytes/Septic Inflammatory Responses/Cytokine Responses: Interleukin (IL)-10, Macrophage Inflammatory Protein-1alpha (MIP-1α), Interferon-Gamma (IFN-γ), Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)
IL-1β/Dexamethasone/Lipopolysaccharide (LPS)

Cellular/Molecular Mechanism of Action: Dexamethasone inhibits phospholipase A2 biochemical activity. Lipopolysaccharide is also referred to as bacterial endotoxin. Systemically, LPS can bind

to lipopolysaccharide-binding protein and membrane-associated LPS receptor complexes (CD14).

Physiological Mechanism of Action: Dexamethasone functions as a immunosuppressive agent due to its ability to inhibit normal protein synthesis and stabilization of cell membranes in a manner the inhibits cell activation and degranulation phenomenon. Bacterial lipopolysaccharide fractions (LPS, endotoxin) promote inflammatory responses in primarily leukocyte and endothelial cell populations. The cytokine IL-1β functions as an endogenous mediator of inflammation.

Application: Lipopolysaccharide (LPS, bacterial endotoxin) can be utilized to induce septic inflammatory responses. Dexamethasone can be used as a probe to study alterations in the production of endogenous mediators associated with inflammatory and immune responses during allergen-induced reactions.

Implementation: Evaluation of the effect of inhaled corticosteroid budesonide on the release of the anti-inflammatory cytokine IL-10 and of proinflammatory cytokines MIP-1α, IFN-γ, and GM-CSF from blood monocytes and alveolar macrophages.

Human Model: Cases of mild asthma used as donors for alveolar macrophages obtained by bronchoalveolar lavage at the end of each treatment phase (double blind, crossover, placebo-controlled study).

Interpretation and Analysis: Budesonide reduces bronchial hyperresponsiveness and improves baseline FEV_1. Alveolar macrophages obtained by bronchoalveolar lavage performed at the end of each treatment phase. Interleukin-10 from blood monocytes is not altered, but both IL-10 mRNA and protein expression from alveolar macrophages stimulated by lipopolysaccharide and IL-1β are increased after corticosteroid therapy. By contrast, alveolar macrophages release significantly less MIP-1α, IFN-γ, and GM-CSF after steroid challenge. In comparison to alveolar macrophages from normal non-asthmatic reference controls, those from cases of asthma release more MIP-1α, IFN-γ, and GM-CSF but lower amounts of IL-10, particularly at baseline and after IL-1β stimulation. The ability of steroids to inhibit proinflammatory cytokines but to enhance the anti-inflammatory cytokines such as IL-10 may contribute to their beneficial actions in asthma. Asthma is characterized by alveolar macrophages exhibiting both an enhanced capacity to release proinflammatory cytokines and a reduced capacity to produce IL-10.

Inhaled corticosteroids increase interleukin-10 but reduce macrophage inflammatory protein-1alpha, granulocyte-macrophage colony-stimulating factor, and interferon-gamma release from alveolar macrophages in asthma. John M, Lim S, Seybold J, Jose P, Robichaud A, O'Connor B, Barnes PJ, Chung KF. Am J Respir Crit Care Med 1998 Jan; 157 (1), pp. 256–62.

Immune Hypersensitivity: Bronchial Hyperresponsiveness (BHR)/Bronchial Lavage Fluid Eosinophils, Lymphocytes, and Neutrophils/Allergic Airway Eosinophilia Reactions/Type Th1 and Th2 Cytokine Expression Profiles

Ovalbumin/Dexamethasone/Cyclosporine

Cyclosporin A is an immunomodulatory agent that acts specifically at an early stage in the activation of T-lymphocytes. In this context, in contrast to azothioprine and other cytotoxic agents, cyclosporin suppresses T-lymphocyte mediated cellular immune responses without causing major effects on antibacterial defenses.

Cellular/Molecular Mechanism of Action: Ovalbumin is the avian equivalent of mammalian serum albumin and can be applied as an immunogenic protein fraction. Dexamethasone is a corticosteroid that has an ability to inhibit phospholipase A2 biochemical activity.

Physiological Mechanism of Action: Dexamethasone is a corticosteroid that promotes immunosuppressive properties in part due to inhibition of leukocyte degranulation phenomenon and general inhibition of protein synthesis.

Background Information: Cyclosporin A and dexamethasone exhibit different effects on allergic airway eosinophilia and BHR.

Application: Characterization of the molecular pathogenesis of normal and hypersensitivity immune responses including alteration of cytokine expression such as changes in the profile of Th1- vs Th2-derived cytokines. The agent can be applied as part of an investigative strategy to delineate the efficacy of various therapeutic agents possessing anti-inflammatory and immunosuppressive properties.

Implementation: Evaluation of the influence of cyclosporine or dexamethasone on the development of immune hypersensitivity reactions to ovalbumin aerosol challenge. Bronchial responsiveness is measured 18–24 hours after aerosol exposure. Airway cellular influx can be determined by bronchoalveolar lavage and tissue immunohistochemistry. Expression of Th1 and Th2 cytokine messenger RNA (mRNA) are then analyzed by reverse transcriptase-PCR.

Animal Model: Rat (Brown Norway rats sensitized to ovalbumin).

Interpretation and Analysis: Ovalbumin exposure induces significant BHR reactions, with increases in eosinophils, lymphocytes, and neutrophils in bronchoalveolar lavage fluid and an increase in eosinophils, CD2+ and CD8+, but not CD4+ T cells, in the airway submucosa. Interleukin-2, IFN-γ, IL-4, and IL-5 mRNA expression in ovalbumin-sensitized lungs increases ($p < 0.05$) compared with controls. Cyclosporin A does not significantly affect BHR and neutrophil accumulation but reduces the number of bronchoalveolar lavage eosinophils ($p < 0.002$), airway submucosal eosinophils, and CD4+ and CD8+ T cells ($p < 0.02$). It also suppresses the induction of mRNA expression of IL-2, IL-4, IL-5, and IFN-γ. By contrast, the inflammatory cell influx and mRNA expression of IL-2, IL-4, and IL-5, as well as BHR, is suppressed by dexamethasone. However, increases in IL-10 and IFN-γ mRNA expression can sometimes not be detected depending on the analytical system evaluated. The differential activities of cyclosporin A and dexamethasone on inflammatory cell influx, particularly neutrophils, or cytokine expression such as IL-10 and IFN-γ may underlie their contrasting effects on BHR.

Diagnostic pharmacology: Differential effect of corticosteroids and cyclosporin differential regulation of cytokine expression after allergen exposure of sensitized rats by cyclosporin A and corticosteroids: Relationship to bronchial hyperresponsiveness. Huang TJ, Newton R, Haddad EB, Chung KF. J Allergy Clin Immunol 1999 Sep; 104 (3 Pt 1), pp. 644–52.

Inflammatory Response: Nasal Mucosa Responses/Nasal Mucosa Cyclooxygenase (COX)-1 and COX-2 Synthesis

Dexamethasone/Interleukin (IL)-10/Actinomycin-D/Cyclohexamide/Proinflammatory Mediators (Interferon-Gamma [IFN-γ], IL-1β, and Tumor Necrosis Factor-Alpha [TNF-α])

Cellular/Molecular Mechanism of Action: Actinomycin-D intercalates between DNA strands within the DNA helix. Dexamethasone inhibits phospholipase A2 biochemical activity.

Physiological Mechanism of Action: Dexamethasone functions as an immunosuppressive and anti-inflammatory agent due to an ability to inhibit normal protein synthesis and stabilize cell membranes in a manner sufficient to inhibit cell activation and leukocyte

degranulation events. Actinomycin-D inhibits translation events while cyclohexamide inhibits transcription. Interleukin-10 exerts relatively profound anti-inflammatory properties.

Background Information: Cyclooxygenase converts arachidonic acid in prostanoids. Cyclooxygenase exists in 2 isoforms: COX-1 is the constitutive, whereas COX-2 is the inducible isoform. The regulation of COX-1 and COX-2 expression in nasal mucosa has not been extensively investigated.

Application: Characterization of the molecular pathogenesis of disease states, immune reactions/responses, and efficacy of various forms of therapeutic intervention. Dexamethasone, therefore, can be utilized as a probe for delineating the role of endogenous inflammatory mediators in immune responses and inflammatory reactions.

Implementation: Evaluation of alterations in endogenous COX-1 and COX-2 production *in vitro* in nasal biopsy tissues applying agents that promote proinflammatory and anti-inflammatory properties in addition to inhibitors of transcription and translation events as molecular probes. In this manner, it is possible to gain greater understanding about mechanisms involved in the expression and regulation of COX-1 and COX-2 by cytokines and corticosteroids. The specific design of such investigations can entail employing the use of cultured normal/healthy human nasal explants exposed/incubated with individual agents known to promote (i) proinflammatory properties (IFN-γ, IL-1β, and TNF-α); (ii) anti-inflammatory properties (dexamethasone, IL-10) and inhibitors of translation (actinomycin-D) and transcription (cycloheximide) events. Tissue culture preparations are subsequently analyzed for the detection of alterations in COX-1 and COX-2 expression by semi-quantitative competitive PCR and Western blot analyses.

Human *Ex Vivo* Model: Nasal mucosa biopsy tissues.

Interpretation and Analysis: Baseline expression of COX-2 mRNA is higher than COX-1 mRNA. In a tissue culture environment, there is a slight spontaneous upregulation of COX-1 and a strong COX-2 mRNA and protein upregulation. Incubation of nasal explants with proinflammatory cytokines increases the expression of COX-2 mRNA and protein, from 1 to 24 hours of incubation in a dose-related manner. Regulation of these effects occurs at the levels of both transcriptional and posttranscriptional phases. Dexamethasone and IL-10 abrogate cytokine-induced COX-2 mRNA and protein expression. Proinflammatory cytokines, dexamethasone and IL-10 have no effect on COX-1 mRNA expression. Prostanoids, therefore, appear to have an important regulatory effect on immunologically (cytokine)-mediated inflammatory responses.

Regulation of cyclooxygenase-1 and -2 expression in human nasal mucosa. Effects of cytokines and dexamethasone. Fernández-Morata JC, Mullol J, Fuentes M, Pujols L, Roca-Ferrer J, Pérez M, Xaubet A, Picado C. Clin Exp Allergy 2000 Sep; 30 (9), pp. 1275–84.

RANTES Production: Airway Smooth Muscle
Tumor Necrosis Factor-Alpha (TNF-α) and Interferon-Gamma (IFN-γ)/Interleukin (IL)-4, IL-10, and IL-13/Dexamethasone

Cellular/Molecular Mechanism of Action: RANTES is a basic 8-kDa polypeptide of the C-C chemokine subfamily that promotes strong chemotactic response activity in eosinophils, lymphocytes, and monocytes.

Implementation: Evaluation of mechanisms that regulate RANTES production by human airway smooth muscle cells in culture.

Interpretation and Analysis: While TNF-α, but not IFN-γ, increases RANTES mRNA expression and protein release, the combination of TNF-α and IFN-γ causes a greater degree of expression and release in a time- and dose-dependent manner. Sequential treatment of airway smooth muscle cells with TNF-α and IFN-γ reveals that IFN-γ sensitizes cells to the stimulatory effect of TNF-α. Using a modified Boyden chamber technique, RANTES separated by reverse-phase liquid chromatography from cell culture supernatants of airway smooth muscle cells stimulated by TNF-α and IFN-γ shows a strong chemoattractant effect on human eosinophils, an effect that is inhibited by an anti-RANTES antibody RANTES production induced by TNFα and IFN-γ is inhibited partly by the Th2-derived cytokines, IL-4, IL-10, and IL-13, as well as by dexamethasone. Studies indicate that, in addition to contractile responses and mitogenesis, airway smooth muscle cells have synthetic and secretory potential with the release of RANTES. They may participate in chronic airway inflammation by interacting with both Th1- and Th2-derived cytokines to modulate chemoattractant activity for eosinophils, activated T lymphocytes, and monocytes/macrophages.

Human airway smooth muscle cells express and release RANTES in response to T helper 1 cytokines: Regulation by T helper 2 cytokines and corticosteroids. John M, Hirst SJ, Jose PJ, Robichaud A, Berkman N, Witt C, Twort CH, Barnes PJ, Chung KF. J Immunol 1997 Feb 15; 158 (4), pp. 1841–7.

6 Hepatic System

BILIARY AND HEPATIC DIAGNOSTICS

BILIARY

Biliary Atresia (Infant): Jaundice/Frail and Compromised Patients
[^{131}I]-Rose Bengal (Fecal Excretion Test)/[^{99m}Tc]-Pyridoxylidene Glutamate (^{99m}Tc-PG)

Cellular/Molecular Mechanism of Action: Pyridoxylidene glutamate and rose bengal are both removed from the plasma by viable hepatocytes.
Application: Assess postoperative bile drainage with repeat scans in infants with biliary atresia. Scintigraphic imaging with [^{99m}Tc]-PG may also be useful as a screening test in difficult cases of jaundice, especially in frail patients, and cases with complications.
Route of Administration: Intravenous.
Implementation: Evaluation of hepatic function in cases of systemic jaundice applying [^{99m}Tc]-PG for nuclear scan imaging.
Human Model: Cases of systemic jaundice (n = 24 adults with mean total bilirubin = 255 μmol/l; n = 11 infants with prolonged obstructive jaundice and mean total bilirubin = 165 μmol/l).
Interpretation and Analysis: Absence of radioactivity in the gastrointestinal tract is interpreted as complete biliary obstruction and assumed to be the cause of jaundice (e.g., n = 10/24 adult and n = 6 infant jaundice cases). Using this criterion, occlusion or patency of the bile ducts can be correctly determined in a high percentage of cases (e.g., n = 21/24 adults; and n = 6/11 infants). A low percentage of jaundice cases display either false-negative gut images (e.g., n = 1/21 adults; and n = 2/11 infants) or inconclusive results (e.g., n = 2/24 adults; and n = 1/11 infants). Scans are unable to show details about the site of obstruction or pathology but the technique is simple, atraumatic, and safely performed in cases with serious complications (e.g., renal failure, coagulation defects, septicmia). In infants the [^{99m}Tc]-PG scan compares well with the [^{131}I]-rose bengal fecal excretion test and with liver biopsy in the investigation of prolonged obstructive jaundice.

Hepatobiliary imaging: The use of ^{99m}Tc-pyridoxylidene glutamate scanning in jaundiced adults and infants. Jenner RE, Howard ER, Clarke MB, Barrett JJ. Br J Radiol 1978 Nov; 51 (611), pp. 862–6.

Biliary Colic/(Sphincter of Oddi Spasm)
Codeine/(Ultrasound)

Background Information: Biliary colic from spasm of the sphincter of Oddi is difficult to diagnostically prove.
Application: Codeine may be a useful provocative agent and ultrasound measurements of changes in common bile duct diameter may provide a useful method in diagnostic approaches for the detection of sphincter of Oddi spasms.
Implementation: Biliary colic.
Interpretation and Analysis: Diagnosis can be established by (i) using a pharmacological provocative test employing codeine to reproduce pain; (ii) detection of changes in liver and pancreatic serum enzymes; and (iii) ultrasound imaging to demonstrate a transient increase in common bile duct diameter. Implemenation of such procedures prior to surgical sphincteroplasty reproduces symptoms and brings about marked elevations in pancreatic and liver enzyme fractions and increases in common bile duct diameter measured by ultrasound examination (e.g., 0.4 to 1.0 cm). Such events often cannot be appreciated after sphincteroplasty.

Ultrasound in the diagnosis of sphincter of Oddi spasm. Berezny GM, Beck IT, DaCosta LR, O'Brien PG, Paloschi GB. J Clin Gastroenterol 1985 Dec; 7 (6), pp. 528–32.

Biliary Dyskinesis/Cholecystography: Postevacuation
Kinevac/Sincalide/Secretin

Cellular/Molecular Mechanism of Action: Sincalide is a synthetic analog of cholecystokinin.
Physiological Mechanism of Action: Sincalide causes a prompt contraction of the gallbladder as compared to the stimulus of a fatty meal, which causes progressively more pronounced contractions that become maximal in about 40 minutes. Kinevac accelerates transit time through the lumen of the small intestine.
Application: Sincalide is used in postevacuation cholecystography. Kinevac, due to its physiological properties, can be applied to decrease the extent of radiation exposure associated with fluoroscopy and length of radiographic examinations of the intestinal tract.
Considerations: Serious reactions to sincalide have not been reported.
Implementation: Facilitation of duodenal fluid collection that is high in bile content.
Interpretation and Analysis: Duodenal aspirations obtained after the administration of Kinevac provide a sample of concentrated bile entirely suitable for analysis of cholesterol, bile salts, phospholipids, and crystals. When used in conjunction with secretin to stimulate pancreatic secretion, an aspirate can be readily obtained for analysis of enzyme activity, composition, and cytology. As the development of endoscopic manometry affords a modality to measure and record sphincter of Oddi pressures, the paradoxical responses noted to the intravenous administration of cholecystokinin (CCK) during manometric evaluation support the diagnostic value of Kinevac used as a provocative agent in the evaluation of biliary dyskinesia.

Kinevac (sincalide for injection)/Squibb Diagnostics. Maher KA. Gastroenterol Nurs 1991 Oct; 14 (2), pp. 98–100.

Biliary Tract: Sphincter of Oddi Spasms and Biliary Colic/Sphincter of Oddi Spasm Induction/ Ultrasound Imaging: Detection of Changes in Diameter
Codeine

Physiological Mechanism of Action: Codeine can promote alterations in the function of the sphincter of Oddi in conditions prone to spasms.
Background Information: Biliary colic from spasm of the sphincter of Oddi has been a difficult diagnosis to prove.
Application: Provocative test for the diagnosis of biliary colic due to spasms of the sphincter of Oddi in a manner that can be detected on ultrasound examination.
Implementation: Evaluation of conditions of possible biliary colic due to spasms of the sphincter of Oddi.
Interpretation and Analysis: Codeine can be applied as a valuable provocative testing agent for reproducing episodes of biliary colic (pain) due to spasms of the sphincter of Oddi. Affected cases may also promote changes in liver and pancreatic serum enzymes. A 2nd diagnostic benefit of codeine is its ability to demonstrate before surgical sphinteroplasty transient increases in common bile duct diameter that can be detected by ultrasound imaging (e.g., 0.4 cm → 1.0 cm). Such events cannot be recognized after successfully performing sphincteroplasty procedures. Codeine may be useful as a provocative testing agent, and ultrasound measurements of changes in common bile duct diameter may provide a useful method as a diagnostic approach for detecting sphincter of Oddi spasms.

Ultrasound in the diagnosis of sphincter of Oddi spasm. Berezny GM; Beck IT; DaCosta LR; O'Brien PG; Paloschi GB. J Clin Gastroenterol 1985 Dec; 7 (6), pp. 528–32.

HEPATOBILIARY

Gilbert's Syndrome (GS)/Hepatic Dysfunction
Rifampicin

Cellular/Molecular Mechanism of Action: Rifampicin is removed from the plasma, excreted into the bile, partially metabolized by gastrointestinal bacterial flora, and then absorbed within the small intestine (e.g., enterohepatic circulation route).
Background Information: Gilbert's syndrome is characterized by the existence of chronic mild unconjugated hyperbilirubinemia.
Application: Provocative test for GS but also causes increases in unconjugated bilirubin in some cases of chronic hepatic disease.
Dosage: Rifampicin (600 mg).
Implementation: Evaluation of the relative value of rifampicin as a provocative test for the diagnosis of GS compared to a fasting-based test. In the fasting test, subjects are given a 400-calorie/day diet for 24 hours; in the rifampicin test, unconjugated bilirubin levels are measured before and 4 hours after administration.

Human Model: Cases of GS (n = 22 GS; n = 15 chronic liver disease; n = 20 healthy reference controls). All cases evaluated with both provocative test procedures.
Interpretation and Analysis: Both tests achieve a significant increase in mean unconjugated bilirubin levels in patients with GS but not in the controls. The sensitivity and specificity of a rifampicin test in the diagnosis of GS is comparable with the fasting test. However, both tests cause a significant increase in unconjugated bilirubin levels in nearly half the patients with chronic liver disease. A rifampicin test may be used in the diagnosis of suspected GS instead of a fasting test, as it is simpler and more practical. However, its specificity for GS is not sufficient, because it also causes an increase in unconjugated bilirubin levels in some patients with chronic liver disease.

Rifampicin test in the diagnosis of Gilbert's syndrome. Erdil A, Kadayifci A, Ates Y, Bagci S, Uygun A, Dagalp K. Int J Clin Pract 2001 Mar; 55 (2), pp. 81–3.

Gilbert's Syndrome (GS)
Rifampicin/(Fasting Test Alternative)

Cellular/Molecular Mechanism of Action: Following oral ingestion, rifampicin undergoes multiple enterohepatic cycles.
Application: Gilbert's syndrome is characterized by the existence of chronic mild unconjugated hyperbilirubinemia. The specificity of the rifampicin test for GS is not sufficient, because it also causes an increase in unconjugated bilirubin levels in some patients with chronic liver disease.
Route of Administration: Oral (per os).
Dosage: Rifampicin 600 mg.
Implementation: Rifampicin and fasting tests can be applied to identify cases of GS. In the fasting test, cases are given a 400-calorie/day diet for 24 hours. Alternatively in the rifampicin test, unconjugated bilirubin levels are measured before and 4 hours after rifampicin (600 mg per os).
Interpretation and Analysis: Both tests achieve a significant increase in mean unconjugated bilirubin levels in patients with GS but not in normal subjects. The sensitivity and specificity of a rifampicin test in the diagnosis of GS are comparable with the fasting test. However, both tests cause a significant increase in unconjugated bilirubin levels in nearly half the patients with chronic liver disease. A rifampicin test may be used in the diagnosis of suspected GS instead of a fasting test, especially because it represents a simpler and more practical methodology.

The utility of rifampicin in diagnosing Gilbert's syndrome. Murthy GD, Byron D, Shoemaker D, Visweswaraiah H, Pasquale D. Am J Gastroenterol 2001 Apr; 96 (4), pp. 1150–4.

Hepatic Bile Acid Transport/Visual Detection and Monitoring
Lysyl Fluorescein Conjugated Bile Acid Analogues (LFCBAA)

Background Information: Lysyl fluorescein conjugated bile acid analogues closely parallel their natural counterparts.
Application: Lysyl fluorescein conjugated bile acid analogues can be applied as molecular tools or probes for visualizing bile acid transport within hepatic tissues.
Route of Administration: Intravenous or retrograde injection into the biliary tree.
Semi-Synthetic Methods: Conjugation of lysyl fluorescein to bile acid analogues.
Implementation: Physiological concentrations of the primary bile acid analogue cholyllysyl fluoroscein (CLF) and of the secondary bile acid analogue lithocholyllysyl fluorescein (LLF) are administered systemically, followed by the collection of serial liver biopsies at fixed timed intervals. Both compounds are also injected retrogradely into the biliary tree. Frozen sections are then examined by fluorescence microscopy.

Animal Model: Rat (Wistar).
Interpretation and Analysis: Both CLF and LLF are rapidly taken up from sinusoidal blood but differ significantly in their hepatic handling. Cholyllysyl fluoroscein is rapidly transported into the bile, whereas LLF transport is slower and produces significantly more bile duct fluorescence. Lithocholyllysyl fluorescein clearance involves a

lobular gradient with the last remaining bile acid being confined (largely zone 3). Both compounds are avidly taken up by cholangiocytes after intravenous or retrograde injection into the biliary tree. Visualization of LFCBAA by fluorescence microscopy may yield further information regarding hepatobiliary bile acid localization during studies designed to characterize physiological and pathological mechanisms involved in the transport of bile acids. The presence of both compounds within cholangiocytes strongly suggests that they may undergo a degree of chole-hepatic recirculation.

Instrumentation: Fluorescence microscopy.

Visualization of the transport of primary and secondary bile acids across liver tissue in rats: *In vivo* study with fluorescent bile acids. Milkiewicz P, Mills CO, Hubscher SG, Cardenas R, Cardenas T, Williams A, Elias E. J Hepatol. 2001 Jan; 34 (1), pp. 4–10.

HEPATIC BLOOD/PLASMA FLOW AND PERFUSION

Hepatic Cirrhosis: Alterations in Functional Blood Flow/Perfusion and Metabolic Capacity/Volume
D-Sorbitol

Cellular/Molecular Mechanism of Action: D-sorbitol is a carbohydrate molecule that is normally removed from the intravascular compartment by viable hepatocytes.

Application: Evaluation of the overall functional reserve of cirrhotic liver by assessing of hepatic functional blood flow, liver volume, Child-Pugh's classification, and discussion of its value for clinical application.

Implementation: Blood and urine samples are collected 4 times before and after intravenous D-sorbitol infusion. Hepatic clearance (CL_H) of D-sorbitol is then calculated according to an enzymatic spectrophotometric method while total blood flow (Q_{TOTAL}) and intrahepatic shunting (R_{INS}) can be detected by multicolor Doppler ultrasound, while liver volume is measured by spiral CT. Laboratory results are analyzed by t test, variance calculations, and chi^2 analysis. The relationships among all these parameters and different groups are then investigated according to Child-Pugh classification and postoperative complications, respectively.

Human Model: Cases of portal hypertension due to hepatic cirrhosis ($n = 92$ and all with a history of hematoemesis and hematochezia, esophageal and gastric fundus varices, splenomegaly and hypersplenia, with cases being followed during a 2-year monitoring period [$n = 22$ normal healthy volunteer controls]).

Interpretation and Analysis: Steady blood concentration is achieved 120 minutes after D-sorbitol intravenous infusion, which is (0.358 ± 0.064) mmol $\times L^{-1}$ in cirrhotic group and (0.189 ± 0.05) mmol $\times L^{-1}$ in control group ($p < 0.01$). $CL_H = (812.7 \pm 112.4)$ ml $\times$ min^{-1}, $Q_{TOTAL} = (1280.6 \pm 131.4)$ ml $\times$ min^{-1}, and $R_{INS} = (36.54 \pm 10.65)$ % in cirrhotic group and $CL_H = (1248.3 \pm 210.5)$ ml $\times$ min^{-1}, $Q_{TOTAL} = (1362.4 \pm 126.9)$ ml $\times$ min^{-1}, and $R_{INS} = (8.37 \pm 3.32)$ % in control group ($p < 0.01$). The liver volume of cirrhotic group is approximately 1057 ± 249 cm^3, 851 ± 148 cm^3, and 663 ± 77 cm^3 in Child A, B, and C groups, respectively, with significant difference ($p < 0.001$). The average volume of cirrhotic liver in Child B, C group is significantly reduced in comparison with that of control subjects ($p < 0.001$). Cases that have a decrease in liver volume of 40% and CLH below 600 ml $\times$ min^{-1} may have a higher incidence of postoperative complications. There is no strict correspondent relationship among CL_H, liver volume, and Child-Pugh's classification.

The hepatic clearance of D-sorbitol and CT measured liver volume can be reliably used for the evaluation of hepatic functional blood flow and liver metabolic volume. Combined with the Child-Pugh's classification, it could be very useful for further understanding the liver functional reserve, therefore helping to determine a reasonable therapeutic plan and choose surgical procedures and determining the appropriate time to operate.

Evaluation of liver functional reserve by combining D-sorbitol clearance rate and CT measured liver volume. Li YM, Lv F, Xu X, Ji H, Gao WT, Lei TJ, Ren GB, Bai ZL, Li Q. World J Gastroenterol 2003 Sep; 9 (9), pp. 2092–5.

Hepatic Plasma Flow
Sorbitol/Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Sorbitol is an organic compound that is removed from the plasma by the liver.

Application: Evaluation of whole-body removal kinetics of sorbitol using extrarenal sorbitol clearance to estimate hepatic plasma flow in humans and to compare measurements of liver flow by Fick's principle using either ICG or sorbitol.

Route of Administration: Sorbitol (intravenous bolus).

Dosage: Sorbitol (5 mmol/kg) or sorbitol infusion (287 μmol/min in liver patients and controls).

Implementation: Determination of the sorbitol elimination capacity (SEC) and distribution volume, $V_{sorb}d$, following bolus administration or sorbitol infusion. Extrarenal sorbitol clearance ($V_{sorb}x$) is calculated as a function of infusion rate (corrected for renal excretion and accumulation in $V_{sorb}d$) divided by arterial concentration. Liver flow (Q_{ICG}) is calculated from the ICG infusion and arterial and hepatic venous ICG concentrations according to Fick's principle.

Human Model: Healthy cases (bolus infusion in $n = 6$ controls, compared to infusion administration in $n = 17$ hepatic cases and $n = 11$ controls).

Interpretation and Analysis: Average SEC is 73 μmol/min/kg, $V_{sorb}d$ is approximately 0.16 L plasma per kilogram, and *in vivo* $V_{sorb}d$ is 3 mmol/L. Renal sorbitol excretion rate is 0.03–0.31 of infusion rate. Extrahepatic extrarenal removal is not significantly different from zero but varies considerably. Hepatic extraction fraction of sorbitol, (E_{sorb}), measured by liver vein catheterization, is 0.35–1.04 (median, 0.86) in cirrhotic patients and 0.90–0.98 (0.86) in controls. The requirement for using $Cl_{sorb}x$ as an estimate of Q_{ICG} is not violated by the data in controls, $Cl_{sorb}x/Q_{ICG}$ 0.70–1.55 (median, 1.08), whereas there is a systematic underestimation in cirrhotic patients (0.72–1.08 [0.85]). Liver flow calculated by Fick's principle using either sorbitol or ICG agrees well. $E_{sorb} > E_{ICG}$ in the vast majority of cases. Curvilinear relationships between E_{sorb} and E_{ICG} are in agreement with different kinetic parameters for sorbitol and ICG, and do not require additional assumption of intrahepatic shunts.

Sorbitol as a test substance for measurement of liver plasma flow in humans. Keiding S, Engsted E, Ott P. Hepatology 1998 Jul; 28 (1), pp. 50–6.

HEPATIC EXCRETORY FUNCTION

Hepatic Excretory and Biochemical Function/ Provocative Hepatic Probe Interference by Adenosine
Indocyanine Green (ICG) Disappearance/Galactose Elimination Capacity (GEC)/Lidocaine Monoethylglycinxylidide (MEGX) Metabolite

Physiological Mechanism of Action: Indocyanine green is removed from the plasma compartment and excreted into the bile but is not metabolized by hepatocytes. Galactose is removed from the

intravascular compartment by the liver. An extremely high percentage of lidocaine is removed from the portal circulation as it perfuses through the hepatic sinusoids and is subsequently metabolized by hepatocytes to MEGX.

Background Information: In cirrhosis, hepatic arterial vasodilatation occurs in response to reduced portal venous blood flow. However, although the hepatic arterial flow reserve is high in patients with cirrhosis, its impact on hepatic function is unknown.

Application: Indocyanine green disappearance, GEC, and formation of lidocaine metabolite MEGX can be used to assess hepatic function.

Route of Administration: Adenosine (intravenous infusion). Indocyanine green, lidocaine, and galactose are administered intravenously.

Dosage: Adenosine (2–30 μg/min/kg body wt). Indocyanine green, lidocaine, and galactose are administered at doses of 0.5, 1.0, and 500 mg/kg body weight, respectively.

Implementation: Evaluate the effect of adenosine-induced hepatic arterial vasodilatation on different markers for liver function. Adenosine is infused into the hepatic artery and hepatic arterial average peak flow velocities (APV), pulsatility indices (PI), and blood flow volumes (HABF) are measured using digital angiography and intravascular Doppler sonography. Indocyanine green, lidocaine, and galactose can be administered in the presence of adenosine-induced hepatic arterial vasodilatation, and again on a separate study day, without adenosine. Indocyanine green disappearance, GEC, and formation of the lidocaine metabolite MEGX are then assessed.

Human Model: Cases of hepatic cirrhosis (n = 20; Child-Pugh class A/B/C: n = 2/7/11).

Interpretation and Analysis: Adenosine markedly increases hepatic arterial APV and HABF, while markedly decreasing PI. Serum MEGX concentrations are approximately 63.7 ± 18.2 (median, 62; range, 36–107) and 99.0 ± 46.3 (82.5; 49–198) ng/mL in the absence and presence of adenosine infusion, respectively ($p = 0.001$). Adenosine-induced changes in MEGX concentrations correlate inversely to changes in hepatic arterial average peak flow velocities (APV $r = -0.5$, $p = 0.02$) and PI ($r = -0.55$, $p = 0.01$) and are more marked in Child-Pugh Class C compared with Child-Pugh Class A patients (57.4 ± 49.9 [44; −14–140] vs 8.4 ± 16.5 [13; −11–35] ng/mL, $p < 0.01$). Therefore, hepatic arterial vasodilatation provides substantial functional benefit in cases with cirrhosis. The effect does not depend directly on hepatic arterial macroperfusion and is observed preferentially with decompensated disease.

Functional significance of hepatic arterial flow reserve in patients with cirrhosis. Zipprich A, Steudel N, Behrmann C, Meiss F, Sziegoleit U, Fleig WE, Kleber G. Hepatology 2003 Feb; 37 (2), pp. 385–92.

Hepatic Excretory Function
Bromosulfophthalein (BSP)/Comparison to Bile Acids

Cellular/Molecular Mechanism of Action: In the intravascular compartment, the vast majority of the BSP becomes bound to serum albumin fractions. However, within the liver, it readily diffuses across the endothelium that lines the hepatic sinusoids because they are uniquely permeable to protein fractions. Bromosulfophthalein dissociates from its protein fraction, diffuses across the intact hepatocyte membrane, and then becomes reassociated with a protein fraction within the intracellular environment of hepatocytes. The majority of intracellular BSP within the hepatocyte then subsequently becomes conjugated to glutathione. Excretion of both conjugated and unconjugated forms of BSP occurs in essentially an exclusive manner into the biliary canaliculi.

Hepatic extraction of BSP from the systemic circulation (intravascular compartment) is maximal during the period immediately following intravenous injection. Compromised hepatic function results in delayed systemic clearance of BSP.

Diagnostic Application: Diagnosis of compromised hepatic function.

Route of Administration and Dosage: Injected intravenously at a dosage of 2 mg/kg. Blood samples should be collected from a vein different than the 1 used for administration.

Considerations: Clearance of BSP should be delayed if direct and indirect bilirubin levels are already elevated. Although BSP is less expensive than indocyanine green, it has a relatively higher degree of renal excretion and at the present time it is not available on a commercial basis.

Implementation: Following BSP administration by injection, venous blood samples are collected at 4-minute intervals. Examples of acceptable time intervals include 5 and 9 minutes, and 7 and 9 minutes postinjection.

Interpretation and Analysis: In conditions of compromised hepatic function, the plasma BSP clearance is delayed.

Based upon results obtained from a standard reference curve, individual measurements are then plotted on a vertical axis on semi-log paper with time (minutes) on the horizontal axis. Estimated $T_{1/2}$ is then calculated from this curve.

Normal values:

canine	≤ 5% retention at 30 minutes
equine	2.8% +/− 0.50 minutes
bovine	
-mature dairy cow	3.1% +/− 0.60 minutes
-yearling	4.5% +/− 0.32 minutes
ovine	2.0% +/− 0.30 minutes

Laboratory Instrumentation: Quantitative measurement of BSP in blood samples is achieved by adding plasma (2.0 ml) to tubes containing NaOH (0.1 N, 3.0 ml). Blank tubes should contain double distilled water (1.0 ml) and HCl (0.1 N, 3.0 ml). Spectrophotometric transmission is then measured at 565 nm and values plotted against time.

Hepatic Excretory Function
Indocyanine Green (ICG)/Sulfobromophthalein (BSP)

Physiological Mechanism of Action: Elimination of BSP via the biliary system following intravenous injection requires dissociation from albumin in plasma, translocation across the sinusoidal membrane, conjugation with glutathione within the hepatocyte, translocation across the bile canalicular membrane, and excretion in bile.

Application: Evaluation of hepatic excretion.

Route of Administration: Sulfobromophthalein and ICG are given as a single-dose IV injection.

Dosage: Sulfobromophthalein (5 mg/kg); ICG (1.5 mg/kg).

Implementation: Evaluation of hepatic viability as a function of BSP and ICG plasma disappearances. The half-life, disappearance rate (percent per minute), and clearance (ml/min/kg) are determined during the initial phase of plasma dye elimination.

Animal Model: Feline (example).

Interpretation and Analysis: The half-life for BSP is 2.2 ± 0.7 minutes, and for ICG, 3.8 ± 0.9 minutes. The disappearance rate for BSP is 34.7 ± 10.1, and for ICG, 19.2 ± 4.5. The clearance for BSP is 26.3 ± 23.1, and for ICG, 8.6 ± 4.1. The 30-minute percentage retention for BSP is 0.6 ± 0.8%, and for ICG, 7.3 ± 2.9%. In the cat,

ICG is cleared from the plasma less rapidly than BSP. There are no significant differences between males and females for these values. For both BSP and ICG, a significantly shorter half-life, faster disappearance rate, and lower 30-minute percentage retention is observed in the cat, compared with values observed in the dog given similar dye dosages. Clearance curves for BSP and ICG in the cat are similar to those of the dog, indicating that the 2 species may have similar volumes of dye distribution and excretory mechanisms. A measurement of a 30-minute plasma level following a 5 mg/kg dose of BSP in normal cats is often too low for measurement, whereas measurement of a 30-minute plasma concentration of ICG following a 1.5 mg/kg dose is adequate. For the 30-minute dye retention test in the cat, ICG may be a preferred diagnostic agent.

Hepatic Excretory Function/Cirrhosis Conditions/SPECT Correlation with Hepatic Function Tests
Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Indocyanine green is removed from the intravascular compartment by the liver without being metabolized and is subsequently excreted into the bile.
Background Information: Accurate quantitative determination of liver function is critical in cirrhotic patients in order to predict outcome, particularly in patients who undergo hepatic resection or nonhepatic surgery. As colloid uptake by perfused Kupffer cells is proportional to perfused hepatocyte mass, quantitative liver spleen scans may be used as an index of perfused hepatocyte mass.
Considerations: Single photon emission computed tomography (SPECT) of [^{99m}Tc]-phytate colloid uptake by the liver can be applied as a test for hepatic function in cirrhotic patients.
Application: Profiles for systemic ICG concentrations can be correlated with findings observed with SPECT for the purpose of assessing liver function in various disease states, including hepatic cirrhosis.
Route of Administration: Indocyanine green (intravenous).
Implementation: Indocyanine green can be applied in concert with quantitative SPECT to assess liver function in conditions of hepatic cirrhosis. Single photon emission computed tomography can be used to measure liver volume, quantitative colloid uptake by the liver, and percentage of injected dose/ml of liver tissue.

Human Model: Cases of hepatic cirrhosis (n = 75); noncirrhotic patients with chronic liver disease (n = 52); and patients without liver disease (n = 36).
Interpretation and Analysis: Although liver volume is similar among cirrhotic, non-cirrhotic, and chronic liver disease states, cases with cirrhosis have significantly lower total quantitative uptake and quantitative uptake/ml compared to hepatic disease group types ($p < 0.001$). Quantitative liver uptake in cirrhotic patients highly correlates with Child-Pugh scores ($r = -0.64$, $p < 0.0001$) and with ICG retention at 15 minutes ($r = -0.84$, $p < 0.0001$). Quantitative SPECT of the liver may be an additional, useful, non-invasive quantitative test for assessment of hepatic function and severity of liver disease in cirrhotic patients.

Quantitative liver-spleen scan using single photon emission computed tomography (SPECT) for assessment of hepatic function in cirrhotic patients. Zuckerman E, Slobodin G, Sabo E, Yeshurun D, Naschitz JE, Groshar D. J Hepatol 2003 Sep; 39 (3), pp. 326–32.

Hepatic Excretory Function/Example: Cadmium Hepatotoxic Injury
Bromosulfophthalein (BSP)

Cellular/Molecular Mechanism of Action: Bromosulfophthalein is removed from the intravascular compartment through the functions of the hepatic biliary system.
Physiological Mechanism of Action: Elimination of BSP via the biliary system following intravenous injection requires dissociation from albumin in plasma, translocation across the sinusoidal membrane, conjugation with glutathione within the hepatocyte, translocation across the bile canalicular membrane, and excretion in bile.
Application: Bromosulfophthalein is a relatively non-toxic organic anion used as an *in vivo* indicator of liver performance.
Implementation: Characterization of the *in vivo* hepatotoxicant effects of cadmium (Cd) on BSP kinetics in isolated perfused rat liver (IPRL) to determine the degree of association between liver toxicity and BSP kinetics. After a 30-minute period for acclimation to the IPRL system, livers are dosed with cadmium acetate in the presence of 0.25% bovine serum albumin, sufficient to achieve initial concentrations of 10 and 100 μM. Sixty minutes after Cd dosing, the IPRL system is dosed with BSP to give an initial concentration of 150 μM and the elimination kinetics of BSP from the perfusion medium monitored. Cadmium concentrations in livers at the end of the experiments are 60 ± and 680 ± 210 μmol/kg for the 10 and 100 μM doses, respectively.

Animal Model: Rat (Fisher strain, n = 344 males; isolated perfused liver preparations).
Interpretation and Analysis: Exposure to 10 μM Cd for 60 minutes results in a reduction in bile flow, no significant effect on lactate dehydrogenase (LDH) leakage, and slight effects on BSP clearance. Similar studies following exposure to 100 μM Cd show dramatic decreases in bile flow with complete cholestasis 60 minutes after Cd addition. Total leakage of LDH into perfusion medium is < 10%, indicating that Cd affects bile production well before the liver shows significant signs of necrosis. Clearance of BSP from the perfusion medium is dramatically reduced. Taken together, the data indicate that Cd has a significant effect on the kinetics of BSP in the IPRL and the dominant effects are mediated through Cd-mediated cholestatic effects.

Effect of cadmium on bromosulfophthalein kinetics in the isolated perfused rat liver system. Soto A, Foy BD, Frazier JM. Toxicol Sci 2002 Oct; 69 (2), pp. 460–9.

Hepatic Excretory Function/Lipidosis Example/ Correlation with Sulfobromophthalein (BSP) $T_{1/2}$ and Serum Bile Acids (No Diagnostic Relationship)
BSP

Cellular/Molecular Mechanism of Action: Sulfobromophthalein functions as a substrate for hepatic conjugation and excretion into the bile.
Physiological Mechanism of Action: Sulfobromophthalein is eliminated via the biliary system following intravenous injection. The excretion process requires dissociation of BSP from albumin fractions in the plasma, translocation across intact sinusoidal membranes, conjugation to glutathione intracellularly within the hepatocyte,

translocation across the bile canalicular membrane, and then excretion into the bile.

Application: Hepatic excretion evaluation.

Route of Administration: Sulfobromophthalein (intravenous).

Implementation: Evaluation of liver function and/or hepatic fat infiltration in dairy cattle as a function of BSP half-life ($T_{1/2}$), serum bile acid concentrations, and hepatic fat content assessed by histopathological analysis of liver biopsy specimens. Serum bile acid concentrations are measured in healthy dairy cattle at different stages of lactation after fasting or feeding.

Animal Model: Bovine (healthy dairy cattle potentially suffering from hepatic fat infiltration).

Interpretation and Analysis: Serum bile acid concentrations are higher in cows in early lactation and with higher daily milk production. Compared with prefasting values, bile acid concentrations are decreased at 8, 14, and 24 hours of fasting. Blood samples from fed cows at 1- to 2-hour intervals have wide and inconsistent variations in bile acid concentration. Because serum bile acids correlate well with BSP $T_{1/2}$, it is suggested that both measurements evaluate a similar aspect of liver function. Neither bile acids nor BSP $T_{1/2}$ correlates with differences in liver fat content among cows. Because of large variability in serum bile acid concentrations in fed cows and the lack of correlation of measured values with liver fat content, bile acid determinations do not appear useful for showing changes in hepatic function in fed cows with subclinical hepatic lipidosis nor for serving as a screening test for this condition.

Serum bile acid concentrations in dairy cattle with hepatic lipidosis. Garry FB, Fettman MJ, Curtis CR, Smith JA. J Vet Intern Med 1994 Nov–Dec; 8 (6), pp. 432–8.

Hepatic Excretory Function/Pharmaceutical Evaluation/Pharmaceutical Modification of Hepatic Blood Flow
Indocyanine Green (ICG)/[Diltiazem (DTZ)]

Cellular/Molecular Mechanism of Action: Indocyanine green is removed from the intravascular compartment by the liver when the reagent enters the hepatic sinusoids and is then excreted into the bile.

Application: Indocyanine green is a hepatic function test marker molecule that is not metabolized in the liver, but rather only excreted into the bile. The *in vivo* pharmacokinetic profile of ICG at steady state can be applied to detect pharmaceuticals that alter hepatic blood flow in a manner that can change hepatic blood clearance parameters.

Route of Administration: Indocyanine green (intravenous at a constant infusion rate).

Dosage: Indocyanine green (3.78 mg/kg bolus and constant rate infusion of 10,100 μg/kg/hr is administered until a steady state concentration of Css = 10 μg/ml is achieved at 20, 25, and 30 minutes).

Implementation: Evaluation of the influence of DTZ on the hepatic blood clearance of ICG as a function of its pharmacokinetic profile at steady state. Following development of a steady state concentration of ICG of 10 μg/ml and a subsequent 90-minute washout period, an intravenous bolus injection (108, 430, 860, and 1,720 μg/kg) and a constant-rate infusion (108, 433, 866, and 1,730 μg/kg/hr) of test pharmaceutical (e.g., DTZ) is introduced into the right femoral vein for the purpose of achieving steady state plasma concentrations (e.g., Css = 50, 200, 400, and 800 ng/ml DTZ) confirmed at 60, 70, and 80 minutes. During the steady state phase for the test pharmaceutical (e.g., DTZ), the intravenous bolus injection and the constant-rate infusion of ICG into the left femoral vein are made and also the steady state plasma concentration of ICG measured at 20, 25, and 30 minutes. Plasma concentrations of DTZ and ICG are determined by high-performance liquid chromatography analysis.

Animal Model: Rat (left femoral vein injection site).

Interpretation and Analysis: At steady state, the hepatic blood clearance of ICG is derived from values for ICG plasma concentration and the blood-to-plasma concentration ratio (RB). An example of a pharmaceutical that does not influence ICG hepatic clearance is DTZ. Pretreatment with various doses of DTZ does not influence plasma concentrations, RB, and plasma free fraction (fp) of ICG. So the hepatic blood clearance of ICG is independent of DTZ concentration. The hepatic blood clearance of ICG can possibly be affected by both hepatic blood flow and hepatic intrinsic clearance. However there is no change in the hepatic blood clearance of ICG between the control and DTZ-pretreated rats. Diltiazem therefore may not influence hepatic blood flow.

Instrumentation: High-performance liquid chromatography analytical system.

No effect of diltiazem on the hepatic clearance of indocyanine green in the rats. Joo EH, Lee YB. Arch Pharm Res 1998 Aug; 21 (4), pp. 411–7.

Hepatic Excretory Function/Insufficiency
Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Excreted by hepatic transport mechanisms into the bile.

Diagnostic Application: Detection of hepatic dysfunction.

Route of Administration: Intravenous.

Dosage: Indocyanine green (0.8–1.1 mg/kg.).

Considerations: Indocyanine green is more accurate in detecting subtle changes in hepatic conjugation function than is BSP because significant amounts of the latter reagent are eliminated from the systemic circulation by renal excretory mechanisms. Unfortunately, ICG is relatively more expensive than BSP, which can be of particular concern when applied as a diagnostic pharmaceutical in large animal species such as the horse.

Interpretation and Analysis: Delayed elimination of ICG from the vascular compartment indicates the presence of hepatic dysfunction. Biopsy specimens and serial collections of enzymology profiles are necessary to determine the extent of hepatic dysfunction, possible cause, and if resolution or degradation occurs over time.

Normal $T_{1/2}$ in fed and fasted horses is 3.5 ± 0.67 and 1.6 ± 0.57 ml/min/kg, respectively.

Hepatocellular Excretory Function
Indocyanine Green (ICG) Dye

Cellular/Molecular Mechanism of Action: Indocyanine green is removed from the vascular compartment by the function of normal hepatocytes.

Background Information: Although depression in hepatocellular function occurs early after trauma and severe hemorrhage and persists despite fluid resuscitation, it remains unknown whether reactive oxygen species (ROS) play any role in the initiation of hepatocellular depression and damage under those conditions. It has been hypothesized that administration of an ROS scavenger at the beginning of resuscitation will attenuate organ injury after severe shock.

Application: Evaluation of hepatic function.

Implementation: Male Sprague-Dawley rats following laparotomy are bled and then maintained at a mean arterial pressure of 40 mm Hg until 40% of the maximal bleed-out volume is returned in the form of Ringer's lactate (RL). Animals are then resuscitated with 4 times the volume of maximal bleed-out with RL over a 60-minute

period. The ROS scavenger 2-mercaptopropionyl glycine (30 mg/kg) or vehicle is then administered intravenously as a bolus at the beginning of resuscitation. At 2 hours after completion of crystalloid resuscitation or the equivalent interval after sham-operation, the cardiac index is measured using a dye-dilution technique. Hepatocellular function, that is, the maximum velocity of ICG clearance (Vmax) and efficiency of the active transport (Km), can be determined using an *in vivo* hemoreflectometer. In addition, serum levels of tumor necrosis factor-alpha (TNF-α) and alanine aminotransferase can be determined with ELISA and colorimetrically, respectively.

Animal Model: Male Sprague-Dawley rats (275–325 g) subjected to laparotomy (i.e., induction of soft tissue trauma).

Interpretation and Analysis: At 2 hours following trauma, hemorrhage and resuscitation, cardiac index, and hepatocellular function are markedly depressed with concomitant increases in serum levels of TNF-α and alanine aminotransferase ($p < 0.05$). Administration of 2-mercaptopropionyl glycine, however, restores depressed cardiac and hepatic function and markedly attenuates liver enzyme release and serum levels of TNF-α ($p < 0.05$). Reactive oxygen species therefore play a role in the induction of depressed organ function after severe hemorrhagic shock. Adjuncts that attenuate the detrimental effects of ROS may be useful for improving the depressed cardiac and hepatocellular functions after trauma hemorrhage and resuscitation.

Critical role of oxygen radicals in the initiation of hepatic depression after trauma hemorrhage. Jarrar D, Wang P, Cioffi WG, Bland KI, Chaudry IH. J Trauma. 2000 Nov; 49 (5), pp. 879–85.

Hepatocyte Excretory Function/Sinusoidal Endothelial Cell Function/[Experimental Model of Acute and Chronic Liver Failure]
Indocyanine Green (ICG)/Hyaluronic Acid

Cellular/Molecular Mechanism of Action: Indocyanine green and hyaluronic acid are removed from the peripheral circulation by the normal function of hepatocytes and sinusoidal endothelial cells.

Background Information: Experimental models of liver transplantation use normal recipients, although most patients undergoing liver transplantation suffer from acute or chronic liver failure.

Application: Indocyanine green and hyaluronic acid uptake can be utilized to evaluate the *in vivo* function of hepatocytes and sinusoidal endothelial cells.

Implementation: Evaluation of the outcome for orthotopic liver transplant in compromised hosts. Hepatic injury/dysfunction can be evaluated by collectively monitoring enzymes, bilirubin, ammonia levels, prothrombin, thrombin time, and cytokines. The *in vivo* function of hepatocytes and sinusoidal endothelial cells can be evaluated applying ICG and hyaluronic acid uptake.

Animal Model: Rat (D-galactosamine-induced acute liver failure or chronic liver failure secondary to common bile duct ligation). Transplantation performed in normal, acute, and chronic liver failure rats at different time points using either freshly harvested or cold-preserved syngeneic livers.

Interpretation and Analysis: Survival with fresh grafts decreases significantly when transplants are performed 48 hours after the induction of acute liver failure. Rats with acute liver failure almost invariably do not survive transplantation with grafts stored for 12 or 24 hours, but in chronic failure survival is more than 80%. Survival of acute liver failure rats receiving grafts preserved for 6 hours is 16.6% compared with 83.3% observed with fresh grafts transplanted at the same time point after D-galactosamine exposure. Elevated tumor necrosis factor-alpha and interleukin-1β levels as well as impaired sinusoidal endothelial cell function can be detected in acute liver failure rats with grafts preserved for 6 hours. Speculation therefore suggests that preoperative status and different host factors have a significant effect on outcome and graft function after liver transplantation in rats.

Graft function and survival depend primarily on host factors in compromised recipient models of orthotopic liver transplantation in the rat. Wang L, Roayaie S, Basile J, Florman S, Liu J, Tarcsafalvi A, Boros P, Miller CM. Transplantation 2001 Jan 15; 71 (1), pp. 14–20.

HEPATOCYTE PHASE I METABOLISM PATHWAYS

Hepatic Biochemical Cytochrome P450 Metabolism Capacity
Cimetidine/Indocyanine Green (ICG)/Lidocaine

Cellular/Molecular Mechanism of Action: Indocyanine green serves as a global marker of function, while lidocaine and its metabolite, MEGX, have utility as specific markers of the CYP450 enzyme system. Cimetidine functions as a CYP450 enzyme system inhibitor.

Application: Indocyanine green can be applied to assess general hepatic function, while lidocaine and its metabolite, MEGX, can be used as specific markers of the CYP450 enzyme system.

Route of Administration: Infusion of ICG and lidocaine via the portal vein after a 40-minute stabilization period until steady state concentrations are reached in the venous outflow.

Dosage: Cimetidine (80 mg/kg daily for 3 days); ICG and lidocaine are infused after a 40-minute stabilization period into the portal vein until steady state concentrations are reached in the venous outflow.

Considerations: Endotoxin administration and cecal ligation and puncture produce significant hepatocellular dysfunction when studied *in vivo*. Specific factors that are present *in vivo* after endotoxin administration and cecal ligation and puncture, such as alterations in liver blood flow, circulating mediators, and hypoxia, can alter hepatic function.

Implementation: Delineation of hepatic clearance and CYP450 function during fabricated conditions of endotoxemia. Indocyanine green (control, $n = 6$; endotoxin, $n = 5$) or lidocaine (control, $n = 8$; endotoxin, $n = 8$) is infused into livers of control and endotoxin-exposed rat populations. Cimetidine (CYP450 enzyme system inhibitor) can be employed as a reference control (e.g., $n = 6$ rats).

Animal Model: Rats exposed to endotoxin (*Escherichia coli* lipopolysaccharide@45 mg/kg i.p.) followed by a 6-hour monitoring period and subsequent isolation of an *in situ* perfused liver preparation. Livers are perfused via the portal vein using a single-pass system with a balanced salt solution 6 hours after receiving either endotoxin or saline or 24 hours after receiving the last dose of cimetidine.

Interpretation and Analysis: Total hepatic clearance and intrinsic hepatic clearance for ICG and lidocaine are unchanged in the livers obtained following endotoxin treatment. Such animal models can adequately detect CYP450 inhibition because cimetidine-treatment results in significantly lower initial MEGX concentrations (0.63 ± 0.03 mg/L) compared with control (0.77 ± 0.03 mg/L) and endotoxin-treated (0.74 ± 0.04 mg/L) test subjects (e.g., rat animal model). Septic livers have significantly higher initial hepatic oxygen consumption (HVO_2) than do control livers (45 ± 3 μL/min/g vs 82 ± 9 μL/min/g). The HVO_2 remains higher in the septic livers and significantly increases throughout the course of observation and demonstrates that livers remain viable and functional. These data indicate that there is no detectable hepatocellular dysfunction after endotoxin shock using ICG, lidocaine, and MEGX in the isolated

perfused liver; therefore the dysfunction reported from *in vivo* studies may be reversible when the liver is removed from the shocked environment.

Effect of endotoxin shock on the clearance of lidocaine and indocyanine green in the perfused rat liver. McKindley DS, Chichester C, Raymond R. Shock 1999 Dec; 12 (6), pp. 468–72.

Hepatic Metabolism/Age-Related Changes in Biochemical Capacity/Geriatric Metabolism Alterations
[^{13}C]-Methacetin Breath Test

Cellular/Molecular Mechanism of Action: [^{13}C]-methacetin is a radioactive analog of methacetin, which can be metabolized in the liver, yielding [$^{13}CO_2$].
Background Information: The issue of whether or not liver function is compromised in the healthy elderly population remains unsolved. However, it is known that endogenous CO_2 production changes with age, motor activity, and nutrition.
Application: Evaluation of the biochemical capacity of the liver. In this manner it can be used to investigate the putative age-related modifications of hepatic function in the form of the [^{13}C]-methacetin breath test.
Implementation: Evaluation of hepatic biochemical capacity by assessment of CO_2 production following [^{13}C]-methacetin administration. Trans-abdominal echosonography with Doppler pulsed wave analysis of the celiac axis and portal vein can be used to complement the [^{13}C]-methacetin breath test.

Human Model: Geriatric (n = 29 elderly cases; n = 17/12 female/male ratio; mean age = 79.8 ± 7.9 years); and adults (n = 28 adults; n = 13/15 female/male ratio; mean age = 40.6 ± 12.3 years).
Interpretation and Analysis: Although the [$^{13}CO_2$] peak occurs within 15 to 30 minutes in both elderly and adult subjects, it is significantly decreased in the former (30.66% ± 9.2% vs 38.33% ± 6.05%; $p < 0.001$), as is the cumulative excretion (33.07% ± 7.06% vs 39.81% ± 5.68%; $p < 0.001$). When correcting for the effects of CO_2 excretion by age, the age-related modification of the cumulative dose becomes more evident (elderly group 30.15% ± 6.46% vs adult group 37.97% ± 5.92%; $p < 0.0001$). Elderly cases also show an increase in the intrahepatic resistance index using Doppler pulsed wave analysis that inversely correlates with results from breath tests. Hepatic function is not well preserved in healthy humans throughout life and may be due to an increase in vascular resistance.

Study of liver function in healthy elderly subjects using the [^{13}C]-methacetin breath test. Ciccocioppo R, Candelli M, Di Francesco D, Ciocca F, Taglieri G, Armuzzi A, Gasbarrini G, Gasbarrini A. Aliment Pharmacol Ther 2003 Jan; 17 (2), pp. 271–7.

Hepatic Metabolism/Carbohydrate Biochemical Metabolism/Hepatic Residual Metabolizing Capacity Posthepatectomy
[^{13}C]-Labeled Glycerol/6,6 [$^{2}H_2$]Glucose

Cellular/Molecular Mechanism of Action: [^{13}C]-labeled glycerol can function as a biochemical substrate precursor for the hepatic synthesis of [^{13}C]-glucose (gluconeogenesis pathway).
Physiological Mechanism of Action: Glycerol is a substrate molecule that can be utilized by hepatocytes within the liver to synthesize glucose.
Background Information: Major liver resection can be used in the treatment of liver cancer. The functional capacity of liver parenchyma needs to be evaluated preoperatively because it determines outcome.
Application: [^{13}C]-labeled glycerol may function as a suitable simple probe for assessing liver biochemical capacity as a function of hepatic [^{13}C]-glucose synthetic capacity (e.g., gluconeogenesis pathway).
Route of Administration: [^{13}C]-labeled glycerol (intravascular).
Dosage: [^{13}C]-labeled glycerol (16 μmol/kg/min) during a 120-minute infusion phase.
Implementation: Assessment of hepatic metabolizing capacity as a function of whole-body glycerol clearance. Glycerol, in the form of [^{13}C]-labeled glycerol, can be administered systemically during a 120-minute infusion phase following a 150-minute basal period. Whole-body glycerol clearance is calculated from changes in plasma glycerol concentration. Whole-body glucose production is measured with 6,6 [$^{2}H_2$]glucose infused as a tracer in the basal state and during glycerol infusion. In addition, [^{13}C]-glucose synthesis can be monitored to quantitate gluconeogenesis from glycerol.

Human Model: Cases of major hepatectomy (n = 7); colectomy (n = 6); and healthy normal controls (n = 12). Patients are assessed on the 1st day after surgery.
Interpretation and Analysis: Postoperative liver resection cases have higher plasma glycerol concentrations and lower whole-body glycerol clearance than normal healthy reference controls or cases subjected to colectomy. Postoperative liver resection cases also have higher plasma glucagon concentrations. Their fasting glucose production is mildly elevated in the fasting state and does not change after glycerol infusion, indicating normal hepatic autoregulation of glucose production. The whole-body glycerol clearance can be simply determined from plasma glycerol concentrations during exogenous glycerol infusion. It is significantly reduced following major hepatectomy surgical procedures.

Measurement of the whole body clearance of infused glycerol as a test of liver function after major hepatectomy. Tappy L, Cayeux MC, Gillet M, Koestinger A, Matter M, Revelly JP, Berger M, Vallet C, Chioléro R. Clin Physiol Funct Imaging 2002 Jul; 22 (4), pp. 266–70.

Hepatic Metabolism/Cirrhosis Biochemical Capacity/Hepatic Cirrhosis Staging/Metabolic Probes Compared to Clinical Pathology Parameters
Lidocaine [Monoethylglycinexylidide]/Antipyrine

Cellular/Molecular Mechanism of Action: Lidocaine is rapidly removed from the systemic circulation and metabolized to monoethylglycinexylidide (MEGX).
Application: Evaluation of hepatic metabolic capacity as in conditions of cirrhosis of the liver.
Route of Administration: Lidocaine (intravenously); antipyrine (oral).
Dosage: Lidocaine (1 mg/kg); antipyrine (single 1,000-mg dose).
Implementation: Evaluation of liver function in conditions of hepatic cirrhosis as a function of lidocaine metabolism (e.g., MEGX metabolite) and antipyrine complemented by analysis of standard biochemical parameters used for assessment of liver function in cirrhotic patients. Each affected case can be evaluated with each of the 2 dynamic liver tests (e.g., MEGX and antipyrine in a crossover schedule with at least a 5-day interval). Characterization of the formation of MEGX metabolite involves the administration of a bolus dose and collection of blood samples 15 minutes postadministration for MEGX assays. Antipyrine concentrations are measured in samples collected over a 24-hour period and antipyrine concentrations measured spectrophotometrically. Standard biochemical parameters used for liver assessment are measured by means of routine laboratory methods.

Human Model: Case of hepatic cirrhosis (n = 30 Child-Pugh's score to subgroups A [n = 11], B [n = 12],and C [n = 7]) in addition to healthy reference controls (n = 14).
Interpretation and Analysis: In cases of hepatic cirrhosis, liver dynamic tests appear to be better predictors of hepatic function. The MEGX test is more feasible in a clinical setting, but the antipyrine test is more sensitive in staging liver cirrhosis.
Instrumentation: Fluorescence polarization immunoassay instrumentation (MEGX assay) and a spectrophotometer (antipyrine assay).

Comparison of MEGX (monoethylglycinexylidide) and antipyrine tests in patients with liver cirrhosis. Wojcicki J, Kozlowski K, Drozdzik M, Wojcicki M. Eur J Drug Metab Pharmacokinet 2002 Oct–Dec; 27 (4), pp. 243–7.

Hepatic Metabolization/Age-Related Biochemical Capacity/Age-Related Declines/Urea Cycle
Alanine

Cellular/Molecular Mechanism of Action: Alanine is 1 of the biochemical substrates for urea synthesis.
Background Information: Studies have shown that hepatic function, quantitatively measured by dynamic liver function tests, progressively declines with aging. Urea synthesis is a specific process taking place in the liver; a reduced urea synthesis in response to a protein-rich metal has previously been demonstrated in the elderly, but the process has never been standardized in relation to amino acid supply.
Application: Characterization of chronological declines in functional capacity in aging hepatic parenchyma.
Implementation: Evaluation of the influence of alanine on the hepatic conversion of α-amino nitrogen to urea.

Human Model: Cases in good health (e.g., n = 32) with normal routine liver and renal function tests and without evidence of previous hepatic disorders (n = 3 age groups; ≤ 55 years vs 56–70, vs ≥ 71).
Interpretation and Analysis: Functional hepatic nitrogen clearance is reduced on average by 20% in subjects aged 56–70 years, and by 30% in subjects over 70 years old in comparison to the age group under 55 years (ANOVA: $p = 0.0001$), and significantly correlates with age ($r = -0.684$). No sex differences can be appreciated on the effects of age on hepatic clearance. Also, liver volume, measured by ultrasonography, is reduced with advancing age, but the age-related decrease in hepatic nitrogen conversion is not primarily dependent on decreased liver volume. The measurement of functional hepatic nitrogen clearance has already been validated as a quantitative liver function test in clinical hepatology. In keeping with previous studies, the age-related decline in hepatic nitrogen conversion points to a decrease in functional capacity of the aging hepatic parenchyma.

Kinetics of hepatic amino-nitrogen conversion in aging man. Fabbri A, Marchesini G, Bianchi G, Bugianesi E, Zoli M, Pisi E. Liver 1994 Dec; 14 (6), pp. 288–94.

Hepatic Metabolization/Carboxylic Acid Biochemical Transformation/Nitrogen Metabolism/Gastrectomy, Hepatic Failure, Renal Failure, Myotonic Dystrophy
1-[^{14}C]-α-Ketoisovaleric Acid (KIV)

Cellular/Molecular Mechanism of Action: 1-[^{14}C]-α-ketoisovaleric acid is a keto analogue of valine and can function as a biochemical substrate for mechanisms of carboxylic acid metabolism.
Background Information: The keto analogues of essential amino acids represent a promising therapeutic modality in hereditary and acquired disorders of nitrogen metabolism. The utilization of these substances in humans has been assayed primarily by nitrogen balance studies.
Application: Endogenous biochemical metabolism of KIV can be measured using the [$^{14}CO_2$] breath excretion test. In this context, the agent can be applied as a tool for evaluating dietary formulation.
Route of Administration: Oral.
Implementation: Assessement of the *in vivo* decarboxylation of KIV by measurement of [$^{14}CO_2$] using a simple and accurate breath excretion test. Protein diets (5 g) supplemented with essential amino acids and KIV (substituted for valine) are then evaluated. Diets of 120 g of protein/day are then reevaluated in gastrectomy cases.

Human Model: Normal volunteers and cases suffering from assorted disease states (n = 6 diseased; gastrectomy, hepatic failure, renal failure, and myotonic dystrophy).
Interpretation and Analysis: In situations of low protein intake, 13–32% of ingested KIV undergoes rapid decarboxylation, and this proportion appears to correlate inversely with damage to organ systems containing branched-chain keto acid dehydrogenase. With high protein intake, the proportion of decarboxylated substrate increases from 44% to 53%. Such findings confirm that the decarboxylation of KIV in man varies under different conditions of dietary intake and metabolic disease. The [$^{14}CO_2$] breath excretion test is applicable to other related analyses of carboxylic acid metabolism in human subjects.

Decarboxylation of α-ketoisovaleric acid after oral administration in man. Epstein CM, Chawla RK, Wadsworth A, Rudman D. Am J Clin Nutr 1980 Sep; 33 (9), pp. 1968–74.

Hepatic Metabolization/Cirrhosis Biochemical Capacity/Assessment of Postoperative Risk Following Hepatic Resection/Hepatic Insufficiency/Cirrhosis/Hepatocellular Carcinoma
Lidocaine [Monoethylglycinexylidide (MEGX)]

Cellular/Molecular Mechanism of Action: Lidocaine is rapidly removed from the systemic circulation and metabolized to MEGX.
Application: Preoperative risk assessment.
Route of Administration: Lidocaine (intravenously).
Dosage: Lidocaine (1 mg/kg).
Implementation: Evaluation of the potential for MEGX to function as a preoperative risk assessment parameter for predicting the potential for development of postoperative complications in cases of cirrhosis and hepatocellular carcinoma that are candidates for curative liver resection.

Human Model: Cases in postoperative phase of hepatic resection evaluated with lidocaine test (e.g., n = 51; n = 22 with MEGX < 25 ng/ml; and n = 29 with MEGX > 25 ng/ml).
Interpretation and Analysis: Each type of case group is comparable for preoperative clinical parameters and surgical procedures. Cases with MEGX < 25 ng/ml have a significantly higher rate of postoperative complications (73% vs 28%, $p < 0.005$) and a tendency toward a longer hospital stay, compared to cases with an MEGX > 25 ng/ml concentration. The lidocaine value is an effective index of hepatic function. A preoperative MEGX value lower than 25 ng/dL in cirrhotic patients is related to a significantly higher risk of liver insufficiency and postoperative complications after hepatic resection.

Operative risk by the lidocaine test (MEGX) in resected patients for HCC on cirrhosis. Ravaioli M, Grazi GL, Principe A, Ercolani G, Cescon M, Gardini A, Varotti G, Del Gaudio M, Cavallari A. Hepatogastroenterology 2003 Sep–Oct; 50 (53), pp. 1552–5.

Hepatic Metabolization/Cirrhosis and Gastric Mucosa Integrity
Lysine Acetylsalicylate

Application: Evaluate the functional disruption of the gastric mucosa in conditions of cirrhosis by measuring the gastric potential difference.

Background Information: Lysine acetylsalicylate–induced bronchoconstriction can be used to evaluate the efficacy of various pharmaceutical agents pertaining to their ability to alleviate induced bronchoconstrictive responses. Additionally, it has been applied to characterize pharmaceutical efficacy and physiological processes in the kidney that are mediated by prostaglandin synthesis.

Route of Administration: Local installation of lysine acetylsalicylate.

Dosage: Lysine acetylsalicylate (500 mg).

Implementation: Potential differences are measured in the morning, on an empty stomach, and at least 3 days after endoscopy, employing a method that uses a double channel gastric perfused probe placed under fluoroscopy 10 cm above the cardia, and a subcutaneous reference, both connected to a millivoltimeter via gelose agar-KCl bridges. Potential differences are recorded in each case 20 minutes before (baseline) and after local instillation of lysine acetylsalicylate (500 mg) as a provocative test.

Human Model: Cases of hepatic cirrhosis ($n = 28$, consecutive conditions with endoscopically proven congestive gastropathy) and negative reference controls ($n = 12$).

Interpretation and Analysis: Cirrhotic patients have significantly lower basal potential differences than controls (-28.3 ± 1.5 mV vs -33.8 ± 1.3mV, $p = 0.007$). Potential differences are significantly lower in cases with severe gastropathy than in conditions with mild gastropathy (-20.5 ± 2.1 and -28.9 ± 1.6 mV, respectively, $p < 0.01$). After stimulation with acetylsalicylate, the area under the curve and the irritability index are greater in patients with gastropathy (81.4 ± 12.8 vs 41.2 ± 8.6 mV.min, $p = 0.032$ and 0.935 ± 0.19 vs 0.290 ± 0.07 mV.mV.min, $p = 0.022$, respectively). These differences are explained by a higher drop in potential difference (delta DPmax/baseline; 28.1 ± 3 vs 16.1 ± 3 p. 100, $p = 0.006$), whereas basal return time remains unchanged (16.2 ± 2.1 vs 13.7 ± 2.2 minutes).

Functional study, in man, of congestive gastropathy in cirrhosis by measurement of potential difference. Pienkowski P, Payen JL, Calès P, Monin JL, Gerin P, Pascal JP, Frexinos J. Gastroenterol Clin Biol 1989 Oct; 13 (10), pp. 763–8.

Furosemide: Progress in understanding its diuretic, anti-inflammatory, and bronchodilating mechanism of action, and use in the treatment of respiratory tract diseases. Prandota J. Am J Ther 2002 Jul–Aug; 9 (4), pp. 317–28.

Hepatic Metabolization/Decarboxylation Biochemical Capacity (Mitochondrial)/ Mitochondrial Respiration Uncoupling
[^{14}C]-α-Ketoisocaproic Acid/Exhaled [$^{14}CO_2$]/ Ethanol/Sodium Salicylate

Cellular/Molecular Mechanism of Action: α-ketoisocaproic acid is a substrate for enzyme decarboxylation mechanisms mediated through the function of hepatocyte mitochondria. Ethanol suppresses these biochemical processes. Sodium salicylate uncouples mitochondrial respiration and can therefore promote increased decarboxylation processes.

Application: α-ketoisocaproic acid can be applied in a breath test to assess *in vivo* hepatic mitochondrial function. Ethanol can be applied as a control reagent due to its ability to inhibit hepatic mitochondrial decarboxylation mechanisms.

Route of Administration: 1-[^{14}C]-α-ketoisocaproic acid (intraperitoneal).

Implementation: Evaluation of *in vivo* hepatic mitochondrial metabolic capacity as a function of [$^{14}CO_2$] exhalation following 1-[^{14}C]-α-ketoisocaproic acid administration.

Animal Model: Rat.

Interpretation and Analysis: Following administration of 1-[^{14}C]-α-ketoisocaproic acid, exhaled [$^{14}CO_2$] reaches a peak within 10 to 20 minutes and then declines exponentially, with a half-life of 14.3 minutes. In controls, approximately 38.6% of the administered radioactivity is exhaled within 1 hour. In functionally anhepatic animals, [$^{14}CO_2$] in breath amounted to 23% of that in control animals, indicating that α-ketoisocaproic acid decarboxylation reflects mainly *in vivo* hepatic mitochondrial function. Ethanol (3 gm/kg) significantly decreases α-ketoisocaproic acid decarboxylation (21.8% of the dose appearing in breath in 1 hour), probably due to the ethanol-induced shift in the NAD+:NADH ratio. In contrast, uncoupling of mitochondrial respiration with sodium salicylate (375 mg/kg), increases decarboxylation of α-ketoisocaproic acid (56.3% of the dose recovered as [$^{14}CO_2$] in 1 hour). Mitochondrial damage induced by 4-pentenoic acid decreases the decarboxylation of α-ketoisocaproic acid but does not affect the microsomal metabolism of antipyrine. The present data indicate that the α-ketoisocaproic acid breath test provides a non-invasive estimate of hepatic mitochondrial function *in vivo* that, when applied to man, might yield clinically useful information.

Assessment of mitochondrial function *in vivo* with a breath test utilizing α-ketoisocaproic acid. Michaletz PA, Cap L, Alpert E, Lauterburg BH. Hepatology 1989 Nov; 10 (5), pp. 829–32.

Hepatic Metabolization/Demethylation Biochemical Capacity
[^{13}C]-Aminopyrine

Cellular/Molecular Mechanism of Action: [^{13}C]-aminopyrine is demethylated by biochemical fractions residing within hepatocytes.

Application: Detection or confirmation of cases suspected of suffering from various stages of hepatic disease.

Route of Administration: [^{13}C]-aminopyrine.

Dosage: [^{13}C]-aminopyrine (2 mg/kg).

Implementation: Evaluation of suspected hepatic disease states using the [^{13}C]-aminopyrine demethylation blood test as a potential diagnostic parameter. A baseline blood sample is collected, followed by the administration of [^{13}C]-aminopyrine, followed by the collection of another blood sample at 45 minutes postinjection. Carbon dioxide is extracted from blood samples and analyzed using fractional mass spectrometry. Results from the [^{13}C]-aminopyrine demethylation blood test are then compared to clinical data and histologic findings.

Animal Model: Canine ($n = 6$ dogs initially suspected of having hepatic disease based on their history, physical examination, imaging studies, general laboratory parameters, or any combination).

Interpretation and Analysis: Intravenous administration of [^{13}C]-aminopyrine leads to a decrease in the percent dose of [^{13}C] recovered from dogs with histologically confirmed liver disease. Based on these results, a full-scale investigation of the potential clinical usefulness of a [^{13}C]-aminopyrine demethylation blood test for assessment of hepatic function in dogs is warranted.
Instrumentation: Fractional mass spectrometry system.

Use of a ^{13}C-aminopyrine blood test: First clinical impressions. Chiaramonte D, Steiner JM, Broussard JD, Baer K, Gumminger S, Moeller EM, Williams DA, Shumway R. Can J Vet Res 2003 Jul; 67 (3), pp. 183–8.

Hepatic Metabolization/Pharmacokinetic Profile Prediction with Cirrhosis Biochemical Changes/ Example: Cefoperzone/Correlation of Pharmacokinetic Alterations with Hepatic Function Profiles
Galactose

Cellular/Molecular Mechanism of Action: Galactose is normally removed from the intravascular compartment by viable hepatocytes.
Application: Galactose can be utilized to detect and characterize alterations in hepatic functional capacity. In this fashion, it can serve as a valuable probe that can be used to correlate changes in the pharmacokinetic/excretion profiles for various agents (e.g., cefoperzone) with alterations in hepatic viability. In this fashion, galactose can potentially be used to design administration strategies prior to the administration of therapeutic agents in various disease states.
Dosage: Galactose (0.5 g/kg).
Implementation: Evaluation of residual hepatic function using the galactose single point (GSP) technique. The method involves measuring galactose blood concentration 1 hour after galactose administration. The GSP method, the galactose elimination capacity (GEC) test, and the modified galactose elimination capacity (MGEC) test can each be applied to compare their relative ability to measure residual liver function.

Human Model: Characterization of cefoperazone pharmacokinetics in cases of hepatic cirrhosis. Cases of hepatic cirrhosis ($n = 12$) and healthy volunteers ($n = 11$) are administered intravenous doses of cefoperazone (1 g). Cefoperazone concentrations are then measured in blood and urine samples collected at appropriate intervals after drug administration. All blood and urine samples are preserved at $-30°C$ prior to quantitative analysis.
Interpretation and Analysis: Cefoperazone plasma concentrations are much higher in cirrhosis patients than in normal reference controls at all time intervals. The elimination half-life, hepatic clearance, mean residence time, and renal clearance of cirrhosis patients differ significantly from those of healthy volunteers. Plasma protein binding is not altered in either normal or cirrhosis cases. Urinary excretion of cefoperazone is significantly increased in cirrhosis patients ($23.95 \pm 5.06\%$ for normal men and $51.09 \pm 11.50\%$ in cirrhosis patients). Hepatic clearance, fraction excreted in urine, and total clearance significantly correlates with GSP, GEC, and MGEC ($p < 0.001$).
Instrumentation: High-performance liquid chromatography analysis.

Novel galactose single point method as a measure of residual liver function: Example of cefoperazone kinetics in patients with liver cirrhosis. Hu OY, Tang HS, Chang CL. J Clin Pharmacol 1995 Mar; 35 (3), pp. 250–8.

Hepatic Metabolization/Protein Biochemical Synthetic Function/Synthesis of Plasma and Hepatic Proteins/Vitamin D Deficiency
[^{14}C]-Labeled Amino Acids/[Bromosulphthalein (BSP)]

Cellular/Molecular Mechanism of Action: [^{14}C]-labeled amino acids are synthetically incorporated into biological protein fractions during intracellular translation events.
Application: Detection and characterization of *de novo* protein synthesis.
Route of Administration: [^{14}C]-labeled amino acids (variable but ideally intravenously).
Implementation: Evaluation of *de novo* hepatic and plasma protein synthesis in response to induced vitamin D deficiency. Liver function and protein metabolism is assessed by BSP clearance, liver histology, plasma transaminases, plasma alkaline phosphatase, and [^{14}C]-labeled amino acid incorporation into liver and plasma proteins.

Animal Model: Rats that are rendered vitamin D–deficient by housing them in a room free of ultraviolet light and maintained for 20 weeks on a diet devoid of only vitamin D. The vitamin D–deficiency state is confirmed by the undetectable levels of circulating vitamin D metabolites, severe hypocalcalcemia, and significantly reduced intestinal calcium transport.
Interpretation and Analysis: Subtle alterations in hepatic function are manifested by delayed BSP clearance and elevated levels of plasma transaminases and alkaline phosphatase. Liver histology reveals changes consistent with periportal necrosis. Synthesis of liver and plasma proteins is reduced by 26 to 34% ($p < 0.01$) without affecting the circulating levels of plasma proteins, suggesting reduced protein turnover with vitamin D deprivation. Alterations in hepatic function, therefore, appear to be directly and/or indirectly mediated by the properties of vitamin D.

Altered hepatic function in vitamin D–deprived rats. Pahuja DN, Deshpande UR, Soman CS, Nadkarni GD. J Hepatol 1989 Sep; 9 (2), pp. 209–16.

Hepatic Metabolization: Urea Cycle Biochemical Function/Congenital Portosystemic Vascular Anomalies
Ammonia Tolerance Test

Cellular/Molecular Mechanism of Action: Hepatocytes normally convert free ammonia into urea as a detoxification process. In conditions of compromised hepatic function, there is a delay or absence of ammonia detoxification by hepatocytes, resulting in higher than normal blood ammonia concentrations.
Application: Detection of conditions associated with hepatic disease.
Considerations: Contraindicated in patients with encephalomyelopathy or severe hepatic disease due to the risk of creating additional CNS dysfunction.
Implemenation: Evaluation of hepatic function based on the capacity to detoxify ammonia through conversion in the urea cycle. A postprandial ammonia tolerance test (PPATT) is performed in concert with trans-colonic scintigraphy, liver biopsy, or both and then classified as extrahepatic disease, primary hepatocellular, or congenital portosystemic vascular anomaly (PSVA) groups. Each dog is fed a chicken and rice diet providing 25% of its estimated daily metabolizable energy requirement (MER) as an ammonia challenge. This is practical in cases with liver disease because ammonium

chloride administration often causes vomiting or ammonia toxicity. Venous ammonia concentrations are measured before feeding and every 2 hours after feeding for 8 hours.

Animal Model: Canine (normal and with suspected hepatic disease),

Interpretation and Analysis: No difference in mean ammonia concentrations between dogs with extrahepatic disease and control dogs can be found. Therefore, the specificity of the PPATT is 100%. Dogs with hepatocellular disease show no change in mean ammonia concentration at any time point, before or after feeding, but sensitivity is greatest when venous ammonia is measured 6 hours after feeding (sensitivity before feeding, 28%, and after feeding, 36%). Among dogs with congenital PSVA, mean ammonia concentrations are higher than the reference range at all time points before and after feeding, and peak mean ammonia concentration occur 6 hours after feeding. In such cases, the sensitivity of the PPATT is 81% before feeding and 91% 6 hours after feeding. Measurements of venous ammonia concentration are a useful test to detect congenital PSVA, and the sensitivity of the test may be improved by sampling 6 hours after feeding. The PPATT has poor sensitivity in detecting primary hepatocellular disease.

Postprandial venous ammonia concentrations in the diagnosis of hepatobiliary disease in dogs. Walker MC, Hill RC, Guilford WG, Scott KC, Jones GL, Buergelt CD. J Vet Intern Med 2001 Sep–Oct; 15 (5), pp. 463–6.

Hepatic Metabolization/Warning for Administration Sequelae with Function Tests
Hepatotropic Diagnostic Media

Considerations: Hepatotropic diagnostic media when combined with protein solutions have been noted to create precipitates. The examination of different proteins and media has allowed the coagulative mechanism to be characterized and has revealed the development of electrostatic interactions between di- and polyvalent ligands. Positively charged protein groups play the major role and it has been suggested that this particular phenomenon contributes to the nephrotoxicity of some drug groups.

Hepatic Metabolization Capacity/Biochemical Marker/Cardiovascular Surgery Influence
Antipyrine

Cellular/Molecular Mechanism of Action: Antipyrine is a substrate for biochemical/metabolizing enzyme systems found in hepatic tissues.

Application: Molecular probe for assessing changes in hepatic drug metabolization.

Implementation: Evaluation of the effect of open-heart surgery on hepatic drug metabolism using the rate of antipyrine elimination as a reference index.

Human Model: Cases of open-heart surgery (n = 17).

Interpretation and Analysis: A degree of correlation exists between preoperative heart size and antipyrine elimination rate. In cases with a markedly dilated heart, the plasma antipyrine half-life is prolonged and apparent clearance significantly impaired. Immediately postoperatively, antipyrine elimination is impaired in all patients. Later, drug metabolism improves in cases with atrial septal defect, changes temporarily in patients with aortic valve replacement, and remains unchanged in patients with mitral valve replacement. The results indicate that adaptive changes in drug metabolizing capacity occur in cases undergoing cardiac surgery. The changes are related to the type of lesion corrected, the preoperative functional capacity of the liver, and the time lapse after surgery.

Liver drug metabolism in patients undergoing open-heart surgery. Kairaluoma MI, Sotaniemi EA, Mokka RE, Nuutinen L, Kärkölä P, Larmi TK. Scand J Thorac Cardiovasc Surg 1979; 13 (3), pp. 281–5.

HEPATOCYTE PHASE II BIOCHEMICAL METABOLISM PATHWAYS

Hepatic N-Methylation: Nicotinamide N-Methyltransferase (NNMT)/Pyrimidines Structurally Similar to Nicotinamide
Nicotinamide

Cellular/Molecular Mechanism of Action: Nicotinamide N-methyltransferase catalyses the N-methylation of nicotinamide and structurally related pyrimidines.

Background Information: Nicotinamide N-methyltransferase enzymatic activity in human liver varies over a 5-fold range with a bimodal frequency distribution. This observation raises the possibility that the expression of this enzyme fraction is regulated by genetic polymorphism.

Application: Substantial variations in NNMT biochemical activity (hepatic origin) are not associated with genetic polymorphisms associated with the 3 exons or 5′-flanking regions of the NNMT gene sequence.

Implementation: Initially, Northern blot analysis can be applied to confirm the expression of NNMT in liver biopsy specimens. Quantitative immunodetection (Western blot) analysis can then be applied to measure the amount of immunoreactive NNMT contained in tissue samples. Values for laboratory reference controls can be determined through analysis of liver biopsy samples collected from cases previously determined to have "low" or "high" levels of NNMT biochemical activity. The 3 exons for the NNMT gene can be amplified applying polymerase chain reaction (PCR) methodologies using hepatic biopsy specimens as a source of genetic material. Genetic polymorphism can then be detected applying DNA sequence analysis in order to determine if there is a degree of correlation with the "nicotinamide N-methyltransferase phenotype."

Interpretation and Analysis: Based on Northern blot analysis, NNMT is highly expressed in human liver tissue. There is a highly significant correlation ($r^s = 0.96$, $p < 0.0001$) between NNMT activity and immunoreactive protein in these samples. A potent promoter is located within the initial 700 bp of the 5′-flanking region of the human NNMT gene sequence. The gene consists of 3 exons, with an initial 1,240 bp intron and a 2nd intron that is approximately 14 kb in length. Analysis of DNA samples isolated from hepatic tissues associated with "low," "intermediate," or "high" levels of NNMT activity (e.g., n = 27 human biopsies) reveals that the 3 exons are all 1,240 bp of intron 1 and approximately 700 bp of the 5′-flanking region of the NNMT gene. No single-nucleotide polymorphisms (SNPs) or insertion/deletion events have been detected within either the exons or 5′-flanking regions of NNMT (e.g., n = 27 human hepatic biopsy samples). Although some single nucleotid polymorphism (e.g., n = 8/27) exists within intron 1, none has been detected to be systematically related to the level of NNMT biochemical activity. These results indicate that the exons and 5′-flanking region of the NNMT gene display little or no sequence variation.

Human nicotinamide N-methyltransferase pharmacogenetics: Gene sequence analysis and promoter characterization. Yan L, Otterness DM, Weinshilboum RM. Pharmacogenetics 1999 Jun; 9 (3), pp. 307–16.

Hepatocyte Conjugation/Phase II Biotransformation Capacity
Paracetamol

Cellular/Molecular Mechanism of Action: Paracetamol is biotransformed into glucuronide and sulfate metabolites that are ultimately excreted into the urine.
Application: Determination of phase II metabolism capacity.
Considerations: The use of wavelength-switching UV detection for the simultaneous detection of paracetamol and its glucuronide and sulfate metabolites in urine allows for minimal sample manipulation but maximal specificity in the analysis of biohazardous biological fluids.
Instrumentation: Reverse-phase high-performance liquid chromatography. The solvent system involves a simple isocratic elution with a composition of 50 mM sodium acetate buffer, pH adjusted to 3.5, and acetonitrile (96:4 v/v) modified with 0.35% trifluroacetic acid. The validated method is highly reproducible with an interassay variation of $< 7\%$. This method also shows good precision and sensitivity, making it an ideal assay for phenotyping studies to determine the extent of glucurondiation and sulfation activities.

A validated method for the determination of paracetamol and its glucuronide and sulfate metabolites in the urine of HIV+/AIDS patients using wavelength-switching UV detection. Di Girolamo A, O'Neill WM, Wainer IW. J Pharm Biomed Anal 1998 Sep 1; 17 (6–7), pp. 1191–7.

Hepatocyte Trans-Sulferation Capacity/Alcohol-Induced Cirrhosis
[$^2H_3$]-Methyl-1-[^{13}C]Methionine/[$^{13}CO_2$] Exhalation

Cellular/Molecular Mechanism of Action: [$^2H_3$]-methyl-1-[^{13}C]methionine is a radiolabeled analog of methionine that is metabolized within the liver along the same pathways as are similar amino acids. In this context, methionine can function as a substrate for both trans-sulfuration and remethylation metabolic pathways. Trans-sulfuration through decarboxylation of [$^2H_3$]-methyl-1-[^{13}C] methionine to yield [$^{13}CO_2$] is followed by remethylation involving the replacement of the labeled methyl group by an unlabeled methyl group.
Background Information: Disturbances of the methionine cycle may result in liver injury. Patients with alcohol-induced liver disease often exhibit hypermethioninemia and a delayed clearance (CL) of methionine, but the extent to which trans-sulfuration and remethylation pathways of the cyclic methionine metabolism are affected is largely unknown.
Application: Assessment of liver-associated biochemical metabolizing function, which can serve as a indicator of hepatic functional capacity.
Route of Administration: [$^2H_3$]-methyl-1-[^{13}C]methionine (oral).
Dosage: [$^2H_3$]-methyl-1-[^{13}C]methionine (2 mg/kg).
Implementation: Evaluation of methionine metabolism in conditions of alcohol-induced cirrhosis using [$^2H_3$]-methyl-1-[^{13}C]methionine as a metabolic probe. Specifically, the application of this agent permits monitoring trans-sulfuration by decarboxylation to [$^{13}CO_2$] and remethylation by replacement of the labeled methyl group by an unlabeled "1" molecule.

Human Model: Cases of alcohol-induced cirrhosis ($n = 6$ cases; $n = 7$ normal healthy volunteers).
Interpretation and Analysis: Basal plasma concentrations of endogenous methionine (50 ± 5 vs 25 ± 2 μmol/L, mean ± SEM, $p < 0.001$) are significantly higher in patients with cirrhosis and its clearance is significantly decreased (774 ± 103 vs $2{,}050 \pm 141$ mL/min, $p < 0.001$). Methionine turnover is much slower in conditions of cirrhosis compared to healthy controls (e.g., 27 ± 3 vs 42 ± 4 μmol/kg/hour, $p < 0.05$) respectively. The fraction of administered methionine undergoing remethylation is lower in cirrhosis (7.6 ± 1.5 vs $14.1 \pm 1.1\%$, $p < 0.005$). However, because of the larger pool of circulating methionine, the total flux of methionine through the remethylation pathway is similar in both cirrhosis and normal reference controls. A significantly lower fraction of the administered dose appears in the form of [$^{13}CO_2$] in the breath from patients with cirrhosis (2.2 ± 0.4 vs $11.0 \pm 0.8\%$, $p < 0.001$). Cirrhosis of the liver compensates for a decreased activity of remethylating enzymes by operating at higher concentrations of methionine. In contrast, trans-sulfuration is impaired in patients with alcohol-induced cirrhosis such that an assessment of trans-sulfuration by a simple breath test may provide a clinically useful estimate of hepatic function.

Remethylation and trans-sulfuration of methionine in cirrhosis: Studies with L-[H_3-methyl-1-C]methionine. Russmann S, Junker E, Lauterburg BH. Hepatology 2002 Nov; 36 (5), pp. 1190–6.

HEPATIC PATHOLOGY AND DISEASE STATES

Hepatic Inflammation in Hepatitis: Alcohol-Induced/H_2O_2/L-Selectin/IL-8/Tumor Necrosis Factor-Alpha (TNF-α)/IL-10
Corticosteroids

Background Information: Several observations point to an important role of interactions between polymorphonuclear neutrophils and cytokines in severe alcoholic hepatitis. The polymorphonuclear neutrophil activation status and the local and systemic pro- and anti-inflammatory cytokine responses are quantified. The effect of corticosteroids, widely used in this setting, is evaluated using these parameters.
Application: Potential differentiation of alchohol-induced hepatitis and alcohol-induced cirrhosis without hepatitis and normal reference (healthy) controls.
Implementation: Evaluation of blood polymorphonuclear neutrophil functions pertaining to L-selectin and β_2-integrin expression, H_2O_2 production, and IL-8 and TNF-α synthetic capacity. Complementary analysis includes measurement of plasma and hepatic IL-8, TNF-α, and IL-10 levels. The impact of a 28-day course of corticosteroids on blood neutrophils activation status and cytokine levels can be of benefit in evaluating patients with alcoholic hepatitis.

Human Model: Cases of alcoholic hepatitis ($n = 15$; compared to $n = 15$ conditions of alcoholic cirrhosis without alcoholic hepatitis; compared to $n = 10$ healthy volunteers).
Interpretation and Analysis: Blood polymorphonuclear neutrophils in conditions of alcoholic hepatitis are activated, as shown by increases in H_2O_2 production (48 ± 6 vs 29 ± 6 MFI in healthy controls), and decreases in L-selectin expression (300 ± 61 vs 449 ± 59 in healthy controls). Upon stimulation, polymorphonuclear neutrophils synthesize large amounts of IL-8 (21.7 ± 9.2 ng/ml vs 8.8 ± 10 ng/ml in healthy controls) and TNF-α (524 ± 132 pg/ml vs 79 ± 144 pg/ml in healthy controls). Tumor necrosis factor-alpha and IL-8 plasma and tissue levels markedly increase in contrast to IL-10, which is barely detectable in alcoholic hepatitis patients, compared to cirrhotic patients and healthy controls. During steroid therapy, plasma levels of the proinflammatory cytokine IL-8 fall as

early as day 14, while levels of the anti-inflammatory cytokine IL-10 increase on day 21. Finally, polymorphonuclear neutrophil functions return to normal after treatment. Severe alcoholic hepatitis appears to be associated with polymorphonuclear neutrophil activation and an imbalance between pro- and anti-inflammatory cytokines; during steroid therapy a normalization of these parameters is observed.

Blood neutrophil functions and cytokine release in severe alcoholic hepatitis: Effect of corticosteroids. Taïeb J, Mathurin P, Elbim C, Cluzel P, Arce-Vicioso M, Bernard B, Opolon P, Gougerot-Pocidalo MA, Poynard T, Chollet-Martin S. J Hepatol 2000 Apr; 32 (4), pp. 579–86.

Hepatic Neoplastic Disease: Metastatic Midgut Carcinoid
Pentagastrin (PG)/Calcium Infusion/Ketanserin

Cellular/Molecular Mechanism of Action: Pentagastrin is a synthetic pentapeptide that normally stimulates gastric function. Ketanserin binds to serotonin receptors and blocks binding of serotonin to these complexes.
Application: Pentagastrin has been applied successfully to detect conditions of carcinoid syndrome.
Implementation: Evaluation of hepatic midgut carcinoid metastatic conditions by measuring the clinical and hormonal response to PG compared to calcium infusion. Peripheral blood samples are then collected for measurement of serotonin (5-HT) and substance P (SP) concentrations. Ketanserin can be co-administered to delineate the molecular pathogenesis of gastrointestinal systems associated with carcinoid syndrome.
Interpretation and Analysis: Pentagastrin causes flushing and gastrointestinal symptoms in addition to promoting elevated levels of circulating serotonin (5-HT), but not SP. Pretreatment with a 5-HT2 receptor blocking agent (ketanserin) alleviates gastrointestinal symptoms but has no influence on either 5-HT release or PG-induced flushing. Calcium infusion can induce carcinoid symptoms in approximately 30% of affected cases (e.g., n = 2/6) that have associated elevations in 5-HT levels. Elevations in SP may be seen in only a limited number of cases. Serotonin (5-HT) appears to be important for the development of gastrointestinal symptoms but not flushing. Ketanserin may alleviate gastrointestinal symptoms but does not influence pentagastrin-induced release of 5-HT. Substance P and 5-HT do not seem to share a common release mechanism. Pentagastrin testing is superior to calcium infusion as a provocative test in patients with the carcinoid syndrome.

The pentagastrin test in the diagnosis of the carcinoid syndrome. Ahlman H, Dahlström A; Grönstad K, Jaffe BM, Nilsson O, Oberg K. J Cardiovasc Pharmacol 1985; 7 Suppl 7, pp. S86–8.

Hepatic Neoplastic Disease: Metastatic Midgut Carcinoid
Pentagastrin (PG)/Calcium Infusion/Ketanserin

Cellular/Molecular Mechanism of Action: Pentagastrin is a synthetic pentapeptide that normally stimulates gastric function. Ketanserin binds to serotonin receptors and blocks binding of serotonin to these complexes.
Application: Pentagastrin has been applied successfully to detect conditions of carcinoid syndrome. Ketanserin can be used as a validation pharmaceutical agent that blocks gastrointestinal signs precipitated by elevations in systemic serotonin concentrations.
Route of Administration: Pentagastrin (intravenous).
Implementation: Evaluation of carcinoid syndrome by characterizing the clinical response and measurment of changes in 5-hydroxytryptamine (serotonin, 5-HT) and substance P (SP) concentrations in response to intravenous PG and calcium infusion.
Human Model: Cases of known midgut carcinoid (n = 17 midgut carcinoid; n = 16/17 hepatic metastasis; n = 17/17 with supranormal basal levels of 5-HT and SP).
Interpretation and Analysis: Pentagastrin administration in conditions of midgut carcinoid syndrome causes (i) flushing in a high percentage of affected cases (e.g., n = 17/17); and (ii) gastrointestinal symptoms in most cases affected with hepatic involvement (e.g., n = 15/16); while it also universally elevates circulating 5-HT levels. Pretreatment with the 5-HT2-receptor blocking agent, ketanserin, abolishes the gastrointestinal effects but has virtually no influence on either 5-HT levels or flushing induced by intravenous pentagastrin. In contrast, calcium infusion induces carcinoid symptoms in only approximately 30% of cases (e.g., n = 2/6) and is a feature that is consistently associated with stimulation of circulating serotonin levels. Therefore, (i) 5-HT may be responsible for the gastrointestinal symptoms in carcinoid patients, but it does not seem to play any role in flushing; (ii) ketanserin may be a useful therapeutic agent in alleviating gastrointestinal symptoms in carcinoid patients; (iii) differential responses to PG suggests that SP is released from a site different from that of serotonin (5-HT); (iv) it is possible that SP may contribute to the mediation of flushing, but it cannot be the sole agent causing this symptom; and (v) the pentagastrin test with measurements of 5-HT levels in peripheral blood seems to be superior to calcium infusion as a provocative test in documenting the diagnosis of carcinoid disease.
Instrumentation: High-performance liquid chromatography-electron capture and radioimmunoassay methods.

Characterization of hepatic cytochrome P450 3A activity in patients with end-stage renal disease. Dowling TC, Briglia AE, Fink JC, Hanes DS, Light PD, Stackiewicz L, Karyekar CS, Eddington ND, Weir MR, Henrich WL. Clin Pharmacol Ther 2003 May; 73 (5), pp. 427–34.

Hepatic Organophosphate Metabolism/ Cytochrome P450/Genetic Suceptibility: Oxytremorine/Nicotine: Genetic Susceptibility
Diisopropylfluorophosphate (DFP)

Cellular/Molecular Mechanism of Action: The organophosphate DFP binds to acetylcholine esterase, thereby preventing the degradation of acetylcholine neurotransmitter.
Physiological Mechanism of Action: Inhibition of acetylcholine esterase causes an accumulation of acetylcholine neurotransmitter in a manner that promotes over-stimulation of the parasympathetic segment of the autonomic nervous system (e.g., diarrhea, salivation, altered cardiac function).
Application: Detection of genetic parameters that influence vulnerability or resistance to organophosphate intoxication (e.g., DFP). Examples could include variations in the genetic expression of certain microsomal enzyme P450 fractions within the liver.
Implementation: Inbred stains of mice (e.g., C57BL, DBA, C3H) can be applied to investigate relative differences in a battery of physiological and locomotor tests including respiratory rate, heart rate, body temperature, Y-maze activity, and rotarod performance in response to DFP exposure.
Interpretation and Analysis: In dose-response and time-course studies, marked affects are noted approximately 15 minutes after injection with maximal effects occurring approximately 2 hours after initial exposure. Strain comparisons made at the 2-hour time point reveal that males and females are affected about equally except for respiratory rate and rotarod performance in which females are slightly more affected. Strain comparisons reveal that for most of the tests the C57BL mice are most affected by the DFP in contrast to C3H mice that are least affected. In contrast, DBA mice strains are

most vulnerable to DFP-mediated alterations in heart rate. Analogous studies have demonstrated a similar rank ordering of inbred strains of mice in their responses to oxotremorine and nicotine. The strain differences in response to these agents is not easily explained by differences in number or affinity of brain muscarinic or nicotinic receptors. The genetic influence on cholinergic drug response may involve receptor coupling mechanisms.

A strain comparison of physiological and locomotor responses of mice to diisopropylfluorosphosphate. Smolen A, Smolen TN, Oh EI, Collins AC. Pharmacol Biochem Behav 1986 Apr; 24 (4), pp. 1077–82.

Hepatic Vascular Malformation: Portosystemic Shunt/Non-Invasive Detection of Portosystemic Shunt Patency/Postoperative Shunt Anastomosis Occlusion
D-Xylose/[Urinary Excretion]

Physiological Mechanism of Action: D-xylose is normally assimulated by hepatocytes. In circumstances where the plasma concentration of D-xylose exceeds the renal threshold, significant amounts are excreted into the urinary filtrate.
Application: The D-xylose excretion test appears to be a useful method of monitoring shunt patency after a portasystemic venous anastomsis for portal hypertension.
Implementation: Evaluation of cases of hepatic portosystemic shunt using a D-xylose 5-hour urinary excretion test.

Human Model: Cases of hepatic portosystemic shunt.
Interpretation and Analysis: A 5-hour D-xylose urinary excretion test yielding a total greater than 6 g appears to be an acceptable indicator that a patent shunt is present. A 2nd criterion for patency is an increase of 4 g or more over the result of preoperative tests. If the excretion rate falls in the postoperative period or remains $<$ 4–2 g/5 hours, the anastomosis may be assumed to be occluded.

Assessment of portasystemic shunt patency by estimation of D-xylose excretion. Smith RC, Macpherson AI. Br J Surg 1976 Jun; 63 (6), pp. 435–7.

EXTRAHEPATIC DISEASE CAUSED BY LIVER DYSFUNCTION

Hepatic Encephalopathy/Acute Hepatic Encephalopathy/Encephalopathy Associated with Hemorrhage/Potential Prognostic Indicators
Flumazenil/Pharmaco-Electroencephalography

Background Information: Randomized controlled trials testing flumazenil in hepatic encephalopathy have shown conflicting results.
Application: Evaluate the effects of flumazenil on conditions of hepatic encephalopathy in patients with liver cirrhosis and the potential for therapeutic response to correlate with prognosis.
Route of Administration: Flumazenil (intravenous).
Dosage: Flumazenil (2 mg).
Implementation: Evaluation of the response to flumazenil in conditions of encephalopathy associated with hepatic cirrhosis. Administration of flumazenil or placebo is accompanied by the co-administration of conventional treatments (e.g., branched-chain amino acid, saline, glucose, and lactulose). Alterations in clinical signs are assessed over a 24-hour observation period. Clinical improvement is defined as a 3-point decrease in the Glasgow Coma Score at any time within 24 hours.

Human Model: Cases of encephalopathy associated with hepatic cirrhosis (n = 54 cases with hepatic encephalopathy grade III–IV). For each end point, heterogeneity and treatment efficacy are assessed.

Study Design: Double blind randomized controlled trials (n = 6 with n = 641 patients; n = 326/641 treated with flumazenil, n = 315/641 placebo); the treatment duration can range between 5 minutes and 3 days. (Note: Heterogeneity tests between control groups not significant.)
Interpretation and Analysis: In trials (e.g., n = 5), the mean percentage of clinical improved is approximately 27% with pharmaceutical challenge and about 3% with placebo reference controls (Peto methodology: odds ratio = 6.15; 95% confidence interval, 4.0–9.5; $p < 0.001$; Der Simonian methodology: mean rate difference, 29%; 95% confidence interval, 17–41; $p < 0.001$). The mean percentage of cases with electroencephalographic improvement is approximately 19% with flumazenil but 2% with placebo. The difference is significant only with the Peto method (odds ratio = 5.8; 95% confidence interval, 3.4–9.7; $p < 0.001$). Sensitivity analysis reveals similar findings. Meta-analysis of this type reveals that flumazenil induces clinical and electroencephalographic improvement of hepatic encephalopathy in patients with cirrhosis.

In related investigations, clinical improvements have been appreciated in a large percentage of affected cases (e.g., n = 22/28 with flumazenil; n = 14/26 placebo@$p < 0.05$). Improvement is observed within the 1st 6 hours in the vast majority of cases given flumazenil (e.g., n = 21/22 patients vs n = 3/14 placebo). Unfortunately, the mortality rate is not different between case groups receiving either flumazenil challenge or placebo. However, a large percentage of non-responders subjected to flumazenil challenge died within 24 hours (e.g., n = 6/6 or 100%) in contrast to only slightly less than half of placebo-treated cases (e.g., n = 5/12 non-responders).

In conditions of postbleeding encephalopathy, over half of affected cases challenged with flumazenil improve (n = 11/17) compared to a very low number of placebo cases (e.g., n = 2/14@$p < 0.001$). Flumazenil therefore exerts a beneficial effect in a subset of patients with acute hepatic encephalopathy; encephalopathy associated with bleeding is more likely to respond to flumazenil; and responders to the treatment usually improve within the 1st 6 hours, while lack of response usually represents a bad prognostic sign.

Flumazenil in the treatment of acute hepatic encephalopathy in cirrhotic patients: A double blind randomized placebo controlled study. Laccetti M, Manes G, Uomo G, Lioniello M, Rabitti PG, Balzano A. Dig Liver Dis 2000 May; 32 (4), pp. 335–8.

Flumazenil vs placebo in hepatic encephalopathy in patients with cirrhosis: A meta-analysis. Goulenok C, Bernard B, Cadranel JF, Thabut D, Di Martino V, Opolon P, Poynard T. Aliment Pharmacol Ther 2002 Mar; 16 (3), pp. 361–72.

PHARMACOGENETICS

PHARMACOGENETICS CONCEPTS AND DISEASE EXAMPLES

Amitriptyline: Individualization of Dosage Regimens
Hamilton Score/Multiple Points Method/Modified Bayesian Method

Background Information: Individualization of an amitriptyline dose regimen offers substantial advantages over non-individualized treatment.
Application: Individualization of amitriptyline dose regimens for the purpose of maximizing therapeutic effect and minimizing adverse side effect.
Implementation: In patients with disorders of major depression and receiving amitriptyline therapy, the assessment of clinical effects, adverse effects, and plasma steady state concentrations can be

applied to evaluate cases within the following 3 categories: (i) patients in Group A taking non-individualized doses of amitriptyline; (ii) patients in Group B taking doses of amitriptyline individualized by the modified Bayesian method; and (iii) patients in Group C taking doses of amitriptyline individualized by the multiple point method.

Interpretation and Analysis: Individuals within Group A take significantly higher doses throughout the treatment course; the initial doses for cases in Group B are higher than doses for the patients in Group C, but after corrections based on measured steady state plasma concentrations they are found to be similar.

While the Hamilton score descends uniformly in all 3 groups, both adverse effects and steady state plasma concentrations of amitriptyline are higher in the non-individualized group during the whole treatment course. The multiple points method is considered to be the most precise but the most tedious and sometimes impractical technique. The modified Bayesian method with corrections based on 1st measured plasma steady state concentrations of amitriptyline offers similar therapeutic outcome and adverse effects scores combined with low cost and convenient and easy-to-use protocols.

Comparison of 2 approaches to amitriptyline dose individualization. Jankovic SM, Timotijevic I, Mihajlovic GS, Dukic-Dejanovic S. Eur J Drug Metab Pharmacokinet 1999 Apr–Jun; 24 (2), pp. 163–8.

Arylamine N-Acetyltransferase Genetic Polymorphism

Application: Human acetylation polymorphism, which confers marked interindividual variation in the effect and toxicity of numerous drugs, chemicals, and potential carcinogens.

Considerations: Human acetylation polymorphism confers marked interindividual variation related to the effect and toxicity of numerous drugs, chemicals, and potential carcinogens.

Animal Model: New Zealand white rabbit.

Implementation: Genetically polymorphic arylamine N-acetyltransferase (NAT; acetyl-CoA: arylamine N-acetyltransferase, EC 2.3.1.5) from rabbit liver can be successfully expressed in monkey kidney COS-1 cell populations. Applying the genetic clones and anti-NAT antibodies, it is possible to investigate the relationship among NAT activity, liver enzyme protein, and the level of mRNA in livers from *in vivo* phenotyped rapid-acetylator and slow-acetylator rabbits.

Interpretation and Analysis: Livers from slow acetylators are devoid of both immunodetectable NAT protein and its corresponding mRNA sequence. Analysis of genomic DNA with a panel of restriction enzymes reveals a loss of specific hybridizing bands in the DNA of slow-acetylator rabbits. Defective arylamine N-acetylation in certain strains of rabbits is believed to be caused by a gene deletion resulting in an absence of specific mRNA and NAT enzyme protein.

N-acetylation pharmacogenetics: A gene deletion causes absence of arylamine N-acetyltransferase in liver of slow acetylator rabbits. Blum M, Grant DM, Demierre A, Meyer UA. Proc Natl Acad Sci U S A. 1989 Dec; 86 (23), pp. 9554–7.

Azothioprine/6-Mercaptopurine Inflammatory Bowel Disease (IBD): Crohn's Disease/Sugar Permeability Test
Pharmacogenetics: Dosage Individualization

Background Information: The diagnosis and management of IBD in children and adolescents is a challenge to patients, to their families, and to the health-care team. Among the most prominent advances are new diagnostic serologic assays that can help screen for IBD in the absence of physical signs of disease and help discriminate between ulcerative colitis and Crohn's disease.

Application: Individualization of pharmaceutical dosage in conditions of IBD/Crohn's disease.

Interpretation and Analysis: Other tests that have been identified as potential non-invasive markers of disease activity include Doppler abdominal ultrasound. Recent advances in pharmacogenetics concepts afford the ability to optimize and individualize therapy using azathioprine or 6-mercaptopurine. Finally, bone health has come forth as a major issue in the complete management of pediatric IBD.

Recent advances in the diagnosis and treatment of pediatric inflammatory bowel disease. Seidman EG. Curr Gastroenterol Rep 2000 Jun; 2 (3), pp. 248–52.

Barbiturate Elimination: Genetic Variation
Amobarbital

Cellular/Molecular Mechanism of Action: Amobarbital is a barbiturate agent.

Application: Delineation of the influence of genetics on the pharmacokinetic profiles of amobarbital. Diagnostically, amobartital is frequently selected as the preferred agent for performing the Wada test in conditions affecting the central nervous system (e.g., selective delivery by arterial catheter to localize abnormal/dysfunctional regions of the brain as in intractable cases of epilepsy).

Route of Administration: Amobarbital (intravenous).

Dosage: Amobarbital (125 mg).

Implementation: Evaluation of the time course profile of plasma amobarbital sodium concentrations following intravenous administration (125 mg).

Human Model: Cases of dizygotic twins (n = 7 pairs) and monozygotic twins (n = 7 pairs).

Interpretation and Analysis: The number of detectable compartments varies from between 1, 2, or 3 but is consistent within a given subject. The terminal slope of the semilogarithmic concentration-time plot (biologic half-life of 22.8 hours) does not represent the elimination rate constant even in cases with apparently single-compartmental profiles. The redistribution of amobarbital is relatively more rapid compared to the elimination phase. The rate of the latter (characterized by k_{el} = 0.051 hr-1, plasma clearance = 37.7 ml/min) can be closely correlated with the rate of metabolism. Results obtained from twin subjects reveal that genetic factors influence the kinetic parameters characterizing the rate of amobarbital elimination and, therefore, the rate of its metabolism. Correlation analysis suggests that genetic factors function in a manner that is independent of body size (strongly heritable phenotype). Based on these observations, it is recommended that during the course of performing pharmacogenetic studies, it is important to assess model-independent kinetic parameters, such as plasma clearance with or without adjustments for body weight.

Genetic study of amobarbital elimination based on its kinetics in twins. Endrenyi L, Inaba T, Kalow W. Clin Pharmacol Ther 1976 Dec; 20 (6), pp. 701–14.

Carvedilol: Hepatic Metabolization Polymorphism/ Extrapolation from Debrisoquin and Mephenytoin
Mixed-Adrenergic Receptor Antagonists/Carvedilol/ Debrisoquin/Mephenytoin

Cellular/Molecular Mechanism of Action: Carvedilol is a mixed α-adrenergic and β-adrenergic receptor antagonist agent. Although the 2 isomers are equally potent as α1-blockers, the S(-)-isomer is principally responsible for the beta blockade of carvedilol.

Application: Utilization of metabolization profiles for debrisoquin and mephenytoin to determine their value as predictive molecular probes for the estimation of carvedilol metabolization profiles.
Dosage: Administered as a racemic mixture.
Implementation: Determination of the role of pharmacogenetics in the metabolism of carvedilol through the investigation of (i) individuals that extensively metabolize both debrisoquin and mephenytoin; (ii) individuals that poorly metabolize debrisoquin but are extensive metabolizers of mephenytoin; and (iii) poor metabolizers of mephenytoin but extensive metabolizers of debrisoquin.
Interpretation and Analysis: The clearance of R-carvedilol is significantly lower than S-carvedilol in both debrisoquin phenotypes. Poor metabolizers of debrisoquin have a significantly lower clearance of R-carvedilol than extensive metabolizers of debrisoquin. The partial metabolic clearance of carvedilol to the 2 ring-hydroxylated metabolites 4- and 5-hydroxyphenyl carvedilol is significantly reduced in poor metabolizers of debrisoquin. No effect of mephenytoin phenotype on carvedilol kinetics can be appreciated. Carvedilol is therefore stereoselectively metabolized in humans, and the clearance of S-carvedilol is higher than that of R-carvedilol. In poor metabolizers of debrisoquin the clearance of R-carvedilol is further reduced, resulting in higher plasma concentrations and perhaps greater levels of alpha-blockade.

Stereoselective disposition of carvedilol is determined by CYP2D6. Zhou HH, Wood AJ. Clin Pharmacol Ther 1995 May; 57 (5), pp. 518–24.

Pharmacogenetics Attributes and Perspectives

Pharmacogenomics is an emerging scientific discipline examining the genetic basis for individual variations in response to therapeutics. Genetic polymorphisms are a major cause of individual differences in drug response. Metabolic phenotyping can be accomplished by administering a probe drug or substrate and measuring the metabolites and clinical outcomes. However, this approach tends to be labor intensive and requires repeated sample collection from the individual being tested. Alternatively, genotyping allows determination of individual DNA sequence differences for a particular trait. Commonly used genotyping methods include gel electrophoresis-based techniques, such as polymerase chain reaction (PCR) coupled with restriction fragment length polymorphism analysis, multiplex PCR, and allele-specific amplification. Fluorescent dye-based high-throughput genotyping procedures are increasing in popularity, including oligonucleotide ligation assay, direct heterozygote sequencing, and TaqMan (Perkin Elmer, Foster City, CA) allelic discrimination. High-density chip array and mass spectrometry technologies are the newest advances in the genotyping field, but their wide application is yet to be developed. Novel mutations/polymorphisms also can be identified by conformation-based mutation screening and direct high-throughput heterozygote sequencing. Rapid and accurate detection of genetic polymorphisms has great potential for application to drug development, animal toxicity studies, improvement of human clinical trials, and postmarket monitoring surveillance for drug efficacy and toxicity.

Technologies for detecting genetic polymorphisms in pharmacogenomics. Shi MM, Bleavins MR, de la Iglesia FA. Mol Diagn 1999 Dec; 4 (4), pp. 343–51.

Pharmacogenetics Attributes and Perspectives

The majority of the research and clinical-oriented manuscripts published in the field of pharmacogenetics, genetic defects, and predictive maternal genotype assays between 1985 and 1999 have primarily addressed the topics of (i) polymorphisms, (ii) genotyping, (iii) cytochrome P450 enzyme systems, (iv) epoxide hydrolase, (v) folate metabolism, metabolism of anticonvulsant medications, (vi) molecular genetics of neural tube defects, (vii) variations in drug metabolism, and (viii) environmental exposures. Collectively, this body of work has emphasized that individuals vary in how they metabolize drugs and handle toxic environmental exposures. In an ideal pregnancy, there is no or limited exposure to medications and environmental agents. However, in women with chronic medical conditions such as heart disease and seizures, this is often not possible. Unfortunately, no techniques have been developed to identify those at risk in this treatment subpopulation. Gene polymorphisms for a specific enzyme may result in an absence or reduction in the level of enzyme activity or in no change at all, with little effect on the structure/function of the gene product(s); they are not associated with clinical phenotypes in either the mother or the fetus. Other polymorphisms may be only markers. Thus, developing genotyping assays for women that are predictive of phenotype expression in the fetus is the key to screening for polymorphisms. As more mutations are identified and clinical, pharmacologic, biologic, and pharmacokinetic relationships are established, using these polymorphisms to develop a genotyping assay for women may become a clinical reality, possibly leading to preventive prepregnancy or prenatal treatment that may play an increasingly effective role in maternal care.

Pharmacogenetic screening for susceptibility to fetal malformations in women. Van Dyke DC, Ellingrod VL, Berg MJ, Niebyl JR, Sherbondy AL, Trembath DG. Ann Pharmacother 2000 May; 34 (5), pp. 639–45.

Pharmacogenetics Attributes and Perspectives

Genomics, particularly high-throughput sequencing and characterization of expressed human genes, has created new opportunities for drug discovery. Knowledge of all the human genes and their functions may allow effective preventive measures and change drug research strategy and drug discovery development processes. Pharmacogenomics is the application of genomic technologies such as gene sequencing, statistical genetics, and gene expression analysis to drugs in clinical development and on the market. It applies the large-scale systematic approaches of genomics to speed the discovery of drug response markers, whether they act at the level of the drug target, drug metabolism, or disease pathways. The potential implication of genomics and pharmacogenomics in clinical research and clinical medicine is that disease could be treated according to genetic and specific individual markers, selecting medications and dosages that are optimized for individual patients. The possibility of defining patient populations genetically may improve outcomes by predicting individual responses to drugs, and could improve safety and efficacy in therapeutic areas such as neuropsychiatry, cardiovascular medicine, endocrinology (diabetes and obesity), and oncology. Ethical questions need to be addressed and guidelines established for the use of genomics in clinical research and clinical medicine. Significant achievements are possible with an interdisciplinary approach that includes genetic, technological, and therapeutic measures.

Impact of genomics on drug discovery and clinical medicine. Emilien G, Ponchon M, Caldas C, Isacson O, Maloteaux JM. QJM 2000 Jul; 93 (7), pp. 391–423.

Pharmacogenetics Attributes and Perspectives

Pharmacogenetics is the science of the influence of heredity on pharmacological response. One issue related to this consideration is the cost of severe adverse drug reactions in individuals, which has

been estimated in the United States alone to be in excess of $4 billion. It has been argued that in a significant proportion of cases, the efficacy and toxicity profiles of drug therapy would be substantially improved in individuals if characteristics due to genetic variation are taken into account. Methods are now available that make screening for susceptibility feasible. There are several therapeutic areas in which screening may give rise to significant improvements in outcome with cost benefits to both the individual and the community. However, there is currently a lack of data on which cost-benefit analysis can be based. The challenge is to provide this information for new drugs and for drugs with established therapeutic roles.

Pharmacogenetic screening and therapeutic drugs. Steimer W, Potter JM. Clin Chim Acta 2002 Jan; 315 (1–2), pp. 137–55.

Pharmacogenetics Attributes and Perspectives

Genetic variability in drug response occurs as a result of molecular alterations at the level of drug-metabolizing enzymes, drug targets/receptors, and drug transport proteins. Reports have discussed the possibility that therapeutic drug monitoring (TDM) in the future will involve not the mere measurement and interpretation of drug concentrations but will include both traditional TDM and pharmacogenetics-oriented TDM. In contrast to traditional TDM, which cannot be performed until after a drug is administered to the patient, pharmacogenetics-oriented TDM can be conducted even before treatment begins. Other advantages of genotyping over traditional TDM include, but are not limited to, the following: (i) it does not require the assumption of steady state conditions (or patient compliance) for the interpretation of results; (ii) it can often be performed less invasively (with saliva, hair root, or buccal swab samples); (iii) it can provide predictive value for multiple drugs (e.g., a number of cytochrome P450 [CYP] 2D6, CYP2C 19, or CYP2C9 substrates) rather than a single drug; (iv) it provides mechanistic, instead of merely descriptive, information; and (v) it is constant over an individual's lifetime (and not influenced by concurrent drug administration, alteration in hormonal levels, or disease states). Pharmacogenetic information can be applied as a priority for initial dose stratification and identification of cases where certain drugs are simply not effective. However, traditional TDM will still be required for various reasons. In current clinical practice, pharmacogenetic testing is performed for only a few drugs (e.g., mercaptopurine, thioguanine, azathioprine, trastuzumab, and tacrine) and in a limited number of teaching hospitals and specialist academic centers. It has been proposed that other drugs (e.g., warfarin, phenytoin, codeine, oral hypoglycemics, tricyclic antidepressants, aminoglycosides, digoxin, cyclosporine, cyclophosphamide, ifosfamide, theophylline, and clozapine) are potential candidates for pharmacogenetics-oriented TDM. However, prospective studies of pharmacogenetics-oriented TDM must be performed to determine its efficacy and cost-effectiveness in optimizing therapeutic effects while minimizing toxicity. In the future, in addition to targeting a patient's drug concentrations within a therapeutic range, pharmacists are likely to be making dosage recommendations for individual drugs on the basis of the individual patient's genotype. Upon entering the era of personalized drug therapy, it will be possible to identify not only the best drug to be administered to a particular patient but also the most effective and safest dosage from the outset of therapy.

Pharmacogenetics: The therapeutic drug monitoring of the future? Ensom MH, Chang TK, Patel P. Clin Pharmacokinet 2001;40 (11), pp. 783–802.

Pharmacogenetics Attributes and Perspectives

In recent years intense activity in both academic and industrial sectors has provided a wealth of information on the human genome with an associated impressive increase in the number of novel gene sequences deposited in sequence data repositories and patent applications. This genomic industrial revolution has transformed the way in which drug target discovery is now approached. Previous reports have discussed how various differential gene expression (DGE) technologies are being utilized for cardiovascular disease (CVD) drug target discovery. Other approaches such as sequencing cDNA from cardiovascular-derived tissues and cells coupled with bioinformatic sequence analysis are used with the aim of identifying novel gene sequences that may be exploited toward target discovery. Additional leverage from gene sequence information is obtained through identification of polymorphisms that may confer disease susceptibility and/or affect drug responsiveness. Pharmacogenomic studies are described wherein gene expression-based techniques are used to evaluate drug response and/or efficacy. Industrial-scale genomics supports and addresses not only novel target gene discovery but also the burgeoning issues in pharmaceutical and clinical cardiovascular medicine relative to polymorphic gene responses.

Application of industrial scale genomics to discovery of therapeutic targets in heart failure. Mehraban F, Tomlinson JE. Eur J Heart Fail 2001 Dec; 3 (6), pp. 641–50.

Pharmacogenetics Attributes and Perspectives

The 1st observations of inherited differences in drug effects in the 1950s led to the recognition of a genetic basis for drug response. With the development of genetics and molecular biology, it became clear that certain drug responses could be associated with specific genetic variations or polymorphisms. There are now examples of polymorphisms that affect response to drugs ranging from common analgesics to chemotherapeutics. The goal of pharmacogenetics is to identify polymorphisms that can serve as predictive markers of drug response. Reviews have summarized how existing pharmacogenomic technologies can be applied advantageously throughout drug development to bring drugs successfully to market along with diagnostic tests that ensure their appropriate use.

Integrating pharmacogenomics into drug development. Ferentz AE. Pharmacogenomics 2002 Jul; 3 (4), pp. 453–67.

Pharmacogenetics Attributes and Perspectives

The introduction of targeted therapeutics into clinical practice has created major opportunities for further development of the molecular diagnostics industry. Emerging genomic and proteomic technologies and information are now resulting in the molecular subclassification of disease as the basis for diagnosis, prognosis, and therapeutic selection. The ultimate goals of personalized medicine are to take advantage of a molecular understanding of disease, both to optimize drug development and direct preventive resources and therapeutic agents at the right population of people while they are still well. Single nucleotide polymorphisms identification and genotyping have uncovered predisposition markers from cancer and heart disease as well in the prediction of both drug efficacy and toxicity. Pharmacogenomic and pharmacodynamic assays are being developed to enhance the speed and decrease the cost of drug development, as

well as reduce side effects and increase response rates in a variety of diseases. The traditional trial and error practice of medicine is progressively eroding in favor of more precise marker-assisted diagnosis and safer and more effective molecularly guided treatment of disease. For the diagnostics industry this represents an unprecedented opportunity for integration, increased value, and commercial opportunities for molecularly derived tests.

Integration of molecular diagnostics with therapeutics: Implications for drug discovery and patient care. Ross JS, Ginsburg GS. Expert Rev Mol Diagn 2002 Nov; 2 (6), pp. 531–41.

Pharmacogenetics Attributes and Perspectives

It is widely anticipated that during the next 5 years the molecular diagnostic industry will continue to grow at a double-digit pace to meet increasing demand for personalized medicine. A wide variety of drugs in late preclinical and early clinical development are being targeted to disease-specific gene and protein defects that will require co-approval of diagnostic and therapeutic products by regulatory agencies. An increasingly educated public will demand more information about their predisposition for serious diseases and how these potential illnesses can be detected in an early stage when they can be arrested or cured with new therapies custom designed for their individual clinical status. To respond to this demand, major pharmaceutical companies will partner with diagnostics companies or develop their own in-house capabilities that will permit efficient production of more effective and less toxic integrated personalized medicine drug and test products. For clinical laboratories and pathologists, this integration of diagnostics and therapeutics represents a major new opportunity to emerge as leaders of the new medicine, guiding the selection, dosage, route of administration, and multidrug combinations and producing increased efficacy and reduced toxicity of pharmaceutical products.

The integration of molecular diagnostics with therapeutics: Implications for drug development and pathology practice. Ross JS, Ginsburg GS. Am J Clin Pathol 2003 Jan; 119 (1), pp. 26–36.

Pharmacogenetics Ethics and Practices

Pharmacogenomics holds much promise for the application of genetic information to the improvement of clinical care. Ethical issues for pharmacogenomics arise at the intersection of the spheres of drug development and genetic testing. Clinical drug trial designs that use subject selection based on genotype must consider the features of scientific validity, social value and risk-benefit ratio, and, later, the impact of this strategy on postmarket studies and clinical use of drugs. Although the testing context for pharmacogenomic tests is different from other genetic tests, decisions to use any new clinical tests in medical practice will require evaluation of not only the benefit linked to improved drug use but also the risks arising in part from the scale of testing, predictive value, and collateral potential of the genetic test. Integration of pharmacogenomic information into clinical practice will require clinical trials to assess clinical usefulness, including the impact of tests on therapeutic outcomes. Trials will also be needed to demonstrate the effectiveness of education, informed consent, and counseling.

Emerging ethical issues in pharmacogenomics: From research to clinical practice. Freund CL, Wilfond BS. Am J Pharmacogenomics 2002; 2 (4), pp. 273–81.

Pharmacogenetics of Antidepressants in Females

Background Information: In the medical literature, there is a lack of sex-specific information regarding the efficacy, metabolism, and side effects associated with psychopharmacologic treatment. In part, this lack results from the historic underinclusion of women in clinical trials during early drug development, but it also occurs because investigators of treatment and metabolic studies do not routinely analyze results according to sex. In 1993, the U.S. Food and Drug Administration (FDA) announced changes that encourage the inclusion of women in early pharmacokinetic studies and emphasize the need for subset analyses using sex and age parameters. In conjunction with advances in basic science regarding drug metabolism, these modifications have led to modest increases in information regarding sex differences in drug metabolism and efficacy. In the referenced article, current information regarding potential sex differences in the pharmacotherapy of Major Depressive Disorder is reviewed.
Data Sources: A MEDLINE search using the terms "antidepressants," "sex-factors," "gender differences," and "women" for the years 1966–2000.
Data Synthesis and Conclusions: There are data supporting sex differences in the activity of various antidepressant-metabolizing enzymes. However, there is a paucity of investigation regarding how these differences might translate into differences in clinical efficacy. Notably, there is little work using existing databases to perform the subgroup analyses recommended by the FDA. The widespread dissemination of such work is needed, and, if conducted, investigations in this area have the potential to enhance psychopharmacologic treatment for both men and women.

The pharmacologic treatment of depression: Is gender a critical factor? Yonkers KA, Brawman-Mintzer O. J Clin Psychiatry 2002 Jul; 63 (7), pp. 610–5.

Pharmacogenetics of Antidepressants and Mood Disorders

Organization: Pharmacologic and Somatic Treatments Section of the National Institute of Mental Health Strategic Plan for Mood Disorders Committee on advancing novel pharmacologic and somatic treatments for mood disorders.
Topic: Current pharmacologic treatments and new directions in the field.
Discussion: Specific research initiatives exist that can advance the current therapeutics for mood disorders, including new basic and clinical research in *in vivo* human imaging procedures, somatic therapeutics, and the vast new area of pharmacogenetics. New scientific and technical opportunities are available today based on advances in basic neuroscience, opportunities in clinical testing, industry interest in advancing central nervous system therapeutics, and active consumer advocacy groups. The question of how to bring all of these positive forces together to accelerate discovery in mood disorder therapeutics is of major importance.

Developing novel treatments for mood disorders: Accelerating discovery. Tamminga CA, Nemeroff CB, Blakely RD, Brady L, Carter CS, Davis KL, Dingledine R, Gorman JM, Grigoriadis DE, Henderson DC, B Innis RB, Killen J, Laughren TP, McDonald WM, M Murphy GM Jr, Paul SM, Rudorfer MV, Sausville E, Schatzberg AF, Scolnick EM, Suppes T. Biol Psychiatry 2002 Sep 15; 52 (6), pp. 589–609.

Pharmacogenetics of Chemotherapeutic Agents

Background Information: Cancer chemotherapy doses are empirical in that the majority are administered at a fixed dose (mg/m^2 or mg/kg). One reason for this is that the intrinsic sensitivity of the tumor or host cells to 1 particular chemotherapy agent is unknown. Therefore, the likelihood of response or toxicity is unpredictable. This contrasts with antimicrobial chemotherapy, where sensitivity (minimum inhibitory concentration) can be determined for a specific bacterium. The pharmacokinetics of cancer chemotherapy agents is also highly variable between patients. In addition, the small therapeutic index of these drugs, combined with the lack of good surrogate markers of toxicity or response, adds to the empiricism of the administration of cancer chemotherapy. In the past few years, numerous studies have established good relationships between systemic exposure to cancer chemotherapy and both response and toxicity. These relationships have been used to individualize chemotherapic dose administration.

Interpretation and Analysis: Examples of some pharmaceuticals that are currently individualized based on their pharmacokinetics include methotrexate, busulfan, and carboplatin. Other examples of antineoplastic agents that may eventually be individualized based on their pharmacokinetics are mercaptopurine, fluorouracil, etoposide and teniposide, and topotecan and suramin. New strategies are being investigated to improve the therapeutic index of cancer chemotherapy agents such as biomodulation, pharmacogenetics, circadian administration, and the modification of drug scheduling. Pharmacokinetic studies have also played a major role in these areas. Thus, despite the empiricism associate with cancer chemotherapy administration, some progress has been made and shown to have an impact on outcome. However, more studies are needed to improve cancer chemotherapy administration.

Pharmacokinetic optimization of cancer chemotherapy. Effect on outcomes. Masson E, Zamboni WC. Clin Pharmacokinet 1997 Apr; 32 (4), pp. 324–43.

Pharmacogenetics of Epilepsy

Despite the recent development of new antiepilepsy drugs, a significant number of children are still unable to achieve seizure freedom without side effects. Understanding the factors behind individual variability in antiepilepsy drug tolerability and dose response and incorporating these factors into a treatment plan would represent an important advance in epilepsy pharmacotherapy. A more thorough understanding of the epileptogenic process may allow clinicians to select antiepilepsy drugs that interrupt or modify various steps in the epileptogenic progression (i.e., disease modification). Additionally, advances in the understanding of human genetics may allow for selection of antiepilepsy drugs and dosage regimens based on a patient's potential improvement in the medical treatment of patients with epilepsy. Such methods of tailoring antiepilepsy drug therapy would be preferable to the trial and error system that is currently used.

Advancing the medical management of epilepsy: Disease modification and pharmacogenetics. Glauser TA. J Child Neurol 2002 Jan; 17 Suppl 1, pp. S85–93.

Pharmacogenetics of Infectious Disease/ Polymorphism of Pathogen and Host

The impact of pharmacogenomics on the prevention, diagnosis, and treatment of infectious diseases has been previously described. The application of pharmacogenomics to infectious diseases requires consideration of the genomes of both the pathogen and the host. The pathogen's genome may be used for antigen identification, to identify infecting organisms, and to determine antimicrobial resistance. Diagnostic tool development and vaccine design can be aided by knowing which portions of a pathogen are important antigenic determinants. The unique genetic makeup of a pathogen can facilitate its identification as an augmentation to the traditional culture. Important genes conferring resistance to antibiotics can be detected, and this information can be used to choose appropriate antibiotic therapy. The genome of the host may reveal susceptibility genes and new drug targets that may be used in the treatment of infectious diseases. Thus far, polymorphisms in genes of the host immune system have been associated with susceptibility to infections and response to treatment. Examples of these findings are described in the referenced paper. Pharmacogenomics has the potential to revolutionize the prevention, diagnosis, and treatment of infectious diseases.

Pharmacogenomics and infectious diseases: Impact on drug response and applications to disease management. Hayney MS. Am J Health Syst Pharm 2002 Sep 1; 59 (17), pp. 1626–31.

Pharmacogenetics of Malignant Hyperthermia/ Long Q-T Syndrome/Venous Thromboembolic Disease/Tardive Dyskinesia/Drug Addiction

In the last decades, advances in molecular biology have led to modern pharmacogenetics, which started as a science that focused on investigating drug metabolizing enzymes and genetic determinants of pharmacokinetic variability. As more evidence has become available on the structure of drug targets and the genes coding for them, increasing attention has been directed toward pharmacodynamic explanations of variability in therapeutic response as well as in the risk for adverse drug reactions. Traditionally, genetic drug safety research has focused on variations in single genes whose functions are known to be related to given adverse drug reactions. Relevant examples include malignant hyperthermia, the long Q-T syndrome, venous thromboembolic disease, tardive dyskinesia, and drug addiction. In the future, results from the Human Genome Project, together with tools such as DNA microarray technology, high-output screening systems, and advanced bioinformatics, will permit a more thorough elucidation than is currently possible of the genetic components of adverse drug reactions. By screening for a large number of single-nucleotide polymorphisms (SNPs), SNP patterns associated with adverse drug reactions can be discovered even though the functions of the SNPs as such are completely unknown. On the basis of these findings, it can be expected that pharmacogenetic research will identify situations where a drug should be avoided in certain individuals in order to reduce the risk for adverse drug reactions. If so, it will be feasible to use molecular diagnostics to select drugs that are safe for the individual patient.

Genotyping of drug targets: A method to predict adverse drug reactions? Guzey C, Spigset O. Drug Saf 2002; 25 (8), pp. 553–60.

Pharmacogenetics of the Hepatic Cytochrome P450 Enzyme Systems

Background Information: Drug-metabolizing enzymes or xenobiotics-metabolizing enzymes (DMEs or XMEs) play central roles in the biotransformation, metabolism, and/or detoxification of xenobiotics or foreign compounds that are introduced to the human body. In general, DMEs protect or defend the body against the potential harmful insults from the environment. Once in the body, many

xenobiotics may induce signal transduction events either specifically or non-specifically leading to various cellular, physiological, and pharmacological responses including homeostasis, proliferation, differentiation, apoptosis, or necrosis. For the body to minimize the insults caused by these xenobiotics, various tissues/organs are well equipped with diverse DMEs including various Phase I and Phase II enzymes, which are present in abundance either at the basal level and/or increased/induced after exposure. Better understanding of the pharmacogenomic/gene expression profile of DMEs and the underlying molecular mechanisms after exposure to xenobiotics or drugs can be gained by review of current knowledge of DNA microarray technology in gene expression profiling and the signal transduction events elicited by various xenobiotics mediated by either specific receptors or non-specific signal transduction pathways. Pharmacogenomics is the study of genes and the gene products (proteins) essential for pharmacological or toxicological responses to pharmaceutical agents. In order to assess the battery of genes that are induced or repressed by xenobiotics and pharmaceutical agents, cDNA microarray or oligonucleotide-based DNA chip technology can be a powerful tool to analyze, simultaneously, the gene expression profiles that are induced or repressed by xenobiotics. The regulation of gene expression of the various phase I DMEs such as the cytochrome P450 (CYP) as well as phase II DMEs generally depends on the interaction of the xenobiotics with the receptors. For instance, the expression of CYP1 genes can be induced via the aryl hydrocarbon receptor (AhR), which dimerizes with the AhR nuclear translocator (ARNT), in response to many polycyclic aromatic hydrocarbons (PAHs). Similarly, the steroid family of orphan receptors, the constitutive androstane receptor (CAR) and pregnane X receptors (PXR), heterodimerize with the retinoid X receptor (RXR) and transcriptionally activate the promoters of CYP2B and CYP3A gene expression by xenobiotics such as phenobarbital-like compounds (CAR) and dexamethasone and rifampicin-type of agents (PXR). The peroxisome proliferator activated receptor (PPAR), which is 1 of the 1st characterized members of the nuclear hormone receptor, also dimerizes with RXR, and it has been shown to be activated by lipid lowering agent fibrate-type of compounds leading to transcriptional activation of the promoters on the CYP4A genes. The transcriptional activation of these promoters generally leads to the induction of their mRNA. The physiological and the pharmacological implications of common partner of RXR for CAR, PXR, and PPAR receptors largely remain unknown and are under intense investigations. For the phase II DMEs, phase II gene inducers such as phenolic compounds butylated hydroxyanisol (BHA), tert-butylhydroquinone (tBHQ), green tea polyphenol (GTP), (-)-epicatechin-3-gallate (EGCG), and the isothiocyanates (PEITC, sulforaphane) generally appear to be electrophiles. They can activate the mitogen-activated protein kinase (MAPK) pathway via electrophilic-mediated stress response, resulting in the activation of bZIP transcription factors Nrf2, which dimerizes with Mafs and binds to the antioxidant/electrophile response element (ARE/EpRE) enhancers that are found in many phase II DMEs as well as many cellular defensive enzymes such as thioredoxins, gammaGCS, and HO-1, with the subsequent induction of gene expression of these genes. It appears that in general, exposure to phase I or phase II gene inducers or xenobiotics may trigger a cellular "stress" response leading to the increase in the gene expression of these DMEs, which ultimately enhance the elimination and clearance of the xenobiotics and/or the "cellular stresses" including harmful reactive intermediates such as reactive oxygen species (ROS), so that the body will remove the "stress" expeditiously. Consequently, this homeostatic response of the body plays a central role in the protection of the organism against environmental insults such as xenobiotics. Advances in DNA microarray technologies and mammalian genome sequencing will soon allow quantitative assessment of expression profiles of all genes in the selected tissues. The ability to predict phenotypic outcomes from gene expression profiles is currently in its infancy, however, and will require additional bioinformatic tools. Such tools will facilitate information gathering from literature and gene databases as well as integration of expression data with animal physiology studies. The study of pharmacogenomic/gene expression profile and the understanding of the regulation and the signal transduction mechanisms elicited by pharmaceutical agents can be of potential importance during drug discovery and the drug development.

Pharmacogenomics, regulation and signaling pathways of phase I and II drug metabolizing enzymes. Rushmore TH, Kong AN. Curr Drug Metab 2002 Oct; 3 (5), pp. 481–90.

Pharmacogenetics/Acute Lymphoblastic Leukemia (ALL)

Malignancies in childhood occur with an incidence of 13 to 14 per 100,000 children under the age of 15 years. Acute lymphoblastic leukemia with an incidence of 29% is the most common pediatric malignancy, whereas acute myeloid leukemias account for about 5%. The treatment of acute leukemias consists of sequential therapy cycles (induction, consolidation, intensification, maintenance therapy) with different cytostatic drugs over a time period of up to 1.5 to 3 years. Over the last 25 years of clinical trials, a significant rise in the rate of complete remissions as well as an increase in long-term survival has been achieved. Therefore, growing attention is now focused on the long-term effects of antileukemic treatment. Several cytostatic drugs administered in the treatment of acute leukemia in childhood are known to cause long-term adverse effects. Anthracyclines may induce chronic cardiotoxicity, alkylating agents are likely to cause gonadal damage, and secondary malignancies and the use of glucocorticoids may cause osteonecrosis. Most of the long-term adverse effects have not been analyzed systematically. Approaches to minimizing long-term adverse effects without jeopardizing outcome have included the design of new drugs such as a liposomal formulation of anthracyclines; the development of anthracycline-derivates with lower toxicity; the development of cardioprotective agents, or, more recently, the use of targeted therapy; alternative administration schedules like continuous infusion or timed sequential therapy; and risk group stratification by the monitoring of minimal residual disease. Several attempts have been made to minimize the cardiotoxicity of anthracyclines: decreasing concentrations delivered to the myocardium by either prolonging infusion time or using liposomal formulated anthracyclines or less cardiotoxic analogues, or the additional administration of cardioprotective agents. The advantage of these approaches is still controversial, but there are ongoing clinical trials to evaluate the long-term effects. The use of new diagnostic methods, such as diagnosis of minimal residual disease, which allow reduction or optimization of dose, offers potential advantages compared with conventional treatment in terms of reducing the risk of severe long-term adverse effects. Most options for minimizing long-term adverse effects have resulted from theoretical models and *in vitro* studies, but only some of the modalities, such as the use of dexrazoxane, the continuous infusion of anthracyclines, or timed sequential therapy, have been evaluated in prospective, randomized studies in patients. Future approaches to predict severe toxicity may be based upon pharmacogenetics and gene profiling.

Minimizing the long-term adverse effects of childhood leukemia therapy. Langebrake C, Reinhardt D, Ritter J. Drug Saf 2002; 25 (15), pp. 1057–77.

Pharmacogenetics/Acute Lymphoblastic Leukemia (ALL)
Therapeutic Response

Pharmacogenomics is a burgeoning field that aims to elucidate inherited differences in drug disposition and treatment response toward individualizing therapy to enhance efficacy and reduce toxicity. Approximately 80% of children with ALL can be cured with modern therapy. Despite this success, the number of cases of relapsed ALL remains greater than the number of new cases of most childhood cancers. New strategies are needed to develop curative therapy for the 20% of patients who are not being cured today and to develop less toxic and less onerous treatment for ALL patients. Molecular genetics investigations have provided important insights to the mechanisms of leukemogenesis and are now routinely used to define the prognosis and guide treatment intensity for childhood ALL. As a result, substantial progress has been made recently in this field of study pertaining to conditions of childhood ALL that will hold great promise in further enhancing the treatment of this most common cancer in children.

Pharmacogenomics of childhood acute lymphoblastic leukemia. Brenner TL, Pui CH, Evan WE. Curr Opin Mol Ther 2001 Dec; 3 (6), pp. 567–78.

Pharmacogenetics/Genetics and Human Genome Project

The explosion of information generated by large-scale functional genomics technologies has resulted in an exponential increase in the number of potential genes and proteins available for pharmaceutical and diagnostic research development. In order to tap this potential, the primary challenge is to develop a strategy to effectively integrate and extract meaning from the human genomic sequence information that has been generated since the start of the Human Genome Project. Strategies have been applied by academics and by the biotechnology sector to sort and triage this information with the ultimate goal of identifying future therapeutic targets for cancer and other diseases.

Implications of oncogenomics for cancer research and clinical oncology. Herrmann JL, Rastelli L, Burgess CE, Fernandez EE, Rothberg BE, Rothberg JM, Shimkets RA. Cancer J 2001 Jan–Feb; 7 (1), pp. 40–51.

Pharmacogenetics/Microarray Technology Platforms

Background Information: High-density microarrays are ideally suited for analyzing thousands of genes against a small number of samples. The next step in the discovery process is to take the resulting genes of interest and rapidly screen them against thousands of patient samples, tissues, or cell lines to further investigate their involvement in disease risk or the response to medication.
Implementation: Microarray technology platforms can be applied for the detection of both single-nucleotide polymorphisms (SNPs) and alterations in protein expression. Each microarray contains up to 250 elements that can be customized for each application. Slides are usually designed in either a 16- or 96-microarray format (4,000–24,000 elements per slide), thereby allowing the corresponding number of samples to be rapidly processed in parallel (simultaneously).
Interpretation and Analysis: Findings for SNP genotyping and protein profiling agree with results of restriction fragment length polymorphism (RFLP) analysis or ELISA, respectively. Genotyping analyses, using the microarray technology, on large sample sets over multiple polymorphisms in the NAT2 gene are in full agreement with traditional methodologies, such as sequencing and RFLP analysis. The multiplexed protein microarray provides correlation coefficients of 0.82 to 0.99 (depending on analyte) compared with ELISAs. The integrated microarray technology platform is adaptable and versatile, while offering the high-throughput capabilities needed for drug development and discovery applications.

High-throughput genomic and proteomic analysis using microarray technology. Huang JX, Mehrens D, Wiese R, Lee S, Tam SW, Daniel S, Gilmore J, Shi M, Lashkari D. Clin Chem 2001 Oct; 47 (10), pp. 1912–6.

Toborinone Pharmacokinetic/Pharmacodynamic Prediction/Hepatic Substrate Metabolism and Clearance/Congestive Heart Failure (CHF) Renal Glomerular Filtration Rate
Caffeine/Indocyanine Green (ICG)/Iothalamate

Cellular/Molecular Mechanism of Action: Caffeine is a substrate for hepatic cytochrome P450 1A2 (CYP1A2) and the biochemical activity of this enzyme system yields a metabolite that can be measured or quantified. Indocyanine green is not metabolized by the liver but instead is removed from the intravascular compartment by hepatocytes and eliminated in the bile. Iothalamate is simply eliminated from the intravascular compartment by mechanisms of glomerular filtration and excreted in the urinary filtrate.
Application: Plasma clearance of iothalamate can be used to evaluate glomerular filtration. Caffeine metabolism is useful as a molecular probe for evaluating hepatic metabolic capacity while ICG can serve as a marker molecule for characterizing hepatic clearance parameters.
Implementation: Delineation of the pharmacokinetic profile of toborinone in disease states affecting mutiple organ systems that influence circulation, metabolism, and excretion. In this context, objective evaluation of the glomerular filtration rate can be established by measuring iothalamate clearance, while hepatic function can be assessed by delineating caffeine metabolism profiles and clearance of indocyanine green.
Human Model: Cases of CHF complicated by concomitant renal and/or hepatic disease. Cases can be divided into groups based on estimated creatinine clearance and serum bilirubin concentrations.
Interpretation and Analysis: No significant differences can be observed for mean toborinone pharmacokinetic parameters among the 4 study groups. Positive correlations can be appreciated between toborinone clearance and measured indices for renal and hepatic function: creatinine clearance, iothalamate renal clearance, paraxanthine/caffeine ratio, and ICG clearance. Toborinone clearance decreases with decreasing creatinine clearance, decreasing glomerular filtration rate, decreasing demethylation metabolic activity, and decreasing hepatic bloodflow, although no significant differences are observed in any mean toborinone pharmacokinetic parameters evaluated among the 4 study groups.

The pharmacokinetics of toborinone in subjects with congestive heart failure and concomitant renal impairment and/or concomitant hepatic impairment. Tammara B, Trang JM, Kitani M, Miyamoto G, Bramer SL. J Clin Pharmacol 2002 Dec; 42 (12), pp. 1318–25.

PHARMACOGENETICS: GENERAL HEPATIC BIOCHEMICAL METABOLIZATION

Acyclovir: Optimization of Individual Pharmacokinetic Profiles/Renal Dialysis: Induced Pharmacokinetic Variability
Bayesian Method

Cellular/Molecular Mechanism of Action: Acyclovir is a synthetic purine nucleoside analog [9-[(2-hydroxy-ethoxy)methyl] guanine] that functions as a false (decoy)analog corresponding to guanosine. Viral thymidine kinase has a much higher affinity for acyclovir than does mammalian thymidine kinase.
Physiological Mechanism of Action: Acyclovir functions as an antiviral agent (herpes viruses).
Background Information: The therapeutic regimen for intravenous acyclovir in pediatric patients can often be complicated by evolving renal impairment directly related to intraindividual pharmacokinetic variability linked to the patient's clinical condition.
Application: Acyclovir is traditionally applied as an antiviral agent.
Route of Administration: Acyclovir (intravenous).
Dosage: Acyclovir.
Implementation: Acquisition of therapeutic drug monitoring data can be utilized to assess acyclovir intraindividual pharmacokinetic variability during several types of renal replacement therapy. In this manner, Bayesian adaptive control of acyclovir dosage regimens can be performed in pediatric patients with bone marrow transplants that subsequently develop severe renal impairment. Acyclovir pharmacokinetic parameter values corresponding to different techniques and periods of renal replacement therapy can be estimated using USCPACK PC Clinical Programs and therapeutic drug monitoring data.
Interpretation and Analysis: Clinical experience has shown that a wide variation in intraindividual pharmacokinetic profiles exists during the application of different dialysis techniques (e.g., CAVH, CAVHDF, CVVHD). Such findings reflect not only the performance (effectiveness) of each dialysis technique but also the difficulty in their clinical utilization. The acyclovir elimination rate constant is higher during CVVHD compared to CAVH or CAVHDF. Bayesian method appears to be valuable in assessing intraindividual pharmacokinetic variability, as it allows the clinician to deal with sparse routine patient data.

Assessment of acyclovir intraindividual pharmacokinetic variability during continuous hemofiltration, continuous hemodiafiltration, and continuous hemodialysis. Bleyzac N, Barou P, Massenavette B, Contamin B, Maire P, Berthier JC, Aulagner G. Ther Drug Monit 1999 Oct; 21 (5), pp. 520–5.

Pharmacogenetics and Pharmacogenomics/ Proteomics Technologies: 2D-PAGE/Mass Spect/ Microarray Analysis Platforms: Investigative Methodologies/Human Tumor Gene Index/Laser Capture Microdisection (LCM)

Genomics has expanded the field of molecular oncology, and proteomics is complementing genomics in the fields of elucidation of pathophysiology, gene function, molecular diagnosis, and anticancer drug discovery. This trend is reflected in the establishment of the Human Tumor Gene Index by the National Cancer Institute (NCI), which is now followed by the Tissue Proteomics Initiative. Laser capture microdissection provides an ideal method for extraction of cells from specimens in which the exact morphologies of both the captured cells and the surrounding tissue are preserved. Proteomic technologies can be applied for the further characterization and analysis of proteins. Laser capture microdissection can also be combined with the protein chip technology. Proteomic technologies have been used for the study of cancer of various organs including the liver, prostate, breast, bladder, and esophagus. Some of the anticancer strategies are directed against proteases that facilitate several steps in cancer progression. Proteomic mapping of blood vessels in normal and malignant tissues can be used to identify tissue-specific markers on the endothelium that serve as potential targets for *in vivo* drug delivery. Studies of global protein expression in human tumors have led to the identification of various polypeptide markers, potentially useful as diagnostic tools. Genes that encode proteins that are overexpressed in tumors are being identified. Demonstration of tissue or cell-type specific expression of some nuclear matrix proteins has led to the search for tumor-specific nuclear matrix proteins. There is considerable activity in the commercial sector to develop diagnostic tests, as well as to facilitate anticancer drug discovery using proteomic technologies. Continued refinement of techniques and methodologies to determine the abundance and status of proteins *in vivo* holds great promise for future study of normal cells and associated neoplasms.

Applications of proteomics in oncology. Jain KK. Pharmacogenomics 2000 Nov; 1 (4), pp. 385–93.

Pharmacogenetics and Pharmacogenomics: Genomic Polymorphism as a Function of Protein Biological Activity

There is a rapidly growing body of evidence linking genetic polymorphisms with functional changes in proteins that are responsible for the metabolism and disposition of many medications. Likewise, polymorphisms in genes encoding the targets of medications (e.g., receptors) can alter the pharmacodynamics of the drug response by changing receptor sensitivity. As a result, the inherited basis of drug effects is often polygenic in nature, and thus more challenging to define. However, technological advances, coupled with new insights into the molecular pharmacology of medications and the functional consequences of polymorphisms in the human genome, are providing the tools needed to elucidate genetic determinants of drug response and translate functional genomics into personalized medicine.

Molecular diagnostics as a predictive tool: Genetics of drug efficacy and toxicity. Johnson JA, Evans WE. Trends Mol Med 2002 Jun; 8 (6), pp. 300–5.

Pharmacogenetics and Pharmacogenomics: Human Proteome/Genome

Now that the sequencing of the human genome has been completed, the basic challenges are finding the genes, locating their coding regions, and predicting their functions. This will result in a new understanding of human biology as well as in the design of new molecular structures as potential novel diagnostic or drug discovery targets. The assessment of gene function may be performed using the tools of the genome program. These tools represent high-throughput methods used to evaluate changes in the expression of many or all genes of an organism at the same time in order to investigate genetic pathways for normal development and disease. This will lead to a shift in the scientific paradigm: In the preproteomics era, functional assignments were derived from hypothesis-driven experiments designed to understand specific cellular processes. The new tools describe proteins on a proteome-wide scale, thereby creating a new

way of doing cell research that results in the determination of 3-dimensional protein structures and the description of protein networks. These descriptions may then be used for the design of new hypotheses and experiments in the traditional physiological, biochemical, and pharmacological sense. The evaluation of genetically manipulated animals or newly designed biomolecules will require a thorough understanding of physiology, biochemistry, and pharmacology and the experimental approaches will involve many new technologies, including *in vivo* imaging with single photon emission computed tomography and positron emission tomography. Nuclear medicine procedures may be applied for the determination of gene function and regulation using established and new tracers or using *in vivo* reporter genes such as enzymes, receptors, antigens, or transporters. Pharmacogenomics will identify new surrogate markers for therapy monitoring that may represent potential new tracers for imaging. Also, drug distribution studies for new therapeutic biomolecules are needed, at least during preclinical stages of drug development. Finally, new biomolecules will be developed by bioengineering methods that may be used for isotope-based diagnosis and treatment of disease.

Functional genomics and proteomics—The role of nuclear medicine. Haberkorn U, Altmann A, Eisenhut M. Eur J Nucl Med Mol Imaging 2002 Jan; 29 (1), pp. 115–32. Epub 2001 Nov.

Pharmacogenetics and Pharmacogenomics: Mass Spectrometry

Single-nucleotide polymorphisms (SNPs) are currently being identified and mapped at a remarkable pace, providing a rich genetic resource with vast potential for disease gene discovery, pharmacogenetics, and understanding the origins of modern humans. High-throughput, cost-effective genotyping methods are essential in order to make the most advantageous and immediate use of these SNP data. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) can be incorporated as a tool for differentiating genotypes based on the mass of the variant DNA sequence, and this method has been utilized for production scale SNP genotyping. A 4-μl polymerase chain reaction (PCR) amplification reaction using 3 ng of genomic DNA can be combined with a secondary enzymatic reaction (mini-sequencing) containing oligonucleotide primers that anneal immediately upstream of the polymorphic site, dideoxynucleotides, and a thermostable polymerase used to extend the PCR product by a single base pair. Mass spectrometry (MS) analysis of mini-sequencing reactions is performed using a MALDI-TOF instrument (Voyager-DE, Perseptive Biosystems, Framingham, MA). Both single and multiplex PCR can be applied along with mini-sequencing reactions, for genotyping different variant sites in random samples (e.g., n = 989 individuals). Genotypes generated with MS methods are then compared with genotypes produced using a 5′ exonuclease fluorescence-based assay (Taqman, Applied Biosystems, Foster City, CA) and a gel-based genotyping protocol. Because multiple polymorphisms can be detected in a single reaction, the MS technique provides a cost-effective and efficient method for high-throughput genotyping.

High-throughput multiplex SNP genotyping with MALDI-TOF mass spectrometry: Practice, problems and promise. Bray MS, Boerwinkle E, Doris PA. Hum Mutat 2001 Apr; 17 (4), pp. 296–304.

Pharmacogenetics and Pharmacogenomics: Mass Spectrometry

The use of liquid chromatography-mass spectrometry (LC-MS) has recently exploded in various analytic fields, including toxicology and therapeutic drug monitoring (although still far behind pharmacokinetics). There is no doubt that LC-MS is currently competing with gas chromatography (GC)-MS for the status of the reference analytic technique in toxicology. The principles, advantages, and drawbacks have been described for LC-MS systems using atmospheric pressure interfaces. Overviews have also reported the analytic methods for xenobiotics that could be set up with these instruments for clinical or forensic toxicology. In particular, as far as quantitative techniques are concerned, reviews have highlighted the large number and variety of drugs or classes of drugs (drugs of abuse, therapeutic drugs) or toxic compounds (e.g., pesticides) that can be readily determined using such instruments, the respective merits of the different ionization sources, and the improvements brought about by tandem MS. New applications have also been addressed for LC-MS in the field of toxicology, such as "general unknown" screening procedures and mass spectral libraries using LC-atmospheric pressure ionization (API)-MS or MS-MS, presenting the different solutions proposed to overcome the naturally low fragmentation power of API sources. Finally, the opportunities afforded by the most recent or proposed instrument designs have been clarified.

Progress of liquid chromatography-mass spectrometry in clinical and forensic toxicology. Marquet P. Ther Drug Monit 2002 Apr; 24 (2), pp. 255–76.

PHARMACOGENETICS: PHASE I METABOLIZING ENZYME SYSTEMS

MICROSOMAL ENZYME METABOLIZING CAPACITY (GENERAL)

Hepatic Microsomal Enzyme Metabolizing Capacity/Phenobarbital (PB) Induction of Cytochrome P450
Antipyrine

Application: Assessment of hepatic function. Antipyrine total body clearance directly correlates with hepatic cytochrome P450 activity. In this context, antipyrine as been applied as an indicator of decreasing hepatic function in dogs with experimentally-induced progressive liver disease (e.g., hepatotoxin: dimethylnitrosamine).
Route of Administration: Dogs: rapid intravenous administration.
Dosage: Canine: 20 mg/kg of body weight, and serum samples are obtained at intervals for determination of at least 5 terminal-phase drug half-lives.
Considerations: Disposition of antipyrine has been used as an indicator of decreasing hepatic function in dogs with experimentally-induced progressive liver disease.
Implementation: Evaluation of hepatic injury/insult caused by the hepatospecific toxin dimethylnitrosamine as a function of antipyrine plasma concentration that reflects rate and extent of liver metabolization.
Animal Model: Canine hepatic injury model induced through the oral administration of dimethylnitrosamine (n = 16 dogs with 6 negative controls). Disposition of antipyrine is studied 3 weeks after the last dose of toxin in each dog.
Interpretation and Analysis: Clearance and mean residence times vary among different histiological groups (e.g., mild, moderate, and severe) observed with dimethyletirosamine treated dogs ($p \leq 0.01$). Clearance of antipyrine is decreased in moderate and severe groups compared with negative controls and mild histiologically affected dogs. Antipyrine mean residence times are longer in moder-

ately affected dogs, compared with controls and mildly affected animals. Correction of antipyrine clearances for hepatic weight increases the ability to discriminate between moderately and severely affected dogs. Comparison of the clearance and mean residence time ratios of antipyrine calculated for each group with values for negative reference controls reveals there is no difference in the ratios among untreated and mildly affected dogs. Experimental findings also reveals that the disposition of antipyrine and caffeine appears to change similarly with progression of (dimethylnitrosamine-induced) liver disease.

In qualitative and quantitative evaluations of canine hepatic pharmaceutical metabolizing capacity, most of these enzyme systems reach maximal concentrations or biochemical activity by the 5th to 8th week after birth; they tended to decrease after weaning. Examples in this regard include (i) cytochromes P450 and b5 in addition to the NADPH and NADH-dependent reductases associated with each of these cytochromes; (ii) cytochrome P450-mediated enzymes (e.g., aniline and coumarin hydroxylases, aminopyrine N-demethylase, and 7-ethoxycoumarin O-deethylase); (iii) activity of a uridine diphosphoglucuronic acid glucuronyl transferase; and (iv) glutathione-S-transferase activities. The activity of dichloronitrobenzene-glutathione transferase in geriatric dogs (312 to 525 weeks old) is approximately 2-fold greater than that of 8-week-old puppies. There appear to be no gender-related differences in any of the enzyme concentrations or biochemical activities. Individual variation is pronounced even in homogeneous canine populations.

Antipyrine total body clearance has been applied to evaluate the effect of oral PB (antiepileptic therapeutic dose $\times$ 35 days) on hepatic cytochrome P450 function and plasma α1-acid glycoprotein concentrations. In this context, antipyrine total body clearance directly correlates with hepatic cytochrome P450 activity. Phenobarbital promotes increases in antipyrine total body clearance that approach a 3-fold elevation compared to preadministration levels. In concert with these observations, α1-acid glycoprotein levels increase approximately 4-fold. Following 35 days of PB administration, canine hepatic cytochrome P450 content and enzyme kinetics reveal values that are approximately 2-fold higher than that from untreated dogs. The Vmax values for cytochrome P450 1A-like activity (ethoxyresorufin O-deethylation); cytochrome P450 2B-like activity (ethoxycoumarin O-deethylation); cytochrome P450 2C-like activity (tolbutamide hydroxylation); and cytochrome P450 3A-like activity (midazolam 4-hydroxylation) are higher (2- to 4-fold) than analogous values observed in dogs not receiving PB therapy. In summary, a therapeutic dose of PB for antiepileptic therapy significantly induces hepatic cytochrome P450 enzymes and plasma α1-acid glycoprotein in dogs. As a consequence, it is important during PB antiepileptic therapy that precautions be taken to recognize the potential effect this may have on the pharmacokinetic profile of drugs simultaneously administered.

In sheep, the amount of aminopyrine N-dimethylease and most other hepatic metabolizing enzyme systems progressively increases up until and past the time of weaning (0 to 12 weeks). However, cytochrome b5 and uridine diphosphoglucuronic acid transferase activity are not affected by age, whereas NADPH cytochrome c (P450) reductase activity actually decreases after weaning. In some instances (e.g., coumarin hydroxylase, cytochrome P450, and dinitrochlorobenzene-glutathione-S-transferase), differences from preweaning hepatic pharmaceutical metabolizing capacity can only be observed in sheep that are 6 months of age or older. The simultaneous occurrence of sore mouth, pneumonia, foot rot, parasitism, and systemic bacterial infections has a minimal effect on the metabolizing capacity of hepatic (i) cytochromes P450 and b5 in addition to the NADPH and NADH-dependent reductases associated with each of these cytochromes; (ii) cytochrome P450-mediated reactions (e.g., aniline and coumarin hydroxylases); (iii) aminopyrine N-demethylase; (iv) 7-ethoxycoumarin 0-deethylase; (v) uridine diphosphoglucuronic acid glucuronyl transferase; and (vi) glutathione-S-transferase.

In young (4–6 years) and older (15–20) Cebus monkeys (Cebus albifrons), vitamin E supplementation significantly ($p < 0.05$) increases antipyrine clearance consistent with decreased N-demethylation of this indicator pharmaceutical. The effect of dietary vitamin E on the decreased half-life and increased clearance of antipyrine is most prominent when results from both age groups are evaluated collectively. The implication of these findings is that dietary antioxidants appear to consistently enhance the clearance of diagnostic pharmaceuticals that undergo hepatic oxidative metabolism.

In obese rats subjected to very-low-energy diet with essential nutrients to cause declines in liver mass and total liver protein, the administration of 9.25 k Bq (0.25 μcurie) [dimethylamine-^{14}C] aminopyrine reveals an increased half-life of exhaled $^{14}CO_2$ ($p < 0.01$) and a decreased rate constant of aminopyrine elimination ($p < 0.01$). These findings imply that these dietary changes decrease the N-demethylation of aminopyrine. Furthermore, identification of decreases in hepatic glutathione suggests a reduced capacity of the liver to detoxify drugs through this particular conjugation pathway. Animals on very-low-energy diets are therefore likely to experience a decreased capacity to metabolize various pharmaceuticals and toxins through oxidative mechanisms.

Hepatic Microsomal Enzyme Metabolizing Capacity *Caffeine/β-Naphthoflavone/Tolbutamide/ Sulphaphenazole/Sulphadimethoxine/Quinine/ Antipyrine/Phenobarbital*

Cellular/Molecular Mechanism of Action: Caffeine is metabolized by the hepatic P450 cytochrome oxidase system.

Application: The clearance of caffeine can function as an excellent quantitative test of hepatic function in human beings and domestic animals (mammals). It is currently used in much the same way that creatinine clearance is used to assess renal function in that caffeine can be used as an indicator of decreasing hepatic function. Caffeine has been applied in this manner in cattle and in canine models of experimentally-induced progressive liver disease (e.g., hepatotoxin: dimethylnitrosamine).

Route of Administration: Intravenous (canine studies have applied a rapid IV infusion rate).

Dosage: Caffeine sodium benzoate administered at a dose of 2 mg of caffeine/kg of body weight has been successfully applied to measure hepatic function in lactating dairy cattle. In canine subjects, it can be administered at 20 mg/kg of body weight with serum samples obtained at intervals that span the duration of at least 5 terminal-phase drug half-lives.

Considerations: In lactating dairy cattle, no adverse effects have been observed following caffeine administration.

Cytochrome P450 activities *in vivo* and *in vitro* and enzyme induction by phenobarbital, β-naphthoflavone, isoniazid, and triacetyloleandomycin have been investigated in female dwarf goats.

Disposition of caffeine has been used as an indicator of decreasing hepatic function in dogs with experimentally-induced progressive liver disease. Disposition of caffeine can be studied 3 weeks after the last dose of the hepatospecific toxin, dimethylnitrosamine, in individual dogs.

Interpretation and Analysis: In lactating dairy cattle (n = 6), serum caffeine concentration-time curves best fit an open 2-compartment pharmacokinetic model. Harmonic mean elimination half-life is 3.8 (range, 2.6–6.9) hours, and total clearance is 0.118 (range, 0.090–0.197) L/kg/h. Milk caffeine concentration is similar to serum concentration 1.5–24 hours after caffeine administration. Adverse effects are not observed in cows given caffeine. In the bovine, antipyrine and sulphadimidine do not affect the pharmacokinetic profile of caffeine.

In β-naphthoflavone treated goat, the microsomal ethoxyresorufin-O-deethylation rate becomes markedly increased. Beta-naphthoflavone also induces caffeine plasma clearance but does not affect microsomal caffeine 1- and 3-demethylation rates. Phenobarbital also increases caffeine plasma clearance. In contrast to β-naphthoflavone, phenobarbital increases microsomal caffeine 1- and 3-demethylation rates. Goat hepatic microsomes are able to hydroxylate tolbutamide (predominantly a CYP2C9 activity in man) and debrisoquine (a CYP2D activity in various species). These activities are not affected by either β-naphthoflavone or phenobarbital. Sulphaphenazole is a more potent inhibitor of tolbutamide hydroxylation than sulphadimethoxine, and quinine is a more potent inhibitor of debrisoquine hydroxylation than is quinidine. As might be anticipated, microsomal aniline-4-hydroxylation rate (CYP2E) increases after isoniazid treatment. The microsomal testosterone 6 β-hydroxylation rate (CYP3A) is increased after phenobarbital and triacetyloleandomycin treatment. Antipyrine plasma clearance is also increased after phenobarbital treatment. As cytochrome P450 activities and inducibility in the dwarf goat are similar to patterns appreciated in man, they may be of value as a model for human biotransformation research.

In dogs, the clearance of caffeine is decreased in conditions of moderate and severe hepatic disease, compared with negative controls and mild histiologically affected animals. Caffeine mean residence times are longer in moderately affected dogs, compared with controls and mildly affected animals. Correction of caffeine clearances for hepatic weight increases the ability to discriminate between moderately and severely affected dogs. Comparison of the clearance and mean residence time ratios of caffeine calculated for each group with values for negative reference controls revealed there is no difference in ratios among untreated and mildly affected dogs. Experimental findings also revealed that the disposition of antipyrine and caffeine appears to change similarly with progression of (dimethylnitrosamine-induced) liver disease.

Instrumentation and Data Analysis: Caffeine concentration can be analyzed utilizing automated enzyme immunoassay techniques. Such analytical systems have a lower limit of detection of the assay for caffeine in serum of approximately 0.079 μg/ml.

In vivo kinetics of antipyrine, sulphadimidine, and caffeine are studied separately and as a combination ("cocktail"). After establishing a lack of interaction among these compounds the effects of the inducing agents can be investigated. *In vitro,* hepatic microsomal enzyme activities and apoprotein levels are then determined.

MICROSOMAL CYTOCHROME P450 ENZYME SYSTEMS (GENERAL)

Hepatic Cytochrome P450: Microsomal Fractions
Doxifluridine (5′-DFUR)/Tegafur (FT)

Cellular/Molecular Mechanism of Action: Doxifluridine (5′-DFUR) and tegafur (FT) are 2 fluoropyrimidine prodrugs that are metabolized to 5-fluorouracil (5-FU) by hepatic microsomal enzyme fractions.

Application: Characterization of differences in the *in vitro* metabolic profiles for chemotherapeutic agents including doxifluridine (5′-DFUR) and tegafur (FT).

Implementation: Microsomal and cytosolic fractions processed from hepatic tissue (e.g., human liver) are incubated with doxifluridine (5′-DFUR) and tegafur (FT) preparations (500 μM final concentration). Conversion of these 2 fluoropyrimidine prodrugs to 5-FU is measured by high-performance liquid chromatography. The degree of correlation between the 5-FU-forming activities is determined using various cytochrome P450-dependent reactions.

Interpretation and Analysis: Liver microsomes catalyze 5-FU formation from 5′-DFUR at rates of 10.0 to 160.1 pmol/min per mg protein. These findings correlate well with CYP2A6-dependent coumarin 7-hydroxylase activity. The rates of microsomal 5-FU formation from FT range from 44.9 to 808.3 pmol/min per mg protein and similarly correlate with coumarin 7-hydroxylase activity. The cytosol fractions catalyze 5-FU formation from 5′-DFUR at rates of 3,164.6 to 6,026.6 pmol/min per mg protein, or almost 2 orders of magnitude higher than the rates of cytosolic 5-FU formation from FT (46.8–219.0 pmol/min per mg protein). The cytosolic enzymes in hepatic tissue appear to be important for 5-FU formation from 5′-DFUR. Both cytosolic and microsomal enzymes are involved almost equally in 5-FU formation from FT. The increased formation of 5-FU from 5′-DFUR might provide an answer to the question of why similar blood 5-FU levels are retained despite lower blood levels of 5′-DFUR compared to FT concentrations.

Cytosolic and microsomal activation of doxifluridine and tegafur to produce 5-fluorouracil in human liver. Ozawa S, Hamada M, Murayama N, Nakajima Y, Kaniwa N, Matsumoto Y, Fukuoka M, Sawada J, Ohno Y. Cancer Chemother Pharmacol 2002 Dec; 50 (6), pp. 454–8.

Hepatic Cytochrome P450 (16-α)/Genetic Alteration of Metabolic Capacity
Estradiol/Progesterone/Testosterone

Molecular Mechanism of Action: The enzyme C-P450(16-α) hydroxylates testosterone, progesterone, and estradiol specifically at the 16-α position.

Application: Characterization and profiling the metabolizing capacity for testosterone, progesterone, and estrogen by hydroxylation at the 16-α position. Using conventional transfection procedures, it is theoretically possible to introduce and promote the expression of C-P450(16-α) hydroxylase biochemical activity within mammalian cell populations.

Considerations: It is possible to construct and express chimeras of different P450 gene sequences such as 16-α-hydroxylase [C-P450(16-α)]. Experience with C-P450(16-α) has revealed that the presence of about two-thirds of the corresponding peptide molecule from its C-terminus is necessary for the chimeric cytochrome to maintain steroid 16-α-hydroxylase activity.

In male mice, the expression of C-P450(16-α) is both growth hormone dependent and androgen dependent.

Interpretation and Analysis: A broad steroid substrate specificity with high regio-selectivity and stereoselectivity at 16-α position is a biochemical characteristic of C-P450(16-α).

Functional characterization of 2 cytochrome P450s within the mouse, male-specific steroid 16-α-hydroxylase gene family: Expression in mammalian cells and chimeric proteins. Ichikawa T, Itakura T, Negishi M. Biochemistry 1989 May 30; 28 (11), pp. 4779–84.

Hepatic Cytochrome P450(15-α): Steroid Hydroxylation/Steroid 15-α-Hydroxylase Metabolizing Capacity: Female Hormone Specific
Female Hormone/Growth Hormone

Cellular/Molecular Mechanism of Action: Steroid 15-α-hydroxylase (P450(15-α)) is a female-specific enzyme expressed in the livers of many inbred mice (e.g., strain DBA/2J).
Application: Delineation of the expression of female-specific steroid 15-α-hydroxylase (P450(15-α)) biochemical activity.
Interpretation and Analysis: Run-on assays using liver nuclei from GH-deficient Little mice reveal that the P450(15-α) gene is transcriptionally repressed by growth hormone in male mice. BALB/cJ is a variant strain in which the gene is expressed in the males as well as in the females. Genetic crosses between DBA/2J and BALB/cJ indicate that expression of the P450(15-α) gene in BALB/cJ males is inherited as a recessive trait and is regulated by a single locus. The parental origin of the P450(15-α) gene can be determined by characterizing any restriction site polymorphism that may exist at the exons of P450(15-α) genes. This facilitates the division of F2 males expressing the P450(15-α) gene into 3 phenotypes at a ratio of 1:1:2, including (i) individuals expressing the gene from only BALB/cJ or (ii) DBA/2J; and (iii) individuals expressing the genes from both BALB/cj and DBA/2J parents. Repression of the P450 (15-α) gene in male mice appears to be regulated by a trans-acting regulatory locus between the DBA/2J and BALB/cJ pairs. Because hypophysectomy derepresses the P450(15-α) gene in F1 males and GH represses the gene in hypophysectomized F1 males, the hormone appears to regulate gene repression through a trans-acting locus, referred to as GH-dependent repression (e.g., GDR).

A trans-acting locus regulates transcriptional repression of the female-specific steroid 15-α-hydroxylase gene in male mice. Aida K, Negishi M. J Mol Endocrinol 1993 Oct; 11 (2), pp. 213–22.

Hepatic Cytochrome P450: Steroid 7-α-Hydroxylase/Cytochrome P450: Steroid 15-α-Hydroxylase
Steroid Hormones/Corticosteroids/Testosterone

Cellular/Molecular Mechanism of Action: The murine steroid 7-α-hydroxylase P450(7-α), also referred to ascytochrome P450(7-α), hydroxylates steroid hormones (e.g., testosterone). Similary, 15-α-hydroxylase also converts steroid hormones to a hydroxylated analog.
Application: Corticosteroids can modify the metabolizing capacity of P450(7-α) and P450(15-α) depending on the identity of the amino acid residue located at the 209 position.
Interpretation and Analysis: The leucine amino acid residue at 209 of P450(15-α) is the most important residue in determining the steroid hydroxylase activity of this particular P450 enzyme system. The P450(7-α) contains Asn at the position corresponding to the Leu-209 of P450(15-α), although both P450s hydroxylate testosterone. The CO-reduced P450(7-α) complex is unstable and is quickly converted into inactive P420, whereas P450(15-α) is very stable. The P450(7-α), however, is stabilized either by addition of testosterone or by a mutation of Asn-209 to Leu. Mutant P450(7-α) displays a 17-fold lower Vmax value than the wild-type enzyme. Unexpectedly, it also has 3-fold lower Km and Kd values. Residue 209 in P450(7-α), therefore, appears to be located at a critical site of the haem-substrate-binding pocket. Corticosterone inhibits the testosterone 7-α-hydroxylase activity of wild-type P450(7-α), whereas it does not inhibit the mutant P450(7-α). Interestingly, P450(15-α) activity is inhibited by corticosterone upon the replacement of Leu-209 by Asn. In addition, this mutation increases the corticosterone 15-α-hydroxylase activity of P450(15-α) at least 20-fold. Whereas the inhibition by corticosterone depends on the presence of Asn at position 209, deoxycorticosterone inhibits the activities of the P450s regardless of the type of residue at 209. The results indicate, therefore, that the identity of residue 209 determines the affinity as well as specificity of steroid binding to both P450(7-α) and P450(15-α).

Site-directed mutagenesis of mouse steroid 7-α-hydroxylase (cytochrome P450(7-α)): Role of residue-209 in determining steroid-cytochrome P450 interaction. Iwasaki M, Lindberg RL, Juvonen RO, Negishi M. Biochem J 1993 Apr 15; 291 (Pt 2), pp. 569–73.

Hepatic Cytochrome P450: Genetic Variability of Expression Profiles/(Neoplastic Disease Susceptibility)
Polycyclic Aromatic Hydrocarbons/N-Nitrosamines/Benzene

Background Information: Several cytochrome P450 enzymes, responsible for metabolically activating carcinogens and medications, express wide interindividual variation whose genetic coding has now been identified as polymorphic and linked to cancer risk. For example, a restriction fragment-length polymorphism for cytochrome P450 1A1, which metabolizes polycyclic aromatic hydrocarbons, and cytochrome P450 2E1, which metabolizes N-nitrosamines and benzene, is linked to lung cancer risk. Cytochrome P450 2D6, responsible for metabolizing many clinically important medications, also is linked to lung cancer risk. The frequency for each of these genetic polymorphisms varies among different ethnic and racial groups. In addition to inherited factors for the detection of sensitive populations, determining the biologically effective doses for carcinogenic exposures also should quantitatively and qualitatively enhance the risk assessment process. Levels of carcinogen-DNA adducts reflect the net effect of exposure, absorption, metabolic activation, detoxification, and DNA repair. These effects are genetically predetermined, inducibility notwithstanding. The combination of adduct and genotyping assays provides an assessment of risk that reflects recent exogenous exposure as well as one's lifetime ability to activate and detoxify carcinogens.
Considerations: Risk assessment models strive to predict risks to humans from toxic agents. Safety factors and assumptions are incorporated into these models to allow a margin of error. In the case of cancer, substantial evidence shows that the carcinogenic process is a multistage process driven by the interaction of exogenous carcinogenic exposures, genetic traits, and other endogenous factors. Current risk assessment models fail to consider genetic predispositions that make people more sensitive or resistant to exogenous exposures and endogenous processes.

Pharmacogenetics: Detecting sensitive populations. Shields PG. Environ Health Perspect 1994 Dec; 102 Suppl 11, pp. 81–7.

Hepatic Cytochrome System/Susceptibility to 2nd-Stage Hepatocarcinogenesis
Phenobarbital (PB)/N-Nitrosodiethylamine (DEN)

Cellular/Molecular Mechanism of Action: The metabolite of N-nitrosodiethylamine is a hepatocarcinogenic agent.
Application: N-nitrosodiethylamine can function as a model for the analysis of the pharmacogenetics related to susceptibility to hepatocellular tumor promotion.
Route of Administration: N-nitrosodiethylamine (intraperitoneal).
Dosage: N-nitrosodiethylamine (90 mg/kg body weight).

Implementation: Certain selected strains of inbred mice can be utilized as an animal model for investigating susceptibility to 2-stage liver carcinogenesis. The carcinogen DEN (90 mg/kg body weight) is given as a single dose (e.g., 5-week-old male mice of strains C57BL/6NCr [C57], C3H/HeNCrMTV- [C3H], and DBA/2NCr [DBA]). Reference controls receive intraperitoneal injections of tricaprylin solvent (10 ml/kg). At 2 weeks postinjection, phenobarbital in drinking water (0.05%) is administered to mice. Data points are collected at 12, 24, 36, and 52 weeks of age (5, 17, 29, and 45 weeks for murine subjects exposed to phenobarbital).

Interpretation and Analysis: Phenobarbital significantly increases both the number of hepatocellular foci/cm^2 and the incidence of hepatocellular tumors after 17 weeks of treatment in 24-week-old DEN-initiated mice of strains C3H (0.11 ± 0.07 vs 2.9 ± 0.3 foci/cm^2 and 20 vs 70% incidence of hepatocellular tumors) and DBA (0.09 ± 0.09 vs 3.72 ± 0.6 foci/cm^2 and 0 vs 90% incidence of hepatocellular tumors) but is ineffective in C57 mice (0.04 ± 0.04 vs 0.07 ± 0.07 foci/cm^2). At 36 weeks of age the incidence of liver cell tumors in mice given DEN but not PB is 10 (DBA), 10 (C57), and 50% (C3H); the incidence is increased by PB to 90% in DBA and 100% in C3H mice, but there is no increase in C57 mice. Even at 52 weeks, the low incidence of hepatocellular tumors in C57 mice given DEN only (20%) is not significantly increased by subsequent exposure to PB. Serum PB levels observed at 12, 24, and 36 weeks of age are significantly higher in DBA mice than in C57 or C3H mice. Similar results can be appreciated when PB is administered in drinking water to 7-week-old male mice of these 3 strains for 20 days, during which period serum PB levels are measured at more frequent intervals. DBA mice thus appear to be unable to metabolize PB, which itself rather than its metabolites is probably responsible for tumor-promoting effects. DBA mice are especially sensitive, while C57 mice are refractory to the promotion of hepatocarcinogenesis facilitated by PB. The DBA and C57 strains of mice provide a model for analysis of the pharmacogenetics of susceptibility to hepatocellular tumor promotion. Note that DBA and C57 strains of mice differ with respect to other significant parameters for chemical carcinogenesis including inducibility for aryl hydrocarbon hydroxylase and susceptibility to promotion of hydrocarbon-initiated skin tumors by 12-O-tetradecanoylphorbol-13-acetate.

Interstrain differences in susceptibility to liver carcinogenesis initiated by N-nitrosodiethylamine and its promotion by phenobarbital in C57BL/6NCr, C3H/HeNCrMTV- and DBA/2NCr mice. Diwan BA, Rice JM, Ohshima M, Ward JM. Carcinogenesis 1986 Feb; 7 (2), pp. 215–20.

MICROSOMAL CYTOCHROME P450 1A1 AND P450 1A2

Hepatic Cytochrome P450 1 (CYPI) Metabolic Capacity/(Tropical Chronic Pancreatitis) *Theophylline*

Cellular/Molecular Mechanism of Action: Theophylline is a substrate for cytochrome P450 1.

Application: Measurement of the *in vivo* biochemical activity of cytochrome CYPI as a relevant avenue for determining the ability of this enzyme system to metabolize pharmaceuticals, optimize dosage schemes, determine individual susceptibility to pro-toxin biotransformation, and/or detect therapeutic non-compliance. In this context, theophylline can be applied as an *in vivo* probe to determine kinetic profiles of this pharmaceutical as a parameter that reflects the potentially toxic cytochrome P450 1 pathway of drug metabolism.

Examples of Clinical Implementation: Theophylline clearance is accelerated in patients suffering from conditions of calcific chronic pancreatitis compared to healthy/normal controls (median 69 [range 39–114] vs 45 [33–56] ml/hr/kg, $p = 0.003$). Review of clinical histories reveals that such conditions are frequently accompanied by exposure to xenobiotics known to be inducers of cytochrome P450 1 and/or yield reactive metabolites subsequent to functioning as a biochemical substrate. However, the concentration of D-glucaric acid in urine, as a marker of phase II conjugating pathways of drug metabolism, is oddly similar in both affected cases or normal/healthy control subjects. Such patterns of drug metabolism could predispose to oxidant stress and serve to support the practice of administering micronutrient antioxidant supplements that may have therapeutic and possibly prophylactic value in conditions of tropical chronic pancreatitis.

Hepatic Cytochrome P450 1A1 (CYP1A1) and NQO1 Genetic Polymorphism/Acute Lymphoblastic Leukemia (ALL): Childhood/Genetic Prognostic Marker

Background Information: The origin of ALL, the most common pediatric cancer, can be explained by a combination of genetic factors and environmental exposure. The environmental toxicants to which an individual is exposed are biotransformed and eliminated from the body after metabolic conversion mediated by Phase I and Phase II xenobiotic-metabolizing enzymes. Phase I enzymes catalyze hydroxylation, reduction, and oxidation reactions of xenobiotics (carcinogens/drugs), often converting them into more active or toxic compounds. Phase II enzymes catalyze conjugation reactions (glucuronidation, acetylation, methylation), thereby converting the metabolites into non-reactive, water-soluble products that are eliminated from the organism.

Application: Expression of P450 1A1 and NQO1 variants can be applied in pharmacogenetic and prognostic-related decision making processes pertaining to the childhood variant of ALL.

Implementation: The genetic polymorphism underlying the variation in enzyme activity can modify susceptibility to diverse adult cancers, probably by influencing the activation and removal of toxicants or drugs. Genetic variants of certain Phase I and Phase II enzymes have a role in the development of childhood ALL and represent a viable model for such studies (e.g., short latency period). The genetic contribution to the development of ALL has been examined by association studies that analyze the loci of Phase I enzymes (cytochrome P450, myeloperoxidase) and Phase II enzymes (quinone-oxidoreductase, glutathione-S-transferase, N-acetyltransferase).

Interpretation and Analysis: The loci of the enzyme variants CYPlA1, CYP2E1, NQO1, GSTM1, GSTP1, and NAT2 are associated with disease development, and evidence of gene-gene interactions also appears to exist. Despite the improvements in treatment, resistant cases of ALL remain a leading cause of cancer-related death in children. Although the underlying mechanism of drug resistance is not well understood, differences in the capacity of ALL patients to process drugs and environmental carcinogens could play a role by modifying the risk of recurrent malignancy, as well as the response to therapy. Therefore, polymorphic genes encoding carcinogen- and drug-metabolizing enzymes may not only increase the risk of ALL but also influence the risk of relapse in patients. The prognosis of patients with CYPlA1 and NQO1 variants is worse than that of patients who lack these variants. Therefore, the genotyping of ALL cases for functional polymorphisms of candidate genes can become an important tool in predicting disease outcome.

Hepatic Cytochrome P450 1A1 and P450 1A2 Metabolic Capacity
R-Warfarin

Cellular/Molecular Mechanism of Action: Warfarin (R-warfarin enantiomer) is metabolized as a substrate by cytochrome P450 1A1 (CYP1A1) and P450 1A2 (CYP1A2) enzyme systems.
Application: Phenotyping of P450 1A1 and P450 1A2 for the purpose of assessing procarcinogen susceptibility. Hydroxylation rates for R-warfarin can be applied as a marker system for the detection and measurement of hepatic P450 1A2 metabolizing capacity (human). In addition, the calculation of 6-hydroxylation/8-hydroxylation ratios can be used *in vitro* as a marker system for the detection and measurement of P450 1A1 enzyme fractions.
